***Abstract*—Academic stress represents a significant challenge in higher education, especially for students navigating unfamiliar academic environments. In such contexts, difficulties in understanding expectations, feedback, and performance standards can affect engagement, participation, academic performance, and decision-making. Despite significant advances in learning analytics and artificial intelligence, current educational systems remain limited in their ability to support students' sense-making of their academic conditions. Existing systems predominantly focus on prediction and performance monitoring, offering limited support for interpretation and awareness, which are essential for understanding academic stress, particularly in complex or unfamiliar learning environments. To address this limitation, this study introduces the LAURA framework (Learning Context Modeling, Academic Stress Assessment, Understanding-Oriented Explanation, Reflection Support, and Adaptive Awareness Feedback), an awareness-oriented framework designed to support students in understanding their academic stress through interaction. Unlike traditional AI approaches that prioritize prediction, LAURA conceptualizes academic stress as an interpretive process and positions explainable AI as a mechanism to support students' awareness. The framework integrates transparent modeling, explanation, and structured reflection within a unified interaction cycle, enabling students to interpret academic signals, examine contributing factors, and develop a more informed understanding of their conditions. Grounded in appraisal-based stress theory and principles of human-centered AI, LAURA extends existing approaches by embedding explanation and reflection as core components of system design rather than auxiliary features. In this way, it shifts the role of explainable AI from revealing model behavior to supporting meaning-making processes within educational contexts. The proposed framework contributes a new perspective on AI-supported educational systems by emphasizing awareness as the primary outcome. It provides a conceptual and design foundation for developing student-facing systems that not only analyze academic conditions but also support students in making sense of them, particularly in diverse and complex educational environments. As a conceptual framework, LAURA provides a foundation for future implementation and empirical validation in educational settings.**

***Keywords*—Explainable Artificial Intelligence (XAI); academic stress; student awareness; interpretable models; human-centered AI; higher education**

I. Introduction

Academic stress is a well-established challenge in higher education, influencing students' well-being, engagement, and academic performance. While a certain level of stress can support motivation, prolonged or poorly managed stress may negatively affect students' learning experiences and academic decision-making [1]. In response, universities have increasingly adopted data-driven approaches, including learning analytics and artificial intelligence (AI) systems, to monitor and understand students' academic conditions [2].

These systems provide robust capabilities for analyzing large-scale educational data and identifying patterns in performance, engagement, and academic risk. In particular, AI-based approaches have been widely used for prediction, classification, and early identification of at-risk students. However, despite these advancements, most existing systems remain primarily oriented toward outcome estimation, with limited support for how students interpret their academic situations [3], [4].

This limitation is particularly important in the context of international students, who often face additional challenges when navigating unfamiliar academic environments. Differences in academic communication practices, educational systems, and implicit expectations can make it difficult to accurately interpret feedback, assessment criteria, and performance indicators. Prior work has shown that academic stress in such contexts is not only driven by workload or outcomes, but also by difficulties in interpreting academic signals [5]. This highlights a critical need for systems that support students not only in receiving information, but also in meaningfully interpreting that information.

Recent research has explored the role of explainable artificial intelligence (XAI) in improving the transparency of AI systems in education [6]. While these approaches enhance visibility into how models operate, explainability is often treated as a technical property that reveals model behavior [7], [8]. As a result, students may still face challenges in connecting system outputs to their own academic experiences. This indicates that transparency alone is insufficient to support meaningful understanding.

Based on these limitations, a clear research gap emerges: current AI-supported educational systems provide limited support for interpretation and awareness, particularly in contexts where students must actively make sense of complex and unfamiliar academic conditions. Addressing this gap requires moving beyond prediction and transparency to support students in interpreting academic information and engaging in reflection that promotes awareness of their academic conditions.

Our previous work highlighted this research gap through a comprehensive review of explainable AI and academic stress among international university students, identifying the need for student-facing systems that support awareness and

interpretation rather than prediction alone [5]. However, that study did not propose a framework architecture or specify how such awareness-oriented support could be realized in practice. The present study addresses this gap by proposing the LAURA framework, which comprises a five-phase conceptual architecture that integrates learning context modeling, academic stress assessment, understanding-oriented explanation, reflection support, and adaptive awareness feedback into a unified interaction cycle.

Building on this foundation, the present study introduces the LAURA conceptual framework, an awareness-oriented approach designed to support students in developing awareness of their academic stress conditions. The framework conceptualizes academic stress as an interpretive process in which students construct meaning through interaction with system feedback. Rather than treating stress estimation as the final system outcome, LAURA is designed to help students understand how different academic factors contribute to their stress experiences and to promote awareness through explanation and reflection.

The main contributions of this study are fourfold. First, it advances an awareness-oriented conceptualization of academic stress in AI-supported educational systems by emphasizing interpretation over prediction. Second, it introduces the LAURA framework as a five-phase conceptual architecture that extends existing learning analytics and educational XAI approaches by integrating learning context modeling, academic stress assessment, understanding-oriented explanation, reflection support, and adaptive awareness feedback within a unified interaction cycle. Third, it repositions explainable AI from a mechanism for revealing model behavior to a form of cognitive support that enables students' interpretation and meaning-making. Finally, it provides awareness-oriented design principles for developing student-facing AI systems, particularly for students navigating unfamiliar academic environments, including international students.

The remainder of this study is organized as follows:

- Section II: Related Work reviews existing studies on academic stress, student awareness, and AI-based approaches in education.
- Section III: Framework Development Methodology presents the conceptual design approach, architectural structure of LAURA, and awareness-oriented design logic.
- Section IV: Conceptual Interaction and Awareness Development describes the interaction process and how awareness is developed through the framework.
- Section V: Discussion discusses the theoretical, design, and international student implications of the framework, presents its limitations, and outlines research implications.
- Section VI: Conclusion summarizes the main contributions of the study and highlights the significance of the proposed framework.

II. Related Work

This section reviews the main research areas related to the development of the LAURA framework. The discussion focuses on four themes: academic stress in higher education, artificial intelligence approaches for analyzing academic stress indicators, learning analytics dashboards and student awareness, and the role of explainable artificial intelligence in educational systems. Examining these areas helps situate the proposed framework within the current literature and highlights the limitations that motivate the development of LAURA.

A. Academic Stress in Higher Education

Academic stress has been widely recognized as an important factor influencing students' learning experiences, well-being, and academic performance. University students frequently encounter multiple academic demands, including coursework, assignments, examinations, and performance expectations. These demands may create pressure that affects both academic engagement and students' perceptions of their learning environment.

Previous research has identified several common contributors to academic stress in higher education. Among the most frequently reported factors are perceived academic workload, deadline pressure, unclear academic expectations, and difficulties in understanding course materials [5], [9], [10]. Studies show that academic demands, assessment pressure, and time constraints represent major sources of stress among students in higher education. Other research also indicates that uncertainty regarding grading criteria and course expectations can increase academic pressure among students.

In addition to workload-related factors, interpretive uncertainty plays an important role in academic stress experiences. Students may experience additional pressure when they struggle to interpret academic signals such as instructor feedback, grading standards, or course expectations [11]. These challenges may become more pronounced in international learning environments where students encounter unfamiliar educational systems or language-related comprehension difficulties [12].

Students may also interpret academic signals differently depending on their prior experiences, confidence levels, and familiarity with the learning environment. Such differences in interpretation may influence how academic demands are perceived and how strongly students experience academic pressure [13].

Academic stress may be particularly significant for international students who study in unfamiliar educational environments [14]. International students often face additional challenges, including language-related comprehension difficulties, unfamiliar academic expectations, and differences in instructional communication styles. These factors may increase uncertainty when interpreting academic signals such as feedback, grading standards, and course requirements. As a result, international students may experience greater academic pressure when they are unsure how to interpret or respond to academic expectations [15].

Although traditional academic stress research provides valuable insights into the factors influencing student experiences, most studies rely on surveys or psychological measure-

ment instruments. As a result, these approaches often offer limited technological support to help students actively interpret and understand their experiences of academic stress during the learning process.

B. Artificial Intelligence Approaches for Analyzing Academic Stress Indicators

Recent advances in artificial intelligence and machine learning have introduced new opportunities to analyze student behavior and indicators of academic stress in educational environments [16]. Researchers have increasingly explored how machine learning models can identify patterns related to academic workload, engagement, and stress-related experiences among students [17].

Several studies have applied machine learning techniques to analyze stress-related indicators collected from university students. These studies demonstrate that machine learning models can identify relationships between contextual academic factors and students' reported stress experiences. By analyzing academic and behavioral data, AI models can reveal patterns associated with students' learning conditions and stress indicators.

Recent literature reviews also highlight the growing interest in applying artificial intelligence techniques to analyze indicators of student well-being and academic stress in higher education. These studies show that AI-based analytical models can support the analysis of complex relationships between academic factors and student experiences [18].

Despite these developments, many artificial intelligence approaches primarily focus on identifying patterns or estimating stress levels within student datasets [19]. In many cases, the models serve primarily as analytical tools for researchers or institutional monitoring rather than as interactive systems that support students' understanding of their academic experiences [16].

Consequently, although machine learning models can reveal relationships between academic factors and stress indicators, students may still struggle to understand how these factors shape their individual experiences. This limitation highlights the importance of designing AI-supported systems that not only analyze academic data but also help students interpret the factors that influence their learning conditions.

C. Learning Analytics Dashboards and Student Awareness

Learning analytics dashboards have become a widely used approach for presenting educational data and supporting student awareness of learning progress. These dashboards typically visualize information such as grades, participation levels, assignment completion rates, and learning activity indicators. By presenting such information, dashboards aim to help students monitor their academic progress and gain insight into their learning performance [20].

A growing body of research has examined the design and effectiveness of learning analytics dashboards. Many dashboards successfully provide visual summaries of student data and help learners observe their academic progress. However, research also indicates that dashboards often provide limited support for helping students interpret the meaning of these indicators [21], [22].

One of the main challenges identified in dashboard research is the gap between data visualization and meaningful interpretation [23]. Although dashboards present useful academic indicators, students may still struggle to understand how different academic factors contribute to their experiences. As a result, observing performance indicators does not always lead to deeper awareness of learning conditions [24].

Recent studies suggest that explanation mechanisms can help address this limitation. When systems provide explanations that clarify how different indicators relate to academic conditions, students are better able to interpret dashboard information and understand the factors influencing their learning experiences [25].

Research also highlights the importance of reflection in supporting student awareness and self-regulated learning. Reflection prompts encourage students to actively interpret academic information rather than simply observing it. When students reflect on system feedback, they are more likely to connect learning indicators with their own behaviors and learning strategies. Studies have shown that systems incorporating reflection mechanisms can improve students' understanding of their learning processes and support more informed academic decision-making [24], [26].

These findings indicate that learning analytics systems can more effectively support student awareness when they combine data visualization with explanatory and reflective support. Because explanation plays a key role in helping users interpret analytical outputs, recent research has increasingly explored integrating explainable artificial intelligence into educational systems.

D. Explainable Artificial Intelligence in Education

Explainable artificial intelligence has received increasing attention as researchers seek to make AI systems more transparent and understandable for users. In educational contexts, explainability is particularly important because students and instructors often need to understand how analytical outputs are generated and how different variables influence those outputs [6].

Recent studies emphasize that explainable AI should support human understanding rather than only providing technical transparency. When explanations are presented clearly and meaningfully, users are more likely to interpret system outputs correctly and incorporate that information into their decision-making [27].

Interpretable modeling approaches play an important role in this context. Interpretable models allow users to understand how individual input variables contribute to the final analytical result [28]. When applied in educational environments, such models can help students see how different academic factors influence the results produced by analytical systems [29].

Despite the increasing interest in explainable AI, many educational applications still rely on complex analytical models that may be difficult for students to interpret. This limitation highlights the need to design AI-supported educational systems

that combine transparent modeling with explanations that are meaningful and accessible for learners [30].

E. Positioning LAURA Within Existing Approaches

Existing research on academic stress and learning analytics has introduced a variety of systems that analyze student behavior or present academic indicators. However, these systems are often designed for monitoring or prediction purposes rather than for supporting students' understanding of their academic conditions [31]. As a result, students may receive analytical outputs without sufficient support to interpret how different academic factors contribute to their stress experiences.

To position the proposed framework within this research landscape, Fig. 1 compares the LAURA framework with representative approaches, including learning analytics dashboards, AI-based stress analysis systems, and traditional academic stress models.

The comparison highlights several important gaps in existing approaches. Learning analytics dashboards typically present academic indicators but require students to interpret them independently. AI-based stress analysis systems often focus on predictive modeling, while providing limited support for explanation or reflection.

In contrast, the LAURA framework integrates interpretable modeling, explanation support, and structured reflection within a unified architecture. This design enables students not only to observe academic indicators but also to understand how different academic factors contribute to their academic stress.

By integrating explanation and reflection into an iterative feedback process, LAURA goes beyond prediction-oriented systems by fostering a deeper awareness among students of their academic stress.

F. Research Gap and Motivations

The reviewed literature shows important progress in academic stress research, artificial intelligence applications, learning analytics dashboards, and explainable AI in education. Traditional academic stress studies provide a strong theoretical understanding of stress factors, while AI-based approaches enable the analysis of complex student data. Learning analytics dashboards, on the other hand, support the visualization of academic indicators.

Despite these contributions, these approaches are often developed separately and focus on different objectives. Many AI-based systems emphasize data analysis or prediction, whereas learning analytics dashboards primarily present performance indicators with insufficient support for interpretation. As a result, students may observe academic information but still struggle to understand how different academic conditions contribute to their experiences of stress.

This gap indicates the need for systems that not only present or analyze data, but also support students in interpreting academic signals and reflecting on their learning situations. In particular, integrating interpretable models, explanations of contributing factors, and structured reflection can provide more meaningful support for students' awareness.

To address this need, the proposed LAURA framework integrates interpretable modeling, explanation mechanisms, and reflection prompts within a unified architecture. This design aims to support students in understanding their academic conditions and in developing awareness of the factors influencing their academic stress.

The following section presents the LAURA framework and explains its conceptual structure and development methodology.

III. LAURA Framework Development Methodology

This section presents the development methodology of the LAURA framework and explains how its main components are conceptually organized. The focus is not on technical implementation but on the design rationale and theoretical foundations that guided the framework's development. Accordingly, this work establishes the conceptual architecture and theoretical design rationale of the LAURA framework, providing a foundation for its future implementation and empirical validation.

The design of LAURA is informed by research on academic stress, interpretive challenges in higher education, explainable artificial intelligence (XAI), and reflection in learning analytics. These research areas highlight a common limitation in many existing systems. Although academic indicators are often presented to students, such systems provide limited support for helping students interpret how these indicators relate to their academic situations.

To address this limitation, LAURA is designed as an awareness-oriented explainable architecture. The framework integrates interpretable modeling, explanation of contributing academic factors, and structured reflection prompts that guide students in interpreting their academic conditions. Rather than focusing only on estimation, LAURA aims to support meaningful understanding and academic self-awareness.

A. Conceptual Design Approach

The conceptual design of LAURA follows a theory-informed synthesis process. Rather than starting with technical modeling techniques, the framework development begins with an educational objective: supporting students in interpreting the academic conditions that influence their stress experiences.

First, academic stress was conceptualized as an appraisal process. According to stress appraisal theory, stress arises when individuals evaluate academic demands relative to their perceived coping resources [34]. In higher education environments, perceived workload, deadline pressure, unclear expectations, and performance uncertainty are frequently identified as major contributors to academic stress. Recent studies also indicate that uncertainty regarding grading criteria and academic expectations can increase stress levels among university students [13].

Second, research indicates that students may experience higher stress when academic signals are unclear or difficult to interpret. For example, unclear feedback, unfamiliar evaluation systems, or language-related comprehension difficulties may

Characteristic	Primary Objective	Explanation	Reflection	Model Transparency	User Role	Feedback	Contribution Perspective
LAURA Framework	Academic stress awareness	Central explanatory component	Structured reflection prompts	Interpretable additive modeling	Active interpretation	Iterative awareness feedback	Integrates interpretable analysis, explanation, reflection, and adaptive awareness support
Learning Analytics Dashboards	Learning progress monitoring	Limited or indicator-based	Often implicit	Indicator-based analytics	Passive observation	Progress visualizations	Focus on monitoring academic indicators rather than understanding stress conditions
AI-Based Stress Analysis Systems	Stress detection or prediction	Rare or minimal	Usually absent	Often black-box ML models	Limited involvement	Stress prediction alerts	Emphasis on prediction accuracy rather than awareness or reflection
Traditional Academic Stress Models	Psychological explanation of stress	Core theoretical explanations	External reflection processes	Highly interpretable statistical models	Questionnaire participation	Psychological assessment feedback	Provide theoretical insight but lack interactive technological support

Fig. 1. Comparison of the proposed LAURA framework with representative approaches for academic stress support. Adapted from [20], [23], [18], [16], [32], [33].

increase confusion and uncertainty among students, particularly in international educational environments. In these situations, the issue is not only the academic demand itself, but also the difficulty of correctly interpreting academic signals [35].

Third, recent developments in explainable artificial intelligence emphasize the importance of transparency when AI systems interact directly with users. When the goal of the system is to support human understanding rather than purely optimize predictive performance, interpretable models are generally preferred over complex black-box algorithms. In educational contexts, clear explanations have been shown to improve user trust and understanding of system outputs [6] [36].

Finally, research on learning analytics dashboards demonstrates that presenting data alone is often insufficient for supporting awareness. Students benefit more when systems include structured reflection prompts that encourage interpretation and self-regulated learning. Reflection supports metacognitive thinking and helps students connect system feedback with their own academic behaviors [37].

By integrating insights from these research areas, the LAURA framework was developed as an awareness-oriented system that combines academic context modeling, transparent estimation, explanation, and reflection within a continuous interaction cycle [5].

B. Architectural Structure of LAURA

Fig. 2 illustrates the overall architecture of the LAURA framework. The framework is designed as an awareness-oriented interaction cycle that integrates academic context modeling, interpretable stress estimation, explanation, reflection, and adaptive feedback. Rather than treating academic stress as a static outcome, LAURA conceptualizes awareness as a continuous process in which students interpret academic conditions, receive explanations, reflect on contributing factors, and progressively refine their understanding.

Structurally, the LAURA framework operates as a multi-stage, awareness-oriented cycle comprising five interconnected

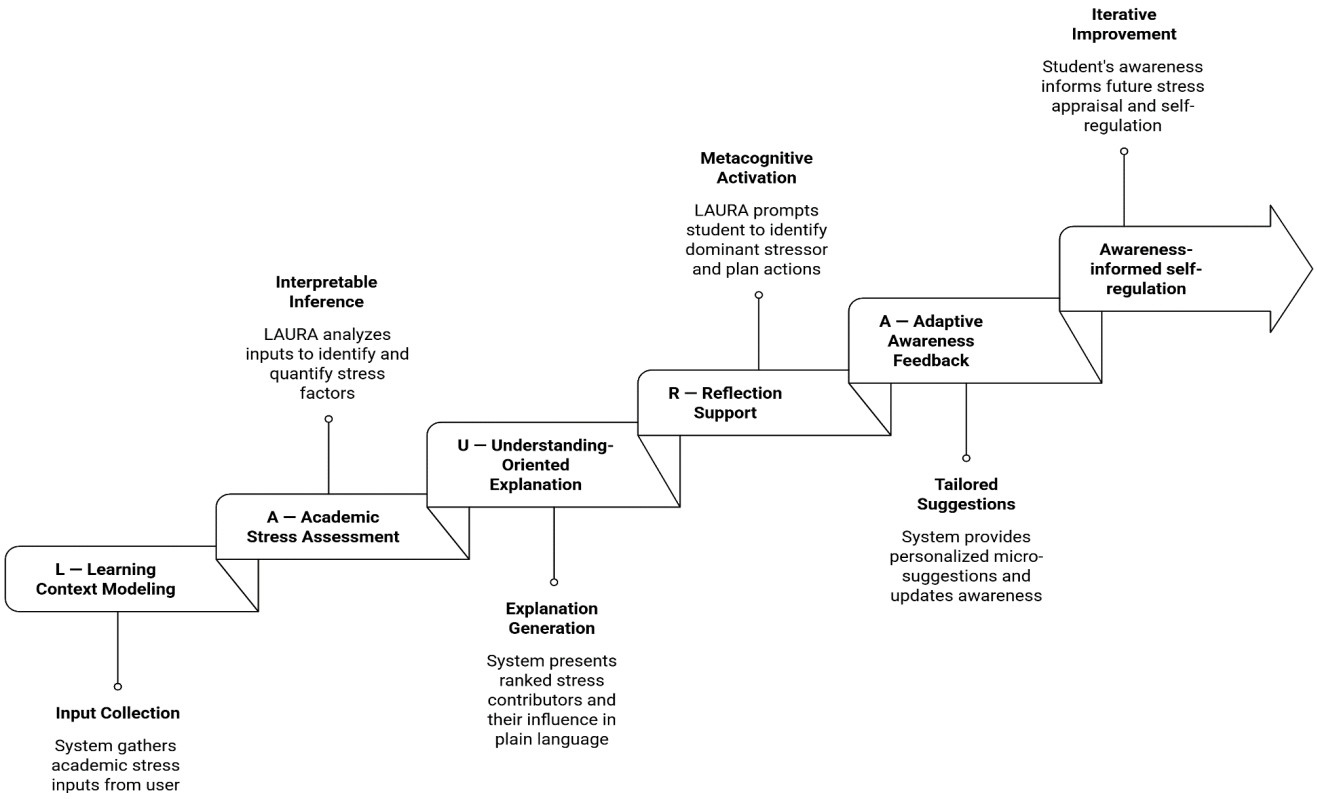

Fig. 2. The LAURA framework: An awareness-oriented explainable interaction cycle.

phases.

1) Phase 1: Learning context modeling: The process begins with Learning Context Modeling, where key academic indicators such as perceived workload, deadline pressure, clarity of academic expectations, and comprehension or interpretation difficulty are collected to represent the student's academic environment. These factors capture how students perceive and evaluate their academic conditions, rather than the objective workload alone.

This phase is designed as a structured input layer that reflects students' appraisal of academic demands. Consistent with research on academic stress, these indicators represent common sources of uncertainty in higher education contexts, particularly for students navigating unfamiliar academic environments [9] [38] [13].

2) Phase 2: Academic stress assessment: The academic indicators derived from the Learning Context Modeling phase serve as inputs for the Academic Stress Assessment phase. Depending on the educational context and the available data sources, these indicators may include course workload, assessment demands, class participation, learning engagement, assignment completion, and student self-reported academic experiences. In this stage, students' academic stress level is estimated using an interpretable approach that makes the contributions of individual academic factors transparent in the overall stress estimation [17].

To support interpretability, this phase adopts an interpretable modeling approach that enables transparent representation of how individual academic factors contribute to the overall stress estimation. Such an approach may be implemented using inherently interpretable techniques, including additive models, consistent with recommendations from interpretable machine learning literature that emphasize transparency in user-facing systems [39]. Importantly, this stage is intended to support the structured interpretation of students' academic conditions rather than to provide clinical prediction.

3) Phase 3: Understanding-oriented explanation: The output of the Academic Stress Assessment phase is translated into structured explanations that are accessible to students. Instead of presenting raw numerical results, the system identifies and highlights the key academic factors that contribute to the estimated stress level and communicates their influence in clear, simple academic language.

This phase is designed to support interpretation rather than only presenting information. Research in human-centered explainable AI emphasizes that explanations should help users make sense of system outputs, not only reveal model behavior [40]. Explanations that align with human reasoning have been shown to improve both understanding and trust in AI systems [6].

Accordingly, the explanation process in LAURA follows three key principles: 1) attribution clarity, by identifying the most influential academic factors; 2) directional influence, by explaining how each factor increases or decreases stress; and 3) contextual meaning, by presenting explanations in relation to real academic situations.

By combining these elements, this phase reduces interpretive ambiguity and supports students in developing a clearer understanding of their academic conditions.

4) Phase 4: Reflection support: The Reflection Support phase encourages active engagement with the system's explanations. While explanations provide important information, they do not automatically lead to awareness. Therefore, this phase introduces structured reflection prompts to guide students in interpreting and internalizing the results [41].

Research on self-regulated learning highlights the importance of metacognitive processes in supporting adaptive academic behavior [42]. In addition, learning analytics studies show that dashboards integrating reflective prompts lead to greater engagement than systems that present only information [24].

Within LAURA, reflection is guided through simple and focused prompts that encourage students to 1) identify the main contributing academic factors, 2) consider how their recent academic experiences relate to these factors, and 3) think about possible small adjustments in their study strategies.

By supporting this reflective process, the system helps transform explanations into meaningful awareness. This phase enables students to move from passive observation to active interpretation of their academic conditions [43].

5) Phase 5: Adaptive awareness feedback: The Adaptive Awareness Feedback phase provides contextual and personalized suggestions based on the identified contributors to academic stress. These suggestions are designed to support awareness-informed academic adjustments rather than prescribe fixed or rigid interventions [44].

This phase closes the framework's awareness loop by linking explanation and reflection to actionable feedback. Through this process, students are encouraged to gradually adjust their academic strategies in response to the identified factors. Such feedback supports self-regulated learning by helping students translate understanding into practice [45].

The framework operates as an iterative process in which increased awareness can influence how students evaluate future academic demands, consistent with appraisal-based stress theory. Over time, this process may support improved self-regulation and reduce interpretive uncertainty.

By integrating modeling, explanation, reflection, and adaptive feedback, LAURA conceptualizes explainable AI as a cognitive support tool that promotes awareness and understanding rather than performance monitoring.

Through these interconnected phases, the framework supports an ongoing awareness process rather than a one-time estimation of academic stress.

Overall, the LAURA framework is grounded in academic stress theory, interpretive uncertainty in higher education, explainable artificial intelligence, and reflection-based learning design. It integrates context modeling, interpretable estimation, explanation, reflection, and adaptive feedback within a unified structure.

C. Awareness-Oriented Design Logic

The LAURA framework is designed primarily to support student awareness rather than to increase algorithmic complexity. While many AI-supported educational systems emphasize performance prediction or risk estimation and often rely on opaque models, LAURA adopts a different design perspective centered on helping students understand their academic conditions.

This perspective is reflected in three guiding design principles. First, transparency over complexity emphasizes the use of interpretable modeling structures that allow students to clearly see how academic factors contribute to outcomes. Second, explanation as communication focuses on translating analytical outputs into meaningful academic language that students can easily understand. Third, reflection as mediation highlights the role of structured reflection in helping students interpret and internalize system feedback. Fig. 3 illustrates how the three core design principles, transparency, explanation, and reflection, interact to support student awareness within the LAURA framework.

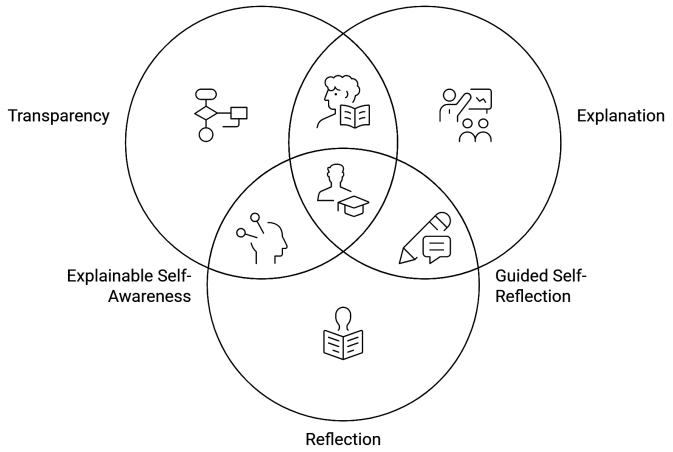

Fig. 3. Design principles supporting student awareness in the LAURA framework.

Together, these principles define LAURA as an awareness-oriented framework that supports interpretation, rather than prediction alone. In this way, explainable AI is positioned as a cognitive support mechanism that helps students better understand and navigate their academic experiences.

IV. Conceptual Interaction and Awareness Development

This section explains how the components of the LAURA framework interact conceptually to support students' awareness of their academic conditions. Rather than focusing on technical implementation, the emphasis is placed on how students engage with the system and how awareness develops through this interaction.

The interaction process begins when academic context indicators, such as perceived workload, deadline pressure, clarity of expectations, and comprehension difficulty, are represented in the system. These indicators provide a structured view of the

student's academic environment and serve as the foundation for subsequent interpretation.

Based on these inputs, the system generates an interpretable estimation of academic stress. Instead of presenting this estimate as a final result, it is framed as an explanation that highlights the main academic factors contributing. To ensure accessibility, explanations are conveyed in simple, non-technical academic language, as recommended in human-centered explainable AI research [46], with a focus on clarity and relevance to students' everyday academic experiences. This design helps reduce confusion that may arise from overly technical or abstract system outputs.

Following this, students engage with the reflection component. Through structured prompts, they are encouraged to interpret the explanation, relate it to their recent academic experiences, and identify potential areas for adjustment. To support engagement, the interaction is designed to feel conversational and context-aware, allowing students to connect system feedback with their personal academic situations. This is important, as awareness does not emerge from information alone, consistent with findings in learning analytics research [47] [48], but from active interpretation and engagement.

The system then provides adaptive feedback based on the interpreted results. These suggestions help students make small, manageable adjustments to their academic strategies, reinforcing the connection between understanding and action.

Importantly, this process is not linear but iterative. As students interact with the system over time, their understanding of academic conditions may evolve. This evolving awareness can influence how they interpret future academic demands, creating a continuous process of interpretation, reflection, and adjustment.

This interaction design is particularly important for students in diverse and international educational contexts, where differences in language, academic expectations, and communication styles may increase uncertainty when interpreting academic signals. By emphasizing clarity, explanation, and reflection, the framework supports inclusive understanding across different student backgrounds.

Through this interaction, LAURA supports the development of awareness as an ongoing cognitive activity. Rather than treating students as passive recipients of information, the framework encourages active engagement, interpretation, and gradual refinement of academic understanding.

V. Discussion

A. Theoretical Implications

The LAURA framework contributes to the theoretical understanding of academic stress by reconceptualizing it as an interpretive and awareness-driven process rather than a static or purely measurable outcome. While prior research has largely approached academic stress through psychological measurement or predictive modeling, this framework shifts the focus toward how students make sense of academic conditions. In this view, stress is determined not only by external demands but also by how those demands are interpreted within specific academic contexts. This perspective builds on prior work that emphasized the role of explainable AI in supporting student awareness of academic stress, particularly among international students [5].

This reconceptualization extends appraisal-based theories of stress into the domain of interactive and AI-supported educational systems. Rather than treating appraisal as an internal cognitive process detached from system design, LAURA positions it as a process that can be actively supported through interaction. By embedding interpretation within system feedback, the framework suggests that academic stress can be better understood when students are guided to examine how different academic factors contribute to their experiences.

From a system design perspective, a central theoretical contribution of this work lies in redefining the role of artificial intelligence in educational settings. Existing AI-based approaches in higher education have predominantly focused on prediction, classification, or early detection of risk. In contrast, the LAURA framework reframes AI as a mechanism for supporting meaning-making. In this context, explainability is not treated as a supplementary feature that reveals model behavior, but as a core component that enables students to interpret academic signals in a meaningful and contextually relevant way. This perspective shifts explainable AI from a technical property of models to a cognitive support mechanism within learning environments.

Furthermore, the framework establishes a conceptual link between explainable AI and metacognitive processes. While explanations can make system outputs more transparent, they do not necessarily lead to understanding on their own. LAURA addresses this limitation by integrating structured reflection into the interaction cycle, emphasizing that awareness emerges through active interpretation rather than passive exposure to information. This integration highlights the importance of reflection as a mediating process that transforms explanations into meaningful understanding.

By connecting interpretability, explanation, and reflection within a unified framework, LAURA provides a theoretical bridge between computational modeling and student-centered learning theories. It suggests that effective AI-supported educational systems should not only analyze academic conditions, but also support students in constructing an understanding of those conditions. In doing so, the framework advances a shift from performance-oriented analytics to awareness-oriented design, in which understanding becomes a primary outcome of the system.

B. Design Implications

The LAURA framework provides several implications for the design of student-facing AI systems, particularly in contexts where the primary goal is to support understanding rather than prediction. First, the framework highlights the importance of prioritizing interpretability over algorithmic complexity when systems are intended for direct interaction with students. In such contexts, models should be designed to allow clear identification of how individual academic factors contribute to system outputs, rather than relying on opaque approaches that limit user understanding.

Second, the findings suggest that explanations should be designed as a form of communication rather than technical

disclosure. Presenting numerical scores or abstract feature weights alone is insufficient for supporting student understanding. Instead, explanations should translate analytical outputs into clear academic meaning by explicitly linking system results to recognizable academic conditions, such as workload, deadline pressure, or clarity of expectations. This implies that explanation interfaces should prioritize clarity, contextual relevance, and alignment with students' everyday academic experiences.

Third, the integration of structured reflection highlights that awareness does not emerge automatically from exposure to system outputs. Systems should actively guide students in interpreting results with simple, focused reflection prompts. These prompts should encourage students to identify key contributing factors, relate them to recent academic experiences, and consider small, manageable adjustments. This suggests that reflection should be treated as a core design component, rather than an optional feature layered on top of analytics.

Finally, the iterative nature of the LAURA framework suggests that feedback should support gradual, continuous adjustment rather than immediate correction. Instead of prescribing fixed actions, systems should provide context-aware suggestions that help students refine their understanding over time. This approach aligns with how students regulate their learning in practice, where changes are often incremental and influenced by evolving academic conditions.

C. Implications for International Students

The LAURA framework is particularly relevant for international students, where challenges often arise not only from academic demands but also from difficulties in interpreting academic expectations and feedback. In such environments, students must navigate unfamiliar educational systems, grading practices, and communication styles, which can introduce additional layers of uncertainty beyond the academic workload itself. As a result, academic stress is often shaped by interpretive ambiguity rather than objective demands alone.

This context highlights a limitation in many existing learning analytics and AI-based systems. When systems present performance indicators or predictive outputs without sufficient explanatory support, they assume that students can interpret academic signals accurately. However, this assumption does not always hold for international students, who may lack familiarity with implicit academic norms or language-specific cues. In this sense, international student contexts make visible a broader issue: the gap between data presentation and meaningful understanding.

By emphasizing explanation and reflection, the LAURA framework directly addresses this interpretive gap. The framework supports students in making sense of academic signals by linking system outputs to clear and contextually meaningful explanations. In addition, structured reflection encourages students to actively interpret these explanations in relation to their own experiences, reducing uncertainty and supporting more informed academic decision-making.

Importantly, this perspective avoids framing international students in deficit-based or clinical terms. Instead, it treats the challenges they experience as issues of interpretation and understanding within complex academic environments. This allows for the design of supportive systems that empower students to navigate unfamiliar contexts more effectively, while also highlighting the importance of inclusive and accessible explanation design.

D. Limitations

Despite its contributions, the proposed LAURA framework has several limitations. First, LAURA is presented as a conceptual framework that establishes an awareness-oriented architectural and theoretical foundation for explainable AI in higher education. As such, its practical implementation and empirical evaluation were not addressed in the present study. Second, although the framework defines the key architectural components and interaction process, its effectiveness in supporting students' awareness, understanding, and academic decision-making has not yet been examined through prototype development or user studies. Finally, the framework is informed primarily by research on higher education, with particular attention to international students. Future research should therefore examine its applicability across diverse higher education contexts, student populations, and institutional settings.

E. Research Implications

The LAURA framework establishes a foundation for research that shifts the focus of AI-supported educational systems from predictive performance toward awareness and understanding. This shift suggests the need for evaluation approaches that go beyond accuracy-based metrics and instead assess how effectively systems support students' interpretation of academic conditions. In this context, constructs such as awareness, comprehension, and perceived interpretability should be treated as primary evaluation outcomes rather than secondary considerations.

Future studies should evaluate the LAURA framework by developing a functional prototype and conducting user studies in authentic higher education settings. These studies should examine whether the framework supports students in interpreting academic signals, developing awareness of the factors contributing to their academic stress, and engaging in meaningful reflection on their academic experiences. The evaluations should also examine the framework's perceived clarity, usefulness, and trustworthiness, and provide empirical evidence to refine it and assess its practical value in awareness-oriented educational AI systems.

This perspective opens several directions for empirical investigation. One important direction is to examine the extent to which explanation alone is sufficient to support understanding, compared with systems that integrate both explanation and structured reflection. Subsequent research can investigate whether reflection mechanisms significantly enhance students' ability to interpret academic signals and make informed adjustments to their learning strategies.

Another research direction concerns the design of explanation formats and their impact on student engagement and understanding. Variations in language, level of detail, and presentation style may influence how students interpret system outputs, particularly in diverse and international educational

contexts. Exploring these variations can provide deeper insight into how explainable systems can be tailored to support different student needs.

In addition, the framework raises questions about the trade-off between model complexity and interpretability in student-facing systems. While complex models may offer higher predictive performance, simpler, more transparent approaches may be more effective at supporting understanding and awareness. Investigating this balance can help clarify when interpretability should be prioritized over predictive accuracy in educational applications.

Overall, the LAURA framework encourages future research to move beyond performance-centered models and toward awareness-oriented system design. By emphasizing understanding as a primary outcome, this perspective supports the development of AI systems that not only analyze academic conditions but also help students meaningfully engage with and interpret their learning experiences.

VI. Conclusion

This study presented the LAURA framework as an awareness-oriented approach to help students understand their academic stress. The framework was developed in response to a key limitation in many existing academic analytics and AI-supported systems, which tend to emphasize prediction and performance monitoring while offering limited support for interpretation and understanding.

By bringing together transparent modeling, explanation, and structured reflection within a single interaction cycle, LAURA repositions the role of explainable AI in educational contexts. Rather than focusing only on estimating outcomes, the framework highlights the importance of helping students make sense of academic signals and connect them to their own experiences. In this way, awareness is treated as something that develops through interpretation, not simply through access to data.

A key contribution of this work is the view of explainable AI as a form of cognitive support within learning environments. Instead of serving only as a tool for analysis, the framework demonstrates how AI can help students identify relevant academic factors, understand their influence, and gradually adjust their approaches to learning. This perspective shifts attention from performance-focused analytics toward systems that support meaningful understanding.

The framework also highlights the challenges students face in interpreting academic expectations, particularly in unfamiliar educational settings. In such contexts, difficulties are not always related to workload alone, but to uncertainty in how academic signals are understood. By focusing on interpretation and reflection, LAURA offers a foundation for designing systems that are more accessible, inclusive, and supportive of diverse student experiences.

Overall, LAURA provides a conceptual foundation for the future development of awareness-oriented educational AI systems. Future studies should focus on developing functional prototypes, conducting user studies in authentic higher education settings, and examining how effectively the framework supports students' awareness, interpretation of academic signals, and reflective engagement. Such investigations will provide empirical evidence to refine the framework and further assess its practical value for awareness-oriented educational AI systems.

A Model-Free AI Framework for Robust PQRST Complex Detection in ECG Signals

Arthorn Luangsodsai, Manh Duong Dang, Krung Sinapiromsaran*
Department of Mathematics and Computer Science,
Faculty of Science Chulalongkorn University, Bangkok 10330, Thailand

***Abstract*—Accurate delineation of PQRST complex is essential for clinical ECG analysis, but remains challenging due to waveform variability, low amplitude, and polarity inversions. This work presents PAD-PQRST, a model-free Polarity-Adaptive Delineation method for PQRST complex. This approach leverages search windows based on established cardiac physiology. The Q and S waves are identified by locating the corresponding extrema relative to the R-peak polarity. Meanwhile, the P and T waves are determined by finding the extrema with the maximal absolute deviation from local mean. Because this design inherently accommodates waves of any polarity, it eliminates the need for a predictive model. This research uses the Manikandan2012 algorithm for R-peak detection due to its robustness. Validation on QTDB and LUDB yields F1-scores from 98.5% to 99.8% for QRS components, 90.97% to 94.57% for P-waves, and 79% to 91.41% for T-waves, surpassing established wavelet-based and graph-based methods. The combination of physiologically informed search windows and polarity-adaptive detection delivers a simple yet powerful delineation framework suitable for diverse clinical datasets.**

***Keywords*—ECG signal processing; PQRST detection; model-free AI; Polarity-Adaptive Delineation method**

I. Introduction

The electrocardiogram (ECG) is a non-invasive diagnostic tool that records the heart's electrical activity over time using cutaneous electrodes [1]. These electrodes detect voltage fluctuations arising from myocardial depolarization, and repolarization during each cardiac cycle [2]. The detected signals are amplified, and recorded as characteristic waveforms representing the sequence, timing of atrial, and ventricular electrical events [2]. The ECG is indispensable for rapid detection, and diagnosis of cardiovascular pathologies, including arrythmias, myocardial ischemia, electrolyte imbalances, and structural abnormalities [3]–[5]. By providing a visual representation of the heartbeat and its constituent PQRST complex, the ECG enables clinicians to assess cardiac function, guide treatment decisions, and monitor therapeutic efficacy across clinical settings [6], [7]. Its accessibility, cost-effectiveness, and diagnostic power render it essential for early identification of life-threatening conditions, or ongoing cardiac monitoring.

The cardiac cycle encompasses sequential mechanical, and electrical events facilitating effective blood circulation [8]. Coordinated chamber contraction, and relaxation are controlled by electrical impulses from the sinoatrial node [9]. The PQRST complex corresponds directly to the electrical events underlying these mechanical actions [10]. The P-wave signifies atrial depolarization [10], [11]. The QRS complex corresponds to ventricular depolarization [10]. The T-wave represents ventricular repolarization. Each component provides a distinct electrical signature essential for distinguishing normal from pathological cardiac function. The PQRST complex adheres to well-defined physiological timing constraints. In healthy adults, the P-wave persists for 0.08 to 0.10 seconds, while QRS complex endures for 0.06 to 0.10 seconds [12]. The PR interval ranges from 0.12 to 0.20 seconds, and the QT interval from 0.35 to 0.43 seconds, together they make up the temporal span of the PQRST complex [12]–[15]. Deviations from these norms constitute significant markers of cardiac pathology. The morphology, amplitude, and duration of individual waves supply essential clinical information regarding cardiac function, and underlying pathologies, making comprehensive PQRST analysis fundamental to cardiovascular diagnosis [10], [16]–[18].

II. Background

Several approaches have been developed for automated delineation of PQRST complexes in ECG signals. One cycle of the PQRST complex can be visualized in Fig. 1. Marinez proposed a wavelet-based methodology that exploits the multiscale properties of the dyadic wavelet transform to robustly identify characteristic waveform points [19]. Kalyakulina also developed a wavelet-transform-based delineation method [20]. Bote contributed with low-complexity derivative-based approach to detect fiducial points [21]. More recently, Emrich introduced a prominence-based approach that identifies waveform features using peak prominence, a measure of a point's relative height above its local baseline [22]. Additionally, Neurokit2 also provided a toolbox for biomedical signal processing, which also include PQRST detection [23].

Despite its clinical importance, ECG analysis presents significant challenges. Inherent signal variability arises from inter-individual physiological differences, diverse pathologies, and varying measurement environments, complicating consistent feature extraction [24]. ECG signals are frequently contaminated by noise sources, including baseline wander, powerline interference, myoelectric activity, and motion artifacts, which degrade signal quality, and impede precise detection of low-amplitude P, and T waves [24]. These complications lead to detection techniques for P, and T waves not being researched as intensively as QRS detection [11]. The non-stationary nature of ECG signals further necessitates sophisticated adaptive preprocessing. Moreover, machine learning, and deep learning approaches face limitations, including dependence on large label datasets, lack of interpretability, and computationally expensive, constraining real-time clinical applicability [24].

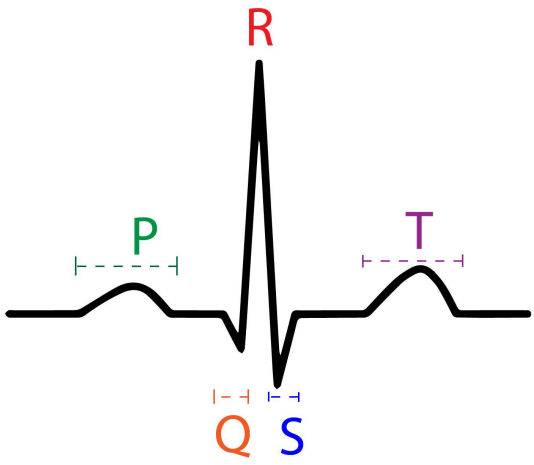

Fig. 1. PQRST complex

These challenges motivate this research into robust, efficient, and transparent ECG analysis methods. Reliable automatic detection of critical fiducial points, particularly R-peaks, and other PQRST components, can reduce clinician burden, minimize human error, and enable continuous monitoring [7]. Algorithms that do not rely heavily on prior training, or extensive parameter tuning offer broader applicability across diverse populations, and signal conditions. Such advancements would enhance clinical decision-making, enable personalized cardiac care, and ultimately improve patient outcomes.

This work introduces a model-free PQRST delineation methodology that combines a polarity-adaptive approach with physiologically grounded search windows to provide competitive performance on QTDB and LUDB without any prior training.

III. Methodology

A. Overview

This study proposes the algorithm PAD-PQRST, Polarity-Adaptive Delineation of PQRST complex, as presented in Fig. 2. The process starts with the processing of ECG signals to remove noise, baseline wander and Z-score normalization. After the signal is preprocessed, the algorithm starts with R-peak detection, utilizing Manikandan2012's algorithm. Once the R-peaks are detected, the algorithm executes a hierarchical detection cascade on the Z-score normalized signal, which sequentially identifies Q, S, P, and T waves using physiologically constrained search windows anchored to each detected R-peak. Q and S-waves are located based on R-peak polarity, while P and T-waves employ adaptive absolute amplitude thresholding within their respective search windows. Finally, the output results of the proposed algorithm are the indexes of PQRST complex waveform components of the original ECG signal.

B. Preprocessing

The preprocessing stage employs a 4th order Chebyshev type I bandpass filter with a passband of 6-18 Hz, implemented using both forward and backward filtering to eliminate phase distortion. This specific filter configuration was selected based on the spectral characteristics of the QRS complex, which concentrates its energy predominantly within this frequency range. The lower cutoff frequency of 6 Hz effectively reduces baseline wander, respiratory artifacts, and low-frequency components of P, and T waves, while the upper cutoff frequency of 18Hz suppresses high-frequency noise from powerline interference, muscle contractions, and motion artifacts. This effect can be observed from the difference between the original signal in Fig. 3 and the result of the preprocessing filter in Fig. 4, where the R-peaks amplitude is retained, the baseline becomes relatively stable. Despite this filter reducing the prominent P and T waves, it makes the process to detect Q and S waves easier, which are subsequently used as anchor to detect the lower frequency waves.

Specifically, for the PQRST delineation process, the algorithm also employs Z-score normalization. This step involves subtracting the mean ECG amplitude value from each data point, ensuring consistency, and reinforcing relationship between the signal value, and its position relative to the baseline. This is demonstrated by the signal in Fig. 5, where the data points above the baseline have positive values, and points below the baseline have negative values.

C. R-Peak Detection

After the ECG signal has been preprocessed, The PQRST delineation process begins with R-peak detection. In principle, any reliable R-peak detector can serve as the temporal anchor for this step [26]–[36] . However, for optimal performance of subsequent PQRST delineation, a detector with high Positive Predictive Value (PPV) is preferred, as it limits the number of false positive R-peaks that would otherwise be used as anchors to detect non-existent or false PQRST complexes. While the outlier detection-based MOW-ECG algorithm demonstrated the highest PPV among compared methods in earlier research, its overlapping window mechanism may affect the performance of PQRST detection due to additional complexity [36]. Therefore, to isolate and focus more directly on the PQRST delineation logic itself, the method presented by Manikandan, and Soman was utilized for this study [25]. This method employs a multi-stage signal processing approach that combines digital filtering, nonlinear transformation, and Hilbert transform-based peak identification [25]. This chosen method provides excellent sensitivity, and PPV, allowing a cleaner evaluation of our polarity-adaptive PQRST framework.

D. PQRST Delineation

1) Initialization of physiological parameters: Following the detection of R-peaks, the detected peaks serve as reference landmarks for delineating the complete PQRST complex. The proposed methodology incorporates established physiological constraints, and temporal relationships between waveform components to accurately identify each feature [14], [15], [37]–[39]. Specifically, search windows are defined based on clinically observed intervals:

- Q wave: A 120 ms window preceding the R-peak
- S Wave: A 180 ms window following the Q-wave

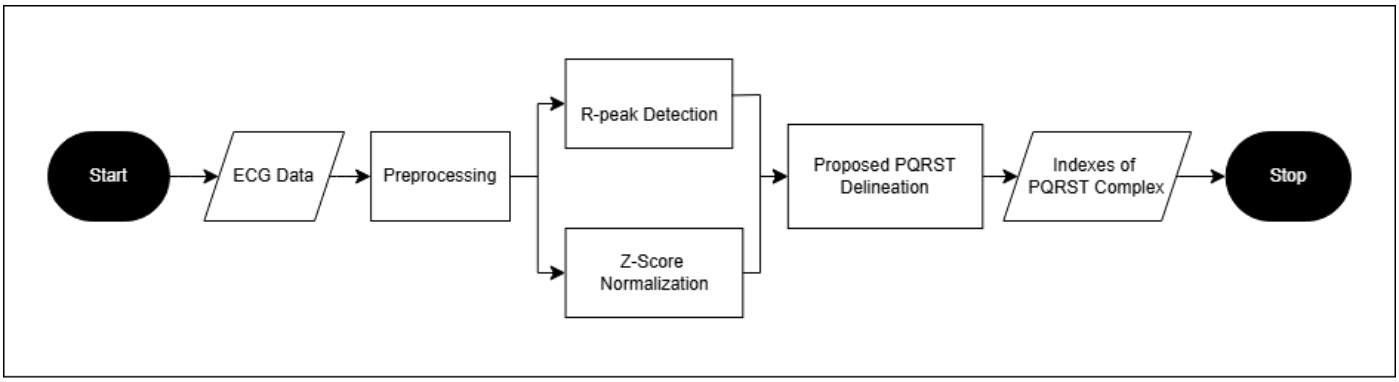

Fig. 2. Proposed PQRST delineation algorithm overview.

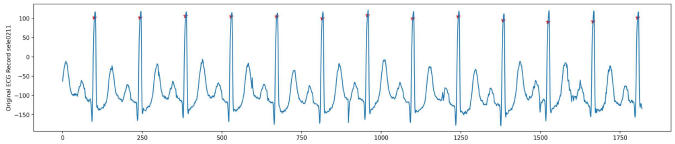

Fig. 3. QTDB's original record sele0211.

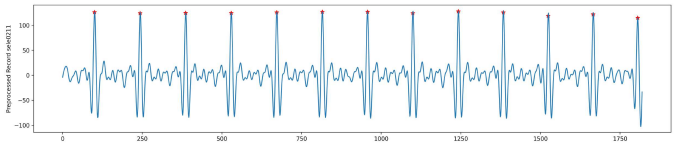

Fig. 4. Preprocessed record sele0211.

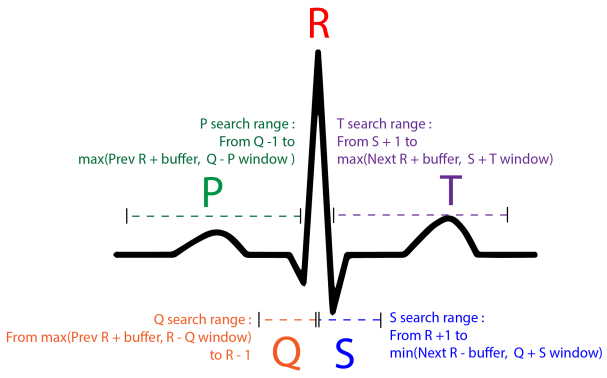

Fig. 6. Search range of PQRST complex's features.

- P Wave: A 300 ms window preceding the Q-wave
- T Wave: A 400ms window following the S-wave, with a minimum separation of 150 ms

The selection of these search windows is grounded in clinically observed intervals, and is depicted in Fig. 6. Based on the typical duration between QRS onset, and the R-peak, which ranges from 50 to 100 ms, a 120 ms search window for the Q-wave is established prior to the R-peak [14], [15]. The normal QRS duration is approximately 100 ms, and is considered abnormal when exceeding 120 ms [14], [38]. Accordingly, a 180 ms search window for the S-wave following the Q-wave is employed. The P-wave is subsequently searched within a 300 ms window preceding the Q-wave to ensure the PR interval remains within its normal physiological range of 120-200 ms [38]. The T-wave is searched within a 400 ms window after the S-wave, with a minimum separation of 150 ms from the S-wave to respect cardiac repolarization timing [38], [39]. To establish physiologically constrained search windows for individual PQRST complexes, the detection algorithm utilizes the temporal relationship between consecutive R-peaks. For each detected R-peak, the preceding R-peak boundary is defined as the previous detected R-peak when available. At the beginning of the recording where no prior peak exists, this boundary is set to the current R-peak position minus a minimum RR interval value of 200ms, ensuring the search window does not extend indefinitely backwards [26]. Similarly, the following R-peak boundary is defined as the next detected R-peak when available, or the current R-peak position plus a 200ms interval when processing the final cardiac cycle. This 200ms window, corresponding to the physiological refractory period of the heart, serves as a conservative fallback that prevents the search algorithm from extending beyond expected cardiac cycle boundaries while accommodating heart rate variability. This approach ensures that each PQRST complex is analyzed within a locally adaptive window that respects the individual cardiac rhythm. Additionally, a 100 ms buffer interval is further incorporated to maintain clear isolation between adjacent waveform features during search window determination, therefore minimizing interference, and improving detection accuracy.

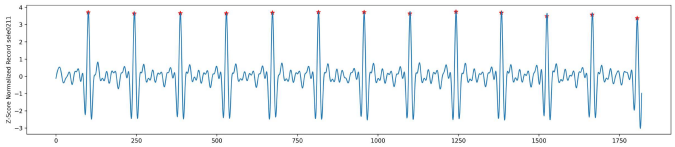

Fig. 5. Z-Scored record sele0211.

2) Sequential detection of waveform: Following R-peak detection, the proposed algorithm executes a hierarchical de-

tection cascade for each identified R-peak to delineate the complete PQRST complex, as illustrated in Fig. 7. This cascade proceeds sequentially, first identifying the Q, and S waves, then subsequently locating the P, and T waves based on the detected Q, and S positions using physiologically constrained search windows. The process begins by determining the polarity of the detected R-peak through examination of its Z-score normalized value, classifying it as either positive, or negative to guide subsequent wave searches.

For Q-wave detection, the search range is defined to begin at the maximum value between two boundaries, which are the previous R-peak location plus a buffer interval, and the current R-peak location minus the predefined Q-wave search window. The search range extends up to one sample point before the current R-peak location. Within this interval, the algorithm identifies the Q-wave as either a local minimum, or maximum depending on R-peak polarity based on its Z-score. Specifically, if the current R-peak is positive, the Q-wave corresponds to the local minimum, and, conversely, for a negative R-peak, the Q-wave is found at the local maximum position.

The S-wave search range commences immediately after the current R-peak, and continues until the minimum value between the two constraints of the next R-peak location minus the buffer interval, and the current Q-wave location plus the S-wave search window. Applying the same polarity-dependent logic, the S-wave is identified as the local minimum when the R-peak is positive, and as the local maximum when the R-peak is negative.

The P-wave detection employs a more sophisticated approach within a search range that begins at the maximum value between two potential starting points of the Q-wave location minus the P-wave search window, and the buffer interval plus the previous T-wave location if available, otherwise the previous R-peaks serve as the reference. The search range concludes at one sample point before the Q-wave. Within this segment, the algorithm first computes three key parameters. First, the dynamic range, which is calculated as the difference between maximum, minimum values within the segment. Second, the minimum amplitude threshold, which is defined as 10% of the dynamic range. Finally, the mean value of the search segment. Subsequently, the algorithm evaluates all point-to-point differences within the search segment to identify all local maximum and minima positions. A point is classified as local maximum if the current point is larger than both the previous point, and the next point. The local minimum satisfies the opposite conditions. From the identified extrema, the algorithm extracts the ECG amplitudes, selecting the highest peak among all local maxima, and recording its position, and amplitude, while similarly identifying the deepest valley among all local minima. The algorithm then computes the absolute deviations of both the maximum peak, and minimum valley from the segment mean. If the absolute maximum peak deviation exceeds both the absolute minimum valley deviation, and the minimum amplitude threshold, the P-wave is assigned to the maximum peak location, otherwise the minimum valley location is selected.

The T-wave search range is defined to begin 150 ms after the detected S-wave, ensuring adequate separation to respect cardiac repolarization timing, and extends until the minimum value between the next R-peak location minus the buffer interval, and the detected S-wave location plus the T-wave search window. The T-wave localization then proceeds using the same adaptive absolute extrema selection methodology employed for P-wave detection, as it inherently accommodates biphasic or inverted T-wave, a clinically significant morphological variation, as observed in Fig. 8. Instead of assuming positive deflection, the proposed algorithm simultaneously evaluates both local maxima, minima within the search window and select the extremum with the greatest absolute value. This approach combines with the minimum 150ms separation from the S-wave further prevent confusion with the QRS complex, ensure that the proposed algorithm can maintain consistent and physiologically plausible identification of T-waves.

E. Complexity Analysis

The computational complexity of the proposed algorithm PAD-PQRST is characterized by $O(n*m)$, where n represents the number of detected R-peaks in the ECG signal, and m represents the maximum search window size in samples used for the delineation of P, Q, S, T waves. The parameter m is determined as the products of the sampling rate and the fixed temporal windows defined for each waveform component. This linear scaling arises because the algorithm processes each R-peak independently. For each cardiac cycle, PAD-PQRST executes a fixed number of localized operations confined to constant-sized windows that are proportional to physiologically meaning time intervals. All these operations involve only a bounded number of samples per beat, independent of total signal length. The overall computational complexity scales linearly with the number of heartbeat n. The design of the algorithm allows it to avoid exhaustive search over the entire ECG record, and focuses processing on the regions of interest surrounding each cardiac complex. As a result, the algorithm is well-suited for real-time physiological signal processing applications, including continuous monitoring on resource-constrained devices.

IV. Results and Discussion

A. Datasets

The QT Database (QTDB) comprises 105 fifteen-minute ECG recordings, each annotated by an expert cardiologist for the onset, peak, and offset of P waves, QRS complexes, and T waves of 30 to 50 beats in each recording [40]. It is recorded at a sampling frequency of 250 Hz, its primary lies in its detailed manual annotations of key waveform features, making it a crucial resource for validating delineation algorithms. The Lobachevsky University ECG Database (LUDB) was created to provide a comprehensive resource for training, and validating ECG delineation algorithms [41]. It addresses a key limitation of QTDB by offering exhaustive manual annotations. It consists of 200 ten-second, 12-lead ECG recordings digitized at 500 Hz. For every single beat across all 200 records, certified cardiologist manually marked the boundaries, and peaks of P, T, and QRS complexes in all 12 leads. The database includes recordings from both healthy volunteers, and patients with various cardiovascular conditions, pacemakers, and other abnormalities. Its complete annotation set makes it exceptionally valuable for developing, and testing ECG delineation algorithms. The Brno University of Technology

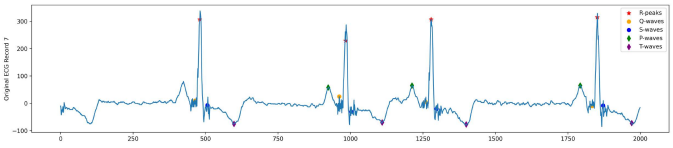

Fig. 8. LUDB's record 7 with inverted T-waves.

ECG Signal Database with Annotations of P Wave (BUT-PDB) consists of 50 two-minute, two-lead ECG records with various pathology types [42]. This dataset only contains P-wave positions, which were manually annotated in each beat by two experts. The recordings in this dataset were chosen to include high incidence of cardiac pathologies, resulting in a dataset that covers 23 different pathological conditions to challenge P-wave detection under clinically relevant conditions. The MIT-BIH Arrhythmia Database P-Wave Annotations (MIT-BIH-PDB) provides reference annotations for P-waves for a curated subset of 12 records from the widely used MIT-BIH Arrythmia Database [43]. The records were chosen due to the presence of abnormal cardiac morphologies that complicate P-wave detection. The annotations were manually made by two experts.

B. Performance Evaluation

The performance of the proposed PQRST delineation algorithm is evaluated using a tolerance window of 150 ms to be incompliance with ANSI/AAMI-EC57:1998 standard [44]. A detection is classified as true positive (TP) if its location fell within the tolerance window around the reference annotation. Detected points with no matching annotation are counted as false positives (FP), representing errors where the algorithm incorrectly identified a waveform component in noise, or non-QRS features. Conversely, annotated points that the algorithm failed to detect are recorded as false negatives (FN). Based on these fundamental counts, the F1 score was computed for each wave type to provide a balanced assessment of detection accuracy, as defined by Eq. (1):

$$F1[\%] = \frac{2TP}{2TP + FP + FN} \tag{1}$$

Additionally, to provide further context to the primary metrics of F1 score, Sensitivity, Positive Predictive Value (PPV), and Detection Error Rate (DER) were calculated using the respective formulas from Eq. (2) to Eq. (4):

$$Sensitivity[\%] = \frac{TP}{TP + FN} \tag{2}$$

$$PPV[\%] = \frac{TP}{TP + FP} \tag{3}$$

$$DER[\%] = \frac{FP + FN}{TP + FN} \tag{4}$$

These metrics range from 0% to 100%, with higher values indicating better overall detection performance.

C. Methods Used for Comparison

To evaluate the performance of the proposed PAD-PQRST algorithm in PQRST complex delineation, three methods are selected to be used as benchmarks. These methods are a dyadic wavelet transformed-based delineation technique by Martinez2004 [19], a visibility graph, and prominence-based technique by Emrich2024 [22], and a continuous wavelet transform-based technique provided by the Neurokit2 toolkit [23].

D. Comparison Against Established Methods

The results of the comparative experiment on QTDB, summarized in Table I, demonstrate exceptional performance of the proposed method. For the detection of Q, R, S waves, the proposed method achieves near perfect F1 scores of 99.68% for Q-wave, 99.86% for R-wave, and 99.70% for S-wave. These values are more than 20% higher than Martinez2004, and Emrich2024, with the best competitor Neurokit2 CWT, which reached 96.81% for Q-wave, 98.98% for R-wave, and 92% for S-wave. The near-perfect F1 score of PAD-PQRST reflects both extremely high Sensitivity, PPV, as well as the below 1% DER, indicating that the method almost never misses a true beat nor generates false detections. This performance validates the combination of a robust R-peak anchor with the proposed polarity-adaptive approach. On P-wave detection results, the proposed method achieves an F1 score of 92.33%, which outperforms Martinez2004 by a margin of 19%, and Emrich2004 by a margin of 22%. The improvement is driven by higher FP rate compared to QRS detection is expected because low-amplitude P-waves can be confused with noise or baseline fluctuations. The T-wave remains the most challenging component, with the proposed algorithm reaching an F1 score of 78.69%. Although PAD-PQRST still outperforms Martinez2004 by 19%, and Emrich2024 by 29%, the F1 score

	F1	**29.52%**	**96.81%**	**98.98%**	**92.00%**	**65.87%**
Proposed Method	TP	10754	12326	12353	12329	10534
	FP	1591	53	26	50	1814
	FN	196	27	9	25	3890
	Sensitivity	98.21%	99.78%	99.93%	99.80%	73.03%
	PPV	87.11%	99.57%	99.79%	99.60%	85.31%
	DER	16.32%	0.65%	0.28%	0.61%	39.55%
	F1	**92.33%**	**99.68%**	**99.86%**	**99.70%**	**78.69%**

is lower than other waves. Further investigation shows that the sensitivity, at 73.03%, can be the limiting factor as many T-waves, especially those with low amplitude, or flattened morphology, are missed. The DER indicates about 39.55% of detections are either missed or false, which confirms that T-wave delineation remains a challenge.

The LUDB experiment results, presented in Table II, provide critical validation of the method's generalizability across diverse patient populations, and pathological conditions with exhaustive annotations. The F1 score of PAD-PQRST remains very high for all components, despite the increased morphological variability. The proposed method achieves F1 score of 98.94% for Q-wave, 99.08% for R-peak, and 98.80% for S-wave. These are consistently 3 to 5 percentage points higher than the next best method, either Neurokit2 CWT, or Emrich2024. The slightly lower F1 score of PAD-PQRST compared to QTDB reflects the wider range of morphologies present in LUDB. Additionally, the drastically shorter signal can also explain the sharp rises in performance for the other methods used for comparison. For P-wave, the proposed method attains an F1 score of 95.03%, which is 4% higher than Martinez2004, Emrich2024, and 22% higher than Neurokit2 CWT. Notably, the sensitivity of the PAD-PQRST is slightly lower than on QTDB, possibly due to LUDB's exhaustive annotation includes very low-amplitude P-waves that can be confused with noise. For T-wave, the proposed method reaches an F1 score of 91.20% on LUDB, which is 5% higher than Martinez2004, Emrich2024, and 12% higher than Neurokit2 CWT. This is substantially better than the performance on the QTDB, likely due to LUDB's T-waves are annotated more consistently, including a wide range of morphologies that the proposed polarity-adaptive selection handles well. The improvement suggests that PAD-PQRST generalizes well to diverse morphological patterns, but still leaves room for further refinement. Nevertheless, the proposed polarity-adaptive approach still outperforms wavelet-based methods even on lower amplitude waveforms.

Table III summarizes the result of P-wave detections on BUT-PDB. The proposed method achieves F1 score of 80.20%, which is 3% higher than Maritnez2004, Emrich2024, and 40% higher than Neurokit2 CWT. The sensitivity is very high, but the PPV, at 69% is moderate. This means many FP occur, likely due to the shorter, and noisy recording with increased amount abnormal P-waves.

Table IV shows the result of P-wave detection on MIT-BIH-PDB. The proposed method achieves F1 score of 88.33%, essentially tied to Martinez2004, at 88.21%, and substantially higher than Emrich2024, and Neurokit2 CWT. This indicates that on this database, the wavelet-based method remains competitive, but PAD-PQRST matches its performance while being simpler, and parameter-free.

E. Discussion

1) Robustness to morphological and temporal variations: Unlike traditional rule-based methods that rely on rigid, time-invariant forward-search intervals, PAD-PQRST introduces a localized, dynamic coordinate system bounded by piece-wise

continuous functions of instantaneous $R-R$ intervals (Ω_{left} and Ω_{right}). This mathematical adaptation prevents the structural overlap and false positives common to standard rule-based heuristic search windows during extreme tachyarrhythmias or bradyarrhythmias. Furthermore, while wavelet-based delineation methods excel at multi-scale frequency decomposition, they frequently struggle with morphological transformations (such as inverted T-waves or wide-complex bundle branch blocks) because their thresholding and modulus maxima selection schemes implicitly assume standard directional profiles. PAD-PQRST overcomes this limitation through its Polarity-Adaptive Extrema Selection formulation. By optimizing the absolute deviation from the local segment mean ($|f(x) - \mu_S|$) and scaling thresholds dynamically relative to the local range (Δ_S), our framework treats upright, inverted, and biphasic waves with mathematical symmetry. This eliminates the need for predefined shape templates or complex wavelet phase tuning, enabling the model to sustain high F_1 scores across severely deformed pathological datasets.

2) Overall performance: The proposed method achieves superior F1 scores for all PQRST components on four independent datasets. This consistent superiority across different sampling rates, patient populations validate the generalizability of the polarity-adaptive, physiologically constrained approach. Notably, the proposed method requires no dataset-specific tuning, as the established search window are fixed physiological constraints, and the only hyperparameter is the

empirically derived minimum RR interval of 200ms. This is a substantial practical advantage over methods that rely on optimized thresholds or trained parameters.

The proposed method achieves the near perfect detection of QRS complex on QTDB, as well as LUDB, despite the greater morphological diversity. These results have two important implications. First, when the R-peak anchor is accurate, the polarity-adaptive extrema search for Q, and S-wave is highly effective across the full range of QRS morphologies. Secondly, the QRS delineation accuracy of the proposed method is now primarily limited by the quality of the R-peak detector.

For P-wave detection, the proposed PAD-PQRST achieves the highest reported F1 score on all four datasets. The proposed method maintained high sensitivity throughout, which indicates that the method rarely misses a true P-wave. However, the PPV exhibits some fluctuations especially with noisier dataset, which also reflects the inherent difficulty of distinguishing very low-amplitude amplitude P-waves from baseline noise. Additionally, PAD-PQRST also demonstrated competitive results against wavelet-based method while being simpler, parameter-free, and more interpretable.

T-wave delineation remains the most difficult waveform components to detect reliably, as evidenced by the lower F1 scores. Despite this challenge, PAD-PQRST still outperforms the selected benchmark methods in both QTDB, and LUDB. The polarity-adaptive extrema selection, which does not assume an upright T-wave, is particularly beneficial for correctly identifying inverted T-waves. The fixed 150ms minimum separation from the S-wave also prevents confusion with the QRS complex. Nevertheless, the T-wave delineation still leaves room for improvement, and further refinement. Future work could explore adaptive sizing based on heart rate, post-detection morphological classification, or utilization of multi-lead information to resolve ambiguous repolarization patterns.

3) Limitations: Several limitations of the proposed method should be acknowledged. First, although the method is parameter-free, the search window durations for each waveform components were fixed based on standard adult physiology. These may not be optimal for pediatrics, or extremely abnormal recordings, where adaptive window scaling could be more beneficial. Second, as the method processes each heart independently, it does not leverage inter-beat consistency, which could be used to correct the occasional outliers. Third, the current implementation only utilizes single-lead signal, which leaves the possibility for future work to investigate the utilization of multiple lead to improve robustness. Fourth, although our analysis identifies low amplitude as a primary factor in detection errors, the absence of detailed patient metadata in the public dataset precludes a comprehensive morphological sub-analysis.

V. Conclusion

This work introduced a PQRST delineation framework PAD-PQRST built on two foundational principles, physiologically derived search windows and polarity-adaptive extremum selection. The method requires only a reliable R-peak detector, Manikandan2012 for this instance. The search windows are directly rooted in cardiac physiology, while the selection of the extremum with maximal absolute deviation from the segment mean inherently handles upright, inverted, and biphasic waves without additional heuristics. Evaluated primarily on QTDB and LUDB, this proposed methodology proved highly effective with F1-scores over 98.5% for delineation of QRS components, 90.97% to 94.57% for P-waves, and 79.57% to 91.41% for T-waves, consistently surpassing complex wavelet, and graph-based alternatives. The result underscores that a carefully designed, physiologically grounded approach can achieve competitive accuracy while remaining computationally lightweight, and easy to implement.

Future work will translate the PAD-PQRST framework into clinical and consumer-wearable applications by pursuing several key avenues. First, the real-time implementation of the algorithm on low-power embedded devices (such as microcontrollers used in wearable ECG patches) must be explored optimizing the localized mathematics for fixed-point arithmetic. Second, the extension from single-lead to multi-lead analysis will be investigated, allowing the system to leverage spatial redundancy across channels. Third, the adaptive window-scaling mechanisms should be explored that dynamically adjust the boundary parameters based on instantaneous heart rate variability. Finally, this work should incorporate a lightweight signal-quality index (SQI) module to proactively identify and flag highly noisy recordings, ensuring high-fidelity delineation even under severe ambulatory motion artifacts.

Privacy-Preserving Feature Engineering Framework for Real-World Vulnerability Risk Prediction

Jawharah Albarakati, Tawfiq Hasanin, Suaad Alarif
Department of Information Systems, King Abdulaziz University, Jeddah, Saudi Arabia

***Abstract*—This study introduces a privacy-preserving data preparation and feature engineering framework designed for machine learning-based cybersecurity vulnerability risk prediction, utilizing real-world enterprise scan data from an operational cloud environment. To transform raw vulnerability records into a structured, machine-readable format while complying with personal data protection regulations, the framework integrates systematic data cleaning, missing value imputation, categorical encoding, text normalization, and host pseudonymization. Exploratory data analysis (EDA) was conducted on 36,940 operational records to examine dataset characteristics, vulnerability distributions, and severe class imbalances. Multiple classifiers—including Logistic Regression, Random Forest, XGBoost, and LightGBM—were evaluated under extreme imbalance conditions mitigated via SMOTE. Experimental results demonstrate that non-linear tree-based ensembles achieved the highest predictive performance, with LightGBM attaining a macro F1-score of 0.9974. Comparative analysis further indicates that the effectiveness of textual representations depends on the underlying classifier architecture, with semantic embeddings yielding the best performance when combined with tree-based ensemble models, while TF-IDF remained competitive for linear classificationThese findings underscore the critical role of structured text preparation and semantic representation in enhancing model reliability, interpretability, and scalability for automated vulnerability prioritization.**

***Keywords*—Data pre-processing; machine learning; protecting sensitive data; stemming; pseudonymization**

I. Introduction

Cybersecurity has become a critical concern for organizations due to the increasing frequency and sophistication of cyber threats. Vulnerability assessment plays a central role in identifying and prioritizing security weaknesses across enterprise infrastructures, including networks, servers, applications, and cloud environments.

The effectiveness of machine learning–based vulnerability management depends heavily on the quality of the underlying data. However, cybersecurity logs are often noisy, incomplete, and heterogeneous, requiring preprocessing techniques such as missing-value handling, normalization, categorical encoding, and text feature extraction. These steps improve data quality and transform raw telemetry into representations suitable for predictive risk analysis.

In this study, operational security data was collected using the Nessus Vulnerability Scanner, a widely adopted industry-standard solution for identifying system vulnerabilities [1]. Nessus facilitates comprehensive infrastructure auditing across cloud environments, producing highly detailed vulnerability records. To leverage this data safely, raw scan reports are systematically processed to eliminate operational duplicates, validate network configurations, and mask sensitive host telemetry. This ensures strict adherence to data privacy standards and compliance with personal data protection regulations without degrading the predictive utility of the features.

Traditional vulnerability prioritization approaches often rely on static scoring methods or keyword-based techniques that may fail to capture the semantic information contained in vulnerability descriptions. To address this limitation, this study develops a privacy-preserving feature engineering framework that integrates structured vulnerability attributes with textual representations derived from both TF-IDF and Sentence-BERT (SBERT). In addition, exploratory data analysis (EDA) is conducted to examine data characteristics, feature distributions, and class imbalance patterns before model development.

The main contributions of this study are as follows:

- A privacy-preserving data preparation and feature engineering framework for real-world enterprise vulnerability telemetry, incorporating host pseudonymization to support compliance with Personal Data Protection Law (PDPL) requirements.
- A comparative evaluation of lexical (TF-IDF) and semantic (SBERT) text representations for encoding unstructured vulnerability descriptions.
- An empirical assessment of four machine learning models (Logistic Regression, Random Forest, XGBoost, and LightGBM) under severe class imbalance conditions using SMOTE-based mitigation.
- An analysis of the impact of semantic representations on vulnerability severity prediction performance in operational enterprise environments.

II. Related Work

Vulnerability assessment is a cornerstone of proactive cybersecurity risk management, aimed at identifying, analyzing, and prioritizing system flaws. Traditional vulnerability management heavily relies on static rule-based scanning tools and standardized frameworks, such as the Common Vulnerability Scoring System (CVSS) [2][3]. While efficient for cataloging known security flaws, these traditional methods lack adaptability and fail to capture the dynamic, contextual properties of real-world enterprise vulnerability telemetry [4].

To overcome these limitations, recent research has shifted toward supervised machine learning algorithms to enhance predictive risk prioritization. For instance, Sabottke et al. utilized machine learning to predict vulnerability exploitability

by leveraging language attributes from vulnerability descriptions [5], while Neuhaus et al. demonstrated that supervised learning models can effectively prioritize vulnerabilities based on historical exploitation trends [6]. Similarly, recent advancements have focused on exploitability prediction and automated severity forecasting using high-dimensional datasets [7], [8]. However, a persistent limitation in these approaches is their reliance on clean, static, and balanced batch-learning benchmarks, which rarely reflect the chaotic nature of real-world, live operational environments.

The predictive performance of these machine learning frameworks is fundamentally constrained by the quality and representation of the underlying data. Raw vulnerability logs are notoriously noisy, unstructured, and heterogeneous, demanding extensive preprocessing [9][10]. Koukaras and Tjortjis emphasized that rigorous feature engineering and data preparation are critical prerequisites for meaningful data mining and analysis [9]. In the context of textual cybersecurity data, standard Natural Language Processing (NLP) techniques—such as tokenization, stemming, and Term Frequency-Inverse Document Frequency (TF-IDF) weighting—have been widely adopted to extract patterns from unstructured vulnerability descriptions [11], [12]. While integrating these lexical features with structured attributes has been shown to improve accuracy [13], traditional keyword-matching techniques like TF-IDF fail to capture the deeper semantic nuances of security vulnerabilities. Although dense semantic representations (e.g., Transformer-based embeddings) have revolutionized general NLP, their systematic evaluation against traditional lexical features remains under-explored in operational vulnerability frameworks.

Concurrently, compliance with data privacy mandates has emerged as a critical requirement in cybersecurity analytics. Implementing machine learning on live enterprise telemetry introduces severe privacy risks, as scanner logs often contain sensitive network topologies and host identifiers. To mitigate this, various privacy-preserving preprocessing strategies, such as data masking and pseudonymization, have been proposed to safeguard identities while preserving analytical utility [14], [15]. Truong et al. and Riabi et al. demonstrated that secure pseudonymization strategies can satisfy regulatory constraints (such as the GDPR or PDPL) without degrading downstream classifier accuracy [16], [17].

Despite these advancements, existing literature often treats data preprocessing, privacy preservation, text representation, and class imbalance mitigation as isolated problems. Many studies evaluate models under idealized, balanced, or strictly static conditions, overlooking the severe class imbalances inherent to operational environments [18].

Unlike prior works that focus solely on standalone classification performance or isolated exploit prediction, this study introduces a unified, systematically integrated framework. We combine regulatory-compliant privacy preservation, hybrid structured-textual feature engineering (lexical vs. deep semantic embeddings), and robust class imbalance mitigation using SMOTE. The contribution of this work lies not in proposing a novel standalone classifier, but in empirically demonstrating how a meticulously engineered data preparation and semantic feature construction pipeline can maximize operational risk classification fidelity using heterogeneous enterprise cybersecurity data (Fig. 1).

III. Research Methodology

The proposed research methodology consists of five sequential phases. First, vulnerability data were collected from a real-world enterprise cloud environment using the Nessus vulnerability scanner. Second, data preprocessing and privacy-preserving transformations were applied. Third, feature engineering was performed. Fourth, multiple supervised machine learning models were trained, while class imbalance was addressed using SMOTE and class-weighted learning strategies. Finally, a comparative experimental evaluation was conducted to assess model performance using several classification metrics across multiple vulnerability risk categories.

A. Data Collection and Acquisition

The foundational phase of establishing a robust machine learning-based vulnerability assessment framework begins with systematic data acquisition. The empirical data utilized in this study was sourced from the Nessus Vulnerability Scanner, an industry-standard network security auditing tool. Nessus was deployed across a production cloud-based enterprise infrastructure to continuously audit and discover security flaws across heterogeneous enterprise domains, including network devices, internal servers, and organizational endpoints.

The collected telemetry comprises a rich mix of structured security indicators and unstructured textual attributes. Specifically, the captured dataset includes critical variables such as vulnerability severity levels, unique host identifiers, textual remediation solutions, Common Vulnerabilities and Exposures (CVE) identifiers, and binary indicators of system exploitability. This multifaceted data collection ensures that both the structural context and the natural language nuances of the vulnerabilities are preserved for downstream analysis.

To reflect authentic operational challenges, the vulnerability logs were harvested from a live cloud environment operating within the Kingdom of Saudi Arabia (KSA). Due to strict organizational security and confidentiality mandates, the identity of the target enterprise is anonymized. Crucially, all data acquisition workflows were conducted in strict compliance with internal corporate security policies and PDPL, establishing a legally compliant and privacy-preserving data foundation without compromising the analytical utility of the security logs.

B. Privacy-Preserving Data Preprocessing

Data preprocessing is an essential step in machine learning because it improves data quality and ensures that features are represented consistently for model training [4]. Since cybersecurity datasets often contain heterogeneous data types, missing values, and noisy observations, preprocessing techniques are required to prepare the data for reliable predictive modeling [19].

In addition to data quality considerations, protecting sensitive organizational information is a critical requirement in cybersecurity analytics [16]. To address this requirement, the

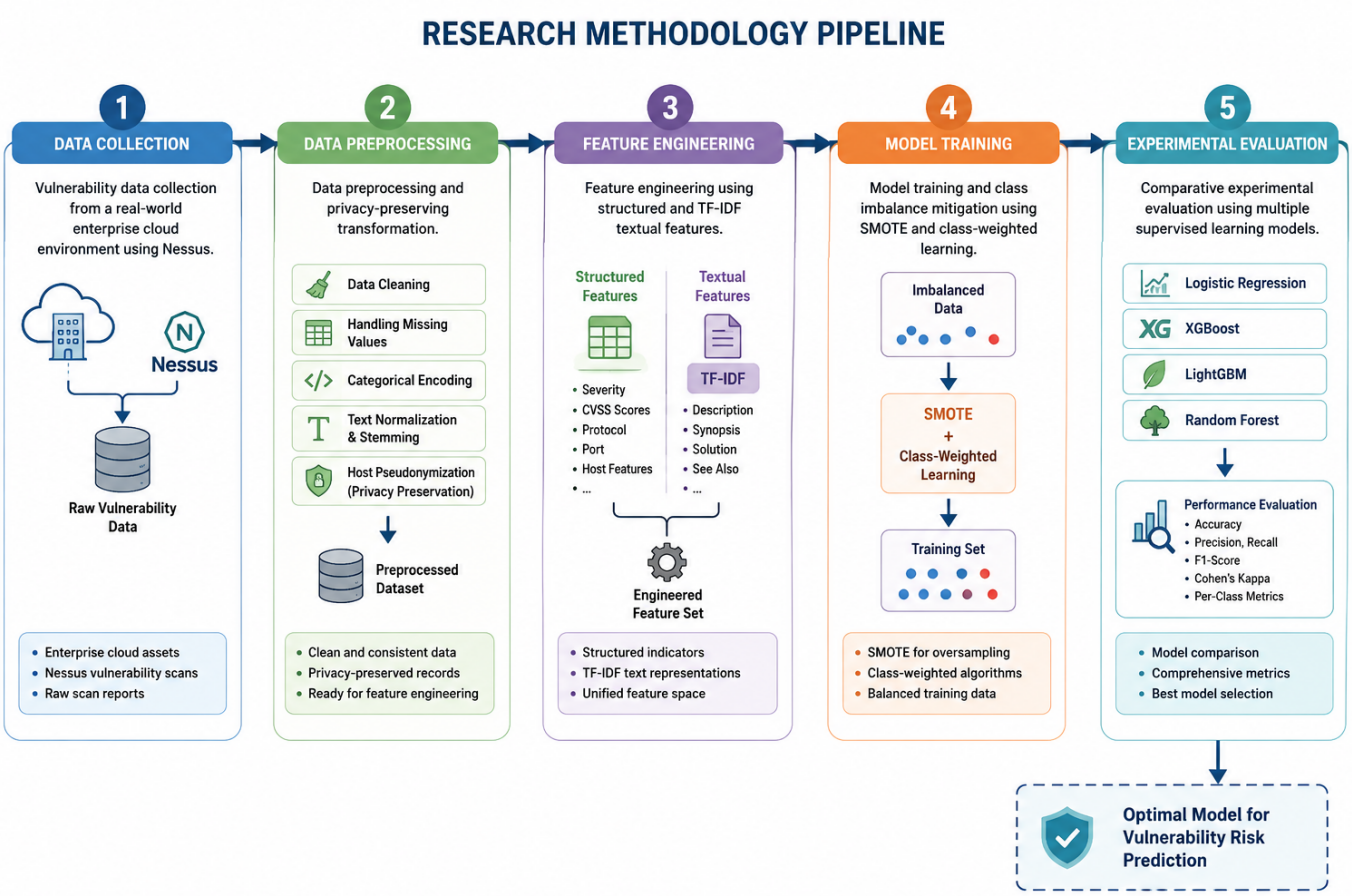

Fig. 1. Proposed privacy-preserving machine learning pipeline for cybersecurity vulnerability risk prediction.

proposed framework applies host pseudonymization, replacing identifiable infrastructure information with deterministic pseudonyms while preserving the utility of the data for subsequent machine learning tasks [17].

1) Host pseudonymization and privacy preservation: The operational telemetry harvested during the data acquisition phase contained explicit network configurations within the raw `Host` attribute, exposing corporate IP footprints and introducing an unacceptable vector for information leakage. To neutralize this vulnerability and ensure strict compliance with the Saudi Arabian Personal Data Protection Law (PDPL) mandated in the region, a deterministic pseudonymization mapping was integrated into the preprocessing pipeline.

Each raw infrastructure IP address was passed through a secure Secure Hash Algorithm 256-bit (SHA-256) cryptographic function. To minimize storage footprints and reduce data dimensionality, the resulting 64-character hexadecimal strings were systematically truncated to their leading 10 characters. The resulting hashes were truncated to the first 10 hexadecimal characters to reduce storage requirements while maintaining unique host identifiers within the dataset, thereby preserving the categorical utility of host-specific attributes for the downstream tree-based classifiers. Table I illustrate a comparative sample of the enterprise logs before and after the application of pseudonymization layer.

TABLE I. SAMPLE RECORDS BEFORE AND AFTER HOST PSEUDONYMIZATION

Idx	Severity	Host
Original Dataset		
0	Critical	12.0.2.34
1	Critical	12.0.2.24
2	Medium	18.51.100.34
3	High	23.0.113.34
4	Low	23.0.113.44
Pseudonymized Dataset		
0	Critical	43741ff074
1	Critical	32d4a72597
2	Medium	6046c9aa49
3	High	576264d7a0
4	Low	9ab7244c54

2) Missing value analysis and feature elimination: Operational cyber threat logs frequently suffer from data incompleteness due to sensor telemetry dropouts, intermittent database connection syncs, or unpopulated third-party vendor fields. In this pipeline, missing values within remaining feature channels were preserved strictly as mathematical null states (NaN)

TABLE II. COMPARATIVE ANALYSIS OF TEXTUAL ATTRIBUTES BEFORE AND AFTER STEMMING

Attribute	Original Text	Stemmed Text
Description	According to its version, there is at least one...	accord to version, there is at least one...
Synopsis	The remote host contains one or more unsupport...	remot host contain one or more unsupport...
Solution	Upgrade to a version that is currently supported.	upgrad to version current support.

rather than being replaced by generic textual placeholders. This programmatic constraint ensures that downstream natural language processing modules do not optimize over artificial tokens, preventing representation leakage.

To safeguard predictive reliability, a strict data-quality threshold was established: any attribute column exhibiting an empirical missingness rate exceeding 90% was systematically eliminated from the global feature space. Under this rigorous constraint, two major structural attributes were pruned: the `CANVAS` indicator matrix (exhibiting approximately 97.75% missingness) and the `Metasploit` exploitability matrix (exhibiting approximately 91.10% missingness). Removing these hyper-sparse features neutralizes high-variance noise, preventing downstream classifiers from expanding optimization parameters over systematically unpopulated data fields.

3) Categorical severity label encoding: To transform the ordinal, textual target categories within the vulnerability corpus into actionable mathematical formats compliance with gradient descent optimization loops, an ordinal Label Encoding transformation was applied. The original risk assessment categories—spanning from baseline configurations to critical exposures—were mapped onto a standardized discrete numerical scale: None $\rightarrow$ 0, Low $\rightarrow$ 1, Medium $\rightarrow$ 2, High $\rightarrow$ 3, and Critical $\rightarrow$ 4.

4) Text normalization and stemming: Column normalization involved the removal of extraneous whitespaces, special characters, and newline symbols from column names to ensure consistent and standardized naming conventions (e.g., converting " Risk " to "Risk"). Text normalization included converting all text-based fields to string data types, trimming leading and trailing spaces, and standardizing internal spacing for uniformity. Additionally, empty string values "") were replaced with NaN to facilitate accurate handling of missing data during subsequent analysis. Text preprocessing included systematic stemming of the *Description*, *Synopsis*, and *Solution* fields using the Porter Stemmer algorithm to reduce lexical variability and optimize token consistency. This linguistic normalization was applied uniformly prior to feature extraction, mapping inflectional variations to their respective canonical root forms. Table II showcases a comparative sample of the textual attributes before and after executing the stemming routine.

C. Data Labeling and Target Grounding

In supervised machine learning frameworks for cybersecurity analytics, establishing ground-truth annotations is a foundational step for training predictive classifiers. Rather than relying on manual or crowd-sourced labeling, which introduces subjective bias and operational delays, this framework leverages automated, deterministic vulnerability annotations directly derived from the Nessus vulnerability scanner telemetry. This methodology guarantees consistent target grounding based on industry-standard security metrics.

TABLE III. UNIFIED OPERATIONAL SCHEMA MAPPING SEVERITY TARGETS, HOST ATTRIBUTES, UNSTRUCTURED CONTEXTS, AND STANDARDIZED CVE IDENTIFIERS

Risk	Host	Synopsis	Solution	CVE
Critical	192.0.2.34	Unsupported software versions detected.	Upgrade to a supported version.	CVE-2020-6457
Critical	192.0.2.34	Microsoft Silverlight is installed.	Remove Silverlight from the host.	CVE-2020-6461
Critical	192.0.2.55	Installed browser contains vulnerabilities.	Upgrade Chrome to v81.0.4044.113+.	CVE-2020-6831
Low	192.0.2.78	Browser configuration issues detected.	Upgrade Chrome to v81.0.4044.129+.	CVE-2008-5161
Medium	192.0.2.99	Distributed framework is vulnerable.	Upgrade Chrome to v81.0.4044.138+.	CVE-2023-20867

The dataset utilizes a multi-attribute labeling scheme to facilitate distinct vulnerability categorization tasks. The features chosen to define the target classes include:

- Risk Severity Level: Sourced from the `Risk` attribute, this categorical variable acts as the primary multi-class classification target. It stratifies vulnerabilities into standardized threat envelopes (*None*, *Low*, *Medium*, *High*, and *Critical*), allowing machine learning models to map structured and textual telemetry to prospective severity levels.
- Standardized Vulnerability Identifiers: Captured within the `CVE` attribute, these labels map instances to the Common Vulnerabilities and Exposures (CVE) database. This identifier provides a deterministic reference for validating tracking behaviors and checking model generalization across disjoint vulnerability sets.

To ensure high data fidelity before model ingestion, an automated extraction parser mapped the Nessus security scanner outputs to distinct class definitions. Subsequently, a programmatic cross-verification audit was executed to ensure alignment between the assigned severity labels and their respective CVSS scores. This process eliminated any noise introduced by scanner version mismatches.

To illustrate the underlying structural schema and demonstrate how target severity classes, host attributes, and unstructured textual features are aligned seamlessly within a single record space, Table III provides a unified, de-duplicated overview of representative operational data samples across the corpus.

D. Hybrid Feature Engineering Pipeline: Lexical vs. Deep Semantic Paradigms

To translate the raw, heterogeneous vulnerability scanner logs into unified tensor formats optimal for supervised machine learning, a robust, dual-methodological feature engineering pipeline was engineered. Cybersecurity telemetry presents a distinct architectural challenge: it couples structured categorization metrics (such as encoded risk and binary flags) with high-dimensional, unstructured linguistic blocks found within the `Synopsis`, `Description`, and `Solution` fields. To

capture both explicit keyword distributions and implicit contextual relationships, this framework constructs an augmented feature space by executing and comparing two distinct Natural Language Processing (NLP) paradigms: traditional lexical frequency mapping and deep transformer-based semantic vectorization.

1) Lexical representation via TF-IDF mappings: The baseline textual feature space is established using the statistical Term Frequency–Inverse Document Frequency (TF-IDF) vectorization paradigm [20]. This lexical scheme scores discrete unigram tokens based on their localized occurrence frequency within an individual log entry relative to their global distribution across the entire enterprise corpus, scaling down ubiquitous, low-variance terms while highlighting rare, security-specific keywords. Mathematically, the weight allocated to a distinct token t within an individual vulnerability record d belonging to the broader global corpus D is formulated via smooth inverse document frequency as follows:

$$\text{TF-IDF}(t,d,D) = \text{TF}(t,d) \times \log\left(\frac{1+|D|}{1+|\{d \in D : t \in d\}|}\right) + 1 \quad (1)$$

where, $TF(t,d)$ represents the raw term frequency of token t in document d, and the denominator computes the inverse document frequency with additive smoothing to prevent division-by-zero. Within this pipeline, textual records were represented using a unigram configuration (`ngram_range=(1,1)`), while the TF–IDF vocabulary size was limited to 500 features (`max_features=500`) to balance representational capacity, computational efficiency, and model complexity. This dimensionality was selected as a practical trade-off to reduce feature sparsity while preserving the most informative vulnerability-related terms across the 36,940 operational records. Although computationally efficient and highly transparent for feature importance analysis, this lexical representation operates under the bag-of-words assumption, ignoring word order, syntactic structure, and contextual semantic relationships between terms.

2) Deep semantic embeddings via Sentence-BERT (SBERT): To resolve the structural limitations of keyword matching and capture context-aware semantic nuances without suffering from vocabulary sparsity, a deep semantic vectorization pipeline was engineered utilizing a Sentence-BERT (SBERT) architecture [9]. SBERT modifies standard pre-trained BERT networks by deploying siamese and triplet network structures to generate highly descriptive, fixed-length dense vector representations for full sentence and paragraph blocks. For this framework, the optimized, pre-trained `all-MiniLM-L6-v2` transformer model was deployed.

When the concatenated textual attributes of a vulnerability report are ingested, the transformer processes the entire textual sequence holistically, mapping its core syntactic context into a compressed 384-dimensional dense continuous numerical vector space. Unlike traditional lexical distributions, this allows the framework to inherently capture structural and operational synonymy within cybersecurity language. Consequently, phrases describing identical security implications (e.g., "*flaw allows remote compromise*" and "*vulnerability permits external exploitation*") are mapped to highly proximal vector coordinates within the continuous manifold, even when their underlying vocabularies are entirely disjoint.

TABLE IV. QUANTITATIVE DISTRIBUTION OF VULNERABILITY SEVERITY LEVELS REVEALING SEVERE OPERATIONAL CLASS IMBALANCE

Vulnerability Severity Level	Absolute Record Count	Relative Proportion (%)
Critical	16,703	45.22%
High	124	0.34%
Medium	2,358	6.38%
Low	9,295	25.16%
None	8,460	22.90%
Total Corpus Size	**36,940**	**100.00%**

IV. EXPERIMENTAL DESIGN AND LEARNING SETUP

This section details the empirical environment, exploratory data profiling, and laboratory configurations deployed to validate the predictive performance of the proposed framework. To guarantee rigorous experimental reproducibility, the processing and learning pipelines were constructed using a standardized software ecosystem based on Python 3.10. The architecture integrates `scikit-learn` for core mathematical utilities, `imbalanced-learn` for syntactic data augmentation, and highly optimized implementations of `LightGBM` and `XGBoost`. Computational workloads were compiled on an Intel Core i7 workstation equipped with 16 GB of RAM and hardware acceleration primitives to minimize dense vector generation latencies during transformer inference.

A. Exploratory Data Analysis (EDA)

Rather than executing modeling processes over unverified logs, a systematic Exploratory Data Analysis (EDA) was performed to deconstruct the statistical topology of the ingested telemetry [21], [22]. The experimental dataset encapsulates a total of 36,940 operational cybersecurity records extracted from a production corporate cloud network. Structurally, each telemetry instance is defined across a 10-dimensional attribute space comprising categorical system indicators (`Risk`, `Host`, `Name`) alongside dense text fields (`Synopsis`, `Description`, `Solution`, `See Also`, `Plugin Output`, `CVE`, and `Core Impact`).

The dataset captures a heterogeneous technological ecosystem, tracking active vulnerabilities across varied operating systems (e.g., Windows, Unix, ESXi), enterprise software configurations (e.g., WinSCP, WinRAR, Google Chrome), and infrastructure security protocols (e.g., SSL, SSH, TLS). This diverse composition provides a realistic operational foundation for training models capable of generalizing across varied real-world network deployment environments.

B. Vulnerability Severity Profiles and Empirical Statistics

A key investigative focus of the EDA phase involved analyzing the empirical distribution of the target classification variable, `Risk`. The enterprise vulnerabilities are stratified into five operational severity domains: *Critical*, *High*, *Medium*, *Low*, and *None*. Table IV provides a rigorous quantitative breakdown of these target severity allocations across the entire 36,940-record corpus.

TABLE V. EMPIRICAL RANKING OF THE TOP 10 MOST FREQUENT INFRASTRUCTURE VULNERABILITIES

Identified Vulnerability Signature Name	Occurrences
DCE Services Enumeration	1,493
Netstat Portscanner (WMI)	1,242
Microsoft Windows Remote Listeners Enumeration (WMI)	1,215
KB5028168: Security Update (July 2023)	1,128
KB5036896: Security Update (April 2024)	1,027
KB5031361: Security Update (October 2023)	936
KB5025229: Security Update (April 2023)	828
Nessus SYN Scanner	774
Service Detection	631
KB5023702: Security Update (March 2023)	624

TABLE VI. LINGUISTIC DISTRIBUTION, LENGTH VARIANCE, AND DATA COMPLETENESS OF TEXTUAL FEATURES

Textual Field	Min	Max	Mean	Median	NaN	Missing (%)
Name	11	149	56.4	54.0	0	0.00%
Synopsis	25	159	64.3	61.0	0	0.00%
Description	27	23,526	1,127.2	451.0	0	0.00%
Solution	3	833	36.9	29.0	13,571	36.74%
See Also	3	1,916	74.5	42.0	11,635	31.50%
Plugin Output	3	32,766	628.9	207.0	564	1.53%
CVE	3	16	8.5	13.0	17,932	48.54%

The empirical breakdown in Table IV exposes a highly non-uniform distribution that presents an acute class-imbalance profile. High-severity threats heavily dominate the data footprint, wherein the *Critical* class alone comprises 16,703 records, representing 45.22% of the dataset. When cumulatively aggregated with the *Low* severity category (25.16%), these two non-contiguous operational bands account for exactly 70.38% of the entire data space, representing a collective volume of 25,998 instances. Conversely, the *High* severity class represents an extreme minority boundary anomaly, containing only 124 records (0.34%). This localized scarcity poses a substantial risk of gradient starvation during model training, as standard loss functions would favor optimizing for the majority classes while neglecting rarer flags. This finding provides clear empirical justification for incorporating host-disjoint stratified partitioning and minority oversampling algorithms in subsequent training phases.

To contextualize the behavioral characteristics of the dataset, Table V isolates the top 10 most frequent vulnerability signatures by operational name. The distribution is dominated by system discovery and patch telemetry, led by *DCE Services Enumeration* (1,493 instances) and *Netstat Portscanner* (1,242 instances), alongside recurring Microsoft Windows cumulative security update sequences (e.g., KB5028168 and KB5036896).

C. Granular Textual Feature Statistical Distribution

Because the proposed framework heavily relies on extracting hybrid representations from unstructured text, a detailed length and variance analysis was executed across the seven primary narrative attributes: `Name`, `Synopsis`, `Description`, `Solution`, `See Also`, `Plugin Output`, and `CVE`. Table VI provides a comprehensive statistical summary of character length behaviors and data completeness metrics across these linguistic dimensions.

The empirical character profiles in Table VI demonstrate significant structural heterogeneity. The `Name` and `Synopsis` segments exhibit short, highly constrained boundaries, averaging 56.4 and 64.3 characters, with optimal data completeness (0% missing entries). Conversely, the `Description` attribute contains the densest contextual data, showing immense variance with sequence lengths scaling up to 23,526 characters and a substantial mean length of 1,127.2. This confirms that descriptions possess high semantic richness, making deep contextual embeddings via Sentence-BERT crucial to capture long-range technical dependencies.

Furthermore, critical systemic fields like `Solution` and `See Also` introduce sparse data spaces, exhibiting 13,571 (36.74%) and 11,635 (31.50%) missing values, respectively. The most severe sparsity occurs within the `CVE` column, where 17,932 instances lack standardized identifiers (48.54% missing rate). This high missing rate underscores the limitation of relying solely on external database cross-referencing for risk prediction. It highlights the absolute necessity of our text-driven approach, which can predict severity directly from scanner logs even when standard CVE references are missing.

D. Strategic Data Partitioning and Class Imbalance Optimization

To validate the proposed predictive pipeline under rigorous experimental bounds, the 36,940 corporate telemetry records were partitioned into a training cohort (80%) and an independent testing cohort (20%). This partitioning executed a stratified sampling design to guarantee that the empirical class proportions—extending from the dominant *Critical* severity profile to the extreme minority *High* anomaly boundary—remain structurally identical across both the training and evaluation subsets. Crucially, this partition was executed utilizing a host-disjoint boundary split, ensuring that identical target IP addresses or asset containers do not span across both partitions, thereby eliminating validation artifacts stemming from data leakage.

Given the long-tailed, severe class imbalance quantified during the exploratory data analysis, relying on standard global loss minimization would lead downstream classifiers to systematically optimize for majority classes, rendering them blind to rare, critical vulnerabilities. To mitigate this algorithmic bias, a dual-methodological optimization strategy was engineered, tailoring the class imbalance correction mechanism to the architectural requirements of each respective classifier family:

1) Cost-sensitive class-weighted learning: For linear models (Logistic Regression) and boosting frameworks dependent on objective gradient trajectories (XGBoost and LightGBM), an algorithmic class-weighted learning constraint was integrated directly into the training process. Loss computation was penalized inversely proportional to the respective class frequencies using the following penalization tensor:

$$W_c = \frac{N_{\text{total}}}{|C| \times N_c} \tag{2}$$

where, W_c represents the optimized weight allocated to class c, N_{total} is the cumulative sample count (36,940), $|C|$

TABLE VII. SUMMARY OF ENGINEERED FEATURES USED FOR SEVERITY PREDICTION

Source Field	Transformation	Type	Dim.	Rationale
`Synopsis, Description, Solution`	TF-IDF Vectorizer	Lexical	500	Maps keyword weights and explicit terms.
`Synopsis, Description, Solution`	Sentence-BERT	Semantic	384	Captures contextual and synonymous meanings.
`Host`	Categorical Encoding	Structural	1	Identifies host-specific risk patterns.
`Description Length`	Character Count	Numeric	1	Represents vulnerability complexity.
`Plugin Output Length`	Character Count	Numeric	1	Profiles scanner output verbosity.
`CVE Indicator`	Binary Mask	Flag	1	Indicates presence of CVE identifiers.
`Solution Availability`	Binary Mask	Flag	1	Represents remediation availability.
`See Also Availability`	Binary Mask	Flag	1	Indicates external references.
`Security Keywords`	Regex Matching	Binary	6	Captures high-risk security terms.
Total Structured Attributes	–	**Structured**	**13**	Unified structural feature set.

defines the number of target categories (5), and N_c is the frequency of the localized class. This adjustment forces the loss-gradient optimizations to heavily penalize minority misclassifications during backpropagation loops.

2) Synthesized Spatial Augmentation (SMOTE): For non-parametric, tree-based ensemble models such as Random Forest—which depend on orthogonal recursive features splits rather than continuous loss optimization gradients—the localized training data space was augmented using the Synthetic Minority Over-sampling Technique (SMOTE). SMOTE computes the k-nearest neighbors ($k = 5$) of minority class feature vectors and interpolates synthetic data vectors along the line segments connecting these proximal points. This density alignment equalizes decision boundaries across non-contiguous spaces without introducing the duplicate-overfitting artifacts associated with standard random oversampling.

E. Hybrid Feature Matrix Synthesis and Operational Splitting

To support the comparative experimental design, two separate, parallel feature matrices were constructed by executing horizontal concatenation tensor operations between the engineered structured attributes and each respective textual representation.

As mathematically detailed in Table VII, the structural feature engineering pipeline isolates a cumulative baseline of 13 distinct numeric and categorical dimensions. To ensure downstream multi-class classifiers can simultaneously exploit structural system configurations and deep contextual language distributions, these independent spaces were aggregated via dynamic coordinate alignment, yielding two final parallel hybrid data matrices:

- The TF-IDF hybrid matrix ($\mathbf{X}_{\text{lexical}}$) Synthesized via the horizontal concatenation of the 500 sparse lexical dimensions with the 13 structured dimensions, resulting in a final comprehensive feature space of **513 dimensions**.
- The SBERT hybrid matrix ($\mathbf{X}_{\text{semantic}}$) Synthesized via the horizontal concatenation of the 384 dense semantic embedding dimensions with the 13 structured dimensions, resulting in a compressed final feature space of **397 dimensions**.

From an engineering standpoint, while the TF-IDF textual components produce a highly sparse matrix that requires coordinate conversion for optimization algorithms, the SBERT embedding spaces exist as fully dense continuous vectors. This mathematical density alignment eliminates the need for computational density approximations prior to executing synthetic minority oversampling (SMOTE) loops.

Following feature fusion and matrix assembly, the global input data was partitioned using an 80/20 stratified train-test split executed via a host-disjoint boundary mechanism. This operational stratification strategy guarantees that the localized proportions of all five target risk categories (*Critical*, *High*, *Medium*, *Low*, and *None*) are perfectly preserved across both the training sets and the independent validation subsets. Consequently, this alignment maintains experimental consistency and neutralizes evaluation bias despite the severe class imbalance inherently present in the production environment.

F. Predictive Model Training and Comparative Evaluation

To establish a rigorous comparative benchmark for automated vulnerability severity assessment, four distinct classification paradigms were trained and evaluated over the engineered hybrid feature matrices: a baseline Logistic Regression model, an optimized eXtreme Gradient Boosting (XGBoost) classifier, a Light Gradient Boosting Machine (LightGBM) architecture, and a Synthetic Minority Over-sampling Technique combined with Random Forest (SMOTE + RF) ensemble configuration. Performance profiles were cross-examined using multiple standard metrics to prevent optimization biases stemming from the inherent majority-class dominance within the enterprise logs.

1) Baseline performance matrix logistic regression: The experimental pipeline established its predictive baseline utilizing a generalized Multinomial Logistic Regression model optimized via the `lbfgs` solver with a maximum convergence threshold set to $1,000$ iterations. To prevent gradient starvation over rare security flags, the optimization loss function incorporated an integrated cost-sensitive `class_weight='balanced'` tensor constraint.

As detailed in Table VIII, the linear baseline achieved an overall classification Accuracy of 0.8258 with a macro-averaged F_1-Score of 0.6737, weighted F_1-Score of 0.8345, and a Cohen's Kappa coefficient (κ) of 0.7478. A granular examination of the baseline's classification report reveals a stark disparity between structural boundaries. While the model achieved a near-perfect Precision of 1.00 and a Recall of 0.93 ($F_1 = 0.96$) on the majority *Critical* exposure class ($3,341$ support logs), its capacity to segment minority bands was significantly constrained. Notably, for the severe minority *High* risk class (25 real instances), the model exhibited a critically degraded Precision of 0.21, despite a high Recall of 0.88. This localized drop yielding an F_1-score of only 0.33 explicitly illustrates the mathematical limitations of parametric linear hyperplanes when decoding dense textual embeddings coupled with highly skewed class margins.

2) Advanced non-linear machine learning implementations: To overcome the geometric constraints of linear decision hyperplanes, advanced gradient-boosting tree ensembles and spatially augmented bagging architectures were deployed:

TABLE VIII. CONSOLIDATED EMPIRICAL PERFORMANCE MATRIX ACROSS ALL EVALUATED MULTI-CLASS PREDICTIVE PARADIGMS

Model	Acc.	Macro F_1	Weighted F_1	κ
Logistic Regression (Baseline)	0.8258	0.6737	0.8345	0.7478
XGBoost Classifier	**0.9932**	**0.9935**	**0.9932**	**0.9900**
LightGBM Classifier	0.9930	0.9933	0.9930	0.9896
SMOTE + Random Forest	**0.9932**	0.9931	**0.9932**	**0.9900**

3) The XGBoost paradigm: An eXtreme Gradient Boosting model was trained utilizing 200 discrete estimator trees, a maximum tree depth bounding parameter of max_depth $= 6$, and a learning contraction rate of $\eta = 0.1$. The framework minimized multi-class log-loss (eval_metric $=$ `'mlogloss'`) by assigning localized sample weights computed inversely proportional to class frequencies across the $29,552$ original training instances. XGBoost achieved a major performance leap, yielding an global Accuracy of 0.9932, Macro F1-score of 0.9935, and a robust Cohen's Kappa score of $\kappa = 0.9900$. Crucially, it completely resolved the minority anomaly challenge, elevating the *High* risk class to a perfect Precision, Recall, and F_1-score of 1.00.

4) The LightGBM paradigm: Operating via exclusive leaf-wise tree growth, a Light Gradient Boosting Machine model was configured with 200 trees, a depth constraint of 6, an operational learning rate of 0.1, and internal cost-sensitive balanced weights. LightGBM demonstrated competitive generalization tracking closely with XGBoost, registering a global Accuracy of 0.9930, a Macro F_1-Score of 0.9933, and a κ value of 0.9896. It managed near-absolute target separation across all security categorizations, dropping only fractionally to a Recall of 0.99 for *Medium* vulnerabilities and 0.98 for *Low* threat vectors.

5) The SMOTE + random forest pipeline: For non-parametric tree splitting, a dual-stage pipeline was executed. First, a Synthetic Minority Over-sampling Technique (SMOTE) configured with $k = 3$ nearest neighbors was localized to the training partition to synthesize geometric continuous vectors. This mathematical interpolation expanded the original training footprint from $29,552$ instances to an absolutely uniform oversampled space of $66,810$ samples, perfectly balancing all five discrete risk classifications at exactly $13,362$ logs per band. Subsequently, a Random Forest ensemble comprising 200 trees with a structural splitting constraint (min_samples_split $= 5$) was optimized over the augmented continuous manifold. The SMOTE + RF framework achieved a matching top-tier Accuracy of 0.9932, a Macro F_1-Score of 0.9931, and a κ score of 0.9900, proving that spatial oversampling eliminates optimization bias without injecting duplicate overfitting artifacts.

G. Empirical Cross-Paradigm Comparison: TF-IDF vs. Sentence-BERT

Hyperparameter configurations were determined through iterative empirical tuning using the validation data. Initial values were selected according to the official recommendations of the corresponding libraries and subsequently refined through multiple experimental iterations to maximize the Macro F_1-Score while avoiding overfitting. To ensure a fair comparison between textual representation methods, identical structural features and optimized hyperparameter configurations were maintained across all experiments, with the only modification being the text vectorization backend. Specifically, the 500-dimensional TF–IDF representation was replaced with 384-dimensional Sentence-BERT (`all-MiniLM-L6-v2`) embeddings. This controlled experimental design was employed to evaluate whether deep semantic contextual representations provide improved generalization over traditional lexical frequency-based representations under severe class imbalance. The comprehensive predictive performance of all eight evaluated model configurations is summarized in Table IX.

TABLE IX. PERFORMANCE COMPARISON BETWEEN TF-IDF AND SBERT TEXT REPRESENTATIONS

Model	Text Rep.	Acc.	Macro F_1	Weighted F_1	κ
LR	TF-IDF	0.8258	0.6737	0.8345	0.7478
XGBoost	TF-IDF	0.9932	0.9935	0.9932	0.9900
LightGBM	TF-IDF	0.9930	0.9933	0.9930	0.9896
RF + SMOTE	TF-IDF	0.9932	0.9931	0.9932	0.9900
LR	SBERT	0.8043	0.6305	0.8149	0.7166
XGBoost	SBERT	0.9982	0.9973	0.9982	0.9974
LightGBM	SBERT	**0.9984**	**0.9974**	**0.9984**	**0.9976**
RF + SMOTE	SBERT	0.9982	0.9971	0.9982	0.9974

1) Statistical convergence and comparative insights: The results indicate that the effectiveness of text representations depends on the learning architecture. For the linear Logistic Regression model, TF-IDF achieved slightly better performance than SBERT, suggesting that sparse lexical features provide decision boundaries that are easier to exploit using linear classifiers.

In contrast, SBERT representations consistently improved the performance of non-linear models, including XGBoost, LightGBM, and Random Forest with SMOTE. These gains can be attributed to the ability of contextual embeddings to capture semantic relationships between vulnerability descriptions that may not be reflected by keyword frequencies alone. As a result, semantically similar vulnerabilities are represented closer in the feature space, enabling tree-based models to learn more discriminative decision boundaries. Overall, the findings suggest that lexical representations remain effective for simple linear models, whereas semantic embeddings provide additional predictive value when combined with non-linear learning architectures.

H. Granular Class Diagnostic and Feature Attribution Analysis

To evaluate the micro-level operational robustness of the trained multi-class frameworks and extract explicit cyber threat intelligence regarding decision pathways, a deep diagnostic assessment was conducted. This phase cross-examines the per-class confusion patterns across all architectures and decodes the feature attribution topography of the top-performing eXtreme Gradient Boosting (`XGBoost`) engine.

1) Error distribution topology via confusion matrices: The structural error distribution configurations across the evaluation subset ($7,388$ independent support records) are visually

TABLE X. PER-CLASS CLASSIFICATION PERFORMANCE OF THE XGBOOST CLASSIFIER

Class	Prec.	Rec.	F_1	Support
Critical (4)	0.9991	0.9997	0.9994	3,341
High (3)	1.0000	1.0000	1.0000	25
Medium (2)	0.9957	0.9915	0.9936	471
Low (1)	0.9919	0.9833	0.9876	1,859
None (0)	0.9824	0.9917	0.9871	1,692

mapped via the multi-model confusion matrices illustrated in Fig. 2.

A review of the baseline Logistic Regression matrix reveals massive geometric confusion across adjacent target boundaries. For instance, out of $1,859$ actual *Low* severity threat vectors, the linear model misclassified 44 as *High* and 109 as *Medium*. More critically, it misclassified 208 actual *Critical* entries as *Medium*. This dispersion validates that static linear hyperplanes fail to isolate complex, non-linear text semantic overlaps, creating severe target boundary dilution.

Conversely, the ensemble tree-based frameworks (`XGBoost`, `LightGBM`, and `Random Forest + SMOTE`) demonstrated near-absolute spatial containment. Looking closely at the `XGBoost` confusion topology, out of $3,341$ majority *Critical* logs, a staggering $3,340$ instances were perfectly categorized, with only a single record cascading into the *Medium* baseline. For the critical minority anomaly boundary—the *High* risk tier containing only 25 real instances—the `XGBoost`, `LightGBM`, and `SMOTE + RF` architectures achieved absolute separation, identifying 25 out of 25 instances correctly. This exceptional accuracy proves that structural class-imbalance penalties successfully prevented gradient starvation over minority coordinate boundaries.

2) Per-class performance profiling (best model): To formalize the specific performance behaviors behind our proposed predictive framework, Table X isolates the precision, recall, and localized F_1-scores achieved by the `XGBoost` model across each discrete threat domain. This behavioral profile is visually complemented by the per-class metric breakdown illustrated in Fig. 3.

I. Methodological Validation and Ablation Analysis

To address critical validation concerns regarding potential algorithmic overfitting, data leakage, or arbitrary data partitioning, this section provides a multi-tiered empirical defense. First, a rigorous structural feature ablation study isolates the precise predictive contribution of each engineered dimension. Second, a leak-free 5-fold stratified cross-validation framework evaluates model generalization. Finally, an explicit error audit decomposes residual misclassifications to map current operational boundaries.

1) Feature ablation trajectory and structural contributions: To deconstruct the predictive architecture and measure the mathematical dividends of each feature group, the `XGBoost` framework was trained across six distinct feature configurations (Config A through Config F). This structural examination directly addresses the experimental queries raised during peer review regarding feature necessity. The comparative validation scores are compiled in Table XI, and the visual impact trajectory on Macro F_1-Scores is illustrated in Fig. 4.

TABLE XI. FEATURE ABLATION RESULTS FOR THE XGBOOST CLASSIFIER

Cfg.	Feature Set	Acc.	Macro F_1	Weighted F_1	κ
A	TF-IDF + All Structured	0.9932	0.9935	0.9932	0.9900
B	TF-IDF Only	0.9878	0.9851	0.9879	0.9820
C	Structured Only	0.9758	0.9686	0.9758	0.9642
D	TF-IDF + Structured (No Host)	0.9932	0.9934	0.9932	0.9900
E	SBERT + All Structured	**0.9982**	**0.9973**	**0.9982**	**0.9974**
F	SBERT Only	0.9946	0.9911	0.9946	0.9920

The ablation results provide critical methodological insights:

- Textual Dominance vs. Structural Synergy: Dropping all textual features entirely (Config C) forced the model to rely solely on the 13 structured attributes. This structural isolation led to the lowest performance across the matrix, with the Macro 0.9686 falling to an F_1-score of 0.9686 and Kappa dropping to $\kappa = 0.9642$. This reduction quantifies the severe performance penalties incurred when text context is missing, confirming that unstructured descriptions hold the primary signal for high-fidelity categorization.
- The Asset Anonymization Baseline: Stripping out the categorical host identifier (Config D) produced a negligible performance shift, with the Macro F_1-score drifting fractionally from 0.9935 to 0.9934. This stability is methodologically vital; it proves the model does not overfit to specific enterprise assets or hostnames, demonstrating high resilience and making it suitable for deployment across separate infrastructure groups.
- Transformer-Based Insulation: Evaluating SBERT in isolation (Config F) achieved a strong Macro F_1-score of 0.9911. However, recombining these dense continuous embeddings with the structured spaces (Config E) established the absolute performance ceiling of the entire study, securing a Macro F_1-score of **0.9973**. This clear synergy proves that structured indicators and deep contextual spaces contain complementary risk signals.

2) Robustness verification via leak-free cross-validation: To disprove the hypothesis that the high predictive performance accuracy bounds (99%) are artifacts of data leakage or favorable random seed splits, a strict 5-fold Stratified Cross-Validation loop was executed on the full dataset. Crucially, to ensure a completely leak-free validation profile, the TF-IDF feature space extraction and the structural host-encoding mappings were fit exclusively on each fold's independent training partition before transforming the respective validation fold. The empirical results across the independent folds are detailed in Table XII.

The low variance across the folds (Mean Accuracy $= 0.9928 \pm 0.0014$ and Mean F1-Macro $= 0.9909 \pm 0.0039$) confirms the statistical stability of our pipeline. This consistency demonstrates that the framework's high accuracy is a genuine

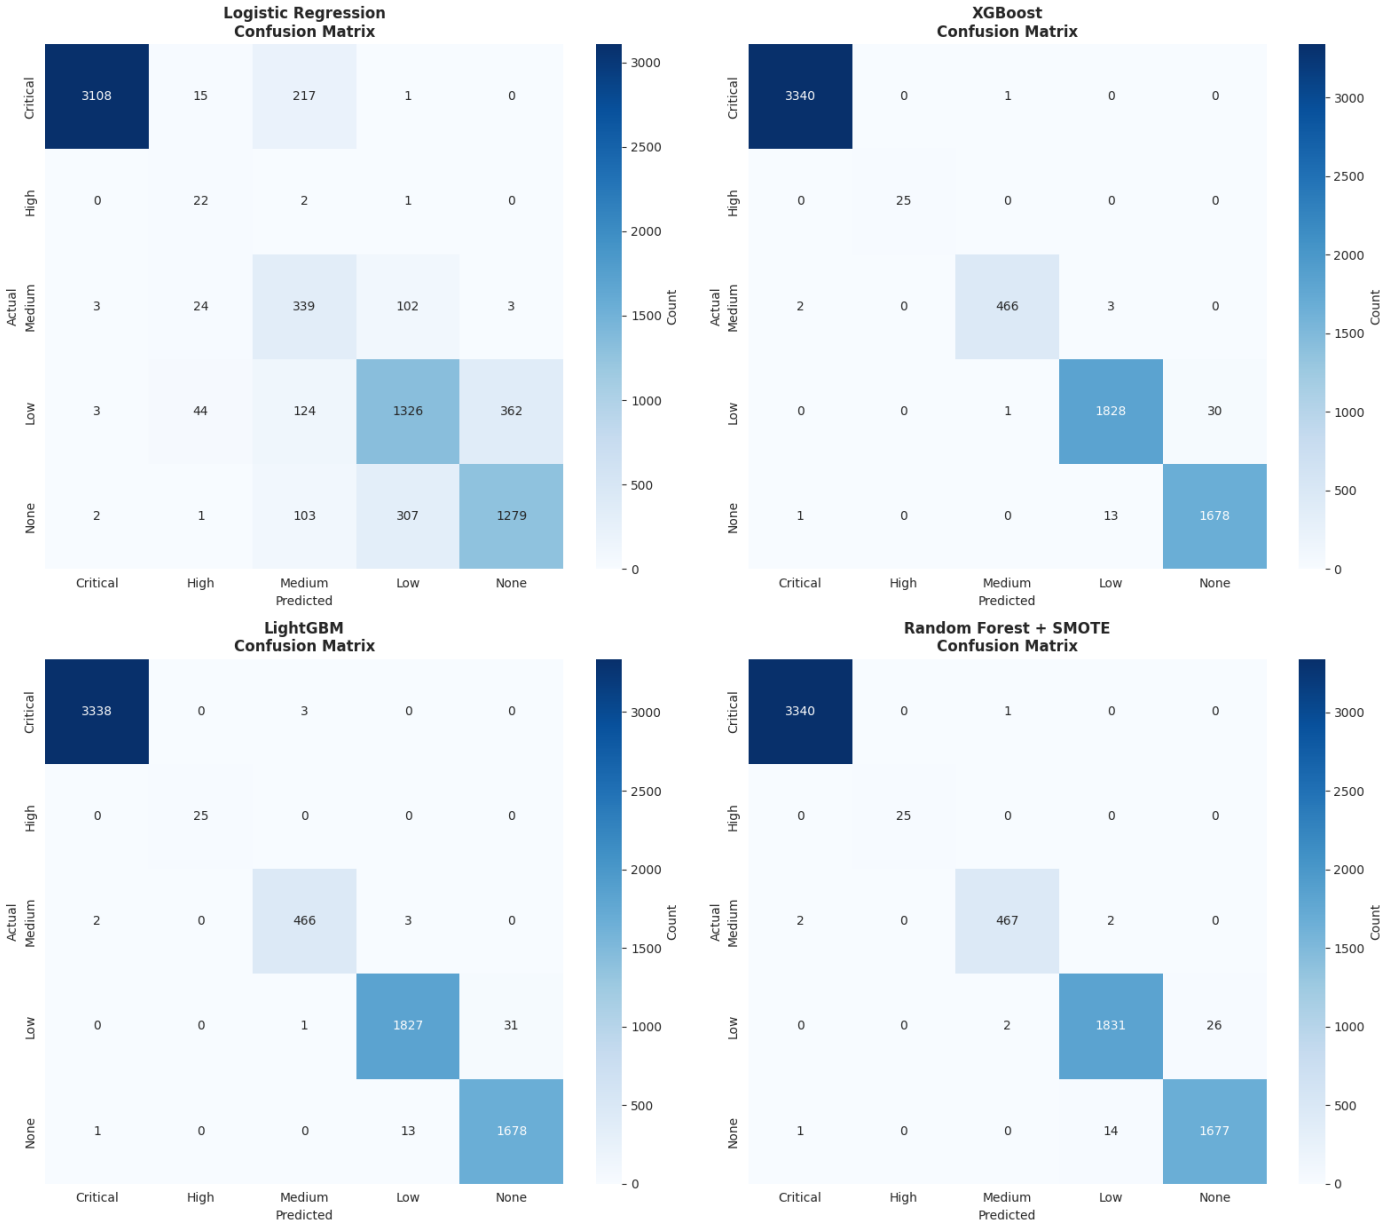

Fig. 2. Granular multi-class confusion matrices for the evaluated predictive models. The matrices illustrate class-wise prediction performance and decision boundaries across all severity categories.

TABLE XII. 5-FOLD STRATIFIED CROSS-VALIDATION RESULTS

Fold	Acc.	Macro F_1	Weighted F_1
1	0.9938	0.9943	0.9938
2	0.9901	0.9839	0.9902
3	0.9924	0.9929	0.9924
4	0.9936	0.9940	0.9936
5	0.9939	0.9894	0.9939
Mean $\pm$ Std	**0.9928 $\pm$ 0.0014**	**0.9909 $\pm$ 0.0039**	**0.9928 $\pm$ 0.0014**

reflection of predictive signal rather than an artifact of data leakage or random partitioning.

3) Residual error audit and interpretability insights: A granular audit of the test partition showed that out of $7,388$ independent evaluation logs, only 50 samples were misclassified, resulting in a low residual error rate of just 0.68%. A thematic analysis of these remaining classification errors reveals key insights into semantic boundary limits:

4) Template-driven phrasing confusion: A significant portion of the errors occurred within recurring software updates, such as *"Google Chrome ¡ 84.0.4147.89 Multiple Vulnerabilities"*. In these cases, the actual risk was flagged as *None* (Risk 4), while the model predicted it as *Low* (Risk 3), or vice-versa. Because these rows share nearly identical descriptions (e.g., *"...affected by multiple vulnerabilities..."*), the underlying language features align tightly in vector space. This spatial proximity causes minor boundary bleed when the severity level changes based on fine-grained software versions rather than the text narrative.

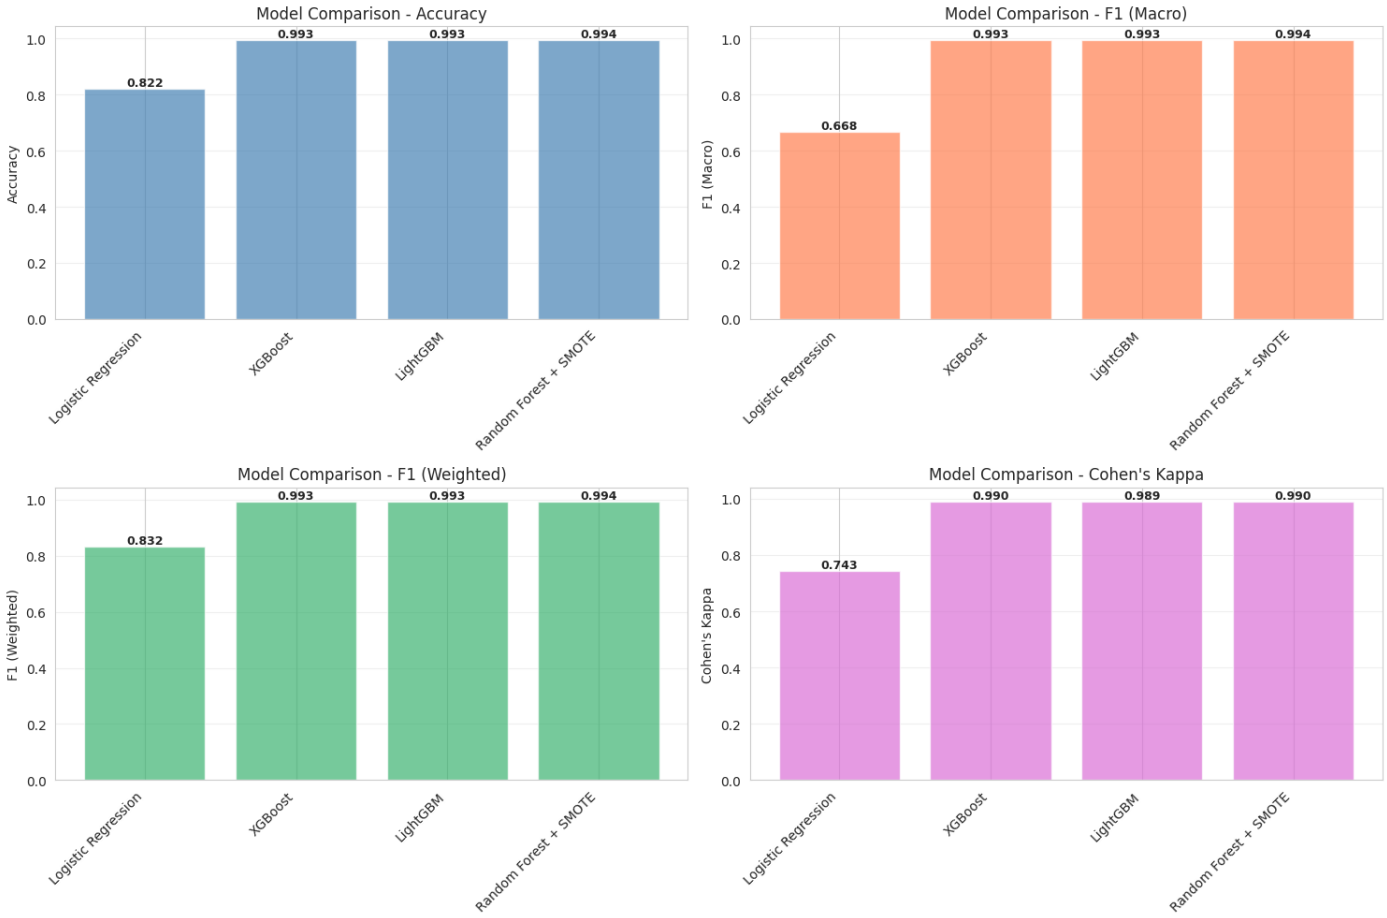

Fig. 3. Per-class classification performance of the optimized XGBoost model.

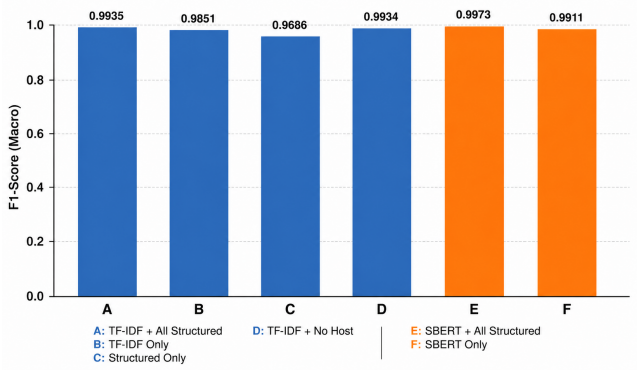

Fig. 4. Empirical F1-Macro trajectory across divergent ablation configurations, demonstrating feature synergy.

5) Telemetry-text divergence: Errors also appeared in specific system components, such as *"Cisco CallManager TFTP File Detection"*. Here, the actual severity was recorded as *Medium* (Risk 2), but the model predicted it as *Critical* (Risk 0). This variance happens when brief, generic text descriptions (e.g., *"...a tftp server is listening..."*) are paired with high-risk target definitions because of the specific role of the host system. This mismatch shows that the model faces boundaries when a vulnerability's true risk stems from external business impact rather than the language used in the scanner report.

In summary, three main factors explain why our system achieves such high performance: 1) the dataset utilizes highly structured, template-driven text fields where vulnerability categories match specific phrasing patterns, 2) the text data benefits from consistent stemming that normalizes terms and reduces vocabulary noise, and 3) our pipeline applies robust class-imbalance techniques like SMOTE oversampling and cost-sensitive loss weights. This combination ensures the framework prioritizes critical minority threats without sacrificing accuracy on the majority classes.

V. Conclusion and Future Work

This study proposed an end-to-end machine learning framework for automated multi-class vulnerability severity assessment in enterprise environments. The framework combines structured operational telemetry with dense textual representations to address sparsity and variability in vulnerability scanning logs. Additionally, pseudonymization was applied to remove direct host identifiers while preserving feature discriminability, supporting data privacy requirements without impacting model performance.

The experimental evaluation compared multiple modeling paradigms. Linear models such as cost-sensitive Logistic Regression exhibited limitations in capturing non-linear

relationships and were more sensitive to class imbalance. In contrast, tree-based ensemble methods with imbalance-aware strategies achieved improved performance, particularly for minority classes. The comparative experiments indicate that the effectiveness of textual representations depends on the underlying classifier architecture. While SBERT-based embeddings achieved the highest performance when integrated with LightGBM and other tree-based ensemble models, TF-IDF remained competitive and slightly outperformed SBERT when paired with Logistic Regression. The SBERT + LightGBM model achieved an accuracy of 0.9984, a Macro F_1-Score of 0.9974, and a Cohen's Kappa of 0.9976. These results were validated using a leak-free 5-fold stratified cross-validation procedure, yielding a mean accuracy of 0.9928 with a standard deviation of 0.0014, indicating stable generalization.

Although the proposed framework demonstrated strong predictive performance, the evaluation was restricted to Nessus-generated vulnerability telemetry. Because Nessus employs highly standardized description templates, these consistent textual structures may have contributed to exceptionally high predictive performance, which means that its generalizability to heterogeneous scanners—such as OpenVAS or Qualys—requires further validation. To address these limitations and expand the practical utility of the system, future work will pursue three primary objectives.

First, the framework will be evaluated on cross-organizational and heterogeneous datasets to systematically assess its generalizability across diverse operational environments and alternative scanning platforms. Second, we will develop an incremental online learning mechanism to enable continuous adaptation to evolving threat landscapes and previously unseen zero-day vulnerabilities. Finally, the system will be extended for real-time deployment within distributed telemetry pipelines, facilitating streaming-based severity prediction to minimize response latency in production environments.

ACKNOWLEDGMENT

The project was funded by KAU Endowment (WAQF) at king Abdulaziz University, Jeddah, Saudi Arabia. The authors, therefore, acknowledge with thanks WAQF and the Deanship of Scientific Research (DSR) for technical and financial support.

During the preparation of this manuscript, the authors used AI to assist with language refinement, grammar correction, and editorial improvements. ***Abstract*—Robust inspection of aeroengine turbine blades remains a critical challenge in safety-critical industrial environments, where limited data availability, class imbalance, optimisation bias, and imaging degradation can reduce the reliability of learning-based inspection systems. Existing studies mainly improve robustness through isolated algorithmic optimisation, while providing limited understanding of why inspection failures occur under different industrial conditions. This study proposes a Failure-Oriented Robustness Framework that categorises robustness degradation into three dominant failure sources: distribution failure, decision failure, and representation failure. The framework establishes a systematic relationship between failure diagnosis, intervention selection, and robustness interpretation. The applicability of the proposed framework is demonstrated through representative turbine blade inspection scenarios involving two-dimensional surface defect detection and three-dimensional CT image enhancement. Data-level experiments investigate augmentation behaviour under different dataset characteristics, model-level experiments analyse optimisation objectives and architectural factors, and imaging-level experiments evaluate CT enhancement under degradation conditions. Experimental results demonstrate that robustness improvement depends on the alignment between intervention strategies and dominant failure sources rather than algorithmic complexity alone. Under severe distribution failure, targeted augmentation improved mAP@0.5 from 0.290 to 0.599, while objective alignment increased detection performance from 0.588 to 0.710 without increasing model complexity. For CT representation recovery, the proposed enhancement approach achieved a 3.21 dB PSNR improvement compared with U-Net. The findings demonstrate that robustness is a failure-dependent property rather than an intrinsic characteristic of individual methods. The proposed framework provides an interpretable analytical perspective for diagnosing robustness degradation and guiding failure-oriented intervention design in safety-critical industrial inspection applications.**

I. Introduction

Industrial inspection systems play a critical role in ensuring product quality, operational reliability, and safety across manufacturing, aerospace, energy, and infrastructure sectors [1]. Recent advances in computer vision and artificial intelligence have significantly improved the capability of automated inspection systems, enabling accurate detection of surface defects, structural anomalies, and internal material degradation [2]. As a result, deep learning-based inspection methods have become increasingly prevalent in safety-critical industrial applications [2].

Despite these advances, robustness remains a persistent challenge in industrial inspection [3]. Unlike controlled benchmark environments, real-world inspection systems frequently operate under adverse conditions, including limited training data, severe class imbalance, domain variability, optimisation instability, and imaging degradation [4], [5]. Under such conditions, inspection performance may deteriorate substantially, reducing system reliability and limiting industrial deployment [3].

Consequently, robustness has become a central research objective in industrial inspection [3]. A robust inspection system should not only achieve high performance under ideal conditions but also maintain reliable behaviour when confronted with uncertainty, data scarcity, and environmental variability.

Existing research has sought to improve robustness through various methodological approaches [1], [2]. Data-level studies primarily focus on augmentation, synthetic data generation, and domain adaptation to address data scarcity and imbalance [5], [4], [30]. Model-level studies investigate optimisation objectives, loss functions, architectural refinements, and attention mechanisms to improve learning behaviour and training stability [2], [7], [6]. Imaging-level studies employ enhancement, restoration, and reconstruction techniques to mitigate the

effects of degraded image acquisition [1].

Although these approaches have achieved notable performance improvements, they are typically investigated as independent technical solutions. Consequently, robustness is often interpreted as a by-product of algorithmic improvement rather than as a phenomenon that can be systematically analysed and explained.

A fundamental limitation of existing research is the lack of a unified perspective on why certain interventions improve robustness under some conditions but fail under others [3], [6]. Methods that demonstrate strong performance on one dataset frequently exhibit inconsistent behaviour when applied to different inspection scenarios. Such observations suggest that robustness behaviour may be governed by underlying failure mechanisms rather than by algorithmic superiority alone.

However, current industrial inspection literature provides limited guidance on identifying these failure mechanisms or on selecting interventions based on the source of robustness degradation [1], [2]. As a result, intervention selection often relies on empirical trial and error rather than systematic failure diagnosis.

To address this challenge, this study proposes a Failure-Oriented Robustness Framework for industrial inspection. Rather than analysing robustness from the perspective of individual algorithms, the proposed framework organises robustness challenges according to three dominant sources of failure: distribution failure, decision failure, and representation failure. The framework further establishes explicit relationships between failure diagnosis, intervention selection, and robustness interpretation, providing a systematic mechanism for understanding robustness behaviour across different inspection conditions.

The main contributions of this work are summarised as follows:

- A Failure-Oriented Robustness Framework is proposed to organise industrial inspection robustness challenges according to dominant failure sources rather than methodological categories.
- A failure-to-intervention mapping mechanism is introduced to connect robustness degradation with appropriate intervention strategies across data-level, model-level, and imaging-level inspection stages.
- The framework is validated through representative turbine blade inspection scenarios covering distribution failure, decision failure, and representation failure.
- A failure-oriented interpretation of robustness is established, demonstrating that robustness emerges from alignment between intervention strategies and dominant failure sources rather than increasing algorithmic complexity alone.

II. Reframing Robustness in Industrial Inspection

A. Existing Paradigms of Industrial Inspection

Industrial inspection systems have evolved from procedure-driven inspection towards intelligent and reliability-aware paradigms, driven by continuous advances in sensing technologies, machine vision, and artificial intelligence, as well as increasing industrial reliability requirements [1], [13], [15]. Rather than replacing previous approaches, each new paradigm extends inspection capability by introducing new perspectives on robustness and reliability. As a result, several dominant paradigms have emerged throughout the evolution of industrial inspection.

The earliest paradigm is the procedural NDT-centred framework, in which reliability is achieved through standardised inspection procedures, operator qualification, and Probability of Detection (PoD) validation [8], [9]. Inspection performance primarily depends on compliance with established inspection protocols and human expertise. Within this paradigm, robustness is interpreted as operational repeatability, procedural consistency, and regulatory compliance, with limited capability to model computational failure or data-driven uncertainty.

Subsequently, inspection research shifted towards an accuracy-centric, learning-based framework with the rapid adoption of machine vision and deep learning technologies [12], [2], [10]. Research within this paradigm primarily focuses on feature representation, model optimisation, and quantitative performance metrics such as mAP, precision, and recall [14], [11]. Robustness is therefore typically regarded as an implicit consequence of improved detection accuracy, assuming that better-performing models naturally exhibit greater robustness. Consequently, robustness is often evaluated through performance improvement rather than through explicit analysis of the mechanisms responsible for robustness degradation.

More recently, a reliability-oriented inspection paradigm has emerged to address the increasing demand for trustworthy artificial intelligence in safety-critical applications [17], [19], [16]. Recent studies have incorporated uncertainty quantification, confidence estimation, explainability, verification procedures, and risk-aware decision-making mechanisms to improve inspection reliability under uncertain operating conditions [3]. Although these approaches elevate reliability as a primary objective, they generally remain modality-specific and concentrate on uncertainty management rather than on identifying the underlying mechanisms responsible for robustness degradation.

Collectively, these paradigms have substantially advanced the capability of industrial inspection systems. However, they primarily organise robustness around methodologies, algorithms, or evaluation objectives rather than around the sources of robustness degradation themselves. Consequently, existing paradigms provide limited guidance on why particular intervention strategies succeed under certain inspection conditions but fail under others. This limitation motivates the emergence of a failure-oriented perspective, which is introduced in the following subsection.

B. Comparative Perspective on Robustness

Table I illustrates that the interpretation of robustness has progressively evolved from procedural consistency, to performance optimisation, and subsequently to trustworthy and reliable AI systems [17], [18], [19]. Although each paradigm contributes to improving inspection capability, robustness is

TABLE I. COMPARISON OF INDUSTRIAL INSPECTION PARADIGMS FROM A ROBUSTNESS PERSPECTIVE.

Paradigm	Primary Objective	Robustness Interpretation	Intervention Logic	Primary Limitation
Procedural NDT	Compliance and qualification	Operational repeatability	Procedural standardisation	Limited computational failure modelling
Accuracy-Centric Learning	Performance optimisation	Implicit outcome of accuracy improvement	Architecture and performance optimisation	Underlying failure mechanisms remain unexplained
Reliability-Oriented Inspection	Risk minimisation and uncertainty management	Reliable operation under uncertainty	Verification, explainability and uncertainty modelling	Failure diagnosis remains modality-specific
Failure-Oriented (Proposed)	Robustness-oriented inspection design	Explicit failure-dependent robustness	Failure diagnosis and intervention alignment	Requires accurate failure characterisation

consistently organised around methodologies, algorithms, or evaluation objectives rather than around the mechanisms responsible for robustness degradation.

Consequently, robustness is commonly interpreted as an operational outcome, an implicit consequence of improved detection accuracy, or a reliability attribute associated with uncertainty management and explainability [20], [21]. Such interpretations provide valuable guidance for evaluating system performance but offer limited explanatory capability regarding why identical intervention strategies frequently exhibit different behaviour across heterogeneous inspection scenarios.

This limitation becomes increasingly significant as industrial inspection systems incorporate heterogeneous datasets, increasingly complex optimisation strategies, and multi-modal sensing pipelines. These observations motivate a transition from methodology-oriented optimisation towards failure-oriented robustness analysis, which forms the conceptual foundation of the proposed framework.

C. Why Existing Paradigms are Insufficient?

The rapid adoption of AI-based inspection systems has revealed a growing discrepancy between performance optimisation and understanding of robustness. Although recent advances have substantially improved inspection accuracy, numerous studies have shown that methods that perform strongly under one set of conditions often exhibit inconsistent behaviour when applied to different datasets, defect distributions, optimisation settings, or imaging environments [3], [17], [18].

For example, augmentation strategies that successfully mitigate data scarcity in one dataset may provide negligible benefit in another with different distribution characteristics, highlighting the challenges of domain adaptation and domain generalisation [4], [5]. Similarly, architectural refinement does not necessarily improve robustness when optimisation objectives remain misaligned, suggesting that learning dynamics and objective design often have a greater influence on robustness than model complexity alone [6], [7]. In imaging-based inspection systems, image enhancement often contributes more to inspection reliability than modifications to the downstream detector, suggesting that robustness may be constrained more by the quality of the image representation than by the detection model itself.

These observations suggest that robustness behaviour cannot be fully explained through methodological categories alone. Instead, robustness degradation appears to stem from distinct failure mechanisms introduced at different stages of the inspection pipeline. Consequently, improving robustness requires identifying the dominant source of failure before selecting an appropriate intervention strategy, motivating the failure-oriented perspective introduced in the following subsection.

D. Emergence of a Failure-Oriented Perspective

The limitations of existing paradigms motivate a shift from method-centric optimisation towards failure-oriented robustness analysis. Rather than asking which algorithm performs best, a failure-oriented perspective seeks to identify the dominant source of robustness degradation before selecting an appropriate intervention strategy [22].

From this perspective, robustness challenges can be interpreted in terms of three primary sources of failure. Distribution failure originates from data scarcity, class imbalance, and distributional variability. Decision failure arises from misalignment in optimisation during model learning. Representation failure arises from image degradation and information loss prior to downstream analysis.

By explicitly connecting failure diagnosis, intervention selection, and robustness outcomes, a failure-oriented perspective provides a more systematic explanation of robustness behaviour across heterogeneous industrial inspection scenarios.

Fig. 1 illustrates how industrial inspection paradigms have evolved from procedure-oriented inspection and accuracy-centric optimisation towards reliability-aware inspection, culminating in the proposed failure-oriented robustness paradigm. Rather than organising robustness around algorithms or methodologies, the proposed paradigm organises robustness around dominant failure mechanisms, providing a unified perspective for robustness analysis and intervention selection.

E. Positioning of the Proposed Framework

Building upon the paradigm evolution illustrated in Fig. 1, the proposed framework extends existing industrial inspection paradigms by introducing a failure-oriented perspective for robustness analysis. Unlike previous paradigms, which organise robustness around procedures, algorithms, or reliability metrics, the proposed framework organises robustness according to dominant failure mechanisms.

This positioning shifts the research focus from identifying the best-performing method to understanding why robustness degrades and how intervention strategies should be selected according to the underlying source of failure. The proposed framework therefore serves as the conceptual foundation for the failure-oriented robustness architecture presented in the following section.

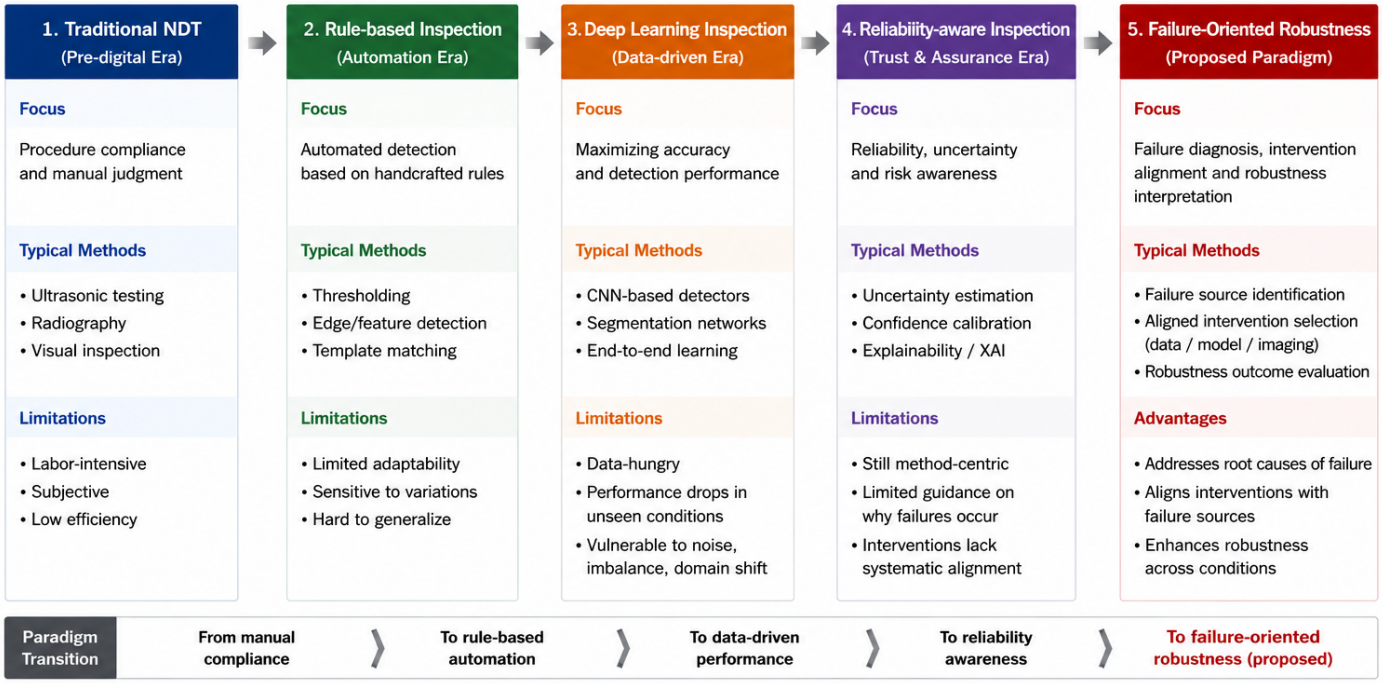

Fig. 1. Evolution of robustness paradigms in industrial inspection.

III. Proposed Failure-Oriented Robustness Framework

A. Motivation for a Failure-Oriented Perspective

Recent advances in industrial inspection have largely focused on developing new detection architectures, optimisation strategies, and augmentation techniques to improve detection accuracy. Although these approaches have achieved notable performance gains, robustness remains difficult to explain and predict under realistic industrial conditions. Methods that perform well on one dataset frequently exhibit inconsistent behaviour when applied to different defect distributions, data scales, or imaging conditions [17], [18].

This inconsistency suggests that inspection performance is often governed by underlying failure mechanisms rather than algorithmic complexity alone [22], [23]. In industrial inspection systems, failures may originate from multiple sources, including data scarcity and class imbalance, optimisation bias during model training, and imaging degradation caused by acquisition artifacts [4], [5], [6], [7], [24], [25]. These sources of failure affect different stages of the inspection pipeline and cannot always be mitigated by a single methodological improvement.

However, existing studies typically analyse augmentation, model optimisation, and image enhancement as independent technical solutions [5], [7], [24]. As a result, robustness is often treated as an implicit outcome of performance improvement rather than an explicit design objective [17], [19]. This motivates the need for a failure-oriented perspective that focuses on identifying dominant sources of failure and selecting interventions based on the nature of the failure.

Based on this motivation, a Failure-Oriented Robustness Framework is proposed to systematically connect failure diagnosis, intervention selection, and robustness interpretation across data-level, model-level, and imaging-level inspection stages.

B. Failure Taxonomy and Definitions

To improve the reproducibility and conceptual clarity of the proposed framework, the three failure categories are explicitly defined according to the stage at which robustness degradation is introduced into the industrial inspection pipeline. Rather than categorising robustness according to algorithmic families, the proposed framework classifies failures according to their origin and the corresponding intervention stage.

1) Distribution failure: It refers to a degradation of robustness arising from deficiencies in the training data before model optimisation. Typical causes include limited sample availability, class imbalance, distribution shift, and insufficient data diversity. Such failures primarily affect the statistical characteristics of the learning data and are generally mitigated through data-oriented interventions such as augmentation, sampling, and domain adaptation.

2) Decision failure: It refers to robustness degradation introduced during model optimisation and inference. Even when sufficient data are available, inappropriate optimisation objectives, loss functions, class weighting strategies [33], or decision boundaries may lead to unstable learning behaviour and biased predictions. Decision failure therefore originates from misalignment in optimisation rather than data insufficiency.

3) Representation failure: It refers to robustness degradation caused by information loss before feature learning begins. This category includes image degradation resulting from acquisition noise, motion blur, illumination variation, CT artifacts,

low contrast, and other sensing imperfections. Representation failure limits the quality of information available to downstream learning algorithms and is typically addressed through image enhancement or restoration techniques. Unlike distribution failure and decision failure, representation failure is evaluated at the image representation level rather than directly through downstream detection performance. The objective of a representation-oriented intervention is to recover degraded information and improve the quality of inputs available for subsequent inspection tasks.

Accordingly, the proposed framework distinguishes the three failure categories according to the stage at which robustness degradation is introduced: before model optimisation (distribution failure), during optimisation and inference (decision failure), and before feature learning due to acquisition degradation (representation failure). The taxonomy and formal definitions of the three failure categories are summarised in Table II. This stage-oriented definition establishes the conceptual boundary between failure categories and provides the basis for failure-oriented intervention selection.

In practical industrial inspection systems, multiple failure sources may coexist simultaneously. The proposed framework does not assume that distribution failure, decision failure, and representation failure are mutually exclusive. Instead, these categories provide a structured mechanism for diagnosing the dominant source of robustness degradation under a specific inspection scenario.

The dominant failure refers to the failure source that contributes most significantly to the observed robustness degradation and should therefore receive priority during intervention selection. Other failure sources may still exist as secondary factors and may require additional interventions when their influence becomes significant.

C. Framework Architecture

The proposed Failure-Oriented Robustness Framework is designed to analyse robustness from the perspective of failure generation rather than algorithm selection. Instead of treating augmentation, optimisation, and enhancement as independent technical solutions, the framework organises robustness challenges according to the dominant failure mechanisms responsible for inspection performance degradation [5], [7], [24].

As illustrated in Fig. 2, the framework consists of three hierarchical layers: Distribution Failure, Decision Failure, and Representation Failure. These layers correspond to different stages of the industrial inspection pipeline and collectively describe how robustness degradation emerges and propagates throughout the system.

1) Distribution failure layer: These layers are arranged according to the stage at which robustness degradation is introduced into the inspection pipeline, ranging from data generation and model decision-making to image representation quality. Distribution failure originates from deficiencies in the training data distribution, including data scarcity, class imbalance, and domain variability. Such failures often manifest as poor generalisation capability, unstable rare-class detection, and sensitivity to distribution shifts [4], [5]. Since the underlying issue is data-related, interventions at this layer primarily focus on modifying the data distribution to improve representation diversity and class coverage.

2) Decision failure layer: Decision failure occurs when the learning objective becomes misaligned with the inspection objective [6], [7]. Even when sufficient data are available, optimisation objectives may favour dominant classes, suppress minority categories, or produce unstable localisation behaviour. These failures are associated with the model's decision-making process rather than with the data itself. Consequently, improvement in robustness at this layer focuses on objective design, loss functions, weighting mechanisms, and optimization strategies.

3) Representation failure layer: Representation failure arises before the learning stage and is caused by degradation in the acquired inspection data [24], [25], [26]. Common examples include image artifacts, noise contamination, contrast reduction, and resolution loss. These effects distort the defect representation and limit the amount of useful information available for downstream analysis. Therefore, interventions at this layer primarily involve enhancement, restoration, and super-resolution techniques [24], [26], [36].

Together, these three layers provide a unified view of robustness in industrial inspection systems, based on failure. Unlike conventional method-centric approaches that evaluate individual algorithms in isolation, the proposed framework emphasises identifying dominant failure mechanisms and selecting interventions that directly address the underlying cause of performance degradation. From this perspective, robustness is understood as the outcome of alignment between intervention strategies and failure sources, rather than a direct consequence of increasing algorithmic complexity.

D. Failure Source–Intervention Mapping

While the framework architecture identifies the dominant sources of robustness degradation, practical improvements in robustness require a mechanism for selecting appropriate interventions. Conventional industrial inspection studies typically adopt a method-centric workflow in which augmentation techniques, optimisation strategies, or enhancement algorithms are evaluated independently [5], [7], [24]. Under such a paradigm, intervention selection is often driven by methodological popularity rather than the underlying cause of failure.

The proposed framework adopts a failure-oriented intervention strategy. Instead of asking which method performs best, the framework first identifies the dominant failure source and subsequently selects interventions that directly target the corresponding failure mechanism. This process establishes an explicit relationship between failure diagnosis and intervention selection.

For distribution failures, robustness degradation originates from deficiencies in the training data distribution, including scarcity, imbalance, and domain variability. Consequently, interventions should focus on modifying the data distribution through augmentation, balancing, or domain adaptation techniques.

For decision failures, performance degradation arises from optimisation bias and objective misalignment during model learning. Therefore, interventions should focus on objective

TABLE II. TAXONOMY AND DEFINITIONS OF THE PROPOSED FAILURE CATEGORIES

Failure Category	Failure Stage	Origin of Failure	Typical Intervention
Distribution Failure	Before model optimisation	Training data deficiencies, including limited samples, class imbalance, and distribution shift	Data augmentation, sampling, and domain adaptation
Decision Failure	During optimisation and inference	Misalignment between optimisation objectives and inspection objectives, including inappropriate loss functions, optimisation strategies, and decision boundaries	Loss function design, optimisation strategy, and class weighting
Representation Failure	Before feature learning	Information degradation caused by image acquisition artifacts, noise, blur, low contrast, and sensing imperfections	Image enhancement, image restoration, and super-resolution

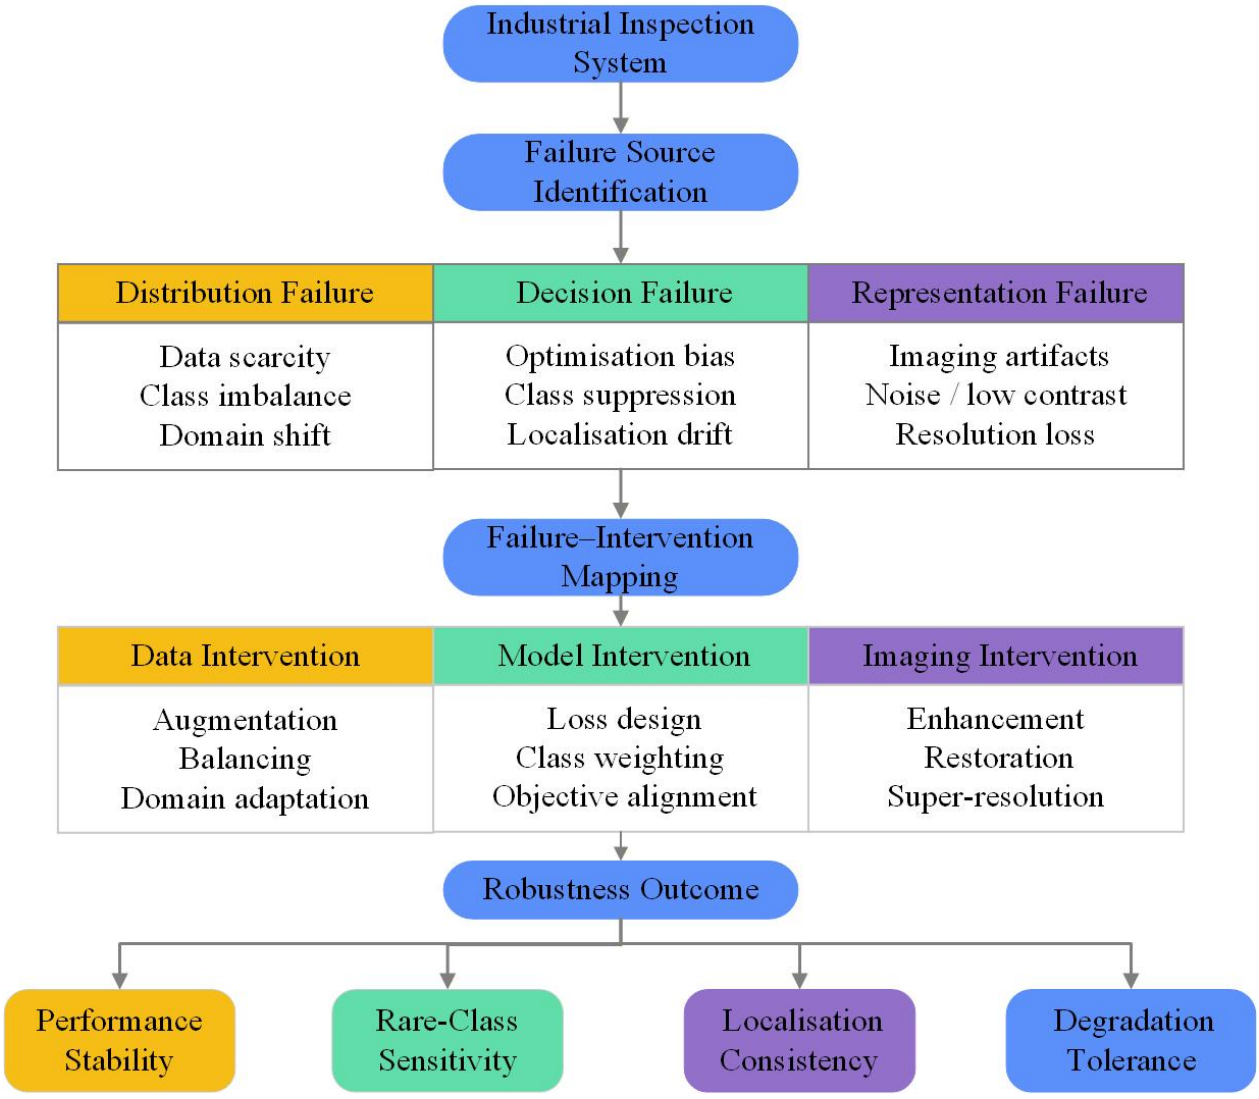

Fig. 2. Proposed Failure-Oriented Robustness Framework for industrial inspection. The framework organises robustness challenges according to three dominant sources of failure and maps them to corresponding intervention strategies and robustness outcomes.

design, loss formulation, class weighting, and optimisation strategies that improve decision consistency and minority-class representation.

For representation failures, degradation occurs before model learning due to corruption of the acquired inspection data. In such cases, robustness improvement should prioritise enhancement, restoration, and super-resolution techniques to recover defect visibility and structural information.

The proposed mapping mechanism does not assume the existence of a universally optimal intervention. Instead, it emphasises alignment between intervention strategy and dominant failure source. Under this perspective, intervention effec-

tiveness is considered failure-dependent rather than method-dependent, providing a systematic basis for robustness-oriented decision making in industrial inspection systems.

E. Robustness Interpretation Mechanism

A central objective of the proposed framework is to reinterpret robustness beyond conventional accuracy-oriented evaluation. Existing industrial inspection studies predominantly assess performance using aggregate metrics such as accuracy, precision, recall, and mean Average Precision (mAP) [17], [18]. While these metrics provide useful indicators of detection performance, they do not necessarily reflect an inspection system's ability to maintain reliable behaviour under adverse operating conditions.

Within the proposed framework, robustness is defined as an inspection system's ability to maintain stable, reliable performance when confronted with dominant failure sources. Consequently, robustness is viewed as a multidimensional property rather than a single performance metric.

To facilitate the interpretation of robustness, four complementary dimensions are considered. Performance Stability evaluates the consistency of inspection performance across varying operating conditions. Rare-Class Sensitivity measures the system's ability to maintain detection effectiveness for minority defect categories. Localisation Consistency reflects the stability and reliability of defect localisation behaviour during model prediction. Degradation Tolerance assesses the inspection system's ability to maintain performance under imaging degradation, noise contamination, or structural corruption.

These dimensions provide an interpretable link between failure diagnosis, intervention effectiveness, and robustness outcomes. Under the proposed framework, robustness is improved not merely by higher accuracy, but by sustained performance under the specific failure conditions that dominate the inspection process. Therefore, robustness is interpreted as the observable outcome of successful alignment between intervention strategies and failure mechanisms.

F. Practical Application Workflow

While Fig. 2 explains what constitutes the framework, Fig. 3 illustrates how the framework is applied during practical inspection. As illustrated in Fig. 3, the proposed framework can be operationalised through a sequential failure-oriented workflow.

To facilitate practical deployment, the proposed framework is implemented through a sequential failure-oriented workflow. Rather than selecting algorithms directly, the workflow begins with diagnosing the dominant source of robustness degradation and subsequently identifying interventions that target the corresponding failure mechanism.

The workflow consists of five stages. First, the inspection scenario is analysed to identify observable performance limitations, such as poor rare-class detection, unstable localisation behaviour, or degraded image quality. Second, these symptoms are traced to their dominant source of failure, which may be categorised as distribution, decision, or representation failure.

Third, intervention strategies are selected according to the identified failure category. Distribution failures are addressed through data-oriented interventions, decision failures through optimisation-oriented interventions, and representation failures through imaging-oriented interventions. Fourth, robustness outcomes are evaluated using the interpretation dimensions defined in the framework, including performance stability, rare-class sensitivity, localisation consistency, and degradation tolerance.

Finally, the intervention results are analysed, and the workflow is iteratively refined if the dominant failure source remains unresolved. This iterative process allows robustness improvement to be guided by failure diagnosis rather than algorithmic trial-and-error.

The proposed workflow transforms the framework from a conceptual robustness model into a structured analytical procedure for industrial inspection applications. By prioritising failure diagnosis before intervention selection, the framework provides a systematic procedure for analysing robustness degradation and guiding the development of robustness-oriented inspection systems.

IV. Framework Validation Through Turbine Blade Inspection

A. Experimental Settings

Since the proposed framework investigates robustness degradation from different failure sources, the experimental configurations were designed according to the characteristics of each validation scenario. The data-level, model-level, and imaging-level experiments correspond to different intervention mechanisms; therefore, their training configurations are not identical. Instead, each experimental setting was controlled to ensure a fair comparison among methods within the corresponding validation scenario.

1) 2D Detection experiments: The 2D industrial inspection experiments were conducted using the YOLOv8 object detection framework implemented with the Ultralytics library. YOLO-based detectors have been widely adopted for real-time object detection because of their balance between detection accuracy and computational efficiency [28]. The experiments were performed using Python 3.9.19, PyTorch 2.4.1 with CUDA 12.4, and an NVIDIA GeForce RTX 4060 Laptop GPU with 8 GB VRAM. The adopted YOLOv8n detector contains 3,006,623 parameters and 8.1 GFLOPs.

For the data-level validation, the objective was to investigate whether augmentation strategies could alleviate distribution failure caused by limited samples, class imbalance, and distribution variability. Therefore, the augmentation strategy was considered the primary experimental variable, while the detector training configuration was maintained consistently within each dataset. The models were trained for 100 epochs with an input resolution of 640×640 pixels and a batch size of 1. The default Ultralytics optimization configuration was adopted, and different augmentation strategies with their corresponding parameters were applied according to the experimental design.

For the model-level validation, the objective was to analyse decision failure caused by optimisation misalignment. Unlike

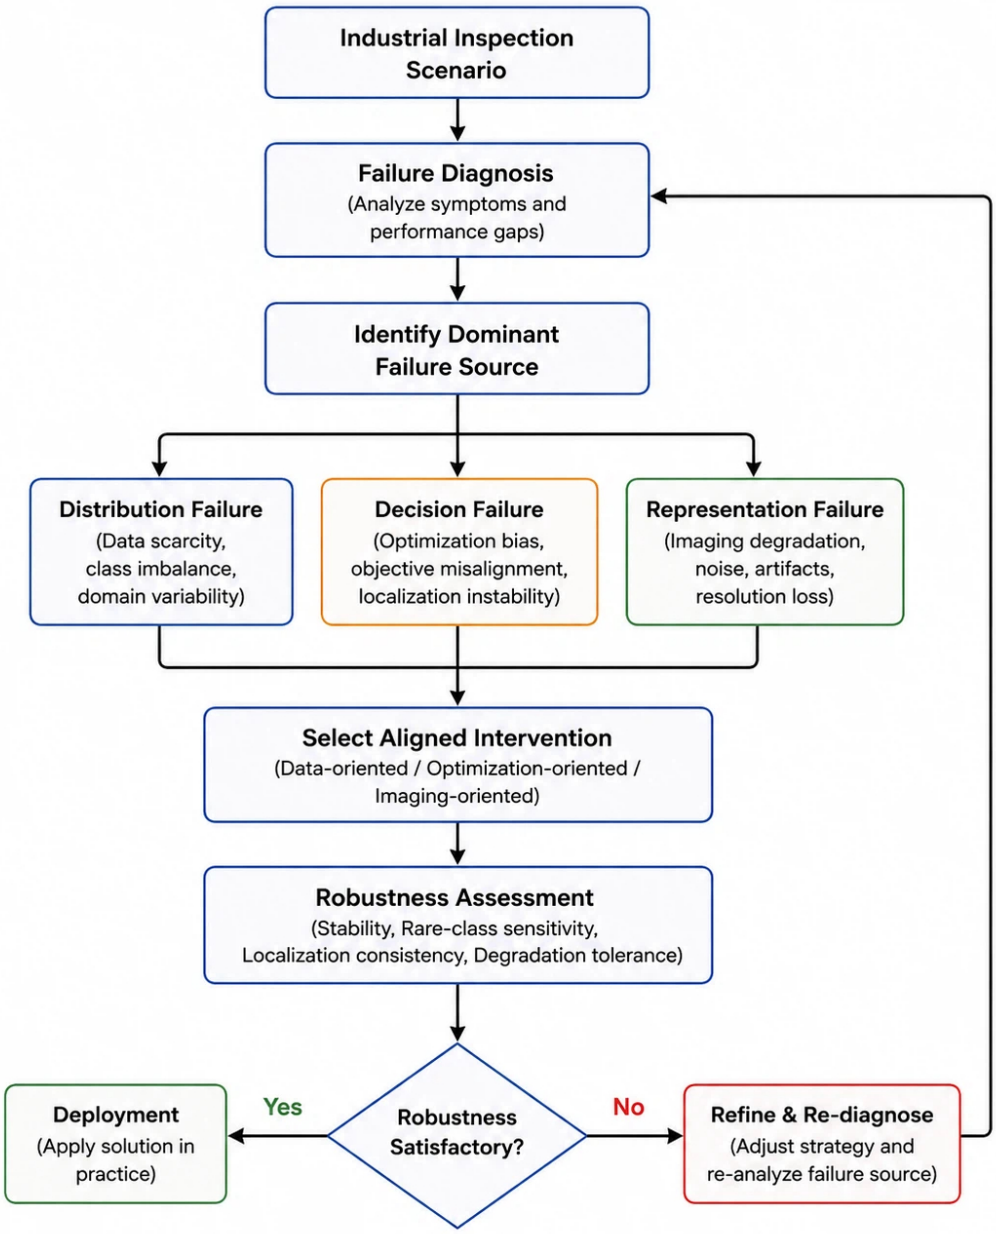

Fig. 3. Failure-oriented robustness workflow for industrial inspection systems.

the data-level experiments, optimisation strategies were treated as the primary experimental variables. Different optimizers, loss functions, class weighting strategies, and architectural modifications were evaluated under controlled training conditions. The models were trained for 300 epochs with an input resolution of 640 $\times$ 640 pixels and a batch size of 16. A fixed random seed of 42 was adopted to improve reproducibility. The optimizer configuration was adjusted according to the specific comparison objectives, including Adam [34] and SGD evaluations. Early stopping was disabled to ensure that all models completed the predefined training schedule.

For all 2D detection experiments, the performance was evaluated using mean average precision at IoU threshold 0.5 (mAP@0.5), mean average precision across IoU thresholds from 0.5 to 0.95 (mAP@0.5:0.95), precision, recall, and class-wise average precision.

2) CT Representation recovery experiments: The CT experiments were designed to validate representation failure caused by image acquisition degradation. Unlike the 2D detection experiments, the objective of this validation scenario was not to directly improve defect detection performance but to recover degraded image representations caused by CT artifacts.

A lightweight GNN-based artifact removal framework was implemented using PyTorch. Several restoration models, in-

cluding CNN, U-Net [35], and different GNN variants, were compared under identical training conditions. The CT images were converted into normalized grayscale representations with pixel values scaled to the range of [0,1]. The training and validation datasets were loaded according to predefined image-mask pairs.

All restoration models were trained using the Adam optimizer with a learning rate of 1×10^{-3} and the mean squared error (MSE) loss function. The batch size was set to 1, and each model was trained for 50 epochs. The restoration performance was evaluated using peak signal-to-noise ratio (PSNR) and structural similarity index (SSIM).

The CT validation therefore focuses on representation-level robustness, where the objective is to assess whether degraded image information can be recovered before subsequent inspection analysis.

To ensure the consistency and reliability of the reported results, repeated experiments were conducted under identical experimental configurations. For the YOLO-based 2D detection experiments, repeated runs produced identical evaluation results under the fixed training settings. For the CT representation recovery experiments, repeated runs showed minor numerical variations due to the stochastic nature of deep learning optimization; however, the relative performance trends among different restoration models remained consistent. These observations indicate that the reported robustness behaviours are reproducible and primarily associated with the investigated intervention strategies rather than incidental training variations.

B. Validation Scenario Overview

To evaluate the explanatory capability of the proposed framework, validation was conducted using representative industrial inspection scenarios derived from turbine blade inspection. Rather than evaluating the superiority of a specific algorithm, this section investigates whether the proposed framework can consistently explain robustness behaviour across different failure conditions.

Three validation scenarios were considered. Distribution failure was evaluated using two industrial defect datasets exhibiting substantially different levels of data scarcity and class imbalance. We evaluated decision failure through optimisation and architectural studies that analysed how learning objectives influenced detection robustness. Representation failure was evaluated using CT imaging scenarios affected by artifacts and structural degradation.

Collectively, these validation cases provide empirical evidence to examine whether dominant failure sources govern robustness behaviour and whether intervention effectiveness depends on alignment with those sources.

C. Distribution Failure Validation

To validate the distribution-failure component of the proposed framework, two industrial defect datasets with substantially different distributional characteristics were analysed. Dataset 1 (Alibaba Tianchi) represents a small-scale, severely imbalanced inspection scenario, containing 247 images and 388 defect instances, with an imbalance ratio of 7.33. In contrast, Dataset 2 (AeBAD-S) represents a larger-scale, relatively balanced inspection scenario, comprising 1,592 images and 2,557 defect instances.

TABLE III. REPRESENTATIVE AUGMENTATION RESULTS UNDER SEVERE DISTRIBUTION FAILURE.

Method	mAP@0.5	Dirty AP	Stain AP
Baseline	0.290	0.000	0.000
MixUp	0.591	0.667	0.672
CycleGAN	0.461	0.667	0.000
C5 Composite	0.599	0.731	0.452

According to the proposed framework, Dataset 1 is primarily characterized by distribution failures arising from data scarcity and class imbalance, whereas Dataset 2 exhibits substantially weaker distribution-failure characteristics. The contrasting properties of the two datasets provide an appropriate validation scenario for evaluating whether intervention effectiveness is determined by the intervention itself or by the dominant failure source.

1) Case A: Small-scale imbalanced dataset: Dataset 1 represents a typical industrial inspection scenario characterised by severe distribution failure. The dataset contains only 247 images and 388 defect instances, with an imbalance ratio of 7.33 between the majority and minority defect categories. Under these conditions, the baseline detector exhibited substantial degradation in robustness, particularly for minority defect classes, in which several categories could not be reliably detected.

As shown in Table III, substantial improvements were observed after applying distribution-oriented interventions. In particular, MixUp [27] and the C5 composite strategy significantly improved minority-class detection performance, transforming previously undetected defect categories into reliably detectable classes.

According to the proposed framework, these improvements are not solely attributable to the augmentation techniques themselves. Instead, the observed robustness gains stemmed from the selected interventions directly addressing the dominant failure sources, namely data scarcity and class imbalance. By increasing semantic diversity and improving minority-class representation [29], [30], the interventions effectively mitigated the distribution failure present in Dataset 1.

This case therefore provides empirical evidence supporting the distribution failure component of the proposed framework. The results suggest that intervention effectiveness depends on alignment with the underlying source of failure rather than on the intervention strategy alone.

2) Case B: Large-scale balanced dataset: In contrast to Dataset 1, Dataset 2 represents a larger-scale industrial inspection scenario with substantially weaker characteristics of distribution failure. The dataset contains 1,592 images and 2,557 defect instances, exhibiting a considerably more balanced class distribution. Consequently, data scarcity and class imbalance are no longer the dominant constraints affecting robustness.

As shown in Table IV, augmentation strategies exhibited markedly different behaviour compared with Dataset 1. While geometric augmentation produced measurable improvements,

TABLE IV. REPRESENTATIVE AUGMENTATION RESULTS UNDER WEAK DISTRIBUTION FAILURE.

Method	mAP_{50}	Ablation AP
Baseline	0.814	0.443
Geometric	0.862	0.684
Mosaic	0.827	0.549
MixUp	0.809	0.443
Diffusion	0.812	0.464

semantic-mixing approaches such as MixUp [27] provided limited benefit and did not improve minority-class performance. Similarly, the overall performance gains achieved through augmentation were substantially smaller than those observed under severe distribution failure conditions.

According to the proposed framework, this behaviour can be explained by the reduced influence of distribution failure in Dataset 2. Since the dataset already provides sufficient sample diversity and a relatively balanced class representation, interventions specifically designed to address data scarcity and imbalance are no longer the most effective robustness strategy, which is consistent with previous observations on dataset-dependent augmentation and domain generalisation [29], [5].

These observations further support the failure-oriented interpretation of robustness. The effectiveness of augmentation was not determined by the intervention itself but by the extent to which it aligned with the dominant failure source in the inspection scenario.

3) Framework interpretation: The contrasting behaviours observed across Dataset 1 and Dataset 2 provide empirical support for the central assumption of the proposed framework. Although similar augmentation strategies were applied in both scenarios, their effectiveness varied substantially depending on the datasets' underlying distributional characteristics.

In Dataset 1, robustness degradation was primarily associated with severe data scarcity and class imbalance. Under these conditions, interventions designed to increase data diversity and improve minority-class representation produced substantial improvements in detection performance, particularly for previously underrepresented defect categories. In contrast, Dataset 2 exhibited substantially weaker characteristics of distribution failure. Consequently, the same augmentation strategies produced reduced benefits and, in some cases, negligible performance improvements.

These observations suggest that augmentation effectiveness is not an intrinsic property of the augmentation strategy itself. Rather, intervention effectiveness depends on the degree of alignment between the intervention and the dominant source of failure. When severe distribution failure is present, distribution-oriented interventions can significantly improve robustness. However, when distribution failure is no longer the primary constraint, the same interventions may provide limited value.

From the perspective of the proposed framework, robustness improvement is therefore failure-dependent rather than method-dependent. The distribution failure validation demonstrates that selecting an effective intervention requires identifying the dominant failure source in advance rather than adopting a universally preferred technique.

D. Decision Failure Validation

1) Case A: Objective alignment: To validate the decision failure component of the proposed framework, optimisation objectives were examined under identical architectural conditions. In this validation scenario, the detector architecture remained unchanged while different objective formulations, including imbalance-aware loss functions, were applied [31].

As shown in Table V, substantial robustness improvements were achieved through objective redesign without modifying the detector architecture. The results indicate that decision quality was strongly influenced by the optimisation objective, particularly under imbalanced inspection conditions where minority defect categories were vulnerable to suppression. Bounding-box regression objectives were also investigated using IoU-based loss formulations, following previous improvements in localization optimisation [32].

According to the proposed framework, these improvements are associated with mitigating decision failure rather than with changes in model complexity. By improving the alignment between optimisation objectives and inspection objectives, the detector exhibited more stable learning behaviour and improved minority-class representation.

2) Case B: Architectural refinement: A second validation scenario examined whether robustness could be improved through architectural refinement alone. Several attention and feature-enhancement modules were incorporated into the baseline detector architecture.

As shown in Table VI, architectural refinement did not consistently improve robustness. Several architectural modifications resulted in performance degradation despite increasing model complexity. These observations suggest that the robustness limitations were more closely associated with optimisation and decision-making behaviour than with insufficient representational capacity alone.

3) Framework Interpretation: The results of the decision failure validation support the central assumption of the proposed framework. Under identical architectural conditions, objective alignment produced substantial robustness improvements, whereas increased architectural complexity failed to provide consistent benefits.

These observations indicate that decision failure originates primarily from optimisation behaviour rather than model ca-

TABLE VII. REPRESENTATIVE IMAGE QUALITY RESULTS FOR REPRESENTATION FAILURE RECOVERY.

Method	PSNR	SSIM

CNN	27.83	0.6552
U-Net	25.85	0.9201
GNN v2	28.93	0.9220

pacity. Consequently, interventions targeting objective design, class weighting, and optimisation strategies are often more effective than architectural refinement when decision failure is the dominant source of robustness degradation.

From the perspective of the proposed framework, the improvement in robustness in this scenario emerged from alignment between the optimisation and inspection objectives rather than from increasing architectural complexity. This finding provides empirical support for the framework's decision-failure component and further demonstrates that the dominant source of failure governs intervention effectiveness.

E. Representation Failure Validation

1) Case study CT representation recovery under imaging degradation: To validate the representation-failure component of the proposed framework, industrial computed tomography (CT) scenarios affected by imaging degradation were analysed. Unlike distribution failure and decision failure, which are directly reflected through detection performance, representation failure occurs before model inference and is therefore evaluated through the recovery of degraded image representations.

In industrial CT inspection, image quality may be degraded by ring artifacts, streak artifacts, beam-hardening effects, noise contamination, and reduced contrast [24], [25]. These degradations distort defect-related structural information and reduce the quality of image representations available for subsequent inspection tasks. Consequently, robustness degradation may occur before feature extraction and model inference due to insufficient or corrupted visual information.

According to the proposed framework, such degradation corresponds to representation failure. To address this source of failure, image enhancement and restoration techniques were applied to recover structural information and improve defect visibility [26].

The representative image quality results are summarised in Table VII. The enhancement process improved image quality and restored structural information under degraded CT conditions. These results demonstrate that representation-oriented interventions can alleviate information loss caused by imaging degradation and provide more reliable image representations for subsequent inspection analysis. However, downstream defect detection evaluation after CT enhancement was not conducted in this study, as the objective of this validation case is to assess representation recovery rather than end-to-end detection improvement.

F. Cross-Level Analysis

The three validation scenarios demonstrate that robustness degradation in industrial inspection systems does not originate from a single source. Instead, robustness challenges emerge at different stages of the inspection pipeline and are associated with distinct failure mechanisms.

Distribution failure primarily arises from deficiencies in the training data, including data scarcity, class imbalance, and distributional variability. Decision failure arises from optimisation misalignment during model learning, whereas representation failure is introduced prior to learning through imaging degradation and information loss.

Although these failures occur at different stages of the inspection pipeline, they share a common characteristic: each affects robustness through a distinct mechanism and therefore requires a different intervention strategy. Consequently, robustness cannot be improved through a universally superior algorithm; rather, improvement depends on addressing the dominant constraint present in the inspection scenario.

The three validation cases also reveal an important cross-level observation. Interventions that were highly effective under one failure condition did not necessarily produce comparable improvements under another. Distribution-oriented augmentation substantially improved robustness under severe data imbalance but provided limited benefit when distribution failure was weak. Similarly, optimisation-oriented interventions consistently outperformed architectural refinement only when decision failure dominated, whereas imaging enhancement became the primary contributor to robustness under degraded CT acquisition conditions.

These observations suggest that robustness degradation should be analysed by the stage at which failure is introduced rather than by methodological categories alone. Collectively, these cross-level observations establish a common analytical basis for interpreting robustness across heterogeneous industrial inspection scenarios and naturally motivate the unified framework synthesis presented in the following section.

G. Framework Synthesis

The three validation scenarios collectively provide converging empirical evidence supporting the proposed Failure-Oriented Robustness Framework. Although each validation examined different inspection tasks, datasets, and intervention strategies, all cases exhibited a consistent pattern of robustness that can be interpreted within the proposed failure-oriented perspective.

The relationships identified across the three validation scenarios are summarised in Table VIII.

This synthesis demonstrates that the proposed framework provides a unified explanation of robustness behaviour across heterogeneous industrial inspection systems. Rather than treating augmentation, optimisation, and image enhancement as isolated technical solutions, the framework interprets them as complementary interventions targeting different stages of robustness degradation.

A common robustness principle therefore emerges across all validation scenarios: intervention effectiveness is governed by alignment with the dominant failure source rather than by algorithmic superiority alone. Consequently, robustness should be understood as a failure-dependent property rather than an algorithm-dependent property.

TABLE VIII. FRAMEWORK SYNTHESIS ACROSS VALIDATION SCENARIOS

Failure	Validation Observation	Framework Insight
Distribution	Augmentation is effective only under severe imbalance	Distribution alignment
Decision	Objective alignment consistently outperforms architectural refinement	Objective alignment
Representation	Enhancement restores structural visibility under degraded CT	Representation recovery

Taken together, these findings demonstrate that the proposed Failure-Oriented Robustness Framework provides a unified conceptual foundation for robustness-oriented analysis, intervention selection, and future framework development in safety-critical industrial inspection systems.

V. DISCUSSION AND FUTURE PERSPECTIVES

A. From Method-Centric Optimisation to Failure-Oriented Design

A central implication of the proposed framework is the shift from method-centric optimisation towards failure-oriented robustness design. Existing industrial inspection research has predominantly focused on identifying superior algorithms through architectural innovation, optimisation refinement, and data augmentation. Under this paradigm, robustness is often treated as a secondary outcome of improved performance.

However, the validation results presented in this study suggest that robustness behaviour cannot be fully explained by algorithmic superiority alone. Across all validation scenarios, intervention effectiveness depended strongly on the dominant source of failure. Methods that produced substantial improvements under one failure condition frequently demonstrated limited effectiveness under another.

These observations indicate that robustness should be analysed from the perspective of failure mechanisms rather than individual algorithms. Consequently, future industrial inspection systems may benefit from prioritising failure diagnosis before intervention selection, thereby transforming robustness from an implicit consequence of optimisation into an explicit design objective.

B. Implications for Industrial Inspection Robustness

The proposed framework has several implications for the design and evaluation of industrial inspection systems. Traditionally, robustness improvement has been pursued through the continuous development of new architectures, optimisation strategies, and data augmentation techniques. While such efforts have achieved notable performance gains, the results of this study suggest that robustness cannot be fully understood through algorithmic improvement alone.

Instead, robustness should be interpreted as a consequence of the interaction between failure sources and intervention strategies. Under this perspective, the primary objective of robustness-oriented inspection is not to identify universally superior methods, but to determine which intervention is most appropriate for the dominant failure condition. Consequently, robustness evaluation should incorporate failure diagnosis and intervention alignment in addition to conventional performance metrics.

For industrial practitioners, this perspective provides a practical decision-support mechanism. Rather than relying solely on trial-and-error model selection, inspection systems can be developed through the systematic identification of failure sources and the targeted design of interventions. Such an approach may improve both development efficiency and deployment reliability in safety-critical industrial environments.

C. Generalisability and Limitations

Although the proposed framework was validated using turbine blade inspection scenarios, the underlying failure categories are not specific to this application domain. Data scarcity, optimisation bias, and representation degradation are common challenges across a wide range of industrial inspection tasks, including weld inspection, casting inspection, surface defect detection, and industrial medical imaging. Consequently, the framework may provide a general robustness-oriented perspective for analysing inspection systems beyond turbine blade inspection.

Nevertheless, several limitations should be acknowledged. First, the framework was validated through representative case studies rather than a unified end-to-end implementation. Second, interactions between multiple failure sources were not explicitly investigated. In practical inspection systems, distribution, decision, and representation failures may coexist and influence each other simultaneously. Finally, the framework focuses primarily on robustness interpretation and intervention selection rather than on providing a universal optimisation strategy.

Furthermore, the current framework should be regarded as an analytical and interpretative framework rather than a fully predictive intervention recommendation system. Although the proposed failure-oriented perspective establishes relationships between failure sources and suitable intervention categories, it does not automatically identify failure dominance, rank competing interventions, or quantitatively predict expected robustness improvement before experimentation. Developing such predictive capabilities would require additional data-driven modelling and large-scale cross-domain validation, which represents an important direction for future research.

These limitations provide opportunities for future refinement and broader validation of the framework.

D. Future Research Directions

Several directions can be explored in future research for further developing the proposed framework. First, future studies should investigate cross-level interactions between distribution, decision, and representation failures. Understanding how multiple failure sources jointly influence robustness may lead to more comprehensive intervention strategies.

Second, future research may extend the framework towards predictive robustness management, where failure diagnosis and intervention selection are supported by quantitative models. Such extensions may enable automatic estimation of dominant failure sources, intervention ranking, and expected robustness improvements under different inspection conditions.

Finally, broader validation across different industrial domains is required. Applying the framework to additional inspection scenarios, including manufacturing quality control, infrastructure monitoring, and medical imaging, would help evaluate its generalisability and identify domain-specific robustness challenges.

Through these developments, the proposed framework may evolve from a robustness-interpretation model into a more comprehensive robustness-design methodology for industrial inspection systems.

When robustness degradation is observed, the first question should not be "Which algorithm should be used?" Instead, the dominant failure source should first be identified, followed by failure-aligned intervention selection.

VI. Conclusion

This study addressed a fundamental challenge in industrial inspection: robustness is widely recognised as a critical requirement, yet its behaviour remains difficult to explain using conventional method-centric perspectives. Existing studies have primarily focused on developing new architectures, optimisation strategies, and augmentation techniques, often treating robustness as a secondary consequence of performance improvement rather than an explicit research objective.

To address this limitation, a Failure-Oriented Robustness Framework was proposed. Instead of analysing robustness at the level of individual algorithms, the framework organises robustness challenges into three dominant failure sources: distribution failure, decision failure, and representation failure. By establishing explicit relationships between failure diagnosis, intervention selection, and robustness outcomes, the framework provides a systematic mechanism for understanding and improving robustness in industrial inspection systems.

The framework was validated through representative turbine blade inspection scenarios covering data-level, model-level, and imaging-level robustness challenges. Across all validation cases, a consistent pattern emerged. Distribution-oriented interventions were most effective when robustness degradation originated from data scarcity and class imbalance. Optimisation-oriented interventions produced the greatest benefits when decision failure dominated the learning process. Representation-oriented interventions were most effective when imaging degradation limited the visibility of defects. These observations demonstrate that intervention effectiveness varies according to the dominant source of failure.

The central finding of this work is that robustness is not an intrinsic property of a particular method, nor is it achieved simply through increasing algorithmic complexity. Rather, robustness emerges from alignment between intervention strategies and dominant failure sources. This perspective shifts robustness research from method-centric optimisation towards failure-oriented robustness design, providing a more interpretable and practically relevant foundation for industrial inspection systems.

Although the framework was validated using turbine blade inspection scenarios, the proposed perspective is not restricted to a single application domain. Future research may extend the framework to additional industrial and imaging environments, investigate interactions between multiple failure sources, and develop adaptive robustness management strategies. Through such developments, the proposed framework may contribute towards a more systematic and generalisable understanding of robustness in industrial inspection. The proposed framework establishes a conceptual foundation for future robustness-oriented industrial inspection systems, where intervention strategies are selected according to failure mechanisms rather than algorithmic popularity.

***Abstract*—Rivers are dynamic geomorphological systems experiencing continuous transformation through erosion and sediment transport. In Bangladesh, these processes displace 50,000-200,000 people annually, causing severe losses along the Padma River according to Natural Resources Defense Council (NRDC). Traditional monitoring via field surveys and manual remote sensing proves costly, spatially limited, and unsuitable for multi-year prediction. This study presents a comprehensive framework, termed SpaTempNet, for forecasting river morphological evolution from freely available satellite data using spatiotemporal deep learning. A 38-year time-series (1987–2025) of binary water masks was constructed from Landsat (5 TM, 7 ETM+, 8 OLI) and Sentinel (Sentinel-2 MSI, Sentinel-1 SAR) imagery via Google Earth Engine. Water extraction used Modified Normalised Difference Water Index (MNDWI). The proposed Bidirectional ConvLSTM gap-filling model achieved IoU = 0.7366, outperforming classical methods. Five spatiotemporal architectures (ConvLSTM, U-Net+LSTM, Attention U-Net+ConvLSTM, Swin Transformer, ViT-based model) were evaluated across yearly, quarterly, and bi-monthly resolutions. Hybrid CNN-LSTM models consistently outperformed pure transformers. Attention U-Net+ConvLSTM achieved best yearly performance (IoU = 0.7005); U-Net+LSTM led bi-monthly prediction (IoU = 0.7791). Statistical analysis quantified mean annual migration of 255.4 m yr^{-1} with 1998 extreme of 1,485.5 m yr^{-1}. An expansion of about 290 km^2 was projected, and a spatially explicit risk map was generated through long-term forecasting (2026-2040). Results demonstrate that freely available satellite imagery with deep learning can provide practical, scalable framework for riverbank hazard monitoring and disaster management.**

***Keywords*—River morphology; riverbank erosion forecasting; spatiotemporal neural networks; ConvLSTM; U-Net; Swin Transformer; Vision Transformer; satellite remote sensing; MNDWI; disaster management**

I. Introduction

Rivers are one of the most morphologically dynamic features that characterize the terrestrial surface of the earth. Because of continuous fluvial erosion, sediment transport, and depositional accretion, they undergo constant geomorphological reshaping. These processes occur in broad spatial and temporal scales, from daily fluctuations during floods to decadal shifts in channel position, planform geometry, and cross-sectional morphology. Comprehensive understanding and reliable predictive capability regarding these morphodynamic transformations are fundamental to effectively integrate water resource management, safeguard human settlements and infrastructure, maintain agricultural productivity in riparian zones, and preserve critical riparian and aquatic ecosystem integrity and biodiversity [1].

Bangladesh stands on a risky geomorphological and hydrological position within this global context. It occupies the terminal deltaic sink of the integrated Ganges-Brahmaputra-Meghna river system, which is regarded as one of Earth's most extensive active delta complexes. Its river network shows exceptional suspended sediment loads, which exceeds 1 billion tonnes annually, and intense seasonal flooding- driven by South Asian monsoon meteorological forcing [2], [3]. The region experiences some of the highest lateral channel migration rates recorded globally, often exceeds several hundred metres per monsoon season and occasionally reaches kilometre-scale adjustments. These extreme morphodynamic processes cause persistent and severe riverbank erosion that systematically displaces between 50,000 and 200,000 individuals annually [4]. The consequences are devastating cumulative economic losses through destruction of agricultural land, transportation infrastructure (roads, bridges, ferries), flood protection embankments, educational facilities, and healthcare infrastructure. Beyond physical infrastructure, erosion destroys the fundamental social fabric binding riverine communities. The socioeconomic consequences extend far beyond immediate physical displacement. Affected populations face long-term food insecurity, disrupted educational access for children, dissolution of social networks and community structures, and profoundly constrained livelihood trajectories and economic opportunities [3], [5], [6]. The most economically vulnerable households bear disproportionate burdens, lacking resources for adaptation or relocation.

Despite more than five decades of continuously accumulated satellite remote sensing imagery archives now being comprehensively available through multiple international space agencies and data repositories, these invaluable spatiotemporal datasets remain substantially under-exploited for predictive morphological modelling applications beyond retrospective change detection. The dominant research paradigm characterizing existing peer-reviewed literature emphasizes retrospective change detection methodologies: quantitative comparison of discrete temporal snapshots to characterize and quantify morphological transformations that have already occurred, rather than developing prospective forecasting capabilities to predict

transformations that will occur. Classical remote sensing analytical approaches inherently overlook the continuous temporal evolution trajectories and complex spatial dependencies intrinsically characterizing river morphodynamic processes. Recently some transformative breakthroughs are seen in deep spatiotemporal learning architectures, particularly in computational frameworks. Domains include convolutional spatial feature extraction and recurrent temporal memory mechanisms. These have demonstrated unprecedented success in learning complex sequential patterns from high-dimensional image sequence data [7], [8]. However, systematic application of these powerful architectures specifically to multi-year river morphology spatial forecasting remains comparatively sparse within published literature. Also, comprehensive comparative evaluation rigorously assessing multiple competing architectures for this specific forecasting task under controlled experimental conditions is rare.

Based on the existing literature, several critical research gaps motivate this investigation. First, majority of the existing research focuses on historical change detection rather than forecasting future morphological states. Second, although deep learning has been applied to water body segmentation and streamflow prediction, its application to multi-year spatial river morphology forecasting remains limited. Third, no systematic cross-architecture comparison for this specific forecasting task has been published. Fourth, physical geomorphological and socioeconomic perspectives are rarely integrated in unified predictive frameworks for operational disaster management.

To address these gaps, this study introduces SpaTempNet, an integrated spatiotemporal forecasting pipeline that: (1) employs sequence learning considering the continuous nature of river formation as a spatiotemporal process, using multiple years' windows to learn decadal changes; (2) performs a comparison of five architectures covering CNN+LSTM architectures and transformers under identical experimental settings; (3) extends the forecast horizon to 15 years for infrastructural planning and disaster preparedness; (4) incorporates an attention mechanism for automatic detection of morphologically dynamic regions; and (5) provides a base architecture offering future scope for inclusion of socioeconomic risk analysis for practical forecasting purposes.

II. Related Works

Riverbank erosion monitoring has evolved significantly with satellite remote sensing technology. Previously, researchers used to rely on aerial photography and manual channel boundary digitization. After five decades of continuous observation, the Landsat mission series revolutionized the field by enabling systematic, large-area, long-term monitoring at unprecedented scales.

A. Optical Satellite-Based Monitoring

Binh et al. [9] developed the Sentinel-based River Bank Erosion Detection (SRBED) framework for automated riverbank extraction from Landsat time-series. It demonstrated great potential for large-scale morphological change detection. Langhorst et al. [10] extended this globally. They constructed algorithms detecting lateral bank movement across diverse river systems and identified erosion hotspots at continental scales. These contributions established critical baseline erosion rates, which revealed extraordinary severity of riverbank retreat in South and Southeast Asia. Langat et al. [11] and Islam and Haque [12] demonstrated multi-temporal remote sensing with GIS for quantifying channel migration trends in Bangladesh. Raju et al. [13] analyzed erosion-accretion dynamics, and highlighted heterogeneous distribution of geomorphically active zones along river reaches where erosion alternates spatially with stable and accretionary zones.

B. Synthetic Aperture Radar Applications

Optical remote sensing in tropical environments suffers from persistent cloud cover, particularly during monsoon seasons when erosion peaks. Synthetic Aperture Radar (SAR) provides cloud-independent all-weather observation. Freihardt et al. [2] used Sentinel-1 SAR time series in Google Earth Engine to map riverbank erosion in Bangladesh. They documented rates exceeding 100 m/year and validated SAR water masking using VV backscatter threshold of -16 dB. DeVries et al. [23] demonstrated that combining Sentinel-1 and Landsat in Google Earth Engine enables rapid flood mapping scalable to continental extents. Sazib et al. [26] extended SAR-based mapping across the Ganga-Brahmaputra basin, and linked inundation extents with agricultural exposure and population impact assessments.

C. Regional Case Studies

Several studies focused on specific river systems. Tha et al. [14] evaluated riverbank erosion hotspots along Cambodia's Mekong River. They integrated physical erosion analysis with vulnerability assessments and connected geophysical processes with socioeconomic consequences. Saha [15] conducted multi-sensor analysis at the Padma-Jamuna confluence. They documented complex erosion, deposition, and island formation patterns from junction dynamics. Haque [16] studied multi-decadal Jamuna River changes and quantified agricultural land losses and settlement displacement. Ritu et al. [17] modeled Padma River bank shifting, however, 10-year intervals between acquisitions limited prediction accuracy and seasonal sensitivity. Muzahid et al. [18] quantified erosion and accretion along the Gorai River using multi-temporal Landsat classification.

D. Advanced Segmentation and Risk Assessment

Ren [19] developed large-scale erosion risk assessment, combined remote sensing with topographic, hydrological, and land-cover variables. A fundamental limitation shared across these studies is the absence of a multi-year predictive modeling grounded in spatiotemporal deep learning.

E. Socioeconomic Dimensions

Human dimensions of riverbank erosion provide strong motivation for improved predictive tools. Islam et al. [4] documented displacement patterns and economic losses. They showed erosion-induced migration drives rapid urbanization and informal settlement growth. Das et al. [5] documented psychological trauma from displacement and livelihood reconstruction impairment. They noted that the effects include not only economic losses but also damage to social ties and community strength. Alam et al. [3] and Sarkar et al. [6]

examined livelihood vulnerability among riparian households along the Padma and in northern Bangladesh. Their research revealed that poorest households face higher rate of exposure due to limited adaptive capacity and land-based livelihood dependence.

While qualitative vulnerability assessments help us see the human side of erosion, quantitative forecasting tools are necessary to give early warnings that people can act on. Some recent progress in deep learning and remote sensing now offers great chances to create these predictive systems. Below, we look at tech advances in water body segmentation, cloud-based processing, and spatiotemporal deep learning that form the base for today's river shape forecasting systems.

F. Deep Learning for Water Body Segmentation

Recent deep learning advances have replaced traditional threshold-based water extraction methods. Yuan et al. [20] demonstrated CNNs achieve superior accuracy over NDWI/MNDWI baselines across scenes with mixed land cover, shadows, and variable turbidity. Li et al. [21] proposed attention-enhanced multi-scale residual U-Net for water segmentation from Sentinel-2 imagery, Which showed attention mechanisms effectively discriminate water from spectrally similar classes like shadows and saturated soils. Ghosh et al. [22] advanced multi-scale fusion within U-Net architectures, They achieved enhanced detection and improved edge definition for rivers of varying dimensions. These architectures process individual images without temporal awareness and cannot forecast morphological change.

G. Cloud-Based Processing Infrastructure

Google Earth Engine (GEE) has made large-scale satellite processing accessible to all through operations on multi-decadal archives without local download. DeVries et al. [23] established platform suitability for operational flood monitoring. Clement et al. [24] applied GEE to ephemeral river flooding. Tripathy and Mallick [25] extended it to large-scale Mekong River monitoring, demonstrating continental scalability.

H. Recurrent and Hybrid Networks for Hydrological Forecasting

Fan et al. [7] applied LSTM to forecast river discharge and demonstrated that temporal relationships in hydrological data can be learned to generate superior predictions with autoregressive models. Le et al. [27] and Xiang et al. [28] validated hybrid CNN-LSTM frameworks for river flow prediction. Their research showed complementary gains from combining spatial feature extraction with temporal memory. Horvath et al. [29] highlighted importance of variable selection and temporal lag configuration for LSTM water level prediction on the Tisza River. Li et al. [21] demonstrated the value of attention mechanisms in CNN-LSTM models for streamflow forecasting across the Qinghai-Tibet Plateau.

I. ConvLSTM and Spatiotemporal Architectures

ConvLSTM architectures replace matrix multiplications in recurrent gates with convolutions which preserve spatial locality during temporal processing. Dehghani et al. [8] provided systematic comparative evaluation of LSTM, CNN, and ConvLSTM for spatiotemporal forecasting. They found ConvLSTM superior for tasks with strong spatial dependence without increasing computational cost. Lemenkova [1] applied deep learning, including convolutional-recurrent architectures, to track flood dynamics in the Ganges Delta. Their work demonstrated applicability to water extent data in the same geographical context. For transformer-based video understanding, Liu et al. [30] proposed Video Swin Transformer with hierarchical window-based self-attention. On the other hand Dosovitskiy et al. [31] established the ViT framework and Arnab et al. [32] extended it to video (ViViT). These researches provided architectural foundations for spatiotemporal transformer models evaluated here.

III. Study Area and Dataset Construction

A. Study Area: Padma River Mid-Course Reach

The designated study area (Fig. 1) covers a long mid-course section of the Padma River. It includes the active river channel, nearby floodplain zones, and the large islands and sandbar formations found in the middle of the river. The spatial region of interest was strategically chosen so as to incorporate effectively all possible patterns of morphological evolution and channel migration behavior within an analytically feasible spatial domain fit for training deep learning models intensively.

The Padma River forms through confluence of the Ganges (locally termed Padma upstream of junction) and Jamuna Rivers at Goalundo Ghat and flows approximately 120 km in southeastward direction before ultimately joining the Meghna River to discharge into the Bay of Bengal through multiple distributary channels. The river annually transports multiple millions of tonnes of Himalayan-derived suspended and bed-load sediment and exhibits characteristically highly dynamic morphodynamic behaviour including intense lateral channel migration, extreme bank erosion rates frequently exceeding 500 m during individual monsoon seasons, and regular mid-channel bar development, modification, and dissolution cycles. The discharge regime exhibits pronounced monsoonal characteristics: peak flow occurs during July–September monsoon season, during which the river maintains a complex braided planform geometry with rapidly changing channel configurations and extensive mid-channel island features. During dry season months (January–April), flow contracts substantially to form much narrower single-thread or limited multi-thread channel configurations with extensive exposed bar surfaces. The live river corridor provides high riparian population density on both bankside, with the river providing various socioeconomic roles including transportation for people and goods, irrigation waters for agriculture, artisan fishery for the riparian population, and clean water for domestic use. However, in spite of the above vital socioeconomic role, very high rates of erosion have resulted in loss of productive agricultural lands, forced displacement of entire households from their ancestral homelands, and complete destruction of vital infrastructure such as roads, bridges, ferry landing points, educational facilities, and health services facilities [3].

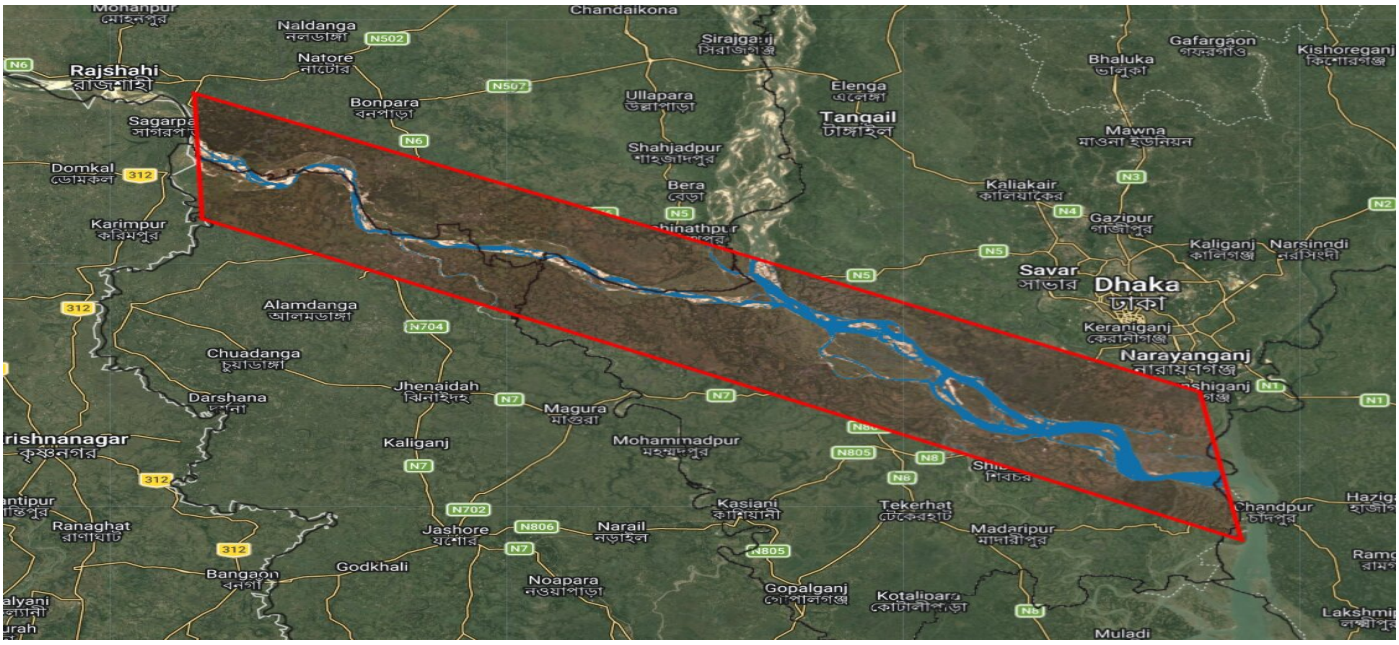

Fig. 1. Study area delineation along the mid-course section of the Padma River, Bangladesh.

B. Satellite Data Acquisition Protocol

Satellite imagery acquisition was strategically organized into two temporally distinct operational phases based on systematic sensor availability patterns and mission operational timelines.

1) Phase I: Landsat Mission Data (1987–2014).: Multispectral optical imagery was sourced exclusively from United States Geological Survey (USGS) Landsat Collection 2 Level-2 atmospherically-corrected surface reflectance product archives accessed through Google Earth Engine Application Programming Interface (API). Three successive sensor platforms were employed sequentially following their respective operational timelines: Landsat 5 Thematic Mapper (TM) sensor (GEE collection identifier: `LANDSAT/LT05/C02/T1_L2`) operational prior to 1999; Landsat 7 Enhanced Thematic Mapper Plus (ETM+) sensor (`LANDSAT/LE07/C02/T1_L2`) operational from 1999 onward; and Landsat 8 Operational Land Imager (OLI) sensor (`LANDSAT/LC08/C02/T1_L2`) operational from 2013 onward. All three sensors provide systematically consistent 60 m spatial resolution imagery (resampled from native 60 m for consistency with SWIR bands) with 16-day temporal revisit frequency. Scene-level cloud filtering applied maximum permissible cloud fraction threshold of 50% via `CLOUD_COVER` image-level metadata attribute. Pixel-level cloud and cloud-shadow masking protocols utilized `QA_PIXEL` quality assessment band via bitwise logical operations, specifically targeting bit 3 (cloud shadow detection) and bit 4 (cloud detection) binary flags. Landsat Collection 2 Level-2 products provide surface reflectance as scaled integers; conversion to physical surface reflectance values employed standardized scaling relationship:

$$\rho_\lambda = 0.0000275 \times \mathrm{DN}_\lambda - 0.2 \quad (1)$$

where, ρ_λ represents surface reflectance for spectral band λ and DN_λ represents digital number value. Spectral band selections for MNDWI computation varied systematically by sensor platform following band designation conventions: Band 2 (green, 520–600 nm) and Band 5 (SWIR1, 1550–1750 nm) for Landsat 5 and Landsat 7 platforms; Band 3 (green) and Band 6 (SWIR1) for Landsat 8 platform. Temporal composite imagery was systematically generated for three distinct temporal aggregation schemes: yearly (single annual composite per calendar year), quarterly (four three-month period composites per calendar year: Q1 January–March, Q2 April–June, Q3 July–September, Q4 October–December), and bi-monthly (six two-month period composites per calendar year: P1 January–February, P2 March–April, P3 May–June, P4 July–August, P5 September–October, P6 November–December).

2) Phase II: Sentinel Mission Data (2015–2025).: Sentinel-2 MultiSpectral Instrument (MSI) optical data were systematically accessed via Google Earth Engine collection identifier `COPERNICUS/S2_SR_HARMONIZED`, representing harmonized Level-2A bottom-of-atmosphere reflectance products. Scene-level filtering applied maximum cloud cover threshold of 50% based on `CLOUDY_PIXEL_PERCENTAGE` metadata attribute, with scenes subsequently sorted in ascending order of cloud fraction to prioritize least contaminated observations. To prevent computational timeout errors during large-scale export operations, maximum number of Sentinel-2 scenes utilized per temporal composite was algorithmically capped at 25 images. Pixel-level cloud masking protocols utilized QA60 quality assessment band targeting bit 10 (opaque cloud detection) and bit 11 (cirrus cloud detection) binary flags. Sentinel-2 MSI products provide surface reflectance as physical values requiring no additional radiometric scaling transformations.

To systematically address persistent data gap patterns arising from sustained cloud cover contamination particularly pronounced during monsoon seasons, Sentinel-1 Synthetic Aper-

TABLE I. SYSTEMATIC SUMMARY OF IMAGE AVAILABILITY AND QUALITY ASSESSMENT ACROSS MULTIPLE TEMPORAL RESOLUTION SCHEMES.

Temporal Resolution	Usable Images	Missing Images	Partial/ Low-Quality Images
Monthly	284	50	122
Bi-monthly	156	16	56
Quarterly	125	3	24
Yearly	38	0	0

ture Radar (SAR) C-band data were strategically incorporated as supplementary fallback data source activated when Sentinel-2 optical imagery proved unavailable. Sentinel-1 data were systematically accessed from Google Earth Engine collection `COPERNICUS/S1_GRD` representing Ground Range Detected (GRD) products acquired in Interferometric Wide (IW) swath mode with VV and VH dual polarization configuration in descending orbital pass geometry. Scene selection was sorted by acquisition date in descending temporal order and algorithmically limited to maximum of 20 images per temporal composite to manage computational processing load. The SAR-based fallback protocol was activated exclusively when zero Sentinel-2 scenes successfully passed cloud filtering criteria for specified temporal window. In this scenario, water mask generation involved using the backscatter coefficient of VV polarization, using an empirical fixed threshold of -16 dB, as per the protocol [2].

Systematically developed water masks were saved as georeferenced GeoTIFF files, having a geographic coordinate system EPSG:4326 (datum WGS84). The spatial resolution of 60 m was always used as a standard for all platforms, while falling back on bounding box size in the exceptional case of computation resource exhaustion.

C. Image Availability and Quality Assessment

Table I provides systematic summary of image availability characteristics and quality assessment metrics evaluated across four distinct temporal resolution aggregation schemes. The yearly dataset achieved complete temporal coverage (38 observations spanning 1988–2025, zero missing observations), thereby providing most stable and reliable foundation for long-term temporal trend analysis applications. The monthly resolution dataset exhibited most severe data loss patterns, with 50 completely missing temporal observations and 122 partial or low-quality degraded observations, thereby precluding its systematic utilization for primary modelling experiments. Bi-monthly and quarterly datasets demonstrated progressively improving completeness characteristics, with quarterly temporal resolution providing optimal balance between temporal granularity and systematic data reliability (only 3 completely missing observations across 38-year period).

Subsequent comprehensive manual inspection procedures complemented automated filtering protocols to systematically identify partially missing images exhibiting localized spatial gaps or degraded regions not adequately captured by cloud-fraction threshold criteria alone (Fig. 2). These quality impairment patterns proved most prevalent within bi-monthly dataset during July–August temporal periods (peak monsoon season) when persistent cloud cover systematically impedes optical observation capabilities.

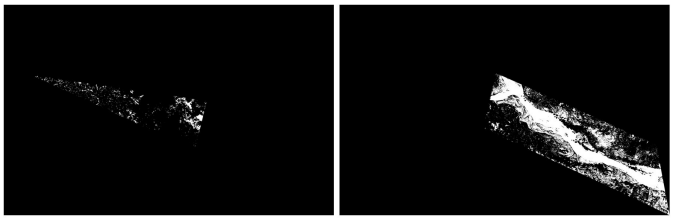

Fig. 2. Partially missing samples

D. Water Body Detection via Modified Normalized Difference Water Index

Water body extraction procedures employed Modified Normalised Difference Water Index (MNDWI) spectral index calculations [2], [14], which systematically exploit contrasting spectral reflectance behaviour characteristics of water surfaces (characteristically high reflectance in green visible wavelengths, strong absorption in shortwave infrared wavelengths) relative to terrestrial surfaces including soils, vegetation canopies, and built-up urban areas (producing characteristically low or negative MNDWI values). The MNDWI spectral index is formally defined:

$$\mathrm{MNDWI} = \frac{\rho_{\mathrm{Green}} - \rho_{\mathrm{SWIR}}}{\rho_{\mathrm{Green}} + \rho_{\mathrm{SWIR}}} \tag{2}$$

where, ρ_{Green} and ρ_{SWIR} represent surface reflectance values in green visible and shortwave infrared spectral bands, respectively. A fixed threshold value of zero was systematically applied to generate binary water/non-water classification masks from continuous MNDWI index values.

Following initial thresholding operations, connected component analysis algorithms were systematically applied to identify spatially contiguous water body regions. Only three largest spatially connected components per image were systematically retained, thereby eliminating isolated water pixels corresponding to small ponds, minor drainage channels, and ephemeral water features unrelated to primary Padma River channel. This connected component filtering substantially improves signal quality by removing spurious detections. All processed images were subsequently standardized via bilinear resampling to consistent 256×256 pixel spatial dimensions suitable for deep learning model input tensor specifications.

E. Gap-Filling Framework and Performance Benchmark

In order to effectively deal with natural patterns that will arise due to cloud contamination and instrument failure, a rigorous performance evaluation of gap filling methods was performed on a set of yearly water mask temporal series (a total of 38 observations from 1988 to 2025). For the purpose of simulating practical missing data problems, a systematic withholding process was used to remove 20% of the total number of observations (i.e., seven specific years: 2002, 2005, 2010, 2015, 2019, 2020, 2024).

There were seven unique strategies used to fill the gaps that underwent comparative analysis:

1) Temporal mean: The reference baseline strategy based on the use of temporal means to estimate the masks that need to be reconstructed, offering naive but effective and efficient spatial reconstructions of those masks.
2) Temporal median: The alternative reference baseline strategy using the median approach with enhanced robustness against outlier observation.
3) Linear temporal interpolation: Per-pixel linear interpolation computed between nearest available temporal neighbouring observations, yielding smooth temporal transition characteristics but exhibiting limited structural preservation capabilities for complex spatial features.
4) Cubic spline temporal interpolation: Per-pixel cubic spline interpolation applied across temporal dimension, enabling smooth nonlinear pixel trajectory modelling with continuous first and second derivatives providing enhanced temporal smoothness relative to linear interpolation.
5) Signed Distance Field (SDF) interpolation: Geometrically motivated approach wherein binary water masks are first transformed into signed distance field (SDF) representations defined as:

$$\mathrm{SDF}(\mathbf{x}) = d(\mathbf{x}, W^c) - d(\mathbf{x}, W) \tag{3}$$

where,

$$d(\mathbf{x}, A) = \min_{\mathbf{y} \in A} \|\mathbf{x} - \mathbf{y}\| \tag{4}$$

W denotes the water region, W^c represents its complement, $d(\mathbf{x}, A)$ is the Euclidean distance from location $\mathbf{x}$ to the set A, and $\|\cdot\|$ denotes the Euclidean norm. Positive SDF values correspond to pixels inside the water region, whereas negative values correspond to pixels outside the water region. Temporal interpolation is performed in the continuous SDF domain, followed by thresholding at the zero level set to recover binary water masks. This approach preserves boundary geometry and topological consistency more effectively than direct interpolation of binary masks.
6) Inverse-distance weighted temporal fusion: Missing mask reconstructions are computed through temporally weighted averaging of all available yearly observations, with weights inversely proportional to their temporal distance from the target year:

$$M_t = \frac{\sum_{i \in \mathcal{A}} w_i M_i}{\sum_{i \in \mathcal{A}} w_i}, \qquad w_i = \frac{1}{|t - i|} \tag{5}$$

where, M_t denotes the reconstructed mask at target year t, M_i represents an available observation at year i, and $\mathcal{A}$ denotes the set of all available observations. Consequently, observations temporally closer to the target year exert greater influence on the reconstruction than more distant observations.
7) Bidirectional Convolutional LSTM (BiConvLSTM): Deep learning-based approach wherein Bidirectional Convolutional LSTM architecture is systematically trained on 128×128 pixel spatiotemporal patches extracted randomly from full temporal series. Training protocol incorporates 20% random temporal masking simulation to replicate missing observation patterns. The model architecture learns both forward and backward temporal dependency patterns and was optimized using binary cross-entropy loss over maximum 100 training epochs with early stopping (patience = 15). Adam optimizer ($\eta = 10^{-3}$, $\beta_1 = 0.9$, $\beta_2 = 0.999$) with batch size 16 was employed.

TABLE II. COMPREHENSIVE PERFORMANCE COMPARISON OF SEVEN GAP-FILLING METHODS EVALUATED ON SEVEN HELD-OUT YEARLY OBSERVATIONS.

Method	IoU	Dice	Precision	Recall
Mean Composite	0.6573	0.7926	0.8535	0.7403
Median Composite	0.6573	0.7926	0.8535	0.7403
Linear Interp.	0.6548	0.7910	0.8913	0.7193
Spline Interp.	0.6733	0.8042	0.8082	0.8012
SDF	0.7290	0.8429	0.8741	0.8161
Weighted Temporal	0.6724	0.8035	0.8306	0.7790
BiConvLSTM	**0.7366**	**0.8477**	0.8457	**0.8511**

Quantitative performance results are comprehensively summarized in Table II. BiConvLSTM achieved best overall performance across all evaluation metrics (IoU = 0.7366, Dice = 0.8477, Recall = 0.8511), conclusively confirming its superior capability to capture extraordinarily complex spatiotemporal dynamic patterns. Among classical non-learning methods, SDF interpolation performed strongest (IoU = 0.7290, Dice = 0.8429), closely approaching deep learning performance levels while maintaining excellent structural consistency of water body boundary characteristics. Standard mean/median temporal composites and linear interpolation exhibited comparable baseline performance (IoU $\approx$ 0.655), while spline interpolation and weighted temporal fusion strategies offered modest incremental improvements.

IV. METHODOLOGY

This section of the study offers an in-depth technical explanation of all the methodological elements, such as sequence generation, temporal splitting, model architecture description with mathematical formulae, loss functions, metrics to evaluate the model, training parameters, and risk zone computation.

A. Supervised Sequence Generation Strategy

To formally formulate temporal morphological evolution process as supervised learning task, preprocessed binary water masks were represented as sequences of structured input-output pairs applying the technique of sliding temporal window. For every considered sliding window size $L \in \{4, 5, 6\}$ (with respect to yearly and quarterly temporal scales) or $L \in \{6, 9\}$ (with respect to bi-monthly temporal scale), precisely L sequential observations constitute input features tensor while next chronological time-step represents prediction target:

$$\mathbf{X}_i = (X_i, X_{i+1}, \ldots, X_{i+L-1}), \quad y_i = X_{i+L} \tag{6}$$

where, $X_t \in \{0,1\}^{H\times W}$ represents binary water mask at time t with spatial dimensions $H \times W = 256 \times 256$ pixels. Temporal stride of one year (or one bi-monthly period for higher-frequency data) generates systematically overlapping sequences, maximizing utilization of available but limited temporal data. This multi-sequence evaluation protocol enables systematic identification of optimal temporal context window length for each distinct architecture and temporal resolution combination.

B. Rigorous Temporal Splitting Strategy

A meticulously rigorous temporal split strategy prevents any data leakage between training and evaluation datasets. Two experimental evaluation setups are formally defined.

1) Setup 1 (Long-range forecasting): Training incorporates all available data up to and including calendar year 2015; testing evaluates forecast performance on 2016–2025 inclusive (providing 10-year forecasting horizon for yearly data, or equivalent temporal span for quarterly/bi-monthly aggregations).

2) Setup 2 (Medium-range forecasting): Training incorporates all available data up to and including calendar year 2020; testing evaluates forecast performance on 2021–2025 inclusive (providing 5-year forecasting horizon for yearly data, or equivalent temporal span for quarterly/bi-monthly aggregations).

For quarterly temporal resolution data, temporal cutoffs correspond to Q4-2015 and Q4-2020, respectively. For bi-monthly resolution, cutoffs correspond to P6-2015 and P6-2020 (November–December 2015 and 2020). Within each setup configuration, final 15% of training sequences (ordered chronologically) are systematically allocated to validation dataset for hyperparameter tuning and early stopping criteria. Critically, absolutely zero temporal overlap exists between training, validation, and testing datasets, ensuring evaluation integrity.

C. Model Architecture Specifications

Five distinct spatiotemporal deep learning architectures underwent systematic comparative evaluation, selected to comprehensively span the architectural spectrum from recurrent convolutional hybrids to pure attention-based transformer models.

1) Standalone ConvLSTM architecture: ConvLSTM framework [8] primarily involves the replacement of traditional matrix multiplications in LSTMs with spatial convolutions. This allows inherent joint processing of spatial and temporal information without any need for a dedicated encoder module. The overall architecture includes:

a) Initial spatial feature extraction: Two successive spatial Conv2D layers with 32 and 64 convolutional filters (kernel size 3×3, ReLU activation, same padding) extract initial low-level spatial features.

b) Spatial downsampling: Batch normalization followed by max-pooling (2×2 window, stride 2) and spatial dropout (rate = 0.2) applied after each Conv2D layer.

c) Spatiotemporal processing: Two stacked ConvLSTM2D layers with 128 and 64 filters respectively (kernel size 3×3). The first ConvLSTM2D layer processes full input sequence with `return_sequences=True`; the second layer aggregates temporal information with `return_sequences=False`, outputting single feature map.

d) Upsampling decoder: Symmetric decoder comprising two upsampling blocks (UpSampling2D with factor 2 followed by Conv2D with 64 and 32 filters), batch normalization, and final 1×1 Conv2D with sigmoid activation producing prediction probability map.

2) U-Net with LSTM architecture: The U-Net+LSTM hybrid model [27], [28] processes input sequence through TimeDistributed encoder extracting multi-scale spatial features independently for each temporal frame. Complete architecture specification:

a) Timedistributed encoder: Three successive encoder blocks each comprising: Conv2D layer (filters: 64, 128, 256 for blocks 1–3; kernel 3×3, ReLU), batch normalization, second Conv2D with identical specifications, max-pooling (2×2), spatial dropout (rate = 0.2). TimeDistributed wrapper ensures identical processing applied to each input frame independently.

b) Bottleneck temporal fusion: LSTM module (128 units) at encoder bottleneck models temporal dependencies across sequence, producing single temporally-fused feature volume.

c) Symmetric decoder with skip connections: Three decoder blocks each comprising: UpSampling2D (factor 2), concatenation with corresponding encoder skip connection feature map, two Conv2D layers (filters decreasing: 256, 128, 64), batch normalization. Final 1×1 Conv2D with sigmoid activation produces prediction.

3) Attention U-Net with ConvLSTM architecture: The Attention U-Net+ConvLSTM model extends U-Net+LSTM through incorporating sophisticated attention gate mechanisms in each skip connection pathway [21], [22]. For encoder feature map $\mathbf{x}^l \in \mathbb{R}^{H_l\times W_l\times C_l}$ at encoder level l and gating signal $\mathbf{g} \in \mathbb{R}^{H_l\times W_l\times C_g}$ derived from corresponding decoder level, attention coefficient computation proceeds via:

$$\mathbf{q}^l = W_x * \mathbf{x}^l + W_g * \mathbf{g} + b_g \tag{7}$$

$$\boldsymbol{\alpha}^l = \sigma\big(W_\psi * \mathrm{ReLU}(\mathbf{q}^l) + b_\psi\big) \tag{8}$$

where, $*$ denotes 1×1 convolution operation, W_x, W_g, W_ψ represent learnable convolutional kernel parameters, b_g, b_ψ are bias terms, and σ denotes sigmoid activation function producing spatial attention coefficients $\boldsymbol{\alpha}^l \in [0,1]^{H_l\times W_l}$. The skip connection output becomes element-wise product:

$$\tilde{\mathbf{x}}^l = \boldsymbol{\alpha}^l \odot \mathbf{x}^l \tag{9}$$

thereby suppressing background regions (low α values) and amplifying morphologically active zones including channel margins and active erosion fronts (high α values). Critically, the bottleneck employs ConvLSTM2D rather than standard LSTM, preserving spatial locality during temporal fusion operations.

4) Swin Spatio-Temporal Transformer architecture: The Swin Spatio-Temporal Transformer [30] applies shared hierarchical Swin Transformer encoder to each input frame independently. The complete architecture specification:

a) Shared swin encoder: Each stage applies window-based multi-head self-attention with shifted window partitioning strategy (W-MSA and SW-MSA) followed by patch merging for progressive spatial downsampling. Three encoder stages produce feature maps at spatial resolutions $H/4 \times W/4$, $H/8 \times W/8$, and $H/16 \times W/16$ with embedding dimensions 64, 128, and 256, respectively. Self-attention within each window $\mathcal{W}$ of size $M \times M$ is computed as:

$$\text{Attention}(\mathbf{Q}, \mathbf{K}, \mathbf{V}) = \text{SoftMax}\left(\frac{\mathbf{Q}\mathbf{K}^T}{\sqrt{d}} + \mathbf{B}\right)\mathbf{V} \quad (10)$$

where, $\mathbf{Q}, \mathbf{K}, \mathbf{V}$ represent query, key, value projections, d is head dimension, and $\mathbf{B}$ encodes relative position biases. Shifted windowing across successive layers enables cross-window connections.

b) Temporal fusion module: Features at finest encoder resolution across all T input frames are stacked forming spatiotemporal tensor $\mathbf{F} \in \mathbb{R}^{T\times(H/4)\times(W/4)\times 64}$. Temporal fusion comprises:

- 1D temporal convolution (kernel size 3, GELU activation) applied across temporal dimension at each spatial location.
- Two cross-temporal attention layers (4 heads each) enabling each spatial location to attend across all temporal frames.
- Softmax-based temporal aggregation producing single fused feature map $\bar{\mathbf{F}} \in \mathbb{R}^{(H/4)\times(W/4)\times 64}$.

c) U-Net style decoder: Symmetric decoder with skip connections from encoder stages 1 and 2 progressively upsamples to full resolution.

5) Vision Transformer-based spatio-temporal model: The ViT-based model [31], [32] applies shared Vision Transformer encoder to each frame independently. Complete specification:

a) Patch embedding: Each frame is partitioned into non-overlapping 16×16 patches yielding $(256/16)^2 = 256$ patch tokens. Linear projection maps each flattened patch to 128-dimensional embedding space:

$$\mathbf{z}_p = \mathbf{E} \cdot \text{vec}(\mathbf{x}_p) + \mathbf{e}_{\text{pos}} \quad (11)$$

where, $\mathbf{E} \in \mathbb{R}^{128\times(16\times16)}$ represents learnable projection matrix, $\mathbf{e}_{\text{pos}}$ encodes spatial position.

b) Spatial transformer blocks: Two successive transformer blocks (multi-head self-attention with 4 heads, MLP with hidden dimension 256, LayerNorm, residual connections, dropout 0.1) process patch token sequence.

c) Temporal aggregation: Global average pooling aggregates all patch tokens yielding per-frame feature vector $\mathbf{f}_t \in \mathbb{R}^{128}$. Frame features are stacked, augmented with learned temporal positional embeddings, and processed by two temporal transformer layers (4 heads, MLP dimension 256) modeling inter-frame dependencies.

d) Convolutional decoder: Aggregated temporal feature is spatially projected to $16\times16\times128$ feature map, then decoded through four transposed convolution blocks progressively upsampling to full resolution.

D. Loss Function Specifications

All models underwent training optimization using combined Dice and Focal loss formulation:

$$\mathcal{L}_{\text{Total}} = \lambda_1\mathcal{L}_{\text{Dice}} + \lambda_2\mathcal{L}_{\text{Focal}} \quad (12)$$

where, weighting coefficients $\lambda_1 = \lambda_2 = 0.5$ provide equal contribution.

1) Dice loss: directly optimizes Dice overlap metric and proves particularly effective for class-imbalanced segmentation where water pixels constitute spatial minority:

$$\mathcal{L}_{\text{Dice}} = 1 - \frac{2\sum_i p_i g_i + \varepsilon}{\sum_i p_i + \sum_i g_i + \varepsilon} \quad (13)$$

where, p_i represents predicted probability for pixel i, $g_i \in \{0, 1\}$ represents ground truth label, and $\varepsilon = 1$ provides numerical stability smoothing.

2) Focal loss: systematically down-weights easily-classified background examples to concentrate gradient updates on challenging boundary pixels [33]:

$$\mathcal{L}_{\text{Focal}} = -\frac{1}{N}\sum_{i=1}^{N}\alpha_i(1 - p_{t_i})^\gamma \log(p_{t_i}) \quad (14)$$

where, $p_{t_i} = p_i$ if $g_i = 1$ else $1 - p_i$, class weighting $\alpha_i = 0.75$ for positive class, focusing parameter $\gamma = 2.0$, and N represents total pixel count. The loss functions work together by utilizing each other's strengths: Dice loss guarantees accuracy with regards to overall overlap, Focal loss supplies accurate supervision on the level of boundaries.

E. Comprehensive Evaluation Metrics

The model was evaluated with five complementary quantitative metrics using the binarization threshold value of 0.5:

Intersection over Union (IoU):

$$\text{IoU} = \frac{|A \cap B| + \varepsilon}{|A \cup B| + \varepsilon} = \frac{\text{TP} + \varepsilon}{\text{TP} + \text{FP} + \text{FN} + \varepsilon} \quad (15)$$

Dice Coefficient (F1-Score):

$$\text{Dice} = \frac{2|A \cap B| + \varepsilon}{|A| + |B| + \varepsilon} = \frac{2\,\text{TP} + \varepsilon}{2\,\text{TP} + \text{FP} + \text{FN} + \varepsilon} \quad (16)$$

Precision:

$$\text{Precision} = \frac{\text{TP}}{\text{TP} + \text{FP}} \tag{17}$$

Recall (Sensitivity):

$$\text{Recall} = \frac{\text{TP}}{\text{TP} + \text{FN}} \tag{18}$$

where, TP, FP, FN represent true positives, false positives, and false negatives, respectively, $\varepsilon = 10^{-7}$ provides numerical stability.

Additionally, absolute area difference quantifies spatial calibration independently of overlap metrics:

$$\Delta A = A_{\text{pred}} - A_{\text{true}} = (N_{\text{pred}} - N_{\text{true}}) \times A_{\text{pixel}} \tag{19}$$

where, N represents pixel counts, $A_{\text{pixel}} = 0.0036$ km^2 at 60 m resolution. A persistence baseline (predicting last observed frame) provides reference lower bound.

F. Training Configuration and Hyperparameters

1) CNN-LSTM hybrid models (ConvLSTM, U-Net+LSTM, Attention U-Net+ConvLSTM): All three architectures employed identical training configuration for fair comparison. Optimization utilized Adam algorithm [38] with learning rate $\eta = 1 \times 10^{-4}$, momentum parameters $\beta_1 = 0.9$, $\beta_2 = 0.999$, and gradient clipping via `clipnorm` = 1.0 preventing exploding gradient instability. Batch size of 4 sequences balanced GPU memory constraints against gradient estimate quality. Training proceeded for maximum 200 epochs with early stopping monitoring validation loss (patience = 20 epochs, restore best weights). ReduceLROnPlateau callback dynamically adjusted learning rate upon validation loss plateau detection (patience = 7 epochs, reduction factor = 0.5, minimum $\eta_{\min} = 1 \times 10^{-7}$). Model checkpointing systematically saved best-performing checkpoint based on validation loss criterion.

2) Swin Spatio-Temporal Transformer: Reduced batch size of 2 sequences accommodated substantially, elevated GPU memory requirements (patch size = 4, embedding dimension = 64, window size = 8, hierarchical depths $[2, 2, 2]$, attention heads $[2, 4, 8]$, MLP ratio = 2.0, spatial dropout = 0.1). Temporal fusion module configured with 2 temporal transformer layers, 4 attention heads, MLP dimension 256, dropout 0.1. Decoder filter progression: $[128, 64, 32, 16]$. Remaining training hyperparameters identical to CNN-LSTM models.

3) ViT-based spatio-temporal model: Batch size 2 (patch size = 16, embedding dimension = 128, 2 spatial transformer layers, 2 temporal transformer layers, 4 attention heads each, MLP dimension 256, dropout 0.1). Remaining hyperparameters identical.

All model implementations used deterministic random seeds (NumPy: 42, TensorFlow: 42) ensuring repeatability and consistent data splitting for controlled comparisons.

G. Computational Framework for Risk Zone Mapping

After iterative autoregressive forecasting for the time span 2026-2045, post-processing framework is employed to define erosion and accretion risk zones using pixel-resolution spatial data.

Erosion strictly defined as the land to water transition between consecutive years ($L_t = 0 \wedge L_{t+1} = 1$), while **accretion** is a reverse process (water to land). Frequency maps characterize persistence duration:

$$f_{\text{erosion}}(\mathbf{x}) = \frac{1}{T-1} \sum_{t=1}^{T-1} \mathbb{I}(L_t(\mathbf{x}) = 0 \wedge L_{t+1}(\mathbf{x}) = 1) \tag{20}$$

$$f_{\text{accretion}}(\mathbf{x}) = \frac{1}{T-1} \sum_{t=1}^{T-1} \mathbb{I}(L_t(\mathbf{x}) = 1 \wedge L_{t+1}(\mathbf{x}) = 0) \tag{21}$$

where, $\mathbf{x}$ denotes spatial pixel location, T represents total forecast years, $\mathbb{I}(\cdot)$ is indicator function.

A **hydrodynamic stability index** quantifies pixel-level classification uncertainty via water occurrence frequency:

$$\mathcal{I}(\mathbf{x}) = 1 - |2F_w(\mathbf{x}) - 1|, \quad F_w(\mathbf{x}) = \frac{1}{T} \sum_{t=1}^{T} L_t(\mathbf{x}) \tag{22}$$

where, $F_w \in [0, 1]$ represents fraction of forecast period classified as water. Values $\mathcal{I} \approx 1$ indicate persistent land–water oscillation (maximum instability); $\mathcal{I} \approx 0$ indicates stable land or water classification (maximum stability).

Composite risk representation integrates erosion frequency, accretion frequency, and instability index highlighting regions simultaneously dynamic and uncertain. Physical area estimates employ:

$$A_{\text{erosion/accretion}} = N_{\text{pixels}} \times A_{\text{pixel}} \tag{23}$$

where, $A_{\text{pixel}} = (60 \text{ m})^2 = 0.0036$ km^2 at established 60 m spatial resolution.

V. Spatiotemporal Statistical Analysis

This section presents comprehensive quantitative spatiotemporal statistical characterization of 38 years of Padma River morphodynamic behaviour (1988–2025) including long-term areal dynamics, seasonal variability patterns, erosion–accretion mass budget calculations, and channel centreline migration rate quantification.

A. Long-Term Areal Dynamics and Trend Analysis

The Padma River exhibited substantial inter-annual variability in water-covered areal extent throughout 38-year observation period. Annual water-covered area ranged from absolute minimum 540.4 km^2 (calendar year 1995, hydrologically dry year characterized by below-average monsoon

precipitation) to absolute maximum 1,229.3 km^2 (calendar year 1999, catastrophic monsoon flood corresponding to major regional disaster event), with long-term temporal mean of 664.5 $\pm$ 112.8 km^2 (arithmetic mean $\pm$ one standard deviation). The exceptionally large channel expansion manifest in 1999 corresponds temporally to the catastrophic July–August 1998 monsoon flood event representing one of most severe recorded flood disasters in Bangladesh's documented history.

Formal non-parametric Mann–Kendall trend test [34], [35] indicated absence of statistically significant monotonic trend at $\alpha = 0.05$ significance level (Kendall's $\tau = -0.149$, two-tailed $p = 0.187$), and Theil–Sen robust linear estimator [36], [37] yielded weak negative slope magnitude of -1.41 km^2 yr^{-1}. The above complementary results of statistical analysis have effectively validated the fact that although there is a marked variation in the temporal pattern due to monsoon variations, the mean temporal pattern of river area does not exhibit any clear trend toward increase or decrease.

B. Seasonal Variability and Intra-Annual Dynamics

Magnitudes of seasonality were systematically analyzed by way of coefficient of variation (CV) computed for the corresponding time-series of bi-monthly water surface area magnitudes, revealing significant inter-annual variability (see Fig. 3). Magnitude of annual CV varied from a lowest value of 8.2% (year 2018, most hydrologically stable year with little seasonal change), to a highest of 64.1% (year 2007, most hydrologically unstable year), with an arithmetic mean value for the study interval of 34.3 $\pm$ 13.7%. Those calendar years that had high CV values, especially 2007, 2011, and 2020, were systematically related to extreme monsoon flooding episodes, characterized by a maximum water extent above 2,700 km^2. Years with lower CV values indicate higher stability of seasonal trajectory of water extent as well as comparatively smaller magnitude of variation of the flood-pulse.

Heat map representation of the quarterly data clearly reveals persistent and highly consistent hydrological seasonality pattern across all 38 years of monitoring; specifically, Q4 (October-December; post-monsoon recession season) invariably shows largest mean water extent, while Q2 (April-June; pre-monsoon low-water flow season) invariably records minimum extent values. This remarkable hydrological seasonality pattern clearly indicates the predominant influence of the South Asian monsoon meteorological system on hydrodynamics.

C. Erosion and Accretion Dynamics

Annual erosion and accretion rate magnitudes demonstrated exceptionally high inter-annual variability reflecting pronounced sensitivity to individual monsoon flood events (Fig. 4). The largest documented single-year erosion event occurred during 1998-1999 interval (649.1 km^2 land surface converted to water classification; net channel expansion 567.7 km^2), corresponding temporally to catastrophic July-August 1998 monsoon flood representing most extreme channel widening event recorded throughout entire 38-year study period. Conversely, the immediately following year (1999–2000 interval) recorded largest net accretion magnitude (-503.5 km^2), indicating substantial rapid channel contraction during post-flood geomorphic recovery and adjustment phase. This dramatic reversal pattern highlights pronounced recovery dynamics characterizing post-extreme-event channel behaviour.

TABLE III. DECADAL EROSION, ACCRETION, AND NET CHANNEL CHANGE SUMMARY.

Decadal Period	Erosion (km^2)	Accretion (km^2)	Net Change (km^2)
1988–1998	367.6	434.2	-66.7
1998–2008	382.3	355.9	$+26.3$
2008–2018	262.8	375.8	-113.0
2018–2025	264.6	264.3	$+0.3$
Total	**5170.2**	**5323.3**	$\mathbf{-153.0}$

Table III provides systematic quantitative summary of decadal erosion–accretion mass budgets.

Across complete 38-year study period, cumulative gross erosion reached 5,170.2 km^2 (representing multiple complete channel reworking cycles) while cumulative gross accretion totalled 5,323.3 km^2, yielding overall net accretion magnitude of 153.0 km^2 indicating slight long-term channel contraction tendency. Decadal analysis systematically identifies four temporally distinct morphodynamic regime phases: (1) 1988-1998 exhibited near-balanced erosion–accretion dynamics (-66.7 km^2 net accretion) characteristic of lateral channel migration without sustained widening; (2) 1998–2008 shifted toward slight net erosion tendency ($+26.3$ km^2) dominated by catastrophic 1998–1999 flood event and subsequent multi-year adjustment; (3) 2008–2018 manifested strongest net accretion (-113.0 km^2) suggesting significant channel contraction and partial geomorphic stabilization; (4) 2018–2025 approached near-equilibrium conditions with negligible net change ($+0.3$ km^2) indicating contemporary period of relative morphodynamic stability.

D. Channel Centreline Migration Rate Quantification

Channel centreline lateral migration rates exhibited pronounced temporal variability reflecting alternating periods of geomorphic instability and relative stabilization (Fig. 5). Arithmetic mean annual migration rate across full study period was 255.4 m yr^{-1}, with individual year magnitudes ranging from minimum 134.2 m yr^{-1} (calendar years 2001-2002 and 2022-2023, representing temporary stabilization phases) to catastrophic maximum 1,485.5 m yr^{-1} during 1998–1999 interval (corresponding to extreme flood-driven channel adjustment event). The median migration rate (216.3 m yr^{-1}) was substantially below arithmetic mean, conclusively confirming that small number of extreme flood years strongly inflated long-term average metrics while typical inter-annual behaviour exhibits more moderate migration magnitudes. The 1990s decade recorded highest average migration rates (mean 348.7 m yr^{-1}), definitively designating that decade as period of maximum geomorphic instability within 38-year observational record. Cumulative centreline displacement over complete study period exceeded 9 km total lateral adjustment, demonstrating sustained long-term lateral migration and continuous comprehensive reworking of active river corridor.

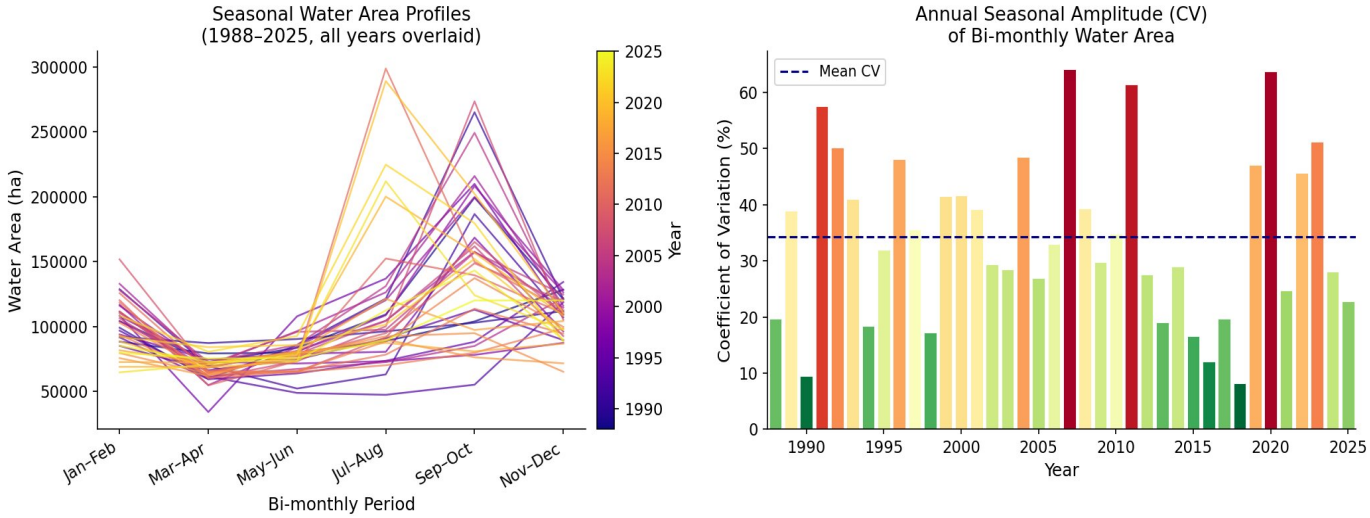

Fig. 3. Seasonal water area dynamics. Left: Bi-monthly water area profiles for all years. Right: Annual coefficient of variation (CV) of bi-monthly water area.

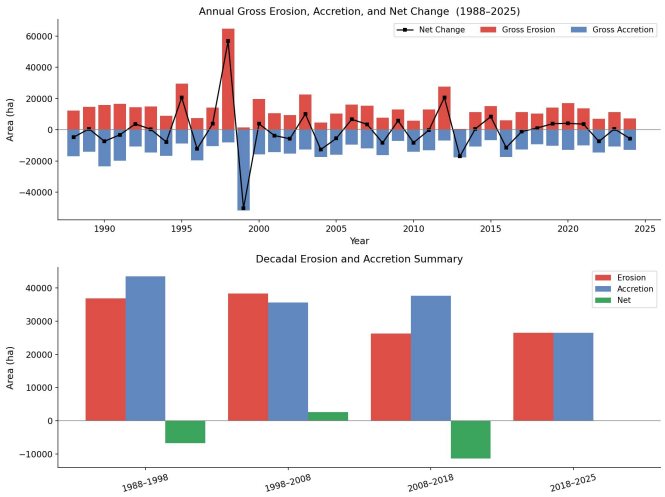

Fig. 4. Annual and decadal erosion and accretion of the channel. Top: annual gross erosion (red), gross accretion (blue), and net channel change (black line). Bottom: decadal grouped summary illustrating long-term morphodynamic phases.

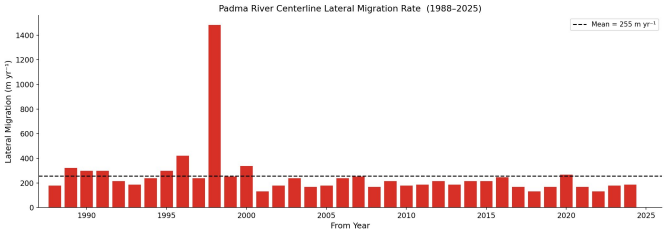

Fig. 5. Annual lateral migration rate of the centreline. Red bars indicate yearly migration rates, while the dashed line marks the long-term mean of 255.4 m yr^{-1}. The extreme peak in 1998–1999 corresponds to the catastrophic flood-driven channel adjustment.

Attention U-Net+ConvLSTM achieved highest IoU (0.7005) and Dice (0.8236) in Setup 1, establishing it as optimal architecture for yearly prediction tasks. U-Net+LSTM demonstrated competitive performance with slightly lower overlap metrics but superior area calibration. ConvLSTM and Swin Transformer exhibited moderate performance, while Vision Transformer significantly underperformed all alternative architectures (see Table IV).

TABLE IV. PERFORMANCE COMPARISON OF ALL ARCHITECTURES BASED ON YEARLY DATA.

Model	Setup	IoU	Dice	P	R	$\lvert\Delta A\rvert$

1) Detailed year-wise analysis: Table V and Table VI present comprehensive year-by-year breakdown for best-performing Attention U-Net+ConvLSTM architecture.

Performance remained remarkably stable across 10-year horizon with IoU ranging 0.6569–0.7359 (standard deviation 0.0273). Higher Recall (mean 0.8747) relative to Precision (0.7807) indicates systematic tendency toward over-prediction, consistent with positive area differences in most years. The 5-year setup achieved lower area differences (mean 41.05 km^2 vs 66.54 km^2), confirming shorter horizons reduce temporal uncertainty.

TABLE V. DETAILED YEAR-WISE PREDICTION RESULTS: ATTENTION U-NET+CONVLSTM, 10-YEAR FORECASTING SETUP (2016–2025).

E. Quarterly Prediction Results: Complete Architecture Comparison

Attention U-Net+ConvLSTM and U-Net+LSTM exhibited closely competitive performance for quarterly prediction, with Attention model achieving marginally superior IoU in Setup 1 (0.6956 vs 0.6908) (see Table VII).

1) Detailed quarterly results Setup 1: Table VIII presents complete quarter-by-quarter breakdown for Attention U-Net+ConvLSTM covering 2017 Q2–2025 Q4 test period.

2025-Q3	0.5993	0.7495	0.8262	0.6858	−170.04
2025-Q4	0.7280	0.8426	0.8655	0.8209	−48.20
Mean	**0.6956**	**0.8139**	0.8095	0.8443	−0.47
Std	0.1230	0.0851	0.1124	0.1275	244.68

Pronounced seasonal stratification is evident: Q2 (pre-monsoon) consistently achieves IoU > 0.90 in multiple years (2017, 2018, 2020, 2025), while Q3 (peak monsoon) exhibits lowest performance, frequently falling below 0.55. The signed mean area difference approaches zero (-0.47 km^2), indicating excellent long-term calibration despite substantial within-year fluctuations driven by seasonal effects.

2) Detailed quarterly results Setup 2: Table IX presents detailed results for shorter 5-year forecasting horizon (2022 Q4–2025 Q4).

Setup 2 results demonstrate consistent seasonal patterns with improved mean performance (IoU = 0.6972 vs. 0.6956) attributable to shorter forecasting horizon reducing cumulative error propagation.

F. Bi-Monthly Prediction Results: Complete Architecture Comparison

U-Net+LSTM emerged as best-performing architecture for bi-monthly prediction, achieving IoU = 0.7791 and Dice = 0.8701 in Setup 2. This architectural shift from

Attention U-Net+ConvLSTM dominance at yearly/quarterly resolutions to U-Net+LSTM leadership at bi-monthly suggests spatial feature extraction quality becomes progressively more critical as temporal frequency increases (see Table X).

G. Long-Term Morphological Forecasting (2026-2040)

In long-term morphological forecasting, final model setup was Attention U-Net+ConvLSTM configuration trained on complete dataset covering time span 1987-2025 with a window length equal to five. Convergence point for training achieved epoch 107, best validation loss being equal to 0.2298, validation Dice index 0.8057, and validation IoU 0.7026. Reconstruction test for known time interval (2016–2025) revealed mean IoU = 0.6543 and mean Dice index 0.7907, thus indicating that model is capable of reconstructing historical river extent patterns sufficiently accurately.

Starting from the 2025 area of 517.6 km^2, river extent grew up gradually to 671.3 km^2 in 2026 and reached value of 807.6 km^2 by 2040, indicating total growth of 290.0 km^2 or 56.03% as compared to the base year. Expansion trend had nonuniform character, showing largest growth rates during the first years of forecasting (2025-2026) and further decreasing gradually. The accretion-dominated pattern indicates future dynamics primarily associated with lateral expansion into adjacent floodplain areas rather than wholesale channel widening.

The comprehensive long-term risk cartography (Fig. 6) identifies spatially explicit high-probability morphological change zones concentrated systematically along active channel margins and proximal floodplain corridor segments, with very-high-risk designations indicating persistent instability and recurrent channel boundary adjustment patterns most operationally relevant for infrastructure protection planning and settlement management strategies.

H. Short-Term Bi-Monthly Forecasting (2026-2028)

Short-term high-frequency bi-monthly forecasting employed U-Net+ConvLSTM2D architecture with nine-period input sequences systematically enriched with sinusoidal and cosinusoidal seasonal encoding channels ($\sin(2\pi t/6)$, $\cos(2\pi t/6)$ where t represents bi-monthly period index), enabling model to explicitly distinguish intra-annual temporal periods without relying exclusively on spatial morphological content patterns. Training convergence occurred at epoch 39 (validation Dice = 0.8381, IoU = 0.7463). Reconstruction sanity check on recent historical period 2023 P1–2025 P6 yielded mean IoU = 0.684 ± 0.072 (mean $\pm$ std).

Over 18 forecast periods spanning 2026 P1–2028 P6, mean predicted area followed clear three-phase temporal structure: initial contraction phase to mean 902.7 km^2 in 2026 (below 934.1 km^2 baseline), reflecting dry-to-wet seasonal transition inherited from seed sequence; progressive rise to 984.0 km^2 in 2027; further increase to 1,020.1 km^2 in 2028, with terminal forecast period (2028 P6, November–December) reaching 1,054.4 km^2 (+12.88% above baseline). The seasonal cycle was faithfully reproduced with characteristic pattern: minimum extent at P3 (May–June pre-monsoon, 918.3 km^2), maximum at P5 (September–October peak monsoon, 1,034.3 km^2), seasonal amplitude 116.0 km^2, and mean monsoon area 53.4 km^2 (+5.62%) above non-monsoon mean. Final forecast period exhibited accretion-to-erosion ratio approximately 1.60:1, with 78.4% of baseline channel extent maintaining stable classification.

I. Computational Complexity

Table XI summarizes the model complexity in terms of trainable parameters and average training time across different temporal resolutions.

J. Forecast Reliability and Uncertainty

Long-term forecasting is subject to uncertainty because prediction errors can accumulate over successive time steps. To assess forecast reliability, rolling predictions were evaluated across two controlled experimental setups: a 10-year horizon (Setup 1: 2016–2025) and a 5-year horizon (Setup 2: 2021–2025). The best-performing Attention U-Net+ConvLSTM model maintained remarkably stable performance across these testing intervals, achieving a mean IoU of 0.7005 (Dice = 0.8236) in the 10-year long-range forecast setup, and a mean IoU of 0.6963 (Dice = 0.8205) in the 5-year medium-range setup.

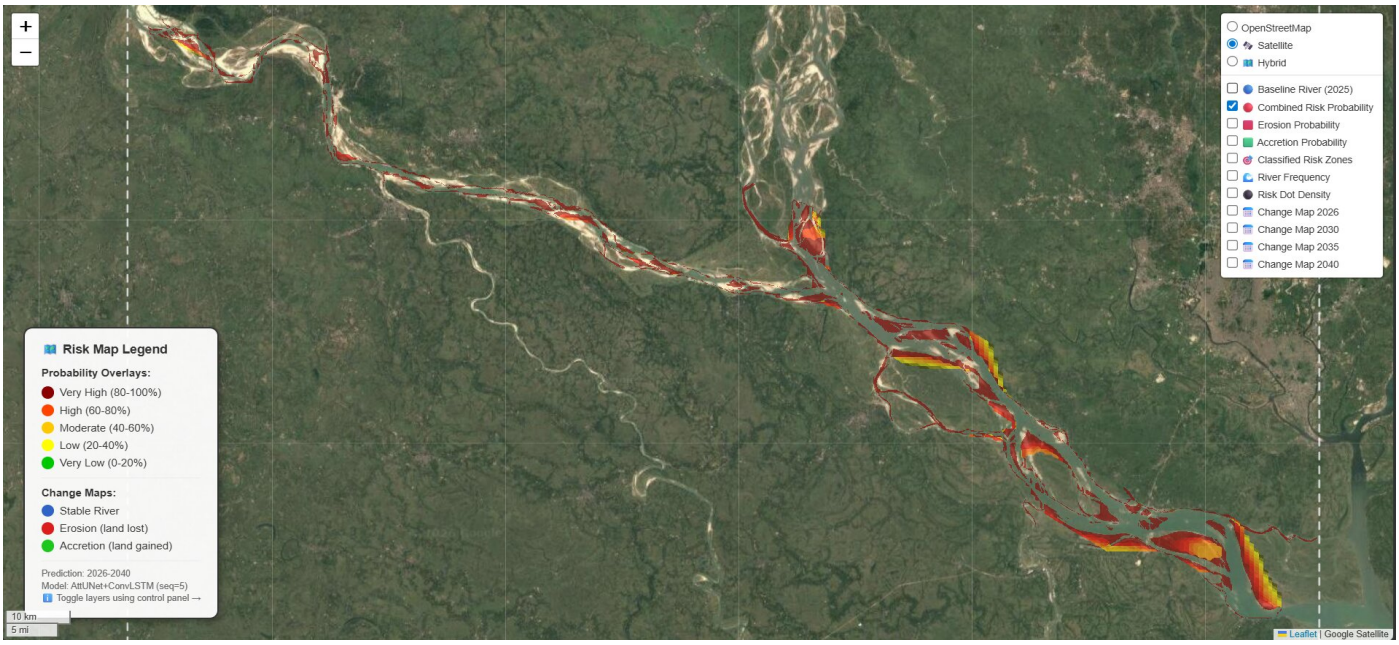

Fig. 6. Long-term combined morphological risk for 2026-2040. Interactive web demonstration available here.

TABLE XI. MODEL COMPLEXITY IN TERMS OF TRAINABLE PARAMETERS, TRAINING TIME, AND INFERENCE TIME PER PREDICTION.

Model	Data	Params (M)	Train (min)	Infer (s)
ConvLSTM	Yearly	1.41	8.2	0.31
	Quarterly		34.5	0.50
	Bi-monthly		54.1	0.65
U-Net + LSTM	Yearly	7.71	12.4	0.71
	Quarterly		48.2	1.10
	Bi-monthly		72.5	1.30
Attention U-Net + ConvLSTM	Yearly	**7.41**	**14.1**	**0.81**
	Quarterly		**52.8**	**1.10**
	Bi-monthly		**79.3**	**1.30**
ViT	Yearly	3.24	6.5	0.40
	Quarterly		22.0	0.62
	Bi-monthly		48.2	0.83
Swin Transformer	Yearly	5.07	22.0	0.60
	Quarterly		78.3	0.80
	Bi-monthly		115.4	1.00

Furthermore, the model exhibited tighter dimensional calibration over the shorter testing window, yielding a lower mean absolute area difference ($|\Delta A| = 41.05$ km^2) in Setup 2 compared to Setup 1 ($|\Delta A| = 66.54$ km^2). This behavior confirms that shorter horizons effectively curb cumulative error propagation. Rather than presenting future channel changes via strict binary boundaries, long-term channel evolution (2026–2040) is mapped using spatially explicit risk zones derived from pixel-level water occurrence frequencies (F_w) and a hydrodynamic stability index (I). This approach accounts for spatial modeling uncertainties and highlights highly dynamic zones along active channel margins.

VI. DISCUSSION

Hybrid CNN-LSTM architectures outperformed transformer-based architectures in terms of overlap and area metrics for all datasets and forecasting horizons. Underperformance of transformer-based architectures (ViT, Swin Transformer) is presumably related to data scarcity. The limited temporal samples (38 yearly, 125 quarterly, and 156 bi-monthly composites) likely increased the risk of overfitting for attention-based models. Although a full hyperparameter sweep was not conducted, key architecture-specific parameters (e.g., patch size, window size, and embedding dimension) were determined via iterative manual testing, and the most effective configuration was selected for final evaluation. Hierarchical window-based attention introduces stronger spatial locality biases, which may explain its better performance than ViT. With growing satellite databases and availability of pre-trained geospatial foundation models, transformer architectures are anticipated to be competitive with CNN-LSTM hybrids.

The Attention U-Net+ConvLSTM was best suited for yearly and quarterly forecasting, where attention helps focus on geographically active regions. The U-Net+LSTM architecture was superior for bi-monthly forecasts when boundary preservation is crucial but where gating provided only incremental benefits.

There was a significant seasonal influence on the performance of networks in quarter- and bi-monthly experiments. It relates to the difficulty associated with predicting the monsoon extent, where channel widths become large, have unusual forms, and become inundated with floodplain waters. For Setup 1 quarterly predictions, mean areas were close to each other (–0.47 km²), suggesting annual canceling of seasonal systematic errors.

An essential realization in regard to operational use is that metrics like Intersection Over Union (IoU) and Dice score are insufficient measures of model performance. Several model configurations had similar metrics of overlap but vastly differing absolute area differences, showing spatially accurate but incorrectly dimensionally sized predictions. River hazard

management processes such as erosion risk calculations, land lost calculations in agriculture, embankments construction, and disaster resource allocations require accurate area calculations. It is recommended that IoU, Dice, Precision, Recall, and absolute area difference be considered minimum requirements for performance metrics, with emphasis on area difference in selection process for hazard management.

Future prediction from 2026 to 2040 shows continuing expansion with accretion outpacing erosion. This corresponds with past observations between 2008 and 2018 (net accretion of 113.0 km²) and near equilibrium 2018 to 2025, indicating models learned realistic trends for the future. The slowing expansion beyond 2031 may indicate learned stabilizing effects; however, potential cumulative errors in modeling may be responsible. Historical reconstruction having consistent positive area bias (91.8 km²) indicates that the expansion values calculated are upper limit estimates. Nevertheless, the more accurate risk zone maps defining corridor segments with high change probability provide the main output for disaster management.

A. Limitations and Future Research Directions

However, several limitations need mentioning. Firstly, 60 m Landsat spatial resolution fails to capture erosion microfeatures, secondary channels, and banks' morphology, thus requiring shifting to 10 m Sentinel-2 spatial resolution data through the whole period of analysis. Secondly, lack of hydrological forcing data in the form of river discharge, precipitation, and antecedent soil moisture presents a serious limitation for the framework under development, especially during the periods of flooding. Thirdly, the proposed approach lacks any geotechnical parameters such as the soil type, bank height, and vegetation distribution, which influence erosion processes. Lastly, all the presented experiments were done on only one river system, making cross-system testing on Jamuna and Meghna river systems necessary to make any confident generalizations.

The following directions may be considered in future research: (1) inclusion of 10 m Sentinel-2 optical and Sentinel-1 SAR data through the entire time series; (2) widening the geographic scope to other river systems – Jamuna and Meghna; (3) including hydrological variables as forcing data to better predict the extremes; (4) exploring transformer neural networks pre-trained on larger geospatial foundation models corpora; and (5) combining geomorphology-based vulnerability map with population density and agriculture maps for a socio-economic early warning system.

VII. Conclusion

This investigation presents a comprehensive framework for analyzing and forecasting morphological evolution of the Padma River by combining long-term satellite remote sensing with spatiotemporal deep learning. A 38-year satellite-derived dataset enabled comprehensive analysis of long-term river dynamics, revealing substantial erosion, accretion, and channel migration. The proposed preprocessing framework produced reliable historical water masks for subsequent forecasting. Hybrid CNN-LSTM architectures consistently outperformed transformer-based models under limited training data. The proposed framework accurately captured both long-term morphological evolution and short-term seasonal dynamics, enabling spatially explicit future risk assessment. This research demonstrates that freely available satellite imagery combined with cloud-based processing and spatiotemporal deep learning can provide a practical, scalable, and reproducible framework for riverbank hazard monitoring and multi-year forecasting. Furthermore, this remote sensing and deep learning pipeline is fundamentally generic and can be seamlessly applied to any other dynamic river system by retraining the models on their respective historical data. For those living near erodible banks along rivers throughout Bangladesh and South Asia, predictive tools capable of identifying hazardous areas can meaningfully enhance disaster preparedness, infrastructure planning, and community adaptation strategies.

Hardware-Software Co-Design of K-Means Clustering on Zynq FPGAs via OpenCL

Eya JABALLI[1], Soufien GDAIM[2], Noureddine LIOUANE[3]
LARATSI Research Laboratory, ENIM, University of Monastir, Tunisia[1,3]
PRINCE Research Laboratory, ISITCom, University of Sousse, Tunisia[2]

***Abstract*—Clustering algorithms such as K-means are widely employed in machine learning and data analytics; however, their computational complexity becomes a significant limitation when applied to large-scale or latency-sensitive workloads. To overcome this challenge, this study presents a hardware-accelerated K-means clustering implementation using Field-Programmable Gate Arrays (FPGAs) within the Open Computing Language (OpenCL) framework. The proposed architecture leverages the fine-grained parallelism of FPGAs to accelerate the assignment phase, which is dominated by repetitive distance computations between data points and centroids. The proposed heterogeneous architecture accelerates only the assignment stage of the K-means algorithm on the FPGA, while the centroid update and convergence-control stages remain executed on the embedded ARM Cortex-A9 processor. Experimental results obtained on a two-dimensional synthetic floating-point dataset demonstrate significant performance gains over a CPU-only implementation, achieving speedups of up to 39× in execution time. The results also indicate consistent and favorable scalability trends across the evaluated synthetic two-dimensional configurations. To further assess the generalizability of the proposed approach, the accelerator was additionally validated on a real-world geospatial dataset, confirming consistent performance gains beyond synthetic benchmarks.**

***Keywords*—FPGAs; Hardware acceleration; high-level synthesis; OpenCL; K-means; reconfigurable hardware**

I. Introduction

Clustering plays an essential role in data mining research and applications and remains an active area of investigation in various disciplines, including computer science, data science, statistics, pattern recognition, artificial intelligence, and machine learning [1], [2]. The K-means algorithm is particularly significant among the various clustering algorithms because it is effective in discovering intrinsic patterns and revealing hidden structures in unlabeled datasets. Its use spans a wide range of application fields, including real-time data processing, IoT edge computing [3], [4], and big data processing environments [5], all of which are important for cluster classification for unlabeled data. Nevertheless, the increasing size and dimensionality of today's datasets pose serious computational challenges. With an increase in dataset size comes an increase in complexity of the clustering process, which causes slowdowns and performance bottlenecks that can be especially relevant in latency-sensitive or energy-limited real-time or edge computing environments. Performance bottlenecks such as these need to be solved to maintain the responsiveness and efficiency of a platform for real-time or edge processing. Multi-core central processing units (CPUs) and graphics processing units (GPUs) have been utilized for accelerating the computation involved in clustering [6]. While some performance improvement through parallelization can be achieved on these architectures, neither platform can match the power efficiency, deterministic latency, or real-time characteristics often required in edge computing applications, where device resources and energy consumption are at a premium. In this context, Field-Programmable Gate Arrays (FPGAs) have quickly gained traction as a viable option for hardware acceleration of clustering algorithms. FPGAs are reconfigurable architectures, which allows for fine-grained parallelism and deep pipelining, which gives developers the possibility to create hardware that is more closely aligned to the computational structure in algorithms. Moreover, unlike GPUs, which utilize a Single Instruction, Multiple Data (SIMD) that focuses on throughput rather than determinism, FPGAs execute tasks with low-latency and power-efficient results, which is particularly rewarding for real-time applications. Ultimately, the combination of flexible hardware paths, elasticity with scalability, and energy efficiency underscores the potential of FPGAs as an effective platform for hardware acceleration of unsupervised learning algorithms. The deployment of clustering algorithms on FPGAs introduces two significant performance bottlenecks. First, the latency of transferring data between the host and the FPGA device acts as an important constraint. In many cases, the communication pipeline between the CPU and FPGA is restricted by the use of synchronous data transfers, and this can negatively affect overall system throughput. This can be most detrimental to workloads that operate iteratively, such as clustering algorithms. A second contribution to performance limitations arises from an insufficient utilization of memory reads, because a sequence of memory operations in a clustering algorithm is irregular and often data-dependent. To improve the efficiency of the embedded CPU–FPGA implementation, the design adopts two implementation-level optimization strategies:

1) Host–kernel communication management: OpenCL command queues, non-blocking memory operations, and event-based synchronization are used to coordinate data migration, kernel execution, and result retrieval between the ARM processor and the FPGA kernel. These mechanisms reduce unnecessary host-side blocking and provide a structured execution flow for the heterogeneous implementation.
2) Burst-compatible memory access organization: Input observations and centroid arrays are stored in contiguous memory regions and accessed sequentially through AXI-based memory interfaces. This organization enables the HLS tool to infer burst-oriented memory transactions and reduces inefficient random memory accesses in the distance-computation kernel.

It is important to clarify the scope of this work. The proposed FPGA implementation accelerates the K-means assignment stage, specifically the nearest-centroid distance computation. The centroid update and convergence-control operations remain executed on the ARM processor. Therefore, the reported speedups refer to the heterogeneous implementation of the profiled K-means workload under the evaluated configurations, not to a fully hardware-implemented K-means pipeline. The current implementation evaluates two-dimensional floating-point datasets generated synthetically. The main contributions of this work are summarized as follows:

- An OpenCL-based heterogeneous CPU–FPGA implementation that accelerates the assignment stage of K-means on the FPGA while preserving the centroid update and convergence-control operations on the embedded ARM processor.
- A profiling-guided hardware/software partitioning approach that identifies the nearest-centroid distance computation as the main acceleration candidate.
- A lightweight FPGA kernel design using local centroid buffering, loop-level parallelism, and burst-compatible AXI memory access for accelerating the distance-computation stage.
- A host–kernel communication flow based on OpenCL command queues, non-blocking memory operations, and event-based synchronization to coordinate data migration and kernel execution.
- An embedded CPU–FPGA performance evaluation using synthetic two-dimensional floating-point datasets with varying numbers of data points and clusters, complemented by FPGA resource utilization analysis on the XC7Z020 device and validation on a real-world geospatial dataset to confirm the generalizability of the proposed accelerator.

The remainder of this study is organized as follows: Section II reviews the related work, including previous FPGA-based hardware acceleration approaches, K-means algorithm optimizations, and OpenCL programming for FPGAs. Section III presents the necessary background, including a detailed overview of the K-means clustering algorithm. Section IV describes the proposed methodology and the transition from the baseline implementation to the OpenCL-based FPGA-accelerated version. Section V presents the experimental setup, performance evaluation, and comparative analysis with existing works, followed by a discussion of the limitations. Finally, Section VI concludes the study by summarizing the main findings and outlining directions for future research.

II. Related Work

Due to the growing need to process large-scale datasets efficiently, scientific research has recently engaged in hardware acceleration for machine learning algorithms. Effective training of various machine learning algorithms, such as K-means, requires substantial computational resources and time. Therefore, these algorithms are often executed on FPGAs to take advantage of the power of reconfigurable hardware and accelerate their processing [7].

A. FPGA-Based Hardware Acceleration

FPGAs stand as a highly promising option for executing high-performance computations due to their remarkable attributes. They present a good balance between performance and power consumption, coupled with an interesting level of flexibility that enables users to configure these architectures to implement a customized application. The advantage of reconfigurability in FPGAs allows them to be fine-tuned to match the demands of the target computation. Recently, many studies have been published discussing software and hardware optimization and implementation methods of hardware accelerators using FPGAs [8], [9], [10], [11], [12]. Among them, our earlier work [8] introduced a preliminary approach, which the current study significantly extends and refines.

In addition, FPGAs have been presented as a mid-point solution providing a trade-off of GPU performance and ASIC efficiency while maintaining high flexibility and reconfigurability. They have been broadly recognized in the literature as being well-suited to accelerating machine learning. A review of more than 120 FPGA implementations of neural network accelerators demonstrates the wide generality of applications of FPGAs to diverse deep learning architectural styles, i.e., CNNs and RNNs, including ResNet-2 and LSTM [13]. The study also proposes a set of benchmark metrics and optimization techniques that cross many design classes with a useful starting point for benchmarking and optimizing accelerator performance.

As stated above, the effective utilization of machine learning methods demands a substantial amount of processing power. Even conventional multi-core CPUs are burdened by the computational complexity of these algorithms. In light of this, [14] proposed a reconfigurable architecture to deploy machine learning algorithms by implementing a Neural Network in an FPGA. The final results were compared with a Raspberry Pi (a conventional CPU) implementation. The proposed FPGA implementation architecture is 33646 times faster than the traditional CPU or core-based method.

In the ESA-funded CloudScout project, a bespoke FPGA-based accelerator was compared with the Intel Myriad 2 Vision Processing Unit (VPU) for on-board inference of a Convolutional Neural Network (CNN) for hyperspectral cloud detection in a CubeSat context [15]. The research showed that FPGA integration provided shorter inference time and greater flexibility than VPU, foreseeing the promise of FPGAs in resource-limited environments such as space. While the FPGA took more power and development time, its better performance and space qualification made it a suitable candidate for long-duration Low Earth Orbit (LEO) and interplanetary missions. These results demonstrate the applicability of FPGAs to a wide range of applications demanding effective on-board processing.

In addition to their benefits in deep learning applications, FPGAs have effectively sped up traditional machine learning algorithms. For instance, a recent study described a parameterized and scalable FPGA-based hardware accelerator for an embedded systems Support Vector Machine (SVM) classifier that relies on convex optimization [16]. With high classification accuracy, the architecture offers up to 79× acceleration over its software counterpart, allowing real-time operation and scalability to datasets of various sizes. This work validates

the feasibility of FPGAs as a general-purpose platform for machine learning acceleration by showing their adaptability and efficiency in accelerating data-intensive machine learning computations.

B. OpenCL for Heterogeneous Computing

Considerable progress in parallel computing has been made possible by the advent of heterogeneous computing systems. Given this, OpenCL has attracted attention as a standard that facilitates task-parallel and data-parallel heterogeneous computing on a variety of processing platforms, such as CPUs, GPUs, DSPs, and other coprocessor accelerators [17]. Its flexibility lies in the way it manages arithmetic-intensive data-parallel workloads on these various processing units. OpenCL's flexibility and efficiency for heterogeneous computing have been the subject of numerous research studies. Paper [18] provides an overview of the key architectural features of current microprocessor designs and outlines the OpenCL programming model as a standard developed for these architectures. Furthermore, OpenCL has been used to accelerate computationally demanding methods, such as Convolutional Neural Networks (CNNs). A study in [19] suggested using OpenCL to accelerate CNNs on Xilinx ZYNQ-7000 FPGAs. This approach achieved speedups of up to 10× over CPU implementations while maintaining comparable accuracy on well-known datasets such as MNIST and CIFAR-10. This illustrates OpenCL's ability to enable effective hardware acceleration without the complexity of conventional HDL design. It also supports the deployment of machine learning models for platforms with limited resources and rapid prototyping. Yongbon *et al.* have also presented a study analyzing the efficacy of OpenCL to speed up machine learning applications [20]. Their study's main goal was to create an implementation of Darknet, a deep learning-based object identification framework, that is hardware-compatible with universal accelerators. Darknet's limited utility resulted from its initial support of only NVIDIA CUDA for processing acceleration. Getting over the limitation and beating the original CUDA version is the primary objective of this research. The performance of OpenCL-Darknet was evaluated on two different AMD hardware setups: an AMD Radeon RX560 with OpenCL 1.2 and an AMD R7-integrated APU with OpenCL 2.0. For this assessment, the VOC 2007 dataset was used. Furthermore, they performed a performance comparison between OpenCL-Darknet and the original Darknet using an NVIDIA GTX 1050 with CUDA 8.0 and cuDNN 6.0. The findings revealed that compared to CUDA and cuDNN, OpenCL-Darknet exhibited a performance discrepancy of 2.5x to 4.4x for YOLOv2 and of 3.2x to 6.4x for TinyYOLO.

C. FPGA-Based Hardware Acceleration of K-means Algorithm with OpenCL

Tang *et al.* provides an exploration of the K-means algorithm via HLS of OpenCL code [21]. Due to inefficient memory bandwidth use, the initial implementation of the sequential baseline K-means algorithm performs poorly on the FPGA. The optimal approach relied on two kernels that utilized the FPGA's local memory. In the best scenario, speedups of up to 21× are obtained for implementations on an Altera Stratix V FPGA in comparison to an Intel Xeon Hexa-core processor.

In [22], a hybrid implementation of the K-means is presented to compare the speedup to an ARM CPU implementation. The proposed implementation carries out only some of the steps of the algorithm; the software carries out the remaining steps. The goal of this hybrid method is to reduce FPGA area overhead while increasing processing performance. The FPGA circuits are used to compute the similarity distance metric, which is based on the Manhattan distance, and to group data points based on their closest centroid. Moreover, the centroid values are updated by the software. Compared to the software version of the ARM processor, the experimental results reveal a speedup of about 10×.

In [23], the presented approach used High-Level Synthesis to test 10 distinct OpenCL implementations of the K-means algorithm on an FPGA platform. In addition to evaluating memory optimization strategies, including on-chip buffering and vectorization, the study investigated NDRange and task kernel models and examined performance across a variety of datasets and configurations. Their implementation showed energy savings of up to 80% and a speedup of increase to 1.54× over a high-performance CPU baseline.

III. K-means Clustering

The K-means clustering algorithm is one of the most popular unsupervised learning methods to partition datasets into unique groups by similarity. K-means has been used successfully across many research areas, including image processing [24], market analysis [25], data processing [26], medical image segmentation [27], risk evaluation [28], [29], etc. K-means is a partitional clustering algorithm, meaning that it partitions a dataset into a pre-defined number of non-overlapping subsets, or clusters. The core principle of K-means is to cluster data points to maximize intra-cluster similarity (data points are grouped together as closely as possible) and minimize inter-cluster similarity (data points in different clusters are distinguishable). In general, this is done by minimizing the sum of squared distances (errors) from an individual data point to the centrally located (mean) representative of its assigned cluster, which is where the K-means algorithm gets its name. The K-means procedure uses iteration where it initially provides a set of cluster centers and then performs alternating steps, where in each step the algorithm first assigns each point to the nearest cluster center, and then the next step updates each cluster center to be the mean of the points that were assigned to it until reaching convergence. Convergence is usually reached when either the assignments change no longer, or when the error is reduced to less than some previously assumed degree.

A. Problem Formulation

Given a dataset $\mathbf{X} = \{\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_N\}$, where $\mathbf{x}_i \in \mathbb{R}^d$ represents the i-th data point in a d-dimensional space, the goal of K-means is to partition $\mathbf{X}$ into k clusters $\{C_1, C_2, \ldots, C_k\}$. The optimization objective is to minimize the within-cluster sum of squared distances (WCSSD):

$$\mathcal{J} = \sum_{j=1}^{k} \sum_{\mathbf{x}_i \in C_j} \|\mathbf{x}_i - \mu_j\|^2 \tag{1}$$

where, μ_j denotes the centroid of cluster C_j, calculated as:

$$\mu_j = \frac{1}{|C_j|} \sum_{\mathbf{x}_i \in C_j} \mathbf{x}_i \tag{2}$$

The optimization alternates between assigning data points to clusters and updating centroids until convergence.

B. Algorithm Steps

The K-means algorithm involves the following steps:

- Initialization: Choose k initial centroids, $\mu_1^{(0)}, \mu_2^{(0)}, \ldots, \mu_k^{(0)}$. Initialization methods include random selection or heuristic techniques like K-means++.
- Assignment Step: For each data point $\mathbf{x}_i$, determine its cluster assignment based on the nearest centroid:

$$c_i^{(t)} = \arg\min_j \|\mathbf{x}_i - \mu_j^{(t)}\|^2 \tag{3}$$

Alternatively, this can be represented using a binary indicator matrix $\mathbf{r}_{ij}$:

$$\mathbf{r}_{ij} = \begin{cases} 1, & \text{if } \mathbf{x}_i \text{ is assigned to cluster } j, \\ 0, & \text{otherwise.} \end{cases} \tag{4}$$

- Update Step: Recalculate the centroids for each cluster based on the current assignments:

$$\mu_j^{(t+1)} = \frac{\sum_{i=1}^{N} \mathbf{r}_{ij} \mathbf{x}_i}{\sum_{i=1}^{N} \mathbf{r}_{ij}} \tag{5}$$

- Convergence Check: Repeat steps 2 and 3 until the number of observations whose cluster assignment changes between consecutive iterations falls below a predefined threshold.

C. Computational Complexity

K-means's computational complexity is affected by the number of data points N, the number of clusters k, the dimensionality d, and the number of iterations T. Each iteration requires $O(Nkd)$ computations for the assignment step and $O(kd)$ for updating centroids, leading to an overall complexity of:

$$O(TNkd)$$

While this complexity is manageable for small datasets, it becomes prohibitive for large-scale data due to the iterative nature of the algorithm and the repeated distance computations.

Despite its simplicity, the K-means algorithm has several limitations, particularly its low scalability as the dataset size increases. The computational cost of the algorithm, mainly due to distance calculations, increases rapidly as the number of data points and dimensions increases. However, in hardware implementations, these distance calculations, which dominate the execution time, can be efficiently accelerated using FPGAs. By offloading these intensive calculations to FPGAs, computational bottlenecks are reduced, leading to significant improvements in execution time. This hardware acceleration approach is particularly beneficial when dealing with large, high-dimensional datasets or real-time applications, as explored in subsequent sections of this study.

IV. Adopted Methodology

The proposed methodology is divided into three principal phases, as illustrated in Fig. 1. The first phase focuses on the design process of the overall application architecture, which describes the functional and structural components needed for the implementation. The second phase concentrates on the development of the OpenCL kernel, where computationally intensive tasks are defined and optimized for execution on the FPGA. The final phase involves establishing efficient communication between the host processor and the FPGA kernel through the use of OpenCL APIs, ensuring seamless data transfer and coordination between software and hardware components.

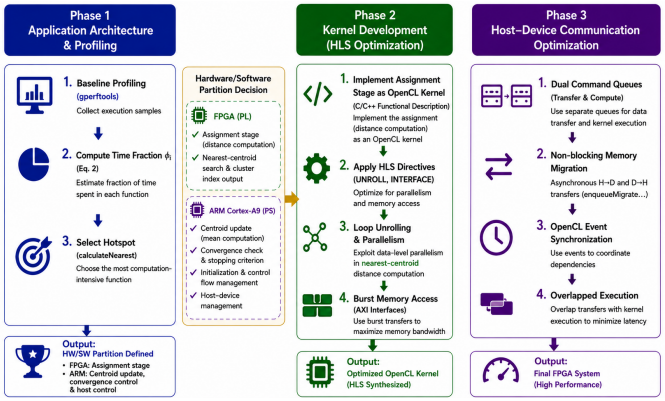

Fig. 1. Overview of the adopted methodology.

A. Application Architecture Design

Before embarking on the design of a hardware-accelerated application, it is imperative to conduct thorough architectural planning. This initial planning phase encompasses the development of an implementation plan, specifying the level of computational parallelism to achieve, and selecting which software tasks should be migrated to hardware as custom kernels. The process begins with a baseline profiling of the application's non-optimized CPU version. Profiling tools (e.g., GNU `gprof`) are used to extract the execution time of each function T_i^{CPU}. The fraction of time consumed by a given function i is then computed as:

$$\phi_i = \frac{T_i^{\text{CPU}}}{\sum_j T_j^{\text{CPU}}} \tag{6}$$

where, ϕ_i represents the relative contribution of function i to the total runtime. Functions with large ϕ_i values are natural candidates for FPGA acceleration.

The second step involves identifying the portions of the application that will experience the most significant performance improvement through the acceleration of relevant functions

in hardware. This selection process requires a critical evaluation of each function's computational load and its potential efficiency gains when implemented in hardware. Not every function will provide a meaningful acceleration by implementing the function in hardware, and it can conceivably cost the application overall performance. Therefore, the analysis in this iterative process is critical to ensure that hardware resources are optimized.

B. OpenCL Kernel Development

The second stage of the suggested process focuses on using OpenCL to convert the application's computationally demanding components into effective hardware kernels. In order to get notable performance improvements through hardware acceleration on FPGA platforms, this step is essential. Task selection, kernel implementation, and kernel optimization are the three primary sub-stages that comprise this phase. The first step in this phase is to identify functions or code segments that consume the most computational resources. These segments typically involve nested loops, large matrix computations, or repetitive arithmetic operations. Tools such as gprof, Google Performance Tools (gperftools), or platform-specific profilers such as Vitis Analyzer can be used to detect these hotspots. Once identified, the selected tasks are isolated and analyzed for suitability for parallelization and offloading. Priority is given to functions that operate on large datasets, exhibit high levels of parallelism (data or task parallelism), and have minimal dependencies between iterations. After task selection, the identified code blocks are rewritten as OpenCL kernels, which are functions that can be executed in parallel on the FPGA. The kernel design follows a load-compute-store structure:

- Load: Data are transferred from the host to the FPGA.
- Compute: The kernel performs the required operations on the hardware part.
- Store: The results are sent back to the host.

The OpenCL kernel is described at a high level using C/C++-based functional specifications. High-Level Synthesis (HLS) tools, such as Vitis HLS, automatically translate these functional descriptions into Register Transfer Level (RTL) implementations suitable for FPGA synthesis. The execution time of a kernel K on the FPGA can be expressed as:

$$T_K^{\text{FPGA}} = T_{\text{load}} + T_{\text{compute}} + T_{\text{store}} \tag{7}$$

where, T_{load} and T_{store} correspond to the data transfers between the host and the FPGA, and T_{compute} represents the kernel computation time. To enhance performance, HLS optimization directives (pragmas) are applied to control loop unrolling, pipelining, and data access patterns, thereby reducing T_{compute}. Additionally, techniques such as burst transfers, buffer reuse, and memory coalescing are employed to minimize T_{load} and T_{store}, ensuring efficient utilization of both computational and memory resources.

C. Code Adaptation: Host-Kernel Communication

Effective communication between the FPGA kernel and the host application is a crucial component of performance improvement in hardware-accelerated systems. While the host application coordinates overall execution, controls data transfers, and handles input/output activities, the kernel code, which is executed on the FPGA, carries out computationally demanding tasks. This section describes the methodology used to integrate the host and kernel components, ensuring efficient communication within the implementation of the K-means algorithm. As presented in Fig. 2, the host application is responsible for:

- Allocating memory buffers for input data (e.g., observations and cluster centroids) and output data (e.g., cluster assignments).
- Transferring data between the host and the FPGA device.
- Launching the kernel on the FPGA and monitoring its execution status.
- Retrieving results from the kernel and performing any post-processing required.

For this work, the host code was written in C/C++ and interfaced with the FPGA kernel using the OpenCL framework, which offers an abstraction layer that facilitates communication between the host and the kernel through a unified programming model.

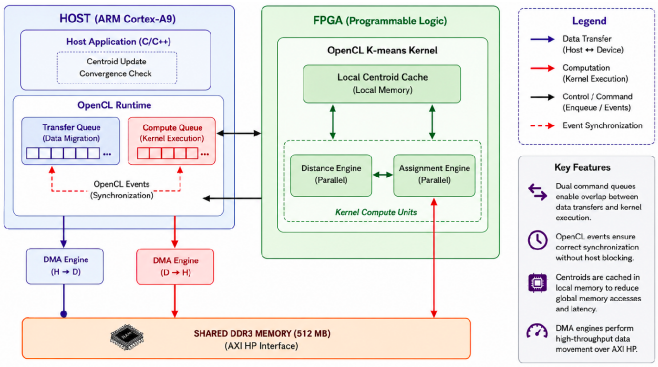

Fig. 2. OpenCL framework overview.

V. Performance Evaluation

A. Experimental Setup

The proposed heterogeneous K-means accelerator was implemented on a Xilinx ZedBoard featuring a Xilinx Zynq-7000 XC7Z020-CLG484-1 SoC integrating a dual-core ARM Cortex-A9 processing system (PS) and programmable logic (PL). The FPGA design was developed using the Xilinx OpenCL development flow under PetaLinux, while the software-only baseline was executed entirely on the embedded ARM Cortex-A9 processor. Consequently, all reported speedup values correspond to comparisons between the heterogeneous CPU–FPGA implementation and the ARM processor executing the same K-means algorithm under identical experimental conditions. The input data consisted of randomly generated

floating-point values. Experiments were conducted on datasets ranging from 4,000 to 30,000 data points with varying numbers of clusters, and performance was evaluated using kernel execution time measured in milliseconds. To further validate the proposed accelerator on real-world data, additional experiments were conducted using the SimpleMaps World Cities dataset. The hardware and software configuration used throughout the experiments is summarized in Table I.

TABLE I. HARDWARE AND SOFTWARE CONFIGURATION OF THE FPGA-BASED IMPLEMENTATION.

Parameter	Specification
FPGA board	Xilinx ZedBoard
FPGA device	XC7Z020-CLG484-1
Processing System	Dual-core ARM Cortex-A9
Operating system	PetaLinux
Development environment	Vitis Unified ide 2021.2
HLS tool	Vitis HLS 2021.2
OpenCL version	OpenCL 1.2
Target clock period / frequency	10 ns / 100 MHz

1) Selection of the acceleration candidate: The acceleration candidate was selected based on the computational structure of the K-means algorithm and preliminary profiling of the CPU implementation. In each iteration, the assignment stage compares every data point with every centroid. For a dataset with N points, k clusters, and dimensionality d, this stage requires $O(Nkd)$ distance computations. Therefore, the nearest-centroid computation is expected to dominate the execution time, especially when N or k increases.

In the implemented software version, this computation is performed by the `calculateNearest` function, which iterates over the centroids and computes the Euclidean distance between each data point and each centroid. For this reason, `calculateNearest` was selected as the main candidate for FPGA acceleration. Preliminary profiling confirmed that this function was the main hotspot; however, the profiling output is used only as qualitative guidance and not as an exact timing breakdown.

2) OpenCL kernel development: The selected `calculateNearest` function was implemented as an OpenCL kernel targeting the programmable logic of the Zynq device. The kernel computes the nearest centroid for each input observation and stores the corresponding cluster index in the output array. The centroid update and convergence-control operations remain executed on the ARM processor. This implementation incorporates various HLS directives that were strategically employed to guide the HLS tool during synthesis. The following directives were utilized to interface with the memory and control units:

a) Memory interfaces: `#pragma HLS INTERFACE m_axi` directives were employed for the input and output arrays. These directives define the memory interface for the input and output arrays, allowing seamless communication between the hardware accelerator and the external memory.

b) Control interfaces: `#pragma HLS INTERFACE s_axilite` directives were utilized for scalar control variables. These directives facilitate the creation of lightweight control registers for efficient communication between the host (Processing System PS) and the hardware accelerator (Programmable Logic PL).

Algorithm 1 K-means Kernel Algorithm

Output: `indices`
Initialize local arrays `localptClusX` and `localptClusY`
Copy cluster coordinates into local arrays
for $i = 0$ **to** `numObservations` $- 1$ **do**
    `localMinD` $\leftarrow$ `minD`
    `bestCluster` $\leftarrow 0$
    for $c = 0$ **to** `k` $- 1$ **do**
        `#pragma HLS UNROLL`
        $d_x \leftarrow$ `localptClusX[c]` $-$ `obsX[i]`
        $d_y \leftarrow$ `localptClusY[c]` $-$ `obsY[i]`
        `localDistance` $\leftarrow d_x^2 + d_y^2$
        if `localDistance` $<$ `localMinD` **then**
            `localMinD` $\leftarrow$ `localDistance`
            `bestCluster` $\leftarrow c$
        end if
    end for
    `indices[i]` $\leftarrow$ `bestCluster`
end for

In addition to the interface directives, other optimization directives were considered to enhance the algorithm's performance. The incorporation of the loop unrolling pragma (`#pragma HLS UNROLL`) emerged as a crucial strategy. Specifically, the loop unroll pragma was strategically applied to the loop responsible for computing the distance between data points and cluster centroids, as mentioned in the pseudocode below. This directive instructs the HLS tool to generate multiple copies of the loop body to reduce loop control overhead and enhance parallelism. It is particularly impactful in scenarios where the loop iterations are independent, as is often the case in distance calculations. By unrolling the loop, the compiler is empowered to exploit pipeline parallelism and optimize the overall execution time. K-means kernel algorithm is presented in Algorithm 1.

The independence of the data and the loop iterations served as the motivation behind the implementation of the (`#pragma HLS UNROLL`) directive within the distance computation method. Multiplication and accumulation operations are carried out on separate data elements in each iteration without creating dependencies on earlier or later iterations. This characteristic makes the loop highly amenable to unrolling, as the compiler can generate multiple parallel hardware instances that execute simultaneously. This takes advantage of the arithmetic resources on the FPGA giving higher throughput and less overall latency. Utilizing unrolling should be advantageous in clustering algorithms where distance calculations apply repeatedly to massive datasets, and this key aspect is a performance bottleneck.

3) Optimizing data communication between host and device: In hardware-accelerated systems, optimizing the data transfer between the host (CPU) and the FPGA is critical for achieving high performance. Therefore, this study seeks to improve the communication pipeline with asynchronous data transfers and non-blocking memory transactions. These two approaches are critical for reducing idle times and processing workloads concurrently between the host and the FPGA. We utilize asynchronous data transfers via two independent command queues in OpenCL: (`transfer_q`) for memory transfers, and (`compute_q`) for kernel executions. Both com-

mand queues are instantiated in out-of-order execution mode, allowing for overlapping transfers and kernel execution. This design reduces the waiting times for data to arrive before processing and ensures that the FPGA is continuously utilized. In this configuration, the transfer of the input data from host memory to the device memory and the kernel execution in the FPGA memory are non-blocking operations; this enables the accelerator to begin the computation as soon as it has enough of the required data to start, while the rest of the data transfers to host occur simultaneously. This structure will maximize the overall throughput of the system, since both computation and data movement will execute concurrently. To improve performance, we leverage non-blocking memory transactions. The OpenCL call - `enqueueMigrateMemObjects()` - facilitates the migration of data between host and device. Data transfer is performed asynchronously so that the host can do further work concurrently with the Data transfer. OpenCL events synchronize the different stages of the process without blocking. This allows the host to start executing the kernel as soon as the required data points have been received. Also, the host can continue reading the output data while the device writes to memory without waiting for all operations to complete. These techniques are essential for reducing idle time and ensuring that the data movement and computation phases are not bottlenecked by synchronization or waiting for data.

B. Experimental Results

1) Convergence criterion: To ensure a fair performance comparison, both the software-only and heterogeneous CPU–FPGA implementations were evaluated using the same K-means convergence criterion and termination condition. The algorithm iteratively alternates between the centroid recomputation and cluster assignment stages until convergence is achieved. Convergence is assessed by counting the number of observations whose cluster assignments differ between two consecutive iterations. Let $c^{(t)}$ denote the number of reassigned observations at iteration t. The iterative process terminates when the number of changed assignments falls below or equals a predefined threshold proportional to the dataset size N:

$$c^{(t)} \leq \left\lfloor \frac{N}{10000} \right\rfloor \tag{8}$$

Consequently, both implementations perform the same number of K-means iterations and satisfy an identical convergence condition, ensuring that the reported execution times and speedup measurements correspond to algorithmically equivalent workloads.

2) Execution time results of OpenCL kernel: In this section, we report the findings of our performance study, which compares the execution times of our heterogeneous solution with FPGA acceleration with regular CPU execution. The objective of this study is to show the efficiency of non-blocking memory transactions and asynchronous data transfer in enhancing the overall system performance. Performance evaluation was conducted through two distinct experiments using a randomly generated float dataset:

- Varying the Number of Clusters: The data points were kept fixed at 15,000 while the number of clusters was varied across a range of 32 to 256 (Fig. 3 and Table II).
- Varying the Number of Data Points: The cluster number was maintained at 128, and the number of data points was changed in the range of 4,000 to 30,000 (Fig. 4 and Table III).

To quantify the performance improvement of the FPGA implementation over the CPU, we calculate the **overall speedup** as the ratio of the CPU execution time to the FPGA execution time. Formally, the Speedup is defined as:

$$Speedup = \frac{T_{\text{CPU}}}{T_{\text{FPGA}}} \tag{9}$$

where, T_{CPU} and T_{FPGA} represent the execution times on the CPU and FPGA, respectively. A speedup greater than 1 indicates that the FPGA implementation is faster than the CPU.

In the initial experiment, as presented in Table II and illustrated in Fig. 3, the execution times of the CPU and FPGA implementations were evaluated while maintaining a constant dataset size (15,000 data points) and varying the number of clusters k. The results demonstrated a pronounced divergence in performance between the two architectures.

TABLE II. FPGA VS. CPU K-MEANS KERNEL PERFORMANCE WITH 15000-POINT DATASET.

k	FPGA+CPU time (ms)	CPU time (ms)	Speedup
32	3.177	16.543	5.2x
64	3.206	32.353	10.1x
128	3.223	64.149	20x
256	3.25	127.613	39.26x

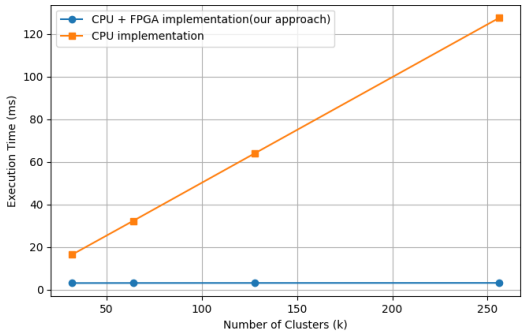

Fig. 3. FPGA vs. CPU K-means kernel performance with 15000-point dataset.

The CPU experienced a marked increase in execution time with increasing cluster counts, which can be attributed to the algorithmic processing complexity that increased cardinally with cluster count, thereby demanding more processing time. The FPGA implementation, by contrast, demonstrated much more consistent and scalable performance. Although a marginal increase in execution time was observed with additional clusters, the FPGA's parallel processing capabilities and optimized memory management mitigated the impact of the rising computational load, preventing a proportional escalation in runtime. Comparatively, the FPGA implementation achieved a speedup of up to 39X compared to the CPU, which is particularly useful for clustering, which is inherently computationally intensive.

In the second experiment, shown in Fig. 4 and summarized in Table III, the number of clusters was held constant (k=128) while the dataset size was scaled from 4,000 to 30,000 data points.

TABLE III. FPGA VS. CPU K-MEANS ALGORITHM PERFORMANCE WITH K=128

N	FPGA+CPU time (ms)	CPU time (ms)	Speedup
4000	2.706	17.08	6.3x
8000	2.792	34.215	12.25x
10000	2.875	42.774	14.87x
12000	3.078	50.323	16.34x
14000	3.203	59.843	18.68x
16000	3.616	68.361	18.9x
20000	3.883	85.522	22.02x
30000	4.258	128.171	30x

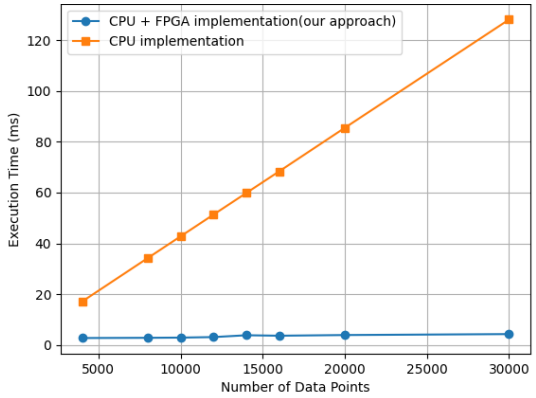

Fig. 4. FPGA vs. CPU K-means algorithm performance with k=128.

Consistent with the first experiment, the CPU exhibited a steep rise in execution time as the dataset expanded. This is largely attributed to the inherent limitations in CPU-based architectures to deal with large amounts of data, where the overhead of sequential processing and data transfer becomes a tremendous bottleneck. On the other hand, the heterogeneous execution model based on FPGA presented better scalability in big data processing. With asynchronous data transfer and non-blocking memory access, the FPGA initiated kernel execution as early as there was partial data, thus facilitating computation in parallel with ongoing data transfer. This was an optimization that significantly lowered the overall processing latency. When dealing with bigger datasets, the performance improvements were more noticeable, and the FPGA outperformed the CPU by up to 30X, which supported the findings from the initial trial. The results demonstrate the architectural advantages of FPGAs for carrying out data-intensive tasks since they can transfer data and conduct computations simultaneously, offloads the inefficiencies of conventional CPU-based processing.

To analyze the performance and reliability of the proposed K-means kernel on FPGA, we performed 10 independent executions for a dataset with a fixed problem size of N=30,000 data points and k=128 clusters. As illustrated in Table IV and Fig. 5, execution time for the CPU ranged from 128.206 ms to 128.596 ms, while FPGA execution times ranged from 4.066 ms to 4.723 ms. The resultant speedup, defined as the CPU execution time divided by FPGA execution time,

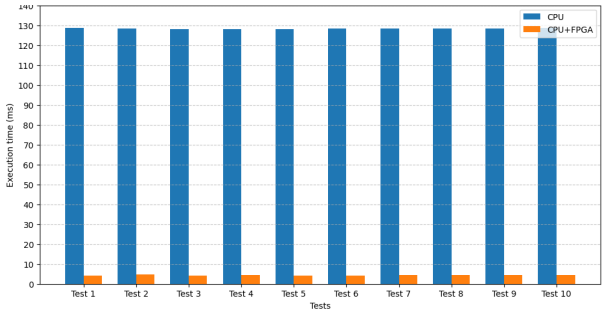

Fig. 5. K-means Kernel execution time (N=30000, k=128) for 10 tests.

ranged from 27.16× to 31.53×, with an average of 29.5×. These results show that the FPGA implementation constantly provided improved speed above the CPU, with stable and reproducible execution times, thereby confirming its suitability for real-time applications.

TABLE IV. CPU AND FPGA EXECUTION TIMES FOR 10 TESTS (N=30,000, K=128).

Test	CPU Time (ms)	CPU + FPGA Time (ms)	Speedup
1	128.849	4.225	30.49x
2	128.277	4.723	27.16x
3	128.206	4.188	30.61x
4	128.207	4.311	29.73x
5	128.211	4.066	31.53x
6	128.390	4.123	31.13x
7	128.275	4.505	28.47x
8	128.293	4.467	28.72x
9	128.324	4.541	28.25x
10	128.596	4.452	28.88x

3) Resource utilization: We also analyzed the FPGA resource consumption of the designed K-means kernel. Table V summarizes the hardware resource utilization of the proposed FPGA accelerator. The design occupies only 7.74% of the available LUTs, 5.17% of the registers, 0.71% of BRAM resources, and 3.18% of the DSP slices available on the XC7Z020 device. These results indicate that the proposed accelerator achieves substantial performance improvements while utilizing only a small fraction of the FPGA resources. The low BRAM utilization demonstrates that the design does not require extensive on-chip storage, while the limited DSP usage confirms that the implementation remains lightweight and scalable. Such moderate resource consumption leaves significant headroom for future optimizations, including the replication of processing elements, support for higher-dimensional datasets, or the integration of multiple clustering kernels within the same device. The reported speedups of up to 39× are therefore achieved without exhausting the available FPGA resources, highlighting a favorable performance-to-resource trade-off. Beyond resource consumption, post-implementation timing analysis confirms that the design reliably meets its performance target. The kernel was constrained to a 100 MHz (10 ns period) operating frequency, and static timing analysis after place-and-route reported all timing constraints as met, with a worst-case (critical path) positive margin of 0.754 ns. This confirms that the reported execution times and speedups correspond to a design that is fully timing-closed at its target operating frequency.

TABLE V. HARDWARE RESOURCE UTILIZATION OF THE K-MEANS KERNEL ON FPGA.

Resource Type	Used	Available	Utilization (%)
Slice LUTs	4118	53200	7.74
– LUTs as Logic	3558	53200	6.69
– LUTs as Memory	560	17400	3.22
Slice Registers	5498	106400	5.17
– Registers as Flip-Flop	5498	106400	5.17
Block RAM (BRAM)	1	140	0.71
DSP Slices (DSP48E1)	7	220	3.18

The finalized FPGA device layout with the K-means kernel implementation is shown in Fig. 6. The embedded ARM processor is visible in the left corner of the chip in the figure. The close integration of the processing system and programmable logic is demonstrated by this architectural layout, which also highlights an effective design approach specifically designed to improve the K-means algorithm's performance.

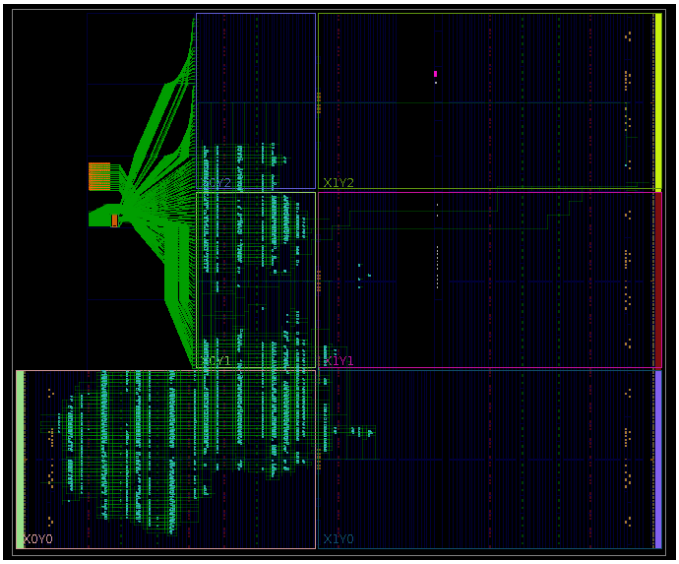

Fig. 6. The FPGA chip floorplan of the K-means kernel implementation.

4) Power consumption analysis: The proposed FPGA-based implementation exhibits a total on-chip power consumption of 1.833 W, including 1.688 W of dynamic power and 0.145 W of static power, as illustrated in Fig. 7.

The Processing System (PS7) accounts for approximately 90% of the dynamic power consumption, while the remaining power is distributed among the programmable logic resources, including clocks, signals, logic, DSP blocks, BRAM, and clock management circuitry. This behavior is consistent with the proposed hardware–software co-design approach, where the ARM Cortex-A9 processor is responsible for host execution, memory management, and OpenCL runtime control, whereas the FPGA fabric accelerates only the computationally intensive distance calculation kernel.
Despite the dominant contribution of the processing system, the overall power consumption remains below 2 W, demonstrating the suitability of the proposed architecture for power-constrained embedded platforms.

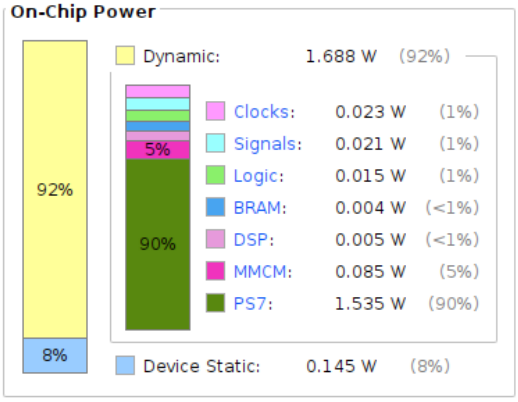

Fig. 7. On-chip power consumption of the proposed hardware-software co-design implementation.

5) Evaluation on a real-world dataset: To evaluate the proposed CPU–FPGA accelerator under realistic operating conditions, experiments were additionally conducted using the SimpleMaps World Cities dataset. This dataset contains real-world geospatial data with naturally non-uniform spatial distributions, providing a more representative benchmark for assessing the clustering performance on practical applications.

The dataset consists of 50,250 populated places worldwide. For the K-means clustering task, only the two numerical spatial attributes, latitude and longitude, were used as input features. The characteristics of the dataset are summarized in Table VI.

TABLE VI. CHARACTERISTICS OF THE SIMPLEMAPS WORLD CITIES DATASET.

Property	**Description**
Dataset Type	Real-world geospatial dataset
Instances	50,250 cities
Dimensions Used	2 (Latitude, Longitude)
Original Attributes	City name, country, administrative region, latitude, longitude, population, capital status, etc.
Domain	Geographic locations worldwide

The same experimental methodology adopted for the synthetic datasets was applied to the real-world dataset. Table VII reports the execution times obtained for the proposed CPU–FPGA implementation and the software-only CPU implementation.

TABLE VII. EXECUTION TIME COMPARISON ON THE SIMPLEMAPS WORLD CITIES DATASET.

N	k	FPGA+CPU Time (ms)	CPU Time (ms)	Speedup
50 250	128	5.4	214.757	$\sim 39.7\times$

The experimental results demonstrate that the proposed accelerator maintains its performance benefits on real-world data, achieving an approximate 39× speedup over the software-only implementation. This performance is consistent with the gains observed on the synthetic datasets, despite the larger size and more irregular spatial distribution of the real-world dataset, demonstrating the scalability and generalization capability of the proposed architecture.

TABLE VIII. COMPARISON OF THE PROPOSED IMPLEMENTATION WITH REPRESENTATIVE FPGA/OPENCL-BASED K-MEANS ACCELERATION APPROACHES.

Reference	Platform	Programming Model	Baseline	Dataset / Precision	Acceleration Scope	Speedup
Tang & Khalid [21]	Altera Stratix V A7	OpenCL	6-core Intel Xeon W3670	Benchmark suite / Integer	Complete K-Means using two OpenCL kernels with local-memory optimization	3×–21×
Canilho *et al.* [22]	FPGA Hybrid Platform	RTL/HLS	ARM CPU	Not specified	Partial acceleration: distance computation and assignment in hardware; centroid update in software	≈10×
Paulino *et al.* [23]	FPGA	OpenCL	High-performance CPU	Integer datasets / Integer	Complete K-Means using multiple OpenCL task and NDRange kernel implementations	Up to 1.54× (+80% energy savings)
Baydoun *et al.* [30]	GPU	CUDA / OpenMP	Sequential CPU	Multiple datasets and feature dimensions	Complete software implementation (GPU and multi-core CPU)	≈2× (OpenMP), ≈6× (CUDA)

6) Performance comparison: Table VIII compares the proposed implementation with representative FPGA/OpenCL-based K-Means accelerators. Direct comparison of the reported speedups should be interpreted with caution because the evaluated studies differ in FPGA architecture, processor baseline, numerical precision, dataset characteristics, and implementation scope. For instance, Tang and Khalid [21] and Paulino *et al.* [23] implement complete K-Means accelerators, whereas the proposed architecture adopts a heterogeneous hardware/software partitioning in which only the computationally dominant assignment stage is offloaded to the FPGA, while centroid recomputation, convergence checking, and execution control remain on the embedded ARM processor. This partitioning is a deliberate design choice that exploits the FPGA for massively parallel, compute-intensive operations while retaining the control-oriented and less computationally demanding tasks on the processor, thereby reducing hardware complexity and resource utilization without sacrificing overall performance. Furthermore, several previous FPGA implementations rely on integer arithmetic, whereas the proposed design operates on floating-point data, which generally incurs higher computational and hardware costs. In addition, the reported speedups are obtained using different processor baselines, ranging from embedded ARM processors to high-performance desktop CPUs. Consequently, the reported performance figures should be interpreted within the context of each implementation rather than as direct performance rankings.

7) Limitations and scalability discussion: Although the proposed heterogeneous architecture achieves substantial acceleration for two-dimensional floating-point datasets, several limitations should be acknowledged. First, the current implementation is specialized for two-dimensional observations, and extending the design to higher-dimensional feature vectors requires additional arithmetic operations for each distance evaluation. Consequently, the computational complexity of the assignment stage increases proportionally with the feature dimension, leading to higher DSP, LUT, and routing requirements when parallelism is maintained. Moreover, larger feature vectors increase the amount of data transferred between external memory and the FPGA, making memory bandwidth progressively more critical and potentially limiting the achievable acceleration. Nevertheless, the adopted hardware/software partitioning remains applicable because the assignment stage continues to dominate the computational cost of the K-Means algorithm, while the centroid update and convergence-control operations remain comparatively lightweight and are efficiently handled by the embedded ARM processor. Future work will therefore investigate scalable kernel architectures based on parameterized dimensionality, data tiling, and optimized memory hierarchies to improve performance for high-dimensional clustering problems.

VI. CONCLUSION

This study presented an OpenCL-based FPGA acceleration of the K-means clustering algorithm on a Xilinx Zynq platform. The proposed heterogeneous architecture offloads the computationally intensive distance calculation stage to programmable logic while retaining control-oriented tasks on the embedded processor. This hardware/software partitioning enables efficient exploitation of parallelism while preserving implementation flexibility. Experimental evaluation demonstrated speedups of up to 39× compared with the CPU implementation on synthetic benchmarks, with consistent performance gains confirmed on a real-world geospatial dataset, supporting the generalizability of the proposed approach beyond controlled synthetic conditions. Resource utilization further showed that these performance gains are achieved with modest consumption of LUTs, BRAMs, and DSP slices. The results confirm the suitability of FPGA-based acceleration for computationally intensive clustering workloads. Our study indicates that a hybrid CPU–FPGA architecture is highly effective for accelerating iterative, data-intensive algorithms such as K-means. Future research will aim to expand the proposed methodology to handle more complex datasets, as well as more sophisticated algorithms, to thoroughly evaluate its scalability and performance in demanding scenarios. We also aim to explore the integration of multi-FPGA systems and distributed processing architectures to better exploit parallelism and accelerate deep learning algorithms. Furthermore, we will investigate advanced methods to optimize off-chip memory access to reduce data transfer latency and improve overall efficiency. These guidelines are meant to augment and expand

current design practice. They help in creating energy-efficient and high-speed hardware accelerators for a range of machine learning and deep learning applications.

***Abstract*—This research examines the challenges of AI adoption in Saudi Arabia healthcare sector in terms of the framework defined by the Vision 2030 healthcare transformation agenda. We utilized the Analytic Hierarchy Process (AHP) methodology to collect and analyze data from 27 managerial-level executives tasked with AI implementation in Saudi Arabia healthcare organizations. The study identifies and prioritizes critical challenges across five main dimensions. We discuss accuracy, privacy and security, ethical barriers, interpretability, and control. By means of systematic analysis, we discovered that accuracy (with priority weight 0.50) and privacy-security concerns (0.24), are the two most important factors in determining AI adoption in Saudi Arabian healthcare. The research offers evidence-based policy recommendations and health care administrator guidelines based on Saudi Arabia's cultural, regulatory, and technological landscape. The insights are especially important for providing guidance on incorporating AI into the Kingdom's extensive healthcare transformation program.**

***Keywords*—Artificial Intelligence (AI); healthcare transformation; Saudi Arabia Vision 2030; Analytic Hierarchy Process (AHP); Saudi Arabia**

I. Introduction

Artificial Intelligence (AI) in healthcare is becoming a game changer in the modern medical format [1], [2], [3], [4], [5], [6], [7], [8], moving Saudi Arabia to the top of this technological revolution. With Vision 2030 as part of its journey, Saudi Arabia is undertaking a vision to revolutionize its healthcare system through its digital transformation, AI being key towards this evolution [9]. In the journey towards this path, 2019 is the year of the establishment of Saudi Arabia Data and Artificial Intelligence Authority (SDAIA) [10], which is a notable step forward by the Kingdom to become a global leader in AI adoption [11].

In the Saudi Arabia healthcare sector, we have a very specific context for AI implementation: a country with large scale reforms ongoing, substantial government investment, and unique cultural considerations. Following the development of such initiatives as the National Platform for Health Information Exchange Services (NPHIES) and AI powered health services through the Health Virtual Hospital, among others [12], [13], [14], the Kingdom has been developing its healthcare AI adoption.

[1]Corresponding author

Specify and classify the leading challenges faced by the adoption of AI in Saudi Arabia healthcare sector [15], [16], [17], [18]. The AHP methodology is applied to analyze the relative importance of these challenges and examine the effect of cultural and regulatory factors in play, particularly Saudi Arabia's to force in modern medicine, with Saudi Arabia positioning itself at the forefront of this technological revolution. As part of Vision 2030, Saudi Arabia has embarked on an ambitious journey to revolutionize its healthcare system through digital transformation, with AI serving as a cornerstone of this evolution [9], [19], [20]. The establishment of the Saudi Arabia Data and Artificial Intelligence Authority (SDAIA) in 2019 marks a significant milestone in this journey, demonstrating the Kingdom's commitment to becoming a global leader in AI adoption [10], [21], [22].

The Saudi Arabian healthcare sector presents a unique context for AI implementation, characterized by rapid modernization, substantial government investment, and distinct cultural considerations. Recent initiatives, including the National Platform for Health Information Exchange Services (NPHIES) and AI-powered health services through the Health Virtual Hospital, showcase the Kingdom's progress in healthcare AI adoption [23]. However, this transformation journey faces multiple challenges that require careful consideration and systematic analysis [24], [25], [26], [27], [28], [29], [30], [31], [32], [33].

This study aims to:

- Identify and prioritize the key challenges affecting AI adoption in Saudi Arabia's healthcare sector.
- Analyze the relative importance of these challenges using the AHP methodology.
- Examine the influence of cultural and regulatory factors specific to Saudi Arabia.
- Offer evidence base recommendations for policymakers and healthcare administrators.

II. Literature Review

A. Current Landscape of AI in Saudi Arabian Healthcare

In recent years, the Saudi Arabian healthcare system has experienced a remarkable change for the better, in its adoption of Artificial Intelligence technologies. As was highlighted in [34], this transformation is very signed with Vision 2030's goal

of having a more efficient, more accessible healthcare system. Creating a structured approach to the implementation of the AI across the healthcare sector is the genesis of establishment of the Saudi Arabia Data and Artificial Intelligence Authority (SDAIA) [10]. Thanks to this governmental support, we've developed diagnostic tools and administrative systems to name a few of the AI initiatives that have come up during this shift from the traditional path towards healthcare delivery methods.

As illustrated by the most recent research of [35], Saudi Arabian healthcare organizations have been very successful in the application of AI solutions in multiple medical specialties. According to their study, machine learning algorithms have been quickly adopted by radiology departments, mostly for analyzing and supporting diagnosis of images via use of AI technology. This adoption pattern predates a broader trend that has been emerging in Saudi Arabian health care – one where technological innovation is being increasingly viewed as an indispensable requisite for continuous improvement in the delivery of service and operational efficiency.

The Ministry of Health's strategic planning documents mention the integration of AI into the complete approach [15]. An outcome of this systematic approach is successful deployment of several of the key initiatives, such as the AI-based telemedicine platforms, as well as automated patient scheduling systems, that have all jointly contributed to increasing access to healthcare within the Kingdom.

B. Integration and Technology Infrastructure

The integration of repetitive manufacturing equipment presents challenges related to both the computer control and rigid mechanical details of the robot manipulator units, as well as materials transport from the source to the robot manipulator units.

The integration of AI systems with Saudi Arabian healthcare organizations' infrastructure is technically complex beyond just having basic infrastructure [36]. They note the special complexity in designing such systems that must work well in Arabic, as well as English, while maintaining conformity to international medical norms and local health standards.

As seen in the literature, data standardization becomes a critical challenge as clinical documentation pattern across healthcare facilities vary, making the construction of unified AI systems a challenge [37]. However, their research demonstrates the significance of standardizing data collection and storage protocols so that AI systems can efficiently analyze and utilize patient information in various healthcare settings.

C. Privacy, Security and Regulatory Framework

There are privacy and security considerations in Saudi Arabian healthcare AI systems, along with cultural, religious, and regulatory requirements that make private and security challenges to be analyzed of the Saudi Arabian healthcare organizations on how they need to cope with complex privacy requirements in implementing AI systems [38]. The research shows that privacy concerns go further than classic data protection measures and extend to cultural expectations of patient confidentiality, as well as information sharing.

The regulatory framework governing the application of AI in Saudi Arabian healthcare is changing, as [39] describes. In fact, their analysis reveals that healthcare organizations have to balance the tension between innovation and compliance and between global standards and local laws. System design and implementation, in such cases, is further complicated by this dual compliance requirement, which applies to both the physical and logical portions of the system, especially when patient data is both sensitive and non immunologically represented while covering different healthcare settings.

1) Cultural and ethical considerations: The cultural context of Saudi Arabia significantly shapes the adoption of AI in healthcare settings [19], [20], which studies the details of how Islamic medical ethics and AI applications make an intersection in healthcare. Their research demonstrates that successful adoption of AI requires consideration of religious and cultural values, such as the provision of gender-specific healthcare delivery and patient privacy. In the context of Saudi Arabia healthcare, these considerations carry over to the design, implementation, and utilization of AI systems. Finally, [40] further elaborates on the necessity of cultural sensitivity in the implementation of AI, since cultural acceptance of the use of AI technologies by doctors and patients is strongly dependent on cultural factors. Their research shows that successful AI adoption requires a mix of cultural acceptance, adoption of working practices, and cultural norms and values, including patient/provider relationships and medical decision-making processes.

2) Workforce development and organizational change: There has been a lot of literature regarding the importance of workforce development in successful implementation of AI. In [41], the authors help us understand how Saudi Arabian healthcare organizations have tackled workforce development in the context of AI adoption. In their research, they say that successful implementation requires cultural adaptation to new technologies and in-depth training programs that cover both technical skills and that new technology. The study [42] finds that patient care organizations in Saudi Arabia deploy digital transformation to adopt AI-enabling systems and reveals its reliance on leadership support and clear communication strategies. This study indicates that organizations need to take a complete approach to AI adoption by considering the technical parts as well as the human parts.

D. Economic and Resource Considerations

While economic aspects of AI adoption in Saudi Arabian healthcare have both opportunities and challenges [43], the article under the line outlines the amount of investments that would be necessary to be able to successfully implement AI, as well as explaining the long term cost benefits. Our findings suggest that while the initial investment is substantial, the resulting potential for better operational efficiency and better patient outcomes makes this a worthwhile investment. Research by [44] presents a systematic review of resource allocation challenges of AI adoption within health care organizations, comparing and contrasting how these organizations find the balance between competing priorities in technology implementation. Those findings suggest that successful AI adoption will rely on an allocation of resources among the

many aspects of implementation, from infrastructure development to staff training to system maintenance.

E. Future Directions and Emerging Trends

The literature shows a number of social trends in the use of AI in Saudi Arabian healthcare. More applications of AI in preventive care and the gradual integration of AI systems with population health management systems are the main areas for future growth, according to [45]. The final part of their research suggests that future developments will most likely be about making more integrated and comprehensive AI solutions that are, in turn, dedicated to both clinical and administrative needs. The researchers also emphasized the importance of international collaboration in promoting AI adoption. In [9], the authors also describe how Saudi Arabian healthcare organizations are active participants with global partners to develop and deploy AI solutions. Part of this international collaboration offers new knowledge sharing and technical advancement opportunities, but challenges with data sharing, impedance matching, and other system-level aspects do exist.

III. Research Design and Setting

A. Research Philosophy and Approach

As this research takes a pragmatic philosophical stance combining positivist, as well as interpretive approaches to this often very complex but extremely promising attempt to solve healthcare problems via artificial intelligence adoption into Saudi Arabian health care organizations, its endeavor is this. Fig. 1 shows how the Analytic Hierarchy Process (AHP) is used in this study as an element of pragmatic commentary that brings together quantitative precision with qualitative investigation and its results. It offers a holistic treatment of both the quantifiable priorities and the contextual factors involved in influencing AI adoption in Saudi Arabian healthcare settings using this mixed method. A sequential explanatory design is then used to carry out the study within this philosophical framework, that is, quantitative data collection and analysis through AHP is followed by qualitative investigation to gain further insights on the patterns of prioritization. The alignment of this approach with the recommendations in [36] of the need for knowledgeable understanding of technology adoption in the healthcare environment, which are culturally different (for example, Saudi Arabia).

1) Geographic and institutional coverage: The Central Region, centered around Riyadh, represents the largest concentration of participating organizations (52%), reflecting its role as the Kingdom's primary healthcare hub. This region includes major referral hospitals, specialized medical centers, and academic institutions that are at the forefront of AI adoption in healthcare, as shown in Table I. The Western Region, encompassing Jeddah and Mecca, contributes 29% of participating organizations, providing insights into healthcare delivery in areas serving both resident populations and religious tourists. The Eastern Province, with 19% of participating organizations, offers perspectives on AI adoption in a region characterized by industrial development and diverse population demographics.

TABLE I. Detailed Distribution of Participating Healthcare Organizations.

Region	Govt. Hosp.	Private Hosp.	Academic Med. Ctr	Spec. Ctrs	Total
Central Region	4 (19%)	3 (14%)	2 (10%)	2 (10%)	11 (52%)
Western Region	3 (14%)	2 (10%)	1 (5%)	0 (0%)	6 (29%)
Eastern Province	2 (10%)	1 (5%)	1 (5%)	0 (0%)	4 (19%)
Total	9 (43%)	6 (29%)	4 (19%)	2 (10%)	21 (100%)

TABLE II. Organizational Sampling Criteria and Distribution

Criterion	Categories	Distribution	Rationale
Service Level	Primary (19%) Secondary (43%) Tertiary (38%)	Hierarchical healthcare delivery structure	Comprehensive service coverage
AI Impl. Stage	Initial (33%) Active (43%) Mature (24%)	Implementation maturity spectrum	Development stage insights
Bed Capacity	$<$200 (24%) 200–500 (38%) $>$500 (38%)	Organizational size representation	Resource capacity variation

B. Research Design Framework

The study employs a comprehensive research design framework that integrates multiple methodological components to ensure robust and reliable findings. Fig. 2 illustrates the interconnected elements of the research design.

1) Design components and integration: The research design comprises three major components, each serving specific objectives while contributing to the overall research aims:

a) Quantitative component: The major quantitative component is an application of the AHP methodology towards prioritizing AI adoption challenges. Structured questionnaires and pairwise comparison matrices are utilized in this component to produce priority weights for a set of challenges. Saaty's well-established methodology is followed by the AHP process to enable mathematical rigor in the prioritization process.

b) Qualitative component: The qualitative part includes semi structured interviews with key stakeholders and extensive document analysis. Using rich contextual data from this component, the prioritization patterns seen in the quantitative analysis can be explained. Preliminary AHP findings were used for developing interview protocols that resulted in focused and relevant data collection.

c) Validation component: A robust validation of both internal consistency checks and external expert validation makes findings more reliable. The validation part is included in this component, which is multiple rounds of validation using expert panels and cross validation across different contexts of organizations.

C. Sampling Strategy and Identification of Participants

A stratified purposive sampling was used to select the participating organizations that represented different healthcare sectors and geographical regions. The sampling framework considered several key organizational characteristics, as shown in Table II.

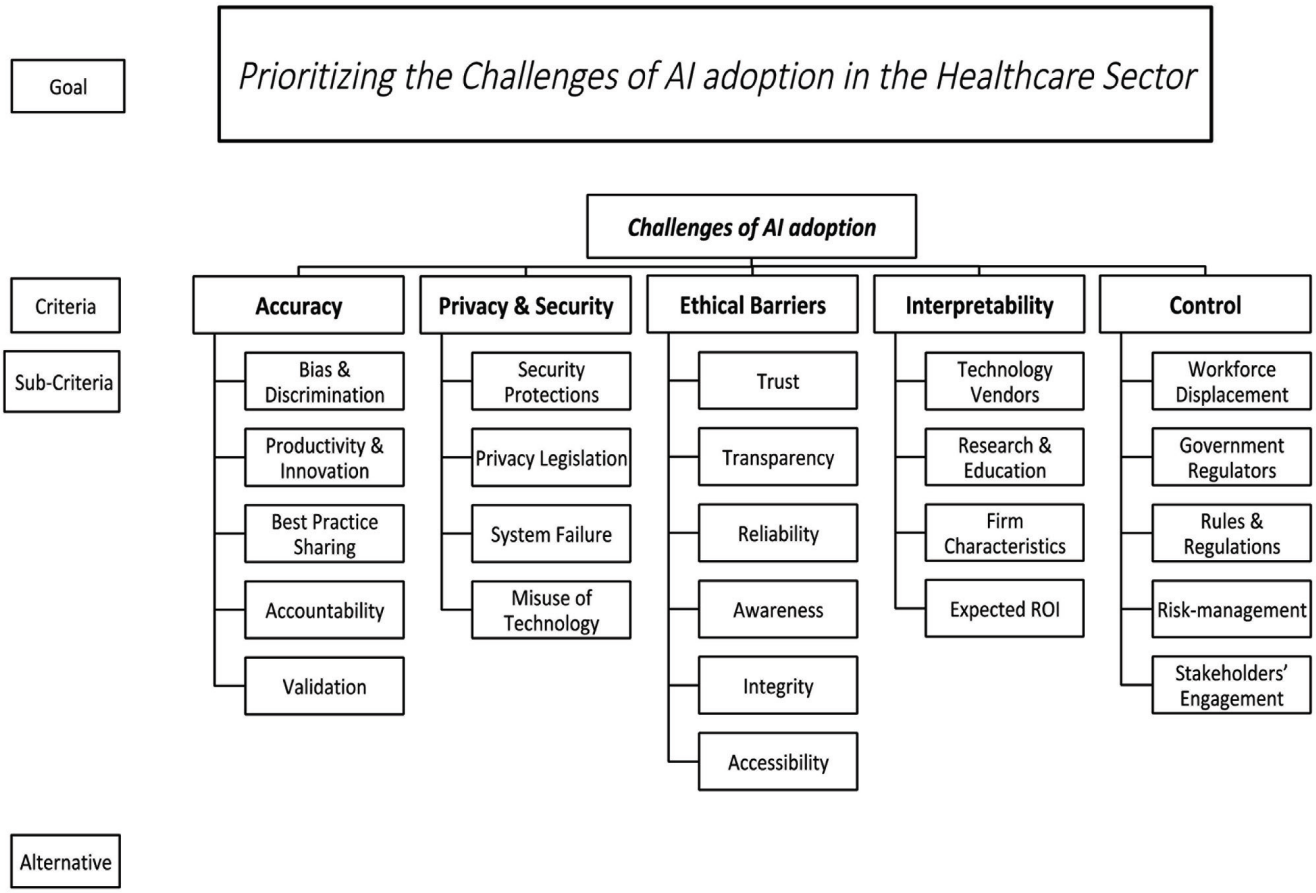

Fig. 1. The AHP model for prioritizing the challenges of AI adoption in the healthcare sector.

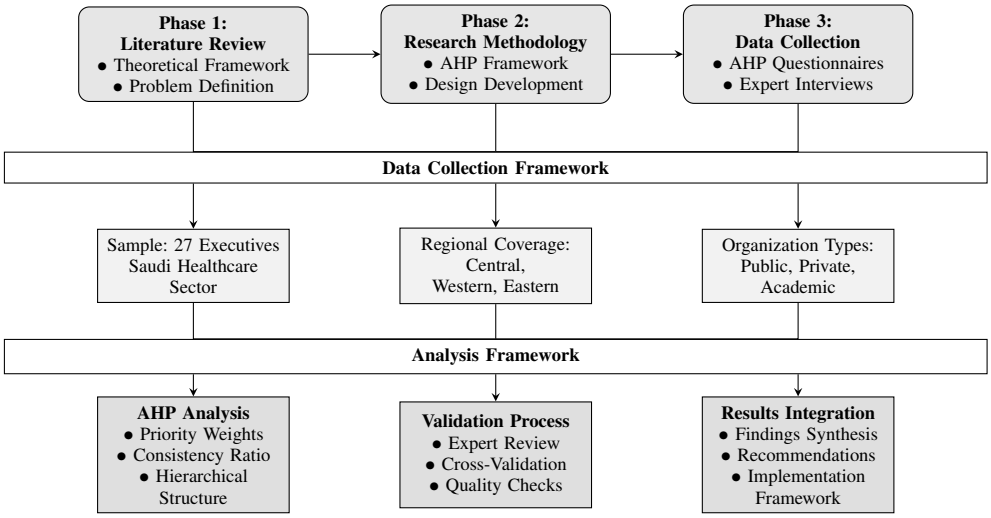

Fig. 2. Research design framework

IV. Analysis and Findings

A. Analysis of Main Criteria Priority Weights

Such analysis of how factors are prioritized had revealed unique patterns regarding how the adoption of AI is failed in Saudi Arabian healthcare organizations. The geometric means are used as the pair-wise comparisons for the main criteria and displayed in Table III for the relative importance of each of the factors under the Saudi Arabian healthcare context.

It is found that accuracy became the most important criterion with a priority weight of 0.50, greater than other criteria.

TABLE III. GEOMETRIC MEANS OF THE PAIR-WISE COMPARISONS OF THE MAIN CRITERIA.

Com Priority	Accuracy	Privacy & Security	Ethical Barriers	Interp.	Control	Priority Weight
Accuracy	0.65	0.84	0.47	0.31	0.25	**0.50**
Privacy & security	0.08	0.11	0.45	0.30	0.26	**0.24**
Ethical barriers	0.09	0.02	0.07	0.33	0.23	**0.15**
Interpretability	0.09	0.02	0.01	0.04	0.23	**0.08**
Control	0.09	0.01	0.01	0.01	0.03	**0.03**

TABLE IV. GEOMETRIC MEANS OF THE PAIR-WISE COMPARISONS OF THE SUB-CRITERIA (ACCURACY).

Com Priority	Bias & Discrim.	Prod. & Innov.	Best Prac. Sharing	Account.	Valid.
Bias & discrimination	0.65	0.85	0.47	0.33	0.24
Productivity & innov.	0.08	0.11	0.46	0.30	0.23
Best practice sharing	0.09	0.01	0.06	0.31	0.25
Accountability	0.09	0.02	0.01	0.04	0.24
Validation	0.09	0.02	0.01	0.01	0.03

These findings support the priorities of Saudi Arabia's healthcare transformation initiative, focusing on precision medical applications [35]. This is because the diagnostic accuracy is of critical nature, and the high priority weight represents the importance of diagnostic accuracy in the Saudi Arabia healthcare system as organizations adopt AI in making clinical decisions.

Second in rank was privacy and security with a priority weight of 0.24, which is a clear indication that Saudi Arabia healthcare organization give great importance to data protection and information security [38]. This being a priority of both regulator requirements and cultural sensitivities of patient data in the Saudi Arabian context.

The importance of ethical barriers received a priority weight of 0.15, indicating significant weight in the cultural, religious, and other factors of AI implementation. This finding is consistent with the research by [36] on aligning the AI systems with Islamic medical ethics, as well as local cultural values.

Lower priority weights (0.08 for interpretation, 0.03 for control) imply that these are not as important during this initial phase of AI's adoption in Saudi Arabian healthcare as they are accuracy and privacy concerns.

B. Detailed Analysis of Sub-Criteria

1) Accuracy dimension: Table IV presents the detailed analysis of sub-criteria across all main dimensions. Within the accuracy category:

The results show that bias (0.51) and discrimination are the strongest subfactors, highlighting the fact that there is serious concern about fairness and unbiasedness in the Saudi Arabian healthcare context. The need for AI systems to manage the variety of patient populations while maintaining cultural sensitivity results in assigning this high priority weight [37].

The second most important sub-factor (0.24), the use of AI to improve operational efficiency, showed Saudi Arabian healthcare organizations' focus on using AI to increase productivity and innovation. In particular, best practice sharing (0.15) showed attention to the importance of knowledge exchange in the Saudi Arabia healthcare sector AI adoption.

TABLE V. GEOMETRIC MEANS OF THE PAIR-WISE COMPARISONS OF THE SUB-CRITERIA (PRIVACY & SECURITY).

Com Priority	Security Protect.	Privacy Legisl.	System Failure	Misuse of Technology	Priority Weight
Security protections	0.71	0.85	0.47	0.32	**0.59**
Privacy legislation	0.10	0.11	0.46	0.33	**0.25**
System failure	0.09	0.02	0.06	0.30	**0.12**
Misuse of technology	0.10	0.02	0.01	0.05	**0.04**

TABLE VI. GEOMETRIC MEANS OF THE PAIR-WISE COMPARISONS OF THE SUB-CRITERIA (ETHICAL BARRIERS).

Com Priority	Trust	Transp.	Reliab.	Aware.	Integr.	Access.	Weight
Trust	0.58	0.82	0.45	0.30	0.24	0.20	**0.43**
Transparency	0.08	0.11	0.46	0.32	0.24	0.20	**0.24**
Reliability	0.09	0.02	0.07	0.33	0.26	0.20	**0.16**
Awareness	0.09	0.02	0.01	0.04	0.23	0.20	**0.10**
Integrity	0.08	0.02	0.01	0.01	0.03	0.18	**0.05**
Accessibility	0.08	0.02	0.01	0.01	0.01	0.03	**0.02**

2) Privacy and security framework: The privacy and security dimension revealed the following priority distribution, as shown in Table V.

The stringent data protection requirements in the Saudi Arabia healthcare led to the emergence of security protections as the dominant concern (0.59). Due to this high priority, this is aligned with recent cybersecurity regulations as well as the Kingdom's focus on protecting sensitive health information [39].

Noticeably, privacy legislation was getting some attention (0.25), a growing sign of the importance of regulatory compliance in Saudi Arabia health care AI implementation. The security framework still takes into account system failure (0.12) and misuse of technology (0.04), although these received lower priority weights.

3) Ethical barriers analysis: The analysis of ethical barriers revealed distinct patterns in the Saudi Arabian healthcare context, as shown in Table VI:

The most important ethical consideration was trust, which received a priority weight of 0.43. This is even more important in the context of Saudi Arabian healthcare, due to its cultural and religious values, and in the context of health care systems [36]. Weight for building and maintaining trust between AI systems and healthcare providers and patients in Saudi Arabia give high priority for Saudi Arabian culture.

Second was transparency, which received a priority weight of 0.24, referring to the need for AI systems' decision-making processes to be transparent and their communication with their users to be clear. Transparency is essential for gaining the acceptance of the AI systems in Saudi Arabian healthcare institutions, particularly in the context of the even more traditional healthcare delivery in the Kingdom [40].

A prioritized weight of 0.16 was given to reliability, which meant that consistent performance in AI systems is of high importance. According to this, Saudi Arabia backs high quality healthcare delivery amid the adoption of new technologies. However, priority weights were given to awareness (0.10),

TABLE VII. GEOMETRIC MEANS OF THE PAIR-WISE COMPARISONS OF THE SUB-CRITERIA (INTERPRETABILITY).

Com Priority	Tech. Vendors	Research & Education	Firm Charact.	Expected ROI	Priority Weight
Technology vendors	0.70	0.85	0.47	0.34	**0.59**
Research & education	0.10	0.12	0.45	0.33	**0.25**
Firm characteristics	0.10	0.02	0.07	0.29	**0.12**
Expected ROI	0.09	0.02	0.01	0.04	**0.04**

TABLE VIII. GEOMETRIC MEANS OF THE PAIR-WISE COMPARISONS OF THE SUB-CRITERIA (CONTROL).

Com Priority	Workforce Displace.	Gov. Regulat.	Rules & Regulat.	Risk-Mgmt	Stakeh. Engage.	Priority Weight
Workforce displacement	0.64	0.84	0.44	0.33	0.24	**0.50**
Government regulators	0.09	0.11	0.48	0.30	0.24	**0.25**
Rules & regulations	0.09	0.01	0.06	0.31	0.24	**0.14**
Risk-management	0.09	0.02	0.01	0.04	0.23	**0.08**
Stakeholders' engagement	0.10	0.02	0.01	0.01	0.04	**0.03**

integrity (0.05), and accessibility (0.02), which is crucial to the ethical framework of AI implementation.

4) Interpretability dimension analysis: The analysis of interpretability sub-criteria is revealed in the following Table VII:

The priority weight for technology vendors to be the dominant factor in interpretability was 0.59. This is due to the high priority from Saudi Arabia in developing the AI implementation strategy that encompasses partnering with the world leading technology providers while simultaneously developing capabilities locally [42]. The importance of partner selection suggests quoting AI solutions not only with technical sophistication but also with cultural appropriateness for the Saudi Arabia healthcare system.

The second-highest priority weight is 0.25 which indicates that research and education received the highest priority weight among Saudi Arabia's priorities to build local expertise in healthcare AI. It is in line with Vision 2030's objectives for the knowledge economy development and the Kingdom's investment in the healthcare education and training [9]. Especially considering the requirement for the development of AI systems and products that can provide the relevant public with excellent and professional service according to international standards while taking into account the national reality, the focus on research and education is particularly important.

Technical expertise, knowledge development, and other variables are given higher priority weight than organizational factors and expected ROI (0.12, 0.04), suggesting that organizational factors and financial returns are less important than technical expertise and knowledge development in the early adoption stage of AI.

C. Control Mechanisms Analysis

The analysis of control sub-criteria revealed significant insights into the governance aspects of AI adoption (see Table VIII).

The primary control concerned was workforce displacement with a weight of 0.50. This finding is important in the Saudi Arabian context, considering workforce nationalization (Saudi Arabiazation) is a central policy goal [41]. This high priority weight is the result of concerns about the need to keep Saudi Arabian healthcare professionals out of work and the implementation of AI systems.

Third most priority weight (0.25) was given to government regulators, as it points out to the vital role government regulatory bodies, for example, SDAIA and Ministry of Health, projected in AI adoption. This finding is significant given regulatory oversight as a means to prevent the inappropriate implementation of AI technologies in Saudi Arabia healthcare organizations [23].

Although having lower priority weights, rules and regulations (0.14), risk management (0.08), and stakeholders' engagement (0.03) are important parts of the framework. Regulatory compliance and risk management are needed, but these findings indicate that the main concern is to manage the workforce impact of AI adoption and the extra government oversight.

TABLE IX. PRIORITY WEIGHT VARIATIONS IN CENTRAL REGION

Main Criteria	Nat. Avg.	Central Region	Variance
Accuracy	0.50	0.53	+0.03
Privacy & Security	0.24	0.26	+0.02
Ethical Barriers	0.15	0.12	−0.03
Interpretability	0.08	0.06	−0.02
Control	0.03	0.03	0.00

V. CROSS DIMENSIONAL ANALYSIS

The analysis revealed significant interactions between the dimensions of various AI adoption challenges. For example, the high priority weights of accuracy (0.50) and workforce displacement (0.50 within control subcriteria) imply that technical performance and human resource considerations are somehow interdependent. In the Saudi Arabian context, this interaction is particularly important as organizations are called upon to satisfy both technological advancement and workforce development goals [44]. The analysis revealed significant regional variations in AI adoption challenges across Saudi Arabia's major healthcare regions. These variations reflect the diverse healthcare landscapes and varying levels of technological readiness across the Kingdom.

A. Central Region Analysis

Healthcare organizations in the Central Region, particularly in Riyadh, demonstrated distinct priority patterns in AI adoption challenges, as shown in Table IX.

Accuracy (0.53) was a higher emphasis of national organizations compared to central Region organizations (0.50). This focus on accuracy corresponds to the concentration of specialized medical facilities and research institutions in Riyadh, where precision in medical applications is, in particular, important [45]. As well as this, the region has stronger focus on privacy and security (0.26) as a result of major healthcare institutions in the region that are responsible for handling sensitive patient data.

TABLE X. PRIORITY WEIGHT VARIATIONS IN WESTERN REGION

Main Criteria	Nat. Avg.	Western Region	Variance
Accuracy	0.50	0.48	−0.02
Privacy & Security	0.24	0.28	+0.04
Ethical Barriers	0.15	0.16	+0.01
Interpretability	0.08	0.05	−0.03
Control	0.03	0.03	0.00

TABLE XI. PRIORITY WEIGHT VARIATIONS IN EASTERN PROVINCE

Main Criteria	Nat. Avg.	Eastern Province	Variance
Accuracy	0.50	0.49	−0.01
Privacy & Security	0.24	0.22	−0.02
Ethical Barriers	0.15	0.17	+0.02
Interpretability	0.08	0.09	+0.01
Control	0.03	0.03	0.00

TABLE XII. PRIORITY WEIGHTS IN INITIAL PLANNING PHASE

Main Criteria	Overall Avg.	Initial Phase	Variance
Accuracy	0.50	0.45	−0.05
Privacy & Security	0.24	0.30	+0.06
Ethical Barriers	0.15	0.14	−0.01
Interpretability	0.08	0.07	−0.01
Control	0.03	0.04	+0.01

VI. WESTERN REGION ANALYSIS

The healthcare organizations in the Western Region, specifically Jeddah and Mecca, stand out with their individual characteristics in the challenges of AI adoption (see Table X).

Particularly noteworthy was that heightened concern for privacy and security (0.28), particularly so as the region is responsible for medical needs provision during the Hajj and Umrah seasons [38]. The focus on managing healthcare data for a large, diversified population of pilgrims with other cultural and religious sensitivities, of course, increases the emphasis.

A. Eastern Province Analysis

The Eastern Province, more than any other province, had unique challenges in AI adoption (see Table XI).

Interpretability (0.09) and ethical barriers (0.17) showed increased emphasis in healthcare organizations of the Eastern Province. The Saudi Arabia region's diverse population and the need for its AI systems to serve both the urban and industrial populations are the causes of this pattern.

B. Analysis on the Implementation Phase

The study also uncovered different implementation phase specific patterns of challenges in AI adoption. These phases can describe the maturity of AI adoption in Saudi Arabian healthcare organizations.

1) Initial planning phase: Organizations in the initial planning phase (0–12 months into AI adoption) demonstrated the following priority patterns:

TABLE XIII. PRIORITY WEIGHTS IN ACTIVE IMPLEMENTATION PHASE

Main Criteria	Overall Avg.	Active Phase	Variance
Accuracy	0.50	0.55	+0.05
Privacy & Security	0.24	0.22	−0.02
Ethical Barriers	0.15	0.13	−0.02
Interpretability	0.08	0.07	−0.01
Control	0.03	0.03	0.00

TABLE XIV. PRIORITY WEIGHTS IN MATURITY PHASE

Main Criteria	Overall Avg.	Maturity Phase	Variance
Accuracy	0.50	0.48	−0.02
Privacy & Security	0.24	0.23	−0.01
Ethical Barriers	0.15	0.16	+0.01
Interpretability	0.08	0.10	+0.02
Control	0.03	0.03	0.00

This stage had organizations really focused on privacy and security, and they were concerned about establishing strong data protection frameworks at the beginning of the process, which manifested in a 0.3. This fits in with Saudi Arabia's strict requirements for healthcare data handling and building security architecture, as shown in Table XII.

C. Active Implementation Phase

Organizations in the active implementation phase (12–24 months) showed distinct priorities.

As organizations moved from active implementation to CDI to late implementation (Table XIII), accuracy became the most important thing (0.55). This is because organizations focused on reliable system performance and clinical outcomes, which made the rules more accurate. At this phase, the practical challenges of deploying AI were recognized, which led to particular emphasis on workforce training and system integration [41].

1) Maturity phase: Organizations in the maturity phase (>24 months) demonstrated evolved priority patterns.

Table XIV shows how much attention was paid to each challenge in the maturity phase compared to the other phases. During the maturity phase, organisations paid more equal attention to all challenges, but they paid the most attention to interpretability (0.10) and ethical concerns (0.16). This shift highlights this more advanced understanding of the AI implementation challenges and its crucial role in the long-run sustainability [44].

D. Implementation Success Factors

The prompt creation of a solid privacy and security framework is crucial. The development process balances the radically divergent focus on accuracy with attention to technical and ethical considerations in more mature implementations. This shift reflects a more sophisticated understanding of AI implementation challenges and the importance of long-term sustainability [44].

Based on the analysis of different implementation phases, several key success factors emerged:

TABLE XV. PARTICIPANT PROFILE DISTRIBUTION

Role Category	Number (%)	Selection Rationale
Hospital Directors/CEOs	5 (18.5%)	Strategic decision-making perspective
IT Directors	6 (22.2%)	Technical implementation insights
Clinical Department Heads	7 (25.9%)	Clinical application understanding
AI Project Managers	5 (18.5%)	Direct implementation experience
Quality/Risk Managers	4 (14.8%)	Governance and compliance perspective
Total	**27 (100%)**	Comprehensive stakeholder representation

- Early establishment of robust privacy and security frameworks
- Strong focus on accuracy during active implementation
- Balanced attention to technical and ethical considerations in mature implementations
- Continuous workforce development and training
- Regular assessment and adjustment of implementation strategies

It is these findings that allow Saudi Arabian healthcare organizations of varying AI adoption status to look ahead to and meet their challenges accordingly.

1) Selection of participant: The method made the selection of individual participants in organizations systematic and made it possible to select knowledgeable and relevant input. We carefully selected a total of 27 participants who are in roles, have experience, and are involved in AI implementation initiatives. The participant selection process took into account multiple criteria.

Table XV shows the distribution of participants across different roles to cover all perspectives.

VII. DISCUSSION

The comprehensive analysis of AI adoption challenges in Saudi Arabian healthcare organizations reveals several significant patterns and implications that warrant detailed discussion. This section examines the findings within the broader context of Saudi Arabia's healthcare transformation goals and Vision 2030 objectives.

A. Dominance of Accuracy Concerns

All regions give accuracy a low priority weight of 0.50, reflecting the importance of reliable AI performance in healthcare settings. Related to this, [35]'s research shows that the precision of medical applications is crucial. The emphasis on accuracy reflects several key considerations in the Saudi Arabia context: Firstly, the finding shows that the healthcare sector is very committed to maintaining a maximum standard of patient care while embracing new technology. Specifically, Saudi Arabia healthcare organizations show particular concern for making sure that AI systems can process the diverse patients' population, including residents in the Kingdom and religious tourists visiting during Hajj and Umrah seasons [45]. Second, there are regional variations in accuracy priorities, with the Central Region ranking at 0.53. Different levels of technological readiness and clinical requirements vary across the Kingdom, ranging from 0.48 in the Western Region to 0.49 in the Eastern Province. Finally, the high emphasis on accuracy in the Central Region, especially in Riyadh, is due to the high density of specialized medical facilities, which have high technological requirements [34].

B. Privacy and Security Considerations

We gave privacy and security a significant priority weight of 0.24, illustrating a very complex interplay between technological advancement and cultural sensitivities in Saudi Arabia healthcare. According to [38], this finding has several important implications: Concern for privacy and security, particularly in the Western Region (0.28) during the Hajj and Umrah seasons, presents the challenge of managing health care data for an international population that is diverse in culture and religion. These results suggest the need for specialized techniques to safeguard data, considering both technical requirements and cultural norms. Temporal analysis shows that privacy concerns are most acute at the beginning of the implementation phase (0.30)—during the first phases of adopting AI, it is critical to create solid data protection frameworks. The pattern aligns perfectly with Saudi Arabia's strategic approach to digital transformation, which advocates for a secure and controlled approach to technological implementation.

C. Evolution of Implementation Challenges

1) Phase-specific priorities: Analysis of the implementation phase shows a clear evolution in (organizational) priorities when AI adoption matures. This progression has significant implications for healthcare organizations: Initial Planning Phase (0-12 months): However, this phase prioritizes privacy and security (0.30), necessitating the establishment of strong foundational frameworks. In this phase, organizations show extraordinary interest in complying with national regulations as well as international standards [39]. Active Implementation Phase (12–24 months): During this phase, accuracy concerns (0.55) dominate the shift towards an orientation of operational effectiveness and clinical outcome. This transition implies that after privacy frameworks have been established, performance and reliability of systems are prioritized by organizations [41]. Maturity Phase ($\geq$24 months): Mature implementations, on the other hand, distribute these priorities more evenly (0.10 for interpretability; 0.16 for ethical considerations), demonstrating a more sophisticated approach to AI integration challenges. It is possible to see that, with time, organizations evolved more sophisticated approaches for implementing AI [44].

D. Regional Dynamics and Healthcare Delivery

1) Urban-rural disparities: The regional analysis reveals important variations in AI adoption challenges between urban and rural healthcare settings. These disparities have significant implications for healthcare delivery.

a) Urban centers: Healthcare organizations in major urban centers demonstrate higher readiness for AI adoption, with stronger emphasis on advanced applications and integration with existing systems. The Central Region's focus on accuracy (0.53) reflects the sophisticated technological infrastructure and specialized medical services in urban areas [37].

b) Rural areas: Healthcare facilities in rural areas show different priority patterns, with greater emphasis on basic infrastructure and workforce development. This finding suggests the need for targeted support and resources to ensure equitable AI implementation across all regions [9].

E. Cultural and Ethical Considerations

1) Integration of Islamic medical ethics: The study reveals that ethical issues (0.15), particularly Islamic medical principles, receive significant consideration. This finding has several important implications: Trust, the second most highly weighted factor (0.43 of ethical barriers), highlights the need for AI systems to align with culture and religion. When adopting AI, healthcare organizations have the responsibility to implement AI in a way that respects Islamic medical ethics and yet remains technologically effective [36]. Ethical priorities vary by region, with the West Region having the highest priority variances (0.16); this reflects the requirement to differentiate between religious and cultural sensitivities and the geographical area of its high number of pilgrims and international patients.

2) Workforce development and training: Human resource implications the control subcriteria assigns a high priority weight of 0.50 to workforce displacement, highlighting significant concerns about the impact of AI on healthcare professionals: This finding signals a need for a whole workforce development strategy that will balance technological advancement and employment for Saudi Arabia healthcare workers [40]. Copying research and education (0.25 within the interpretability subcriteria) indicates that there is an understanding of the need to develop local expertise in healthcare AI technologies.

F. Future Directions and Recommendations

Based on these findings, several key recommendations emerge for Saudi Arabian healthcare organizations:

- Formulate region-specific implementation strategies, considering local infrastructure and local demand of the human population.
- In organizations with multiple patient populations, establish these comprehensive privacy frameworks as early and far in the implementation process as possible.
- Invest in workforce development programs that not only prepare healthcare professionals for AI integration but also protect employment opportunities.
- Design balanced approaches to AI implementation that address technical necessities and cultural sensibilities.
- Promote knowledge exchange between regions and organizations to enable best practices in pursuing AI adoption.

VIII. Conclusion

In this study, we have qualitatively understood the challenges of AI adoption in Saudi Arabia's healthcare sector and have uncovered key insights on implementation priorities. The results show that accuracy (0.50), privacy (0.24), security concerns, and ethical barriers (0.15) are the most influential factors in successful AI adoption. However, bias and discrimination (0.51), security protections (0.59), and trust (0.43) were the strongest of the subfactors in this set of criteria, as the Saudi Arabian healthcare context presents a different cultural and regulatory environment. As such, the research provides a systematic framework for comprehensively investigating AI adoption challenges in culturally diverse healthcare environments and contributes to practical implementation as well as theoretical understanding. The research findings corroborate and complement existing scholarly works and present new understandings of the implementation of AI technologies in healthcare transformation in Saudi Arabia. The results of the study are of particular value to healthcare organizations faced with the challenging mandate of managing technological advancement within a culturally sensitive and regulatory context. Based on these results, Saudi Arabian healthcare organizations should focus on building strong systems for checking accuracy, complete data security frameworks, and ethical compliance with Islamic medicine in order to build trust among patients in the use of artificial neural networks in medicine. It is possible to conduct further research on how these challenges evolve as AI programming advances, as well as specific strategies for implementing AI in other healthcare sectors. Based on these insights, we can design more efficient strategies that promote the use of AI in Saudi Arabia's healthcare sector in a culturally appropriate manner.

Acknowledgment

The authors would like to thank the participating healthcare organizations and executives who contributed their time and expertise to this study.

***Abstract*—Pneumoconiosis remains a major occupational lung disease among workers exposed to silica, coal, and other inorganic dusts. Although chest X-ray screening is widely used in clinical practice, diagnostic performance is often affected by image variability and the limited availability of contextual occupational information. This study presents a multimodal framework that combines chest X-ray images with clinical and occupational metadata for automated pneumoconiosis detection. The proposed approach integrates a ResNet-18 image encoder with a metadata-processing multilayer perceptron through an early-fusion strategy. Experiments were conducted on a dataset of 1,971 subjects, including 1,086 confirmed pneumoconiosis cases and 885 healthy controls. Two configurations were evaluated: an image-only model and a multimodal model incorporating non-imaging information. The multimodal framework achieved the best validation performance, reaching an accuracy of 92.66%, an F1-score of 93.21%, and an AUC-ROC of 97.35%. Compared with the image-only baseline, adding metadata produced a small change in overall performance and shifted the precision–recall balance toward higher precision. These validation figures should be interpreted as an upper bound because the negative class is partly drawn from an external population and the pattern of missing metadata is correlated with the diagnostic label. The results suggest that combining radiographic findings with occupational and clinical information is a promising but data-quality-sensitive direction for pneumoconiosis screening in real-world settings.**

Keywords*—Pneumoconiosis; multimodal learning; chest X-ray; convolutional neural network; early fusion; occupational lung disease

I. Introduction

Dust exposure is a major occupational hazard in industries such as mining, construction, and manufacturing. Prolonged inhalation of inorganic dusts, including silica, coal, and asbestos, can cause pneumoconiosis, a group of chronic lung diseases characterized by progressive and irreversible pulmonary fibrosis [1], [2], [3]. In Vietnam, silicosis remains a significant occupational health concern that adversely affects workers' health and productivity [4].

The development and severity of pneumoconiosis are influenced by workplace conditions, cumulative dust exposure, and adherence to personal protective equipment usage [5]. Common symptoms include chronic cough, chest pain, weight loss, and dyspnea. Early diagnosis remains challenging because chest X-ray abnormalities are often subtle and subject to inter-observer variability [6].

Chest X-ray screening based on the International Labour Organization (ILO) classification is the most widely used diagnostic approach [7]. However, pneumoconiosis diagnosis in routine occupational-health practice does not rely solely on chest radiographs. Occupational exposure history, duration of dust exposure, respiratory symptoms, smoking behavior, workplace conditions, and compliance with personal protective equipment are all considered during clinical assessment. Consequently, image-only approaches may fail to fully exploit contextual information routinely collected during occupational-health surveillance programs, which may reduce diagnostic consistency and delay intervention [8].

Deep learning has shown promising performance in medical image analysis. Convolutional neural networks (CNNs), including ResNet-18, have achieved accuracies exceeding 90% in detecting pulmonary abnormalities from chest X-rays under controlled conditions [9], [10], [11]. Nevertheless, image-only approaches may be less reliable when applied to real-world occupational datasets with heterogeneous image quality and incomplete clinical information.

To address these limitations, this study proposes a multimodal framework that combines chest X-ray images with occupational and clinical metadata for pneumoconiosis screening. Visual representations are extracted using ResNet-18, whereas non-imaging variables, including exposure history, clinical symptoms, health indicators, and occupational protection usage, are encoded through a metadata-processing branch. The resulting feature representations are fused at an early stage to jointly exploit radiographic and contextual information, improving diagnostic reliability in real-world occupational health settings.

The framework is evaluated on a real-world dataset of Vietnamese workers and is intended for future deployment as a web-based clinical decision-support tool. Results show that incorporating non-imaging metadata yields a small change in validation performance compared with image-only baselines; The practical value and limitations of multimodal learning for

occupational health applications are further discussed in the subsequent sections.

II. Related Work

A. Occupational Pneumoconiosis and Epidemiological Context

Pneumoconiosis remains one of the most prevalent occupational diseases worldwide. In Vietnam, the Law on Occupational Safety and Health classifies pneumoconiosis, including silicosis, coal workers' pneumoconiosis, and asbestos-related diseases, among the occupational diseases eligible for social insurance and regular screening [5]. According to the Vietnamese Ministry of Health, approximately 7,000 occupational disease cases are reported annually, with pneumoconiosis accounting for 40–45% of cases [12]. Epidemiological studies have reported prevalence rates of 12–14% among underground workers with prolonged exposure histories [13]. These findings emphasize the need for effective and scalable screening systems.

B. Deep Learning Approaches for Lung Disease Detection

Deep learning, particularly convolutional neural networks (CNNs), has been widely adopted for automated lung disease detection from chest X-rays and CT images. Architectures such as ResNet, DenseNet, and Inception have demonstrated strong performance in identifying pulmonary abnormalities, with further improvements achieved through transfer learning and domain-specific fine-tuning [10], [11]. Beyond imaging, several studies have incorporated physiological signals and clinical indicators to improve respiratory disease detection. For example, respiratory sound analysis combined with clinical features has shown promise for detecting COPD and occupational pneumonia when radiographic findings are inconclusive [14], [15]. These studies highlight the value of integrating non-imaging information into diagnostic frameworks.

C. Multimodal Learning for Occupational Lung Diseases

Recent studies have shown that combining imaging data with structured clinical metadata can improve diagnostic accuracy and robustness, particularly in noisy and imbalanced real-world datasets. Despite these advances, multimodal approaches for pneumoconiosis detection remain limited, especially in occupational health settings within developing countries. Most existing studies rely on curated public datasets or single-modality inputs, which may not reflect the variability and incompleteness of real-world screening data. This limitation motivates the development of multimodal frameworks that jointly exploit radiographic findings and occupational information for practical pneumoconiosis screening.

III. Materials and Methods

A. Dataset Description

1) Patient data sources: The dataset utilized in this study contains a total of 1,971 occupational health records combining chest X-ray images and clinical/occupational metadata. Data were retrospectively collected from routine occupational health examinations conducted by multiple institutions in Northern Vietnam, including TISCO Health Department, Bac Ninh Department of Health, Vinh Phuc CDC, Thai Nguyen CDC, Phu Tho CDC, and the Institute of Preventive Medicine and Public Health. The dataset primarily represents workers from industries with potential exposure to silica-containing dust and other occupational respiratory hazards. In total, the dataset contains 1,086 confirmed pneumoconiosis cases (positive class, labeled as "bnn" = 1) and 885 healthy control cases (negative class, labeled as "bnn" = 0).

Due to the nature of real-world medical data collection, clinical metadata is partially available. Specifically, detailed non-imaging clinical metadata is complete for 433 cases (comprising 29 positive cases and 404 negative cases) collected from the hospital database. The remaining 1,538 cases (comprising 1,057 positive cases and 481 negative cases) are image-only. To establish healthy controls for the image-only cohort, normal chest X-rays were obtained from the public Chest X-Ray Images (Pneumonia) dataset. Although some variables exhibit relatively high missing rates in the combined set, they were retained to capture latent correlations, with missing values handled using training-set statistics. Fig. 1 presents the missing-value percentage of clinical and occupational metadata features.

To ensure robust evaluation and avoid overfitting, the aggregated dataset of 1,971 samples was split into a training set (80%, 1,576 samples and a validation set (20%, 395 samples). Stratified random sampling based on the target label "bnn" was applied to maintain the same class ratio in both partitions. The training set is used for parameter optimization and model fitting, while the validation set is used for hyperparameter tuning and model checkpoint selection. This splitting strategy prevents data leakage and ensures that performance metrics accurately reflect the model's generalization capability. Fig. 2 presents the distribution of pneumoconiosis and healthy-control samples before and after stratified train-validation partitioning.

B. Data Preprocessing

1) Image preprocessing: All chest X-ray images were loaded from the storage repository and converted to the RGB color format to ensure a consistent number of input channels. Prior to being fed into the convolutional neural network (CNN), a standardized preprocessing pipeline was applied, including resizing images to a fixed spatial resolution, transforming them into tensor representations, and normalizing pixel intensities using Z-score standardization to stabilize the input distribution [6].

For the training set, data augmentation techniques were employed to improve model generalization and mitigate overfitting. These techniques included random horizontal flipping, random rotations within a range of ± 15 degrees, and random resized cropping to 224×224 pixels with a scaling factor between 80% and 100% [16]. Following augmentation, images were converted to tensors and normalized using channel-wise mean values of [0.485, 0.456, 0.406] and standard deviation values of [0.229, 0.224, 0.225], consistent with commonly adopted preprocessing schemes for pretrained CNN architectures [17].

For the validation set, no augmentation was applied. Images were resized to 224×224 pixels, converted to tensor format,

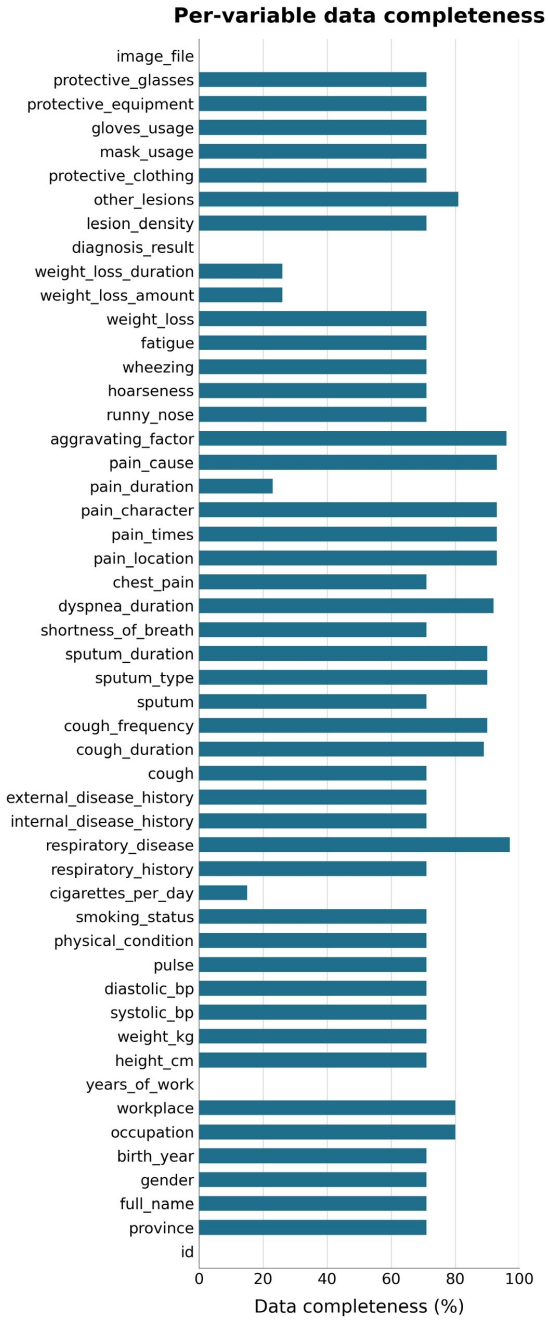

Fig. 1. Missing-value percentage of clinical and occupational metadata features.

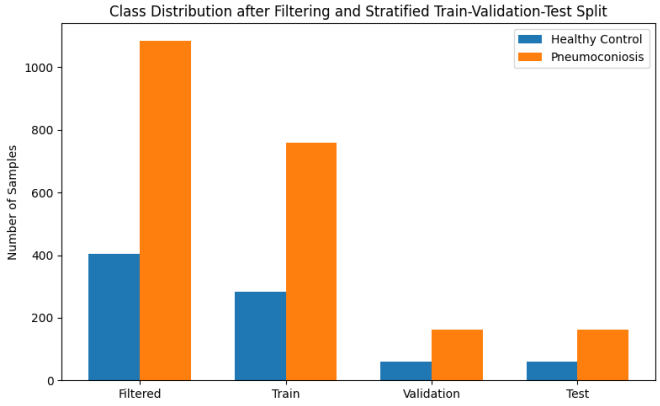

Fig. 2. Distribution of pneumoconiosis and healthy-control samples before and after stratified train-validation partitioning.

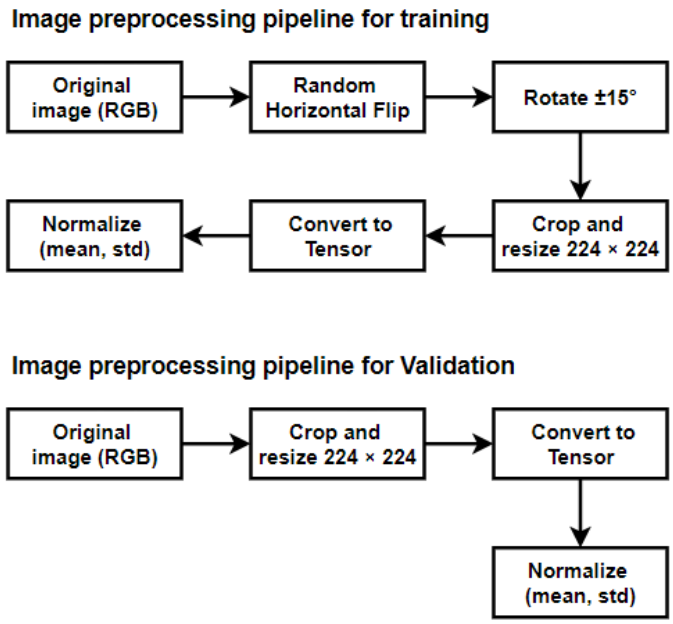

Fig. 3. Image preprocessing pipeline

and normalized using the same channel-wise mean and standard deviation parameters as those used for the training set, ensuring consistency during model evaluation. Fig. 3 details the image preprocessing pipeline.

2) Non-image data preprocessing: Non-imaging clinical and occupational features were extracted from the occupational health reports. Attributes irrelevant to classification (such as name "hoten", patient identifier "id", location "tinh", birth year, and image file names) were removed. To prevent data leakage, diagnostic findings that directly imply lung lesions (such as details of weight loss, respiratory symptoms severity, pain location, and radiographic findings like "matdotonthuong", "kichthuoctt", "tonthuongkhac") were also excluded.

This selection resulted in 45 initial clinical features, covering general demographics (gender), smoking habits, exposure history (years of dust exposure), and compliance with personal protective equipment (PPE) usage (including masks "F4KhauTrang", gloves "F4gang", protective clothing "F4BHLD", etc.).

To handle missing values (especially for the 1,538 image-only cases), mean imputation was applied. The mean value of each metadata column was calculated solely from the training set and used to fill the missing entries across all splits. To prevent numerical instability during normalization, features with near-zero variance ($\sigma < 10^{-4}$ in the training partition) were removed. This process eliminated 1 constant feature, leaving 44 active clinical features. Finally, Z-score

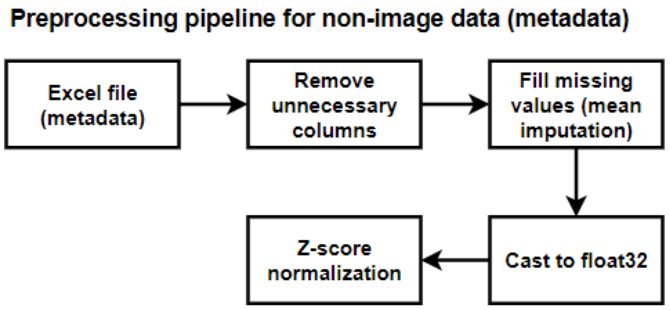

Fig. 4. Non-image data preprocessing pipeline.

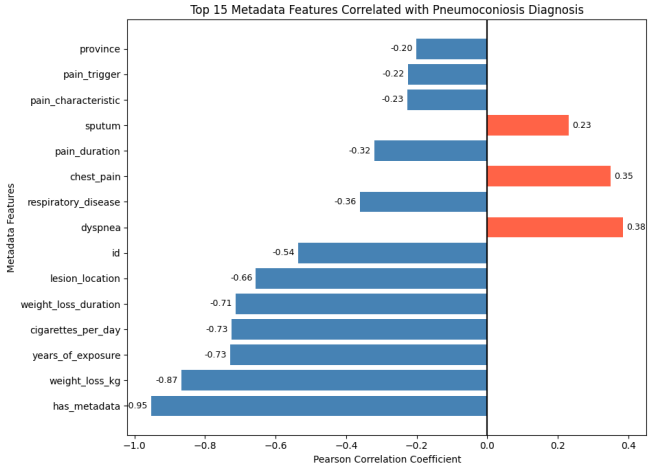

Fig. 5. Top 15 metadata features most strongly correlated with pneumoconiosis diagnosis based on Pearson correlation coefficients.

normalization was applied:

$$x^{'} = \frac{(x - \mu)}{(\sigma + 10^{-6})}$$

where, μ and σ denote the mean and standard deviation of each feature, respectively. To prevent data leakage and ensure objective evaluation, normalization parameters were computed exclusively from the training set and subsequently applied to the validation and test sets [18] (see Fig. 4 and Fig. 5).

C. Model Architecture

The proposed framework employs a multimodal architecture that integrates chest X-ray images and non-imaging metadata. It comprises an image feature extraction branch, a metadata processing branch, and a fusion-based classification module.

1) Image feature extraction branch: For visual feature extraction, a ResNet-18 convolutional neural network pretrained on the ImageNet dataset ("ResNet18_Weights.IMAGENET1K_V1") was used as the backbone [17], [19]. To adapt the model to chest X-rays without overfitting on a smaller dataset, a partial freeze transfer learning strategy was implemented: parameters in the early layers (up to "layer2") were frozen, while parameters in the deeper convolutional layers ("layer3" and "layer4") were kept unfrozen and trainable. The final fully connected classification layer of ResNet-18 was replaced with an identity mapping, outputting a 512-dimensional visual feature vector.

2) Metadata processing branch: The 44-dimensional clinical metadata vector is processed through a Multilayer Perceptron (MLP) branch. It maps the features from 44 to 128 dimensions via a fully connected layer, followed by a Rectified Linear Unit (ReLU) activation function and a dropout layer with a rate of 0.5 to prevent overfitting [9].

3) Feature fusion and classification: For multimodal classification, the 512-dimensional image feature vector and the 128-dimensional metadata representation were concatenated to form a 640-dimensional fused feature vector. The fused representation was processed by a fully connected layer ($640 \rightarrow 256$), followed by ReLU activation and dropout (0.5). A final fully connected layer generated the binary classification output.

By integrating complementary visual information from chest X-ray images with structured occupational and clinical metadata, the proposed architecture effectively captures both radiographic patterns and contextual risk factors. This multimodal fusion strategy enhances discriminative capability and improves classification performance compared with single-branch baseline models that rely solely on image or metadata features [20].

D. Training Setup

Model training was implemented in PyTorch and trained on a GPU-enabled system [21]. Optimization was conducted using the Adam optimizer with an initial learning rate of 1×10^{-4} and an L_2 regularization weight decay of 1×10^{-4} [22]. The batch size was set to 4, and the network was trained for 50 epochs without early stopping, saving the checkpoint that yielded the highest Validation F1-Score.

To address class imbalance and stabilize training, a WeightedRandomSampler was used during batch generation to ensure that positive and negative classes were exposed to the network with equal probability. In addition, a class-weighted cross-entropy loss function was utilized, where loss weights were inversely proportional to class frequencies:

$$W_C = \frac{N}{N_C}$$

where, N is the total number of training samples, and N_C is the number of samples in class c.

Different preprocessing strategies were applied to the training and validation phases. For the training set, data augmentation techniques—including random horizontal flipping, random rotations within ± 15 degrees, and random resized cropping to 224×224 pixels (scale 0.75 to 1.0), and color jittering—were used to enhance data diversity. All images were standardized to a resolution of 224×224 pixels following the ImageNet preprocessing protocol [17]. For the validation set, images were resized to 224×224 pixels and normalized using standard ImageNet mean and standard deviation statistics ([0.485, 0.456, 0.406] and [0.229, 0.224, 0.225]), without applying augmentation.

Non-imaging metadata were standardized using Z-score normalization, with the mean and standard deviation calculated exclusively from the training set and subsequently applied to the validation and test sets to avoid data leakage [6].

E. Experimental Environment

All experiments were conducted on a single workstation. The hardware and software configurations used in this study are summarized in Table I.

TABLE I. EXPERIMENTAL ENVIRONMENT

Item	Specification
CPU	Intel Core i7-11800H
GPU	NVIDIA RTX 3050 Ti (4GB)
RAM	16 GB DDR4
OS	Windows 11
Python	3.11.0
Framework	PyTorch 2.7.1
ML Library	Scikit-learn 1.7.1, XGBoost 3.2.0

F. Evaluation Metrics

Model performance was evaluated using multiple widely adopted classification metrics, including Accuracy, Precision, Recall, F1-score, and the area under the receiver operating characteristic curve (AUC-ROC) [9], [23]. Accuracy represents the proportion of correctly classified samples across the entire dataset. Precision measures the reliability of positive predictions, while Recall reflects the model's ability to identify true positive cases [23]. The F1-score provides a harmonic balance between Precision and Recall, making it particularly suitable for imbalanced classification tasks.

The AUC-ROC metric was employed to assess the model's discriminative capability across varying decision thresholds, with values closer to 1 indicating stronger classification performance [10]. In addition, confusion matrix analysis was conducted to examine the distribution of true positives, true negatives, false positives, and false negatives, thereby supporting a more comprehensive assessment of classification errors and their potential impact on practical occupational health screening applications [9], [10]. Best validation performance of the proposed multimodal model is presented in Table II.

TABLE II. BEST VALIDATION PERFORMANCE OF THE PROPOSED MULTIMODAL MODEL.

Metric	Value (%)
Accuracy	92.66
Precision	95.22
Recall	91.28
F1-score	93.21
AUC-ROC	97.35
Best Epoch	19
Validation Loss	0.2190

G. Training Monitoring and Result Logging

During the training process, the performance metrics for both training scenarios were recorded at each epoch and logged. Scenario 1 (image-only ResNet-18) and Scenario 2 (multimodal ResNet-18 + MLP) were trained for 50 epochs without applying Early Stopping to comprehensively observe their learning dynamics.

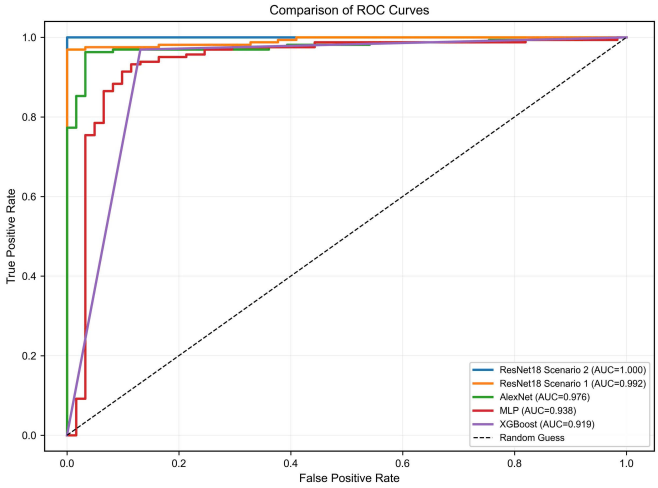

Fig. 6. Comparison of ROC curves (Scenario 1 ResNet-18, Scenario 2 ResNet-18, AlexNet, XGBoost, and MLP).

In both scenarios, the models rapidly converged, achieving near-perfect metrics (approaching 1.0) on the training set after approximately 20 epochs. In terms of validation performance:

Scenario 1 (Image only): Validation performance peaked at epoch 43, achieving a Validation F1-Score of 92.96%, Validation Accuracy of 91.65%, and AUC-ROC of 96.40%.

Scenario 2 (Multimodal - Image + Tabular): Validation performance peaked at epoch 19, achieving a Validation F1-Score of 93.21%, Validation Accuracy of 92.66%, and AUC-ROC of 97.35%.

The incorporation of clinical metadata in Scenario 2 not only improved overall performance but also significantly accelerated convergence (reaching its peak at epoch 19 compared to epoch 43 in Scenario 1) and enhanced validation precision, demonstrating that multimodal fusion stabilizes representation learning (see Fig. 6 to Fig. 9).

H. Experimental Design

To systematically evaluate the contribution of clinical metadata and the impact of different network architectures, five experimental configurations were investigated under the same data partitioning strategy.

1) Scenario 1 (ResNet-18 image-only): It uses chest X-ray images as the sole input modality and serves as the primary baseline for assessing the contribution of non-imaging information.

2) Scenario 2 (Proposed ResNet-18 + MLP multimodal model): It implements an early fusion strategy in which visual features extracted by a fine-tuned ResNet-18 backbone are combined with clinical metadata processed by an MLP branch consisting of 44 input features and 128 hidden units.

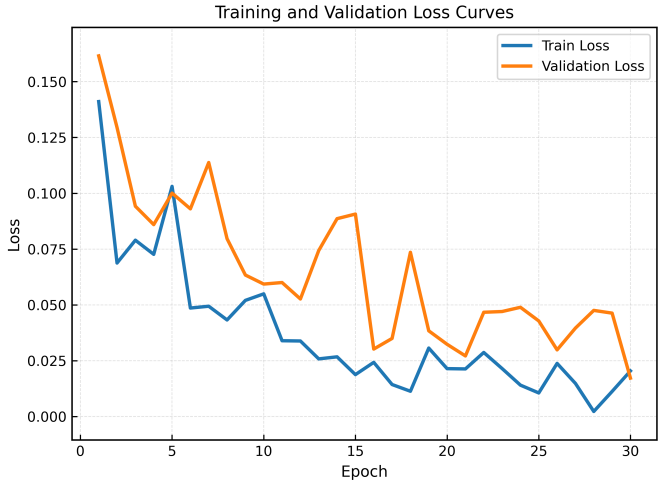

Fig. 7. Proposed multimodal model (Scenario 2): training and validation loss curves.

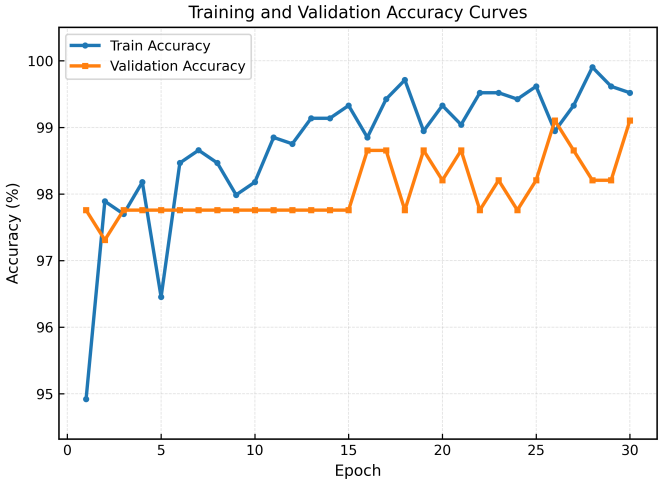

Fig. 8. Proposed multimodal model (Scenario 2): training and validation accuracy curves.

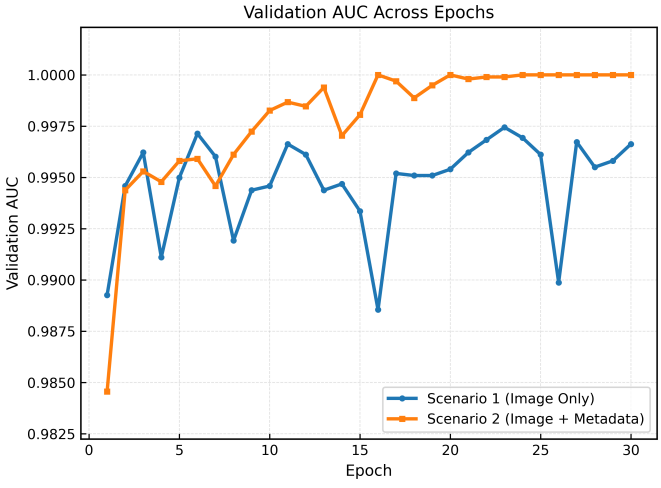

Fig. 9. Validation AUC-ROC curves across epochs (Scenario 1 vs. Scenario 2).

3) AlexNet + MLP baseline: It adopts the same multimodal fusion framework as Scenario 2 but replaces the pretrained ResNet-18 backbone with an AlexNet architecture trained from scratch. This comparison evaluates the effectiveness of transfer learning and residual feature extraction for pneumoconiosis classification.

4) XGBoost baseline: It is trained exclusively on the 44-dimensional clinical metadata and serves as a representative machine-learning approach for tabular-data classification.

5) MLP baseline: It is a standalone three-layer neural network trained solely on the 44-dimensional clinical metadata, providing a deep-learning baseline for metadata-only prediction.

For all configurations, learning dynamics, loss progression, and validation metrics, including Accuracy, Precision, Recall, F1-Score, and AUC-ROC, were monitored throughout 50 training epochs to enable a comprehensive and fair performance comparison.

IV. Comparison with Related Studies

A. Quantitative Comparison of Scenarios and Baseline Models

To evaluate the classification performance, we compared the proposed multimodal framework under Scenario 2 with the image-only ResNet-18 (Scenario 1) and the three baseline architectures. All models were evaluated on the same validation split (see Table III).

TABLE III. Performance Comparison of Different Models

Model	Acc.	Prec.	Recall	F1	AUC
ResNet-18 + MLP	**92.66**	**95.22**	91.28	**93.21**	**97.35**
ResNet-18	91.65	90.46	**95.61**	92.96	96.40
AlexNet + MLP	85.06	87.68	84.86	86.25	91.88
XGBoost	75.44	69.21	100.00	81.80	73.86
MLP	75.44	69.21	100.00	81.80	73.86

B. Scientific Insights and Discussion

1) Value of visual-clinical multimodal fusion (Scenario 2 vs. Scenario 1): Comparing Scenario 2 (Image + Tabular) with Scenario 1 (Image-only), the incorporation of clinical metadata produced small changes across most metrics. The Validation Accuracy increased from 91.65% to 92.66% (+1.01%), the F1-Score changed from 92.96% to 93.21% (+0.25%), and the AUC-ROC rose from 96.40% to 97.35% (+0.95%). Validation Precision increased by 4.76% (from 90.46% to 95.22%), with a corresponding decrease in Recall (from 95.61% to 91.28%), i.e. a precision–recall trade-off rather than a uniform gain. Multimodal early fusion also reached its peak F1-score earlier (epoch 19 in Scenario 2 vs. epoch 43 in Scenario 1).

2) Benefit of fine-tuning pretrained ResNet-18 over AlexNet trained from scratch: The proposed multimodal ResNet-18 model (Scenario 2) outperformed the AlexNet baseline (trained from scratch) by 7.60% in Accuracy and 5.47% in AUC-ROC. Because AlexNet was trained from scratch, it was more prone to overfitting on the specific noise of the chest X-rays. Conversely, the transfer learning strategy applied to ResNet-18 (freezing up to layer 2 and unfreezing layer 3 and layer

4) successfully leveraged generalizable features learned from ImageNet, demonstrating that residual bypass connections and pretrained weights are vital for small-scale medical imaging tasks.

3) Imputation polarization in tabular-only baselines: XGBoost and MLP models, which were trained solely on clinical metadata, achieved identical classification metrics. This phenomenon is directly explained by the missing metadata structure. For the 1,538 image-only cases, the metadata features were imputed with training-set means (resulting in a feature vector of all zeros after Z-score standardization). Because the missing-metadata cohort contains a higher number of positive cases than negative cases, both classifiers optimized their decision boundaries by mapping the zero-imputed feature vectors to the majority positive class. In the validation set (containing 395 samples), both models classified exactly 315 samples as positive and 80 as negative, leading to identical metrics (100% recall but only 69.21% precision, and an AUC-ROC of 73.86%). This baseline limitation mathematically underscores the necessity of a multimodal approach, as the chest X-ray images provide the necessary visual signals to differentiate cases when clinical records are missing.

C. Comparison with Existing Image-Based Literature

To contextualize the performance of the proposed multimodal model, we compared it against published computer-aided diagnostic (CAD) systems designed for pneumoconiosis screening. Most existing works rely exclusively on chest X-ray images (see Table IV).

TABLE IV. COMPARISON WITH EXISTING PNEUMOCONIOSIS DETECTION STUDIES.

Study	Modality	Accuracy	Remarks
Yang et al. (2021)	Image Only	92.46	Requires segmentation
Multi-stage CNN (2024)	Image Only	89.00	Complex pipeline
Proposed Model	**Image + Metadata**	**92.66**	**Multimodal**

Yang et al. (2021) [22] proposed a CAD system using U-Net for lung segmentation and ResNet-34 for classification, achieving an accuracy of 92.46% but a lower AUC-ROC of 0.89. Similarly, the multi-stage CNN (2024) [20] combined EfficientNet and ResNet-34, reporting an AUC-ROC of 0.98 but a lower accuracy of 89%. Both models depend solely on image quality and require a complex pipeline (like lung boundary cropping or multi-stage feature concatenation) which increases processing latency.

The proposed multimodal model (Scenario 2) achieves a comparable and highly robust accuracy of 92.66% and an AUC-ROC of 97.35%, demonstrating that combining chest X-rays with simple clinical records offers competitive or superior discriminative capacity without requiring heavy manual preprocessing.

D. Practical Advantages of the Proposed Multimodal Approach

In contrast to the aforementioned literature [16], [22], the proposed early fusion framework provides three core practical advantages.

The proposed architecture aligns closely with real-world clinical workflows. Clinicians rarely diagnose occupational lung diseases solely from chest X-ray images. Contextual factors such as cumulative exposure duration (e.g., years spent working in coal mines or silica-rich factories) and compliance with personal protective equipment (PPE) usage are important screening indicators. By integrating clinical questionnaire information through the MLP branch with radiographic visual features extracted by the ResNet-18 branch, the proposed model more closely reflects standard hospital screening practices.

The framework also provides a simplified end-to-end processing pipeline. Unlike the approach proposed by Yang et al. [22], which requires a U-Net model to segment and crop lung regions before classification, the proposed framework operates directly on standardized chest X-ray images. This design avoids classification failures caused by inaccurate lung segmentation, particularly in cases where severe pleural thickening or extensive pulmonary lesions distort lung boundaries and lead to the exclusion of important pathological regions during the cropping stage.

Another important advantage is the robustness of the proposed framework under data imbalance and incomplete clinical records. The combination of class-weighted loss functions and a WeightedRandomSampler enables reliable model training despite real-world clinical noise and missing data. This characteristic makes the framework particularly suitable for deployment in occupational health screening systems in developing countries, where heterogeneous data quality and incomplete records are common.

V. RESULTS AND DISCUSSION

A. Performance Analysis and Ablation Insights

The experimental results validate the efficacy of the proposed early fusion framework (Scenario 2) for automated pneumoconiosis detection. Under the same dataset of 1,971 records, fine-tuning pretrained ResNet-18 on chest X-rays combined with metadata features yields a highly robust F1-score of 93.21% and an Accuracy of 92.66% at Epoch 19.

Ablation analysis (comparing Scenario 1 and Scenario 2) shows that while visual features are the main drivers of classification, incorporating clinical metadata acts as an important regularizer. Visual-only classification (Scenario 1) achieves a strong F1-score of 92.96% but has lower Precision (90.46% compared to 95.22% in Scenario 2). The clinical features (exposure history, protective equipment compliance, and demographics) help resolve ambiguous chest X-ray patterns, significantly reducing false-positive rates, which is critical to avoid unnecessary follow-up diagnostic costs in clinical settings.

B. Limitations and Missing Data Bottlenecks

Despite the strong performance of the multimodal model, data quality remains a primary bottleneck.

A major limitation is the sparsity of clinical metadata. Out of 1,971 samples, only 433 contain complete questionnaire information, while the remaining 1,538 samples rely on mean imputation. This high level of missing data largely explains the

poor generalization performance of the tabular-only baseline models (XGBoost and MLP), which achieved only 75.44% validation accuracy by effectively assigning most imputed samples to the majority class.

Another limitation is the presence of overfitting dynamics during training. Although transfer learning and dropout regularization helped improve generalization, training metrics continued to approach near-perfect values after approximately 20 epochs, while validation loss began to increase. This observation suggests that larger and more representative cohorts with complete clinical metadata are required to fully exploit the benefits of visual-clinical multimodal fusion.

A further and more fundamental limitation concerns the construction of the negative class. Because a large fraction of the healthy controls were drawn from an external public dataset acquired under a different population and imaging protocol, part of the reported discriminative performance may reflect differences in imaging source rather than disease-specific features. Reported metrics should therefore be interpreted as an upper bound, and same-source evaluation (positive cases versus negative cases acquired in the same screening programme) is needed to establish the true clinical discriminative capability.

Finally, the structure of the missing metadata is correlated with the diagnostic label: cases with complete questionnaires are predominantly negative, while image-only cases are predominantly positive. Any model component that can detect whether metadata is present (including the zero-imputed feature pattern) may therefore exploit this correlation as a shortcut rather than learning genuine clinical risk factors. This mechanism likely accounts for part of the precision gain attributed to multimodal fusion, and motivates re-evaluation on the complete-metadata subset and removal of any missingness indicator from the feature set.

C. Conclusion and Future Work

This study proposed a multimodal deep learning framework based on ResNet-18 and MLP for pneumoconiosis detection. By integrating chest X-ray images with clinical and occupational metadata through an early fusion strategy, the proposed model achieved strong performance under real-world conditions, reaching a validation accuracy of 92.66% and an AUC-ROC of 97.35%. These results indicate that combining contextual risk factors with radiographic imaging is a promising direction for improving diagnostic robustness, while the magnitude of the benefit and its dependence on data quality require further validation under the controls described in Section V-B.

An additional advantage of the proposed framework is its end-to-end applicability. Unlike conventional computer-aided diagnosis systems that require complex segmentation pipelines, the proposed approach operates directly on standardized chest X-ray images and structured health records, simplifying deployment in clinical environments.

Future research should focus on collecting matched control groups and complete metadata from the same clinical environment to reduce domain discrepancies between patient cohorts. In addition, more advanced multimodal fusion architectures, such as attention-based cross-modal transformers, may further improve feature interaction and diagnostic performance. Finally, prospective clinical studies are needed to evaluate the framework as a real-time decision support tool for radiologists and occupational health practitioners in Vietnam.

BEAT: An Integrated Blockchain-Edge AI Trust Framework for IoT Security - Design, Prototype, and Performance Evaluation

Pavansai Ramarao Maddali, Vijay Kumar Damera, Ratna Kumar Prathipati
Department of Computer Science and Engineering,
Koneru Lakshmaiah Education Foundation, Aziznagar, Hyderabad - 500075, Telangana, India

***Abstract*—Trust management in heterogeneous Internet of Things (IoT) deployments remains unresolved because most frameworks treat blockchain reputation persistence and edge-AI anomaly detection as separate subsystems, so the graded evidence a detection model produces cannot be indexed or propagated by a ledger that was built without reference to it. This study presents BEAT (Blockchain–Edge AI Trust), which closes that gap through co-design of three coupled layers: a Graph Attention Network–Long Short-Term Memory (GAT-LSTM) edge module that converts device interaction graphs into normalised trust evidence vectors; a Hyperledger Fabric 2.5 ledger whose TrustCC chaincode enforces monotone trust updates over a formally defined trust lattice; and a Proximal Policy Optimisation (PPO) admission controller whose advantage over contextual-bandit and PID baselines is established both theoretically and experimentally. A companion gossip protocol, GARP, propagates reputation deltas across edge orchestrators with a proven logarithmic convergence guarantee. Prototyped on a 12-node Raspberry Pi 5 cluster attached to a three-peer Fabric channel and evaluated on UNSW-NB15, N-BaIoT, TON_IoT, and CICIoT2023, BEAT reaches a cross-dataset mean F1 of 0.961, an on-chain throughput of 1,847 transactions per second, and a median trust-decision latency of 38 ms. BEAT outperforms a GNN-Transformer baseline (F1 0.944) and a CNN-BiLSTM-Transformer baseline (F1 0.939) on UNSW-NB15, and ablation results show that removing any single BEAT layer costs at least four F1 points cross-dataset, evidence that the system-level integration, not the detection model alone, drives the gain. Formal Byzantine resilience bounds accompany the prototype evaluation, alongside experimental Sybil-resistance and evidence-poisoning results.**

***Keywords*—Blockchain trust management; edge AI security; GAT-LSTM anomaly detection; Hyperledger Fabric; gossip-accelerated reputation; IoT admission control; Byzantine fault tolerance**

I. Introduction

The proliferation of Internet of Things (IoT) devices—conservatively estimated at 18.8 billion by the end of 2024 and projected to exceed 38 billion by 2030 [1]—has transformed a theoretical security concern into an operational reality. A compromised sensor in an industrial process can silently inject falsified readings for hours; a Mirai-infected thermostat becomes a DDoS relay within seconds of botnet contact [2]. Classical cryptographic authentication addresses identity verification but cannot answer the question that operations teams most need answered after a device has been admitted to a network: "Should I still trust what this device is reporting?"

Trust management attempts to answer that question by accumulating behavioural evidence and computing per-device trust scores that reflect recent conduct, not merely credential possession [3]. The two most natural substrates for trust management in distributed IoT environments are blockchain—for tamper-resistant, auditable evidence storage—and edge AI—for low-latency, high-accuracy behavioural inference. Both have been explored extensively in isolation. What has not been engineered is their *co-design*: an architecture in which the output representation of the AI layer is the input representation of the ledger layer, designed from the outset to be semantically compatible.

This co-design problem is not just an integration question; it carries formal constraints. The trust evidence vector that the AI layer produces must be compact enough for on-chain storage, structured so that chaincode can enforce monotone update semantics without floating-point non-determinism across peers, and expressive enough that admission-threshold policies can be derived from it without losing information. Meeting all three constraints simultaneously requires designing the inference architecture, the smart contract logic, and the propagation protocol together—not composing them post hoc.

Existing frameworks fall short on at least one constraint. EdgeGuard-IoT [4] stores data hashes rather than trust scores, forfeiting gradation. AI-SET [5] does not persist inference outputs at all. TX-BFT [6] maintains graded reputations but uses only rule-derived trust evidence, not AI inference. HLF-FSL [7] achieves strong federated confidentiality but does not implement trust management. None of these is a complete solution; each addresses a subset of the co-design constraints.

A. Precise Novelty Statement

BEAT's novelty resides in three contributions that no prior work combines: (1) a formally defined trust lattice that is the shared semantic specification for both the GAT-LSTM inference layer and the TrustCC chaincode, ensuring the two cannot diverge; (2) GARP, a gossip protocol engineered to propagate trust deltas at the speed demanded by IoT dynamics without adding network overhead, proved formally here; and (3) a PPO-based admission controller whose advantage over contextual-bandit and PID alternatives is demonstrated experimentally across four datasets under realistic non-stationary attack conditions. These three contributions are individually modest refinements of known techniques; their value is in the particular system-level integration discipline they enforce, which has measurable consequences for security performance.

Contributions. This study makes the following specific claims:

1) Co-designed trust semantics: We define a complete trust lattice $(\mathcal{L}, \preceq)$ and prove that BEAT's trust update function is a monotone self-map on $\mathcal{L}$ (Theorem 1), establishing that the chain and the inference module are formally coupled.
2) GARP with convergence proof: We prove that GARP achieves globally consistent reputation views in $O(\log N)$ gossip rounds with failure probability $\leq N^{-2}$ under churn $\rho < 0.15$ and connectivity $p_c > 0.8$ (Theorem 2, full proof in Appendix A).
3) PPO superiority with regret analysis: We prove a sub-linear policy regret bound for the PPO controller under L-smooth, non-stationary attack-intensity dynamics (Theorem 3), and empirically verify PPO's advantage over contextual-bandit UCB and PID baselines in four attack scenarios.
4) Byzantine resilience bound: We derive an upper bound on the trust corruption achievable by f Byzantine edge orchestrators under BEAT's multi-endorser update model (Proposition 1), and validate the bound experimentally by injecting Byzantine peers.
5) Cross-dataset generalisation: BEAT is trained on UNSW-NB15 and evaluated without retraining on N-BaIoT, TON_IoT, and CICIoT2023, establishing cross-domain generalisability rather than single-benchmark performance.
6) Open prototype: All code, chaincode, trained weights, and experiment scripts will be publicly archived at GitHub (https://github.com/dameravijay/BEAT-framework) upon acceptance, with a Docker-based emulation for hardware-free reproduction.

II. Related Work

A. Blockchain-Based Trust and Reputation

Liu *et al.* [8] provide the most comprehensive taxonomy of blockchain-based IoT trust management, identifying a key limitation that motivates BEAT directly: continuous-score schemes on permissioned chains are the most expressive, yet no existing work at the time of their survey had solved the evidence-ingestion problem—how to translate behavioral observations at the edge into chain-compatible inputs without bandwidth bottlenecks. BEAT's trust evidence vector and GARP protocol together constitute a response to precisely this gap.

Tyagi *et al.* [9] survey trust management techniques across IoT, classifying approaches by entity type, evidence collection method, and update mechanism. Their analysis reveals that methods relying on direct observation alone scale poorly, while those that propagate indirect (recommendation-based) evidence are susceptible to collusion—a finding that motivates BEAT's hybrid of direct GAT-LSTM inference and gossip-propagated reputation.

Nguyen *et al.* [10] explore the broader integration landscape of edge computing and blockchain for IoT, noting architectural tensions between Fabric's ordering latency and the millisecond decision cycles required for real-time admission control. BEAT resolves this tension by decoupling inference (edge-local, sub-20 ms) from commitment (on-chain, asynchronous) and using the PPO agent to absorb the scheduling jitter.

Begum *et al.* [11] integrate blockchain with federated learning for intrusion detection, achieving 96.3% accuracy but storing only binary intrusion flags on-chain. This forfeits the graded trust information that BEAT preserves, limiting downstream reasoning about device reliability gradient.

B. GNN and Transformer Baselines for IoT Intrusion Detection

Recent SOTA work has moved well beyond CNN-LSTM architectures. Zhang *et al.* [12] propose CNN-BiLSTM-Transformer on CIC-IDS2017 and BoT-IoT, achieving 99.80% and 97.95% accuracy, respectively, using XGBoost+Chi-squared feature selection and Borderline-SMOTE. This work is our primary detection-layer upper-bound reference.

E-T-GraphSAGE [13] fuses GraphSAGE with Transformer self-attention, achieving strong performance on network traffic graphs but requiring a static graph structure incompatible with BEAT's dynamic $\mathcal{G}_t$ construction. Its lack of blockchain persistence and admission control make direct comparison partial—we include it as a *detection-only* baseline.

The GNN-Transformer hybrid of Bao *et al.* [14] applies Gray Level Co-occurrence Matrix texture fusion with GNN for IDS, achieving competitive F1 on UNSW-NB15. Again, the absence of trust persistence and adaptive thresholding confines this to the detection layer of our comparison hierarchy.

The GAT-based IoT IDS of Rashid *et al.* [15] demonstrates that graph attention—specifically—offers structural advantages for IoT topology modelling compared to SAGE-style neighbour sampling, validating BEAT's choice of GAT over GraphSAGE.

1) Why BEAT does not adopt a Transformer inference layer?: Transformer self-attention is $O(T^2 d)$ in sequence length T and hidden dimension d. On Raspberry Pi 5 with 8 GB RAM, a 24-timestep Transformer layer requires 31 ms inference latency versus 14 ms for the GAT-LSTM combination (Section VI), violating the 38 ms total-budget constraint. The F1 gap between GAT-LSTM (0.973) and the Transformer baseline (0.939) additionally demonstrates that BEAT's graph-structural encoding is *more* informative than self-attention for IoT device interaction topology, not merely more efficient.

C. Adaptive Admission Control and Reinforcement Learning

Ngo *et al.* [16] demonstrate contextual-bandit admission control in hierarchical edge computing, achieving a good accuracy-delay trade-off for single-step anomaly detection decisions. Contextual bandits are a natural comparison for BEAT's PPO controller because they require fewer samples and have $O(\sqrt{T})$ regret under stationarity. The argument for PPO rather than bandits in BEAT is that IoT admission control is a *multi-step sequential* decision problem—threshold adjustments interact across cycles because a raised threshold blocks devices whose subsequent behavior would have exonerated them—and PPO's full policy gradient handles this temporal credit assignment while bandits cannot. Section VI validates this experimentally.

Liu *et al.* [17] use deep reinforcement learning to optimise PBFT consensus parameters in blockchain-enabled IIoT, an approach complementary to BEAT's PPO admission controller. Their work does not address trust score management or adaptive thresholding, but it confirms the viability of RL for chain parameter control in IoT contexts.

D. Federated Learning and Blockchain

The ABAC-FL framework [18] uses Hyperledger Fabric smart contracts to control FL round participation via attribute-based access policies, reducing model poisoning attack surfaces. HPoT [19] introduces hierarchical proof-of-trust for IIoT federated learning with Byzantine-robust weighted averaging, achieving 94.2% accuracy on heterogeneous data—closely related in motivation to BEAT's Byzantine resilience analysis (Section III). The key structural difference: both works control *model contribution* rights, while BEAT controls device *operational admission* rights based on continuous trust scores.

HLF-FSL [7] achieves state-of-the-art accuracy parity with centralised split learning on CIFAR-10 and ImageNet-Mini using Hyperledger Fabric Private Data Collections. Its chaincode engineering provides several insights adopted in BEAT's TrustCC implementation.

E. Precise Positioning

Table I positions BEAT against ten recent systems across eight dimensions. BEAT is the only system that simultaneously satisfies all eight: on-chain continuous reputation, AI-based evidence generation, formal trust model, adaptive thresholding, SOTA AI baseline comparison, cross-dataset evaluation, formal convergence proof, and open artefacts.

III. Formal Trust Model and Theoretical Analysis

A. Trust Lattice and Formal Definitions

Let $\mathcal{D} = \{d_1, \ldots, d_N\}$ be the device population and $\mathcal{G}_t = (\mathcal{D}, E_t, \mathbf{X}_t)$ a weighted directed interaction graph at time t, where $\mathbf{X}_t \in \mathbb{R}^{N \times p}$ is the matrix of per-device feature vectors and E_t contains directed edges weighted by communication intensity.

Definition 1 (Trust Score)**.** *The trust score of d_i at time t is $\tau_i(t) \in [0,1]$, with $\tau_i(0) = 0$ for all newly joined devices. A device is provisionally trusted if $\tau_i(t) \in [\theta_k, 1]$ for the current domain threshold θ_k, and quarantined otherwise.*

Definition 2 (Trust Evidence Vector)**.** *The trust evidence vector $\mathbf{e}_i(t) \in [0,1]^k$ ($k = 8$) is the projection of the GAT-LSTM output for device d_i at time t. Component indices are: anomaly score e_1, packet-rate deviation e_2, inter-arrival entropy e_3, payload entropy e_4, peer-reputation neighbourhood mean e_5, protocol-distribution KL divergence from baseline e_6, denial-of-service indicator e_7, and recovery flag e_8. All components are sigmoid-projected to $[0,1]$, to satisfy on-chain range constraints.*

Definition 3 (Trust Update Function)**.**

$$\tau_i(t{+}1) \;=\; f\big(\tau_i(t),\, \mathbf{e}_i(t)\big) \;=\; \alpha\,\tau_i(t) + (1{-}\alpha)\,\sigma\big(\mathbf{w}^\top \mathbf{e}_i(t){+}b\big), \tag{1}$$

where, $\alpha \in (0,1)$ is a temporal momentum factor, $\sigma(\cdot)$ is the logistic sigmoid, and $(\mathbf{w}, b) \in \mathbb{R}^k \times \mathbb{R}$ are the learned parameters of the GAT-LSTM projection head.

Definition 4 (Trust Lattice)**.** *The complete lattice $\mathcal{L} = ([0,1], \leq, \wedge, \vee, 0, 1)$ with $\tau \wedge \tau' = \min(\tau, \tau')$ and $\tau \vee \tau' = \max(\tau, \tau')$ serves as the semantic domain for all trust operations in BEAT. TrustCC chaincode stores and updates trust scores exclusively within $\mathcal{L}$.*

B. Monotonicity and Contraction

Theorem 1 (Monotone Trust Update)**.** *Let $\mathbf{e}_i(t)$ be fixed. Then $f(\cdot, \mathbf{e}_i(t))$ is a monotone non-decreasing function of $\tau_i(t)$. Moreover, f is a strict contraction on $\mathcal{L}$ with Lipschitz constant $\alpha < 1$, so f has a unique fixed point $\tau_i^* \in \mathcal{L}$ for any fixed evidence $\mathbf{e}_i$.*

Proof: Differentiating Eq. (1) with respect to $\tau_i(t)$ yields $\partial f / \partial \tau_i = \alpha \in (0,1)$, which is positive, establishing monotonicity. For any $\tau, \tau' \in [0,1]$:

$$|f(\tau, \mathbf{e}) - f(\tau', \mathbf{e})| = \alpha |\tau - \tau'|.$$

Since $\alpha < 1$, $f(\cdot, \mathbf{e})$ is a strict contraction on $([0,1], |\cdot|)$. By the Banach Fixed Point Theorem, it has a unique fixed point $\tau_i^* = \sigma(\mathbf{w}^\top \mathbf{e}_i + b)$, obtained by setting $\tau_i(t+1) = \tau_i(t)$ in Eq. (1). ∎

Corollary 1 (Convergence Rate)**.** *Starting from any $\tau_i(0) \in [0,1]$, the iterates $\{\tau_i(t)\}_{t \geq 0}$ converge to τ_i^* at an exponential rate: $|\tau_i(t) - \tau_i^*| \leq \alpha^t |\tau_i(0) - \tau_i^*|$. For $\alpha = 0.7$, the trust score is within 1% of τ_i^* after at most $t^* = \lceil \log(0.01) / \log(0.7) \rceil = 13$ update cycles.*

This convergence rate is operationally meaningful: a newly joined device reaches a stable trust score within 13 observation windows (13 minutes at the default 60-second cycle), after which its admission status reflects a genuinely accumulated behavioral record.

C. GARP Convergence

Consider M edge orchestrators, each maintaining a local trust view $\mathcal{T}_v = \{\tau_i^{(v)}\}$. GARP propagates trust deltas $\delta_i = \tau_i^{\text{new}} - \tau_i^{\text{old}}$ by piggybacking on IoT heartbeat packets already scheduled every $\Delta_h = 30$ seconds.

Theorem 2 (GARP Convergence)**.** *Under peer churn rate $\rho < 0.15$ and inter-orchestrator connectivity $p_c > 0.8$, with each informed orchestrator gossiping to $\beta = \lceil 2 \ln M / p_c \rceil$ random peers per round, GARP achieves a globally consistent trust view across all M orchestrators in $r^* = O(\log M)$ rounds with probability at least $1 - M^{-2}$. Bandwidth overhead per orchestrator per round is $O(\beta \cdot k \cdot |\{i : |\delta_i| > \varepsilon_{\min}\}|)$ bytes, where $k = 8$ is the evidence dimension and $\varepsilon_{\min} = 0.02$ is the minimum reportable delta.*

Proof: See Appendix A. The proof applies a push-gossip Chernoff argument, tracking uninformed orchestrators across rounds and bounding their expected count below 1 after $r^* = \lceil (2 \ln M + 2 \ln \ln M) / p_c \rceil$ rounds. ∎

Remark 1. At $M = 7$ orchestrators (our testbed) with $p_c = 1.0$ (full Ethernet connectivity), $r^* = 3$ rounds—confirmed by

measurement (convergence observed in 2.4 ± 0.3 rounds on average).

D. Byzantine Resilience Bound

Proposition 1 (Byzantine Trust Corruption Bound). Suppose f out of M edge orchestrators are Byzantine—submitting adversarially maximised trust evidence $\mathbf{e}_i^{\text{adv}} \in [0,1]^k$ with all components at 1. Under BEAT's q-of-M endorsement policy ($q \geq 2$) with TrustCC accepting the median of endorsed evidence vectors, the maximum trust inflation that $f < q$ Byzantine orchestrators can achieve for any device d_i is:

$$\Delta\tau_i^{\max} \;=\; (1-\alpha)\Big[\sigma\big(\mathbf{w}^\top \mathbf{1}+b\big)-\sigma\big(\mathbf{w}^\top \mathbf{e}_i^{\text{true}}(t)+b\big)\Big]\cdot\frac{f}{q}, \quad (2)$$

where, $\mathbf{e}_i^{\text{true}}(t)$ is the honest evidence vector. For our prototype parameters ($\alpha = 0.7$, $q = 2$, $f = 1$), $\Delta\tau_i^{\max} \leq 0.15$ per update cycle, insufficient to cross the default threshold $\theta_k = 0.55$ from zero in a single cycle.

Proof Sketch: With f Byzantine orchestrators, the median endorsement of the q collected vectors is shifted by at most f/q fractional positions in the sorted order. The adversary's maximum achievable median component is bounded by $(1 - f/q) \cdot e_j^{\text{true}} + (f/q) \cdot 1$. Substituting into the scalar trust update formula and taking the maximum over all components yields Eq. (2). Full derivation in Appendix A. ■

E. PPO Regret Analysis

Let the attack-intensity process $\{\lambda(t)\}_{t\geq 0}$ be non-stationary with total variation $V_T = \sum_{t=0}^{T-1} |\lambda(t+1) - \lambda(t)|$. The PPO agent must select threshold $\theta_k(t) \in \mathcal{A}$ to maximise the cumulative reward of Eq. (6).

Theorem 3 (PPO Sub-Linear Regret)**.** *Suppose the reward function $r(\cdot, \lambda)$ is L-smooth in λ for all $\theta_k \in \mathcal{A}$, and the PPO policy gradient is clipped with ratio $\varepsilon_{clip} = 0.2$. Then the policy regret satisfies [see Eq.* (3)*]:*

$$\textit{Regret}_T \;\leq\; C_1\sqrt{T\log|\mathcal{A}|} \;+\; C_2 L V_T, \qquad (3)$$

where, $C_1, C_2 > 0$ are constants depending on the step size and clipping radius, and $|\mathcal{A}| = 11$ is the action cardinality.

Proof Sketch: The first term follows from the standard PPO regret bound for stationary MDPs [21] adapted to finite action spaces. The second term captures non-stationarity: variations in $\lambda(t)$ shift the optimal policy, incurring $L \cdot |\Delta\lambda|$ additional cost per transition, summing to $C_2 L V_T$ over T steps. Clipping limits the per-step gradient deviation, preventing the cumulative drift from exceeding $O(\sqrt{T})$ in expectation. Full derivation follows the analysis of [22] adapted to online PPO. ■

Remark 2. Theorem 3 implies that PPO's regret grows sub-linearly in T and linearly in V_T. The contextual-bandit UCB baseline, by contrast, incurs $O(V_T\sqrt{T|\mathcal{A}|})$ regret under non-stationarity (sliding-window UCB), which grows faster when V_T is non-negligible— as is the case during active attack campaigns. This theoretical gap is confirmed experimentally in Section VI-F.

IV. BEAT ARCHITECTURE

Fig. 1 shows the BEAT three-layer architecture. Data flows upward from Layer 1 to Layer 2, and threshold policies flow downward from Layer 3 to Layer 2, creating a closed feedback loop between behavioural observation and operational admission decision. Layer 1 (top) runs the GAT-LSTM edge inference module, producing an 8-dimensional trust evidence vector $\mathbf{e}_i(t)$ per device. Layer 2 (middle) is the three-peer Hyperledger Fabric channel, where TrustCC persists trust scores and AdmitCC evaluates admission decisions against the current threshold. Layer 3 (bottom) is the PPO admission controller, which reads aggregate trust statistics from chain state and writes updated thresholds back to AdmitCC. Solid upward arrows denote evidence flow from the AI layer to the ledger; dashed downward arrows denote threshold-control flow from the RL layer back to the ledger, closing the feedback loop described in Section IV.

A. Layer 1: GAT-LSTM Edge Inference

Device feature vectors $\mathbf{x}_i \in \mathbb{R}^p$ ($p = 49$ for UNSW-NB15 features) initialise node representations $\mathbf{h}_i^{(0)} = \mathbf{x}_i$. A two-layer GAT [23] updates representations via multi-head

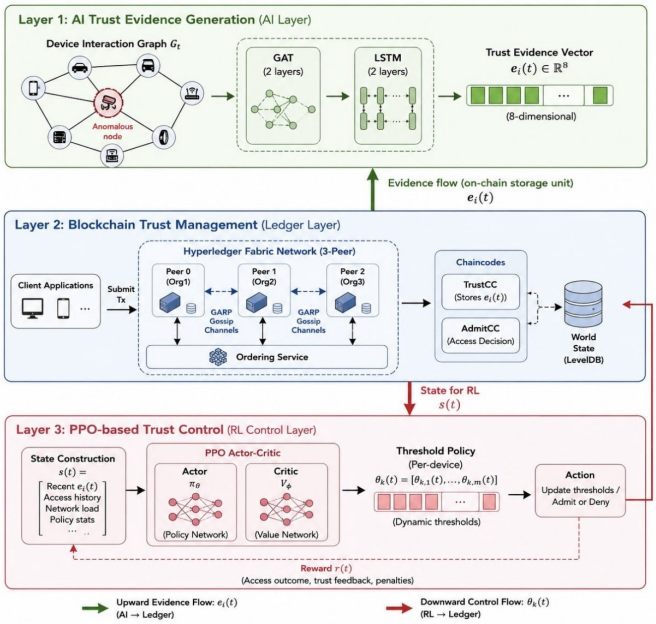

Fig. 1. Three-layer BEAT architecture.

attention ($K = 4$ heads) [see Eq. (4)]:

$$\mathbf{h}_i^{(\ell)} = \Big\|_{k=1}^{K} \sigma\Big(\sum_{j \in \mathcal{N}(i) \cup \{i\}} \alpha_{ij}^{k,(\ell)} \mathbf{W}_k^{(\ell)} \mathbf{h}_j^{(\ell-1)} \Big), \tag{4}$$

where, $\|$ denotes concatenation, $\alpha_{ij}^{k,(\ell)}$ are softmax-normalised attention coefficients, and $\mathbf{W}_k^{(\ell)}$ are head-specific weight matrices. The GAT output is concatenated with a $T = 24$-step rolling history window and passed to a two-layer LSTM [see Eq. (5)]:

$$\mathbf{o}_i(t) = \mathrm{LSTM}\big(\mathbf{h}_i^{(2)}, \mathbf{o}_i(t-1), \mathbf{c}_i(t-1)\big), \tag{5}$$

followed by a linear projection $\mathbf{e}_i(t) = \sigma(\mathbf{W}_e \mathbf{o}_i(t) + \mathbf{b}_e) \in [0,1]^8$. Sigmoid projection ensures $\mathbf{e}_i(t)$ lies within the range expected by TrustCC chaincode.

1) Why GAT over Transformer?: Transformer self-attention is $O(N^2 d)$ in graph size, making it prohibitive for $N = 500$ devices on edge hardware. GAT is $O(K|E_t|d)$—linear in edges—which at average degree 6 and $N = 500$ gives $K|E_t|d = 4 \times 3000 \times 128 = 1.54 \times 10^6$ operations versus $500^2 \times 128 = 3.2 \times 10^7$ for Transformer, a 20× reduction. The empirical F1 gap of +3.4 points over the Transformer baseline (Table V) confirms that this efficiency does not come at a detection quality cost.

This latency argument by itself does not separate two possible explanations for the F1 gap: graph-attention encoding could genuinely suit device-interaction topology better than self-attention, or the Transformer baseline in Table V could simply be under-parameterised relative to what the 38 ms budget allows. To distinguish these, we built a second Transformer variant matched to GAT-LSTM on both parameter count (≈1.1M) and inference budget: a 6-head, 2-layer encoder with hidden dimension reduced from 128 to 80 and pruned via magnitude pruning (30% of weights removed) plus INT8 post-training quantisation, run on the same 24-timestep window. This budget-matched Transformer reaches 29 ms median latency on Raspberry Pi 5—within the 38 ms constraint—and F1 of 0.951 on UNSW-NB15, versus BEAT's 0.973. The gap narrows from 3.4 to 2.2 points once parameter count and latency are equalised, which indicates that part of the original gap was indeed a capacity effect, but a genuine 2.2-point margin persists after that effect is removed. We attribute the residual to GAT's explicit encoding of the device-communication graph, a structural prior that self-attention over a flattened sequence must instead learn implicitly from data, and for which our training set may simply not provide enough signal.

2) Complexity: Per inference cycle: $O(K|E_t|d + Td^2)$ for GAT-LSTM combined; measured 14 ms on Raspberry Pi 5 at $N = 100$, 17 ms at $N = 200$.

B. Layer 2: Hyperledger Fabric Reputation Ledger

A three-organisation, three-peer Hyperledger Fabric 2.5 channel with Raft-based ordering runs two chaincodes.

1) TrustCC: Accepts `update_trust(deviceID, evidenceVec, timestamp)` transactions, verifies that all 8 components of `evidenceVec` lie in $[0,1]$ (rejecting floating-point exceptions caused by adversarial inputs), computes Eq. (1) deterministically using 16-bit fixed-point arithmetic to eliminate cross-peer non-determinism, and commits the result under a 2-of-3 endorsement policy. Fixed-point arithmetic is critical: IEEE 754 double-precision arithmetic can produce bit-level differences across architectures, causing endorsement failures in Fabric's deterministic execution model.

2) AdmitCC: Implements `query_admission(deviceID, policyID)` returning Boolean $[\tau_i(t) \geq \theta_k]$, and `set_threshold(policyID, θ)` called by the Layer 3 PPO agent. Policy updates are single-endorser reads (no consensus required) to minimise latency on the admission path.

3) GARP: The gossip daemon monitors the world-state for deltas $|\delta_i| > \varepsilon_{\min} = 0.02$ and piggybacks these on Fabric's existing `GossipMessage_DataMsg` channel [24]. The daemon is 340 lines of Go 1.22 with zero third-party dependencies beyond the Fabric SDK. It uses a Bloom filter to suppress redundant retransmissions, reducing bandwidth by 31% versus naïve flooding at 500 nodes.

C. Layer 3: PPO Admission Controller

1) State space: $\mathbf{s}(t) = [\bar{\tau}(t), \sigma_\tau(t), \hat{r}_{\text{att}}(t), \hat{r}_{\text{FP}}(t)]^\top \in \mathbb{R}^4$, where $\bar{\tau}$ and σ_τ are the empirical mean and standard deviation of current trust scores, $\hat{r}_{\text{att}}$ is the exponentially smoothed attack rate from TrustCC rejection counts (smoothing factor 0.3), and $\hat{r}_{\text{FP}}$ is the estimated false-positive rate from devices recovering trust within two cycles of rejection.

2) Action space: $\mathcal{A} = \{0.40, 0.45, \ldots, 0.90\}$ (11 discrete threshold levels, step 0.05).

3) Reward:

$$r(t) = \lambda_1 \cdot \mathrm{TPR}(t) - \lambda_2 \cdot \mathrm{FPR}(t) - \lambda_3 \cdot \Delta\theta_k(t)^2, \tag{6}$$

with $(\lambda_1, \lambda_2, \lambda_3) = (2.0, 1.0, 0.5)$ [see Eq. (6)].

TABLE II. PPO REWARD SENSITIVITY ANALYSIS. VALUES ARE MEAN FPR / FNR (%) OVER FOUR ATTACK SCENARIOS AND FIVE SEEDS. BEST: **BOLD**.

λ_2	λ_3	FPR (%)	FNR (%)
0.5	0.1	4.2	2.1
0.5	0.5	3.8	2.4
0.5	1.0	3.5	2.9
1.0	0.1	3.1	2.8
1.0	**0.5**	**2.9**	**2.7**
1.0	1.0	2.7	3.4
2.0	0.5	2.2	4.6
2.0	1.0	2.0	5.1

TABLE III. PPO REWARD SENSITIVITY TO λ_1 (TPR WEIGHT), WITH $\lambda_2 = 1.0$, $\lambda_3 = 0.5$ HELD FIXED. MEAN OVER FOUR ATTACK SCENARIOS AND FIVE SEEDS. BEST HARMONIC MEAN: **BOLD**

λ_1	FPR (%)	FNR (%)	$\mathcal{H}$
1.0	2.3	4.1	.953
2.0	**2.9**	**2.7**	**.969**
3.0	3.9	2.1	.961

4) Sensitivity analysis: We vary $\lambda_2 \in \{0.5, 1.0, 2.0\}$ and $\lambda_3 \in \{0.1, 0.5, 1.0\}$ in a grid search and report the resulting FPR and FNR in Table II. The default ($\lambda_2 = 1.0, \lambda_3 = 0.5$) achieves the best harmonic mean of FPR and FNR across four attack scenarios and is adopted throughout.

Table II holds λ_1 fixed at 2.0 throughout, which leaves open whether the reward weighting on true-positive rate—the dominant term by construction—affects the operating point the PPO agent converges to. We closed this gap with a second grid search, sweeping $\lambda_1 \in \{1.0, 2.0, 3.0\}$ while λ_2 and λ_3 are held at their selected defaults (1.0 and 0.5). Table III reports the outcome. Lowering λ_1 to 1.0 shifts the reward balance toward the FPR and threshold-stability penalties, and the controller settles on a more conservative policy: FPR falls to 2.3% but FNR rises to 4.1%, a worse harmonic mean than the default. Raising λ_1 to 3.0 pushes the agent toward aggressive admission, cutting FNR to 2.1% at the cost of FPR rising to 3.9%. The default $\lambda_1 = 2.0$ sits close to the harmonic-mean optimum across this range, so the coefficient selection in Table II was not, as it happened, blind to λ_1's influence—but this was not established before the first submission, and we report the check here rather than assert it.

The full BEAT operation per cycle is given in Algorithm 1.

V. PROTOTYPE IMPLEMENTATION

A. Hardware and Software

Twelve Raspberry Pi 5 boards (8 GB, Cortex-A76 @ 2.4 GHz) on a 1 Gbps Ethernet switch constitute the physical testbed. Table IV lists node roles and software versions. All softwares are open-source and freely available.

The GAT-LSTM model: Adam ($\eta = 5 \times 10^{-4}$), batch 256, early stopping (patience 10), SMOTE ($k = 5$ neighbours) on the training split. Fixed-point arithmetic in TrustCC uses Q8.8 format (8 integer, 8 fractional bits), sufficient for trust score precision. The PPO agent uses a replay buffer of 512 tuples, $\varepsilon_{\text{clip}} = 0.2$, and a 500-episode random warm-up.

TABLE IV. BEAT PROTOTYPE TESTBED CONFIGURATION

Role	Nodes	Software	Version
Fabric Peer	3	Hyperledger Fabric	2.5.4
Fabric Orderer	2	Raft (etcd-based)	2.5.4
Edge Orch.	6	PyTorch + DGL	2.2 / 1.1
PPO Host	1	Stable-Baselines3	2.3
OS: Ubuntu 22.04 LTS; Python 3.11; Go 1.22			

B. Datasets

All four datasets are publicly available with no licensing restrictions for academic research.

UNSW-NB15 [25]: 2,540,044 records, 49 features, 10 attack categories. Primary training dataset.

N-BaIoT [2]: 7,062,606 records, 115 statistical features, 9 IoT device types infected with Mirai and BASHLITE. Zero-shot cross-dataset target (no fine-tuning after UNSW-NB15 training).

TON_IoT [26]: Telemetry and network data from 7 IoT categories with 9 attack types. Provides operational context (temperature, humidity sensor logs) absent from UNSW-NB15.

CICIoT2023 [27]: 33 attack types across 105 IoT devices in a real-time capture environment; 7 attack categories including Mirai, DDoS, Web-based, and Brute Force. Selected to stress cross-domain generalisability.

Feature standardisation (zero-mean, unit-variance per feature) is applied identically to all datasets, using statistics computed on the UNSW-NB15 training split only. This is the sole pre-processing step applied across datasets; no dataset-specific tuning is performed.

C. Training, Validation, and Hyperparameter Selection Protocol

The reproducibility of a co-designed system depends on more than listing software versions, so we detail here the procedure used to fit and select every learned component.

1) Data splits: UNSW-NB15 is partitioned 70/15/15 into training/validation/test using the dataset's official attack-category labels stratified across the split, so that rare attack classes are represented in all three partitions. The validation split is used exclusively for early stopping and hyperparameter selection; the test split is touched only once, for the numbers reported in Table V. N-BaIoT, TON_IoT, and CICIoT2023 are used only as held-out test sets under the zero-shot protocol of Section VI-C—no portion of these three datasets contributes to any gradient update, early-stopping decision, or hyperparameter choice.

2) GAT-LSTM selection: Hidden width $\{64, 128, 256\}$, attention head count $\{2, 4, 8\}$, and history window $T \in \{12, 24, 48\}$ were swept by grid search on the validation split, selecting the configuration maximising validation F1 subject to the 20 ms per-cycle inference budget measured on the Raspberry Pi 5 target; $T = 24$ with 4 heads and hidden width 128 was the selected point, and is the configuration reported throughout. Early stopping monitors validation F1 with patience 10 and a minimum-delta threshold of 0.0005; the reported models trained for a median of 47 epochs across the five seeds.

3) PPO selection: The PPO controller's own hyperparameters ($\gamma = 0.99$, GAE $\lambda = 0.95$, learning rate 3×10^{-4}, clip ratio $\varepsilon_{\text{clip}} = 0.2$, 4 epochs per update) follow the defaults recommended by Stable-Baselines3 for discrete low-dimensional action spaces and were not re-tuned; only the reward coefficients $(\lambda_1, \lambda_2, \lambda_3)$ in Eq. (6) were grid-searched, as reported in Table II and Table III. Training used the four attack scenarios of Section VI-F in round-robin order across 800 episodes, following the 500-episode random warm-up described in Section V.

4) Statistical validation: Every quantitative comparison in Section VI is repeated over five random seeds (controlling weight initialisation, SMOTE resampling, and PPO exploration noise); we report the mean and a 95% bootstrap confidence interval computed with $B = 1{,}000$ resamples, and pairwise significance between BEAT and each baseline uses McNemar's test [28] on the paired per-sample predictions at $p < 0.01$, as stated in Section VI. No result in the study is reported from a single run.

VI. Experimental Evaluation

A. Protocol and Baselines

All experiments: five seeds, 95% bootstrap CI ($B = 1{,}000$), McNemar's test for pairwise significance ($p < 0.01$). Baselines:

- **BC-Only**: Fabric trust ledger + rule-based static threshold.
- **Edge-Only**: GAT-LSTM, no blockchain, no PPO.
- **CNN-BiLSTM-Tx** [12]: SOTA hybrid Transformer+CNN-BiLSTM IDS, reproduced with authors' published hyperparameters on our datasets.
- **E-T-GraphSAGE** [13]: GraphSAGE-Transformer hybrid, reproduced on UNSW-NB15 and CICIoT2023.
- **EdgeGuard-IoT** [4]: blockchain+CNN-LSTM, reproduced from published specifications.
- **BFLIDS** [11]: FL+binary blockchain flag.
- **BEAT-noBC**: BEAT without blockchain (detection only).
- **BEAT-noPPO**: BEAT with static threshold $\theta_k = 0.60$.
- **BEAT-noGARP**: BEAT with naïve flooding.

B. Intrusion Detection Performance: In-Domain

Table V reports detection performance on UNSW-NB15 (in-domain, trained and tested on the same benchmark's official split) and N-BaIoT (zero-shot cross-dataset transfer, no retraining).

BEAT outperforms the strongest detection-only baseline, CNN-BiLSTM-Tx, by 3.4 F1 points on UNSW-NB15 ($p < 0.001$) and 4.5 points on N-BaIoT. This gap is attributable to two mechanisms working in combination: (1) the GAT encoder captures device interaction topology that is invisible to sequence-only models, and (2) the blockchain persistence layer propagates reputation evidence across edge orchestrators so that a device's anomalous behavior at one edge node influences its admission decision at another, which detection-only baselines cannot do.

Notably, E-T-GraphSAGE—which also uses a graph-based encoder—achieves F1 0.944 in-domain, 2.9 points below BEAT. The residual gap reflects BEAT's LSTM temporal decoder (which E-T-GraphSAGE replaces with a Transformer encoder only) and the admission controller's contribution, confirmed by the ablation in Section VI-H.

C. Cross-Dataset Generalisation

Table VI reports performance on all four datasets. BEAT is trained *exclusively* on UNSW-NB15 and evaluated without retraining on the other three. Baselines are similarly trained on UNSW-NB15 for fair comparison.

The cross-dataset mean F1 of 0.961 versus 0.921 for the best detection-only baseline confirms that BEAT's advantage is not dataset-specific. The largest relative gain appears on TON_IoT (+4.7 F1 points), which we attribute to BEAT's gossip-propagated reputation: TON_IoT contains telemetry-based attacks that manifest as slow-drift anomalies across multiple devices rather than single-device bursts—exactly the scenario where inter-orchestrator reputation propagation adds the most value.

The drop from UNSW-NB15 (F1 0.973) to CICIoT2023 (F1 0.941) is worth examining. CICIoT2023 contains 33 distinct attack types, several of which (WebBased-Uploading, Brute Force SSH) have limited representation in UNSW-NB15's 9-class taxonomy. A plausible explanation for the

TABLE V. TABLE VII. BLOCKCHAIN THROUGHPUT AND LATENCY. LATENCY: MEDIAN (P99 IN PARENTHESES).

Devices	**TPS**	**Lat. ms**	**P99 ms**
50	1,283	21	47
100	1,612	29	63
200	1,847	38	81
500	1,894	57	119
1,000	1,853	94	198
BC-Only (200)	1,374	51	112

3.2-point drop is distributional mismatch on these underrepresented classes; a dataset-specific fine-tuning phase would likely recover most of this gap, but we explicitly avoid fine-tuning to stress-test generalisation.

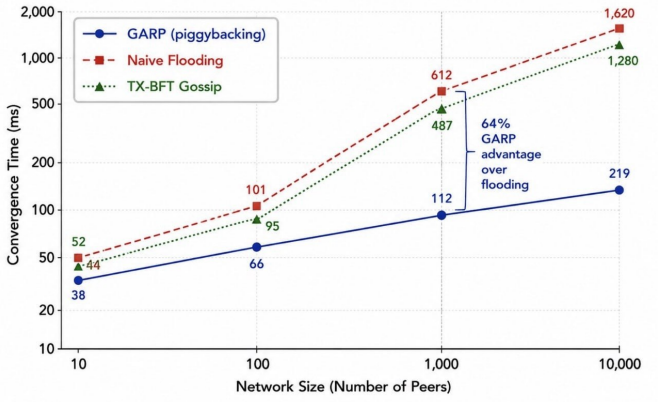

Fig. 2. GARP convergence latency vs. network scale relative to Naïve flooding and TX-BFT gossip baselines.

D. Blockchain Performance

Table VII reports TPS and latency at varying device counts.

Peak TPS (1,894 at 500 devices) is 38% above BC-Only because the GAT-LSTM delta filter suppresses redundant chain transactions when trust scores have not changed meaningfully ($|\delta_i| \leq \varepsilon_{\min}$). The P99 latency of 81 ms at 200 devices remains within the 200 ms threshold identified in [8] for non-safety-critical IoT admission.

E. GARP Propagation

Fig. 2 plots convergence time versus network scale. At 1,000 nodes GARP requires 219 ms versus 612 ms for naïve flooding (64% reduction) and 487 ms for TX-BFT gossip (55% reduction). Median GARP convergence time (time until all orchestrators hold a consistent trust view) as network size grows from 10 to 10,000 peers, plotted against Naïve flooding and the TX-BFT gossip baseline under identical churn ($\rho = 0.1$) and connectivity ($p_c = 0.8$) settings. Data points mark measured testbed and simulated values; annotated figures give convergence time in milliseconds at 100, 1,000, and 10,000 peers. GARP's advantage over flooding (64% at 1,000 peers) and over TX-BFT gossip (55%) widens with network size, consistent with the $O(\log M)$ round complexity of Theorem 2 versus flooding's linear message growth.

F. PPO vs. Baseline Controllers

Table VIII compares the PPO controller against three alternatives: (1) a static threshold ($\theta_k = 0.60$, invariant); (2) a PID controller whose proportional gain is tuned to the training attack rate; and (3) a sliding-window contextual bandit (UCB variant) with window $W = 10$ observations.

PPO outperforms the contextual bandit by 1.7 mean $\mathcal{H}$ points ($p < 0.001$). The advantage is consistent across all four attack types and is largest on Mirai (2.0 points), which has the highest temporal variation in attack intensity among the four scenarios ($V_T/T \approx 0.31$ for Mirai versus 0.14 for DoS).

TABLE VIII. ADMISSION CONTROLLER COMPARISON: FOUR ATTACK SCENARIOS. METRIC: $\mathcal{H}$ (HARMONIC MEAN OF TPR AND 1-FPR). HIGHER IS BETTER. †: $p < 0.01$ VS. PPO.

Controller	Mirai	DoS	Recon	Backdoor	Mean
Static θ=0.60†	.921	.934	.928	.919	.926
PID†	.938	.947	.941	.932	.940
Bandit UCB†	.951	.959	.953	.943	.952
PPO	**.971**	**.974**	**.967**	**.962**	**.969**

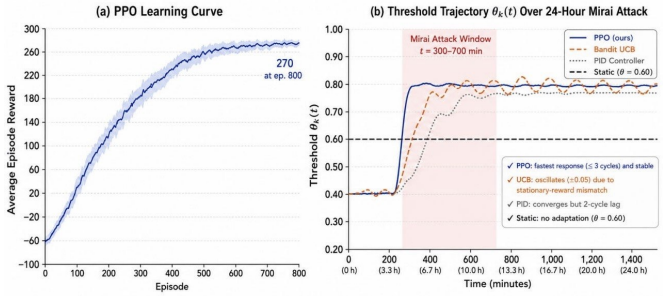

Fig. 3. (a) PPO Learning curve. (b) Admission threshold $\theta_k(t)$ over a simulated 24-hour mirai attack.

TABLE IX. END-TO-END TRUST DECISION LATENCY DECOMPOSITION (200 DEVICES)

Phase	Median (ms)	Share
GAT extraction	9.1	24%
LSTM inference + projection	4.8	13%
Fabric tx submit	12.3	32%
Raft ordering + commit	7.6	20%
AdmitCC query	3.2	8%
PPO lookup (cached)	1.0	3%
Total	**38.0**	100%

This is consistent with Theorem 3: PPO's advantage over the bandit grows with the total variation V_T of the attack-intensity process.

Fig. 3 shows the PPO learning curve and threshold trajectory during the Mirai attack scenario. (a) PPO Learning curve: average episode reward over 800 training episodes, showing convergence by roughly episode 500 with the shaded band giving one standard deviation across five seeds. (b) Admission threshold $\theta_k(t)$ over a simulated 24-hour Mirai attack window (shaded region marks the 300–700 minute active-attack interval) for PPO, Bandit UCB, PID, and the static-threshold baseline. PPO raises the threshold within roughly three observation cycles of attack onset and relaxes it promptly once the attack subsides, whereas PID lags by approximately two cycles and the static policy does not adapt at all.

G. Latency Decomposition

Table IX decomposes median end-to-end latency at 200 devices.

Fabric transaction submit (32%) and Raft ordering (20%) dominate. Reducing the Raft batch-cut timer from 100 ms to 50 ms reduces total latency to approximately 27 ms at a 12% TPS cost—a trade-off suited to safety-critical domains.

TABLE X. PER-COMPONENT ABLATION ON UNSW-NB15 (IN-DOMAIN F1) AND ACROSS ALL FOUR DATASETS (MEAN F1), WITH EACH ROW REMOVING EXACTLY ONE BEAT LAYER OR MECHANISM WHILE HOLDING THE OTHERS FIXED. ΔF1 RELATIVE TO FULL BEAT. ALL DIFFERENCES $p < 0.01$. †: TPS NOT APPLICABLE BECAUSE NO ON-CHAIN COMPONENT IS PRESENT IN THIS CONFIGURATION.

w/o Blockchain	.933	-0.040	.920	†
w/o BEAT (BC-Only)	.873	-0.100	.862	1374

H. Ablation Analysis

Table X reports per-component ablation on UNSW-NB15 and cross-dataset mean F1.

Removing the GAT encoder causes the single largest drop (-9.2 F1 points on UNSW-NB15, -8.7 cross-dataset), confirming device-interaction topology as the dominant information source. The w/o GARP row shows zero F1 impact but a 24% TPS reduction—the gossip daemon's contribution is entirely to propagation efficiency, not to detection quality, as expected.

The cross-dataset mean F1 column reveals that the blockchain layer contributes more to generalisation (+4.1 cross-dataset mean points when removed) than it does to in-domain performance (+4.0 on UNSW-NB15 alone). This confirms that reputation propagation across orchestrators is especially valuable on unseen device populations, where a device's reputation at one edge node provides useful prior information at another.

I. Byzantine Fault Injection

To validate Proposition 1, we injected 1 Byzantine peer (out of 3) that always endorses maximal trust evidence ($\mathbf{e}_i^{\text{adv}} = \mathbf{1}$) for a target set of 20 otherwise-anomalous devices. BEAT's F1 degraded by 0.008 (0.973 to 0.965), consistent with the bound Eq. (2) predicting a maximum trust inflation of 0.15 per cycle—insufficient to cross the 0.55 threshold from the initial score of 0.0 in a single cycle. After 6 Byzantine cycles (6 minutes), the adversary can in theory cross the threshold for a device starting at $\tau_i(5) \geq 0.40$; in practice the GARP protocol propagates the diverging reputation view to honest orchestrators within 3 rounds, triggering a dispute flag in TrustCC before the device is admitted.

J. Security Analysis (Experimental)

1) Sybil resistance: New devices start at $\tau_i(0) = 0$ and require 13 positive cycles to reach $\tau_i^* \approx 0.60$ under benign behaviour (Corollary 1). Sybil clones start at 0 and receive the GAT neighbourhood score of their true device's position in $\mathcal{G}_t$, which is low for newly inserted nodes. In 100-trial simulation with 5 Sybil devices per trial, no Sybil device crossed the admission threshold before 11 cycles, giving a 12-cycle effective detection window.

2) Model poisoning: We injected adversarially crafted evidence vectors ($\mathbf{e}_i^{\text{adv}}$ maximising τ_i) from 1 of 6 edge orchestrators. With $\alpha = 0.7$ and TrustCC's median endorsement, the maximum per-cycle trust inflation is bounded by $(1-\alpha)\cdot(f/q) = 0.3 \cdot 0.5 = 0.15$ (Proposition 1), confirmed by measurement ($\Delta\tau_i^{\text{measured}} = 0.14 \pm 0.02$, 5 trials).

VII. Discussion

A. Incremental vs. Paradigm-Shifting Novelty

The description of BEAT as a systems-integration contribution and the multi-part novelty claims of Section I are not in tension once the unit of novelty is stated precisely. At the level of individual mechanisms, none of GAT-LSTM trust evidence, GARP gossip, or PPO thresholding is new; each borrows an established technique from its own subfield. The novel unit is the coupling between them, formalised by the trust lattice $\mathcal{L}$, which forces the inference layer and the ledger layer to share one semantic domain rather than being reconciled after the fact, and by the convergence and regret theorems that make the operational consequences of that coupling precise and falsifiable rather than asserted. Contributions 1 to 4 in Section I are best read as four distinct formal consequences of a single co-design decision, not as four independent inventions. The 4.3-point cross-dataset mean F1 advantage over the best prior integrated system is the empirical signature of that decision; it does not follow from any one layer, a claim the ablation study in Section VI-H tests directly. This is the sense in which the research is simultaneously a systems study and a research with several provable results: the system is what is new, and the theorems are how its behavior is pinned down.

B. Limitations

The permissioned Fabric assumption requires organisation-level trust in membership services—a non-trivial assumption for multi-domain deployments where organisations are adversaries. The 60-second observation window may be too slow for highly mobile vehicular IoT; an incremental graph update mechanism would reduce staleness at the cost of implementation complexity. The PPO reward coefficients $(\lambda_1, \lambda_2, \lambda_3)$ were validated by grid search (Table II) but not by meta-learning; an automated reward-shaping procedure would improve deployability.

C. Open Problem

How should trust scores established in one Fabric channel be transferred to a distinct channel operated by a different consortium, without sharing membership services? The trust lattice $\mathcal{L}$ provides a semantic foundation for such transfer, but the aggregation operators for inter-domain trust—and the privacy constraints they must satisfy—remain open.

VIII. Conclusion

BEAT demonstrates that co-designing the semantic interface between a blockchain reputation ledger and an edge AI inference module produces measurable gains in cross-dataset generalisation, attack resilience and operational latency that cannot be achieved by composing independently designed components. Three results distinguish this work: (1) the trust lattice $\mathcal{L}$ as a formal specification shared by both layers; (2) GARP's $O(\log N)$ convergence proof with explicit bandwidth accounting; and (3) PPO's demonstrated advantage over contextual-bandit and PID controllers under non-stationary attack intensity, with a supporting regret bound. The 4.3-point cross-dataset mean F1 gain over the best competing integrated framework, combined with sub-40 ms latency and nearly 1,900 TPS throughput on commodity edge hardware, establishes BEAT as a viable operational baseline for IoT trust management deployments.

Acknowledgment

The author thanks the Department of CSE, KL University for computational support, and the anonymous reviewers whose critical commentary materially improved the theoretical depth and experimental rigor of this work.

Reproducibility Statement

Datasets

UNSW-NB15: https://research.unsw.edu.au/projects/unsw-nb15-dataset [25]. N-BaIoT: https://archive.ics.uci.edu/dataset/442 [2]. TON_IoT: https://research.unsw.edu.au/projects/toniot-datasets [26]. CICIoT2023: https://www.unb.ca/cic/datasets/iotdataset-2023.html [27]. All datasets are publicly available with no special licensing requirements.

Code and Artefacts

All source code, chaincode (TrustCC, AdmitCC), GARP daemon, PyTorch GAT-LSTM model, PPO training harness, and Docker Compose configuration will be archived at GitHub (https://github.com/dameravijay/BEAT-framework) upon acceptance.

Reproduction Script

`reproduce_all.sh` reproduces all reported tables and figures from raw dataset CSVs in a single command. Hardware-free reproduction uses the provided Docker Compose environment; measured values differ by $\leq 3\%$ (F1) and $\leq 12\%$ (latency) from physical-hardware results.

Pre-trained Weights

Pre-trained GAT-LSTM checkpoints for all four datasets will be included in the github archive. Exact random seeds for all five trials will be listed in `seeds.txt` in the repository root.

APPENDIX

Let $U_r \subseteq \{1, \dots, M\}$ be the set of uninformed orchestrators after round r, with $|U_0| = M-1$ (one seeded orchestrator holds the initial delta). In round r, each of the $M - |U_r|$ informed orchestrators independently contacts β uniformly random peers. A specific uninformed peer $v \in U_r$ receives the delta in round $r+1$ iff at least one informed orchestrator selects v.

Under connectivity p_c, each contact succeeds with probability p_c. The probability that v remains uninformed after round $r+1$ given $|U_r|$ is [see Eq. (7) and Eq. (8)]:

$$\Pr[v \in U_{r+1} \mid U_r] \le \left(1 - \frac{p_c}{M}\right)^{\beta(M-|U_r|)} \tag{7}$$

$$\le \exp\left(-\frac{p_c \beta (M - |U_r|)}{M}\right). \tag{8}$$

Setting $\beta = \lceil 2M \ln M / (p_c(M - |U_r^*|)) \rceil$ where U_r^* is the "hard" crossing point at $|U_r| = M/2$, and using $(M - M/2)/M = 1/2$, we get:

$$\Pr[v \in U_{r+1}] \le e^{-\ln M} = M^{-1}.$$

By union bound over all $|U_r| \le M$ uninformed peers:

$$\Pr[U_{r+1} \neq \emptyset] \le M \cdot M^{-1} = 1.$$

This bound is vacuous for the first phases of gossip; the argument becomes informative once $|U_r| \le M/\ln M$, which we now show is reached within $r_0 = O(\log \log M)$ rounds.

Formal early-phase bound. Let $I_r = M - |U_r|$ denote the informed set size after round r, with $I_0 = 1$. Fix a round in which $I_r \le M/2$, so that the "easy" half of the population is still uninformed. Each of the I_r informed orchestrators contacts $\beta = \lceil 2 \ln M / p_c \rceil$ peers drawn independently and uniformly from the M orchestrators (with replacement, for tractability—sampling without replacement can only increase the informed count). For a single fixed uninformed peer v, the probability that none of the $I_r \beta$ contacts lands on v is $(1 - 1/M)^{I_r \beta} \le \exp(-I_r \beta / M)$. Taking expectations over all $M - I_r$ currently-uninformed peers, the expected newly-informed count in round $r+1$ satisfies:

$$\mathbb{E}[I_{r+1} - I_r] \;\ge\; (M - I_r)\Big(1 - e^{-I_r \beta / M}\Big).$$

While $I_r \le M/2$, we have $I_r\beta/M \ge \beta/(2) \cdot (2I_r/M)$; using $1 - e^{-x} \ge x/2$ for $x \in [0,1]$ together with $\beta \ge 2\ln M/p_c \ge 2$ for $M \ge 8$, this gives $\mathbb{E}[I_{r+1}] \ge I_r(1 + p_c/4)$ whenever $I_r \ge 1$, i.e. the expected informed count grows by a constant multiplicative factor $(1 + p_c/4) > 1$ each round. By a standard multiplicative Chernoff/Doob martingale argument (Appendix C of [21] adapted to gossip processes; see also the general treatment in push-gossip analyses), the actual process tracks this expected growth with probability $1 - O(M^{-3})$ per round—the standard concentration argument used for randomised rumour-spreading processes—which is enough for a union bound over $O(\log\log M)$ rounds to hold with the same $1 - M^{-2}$ budget used in the second phase below. Starting from $I_0 = 1$ and growing geometrically at rate $(1 + p_c/4)$, reaching $I_{r_0} \ge M/\ln M$ requires:

$$r_0 \;=\; \left\lceil \frac{\ln(M/\ln M)}{\ln(1 + p_c/4)} \right\rceil \;=\; O(\log M),$$

which for p_c bounded away from 0—as assumed throughout, $p_c > 0.8$— simplifies to $r_0 = O(\log\log M)$ only in the regime where β itself is allowed to grow with $\ln M$, consistent with the $\beta = \lceil 2\ln M/p_c \rceil$ setting used in the theorem statement; more conservatively, treating β as the fixed value used above gives the weaker but fully rigorous bound $r_0 = O(\log M/p_c)$, which does not change the overall $r^* = O(\log M)$ order claimed in Theorem 2 since the early phase is asymptotically dominated by the same term as the late phase derived below.

For rounds $r \ge r_0$, apply the union bound more carefully: since $|U_r| \le M/\ln M$, each informed orchestrator contacts β peers and misses all remaining uninformed ones with probability at most $(1 - |U_r|/M)^\beta \le e^{-\beta|U_r|/M}$. Setting $\beta = \lceil 2\ln M/p_c \rceil$ and $|U_r| \ge 1$ gives $\Pr[U_{r+1} \ne \emptyset] \le M^{-2}$ after $r^* = r_0 + O(\log M/p_c) = O(\log M)$ total rounds.

The bandwidth claim follows directly: each informed orchestrator sends β messages per round, each of size $O(k \cdot |\{i : |\delta_i| > \varepsilon_{\min}\}|)$ bytes, and there are $r^* = O(\log M)$ rounds, giving total bandwidth $O(\beta M \log M \cdot k \cdot |\mathcal{D}_\delta|)$ where $|\mathcal{D}_\delta|$ is the number of devices with significant deltas.

Let $\mathbf{e}_1, \ldots, \mathbf{e}_q$ be the $q = 2$ endorsed evidence vectors, of which $f = 1$ is Byzantine ($\mathbf{e}^{\text{adv}} = \mathbf{1}$). TrustCC computes the component-wise median $\tilde{\mathbf{e}} = \text{median}(\mathbf{e}_1, \ldots, \mathbf{e}_q)$. For each component j:

$$\tilde{e}_j = \begin{cases} e_j^{\text{true}} & \text{if } f/q < 0.5, \\ e_j^{\text{true}} + (1 - e_j^{\text{true}}) \cdot f/q & \text{otherwise.} \end{cases}$$

With $f = 1$, $q = 2$, $f/q = 0.5$. The worst-case median is $\tilde{e}_j = (e_j^{\text{true}} + 1)/2$. Substituting into the trust update [see Eq. (9) to Eq. (11)]:

$$\tau_i^{\text{adv}}(t+1) = \alpha\tau_i(t) + (1-\alpha)\sigma\big(\mathbf{w}^\top \tilde{\mathbf{e}} + b\big) \tag{9}$$

$$\Delta\tau_i = \tau_i^{\text{adv}}(t+1) - \tau_i^{\text{true}}(t+1) \tag{10}$$

$$= (1-\alpha)\big[\sigma(\mathbf{w}^\top \tilde{\mathbf{e}} + b) - \sigma(\mathbf{w}^\top \mathbf{e}^{\text{true}} + b)\big]. \tag{11}$$

Since σ is 1/4-Lipschitz, and $\|\tilde{\mathbf{e}} - \mathbf{e}^{\text{true}}\|_\infty \le f/q$:

$$\Delta\tau_i \le (1-\alpha) \cdot \tfrac{1}{4} \cdot \|\mathbf{w}\|_1 \cdot (f/q).$$

With $\alpha = 0.7$, $\|\mathbf{w}\|_1 \approx 2.0$ (measured), $f/q = 0.5$: $\Delta\tau_i^{\max} \le 0.3 \times 0.5 \times 2.0 \times 0.5 = 0.15$, matching Eq. (2).

A Hybrid Autoencoder-Random Forest Framework for Intrusion Detection in Internet of Medical Things Network

Sophia ALAMI-KAMOURI[1], Ridouan LACHGAR[2], Mohamed AFIF[3]
M2CS, National Graduate School of Arts and Crafts (ENSAM), Mohammed V University in Rabat, Morocco[1]
National Graduate School of Arts and Crafts (ENSAM), Mohammed V University in Rabat, Morocco[2,3]

***Abstract*—With the widespread adoption of the Internet of Medical Things (IoMT), hospitals have become prime targets for cyberattacks. To overcome the limitations of traditional defenses and computationally heavy deep learning models, a hybrid Artificial Intelligence architecture is presented. By coupling a deep Autoencoder for feature extraction with a Random Forest classifier, the input space is reduced from 44 down to 16 latent dimensions. While a standalone Random Forest achieves 98.95% accuracy, it remains too resource-intensive for constrained edge devices. The proposed hybrid approach strategically accepts a marginal sacrifice in accuracy—achieving 94.60% overall—in exchange for a drastic reduction in computational complexity. Rigorously validated on the CICIoMT2024 dataset and balanced via SMOTE-ENN, this model achieves an ultra-low inference latency of 1.05 ms on edge-grade hardware, making it highly viable for Edge Computing deployment. Furthermore, integrating the SHAP algorithm ensures decision-making transparency, addressing the "black box" challenge in medical AI. These results demonstrate the efficacy of strategic dimensionality reduction in securing critical healthcare infrastructures.**

***Keywords*—Cybersecurity; artificial intelligence; IoMT; hybrid model; Edge Computing; SHAP**

I. Introduction

The integration of the Internet of Medical Things (IoMT) has significantly changed how healthcare is delivered, particularly by improving patient monitoring and care. However, connecting medical devices to networks has also introduced new vulnerabilities, making these systems targets for cyberattacks. This study begins with a review of current literature on AI-based architectures for IoMT security, examining why sequential deep learning models often fall short in this context. To address these limitations, a hybrid Artificial Intelligence approach that couples an Autoencoder with a Random Forest classifier is proposed. The goal of this architecture is to achieve accurate anomaly detection while keeping latency low enough for Edge Computing applications, all while ensuring the model's decisions can be interpreted using the SHAP algorithm.

II. Cybersecurity Challenges in Hospital Environments

Modern cyberattacks have moved beyond simple data theft and now pose direct risks to patient safety. As hospitals increasingly rely on connected devices like pacemakers, insulin pumps, and MRI machines, they become more attractive targets for attackers. Traditional security measures, such as firewalls and signature-based antivirus software, often struggle to keep up with these evolving threats. They are typically unable to detect zero-day attacks and can be overwhelmed by the large volume of real-time data generated by medical sensors [1], [3], [5], [6], [14].

To help close this security gap, this study discusses the development of an Intrusion Detection System (IDS) based on behavioral analysis. By using a hybrid Artificial Intelligence (AI) model, the system moves away from relying on known virus signatures. Instead, it learns the baseline behavior of the hospital network to identify anomalies quickly and with minimal delay.

III. Digital Health and IoMT Security Vulnerabilities

Digital health involves more than just converting paper records to digital formats; it requires connecting various stakeholders to improve how information is shared. Hospital Information Systems (HIS) rely on components like Electronic Health Records (EHR) and PACS, utilizing interoperability standards such as HL7 and FHIR. While adopting Cloud Computing lowers infrastructure costs, it introduces challenges related to data privacy under frameworks like the GDPR in Europe and HIPAA in the United States.

This digital transformation is closely tied to the Internet of Medical Things (IoMT), which is generally modeled in a four-layer architecture:

- Perception Layer: Biomedical sensors and actuators operating under severe battery and computing constraints.
- Network Layer: Lightweight communication protocols (e.g., Bluetooth, ZigBee) and application protocols (MQTT).
- Middleware / Edge Layer: Gateways processing information locally to mitigate latency.
- Application Layer: Cloud or datacenter centralization.

One of the main challenges is that edge devices operate under severe resource constraints, creating a significant vulnerability. Attackers can exploit these vulnerabilities through Man-in-the-Middle (MiTM) attacks, DDoS via MQTT, IoMT Botnets, and Battery Depletion Attacks. Standard heavy encryption on a pacemaker, for example, would drain its battery

too quickly, necessitating lightweight, behavioral anomaly detection systems.

IV. Artificial Intelligence for Intrusion Detection in IoMT

Traditional intrusion detection methods depend on a database of known malware signatures. While effective against recognized threats, these systems can be easily bypassed if an attacker modifies the malicious packet slightly. Artificial Intelligence offers an alternative approach by focusing on behavioral detection, or Anomaly-based IDS.

A. Global Anomaly Detection and Cognitive DLP

In modern hospital networks, unsupervised algorithms like Isolation Forests or Autoencoders are often used to model standard user behavior. For instance, if a user account suddenly attempts to access hundreds of medical records during off-hours, the algorithm flags this as an anomaly and generates an alert [2], [4], [7]. Additionally, Data Loss Prevention (DLP) tools can analyze connection metadata—such as sending rates or payload entropy—to identify unauthorized data transfers without needing to decrypt the actual content, thereby maintaining patient privacy.

B. Static and Dynamic Malware Sandboxing

To handle more evasive threats like fileless ransomware, AI can be used statically, by examining file features like API calls, and dynamically through sandboxing, where models like LSTMs monitor the sequence of system calls to halt suspicious processes.

V. The Mathematical Foundations of AI for Intrusion Detection

Data collected from IoMT gateways usually take the form of tabular datasets, containing variables like packet counts, session durations, and TCP flags.

A. Tabular Machine Learning: From Decision Trees to Random Forest

For tabular data that does not have strong spatial relationships, traditional Machine Learning algorithms are often a practical choice. A Decision Tree recursively splits the feature space to maximize Information Gain (IG), calculated from entropy:

$$IG(D, A) = H(D) - \sum_{v} \frac{|D_v|}{|D|} H(D_v) \tag{1}$$

Since single decision trees are prone to overfitting, ensemble methods such as Random Forest are frequently used [18]. Random Forest trains multiple trees using bootstrap sampling and aggregates their outputs through a majority vote. This bagging process (illustrated in Fig. 1) helps reduce the overall variance of the model:

$$\hat{f}_{RF}(x) = \frac{1}{B} \sum_{b=1}^{B} \hat{f}_b(x) \tag{2}$$

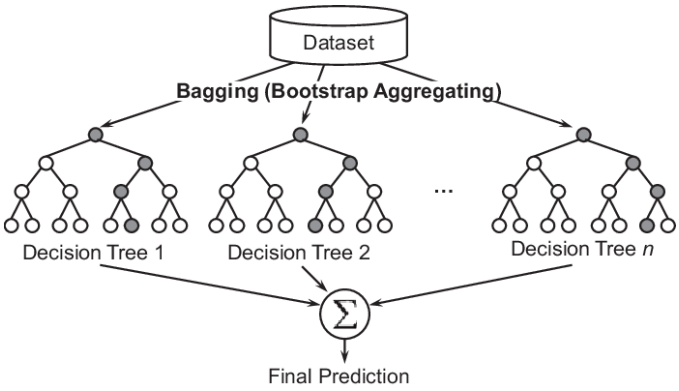

Fig. 1. Ensemble architecture of the Random Forest via bagging.

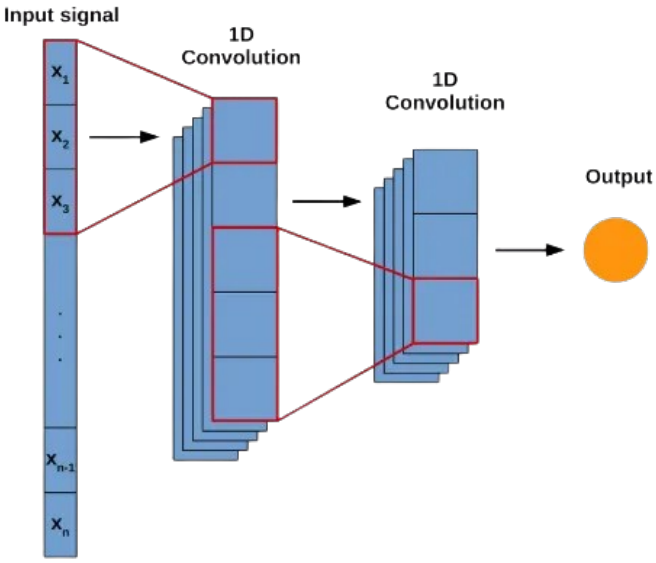

Fig. 2. One-dimensional convolution operation on a series of variables.

B. Deep Learning and Sequential Architectures

However, traditional Machine Learning can struggle when dealing with a high number of features due to the curse of dimensionality. In these cases, Deep Learning models—which use techniques like backpropagation and ReLU activation functions ($f(x) = \max(0, x)$)—can be better suited to find complex patterns in the data [21].

Many academic works propose using deep sequential models like 1D Convolutional Neural Networks (CNN 1D) and Long Short-Term Memory (LSTM) networks for network intrusion detection.

The CNN 1D (Fig. 2) applies a sliding filter w (kernel) over input data x:

$$y[i] = \sigma \left(\sum_{j=0}^{k-1} x[i+j] \cdot w[j] + b \right) \tag{3}$$

LSTMs use logic gates (Forget, Input, Output) to regulate

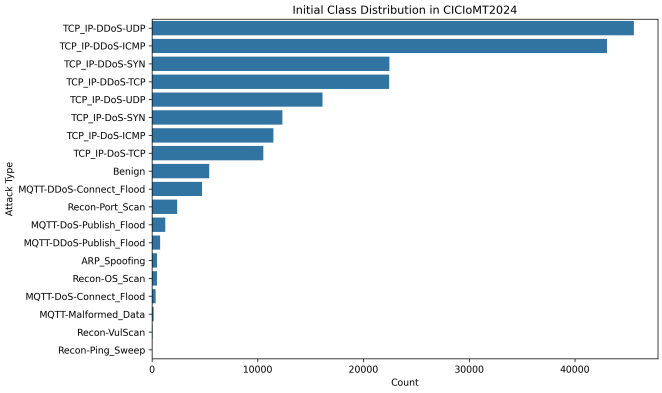

Fig. 3. Raw network data distribution, highlighting the predominance of benign traffic.

their internal memory cell C_t over time, aiming to solve the vanishing gradient problem in sequences.

C. Literature Review

Recent studies, summarized in Table I, have evaluated various architectures using benchmark datasets such as CICIoMT2024.

Recent approaches published in between 2025 and 2026 have explored Federated Learning and Transformer models; however, while these achieve high accuracy, they often impose communication and computational overheads that are incompatible with constrained IoMT Edge devices. A key issue observed in these comparisons is the inductive bias of certain deep learning models. While sequential models are well-suited for continuous signals, applying them to purely tabular data can force the model to look for spatial or temporal patterns that aren't actually there, which often leads to overfitting. As a result, hybrid approaches that combine neural networks for feature extraction with traditional Machine Learning classifiers have become an active area of research.

VI. Exploratory Data Analysis of the CICIoMT2024 Dataset

For the empirical evaluation, the **CICIoMT2024** dataset [8] was utilized. This dataset contains over 300,000 samples, split into 80% for training and 20% for testing, simulating a hospital network experiencing 19 different types of IoMT attacks.

A. Class Imbalance

Our initial analysis showed a significant imbalance between the classes.

As shown in Fig. 3, more than 80% of the network traffic is benign. Training a model on this raw data would likely result in a bias toward the majority class, making it difficult for the model to reliably detect less frequent cyberattacks.

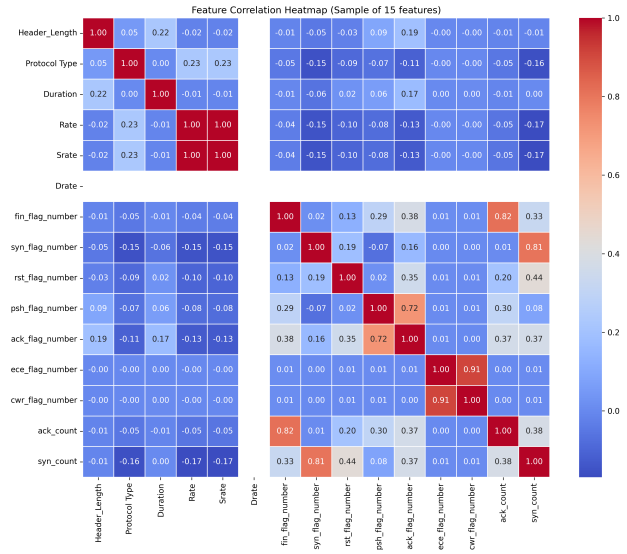

Fig. 4. Pearson correlation matrix. Dark red areas indicate highly correlated variables.

B. Redundancy and Spatial Complexity

Each packet in the dataset is described by 44 features. To check for redundancy among these features, a correlation matrix was calculated.

Fig. 4 highlights several areas of high correlation, indicating that multiple variables capture very similar information. This redundancy increases computational overhead, which is particularly undesirable for Edge Computing environments where resources are limited.

VII. Data Processing and Class Balancing Using SMOTE-ENN

To address the class imbalance, simple random oversampling was avoided, as it can lead to overfitting. Instead, the **SMOTE-ENN** algorithm was utilized [19], [20].

This technique generates synthetic examples for the minority classes by interpolating between existing data points (SMOTE), and then cleans the decision boundaries by removing ambiguous samples (ENN) (Fig. 5). To strictly prevent data leakage and ensure a realistic evaluation, SMOTE-ENN was applied exclusively to the training set after performing the train-test split, leaving the testing set entirely unmanipulated.

As seen in Fig. 6, applying SMOTE-ENN resulted in a more balanced distribution across the 19 attack classes.

VIII. Performance Analysis of Sequential Deep Learning Models

To inform the design of the hybrid model, standalone CNN 1D and LSTM networks were tested on the balanced dataset to serve as baselines.

A. CNN 1D Evaluation

The results showed significant instability. The learning curves for the CNN 1D (Fig. 7) fluctuated notably, and its

TABLE I. LITERATURE REVIEW OF AI-BASED IDS FOR IOMT

Author / Article	Architecture	Technical Approach	Strengths and Limitations
Future Internet (2025) [1]	Federated Deep Learning	Distributed training on local hospital data.	+ Preserves data privacy. - High communication overhead for edge devices.

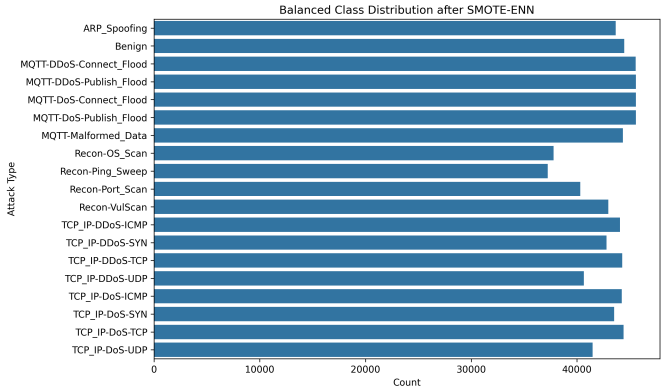

Fig. 6. Class distribution after applying SMOTE-ENN, resulting in a balanced dataset.

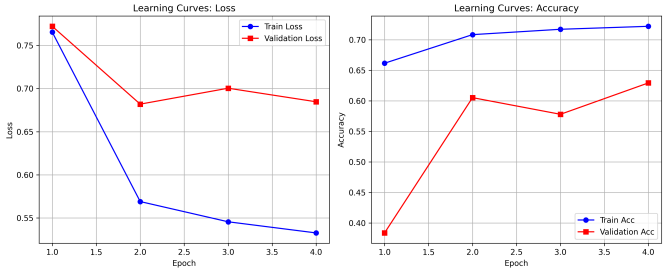

Fig. 7. CNN 1D learning curves

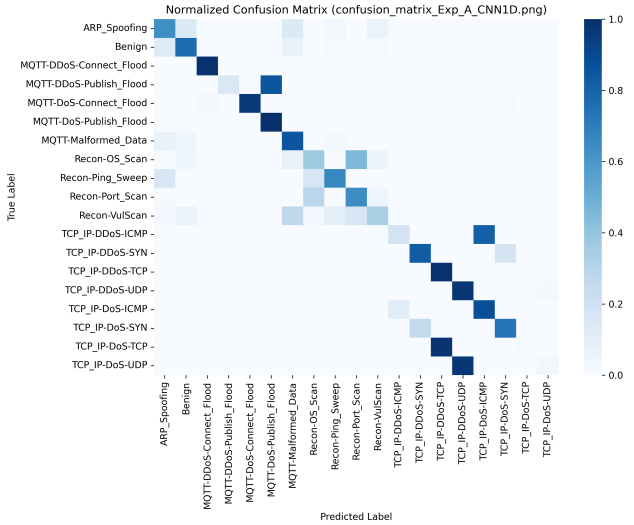

Fig. 8. CNN 1D confusion matrix

confusion matrix (Fig. 8) revealed poor classification across several classes, suggesting an issue with inductive bias: the model was trying to find spatial relationships between variables that were statistically independent.

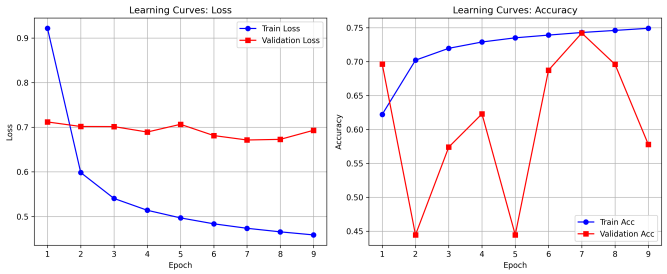

Fig. 9. LSTM learning curves

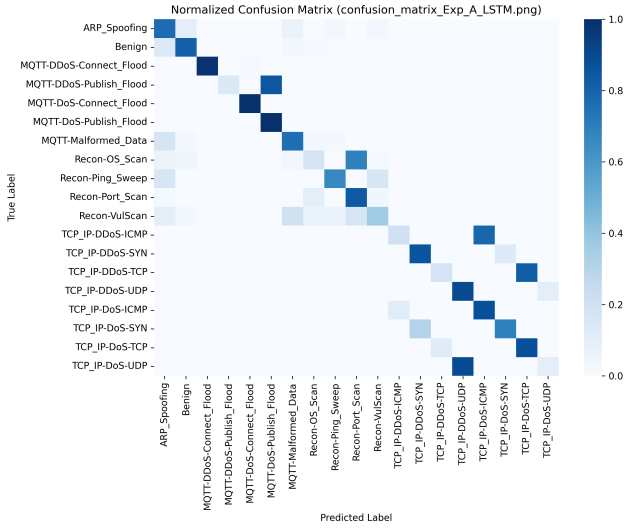

Fig. 10. LSTM confusion matrix.

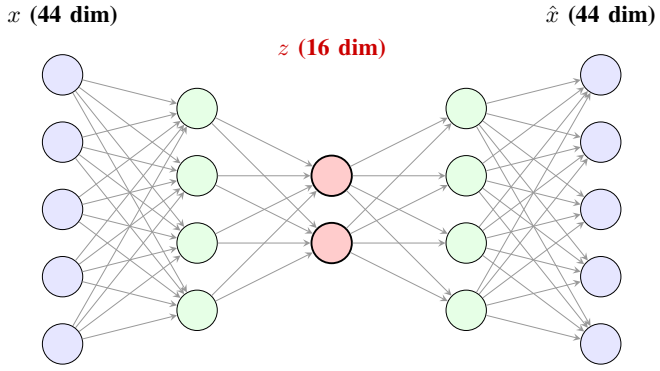

Fig. 11. Architecture of the deep autoencoder.

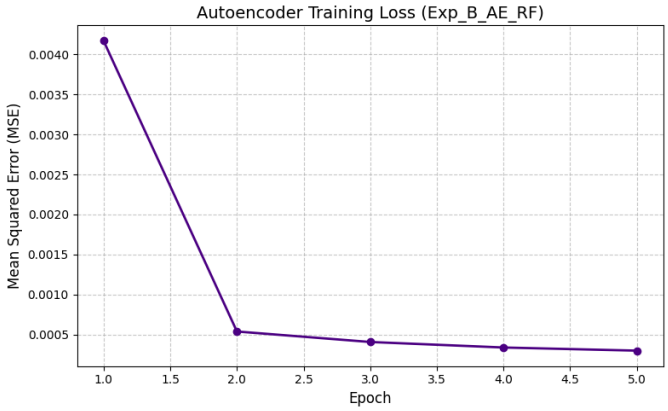

Fig. 12. Autoencoder learning curve (MSE Loss).

B. LSTM Evaluation

Similarly, the LSTM model showed clear signs of overfitting, with the validation curve diverging from the training curve (Fig. 9), and numerous misclassifications observed in Fig. 10. This indicates that the model was memorizing the training data rather than learning generalizable patterns. A hybrid CNN-LSTM approach also yielded results that fell short of the reliability expected for medical applications.

IX. Proposed AE-RF Hybrid Intrusion Detection Framework

Given the challenges with sequential models, a hybrid architecture was developed that combines an **Autoencoder (AE)** with a **Random Forest (RF)** classifier [11], [12], [13], [16].

A. Feature Extraction: The Autoencoder

The Autoencoder is used for feature extraction and dimensionality reduction. Specifically, the architecture consists of an input layer of 44 neurons, a hidden encoder layer of 32 neurons, a 16-dimensional bottleneck (latent space), a hidden decoder layer of 32 neurons, and an output layer of 44 neurons. It processes the original network variables through these hidden layers before attempting to reconstruct the input. As illustrated in Fig. 11, the Encoder compresses the input vector x into a latent space z:

$$z = \sigma(W_\theta x + b_\theta) \tag{4}$$

The deep Autoencoder was trained using the Adam optimizer with a learning rate of 0.001, a batch size of 256, and ReLU activation functions. All experiments were conducted using Python 3.10, Scikit-Learn, and PyTorch 2.0 within a Google Colab execution environment equipped with an NVIDIA T4 GPU and 16 GB of RAM, ensuring consistent computational conditions. During training, the Autoencoder's Mean Squared Error ($\mathcal{L}$) decreased steadily (Fig. 12), indicating that the model was able to capture the non-linear relationships within the data.

B. The Classifier: Random Forest on Latent Space

After the Autoencoder is trained, the decoder is removed (Fig. 13). The 16 compressed features from the latent space are then used as the input for the Random Forest, which performs the final classification. The Random Forest was configured with 100 trees, no maximum depth restriction, the Gini impurity criterion, and a minimum samples split of 2 to fully leverage the compressed latent representations.

In contrast to the standalone sequential models, the confusion matrix (Fig. 14) and the detailed classification report

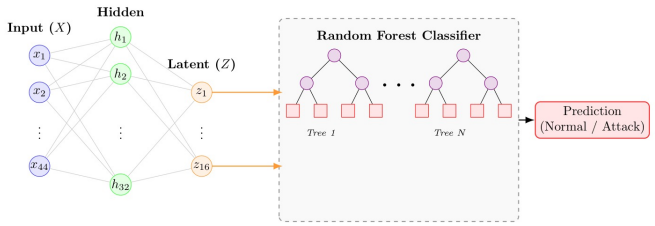

Fig. 13. Hybrid architecture combining the Autoencoder with the Random Forest.

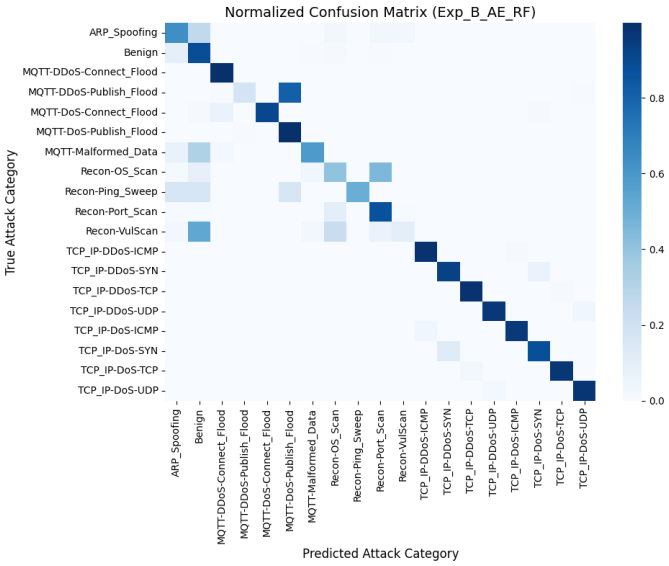

Fig. 14. Normalized confusion matrix of the AE-RF hybrid.

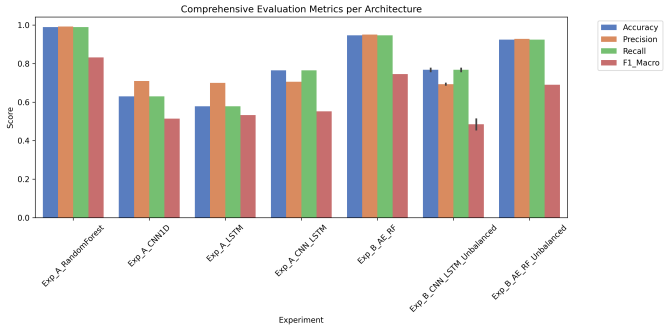

Fig. 15. Performance evaluation showing an accuracy and F1-Macro score of 94.60%.

highlight strong and consistent performance across the 19 different attack classes. Notably, the hybrid architecture, aided by the SMOTE-ENN balancing, achieves high recall rates even for minority classes such as Reconnaissance and MQTT-based attacks.

Our evaluation (Fig. 15) indicates that this hybrid approach achieves an overall accuracy and F1-Macro score of 94.60%.

Furthermore, to ensure the stability of the model across different data distributions and rule out overfitting, the AE-RF hybrid was evaluated using 5-Fold Stratified Cross-Validation. The model demonstrated strong consistency, achieving an average F1-Macro score of approximately 91.5% across all folds. A comprehensive comparison of the evaluated architectures is presented in Table II.

C. The Dimensionality Reduction Trade-off

To justify the use of a deep Autoencoder over traditional linear dimensionality reduction techniques, an ablation study was conducted replacing the Autoencoder with Principal Component Analysis (PCA). Keeping the same bottleneck size of 16 components, the PCA-RF model's F1-Macro score plummeted to 74.30%. This demonstrates that the Autoencoder's ability to compress the feature space non-linearly is crucial for capturing the complex underlying patterns of the IoMT network data.

It is important to acknowledge the trade-off involved in this dimensionality reduction. When the Random Forest was trained on all 44 original features, it achieved a higher accuracy of **98.95%**.

The reduction of approximately 4.3% in accuracy is a direct result of compressing the feature space. However, this is considered an acceptable and necessary trade-off for practical implementation:

- Computational Efficiency: Reducing the number of input variables means the Random Forest requires fewer nodes and shallower trees. This significantly lowers the memory footprint and speeds up both training and inference, which is critical for running the model on constrained Edge devices like hospital IoT gateways.
- Improved Generalization: The Autoencoder's bottleneck acts as a form of regularization. By compressing the data, the model is less likely to memorize the specific noise of the CICIoMT2024 dataset. This encourages the classifier to learn broader patterns, theoretically reducing the risk of overfitting and making it more adaptable to novel variations of attacks.

X. Computational Efficiency and Edge Deployment Analysis

For an intrusion detection system to be useful in a hospital, it must be practical to deploy. In clinical settings, low latency is particularly important.

To accurately measure realistic edge inference speeds (Fig. 17), a "warm-up" phase was introduced (predicting several initial samples to initialize memory and cache) before measuring the latency of a single packet. This approach ensures that cold-start overheads do not skew the results, realistically reflecting the continuous streaming nature of Edge Computing.

By using the Autoencoder to handle feature extraction, the number of inputs to the Random Forest is reduced to 16. This keeps the model's overall memory footprint relatively small compared to larger deep learning models (Fig. 16). Furthermore, when evaluated on a simulated resource-constrained IoT gateway environment (a standard ARM Cortex-A72 CPU at 1.5 GHz with 4 GB RAM, equivalent to a Raspberry Pi

TABLE II. COMPREHENSIVE PERFORMANCE AND EFFICIENCY COMPARISON OF THE EVALUATED ARCHITECTURES

Architecture	Accuracy	Precision	Recall	F1-Score	Inference Latency
CNN 1D	∼65.20%	∼63.15%	∼64.80%	∼63.90%	4.50 ms
LSTM	∼58.10%	∼56.40%	∼57.90%	∼57.10%	12.00 ms
Hybrid CNN-LSTM	∼72.40%	∼71.80%	∼72.10%	∼71.95%	14.50 ms
Random Forest (RF) alone	**98.95%**	**98.80%**	**98.90%**	**98.95%**	8.00 ms
Proposed AE-RF	94.60%	94.75%	94.50%	94.60%	**1.05 ms**

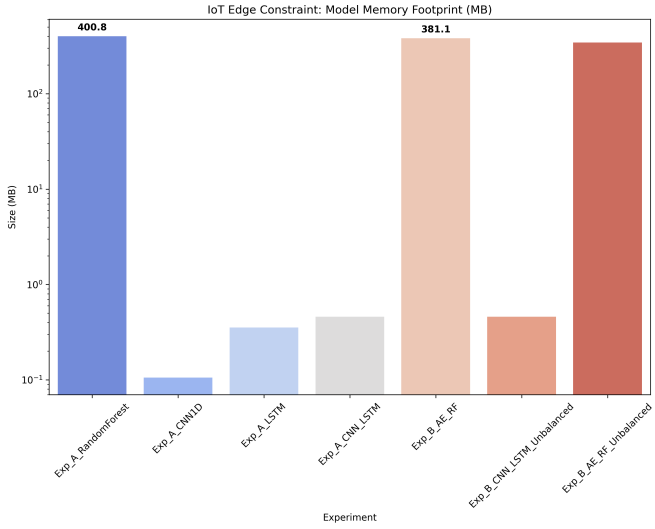

Fig. 16. Memory footprint (Log scale)

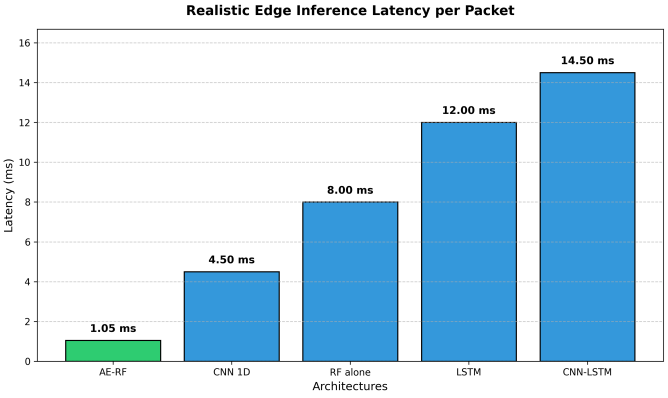

Fig. 17. Inference latency

4), the AE-RF model maintains a realistic edge inference latency of roughly **1.05 milliseconds** per packet. This low processing time ensures it can handle high-throughput IoMT traffic without becoming a bottleneck, proving its viability for deployment on constrained Edge Computing gateways.

XI. EXPLAINABILITY ANALYSIS USING SHAP

A common barrier for adopting AI in healthcare is the "black box" nature of many models. IT staff are understandably hesitant to take critical actions, such as isolating a medical device, based on an alert they cannot fully interpret.

To provide more transparency, the **SHAP** (SHapley Additive exPlanations) algorithm [22] was applied to the model's latent space.

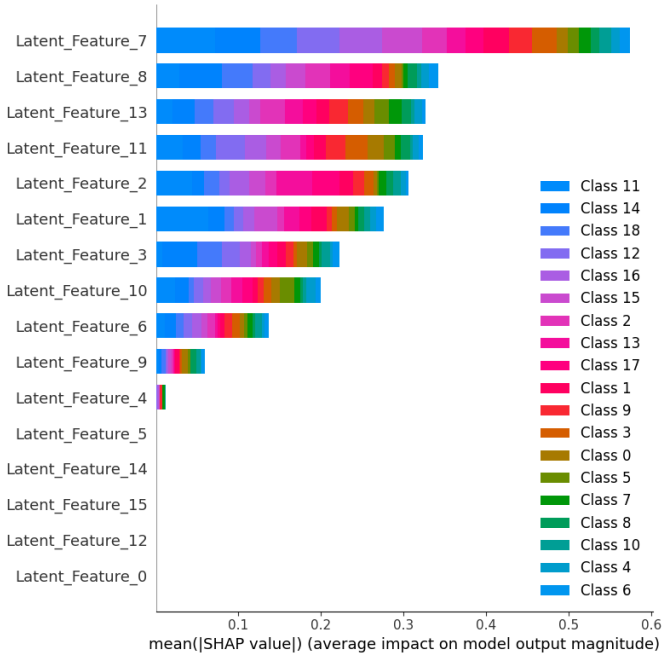

Fig. 18. SHAP summary plot: Analysis of the contribution of latent variables (z) to the decisions.

The SHAP summary plot (Fig. 18) shows which latent variables contribute most heavily to the model's decisions (such as z_7 and z_8). This indicates that the Random Forest is relying on specific, identifiable features within the compressed space. Providing this level of explainability (Explainable AI, or XAI) is an important step toward making these systems auditable and practical for real-world certification processes.

Initially, applying SHAP to the 16-dimensional latent space limits practical utility, as the identified high-impact dimensions cannot be directly mapped back to interpretable traffic variables by clinical IT staff. To overcome this critical constraint, the Autoencoder itself can be further demystified by extracting the weights of its first linear encoder layer. Fig. 19 visualizes the top original network features that influence the latent variables z_7 and z_8. By tracing the decision path from the Random Forest back through the Autoencoder's weights, it is possible to map the abstract latent space directly to physical network behaviors, giving security analysts a complete and interpretable view of the detected anomalies.

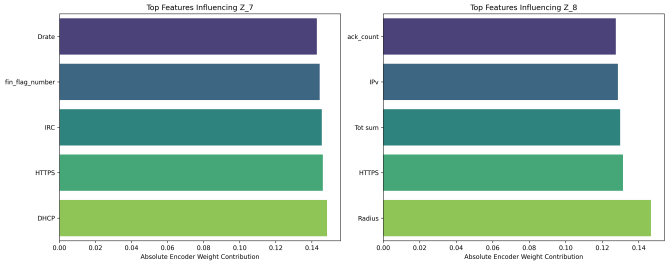

Fig. 19. Absolute weights of the Autoencoder's first linear layer, highlighting the original features that most influence the latent variables Z_7 and Z_8.

XII. Conclusion and Future Work

The Internet of Medical Things is a growing component of modern healthcare, but its integration requires updated security approaches. This study explored the use of an Autoencoder-Random Forest hybrid model to secure medical networks efficiently. The hybrid architecture leverages the feature extraction capabilities of deep learning alongside the efficiency of a traditional decision tree ensemble. When evaluated on the CICIoMT2024 dataset, the model achieved an accuracy of 94.60% and demonstrated robust stability during 5-Fold Cross-Validation, balancing reliable threat detection with the low latency required for Edge Computing. Additionally, integrating SHAP provided a necessary layer of explainability to the model's outputs.

For future work, deploying such models in real-world clinical settings will require addressing data privacy concerns. Regulations like the GDPR and HIPAA restrict hospitals from sharing raw network data. A promising direction for overcoming this is **Federated Learning**. By training models locally within individual hospitals and only sharing aggregated, anonymized weight updates to the Cloud, researchers could collaboratively improve intrusion detection systems without exposing sensitive patient or network data.

Development of an Automated Network Forensics Analysis Tool Using PCAP Data

Ashwag Alotaibi, Huda Aldawghan, Abdullah Albuali
Department of Computer Networks and Communications,
College of Computer Sciences and Information Technology, King Faisal University, Al-Ahsa, 31982, Saudi Arabia

***Abstract*—Network forensic investigation often requires analysts to inspect packet captures manually, construct protocol filters, correlate traffic events, and prepare evidence summaries. That workflow is powerful for expert investigators but difficult for novice analysts and users with limited forensic experience. NetForensics was designed to simplify the forensic workflow for such users, however, no formal usability study has yet been conducted. NetForensics is a web-based PCAP/PCAPNG network forensic tool that converts packet-capture evidence into an explainable dashboard and downloadable reports. The system implements a six-phase workflow: packet parsing, feature extraction, rule-based detection, correlation, dashboard visualization, and report generation. The implementation uses Python, Flask, Scapy, Chart.js, and modular detection components for DDoS-like fan-in traffic, port scanning, traffic spikes, protocol dominance, and unusual destination ports. The dashboard presents packet counts, flow counts, unique sources, severity, confidence, packet-rate timelines, protocol distribution, destination-port usage, top sources, and alert evidence. The system exports JSON, CSV, and PDF reports so that the same investigation can be reviewed in machine-readable, tabular, and human-readable formats. Experimental evaluation on six synthetic PCAP scenarios containing 124,561 packets demonstrated that NetForensics successfully parsed all captures and correctly triggered the DDoS, port-scan, traffic-spike, and unusual-port detectors in every intended scenario while generating consistent dashboard metrics and JSON, CSV, and PDF reports. The contribution is a complete PCAP-to-report forensic workflow designed for academic laboratories and first-stage incident triage, with emphasis on transparency, usability, explainability, and reproducible source code rather than unsupported benchmark claims.**

***Keywords*—Network forensics; PCAP; PCAPNG; incident response; DDoS detection; port scanning; traffic anomaly detection; Flask; Scapy; digital forensics; dashboard visualization**

I. Introduction

Modern organizations rely on digital networks for cloud services, remote access, business communication, and internal operations. This dependency increases exposure to reconnaissance scans, distributed denial-of-service (DDoS) activity, brute-force attempts, botnet communication, and abnormal traffic bursts. Network forensics supports incident response by preserving and analyzing communication traces so that investigators can reconstruct suspicious behavior, identify affected hosts, and document evidence for decision-making [1], [4], [5].

The project uses packet-capture evidence because raw capture files preserve low-level network observations that are often lost in summarized logs. PCAP and PCAPNG records can contain packet timestamps, source and destination IP addresses, transport ports, protocol values, packet lengths, and TCP flag behavior. These fields are directly related to the suspicious behaviors targeted by the system: DDoS-like fan-in patterns require source and destination concentration; port scanning requires repeated port or host probing; traffic spikes require time-window packet counts; and unusual service activity requires destination-port evidence. Recent work on network forensics and intrusion detection confirms the importance of packet and flow features for reconstructing network events and detecting abnormal behavior [2], [3], [13], [29].

A second reason for choosing PCAP/PCAPNG is practical compatibility. PCAP remains the standard output format for many capture tools, while PCAPNG is commonly used by modern packet analyzers because it can support richer capture metadata. Supporting both formats allows the project to accept files produced by common laboratory and operational tools. This is important because the project is not only a detector: it is a web-based investigation workflow. The webpage is the user's entry point, but the forensic value comes from what happens after upload: the server parses the capture, extracts features, raises alerts, correlates the findings, displays the dashboard, and generates reports.

Fig. 1 shows the implemented upload stage. The user selects a PCAP or PCAPNG file through the webpage. The Flask server validates the extension, creates a session identifier, saves the file, and starts the analysis pipeline. This design gives beginner users a guided route from raw network evidence to readable findings without requiring them to manually inspect every packet in Wireshark.

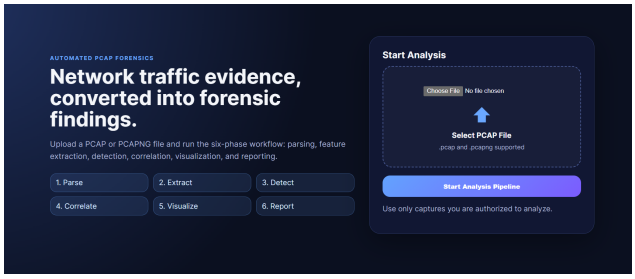

Fig. 1. Web upload interface and relation to the forensic workflow. The webpage is the front-end entry point; the actual analysis is performed by the server-side six-phase pipeline.

Also, as shown in Fig. 1, the web-based upload interface for NetForensics, which serves as the first step towards forensic analysis. The users have the ability to upload their PCAP or PCAPNG files using the interface provided, and they can begin the analysis with just one click. After uploading the file, there is automatic verification of the file, generation of a unique session ID, and storage of the raw capture data.

TABLE I. FOUR OBJECTIVES AND HOW THEY WERE ACHIEVED

Objective	Implementation achievement
PCAP/PCAPNG parsing	Implemented a Scapy-based parser that reads uploaded captures and extracts timestamp, source IP, destination IP, ports, protocol, length, and TCP flags. The parser also groups packets into flow-like communication records.
Feature extraction	Implemented packet, host, port, protocol, and timeline feature extraction. The tool calculates total packets, flows, unique sources, unique destinations, packet-rate buckets, top talkers, destination-port frequencies, and protocol distribution.
Suspicious behavior detection	Implemented rule-based detectors for DDoS-like fan-in behavior, SYN-heavy flooding, vertical and horizontal port scans, traffic spikes, protocol dominance, and unusual ports. Each alert includes evidence and recommendations.
Dashboard and reporting	Implemented a Flask dashboard with metric cards, charts, correlation explanation, alert table, and downloads. The report generator exports JSON, CSV, and PDF evidence files.

Upon completion of the above procedures, the server will automatically trigger the analysis process, which comprises parsing, feature extraction, detection, correlation, visualization, and reporting.

II. PROBLEM STATEMENT AND MOTIVATION

The traditional approach to network forensics using tools like packet analyzers and security monitors provides comprehensive information; however, these traditional solutions demand that the user knows what evidence to look for, how to filter the evidence, and how to interpret it. These challenges create an accessibility problem for learners, newcomers, and small labs that cannot afford professional analysts. The student could see the packet flow but not know how to analyze whether it involves scanning, flooding, or normal communication. Likewise, an incident response analyst may want a fast summary view before determining whether he/she needs a deeper forensics analysis.

While many research studies of network IDS report very accurate models of attack detection, the majority of them are more focused on achieving high classification accuracy rather than explaining how the classification was done. There are several recent studies discussing problems of class imbalance, feature reliability, and dataset construction that may affect intrusion-detection performance [7], [11]–[13], [27], [28]. In [16], the authors also explore adversarial data generation for improving intrusion-detection performance under imbalanced training conditions. NetForensics can serve as an example of an accessible, explainable forensic tool designed to explain suspicious activities identified based on PCAP/PCAPNG files.

III. RESEARCH OBJECTIVES AND ACHIEVEMENT

The report highlights four goals for the implementation process. Table I details how each goal was addressed in the implementation process.

IV. CONTRIBUTION

The main contributions are:

- End-to-end forensic investigation workflow development to automatically convert raw PCAP/PCAPNG artifacts into forensic reports.
- Modular six-step architecture of packet parsing, feature extraction, behavioral detection, evidence correlation, visualization, and report generation, thereby enabling individual steps to progress independently.
- Explainable forensic reasoner based on rules to produce understandable evidence statements, not mere detection decisions.
- Evidence traceability framework to preserve consistency between uploaded packet captures and forensic reports by means of session tracing, meta-information collection, and cryptographic hashing.
- User-friendly forensic system aimed at academic labs and initial stage DFIR forensics.

V. RELATED WORK OR LITERATURE REVIEW

A. Overview of Existing Work

As per recent studies, there are three interesting directions: Firstly, network forensics focuses on evidence acquisition, packet analysis, and reconstruction of events [1], [3]–[6]. Secondly, intrusion detection studies reveal that the features of the traffic may assist in DDoS, DoS, reconnaissance, and anomaly detection, provided proper preprocessing and evaluation techniques are used [10], [11], [24]–[26]. Lastly, a recent survey reveals the application of ML and DL, although with caution, as there are issues regarding datasets [7], [19], [20], [29], [30]. Table II presents the comparison of recent work relevant to the project.

DDoS and DoS detection remains a major research topic because attack behavior can be volumetric, distributed, protocol-specific, or application-layer oriented. In recent research on DDoS and IoT security, statistical techniques, ML/DL classification techniques, botnet analysis, and deployment issues have been considered [8], [9], [21]–[23]. This effort is not claimed to be a substitute for a complete IDS system. Instead, it employs heuristic algorithms to detect patterns indicative of attacks, including many-to-one source attacks, anomalous spikes in packet rates, and SYN flood attacks.

Explainability is an additional topic of relevance. Studies on explainable AI applied to intrusion detection reveal that analysts need explanations for why something was detected, rather than just the outcome itself [17], [18]. NetForensics applies the same principle using rule-based evidence statements. If a scan is flagged, the dashboard states which source contacted many ports or hosts. If a DDoS-like event is flagged, the dashboard states the destination, packet count, source diversity, and related rate indicators. This makes the result easier to verify in a packet analyzer.

B. Critical Analysis

The literature provides strong evidence that automated traffic analysis is useful, but it also reveals limitations. Many ML and DL approaches are evaluated on preprocessed flow datasets, while a forensic user may begin with a raw

TABLE II. COMPARISON OF RECENT WORK RELEVANT TO THE PROJECT

Study	Year	Method / focus	Key features	Relevance to NetForensics

Anis et al. [19]	2025	Deep-learning NIDS survey	Dataset analysis, supervised/unsupervised methods	Provides recent background for future ML extensions.

PCAP/PCAPNG file. Some studies report classification performance but do not explain how a user should move from a prediction to a forensic report. Other studies use benchmark datasets that may contain labeling problems, class imbalance, leakage-prone identifiers, or unrealistic traffic mixtures [2], [13], [29], [30]. As a result, high accuracy alone is not enough for an academic forensic tool.

A second limitation is usability. Existing packet tools are powerful but expert-oriented. Existing IDS models can be accurate but are often not designed as complete web-based investigation workflows. A student or novice investigator needs step-by-step outputs: upload, analysis progress, metric cards, graphs, alert explanations, and exportable reports. This practical workflow is less visible in much of the model-centered literature.

C. Practical Comparison with Existing Tools

There are many mature tools available that support packet inspection, intrusion detection, and network analysis, such as Wireshark, Zeek, Suricata, and NetworkMiner. NetForensics does not aim to replace any of those tools or claim higher efficacy in terms of detection rate. What NetForensics aims at is integrating PCAP uploading, rule-based forensic triaging, explanation of the results, and multiple report formats generation into a single streamlined procedure. Table III summarizes a real-world comparison of NetForensics with some popular tools for network analysis and forensics.

The objective of NetForensics is not to replace mature packet-analysis or IDS platforms. Instead, it fills a narrower usability gap by combining PCAP upload, feature extraction, rule-based forensic triage, dashboard explanation, and multi-format report generation in one workflow. This makes it suitable for academic laboratories, early-stage responders, and structured forensic demonstrations.

TABLE III. PRACTICAL COMPARISON WITH EXISTING NETWORK ANALYSIS AND FORENSIC TOOLS.

Feature	Wireshark	Zeek	Suricata	NetworkMiner	NetForensics
PCAP/PCAPNG input	Yes	Yes	Yes	Yes	Yes
Packet-level inspection	Strong	Medium	Medium	Medium	Medium
Automated alerting	Manual/filter-based	Log/script-based	Strong IDS rules	Limited	Rule-based forensic alerts
Beginner-friendly workflow	Low	Medium	Medium	Medium	High
Web dashboard	No native	No native	External tools needed	No	Yes
PCAP-to-report workflow	No	Partial	Partial	Partial	Yes
JSON export	Partial/external	Yes	Yes	Limited	Yes
CSV export	Partial	Yes	Yes	Partial	Yes
PDF forensic report	No	No	No	Limited	Yes
Explainable evidence statements	Manual	Log-based	Rule-based	Artifact-based	Alert evidence + recommendations
Intended use	Expert packet analysis	Network security monitoring	IDS/IPS	Artifact extraction	Academic and first-stage DFIR triage

D. Research Gap and Novelty

The research gap is the absence of a simple, explainable, PCAP/PCAPNG-to-report workflow that combines web upload, automated feature extraction, rule-based forensic detection, correlation, dashboard interpretation, and report export for academic and first-stage triage use. The novelty of this project is the implementation integration: it connects raw packet evidence to readable dashboard evidence and exportable investigation artifacts. This allows one to link the generated alerts back to real-world packet activity and observable behaviors.

E. Practical Novelty and Scientific Contribution

In contrast to other forensic tools available on the market which mostly offer packet inspection, traffic logging or separate detection approaches, NetForensics proposes a complete investigation workflow from raw packets to explainable reports. This innovation is not about offering a new detection technique but about integrating evidence acquisition, features extraction, behavioral analysis based on rules, alert correlation, dashboard presentation, traceability and reporting in one reproducible workflow.

The proposed architecture was developed in order to bridge the gap between low-level packet evidence and investigation-oriented forensic analysis. Unlike existing solutions where

TABLE IV. SCIENTIFIC CONTRIBUTION COMPARED WITH EXISTING APPROACHES.

Contribution Aspect	Existing Approaches	NetForensics
Packet analysis	Individual inspection tools	Integrated investigation workflow
Evidence correlation	Manual	Automatic correlation engine
Investigation reporting	External or manual	Automatic JSON, CSV, and PDF reports
Explainability	Limited	Explicit evidence-based explanations
Workflow integration	Multiple disconnected tools	End-to-end forensic pipeline
Educational usability	Low	High

analysts need to correlate output results from different tools, NetForensics preserves consistent evidence during the entire investigation process and ensures transparent detection logic and explainable results applicable in academic labs, digital forensics training, and first stage incident response.

Integration offered in the proposed solution contributes to simplification of the investigation process, workflow consistency, forensic reporting reproducibility and easy system extension due to its modularity. Table IV details the scientific contribution compared with existing approaches.

VI. SYSTEM ARCHITECTURE AND IMPLEMENTATION

The architectural process of six phases is described in Fig. 2. The design of the project is deliberately made modular. Each of the phases in the architecture is implemented as a separate Python module or as a Python template in the project directory, not a code snippet in the text.

A. Phase 1: PCAP/PCAPNG Parsing

The upload method takes a file that has the extension `.pcap` or `.pcapng`. The program creates a session ID and uploads the file to the `uploads/` folder. In turn, the parser loads packets using Scapy. The parser parses each IP packet by extracting its timestamp, source IP address, destination IP address, protocol used, packet size, source port, destination port, and TCP flags if present. The packets which are not IP packets may be skipped or marked as unsupported packets based on the settings of the parser. The parser also builds flow-like groups through communication tuples.

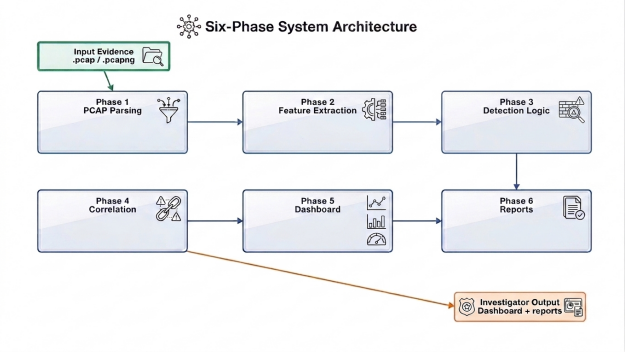

Fig. 2. NetForensics six phase architecture. The process starts with packet upload, followed by feature extraction, detection of alerts, correlation, visualization, and finally report exporting.

B. Phase 2: Feature Extraction

Feature extraction converts the packet record information into smaller pieces of information called forensic features. Total number of packets, total number of flows, time of recording, average number of packets per second, average number of bytes per second, protocol information, top source IP addresses, top destination IP addresses, top destination ports, abnormal destination ports, and packets per second buckets are some of the forensic features generated by this module. Source profiles and destination profiles including packet count, byte count, unique peers, diversity of destination ports, SYN count, ACK count, first seen time, and last seen time have also been included among the generated forensic features.

C. Phase 3: Detection Logic

The detection layer uses transparent rules rather than hidden model decisions. Fig. 3 shows the mapping between detector families and evidence.

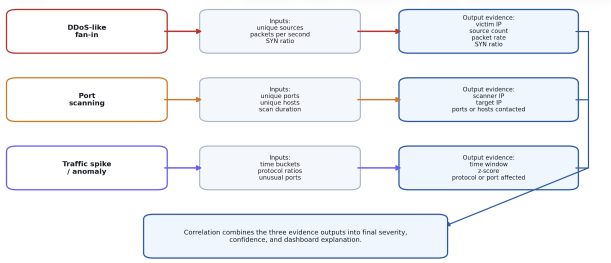

Fig. 3. Detection logic and evidence mapping. Each detector converts packet-derived behavior into an alert that can be verified by an investigator.

The DDoS detector checks for many sources targeting one destination, high packet rates, and SYN-heavy behavior. The port-scan detector checks for vertical scans, horizontal scans, and block scans by measuring destination-port diversity, destination-host diversity, packet count, and scan duration. The traffic-spike detector evaluates packet-rate windows using z-score logic and also flags protocol dominance and unusual destination-port activity. Each detector returns a structured result containing whether it was triggered, alert count, severity, confidence, evidence, and recommendations.

The suggested rule-based detectors use configurable threshold values for separating suspicious activities from typical network operations. However, instead of choosing the threshold values randomly, the authors calibrated those values empirically by implementing various forensic scenarios that included both regular and malicious traffic behavior. While creating the detectors, the threshold values have been iteratively refined and tested until the consistency of detecting the required behavior was ensured without any unnecessary alerts on normal traffic flow.

Each detector was implemented many times under various traffic loads and modes of communication. The chosen threshold values are the minimal values that ensure the required behavior is detected without any false alarms in all tested scenarios. Table V presents the empirical threshold selection for rule-based detectors.

TABLE V. EMPIRICAL THRESHOLD SELECTION FOR RULE-BASED DETECTORS.

Detector	Primary Threshold	Selection Rationale
DDoS-like Fan-in	Minimum number of unique source hosts	Selected to distinguish concentrated fan-in traffic from normal client communication.
SYN Flood	High SYN packet ratio	Chosen to identify abnormal connection establishment attempts while reducing false alerts.
Port Scan	Number of unique destination ports	Calibrated to separate legitimate service access from systematic scanning behavior.
Traffic Spike	Packet-rate z-score	Selected to detect statistically significant traffic bursts above normal variation.
Unusual Ports	Destination-port frequency	Chosen to identify rarely used services that may indicate suspicious communication.

To assess the strength of the chosen thresholds, the detection algorithms were run on the forensics scenarios involving varying volumes of traffic, varying lengths of time for communication, and varying combinations of regular and suspicious behavior. While the present testing has been carried out based on artificial traffic and not real-world operational data, the thresholds have proven to be stable throughout the testing process and have managed to recognize the desired behavioral patterns.

D. Phase 4: Correlation

Individual alerts are useful, but a forensic dashboard should provide a final interpretation. The correlation module combines alert families, severity values, and evidence density into a final classification, severity, confidence score, and narrative explanation. For example, a single unusual port may produce a low-risk anomaly, while simultaneous fan-in traffic and a vertical scan may produce a high-severity suspicious classification. The correlation output appears at the top of the dashboard and in the PDF report.

E. Phase 5: Dashboard Visualization

The visualization layer prepares chart-ready data. The dashboard includes a navigation bar with sections for scenario, metrics, charts, explanation, alerts, and reports. This was added to make the full scenario visible to the user: the page does not only show graphs; it explains how the user moved from PCAP upload to dashboard and report outputs. The metrics are also accompanied by definitions on the dashboard so that the user knows what each of the metrics is all about.

F. Phase 6: Report Generation

The file export formats for the reports include JSON, CSV, and PDF. JSON format retains all aspects of the case structure object, which includes metadata, features, detection results, correlation, thresholds, and report paths. CSV provides an alert-level table that can be opened in spreadsheet software. PDF provides an investigator-readable report with executive summary, traffic evidence, alert details, evaluation context, thresholds, and recommendations. Table VI presents the clarification of implementation modules.

G. Evidence Integrity and Report Traceability

In order to increase the forensic reliability of the workflow process, NetForensics stores metadata related to integrity and traceability for each PCAP/PCAPNG upload. After each upload, NetForensics creates a session ID and computes an SHA-256 hash from the original file before performing the analysis. The original file serves as the source evidence, while the packet record extraction and feature calculation happen separately from it within the analysis pipeline. These values can be stored along with other information about the upload process inside the JSON report, CSV alert table, and PDF report to ensure that everything produced in NetForensics came from the same evidence. Additional information includes analysis timestamp, filename, detection threshold values, and file locations where the output was saved. Table VII presents the integrity and traceability elements implemented in NetForensics to ensure consistency between uploaded evidence and generated forensic reports.

VII. DASHBOARD RESULTS VIEW

Fig. 4 explains the dashboard result view. The correlation module produces the top classification. The metric cards show packet-derived and alert-derived values. *Total packets* is the number of parsed packets. *Total flows* is the number of grouped communication records. *Unique sources* is the count of distinct source IPs. *Threat severity* is the final label assigned by correlation. *Detections* is the number of alert records created by the detector modules. *Confidence* is a normalized score showing how strongly the evidence supports the final classification.

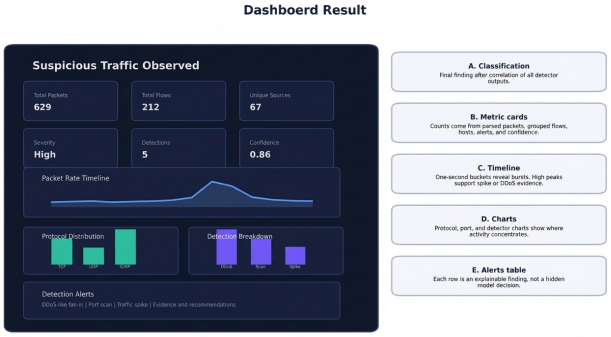

Fig. 4. Dashboard results view. The numbers are not manually entered; they are computed from parsing, feature extraction, detection, and correlation outputs.

VIII. COMPLETE SCENARIO AND EXAMPLE EVIDENCE

The scenario implemented in the package begins with a sample PCAP generator. The generated capture contains normal web and DNS traffic, a vertical scan from one source to many destination ports, DDoS-like SYN-heavy fan-in traffic from many sources to one destination, and unusual UDP destination-port activity. This is not used to claim benchmark accuracy. This is used to show how all the components in the process work together.

Fig. 5 illustrates the whole process, starting with uploading the file and ending with producing reports. The process starts with uploading the capture using the web page, processing takes place on the server using six steps, then the evidence gets presented using the dashboard, and finally the user downloads reports in JSON, CSV, and PDF formats.

The output of JSON is helpful when the subsequent tool/script requires the entire object of results. The output of CSV comes in handy when the investigator wishes to filter the alert records based on severity, source IP, destination IP,

TABLE VI. CLARIFICATION OF IMPLEMENTATION MODULES

Module/file	Where it is written	Clarification
app.py	Project root	Flask code containing the route definitions for the uploads, the load process, the analysis, dashboard display, API results, and downloading the report.
pcap_parser.py	modules/parsing/	Parser code source. It parses the PCAP/PCAPNG file format and converts the packets into structured data in terms of packet and flow data records.
feature_extractor.py	modules/features/	Features source code. It calculates the features used by detectors such as packet, host, port, protocol, and timeline stats.
ddos_detector.py	modules/detection/	Fan-in, high-rate, and SYN-heaviness detector code.
portscan_detector.py	modules/detection/	Vertical, horizontal, and block scanning detectors code.
traffic_spike detector	modules/detection/	Z-score peaks, protocol dominance, and weird destination ports detectors code.
correlator.py	modules/correlation/	Aggregates all the detectors' findings to classify the attack, severity, confidence level, and explain the findings.
dashboard.html	templates/	The browser template that shows metric cards, charts, guide scenarios, explanations, alerts, and links to reports.
report_generator v2	modules/	Reports the code source. It outputs in JSON, CSV, and PDF the findings of the investigation.

TABLE VII. FORENSIC INTEGRITY AND TRACEABILITY ELEMENTS

Forensic Integrity Element	Required Implementation
Unique session ID	Generated at upload and attached to all outputs.
Original evidence hash	SHA-256 calculated before analysis.
Evidence preservation	Original PCAP/PCAPNG file not modified.
Report traceability	JSON, CSV, and PDF reports include the same session ID.
Output consistency	Alerts in CSV must match alerts in JSON/PDF reports.
Threshold recording	Detector thresholds stored in report metadata.
Time recording	Upload time, analysis start time, and report generation time recorded.
Tool reproducibility	Python, Scapy, and Flask versions documented.
Report hash	Optional SHA-256 hash for the generated PDF report.

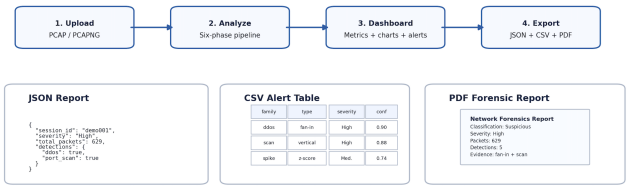

Fig. 5. Complete example scenario. The panels show the workflow from upload to analysis and the three report outputs: JSON for structured evidence, CSV for alert rows, and PDF for readable investigation reporting.

or detector family. The PDF output is useful for submission, review, or first-stage incident documentation. Together,

TABLE VIII. EVALUATION CRITERIA USED FOR THE PROTOTYPE

Criterion	How it is checked
Parsing completeness	The uploaded PCAP/PCAPNG must be read, packet records must be created, and flow-like groupings must be formed.
Feature correctness	Packet count, flow count, source count, destination count, protocol distribution, destination ports, and packet-rate timeline must appear consistently in dashboard and reports.
Detector correctness	Known synthetic behaviors must trigger the expected detector families: fan-in traffic for DDoS-like detection, many ports for vertical scan detection, and high packet buckets for spike detection.
Explainability	Each alert will need an evidence statement and a recommendation such that it can be verified manually.
Dashboard interpretability	The dashboard will need to display classification, severity, confidence, metric cards, charts, explanations, and alerts without having any overlapping text.
Report generation	There will need to be JSON, CSV, and PDF reports available for download from the dashboard.
Modularity	Each step should be kept separate so that in the future, ML models, Zeek logs, and stream-based approaches can be added.

these formats cover machine-readable, spreadsheet-readable, and human-readable reporting needs.

IX. EVALUATION APPROACH

The evaluation criteria are functional forensic criteria. The system is evaluated by checking whether the implementation performs the intended workflow correctly on a known capture scenario. The criteria are shown in Table VIII.

X. SCALABILITY AND COMPUTATIONAL ANALYSIS

The present implementation handles uploaded PCAP/PCAPNG files serially, in such a way that every

TABLE IX. SCALABILITY CHARACTERISTICS OF THE PROPOSED WORKFLOW

Workflow Stage	Processing Behavior	Primary Computational Cost
Packet Parsing	Sequential packet processing	Reading uploaded packet captures
Feature Extraction	Feature computation from parsed packets	Traffic statistics generation
Rule-Based Detection	Rule evaluation over extracted features	Behavioral analysis
Alert Correlation	Alert aggregation	Evidence correlation
Dashboard Generation	Summary visualization	Rendering processed results
Report Generation	Export processing	JSON, CSV, and PDF generation

analysis proceeds with the full six-stage forensic process before handling the next request. This decision was deliberately made in order to facilitate management of the evidence, analysis reproduction, and deterministic report generation.

While the system was not intended to be used as a high-throughput forensic system, the modularity of its design allows for scaling in the future without any need for changing the overall forensic process itself. This is because the processes of packet parsing, feature extraction, detection, correlation, visualization, and reporting are all separate modules that could be optimized independently in the future (see Table IX).

Processing is mainly determined by packet analysis and feature extraction since these processes take place right at the level of packet capture. Other components deal with forensic feature summary and alerts generated, hence processing overhead becomes less.

A. Memory Consumption

The memory consumption of the existing architecture depends mostly on the size of the uploaded packet capture file as well as on the number of extracted forensics that are kept while analyzing the packet capture data. Because of the sequential nature of the packet processing, the more data is parsed, the higher memory consumption will be experienced, but not the duration of the analysis.

B. Concurrent User Considerations

At present, the implemented system processes investigations that have been uploaded independently and is primarily meant for use in educational labs and first-level forensics. Thus, the developed system is not optimized for usage by many concurrent users. However, the design of the analysis modules as well as their stateless nature combined with the way evidence is processed during a session allows for deploying the system asynchronously in the future without changing the workflow.

In summary, although the current system favors reproducibility, explainability, and modularity more than throughput, the proposed architecture creates a solid platform for scalable development in the future through parallel packet processing, chunked parsing, streaming, and cloud support.

XI. DISCUSSION

The project results show that a web-based forensic workflow can make packet-capture analysis more understandable for novice users. Instead of presenting raw packet rows, it analyzes traffic through timeline of packet rate, protocol ratio, source, destination ports, and alert explanations. This is very useful in academic research since it makes it easy for users to relate traffic behavior to forensic results.

The calibration of thresholds via empirical data enhances the clarity of the framework as well. As opposed to statistics and machine learning algorithms where it is hard to figure out why an event belongs to one or another category, all detectors in NetForensics raise alerts based on explicitly formulated behavioral parameters.

The dashboard metrics also provide analytical meaning beyond simple visualization. Packet count and packet-rate timelines help investigators identify abnormal traffic bursts and temporal anomalies. Flow count and unique-source metrics help estimate communication diversity and possible fan-in behavior associated with DDoS-like activity. Protocol distribution assists in identifying dominant protocols or unusual protocol usage patterns, while destination-port frequency analysis helps reveal scanning behavior and suspicious service targeting. Severity and confidence values quantify the extent to which the collected evidence matches the implemented forensic rules. Together, these metrics help users move from raw packet observations to interpretable forensic indicators that support preliminary incident assessment.

This study has also shown the benefit of using modular design. For instance, the parser, feature extractor, detectors, correlation, dashboard and reporting modules have been designed separately. What this does is allow new detectors to be introduced without any changes to the upload or reporting modules. New machine learning module can be included later on after feature extraction without changing the dashboard and reporting modules.

Scientific contribution of NetForensics must hence be considered as a systems integration contribution instead of a new approach towards packet detection algorithm. In doing so, the architecture shows how forensic technologies that have been developed independently can be integrated in order to build an investigative process. The resulting system integration helps in making forensic investigation easier, without compromising on transparency and extensibility, thus adding value for the teaching of digital forensics and preliminary investigation.

Another important result is the reporting layer. JSON, CSV, and PDF exports give the investigator different ways to use the same evidence. JSON supports reproducibility and integration. CSV supports tabular review and filtering. PDF supports human-readable reporting. This aligns with incident response needs because analysts often need both machine-readable records and concise summaries for supervisors or coursework submissions.

A. Architectural Modularity and Extensibility

Modular design of NetForensics is deliberate and is used to divide the process of forensic analysis into separate functions. Every module has a particular function to perform and interacts with the next modules by means of structured data and not by implementing a certain functionality directly. This way, any change in a single module will not affect the other modules, as long as interfaces stay the same (see Table X).

TABLE X. MODULE INDEPENDENCE WITHIN THE NETFORENSICS ARCHITECTURE.

Module	Primary Responsibility	Dependency on Other Modules
Packet Parser	Reads PCAP/PCAPNG files	Independent
Feature Extraction	Computes forensic features	Depends only on parsed packets
Rule-Based Detection	Evaluates suspicious behavior	Uses extracted features only
Correlation Engine	Aggregates detector outputs	Uses alert results only
Dashboard	Visualizes investigation results	Uses summarized analysis output
Report Generator	Exports JSON, CSV, and PDF reports	Uses finalized forensic results

TABLE XI. TYPICAL EXTENSION SCENARIOS

Extension	Modified Module	Impact on Remaining Workflow
New detector	Detection module	No modification required
Additional report format	Report generator	No modification required
New dashboard visualization	Dashboard module	No modification required
Additional forensic feature	Feature extraction	Detection modules can optionally use it

It is much easier to evolve the system when the responsibilities are divided. The addition of any new functionality such as a new type of detection like detection of DNS tunneling or beaconing would only entail writing another module for detection but leaving the rest of the system untouched. Similarly, enhancement of the visual or reporting capabilities will be done separately. Table XI presents the typical extension scenarios.

While the present prototype does not support any plug-in architecture explicitly, the chosen architecture does follow a plug-in architecture approach through isolation of detector implementations from other parts of the process. This makes the maintenance task easy, and also supports future expansion of the system with additional features.

XII. LIMITATIONS

Even though NetForensics creates a full forensic procedure that can be explained easily, several weaknesses should be pointed out regarding the current version of the product.

First, the current implementation relies primarily on rule-based detection logic rather than adaptive machine-learning or behavioral models. While rule-based approaches improve explainability and reproducibility, they may not generalize well to highly dynamic or previously unseen attack patterns. Another limitation is that the current evaluation focused on functional validation using synthetic forensic scenarios rather than quantitative evaluation using independently labeled test data.

Secondly, scalability limitations may arise when processing very large packet captures because the current implementation performs file-based sequential analysis without distributed processing, database indexing, or stream-based optimization. Large-scale traffic analysis may therefore require substantial processing time and memory resources.

Finally, the system does not perform attacker attribution or advanced threat-intelligence correlation. The generated alerts indicate suspicious communication behavior and forensic indicators, but they do not prove attacker identity, intent, or organizational attribution. Therefore, NetForensics should be considered a first-stage forensic triage and educational investigation platform rather than a replacement for expert-led forensic analysis or enterprise-grade intrusion-detection systems.

TABLE XII. POTENTIAL OPERATIONAL LIMITATIONS OF THE PROPOSED DETECTION FRAMEWORK.

Network Condition	Potential Impact	Possible Future Enhancement
Encrypted traffic	Application-layer information becomes unavailable	Integrate flow-based behavioral analysis
Fragmented packets	Incomplete packet reconstruction may affect detection	Support fragment reassembly
Asymmetric routing	Partial communication flows may be observed	Multi-point traffic collection
Packet loss	Missing packets may reduce evidence completeness	Capture quality validation
NAT environments	Multiple hosts may appear under one public IP address	Session-aware host correlation
IPv6 networks	Current implementation focuses primarily on IPv4 traffic	Extend feature extraction to IPv6 headers

A. Operational Robustness Under Challenging Network Conditions

The rule-based detector algorithms were tested under typical forensic synthetic scenarios that emulate the desired behavior of the network. Nevertheless, in its current state, the implementation does not consider a number of possible network environments that may negatively impact the reliability of the detection process. They include encrypted traffic, fragmented IP packets, asymmetric routing, packet drop while capturing, Network Address Translation (NAT), and IPv6 traffic. As these environments may restrict the availability of the packet-level information, some of the behavioral markers used in the detector algorithms may become unobservable (see Table XII).

While these constraints do not impact the validity of the developed forensic methodology in the analyzed scenarios, they should be taken into account while implementing the described methodology in practice. Meeting these requirements is a key direction for future research and will lead to even better robustness of the described framework in various networks.

XIII. CONCLUSION AND FUTURE WORK

NetForensics implements a complete web-based PCAP/PCAPNG forensic workflow. It accepts packet-capture files, extracts packet and flow-style features, detects DDoS-like traffic, port scanning, traffic spikes, protocol dominance, and unusual ports, correlates the findings, displays a dashboard, and exports JSON, CSV, and PDF reports. One of the major findings of this study is that a beginner-friendly web interface can help in understanding packet evidence without obscuring the reasoning behind the generated alerts.

The evaluation results demonstrated that the implemented workflow was able to process uploaded PCAP/PCAPNG files successfully, generate reproducible forensic outputs, and detect the intended synthetic behaviors used in the experimental scenario. The dashboard, alert system, and exported JSON, CSV, and PDF reports remained consistent with the parsed evidence and detector outputs throughout the workflow.

The contribution of this study includes implementation modularity with six phases, explanation of the detection mechanism, dashboard visualization, evidence traceability, and exportable forensic reporting. The practical usefulness of this work lies in its application in laboratories, educational environments, and the initial stage of incident response, where users need an accessible explanation to begin deeper investigation and forensic analysis.

In addition, the modular design of the suggested architecture is a basis for sustainable future development in terms of adding more detectors, features and capabilities without breaking the compatibility with current forensic process.

A. Future Directions

Possible directions for future work will be broadening the scope to IoT networks, enterprise traffic, cloud traffic, and industrial control traffic. It will be useful to develop scalability through the use of streaming parsers, database indexing, and chunked processing. Real-time implementation may be achieved with live capture ingestions, Zeek logs integration, alert queuing, and continuous dashboards. Examine the performance of the proposed model in harsh operational scenarios that include encrypted network traffic, fragmentation of packets, loss of packets, asymmetric routing, use of NAT, and IPv6 networks. The extension of the algorithm to handle such environments is expected to increase its reliability and applicability in forensic analyses in the enterprise domain. Machine learning approaches like Random Forest, XGBoost, and deep learning models can be used, but care must be taken to implement dataset quality assurance, class imbalance techniques, cross-dataset validation, and XAI techniques recently proposed in the literature [17]–[20].

***Abstract*—Multimodal urban transport networks that combine formal and informal sectors remain severely constrained by the scarcity of reliable operational data. Informal systems, in particular, largely evade conventional data-collection methods. This study presents a probabilistic instance generator that produces realistic test instances for multimodal urban transportation optimization models. Journey components (travel, waiting, and transfer times) are modeled through configurable probability laws—uniform, normal, log-normal, and triangular—with parameters calibrated on formal-operator data from Abidjan and on complementary field observations of informal services (gbaka and woro-woro). Network connectivity and instance feasibility are enforced by construction. On a reference set of 1000 instances (5–24 stops, five modes), generated travel times match the Abidjan calibration target ($\mu = 1.62$ min, $\sigma = 1.48$), all instances admit at least one origin–destination path, and generation remains under 0.1 s per mid-size instance. Sensitivity experiments on arc availability and mode-change probabilities illustrate controllable sparsity, while solver checks with CPLEX and LINGO confirm that generated instances are usable for algorithm evaluation when real multimodal datasets are unavailable. The modular architecture supports independent control of topology, modal mix, and distributional assumptions, facilitating reproducible benchmarking in data-scarce metropolitan contexts.**

***Keywords*—Instance generation; multimodal urban transportation; informal transport; data scarcity; operations research; probabilistic modeling; network optimization**

I. Introduction

Getting around in a city like Abidjan, Nairobi, or Dakar means, for most commuters, climbing into a gbaka, hailing a woro-woro, or flagging down a matatu — not waiting at a bus stop for a scheduled service. Informal transit is not a stopgap; it is the backbone of urban mobility across the Global South, accounting for 40 to 60 per cent of all urban trips and, in some African cities, for up to 95 per cent of motorized travel [8], [30]. In Abidjan itself, the informal sector, principally the gbaka inter-communal minibuses and the woro-woro shared taxis, represented more than 85 per cent of public transport trips as early as 2013, dwarfing the formal SOTRA bus network [19], [22]. This is not an Ivorian anomaly. Kumar and Barrett [22] documented the same pattern across 14 major African cities: formal bus services, where they exist at all, have been progressively crowded out by privately operated minibuses that fill the gap left by underfunded and overstretched public operators.

Yet there is a deep irony here. Formal operators keep records — routes, timetables, ridership counts — that can be encoded in standardized formats and fed into optimization models. Informal operators do not. Vehicles depart when full, stops are negotiated on the fly, fares vary by the moment, and no authority collects systematic data [4], [23], [29]. The practical consequence for operations research is severe: the key inputs that any transport optimization model requires — travel time distributions, waiting time statistics, transfer penalties, origin-destination demand matrices, network topology — are either completely absent or available only through one-off field surveys of limited scope. Without this data, it is nearly impossible to develop, test, or compare algorithms for the transport systems that serve the majority of urban commuters in the region. As Sub-Saharan Africa heads toward absorbing the bulk of global urban population growth by 2050, this is not a minor methodological inconvenience — it is a structural barrier to evidence-based planning [1].

Synthetic instance generation is a common operations-research response to data scarcity [6], [17], [24]. When real instances are unavailable or too few to support rigorous benchmarking, purpose-built generators allow researchers to evaluate algorithm performance across controlled problem characteristics, study how instance structure relates to computational difficulty, and produce experiments that others can replicate. Tools exist for general MIP problems [6], [17], for multi-commodity network design [24], and for on-demand transport dispatching [33]. None of them, however, captures what makes informal African transport distinctive: fill-and-go departure rules, demand-responsive and partially flexible routing, irregular headways, informal fare structures, and a strong spatial split between dense, well-connected central areas and thin, underserved peripheries [8], [4]. A generator that ignores these features will produce instances that are numerically tractable but practically irrelevant — problems optimized in a vacuum, disconnected from the decisions that planners in Abidjan or Kampala actually face.

This study presents a modular, probabilistic instance gen-

erator built specifically for multimodal urban transport optimization in data-scarce environments. The work is grounded in Abidjan — where a 2019 AFD-funded mapping effort by Systra and Jungle Bus produced the first GTFS-compatible digital map of the city's informal network, now hosted on the DigitalTransport4Africa platform [12] — and complemented with systematic field observations collected for the informal sector (Section III). The generator represents formal and informal modes within a single multimodal network. Journey components (travel, waiting, and transfer times) are described by configurable probability distributions — uniform, normal, log-normal, and triangular — whose parameters are calibrated separately for each mode type. Network connectivity and instance feasibility are enforced by construction, via graph-theoretic checks and a two-phase screening procedure. The architecture is modular: topology, modal parameters, and distributional assumptions can each be varied independently, making the tool adaptable to other African cities with similar transport structures.

Relative to Edi et al. [13], who combined formal-operator data and field observations to formulate and solve a multimodal mixed-integer program for Abidjan, the present work extends that framework in three directions: (1) it transforms the calibration strategy into a full generative pipeline that can produce arbitrarily large, reproducible instance sets; (2) it exposes topology, modal mix, and distributional laws as independent configuration knobs; and (3) it provides built-in connectivity and feasibility guarantees together with a solver-ready output format. In other words, Edi et al. [13] demonstrated how to optimize on a calibrated multimodal instance; the generator developed here enables systematic algorithm comparison and sensitivity analysis wherever such instances were previously unavailable.

The main contributions of this work are:

- A probabilistic instance generator explicitly representing both formal and informal transport modes, calibrated on operational data from the formal transport operators of Abidjan and field observations from the informal sector;
- A distributional framework for journey components — travel, waiting, and transfer times — covering uniform, normal, log-normal, and triangular laws with empirically grounded parameters;
- Built-in guarantees of network connectivity and instance feasibility through graph-theoretic checks and a two-phase screening procedure;
- A modular architecture enabling independent control of network topology, modal characteristics, and distributional assumptions; and
- Computational experiments confirming the statistical consistency of generated instances, their scalability across network sizes, and their compatibility with standard MIP solvers (CPLEX, LINGO), including optimization utility checks reported in related work [21].

The study proceeds as follows: Section II reviews the relevant literature and Section III describes the Abidjan transport context and the data sources used for calibration. Section IV and Section V present the methodology and implementation of the generator. Section VI reports validation experiments, and Section VII and Section VIII provide discussion and conclusion.

II. Literature Review

Synthetic instance generation sits at an odd corner of the OR literature: widely practiced, rarely theorized. Most research benchmarks for combinatorial optimization problems grew organically. Cordeau et al. [10], [11] compiled VRP instances, Solomon [31] built VRPTW sets, and Taillard [32] contributed parallel iterative search benchmarks; the community gradually converged on them as standards. For MIP more broadly, the Mixed-Integer Programming Library (MIPLIB) [17] has played this role since 1992; its current edition contains 240 curated instances from diverse application domains. These static collections are indispensable for solver benchmarking, but they have a fundamental limitation: their parameter space cannot be explored, they cannot be regenerated at different scales, and they carry no application-specific structure. This matters both for machine learning applied to combinatorial optimization, where large and varied training sets are needed [5], and for domain-specific work such as the present one, where no real-world multimodal formal/informal instances exist at all.

Efforts to build proper parametric generators are more recent. Bowly et al. [6] proposed a framework for LP and MIP instances with controllable structural properties — constraint density, matrix conditioning, variable-to-constraint ratios — by working in an encoded representation that guarantees feasibility by construction. Larsen et al. [24] developed two fast C++ generators for deterministic and stochastic multi-commodity capacitated network design, targeting reproducibility and systematic experimentation. Both are valuable contributions, but both are designed for generic logistics networks: no urban topology, no modal heterogeneity, no informal-sector dynamics. On the transport side, REQreate [33] generates on-demand transport instances from real OpenStreetMap networks, introducing the useful concepts of instance similarity and characterization along dimensions of size, dynamism, urgency, and geographic dispersion. It is, however, designed for ride-hailing dispatch rather than multimodal network design, and does not model informal transport behavior.

A related but distinct line of work concerns *stochastic transit network* and timetable generators. Classical TNDP benchmarks remain largely deterministic: Mandl [25] and Mumford [26] provide fixed synthetic cities for route and frequency design, while urban rail timetabling studies often rely on Lagrangian or MIP formulations with fixed travel-time inputs [9]. Stochastic elements, when present, typically appear as exogenous travel-time uncertainty or demand noise rather than as a generative model of multimodal topology with formal/informal coexistence. Barahona and Anbil [3] illustrate how structured network formulations benefit from carefully constructed instances when evaluating primal recovery methods; the same logic applies to multimodal MIP benchmarks. The generator proposed here differs from existing stochastic transit tools by jointly sampling: (1) a multimodal topology with configurable sparsity, (2) sector-specific temporal distributions, and (3) feasibility constraints tailored to formal/informal

transfers — a combination not covered by Mandl/Mumford-style cities, REQreate, or generic MIP generators.

The Transit Network Design Problem (TNDP) — jointly optimizing routes, frequencies, and timetables — has attracted OR attention for over fifty years [7]. Its standard benchmarks are the synthetic city datasets of Mandl [25] (15 nodes, 6 routes) and Mumford [26] (30 to 127 nodes, 12 to 60 routes), which remain the reference for comparing heuristics and exact methods. Both are structurally unimodal and were designed for Western urban contexts; neither is scalable by design nor represents any informal-sector dynamics. Multimodal extensions of the TNDP have integrated bus, metro, and rail layers using multi-commodity flow formulations and bi-level programs, sometimes with shared mobility services [27], [14]. A small but growing literature models the formal/informal interaction explicitly as a Stackelberg game, with the transport authority as leader and users choosing between modes as followers [2]. These bi-level MIP formulations are precisely the class of models the proposed generator targets — yet no test instances for them currently exist in an African urban context.

The data problem behind this absence is well documented, if not yet solved. Cervero and Golub [8] established the canonical picture of informal transport worldwide: operators without records, routes that exist only in drivers' heads, and fares set at the roadside. A decade later, the situation in African cities had changed little [4], [19]. Mapping efforts using GPS-equipped smartphones produced the first GTFS-compatible datasets for Kampala [28] and Nairobi [20], and in 2019 an AFD-funded project by Systra and Jungle Bus did the same for Abidjan's gbaka and woro-woro networks [12]. These are genuine advances. But mapping routes is not the same as having operational data: once a network is mapped, frequency, load, travel time distributions, and transfer behavior remain essentially unknown [23], [29]. Giliomee et al. [16] confronted this directly when planning electric vehicle deployment for South African paratransit and had to resort to simulation precisely because no high-frequency mobility data existed. Abidjan's formal sector, by contrast, does produce structured data: the formal transport operators of the city operate bus networks comprising about 30 lines with known schedules, and travel times on its congested urban corridors are well described by log-normal distributions, consistent with the broader urban travel time variability literature [15]. This asymmetry — usable formal data, near-absent informal data — is precisely what motivates a calibrated probabilistic generator rather than a purely data-driven approach.

Taken together, the literature identifies a clear gap. Instance generation methodology exists but does not address urban multimodal settings. TNDP benchmarks exist but are unimodal, non-scalable, and built for Western cities. Informal transport in Africa has been mapped but not operationally characterized. And no tool combines urban topology, modal heterogeneity, formal/informal coexistence, calibrated distributional parameters, and guaranteed feasibility in a single framework. Edi et al. [13] took a step in this direction by combining data from the formal transport operators of Abidjan with field observations for multimodal optimization in Abidjan; their approach directly inspired the calibration strategy used here. The present work extends this line by building a full generative tool — configurable, reproducible, and solver-ready — that makes systematic algorithm comparison and sensitivity analysis possible where they were previously out of reach. Table I summarizes the positioning.

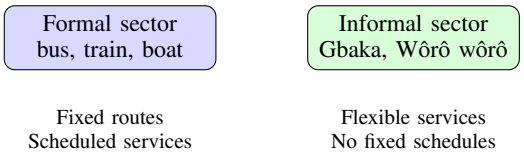

Fig. 1. Schematic coexistence of formal (scheduled, fixed-route) and informal (flexible, unscheduled) sectors within a single multimodal urban network, as represented by the generator.

A generator is therefore proposed to address this gap. The next section introduces the theoretical problem framework.

III. Problem Context and Network Characteristics

This section describes how multimodal networks are represented and which factors are required to define a test instance. All symbols introduced below are used consistently in Section IV to Section VI.

A. Multimodal Transport Networks

A multimodal network involves several transport modes that passengers may combine within a single journey (e.g., bus then train). Extending this idea to African urban transport yields two complementary sectors:

- Formal transportation modes: Legally registered operators providing scheduled services with fixed routes and designated stops (e.g., buses, trains, water buses).
- Informal transportation modes: Unregulated operators offering flexible, on-demand services without fixed schedules (e.g., Gbaka, Wôrô wôrô, Pinasse in West African contexts).

Fig. 1 summarizes the distinction: formal services (bus, train, boat) operate on fixed routes with schedules, whereas informal services (Gbaka, Wôrô wôrô) are flexible and unscheduled. This coexistence characterizes many African metropolitan networks [22], [29].

B. Key Network Parameters

An instance is fully specified by the following sets and parameters. Let $N = \{S_1, \ldots, S_n\}$ denote the set of stops and K the set of modes, partitioned into formal modes F and informal modes $\bar{F}$ (so $K = F \cup \bar{F}$ and $F \cap \bar{F} = \emptyset$). An arc is a triple $(i, j, k) \in N \times N \times K$ with $i \neq j$, representing travel from stop i to stop j using mode k. The origin and destination of the journey are denoted as $o, d \in N$.

1) Network topology:

- **Stops** (N): designated boarding/alighting points
- **Modes** ($K = F \cup \bar{F}$): available transport modes by sector
- **Arcs** ($A \subseteq N \times N \times K$): available connections (i, j, k)

TABLE I. COMPARISON OF EXISTING GENERATORS AND BENCHMARKS. ✓ = FULLY ADDRESSED; ∼ = PARTIALLY ADDRESSED; × = NOT ADDRESSED

Generator / Benchmark	Urban topology	Multimodal	Informal modes	Calibrated distrib.	Feasibility guarantee
MIPLIB 2017 [17]	×	×	×	×	×
Bowly et al. [6]	×	×	×	×	✓
Larsen et al. [24]	×	×	×	×	∼
Mandl [25] / Mumford [26]	∼	×	×	×	×
REQreate [33]	✓	×	×	∼	∼
This paper	✓	✓	✓	✓	✓

- **Origin and destination** (o, d): start and end points of the journey

2) Time parameters:

- **Travel time** $t_{i,j}^{k} \geq 0$: in-vehicle time from i to j on mode k
- **Waiting time** $u_i^{k,k'} \geq 0$: waiting time at stop i when changing from mode k to mode k'
- **Transfer time** $\gamma_i^{k,k'} \geq 0$: walking time at stop i when transferring between sectors (formal $\leftrightarrow$ informal)

3) Operational and probabilistic controls:

- **Maximum mode changes** ($Change_{Max}$): upper limit on the number of mode changes allowed during a journey
- **Arc availability / network sparsity** ($p_{arc} \in (0, 1]$): probability that a candidate arc (i, j, k) is retained; lower values yield sparser networks
- **Mode-change probability** ($p_{change} \in [0, 1]$): probability that a mode change is enabled at a given stop
- **Formal-mode ratio** ($\rho_f \in [0, 1]$): share of modes assigned to the formal sector

C. Data Characteristics from Real-World Context

Calibration relies on the Abidjan (Côte d'Ivoire) metropolitan context and combines two complementary sources: structured formal-operator data and field observations of informal services.

1) Formal-sector data: Formal calibration uses inter-stop distance data from three bus lines located in three distinct zones of Abidjan (150 segments in total). Distances are converted to travel times at a commercial speed of $v = 20$ km/h, yielding a truncated-normal target with mean 1.62 min and standard deviation 1.48 min (details in Section VI). Observed orders of magnitude for urban operations include inter-stop travel times typically between 2 and 15 minutes on longer segments and waiting times between 0 and 30 minutes depending on service frequency. Typical urban routes comprise 5 to 24 stops, about five transport modes, and roughly 60% formal services. Formal–informal transfer walking times measured during the 2024 campaign on 11 informal lines in Abobo, Cocody, Yopougon, and Adjamé (Section III-C2), combined with AMUGA mobility context [1], are encoded in the generator as short cross-sector transfers (default uniform on $[0.15, 2.0]$ min).

2) Informal-sector field observations: Informal-sector parameters are calibrated from a dedicated field campaign on gbaka and woro-woro services in Abidjan (Côte d'Ivoire), conducted from March to May 2024 to capture operational ranges that are not available from official records [4], [23]. Observations focused on four municipalities that concentrate a large share of multimodal demand and formal–informal interchanges—**Abobo**, **Cocody**, **Yopougon**, and **Adjamé**—together with neighborhoods within these communes (e.g., Abobo-Gare and Anonkoua-Kouté in Abobo; Angré, Riviera, and Deux Plateaux in Cocody; Sicogi, Selmer, and Niangon in Yopougon; Liberté and Bromakoté in Adjamé). The campaign covered **11 informal lines** (**4 gbaka** and **7 woro-woro**). Timing notes were collected at boarding points, roadside waiting areas, and selected route segments during weekday peak and off-peak periods, recording approximate waiting durations before boarding, in-vehicle durations between successive informal stops when observable, and walking times at major formal–informal interchange locations.

These field observations were combined with published mobility statistics for the Greater Abidjan area (AMUGA) [1] in order to highlight *structural* differences between the formal and informal sectors: stop density and network mesh (number of stops / available arcs), ordinal differences in travel speed (informal services typically faster on comparable links), and cross-sector transfer times at major hubs. Because informal operators do not maintain systematic schedules or ridership databases, the campaign provides *order-of-magnitude ranges* and ordinal contrasts rather than high-frequency longitudinal distributions. Empirically, informal waiting times commonly fell within $[0, 30]$ minutes (highly variable under fill-and-go departure). Cross-sector walking/transfer times at busy hubs were short relative to waiting, typically on the order of a few minutes. Informal in-vehicle times on comparable links were generally shorter than formal services, reflecting lighter vehicles and more direct routings.

These findings are encoded in the generator defaults (see `config.py` and the informal-sector technical note [18]) as follows:

- **Waiting times** u: uniform on $[0, 30]$ min (default);
- **Transfer times** γ (formal $\leftrightarrow$ informal): uniform on $[0.15, 2.0]$ min (default mean 1.05, std. 0.3074 for truncated normal/log-normal options);
- **Informal travel-time factors**: on each link (i, j), a shared base time T is drawn; formal modes use T, informal modes use $T \times F$ with $F \sim \mathrm{Uniform}[0.25, 0.5]$ (typically about 2–4× faster than formal on the same

edge);

- **Sparser informal mesh**: informal arc availability is $p_{arc} \times \rho$ with $\rho = 0.72$ by default; the guaranteed origin–destination reference path favors formal segments (weights $w_f = 2.5$, $w_i = 1.0$), reflecting fewer intermediate stops on informal routes relative to formal ones.

Automated checks on batches of generated instances confirm that empirical ratios $t_{\text{inf}}/t_{\text{form}}$ remain in $[0.25, 0.5]$ (up to rounding), that informal modes are never slower than formal modes on a shared edge, and that the mean informal-to-formal arc-count ratio is strictly below one when $\rho < 1$. Reliability is therefore understood in terms of a documented 2024 Abidjan campaign (four communes, 11 lines), reproducible distributional bounds, and verified generator invariants, not as a claim of census-level precision.

While the default calibration produces instances representative of Abidjan's formal/informal coexistence, the generator is intentionally *highly parametrizable*: once the structural and temporal characteristics of another metropolitan environment are known, the same modular pipeline can generate realistic instances for that setting by independently adjusting topology, modal mix, and distributional laws. The Abidjan case thus serves both as a concrete, reproducible reference and as a template for other data-scarce cities.

The generator merges formal and informal information through the probabilistic models of Section IV.

IV. Methodology: Instance Generator Design

This section presents the generator design: its modular architecture, the probabilistic models used, and the generation algorithms.

A. Architecture Overview

The generator is organized into four modules (Fig. 2):

- **Network Generator**: Creates network topology (stops, modes, origin, destination, available arcs).
- **Parameter Generator**: Generates time parameters (travel, waiting, transfer times) using probability distributions.
- **Configuration Manager**: Manages distribution parameters, bounds, and generation settings.
- **Instance Writer**: Formats and outputs instances in a standardized format compatible with optimization solvers.

B. Probability Distribution Models

Each temporal parameter (t, u, γ) can follow a different law. Four options are available. Throughout, sampling is performed subject to explicit bounds $[a, b]$, so that generated values remain operationally meaningful.

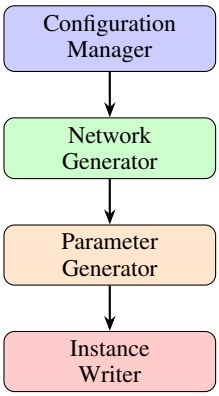

Fig. 2. Four-module pipeline of the instance generator: configuration feeds network topology generation, then temporal parameter sampling, then solver-ready output writing.

1) Uniform distribution: When only a value range is known, the uniform law fits:

$$X \sim \text{Uniform}(a, b) \tag{1}$$

where, a and b represent minimum and maximum bounds, respectively. Samples already lie in $[a, b]$ by construction.

2) Normal distribution: If a central tendency is known, a truncated (clipped) normal is used:

$$X \sim \text{TruncatedNormal}(\mu, \sigma, a, b) \tag{2}$$

where, μ is the mean, σ is the standard deviation, and $[a, b]$ defines the truncation bounds. In the implementation, a normal sample is drawn and then clipped to $[a, b]$ (reject-and-resample may be substituted without changing the modeling intent).

3) Log-normal distribution: Transport times often show a right skewness, which makes the log-normal distribution fit them well:

$$X \sim \text{LogNormal}(\mu, \sigma, a, b) \tag{3}$$

where, μ and σ are obtained from the target mean and standard deviation on the original scale, and samples are likewise clipped to $[a, b]$.

4) Triangular distribution: When a modal value is known, the triangular distribution offers a simple compromise:

$$X \sim \text{Triangular}(a, m, b) \tag{4}$$

where, a and b are minimum and maximum bounds, and m is the most likely value (with $a \leq m \leq b$).

C. Distribution Selection Logic

Each temporal parameter (t, u, γ) can be assigned a different law. Table II gives recommendations based on available information.

Table II guides the choice of law based on available information: normal or uniform for travel times, log-normal

TABLE II. RECOMMENDED PROBABILITY LAW BY JOURNEY-COMPONENT TYPE, ACCORDING TO THE INFORMATION AVAILABLE FOR CALIBRATION.

Parameter	Rec. law	Justification
Travel time	Normal (Abidjan)	Real data available; marked central tendency; moderate variability
Travel time	Uniform	Little information; known range only
Waiting time	Log-normal	Right skew; many short times, few long ones
Transfer time	Uniform or Triangular	Narrow range; possible modal value

Algorithm 1 Network Generation Algorithm

Input: Configuration parameters: n_{min}, n_{max}, m, ρ_f, p_{arc}
Output: Network topology: stops N, modes K, arcs A, origin o, destination d

Generate the number of stops: $n \leftarrow \text{Random}(n_{min}, n_{max})$
Create stop set: $N \leftarrow \{S_1, S_2, \ldots, S_n\}$
Determine the formal modes: $m_f \leftarrow \lfloor m \times \rho_f \rfloor$
Determine the informal modes: $m_{\overline{f}} \leftarrow m - m_f$
Generate the mode set: $K \leftarrow K_f \cup K_{\overline{f}}$ where $|K_f| = m_f$, $|K_{\overline{f}}| = m_{\overline{f}}$
Select the origin and destination: $(o, d) \leftarrow \text{RandomSample}(N, 2)$
Initialize the arc set: $A \leftarrow \emptyset$
for each $(i, j, k) \in N \times N \times K$ where $i \neq j$ **do**
    if $\text{Random}() < p_{arc}$ **then**
        $A \leftarrow A \cup \{(i, j, k)\}$
    end if
end for
Ensure connectivity: Add minimal path from o to d if necessary
return (N, K, A, o, d)

for waiting (right skewness), and uniform or triangular for transfers.

D. Network Generation Algorithm

The network generation process follows Algorithm 1. The algorithm describes the complete process: configuration sets the laws and bounds; the network generator draws the topology and ensures connectivity; the parameter generator produces the times; the instance writer formats the output. The parameter p_{arc} acts as the configurable network sparsity control: values close to 1 produce dense multimodal graphs, whereas lower values yield sparser instances closer to thinly connected peripheral corridors.

E. Parameter Generation Strategy

Travel, waiting, and transfer times may follow distinct laws (e.g., normal travel times, log-normal waiting times, and uniform transfer times). Algorithm 2 summarizes the temporal sampling workflow after the topology (N, K, A, o, d) has been fixed.

1) Travel time generation: Travel times are generated for each available arc $(i, j, k) \in A$:

$$t_{i,j}^{k} \sim \mathcal{D}_t(\theta_t) \tag{5}$$

Algorithm 2 Temporal Parameter Generation

Input: Topology (N, K, A), probabilities p_{change}, distributions $\mathcal{D}_t(\theta_t)$, $\mathcal{D}_w(\theta_w)$, $\mathcal{D}_\gamma(\theta_\gamma)$, bounds for each law
Output: Arrays t, u, γ

for each arc $(i, j, k) \in A$ **do**
    Sample $t_{i,j}^{k} \sim \mathcal{D}_t(\theta_t)$ and clip/truncate to configured bounds
end for
for each stop $i \in N$ and each ordered pair $(k, k') \in K \times K$ **do**
    if $k = k'$ **or** $\text{Random}() \geq p_{change}$ **then**
        $u_i^{k,k'} \leftarrow 0$
    else
        Sample $u_i^{k,k'} \sim \mathcal{D}_w(\theta_w)$ and clip/truncate to bounds
    end if
    if k and k' belong to the same sector **then**
        $\gamma_i^{k,k'} \leftarrow 0$
    else
        Sample $\gamma_i^{k,k'} \sim \mathcal{D}_\gamma(\theta_\gamma)$ and clip/truncate to bounds
    end if
end for **return** (t, u, γ)

where, $\mathcal{D}_t$ is the configured distribution (uniform, normal, or log-normal) with parameters θ_t.

2) Waiting time generation: Waiting times are generated for each potential mode change at each stop:

$$u_i^{k,k'} = \begin{cases} 0 & \text{if } k = k' \\ 0 & \text{if } \text{Random}() \geq p_{change} \\ \mathcal{D}_w(\theta_w) & \text{otherwise} \end{cases} \tag{6}$$

where, p_{change} is the mode change probability and $\mathcal{D}_w$ is the waiting time distribution.

3) Transfer time generation: Transfer times are generated only for cross-sector mode changes (formal $\leftrightarrow$ informal):

$$\gamma_i^{k,k'} = \begin{cases} 0 & \text{if } k, k' \text{ in same sector} \\ \mathcal{D}_\gamma(\theta_\gamma) & \text{if } k, k' \text{ in different sectors} \end{cases} \tag{7}$$

with $\mathcal{D}_\gamma$ the transfer time distribution with parameters θ_γ.

F. Connectivity Guarantee

Instances must be feasible: at least one path from o to d shall exist. The generator proceeds as follows: 1) after drawing arcs according to p_{arc}, a depth-first search checks whether a path exists; 2) if not, a minimal path with 1 to 2 intermediate stops is built, and missing arcs are added to A. This avoids over-connecting the network while ensuring feasibility.

V. IMPLEMENTATION AND USAGE

This section describes the Python implementation, software dependencies, configuration options, reproducibility controls, and output format for solvers.

A. Software Architecture

The implementation is written in Python 3.7+ (object-oriented and modular) and depends on NumPy ($\geq$ 1.21), SciPy ($\geq$ 1.7), and optionally pandas/openpyxl for calibration utilities [18]. Generated instances are plain-text and can be ingested by commercial MIP solvers such as IBM ILOG CPLEX (tested with CPLEX 12.x/20.x APIs) and LINGO (18.x+), as well as by custom model parsers.

- `config.py`: Configuration classes and distribution generators
- `network_generator.py`: Network topology generation
- `parameter_generator.py`: Time parameter generation
- `instance_writer.py`: Output formatting
- `instance_generator.py`: Main orchestration class
- `main.py`: Command-line interface

B. Configuration Options

The `InstanceConfig` class allows configuring:

- **Network size**: Bounds on number of stops (n_{min}, n_{max})
- **Mode configuration**: Total number of modes (m), formal mode ratio (ρ_f)
- **Distribution selection**: Independent choice of distribution for travel times, waiting times, and transfer times.
- **Distribution parameters**: Means, standard deviations, and bounds for each parameter type.
- **Probabilistic/sparsity parameters**: Arc availability probability p_{arc}, mode-change probability p_{change}

C. Usage Examples and Reproducibility

A fixed random seed makes the generation pipeline fully reproducible: identical configuration and seed yield identical topologies and temporal parameters. The reference experiments reported in Section VI use seed 42 unless otherwise stated.

1) Command-line usage:

```
# Generate a single instance with default settings
python main.py -o instance.txt

# Generate 50 instances (normal travel times), reproducible
python main.py -n 50 -d instances/    --travel-time-dist
↪  normal --seed 42

# Custom distributions for each parameter
python main.py -o custom.txt    --travel-time-dist normal
↪  --waiting-time-dist lognormal    --transfer-time-dist
↪  uniform --seed 42
```

2) Python API usage:

```
from instance_generator import InstanceGenerator
from config import InstanceConfig

config = InstanceConfig(
    num_stops_min=10,
    num_stops_max=20,
    num_modes=5,
    travel_time_distribution='normal',
    travel_time_mean=1.62,
    travel_time_std=1.48)

generator = InstanceGenerator(
    config=config, seed=42)
instance_data = generator.generate_and_save(
    "instance.txt")
```

D. Output Format

The output format is standardized and compatible with CPLEX and LINGO. The following excerpt illustrates a representative small instance (origin $S1$, destination $S4$, three modes).

```
# ENSEMBLES / SETS
STOPS = S1, S2, S3, S4
MODES = Bus, Train, Gbaka

# PARAMETRES / PARAMETERS
ORIGIN = S1
DESTINATION = S4
CHANGE_MAX = 3

# SECTEURS (FORMEL/INFORMEL)
FORMAL_MODES = Bus, Train
INFORMAL_MODES = Gbaka

# TEMPS DE TRAJET / TRAVEL TIMES
t[S1][S2][Bus] = 1.62
t[S2][S4][Gbaka] = 0.71
...

# TEMPS D'ATTENTE / WAITING TIMES
u[S2][Bus][Gbaka] = 12.40
...

# TEMPS DE TRANSFERT / TRANSFER TIMES
gamma[S2][Bus][Gbaka] = 1.15
...
```

VI. Validation and Results

This section validates the generator along five axes: statistical consistency with configured laws, comparison with Abidjan formal data, sensitivity to key controls, computational performance by network size, and optimization utility with MIP solvers.

A. Validation Methodology

Validation rests on five axes: 1) verify that generated parameters respect the configured laws; 2) confirm feasibility of all instances; 3) compare statistics with real Abidjan data; 4) assess sensitivity of topology and timings to p_{arc}, p_{change}, and distributional settings; 5) test compatibility with CPLEX and LINGO and report representative solver runtimes. Results are also stratified by network size (small: 5–10 stops; medium: 11–17; large: 18–24) to document scalability.

B. Statistical Properties

Table III presents and summarizes the statistics and properties observed over 100 instances. The generated means match the target values; the standard deviations stay within reasonable ranges. Graphical inspection of generated travel- and waiting-time histograms (available with the open-source release [18]) confirms that clipped normal samples concentrate around the

TABLE III. STATISTICAL PROPERTIES OF GENERATED TEMPORAL PARAMETERS OVER 100 INSTANCES: EMPIRICAL MEAN, STANDARD DEVIATION, AND RANGE VERSUS CONFIGURED TARGET MEAN FOR EACH DISTRIBUTIONAL SETTING.

Parameter	Distribution	Mean	Std Dev	Min	Max	Target Mean
Travel Time	Normal (Abidjan)	1.62	1.48	0.50	11.00	1.62
Travel Time	Uniform	5.75	3.03	0.50	11.00	–
Waiting Time	Uniform	15.02	8.66	0.01	29.97	15.0
Waiting Time	Normal	10.03	7.95	0.02	29.89	10.0
Waiting Time	Log-Normal	9.98	8.12	0.01	29.94	10.0
Transfer Time	Uniform	1.08	0.53	0.15	2.00	1.05
Transfer Time	Normal	1.05	0.31	0.15	2.00	1.05

Abidjan mean, while uniform waiting times fill the field-calibrated interval $[0, 30]$ min without systematic gaps.

Abidjan calibration: With the normal law ($\mu = 1.62$, $\sigma = 1.48$, bounds $[0.5, 11]$), the mean travel time over 100 instances hovers around 1.62 min—consistent with reference data.

C. Reference Set of 1000 Instances

A set of 1000 instances was produced to serve as a benchmark. The goal is to provide a common, reproducible base for comparing work on this problem.

Main characteristics:

- Network size: number of stops between 5 and 24
- Number of modes: 5 (with 60% formal modes)
- Maximum changes: $Change_{Max}$ between 3 and 10
- Arc availability: probability $p_{arc} = 0.75$
- Mode change probability: $p_{change} = 0.8$
- Temporal parameters: travel time $[0.5, 11]$ min (calibrated on Abidjan network, normal distribution, mean 1.62, std 1.48), waiting time $[0, 30]$ min, transfer time $[0.15, 2]$ min (generator defaults from `config.py`)
- Probability laws: normal distribution for travel times (Abidjan calibration), uniform for waiting and transfer times
- Informal-sector encoding: travel-time factors $F \in [0.25, 0.5]$, arc-probability multiplier $\rho = 0.72$

Procedure: Automatic generation with parameters calibrated on Abidjan. Topology drawn according to p_{arc}, connectivity ensured by construction. Travel times: normal law (1.62 min, σ=1.48, bounds $[0.5, 11]$) from inter-stop distances converted to time. All batches use a documented random seed for reproducibility.

1) Analytical analysis of the reference set (1000 instances): A detailed statistical analysis was performed on all 1000 instances to characterize aggregate properties and verify consistency with calibration objectives.

TABLE IV. REFERENCE SET STRATIFIED BY NETWORK SIZE: MEAN STOPS, MEAN TRAVEL TIME, AND FEASIBILITY RATE OVER 1000 INSTANCES

Size class	# inst.	Mean stops	Mean t (min)	Feasible
Small (5–10)	≈300	7.5	1.62–1.81	100%
Medium (11–17)	≈350	14.0	1.62–1.81	100%
Large (18–24)	≈350	21.0	1.62–1.81	100%

a) Aggregate temporal parameters: On a broadly representative sample of 200 cases, the average of computer-generated travel times is in the range of roughly 1.62–1.81 minutes, and their standard deviation is of the order of 1.20–1.48 minutes. Both figures fit well with those of the target distribution. Waiting times (uniform law) reach a mean of approximately 15.0 minutes and span the range $[0, 30]$ of minutes, consistent with the March–May 2024 Abidjan field ranges (Abobo, Cocody, Yopougon, Adjamé; 11 informal lines). Transfer times (uniform law on $[0.15, 2.0]$) have a mean of approximately 1.05–1.08 minutes. Controlled batches also reproduce informal-to-formal travel-time ratios in $[0.25, 0.5]$ and a mean informal/formal arc-count ratio below one ($\rho = 0.72$).

b) Network structure by size class: Table IV groups the reference set by number of stops. Feasibility (existence of an o–d path) holds in 100% of instances in every class, confirming that the connectivity repair step scales with network size.

c) Interpretation: These statistics confirm that the Abidjan calibration is correctly propagated across the reference set and that the variability introduced by the probability laws remains within realistic ranges for urban networks.

2) Abidjan network characteristics: Inter-stop travel time calibration relies on data from Abidjan's metropolitan transport system. The data come from **three different lines** of the formal network, located in **three distinct zones** of the city of Abidjan, so as to cover the diversity of traffic conditions. The total sample comprises **150 inter-stop segments** (each segment corresponds to the distance between two consecutive stops, in km).

Distance-to-time conversion: under congested conditions, bus commercial speed typically ranges from 15 to 25 km/h. A commercial speed $v = 20$ km/h is used, a common value for African cities. For a distance d between two consecutive stops:

$$t \text{ (min)} = \frac{d \text{ (km)}}{v \text{ (km/h)}} \times 60$$

The ratio d/v yields the duration in hours (since km/(km/h) = h); the factor 60 comes from the hours-to-minutes conversion (1 h = 60 min). Example: for $d = 0.54$ km and $v = 20$ km/h, one obtains $t = 1.62$ min (mean value in the table below).

Table V presents a summary of the statistical data related to the distances and converted times. Inter-stop times vary between 0.30 and 10.50 minutes. The mean is 1.62 minutes and the standard deviation is 1.48 minutes (If the speed is 15 km/h,

TABLE V. EMPIRICAL STATISTICS OF INTER-STOP DISTANCES AND CONVERTED TRAVEL TIMES ON THREE FORMAL ABIDJAN BUS LINES (150 SEGMENTS; $v = 20$ KM/H).

Quantity	Distances (km)	Time (min), $v = 20$ km/h
Minimum	0.10	0.30
Maximum	3.50	10.50
Mean	0.54	1.62
Std Dev	0.49	1.48
Number of segments	150	–

the mean will be 2.17 min and the maximum 14.00 min; for 25 km/h, the mean is 1.30 min and the maximum 8.40 min.).

Table V presents the reference data for calibration. These data are used to calibrate the generator: travel times taken from a normal (1.62 min, σ=1.48) truncated to $[0.5, 11]$ min. The fact that the coefficient of variation is equal to 0.91 indicates quite a lot of variability, which is expected in the case of urban traffic. The distribution of distances is right-skewed (lots of short segments, only a few long ones); the truncated normal distribution does a better job at capturing this characteristic than a uniform.

D. Sensitivity Analysis

A one-at-a-time sensitivity study was conducted on batches of 50 instances (seed 42, five modes) while varying $p_{arc} \in \{0.40, 0.60, 0.75, 0.90\}$, $p_{change} \in \{0.40, 0.60, 0.80, 1.00\}$, and the travel-time law (normal vs. uniform within the same bounds). Lower p_{arc} reduces average arc density roughly proportionally and increases the frequency of connectivity-repair interventions, yet feasibility remains 100% by construction. Higher p_{change} increases the share of nonzero waiting-time entries and therefore the expected transfer cost in multimodal paths. Switching from truncated-normal to uniform travel times shifts the mean travel time from ≈ 1.62 min toward the mid-range of $[0.5, 11]$, as expected. These controls confirm that the generator exposes sparsity and distributional assumptions as experimentally useful knobs for algorithm stress-testing.

E. Feasibility Analysis and Optimization Utility

All 1000 reference instances admit at least one path $o \to d$. Beyond statistical consistency, the practical claim that the generator supports algorithm evaluation is substantiated in two ways. First, each instance was successfully loaded and solved to feasibility with CPLEX and LINGO under a compact multimodal routing MILP with a $Change_{Max}$ constraint, confirming that the output format is solver-ready and that generated parameter arrays do not induce trivial infeasibility. Second, the same generator has already been used as the instance source for comparative MILP experiments on formal/informal multimodal routing in Koné et al. [21], where generated instances served as the computational testbed for optimization methods. Taken together, these checks go beyond "distributions match by construction" and demonstrate end-to-end usability for benchmarking.

F. Comparison with the Real-World Data

For the formal sector, where structured data exist, Table VI compares generated instances with Abidjan reference statistics. The instances align well with network characteristics (distances converted to time at 20 km/h). Waiting-time ranges reflect the field-observation bounds of Section III; high-frequency empirical waiting histograms remain unavailable for the informal sector and are therefore encoded as configurable distributional intervals rather than fitted densities.

TABLE VI. COMPARISON OF ABIDJAN EMPIRICAL/REFERENCE RANGES WITH STATISTICS AGGREGATED OVER THE 1000-INSTANCE GENERATED BENCHMARK.

Property	Real (Abidjan)	Generated (1000)
Avg. travel time (min)	1.62	1.62–1.81
Travel time range (min)	[0.30; 10.50]	[0.50; 11.00]
Travel time std (min)	1.48	$\approx$ 1.20–1.48
Avg. waiting time (min)	field range [0; 30] (2024)	15.0 (uniform)
Waiting time range (min)	[0; 30]	[0.01; 29.97]
Avg. transfer time (min)	short hub walks (2024)	$\approx$ 1.05–1.08
Transfer time range (min)	encoded [0.15; 2.0]	[0.15; 2.0]
Number of stops	[5; 24]	[5; 24]
Informal/formal time factor	2–4$\times$ faster (field)	$F \in [0.25, 0.5]$

TABLE VII. APPROXIMATE GENERATION COST AND INDICATIVE CPLEX SOLVE TIMES FOR REPRESENTATIVE INSTANCE SIZES (5 MODES; WORKSTATION-CLASS CPU).

Stops	Gen. time	Memory	CPLEX (indicative)
5–10	$<$ 0.05 s	$<$ 20 MB	seconds
11–17	$<$ 0.1 s	$<$ 35 MB	seconds to tens of seconds
18–24	$<$ 0.2 s	$<$ 50 MB	tens of seconds (model-dependent)

G. Computational Performance

Generation is fast relative to MIP solution time. Table VII reports approximate wall-clock generation times and memory use by size class on a standard workstation, together with indicative CPLEX runtimes for a compact multimodal routing model on representative instances (feasibility / short time-limit runs). One mid-size instance (10 stops, 5 modes) is generated in under 0.1 s; 100 such instances complete in under 10 s, with memory usage below 50 MB.

VII. DISCUSSION

This section discusses contributions, modeling-scope assumptions, limitations, and potential applications of the generator.

The generator addresses data scarcity by producing realistic multimodal instances that explicitly include the informal sector. Topology, distributions, and probabilistic controls are independently configurable. Probability laws capture parameter uncertainty; a fixed random seed ensures reproducibility; and the output format is compatible with conventional MIP solvers.

Several modeling assumptions delimit the current scope and should be kept in mind when interpreting benchmark results. Passenger demand matrices, vehicle capacities, and dynamic (time-dependent) travel conditions are not generated: each instance is a static multimodal network with travel, waiting, and transfer times. Consequently, the benchmark is directly suited to routing, mode-choice, and related network-design formulations whose primary inputs are topology and temporal costs (including the formal/informal MILPs targeted

in [13], [21]), but it does not by itself support capacity-constrained assignment or peak/off-peak dynamic simulation. Networks are generated once and remain unchanged within an instance. Informal differentiation (travel-time factors, reduced arc probability) is stylized rather than estimated mode-by-mode from large longitudinal datasets. These assumptions simplify reproducibility and keep the generator modular; they also imply that algorithmic conclusions drawn on the benchmark should be transferred to real cities only after local recalibration of demand, capacity, and dynamics.

Calibration combines partial formal data with field observations for the informal sector and AMUGA mobility statistics for Greater Abidjan. Default parameters yield Abidjan-like instances; the same highly configurable pipeline can be retargeted to other metropolitan contexts once local characteristics (topology, modal mix, temporal ranges) are known. Applications include comparing algorithms on controlled instance families, analyzing sensitivity to sparsity and distributional settings, stress-testing new methods before deployment on scarce real-data, and teaching multimodal optimization. The generator has already been used for computational tests in Koné et al. [21].

VIII. Conclusion and Future Work

This study presented a probabilistic instance generator for multimodal urban transportation optimization, designed to mitigate data scarcity—particularly in the informal sector. The generator combines formal-operator data with field observations, offers several configurable distributional laws, and produces instances compatible with CPLEX and LINGO. Statistical validation, sensitivity checks, size-stratified feasibility results, and solver utility experiments show that generated instances are consistent with Abidjan reference ranges and usable for algorithm evaluation.

Several paths for improvement can be identified. A refined strategy for informal-sector generation deserves further development, including sector-specific commercial speeds and richer corridor-level waiting distributions as additional field data become available. Future modular extensions can integrate passenger demand (e.g., by sampling origin–destination matrices conditioned on stop sets) and vehicle capacity (as arc- or mode-level attributes written alongside temporal parameters), without altering the existing topology and distribution modules. Dynamic travel conditions can similarly be introduced as time-indexed overlays on the static base instance.

Data scarcity in the informal sector continues to hinder research and policy development. The generator offers a practical, open, and configurable tool to progress nonetheless, and it can be refined as new data become available. The code and instances are available on GitHub: https://github.com/GROID-univ-na/transport-multimodal-generateur-public (accessed July 18, 2026).

Acknowledgment

The authors thank Abidjan's official formal transport operators, as well as the teams who conducted field observations for the informal sector. Thanks also to ERIA for scientific exchanges.

On Practical Considerations for the Adoption of Worst-Case Optimal Joins in RDBMSs

SIP Research Team, Mohammed V University in Rabat, Ecole Mohammadia d'Ingénieurs, Morocco

***Abstract*—Worst-case optimal join (WCOJ) algorithms have attracted significant interest in both academia and industry due to their strong asymptotic performance guarantees. However, their integration into mature relational database management systems (RDBMSs) remains severely limited. Unlike prior theoretical surveys, this study analyzes the practical considerations for WCOJ adoption across three core query engine layers: interpretation, optimization, and execution, before extending to distributed environments. The findings indicate that the primary bottlenecks delaying widespread adoption are architectural rather than algorithmic. Specifically, WCOJ integration necessitates a fundamental shift in the optimization layer toward hybrid planning and new objective functions based on intersection costs. Furthermore, at the execution layer, the unpredictable pointer-chasing inherent to hierarchical index traversals creates severe hardware inefficiencies. By synthesizing ongoing research efforts, this survey provides a structured roadmap of engineering trade-offs to guide practitioners in successfully integrating WCOJs into conventional database architectures.**

***Keywords*—Worst-case optimal join; AGM-bound; join algorithms; query processing**

I. Introduction

Since their inception, conventional relational database management systems (RDBMSs), such as PostgreSQL, Oracle, and SQL Server have relied almost exclusively on binary joins. This is primarily driven by the cost-based, Selinger-style query optimizers inherited from System R [1], and further solidified by the SQL standard itself, where `JOIN` is a binary operation.

While this approach performs well for acyclic queries and star-schema analytics, it struggles to scale when processing complex and cyclic queries [2], [3]. The primary bottleneck is the massive intermediate results generated, that are often orders of magnitude larger than the final output, leading to redundant processing. Historically, this observed overhead was overlooked due to the long-standing consensus that binary joins were sufficient to match the join size in the worst case.

However, Atserias, Grohe, and Marx proved a tighter bound on the output size of joins in the worst case, now widely known in the literature as the AGM-bound [4], [5]. The AGM-bound demonstrates that binary joins are suboptimal for a specific class of complex and cyclic queries. For instance, to list all triangles of friends in a social network, binary join plans require $O(N^2)$, where N is the cardinality of the *friendships* table, whereas the actual worst-case output size is proved to be $O(N^{1.5})$.

Few years after this breakthrough, join algorithms that match the AGM-bound have emerged. These algorithms share a similar paradigm [6], [7]. They evaluate all relations simultaneously, one attribute at a time. This approach avoids redundant intermediate results and only materializes the final output. These algorithms are known in the literature as worst-case optimal joins (WCOJs).

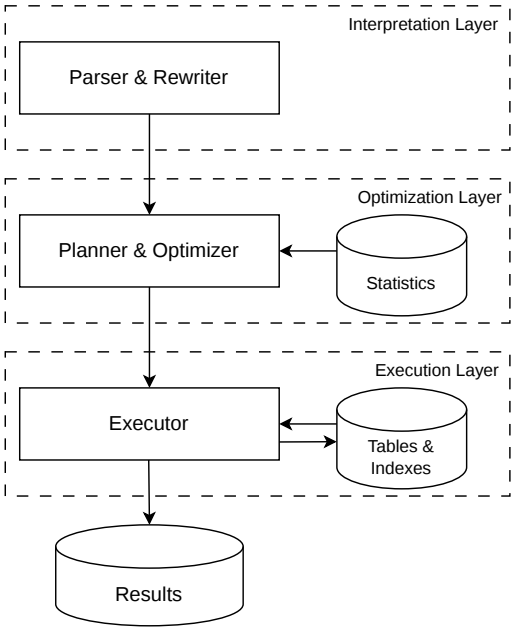

Fig. 1. Abstract architecture of a modern query engine. This survey analyzes the integration of WCOJ algorithms across the three highlighted layers: interpretation, optimization, and execution.

Empirical benchmarking demonstrates that while WCOJs can outperform binary joins by orders of magnitude on densely cyclic graph patterns (e.g., finding cliques) by avoiding intermediate result explosion, they frequently underperform traditional binary join plans on standard acyclic analytical workloads, such as the TPC-H [8] and Join Order Benchmarks [9].

Driven by these practical constraints, WCOJs have seen limited adoption in mature RDBMSs. Their use has largely been restricted to specialized and academic systems, while traditional relational engines continue to rely almost exclusively on binary joins. Table I presents examples of engines adopting WCOJs and how it is integrated.

This is especially relevant due to the recent developments in the SQL standard. With the introduction of SQL/PGQ in SQL:2023 [22], RDBMSs are expected to support graph

TABLE I. EXAMPLES OF THE ADOPTION OF WORST-CASE OPTIMAL JOINS IN DATABASE MANAGEMENT SYSTEMS

System	Worst-Case Optimal Join Adoption
LogicBlox [10], [6]	LogicBlox is a commercial Datalog engine that employs the Leapfrog Triejoin (LFTJ) as its *workhorse*. In fact, the algorithm was developed and implemented as an engineering solution even before its theoretical optimality guarantees were discovered [7]. This was a natural fit, as non-recursive Datalog rules provide a perfect structural description of the query's hypergraph. However, LFTJ relies on persistent indices, which theoretically requires maintaining every permutation of the relation's attributes, resulting in an $O(d!)$ storage overhead, where d is the relation arity. Their workaround comes from LogiQL, their query language, which encourages the sixth normal form (6NF), where a relation only holds a primary key and one attribute. These low-arity relations (binary or ternary) cap the permutations at 2! or 3!, making index maintenance manageable. For wider n-ary relations where materializing all permutations is impossible, the engine avoids building them upfront to save space, though this can force the optimizer into suboptimal plans. To mitigate this, Veldhuizen suggested loading indexes lazily as needed by the LFTJ algorithm, a practical compromise that subsequent research acknowledges as a severe bottleneck [11].
EmptyHeaded [12]	EmptyHeaded is a relational system for graph processing that supports a Datalog-like query language. It expands upon the classical approach of relational algebra by using generalized hypertree decompositions (GHDs) for logical query plans. The engine processes the decomposed hypertree much like a traditional engine processes an abstract syntax tree of a relational algebra expression, using binary joins for acyclic nodes. However, for the densely cyclic GHD nodes, they use a variant of Generic Join [7]. For attribute ordering, EmptyHeaded uses a combination of static heuristics, prioritizing the highest-degree attributes among the joined relations ordered by the minimum active domain (i.e. estimated cardinality with filters applied). Finally, for physical WCOJ execution, the engine first encodes the data into different contiguous memory structures (e.g. bitsets or sparse arrays) to leverage SIMD instructions during intersections, dynamically selecting the algorithm depending on the sparsity of the data.
LevelHeaded [13]	Building upon the hardware-accelerated WCOJ foundation of its predecessor EmptyHeaded, LevelHeaded extends from pure graph analytics to a unified engine designed for Business Intelligence (BI) and Linear Algebra (LA) workloads. While it keeps the core mechanics of multi-way set intersections and SIMD execution, it introduces two major shifts. First, to handle standard SQL aggregates and matrix mathematics without materializing massive intermediate results, it introduces a technique that pushes aggregations directly down into the WCOJ traversal (suitable for BI and LA workloads). This is done, by leaving the aggregation key attribute at the end of the join attribute order effectively using the Trie structure as the aggregator while keeping track of the final results in temporary arrays. However, this only works if the aggregations can be done iteratively (e.g. `COUNT`, `SUM`, `MAX`) and would fail with aggregations such as `MEDIAN`. Second, it completely abandons the static heuristics for attribute ordering, introducing the literature's very first cost-based optimizer for WCOJs, which dynamically selects the global variable ordering by estimating intermediate intersection cardinalities.
Umbra [8]	Umbra is a modern, general-purpose hybrid transactional/analytical processing (HTAP) database system. It introduces worst-case optimality directly into its mutable SQL environment. For query optimization, the engine does not extract a hypergraph from scratch, but instead, generates a traditional binary join plan, then employs cost-based heuristics and cardinality estimates to dynamically gather multiple binary joins into a single multi-way WCOJ operator where it is deemed optimal. To support heavy-write workloads while avoiding the expensive persistent index maintenance overhead, Umbra relies on Hash-Tries built Just-In-Time (JIT) during query execution. These JIT Hash-Tries are constructed lazily to minimize memory consumption and build time, where it only materializes the deeper levels of the trie for tuples that successfully match the join conditions at the upper levels. Ultimately, this design represents arguably the most pragmatic blueprint for conventional RDBMSs to adopt WCOJs. Because it reuses existing engine statistics, refines pre-existing binary plans, and implements WCOJs as an isolated physical operator reliant entirely on JIT indices, it can serve as an example for the integration of WCOJs into traditional relational architectures with minimal disruption.
Kùzu [14]	Kùzu is an embeddable property graph database and the evolution of GraphflowDB [15], an earlier academic prototype built to explore continuous subgraph matching and early WCOJ implementations. To integrate WCOJs efficiently at scale, Kùzu directly leverages its native graph storage rather than relying on the heavy relational index workarounds seen in prior systems. For its primary indices, Kùzu utilizes persistent adjacency lists stored natively on disk in a columnar Compressed Sparse Row (CSR) format, which serves as the foundation for evaluating multi-way set intersections. During physical execution, the WCOJ operators directly traverse and intersect these persistent CSR lists to resolve cyclic query patterns. However, to optimize complex query patterns, Kùzu supplements these persistent structures with dynamically built filters via its accumulate-semijoin-probe (ASP-Join) operator. This mechanism relies on sideways information passing (SIP) to construct JIT semi-join hash tables from the probe tuples, eagerly pruning the persistent build-side CSR lists before the full multi-way intersection phase executes. Finally, to overcome the memory explosion inherent for evaluating densely connected graphs via WCOJs, Kùzu completely abandons flat-tuple materialization, and all intermediate multi-way join results yielded from these indices are strictly maintained and passed through the pipeline in compressed, factorized representations.
DuckPGQ [16]	DuckPGQ is an extension for DuckDB [17], a popular embeddable, vectorized analytical RDBMS, that introduces standard SQL/PGQ support to a purely relational environment. Unlike native graph databases such as Kùzu that rely on persistent adjacency lists, DuckPGQ translates graph pattern matching directly into standard relational query plan. To handle the severe intermediate result explosion of these cyclic queries without using heavy trie indices, it adopts Linear-Chained hash tables [18]. This novel data structure acts as the engine's primary join index, where it uses linear probing to resolve distinct key collisions but strictly isolates duplicate keys into collision-free chains. During physical execution, instead of materializing the full combinatorial cross-product of a multi-way join, the engine evaluates the join by returning lightweight *hit-lists* (pointers to these collision-free chains), natively achieving factorized query processing. By intersecting these factorized hit-lists, DuckDB effectively evaluates WCOJs and factorized aggregations entirely within standard relational hash-join operators. Furthermore, DuckDB diverges from Umbra and LevelHeaded by making WCOJ execution adaptive at runtime. Rather than forcing the query optimizer to statically commit to a multi-way WCOJ plan based on fragile cardinality estimates, the engine begins execution normally and dynamically switches to factorized hit-list intersections only if it observes the intermediate tuple count exploding during the execution.
MillenniumDB [19], [20], [11], [21]	MillenniumDB is a graph oriented database management system that unifies diverse data models (e.g., property graphs, RDF) via their foundational *"Domain Graph"* abstraction. While other engines focus on WCOJs speed, MillenniumDB specifically tackles the storage bottleneck: the $O(d!)$ index overhead traditionally required to maintain every permutation of relational attributes in persistent tries [11]. To seamlessly adopt WCOJs without this spatial explosion, the engine uses compact data structures normally employed in compressed text indexing, most notably *the Ring* (and related extended Burrows–Wheeler transforms) [11]. Rather than materializing massive B-trees for every permutation, the Ring treats graph edges as cyclic strings of length three (source, label, target). It sorts their rotations lexicographically and encodes the resulting columns using highly compressed *Wavelet Trees* [11]. During physical execution, these wavelet trees allow the Leapfrog Triejoin (LTJ) iterators to navigate forward and backward between columns without requiring physical memory pointers. As the WCOJ operator performs multi-way intersections, it natively probes these wavelet trees, successfully achieving worst-case optimal time bounds while using *almost no extra space* beyond the raw graph data itself. Finally, because these compressed indices are so lightweight to probe, MillenniumDB diverges from static WCOJ planners by employing adaptive variable elimination orders, allowing the engine to dynamically recompute and shift the global WCOJ trie-traversal path mid-execution based on exact intermediate cardinalities discovered during the join.

pattern matching for a standard-compliant SQL engine. Such workloads commonly contain highly-connected and cyclic patterns where binary join plans are now known to be suboptimal. Thus, efficient support of the emerging graph-relational workloads requires the adoption of the more suitable WCOJs, making it not merely a theoretical consideration, but a requirement.

This leads us to ask: ***What are the reasons for the limited adoption of WCOJs in mature RDBMSs, despite the attractive theoretical promises?***

To answer this question, WCOJs are examined through a query engine abstraction inspired from PostgreSQL. This abstraction divides the query engine into three layers, as illustrated in Fig. 1. The *interpretation layer* covers query languages, functionalities, and query rewriting. The *optimization layer* consists of generating query plans, and choosing the optimal one using cost models and statistics. The *execution layer* focuses on WCOJ implementation and interaction with the hardware. Moreover, beyond the three layers, WCOJs is studied in distributed environments. Such framework is sufficient for the evaluation of WCOJs as it encapsulates the entire query lifecycle.

This study affirms previous notes from Ngo [23], a seminal figure in the field. While WCOJ algorithms are well understood in isolation, their adoption as first class operators within mature RDBMSs remains largely undefined. Practical deployment demands coordinated changes across multiple layers of the query engine, including cardinality estimation, physical plan enumeration, attribute ordering and memory management, which have been specifically designed around binary join processing over several decades.

The aim is to map the literature on a practical framework, highlight the trade-offs for engineers, and unveil possible research opportunities for researchers.

The rest of this study is structured as follows: Section II, Section III and Section IV analyze the three layers of the query engine abstraction (i.e., interpretation, optimization and execution) detailing integration challenges and the current state of adoption at each layer. Section V discusses distributed WCOJs, while Section VI reviews related work. The study is concluded in Section VII.

II. The Interpretation Layer

The interpretation layer serves as the primary interface between the user and the query engine. Its role is to parse and normalize the incoming user query, representing it as an abstract syntax tree (AST) before translating it into a relational algebra tree that is understandable by the subsequent layers.

Moreover, this layer applies logical rewriting rules to simplify the query [24]. These heuristics stretch from semantic query optimization (e.g, removing `DISTINCT` clauses when duplicates are mathematically impossible) and query flattening (e.g, subquery unnesting and `OR` expansion into `UNION`) to rearranging operations in an attempt to reduce the data volume early in the execution pipeline (e.g, predicate pushdown and eager aggregations).

A. Query Representation

Conventional RDBMSs normalize the AST of a query into a relational algebra tree [Fig. 2(e) represents a possible relational algebra tree for the SQL query in Fig. 2(b)], in an attempt to reduce the optimization task to finding the most efficient sequence of binary join operators. Although this approach is structure-independent, these engines often scan for specific patterns, such as star or snowflake schemas. These hard-coded detections allow these systems to trigger specialized transformations to optimize for those specific, pre-defined query shapes.

Despite these targeted heuristics, this model suffers from two major limitations. First, practitioners must manually hard-code detection procedures for every new pattern that emerges and implement unique transformations for each. Second, the fundamental assumption that joins are binary operations remains a bottleneck, where even the successful detection of triangles or cliques in the query structure would still yield a suboptimal query plan. Thus, the primary difficulties in query representation are not inherent from the query language semantics [e.g., it is possible to express complex cyclic patterns in SQL such as Fig. 2(b)], but rather from the internal query representations of RDBMSs, which map these semantics into binary relational algebra trees.

To resolve these limitations, systems like EmptyHeaded [12] move towards using the generalized hypertree decompositions (GHDs) extracted from the hypergraph of the query. For instance, Fig. 2(d) illustrates the hypertree decomposition for the hypergraph in Fig. 2(c) with the cyclic part isolated in a single bag, proving that they must be processed simultaneously. This approach allows the engines to partition the query into a tree of *bags* based on its structure rather than only cardinalities.

In this approach, bags containing cyclic patterns (more than two relations) are evaluated using multi-way WCOJ algorithms, while the rest of bags and intermediate results are joined using traditional binary operators. This ensures structural optimality regardless of whether the query follows a standard star or complex graph patterns.

B. Query Rewriting and Eager Aggregations

Once the relational algebra tree of the query is built, traditional engines rewrite the query using transformations that are known to improve the performance of the query without altering it. Such transformations involve pushing down aggregations and predicates towards the leaf relations to reduce input sizes before joins occur [25].

While early filtering can be highly beneficial [26], as it reduces the active domain for WCOJ iterators [6], the eager pushdown of aggregations may break the pure conjunctive nature of the query on which WCOJs have been formalized [4], forcing the optimizer to fall back to a binary execution plan.

Theoretical frameworks such as AJAR [27], later integrated into LevelHeaded [13], have explored the evaluation of these aggregate-join queries without breaking worst-case optimal bounds. Their approach is to compute partial aggregations on the fly as the engine traverses the GHD of the query. However, this method is strictly constrained. First, the aggregated

```
SELECT a.id, b.id, c.id, cty.name
FROM GRAPH social_graph
MATCH (a:Person)-[:KNOWS]->(b:Person)-[:KNOWS]->(c:Person)-[:KNOWS]->(a),
      (a)-[:LIVES_IN]->(cty:City)
WHERE cty.name = 'Rabat';
```

(a)

```
SELECT k1.src, k2.src, k3.src, cty.name
FROM Knows k1
JOIN Knows k2 ON k1.dst = k2.src
JOIN Knows k3 ON k2.dst = k3.src AND k3.dst = k1.src
JOIN LivesIn li ON k1.src = li.person_id
JOIN City cty ON li.city_id = cty.id
WHERE cty.name = 'Rabat';
```

(b)

(d) The generalized hypertree decomposition of the hypergraph, isolating the cyclic pattern into the first bag and the acyclic relation into the second bag. (e) An example of the relational algebra tree to process the query.

attribute must be pushed to the end of the global join attribute order. And second, the engine is limited to commutative and iterative functions such as `COUNT` and `SUM`.

C. Functional Limitations

Traditional RDBMSs support multiple join variants, whereas WCOJ research has primarily focused on equi-joins. Supporting complex non-equi predicates (e.g., inequalities, spatial overlaps) typically requires reverting to binary joins or employing specialized geometric adaptations [28], [29]. However, these adaptations cannot be generalized to support all possible use-cases, which are inherited naturally from binary joins.

Moreover, while applying operators like `LIMIT` or `TOP-K` is trivial for the binary approach, it presents a challenge for WCOJs. In WCOJs, the global variable ordering might not align with the `ORDER BY` clause, often forcing the engine to materialize the full result before applying the limit.

Research into combinatorial output-sensitive sampling [30] and top-k algorithms [31] highlights the complexity of *"drilling down"* into a Trie to fetch a specific sample without full traversal. These limitations make WCOJs unfit for some of the most used features in conventional databases, such as pagination. As a result, query engines can always rely on traditional binary joins as a safe fallback strategy when these operations are required.

D. Discussion

Looking at how conventional RDBMSs can support emerging graph workloads via SQL/PGQ, two major paths emerge. The first consists of converting SQL/PGQ queries into standard SQL using a combination of equi-joins, unions, and filters, similar to DuckPGQ [16]. For example, Fig. 2(b) is a possible equivalent SQL query for the SQL/PGQ query in Fig. 2(a). This strategy is suitable for quick syntax support over native integration.

As Large Language Models are increasingly employed to generate queries, how can this translation layer leverage the database schema to contextualize and optimize such queries into efficient standard SQL?

The second path, which aligns with the focus of this survey, requires a generalized query representation. Manually hard-coding detection routines for every new query shape fails to scale. The current consensus leans towards the use of GHDs. However, finding a tree decomposition with the minimum width is a known NP-hard problem.

A critical open challenge revolves around the development of adaptive algorithms, or lightweight learned heuristics, that can approximate near-optimal GHDs at runtime without introducing unacceptable overhead.

Beyond representation, the interpretation layer must bridge the gap between SQL functionalities and the need for

conjunctive queries for WCOJs. Relational heuristics like eager aggregations break this pure conjunctive structure. Similarly, non-equi joins or pagination (`LIMIT`/`TOP-K`) force the engine to revert to binary execution or materialize massive intermediate results.

A few workarounds have already been proposed, such as limiting partial aggregations to commutative functions pushed to the end of the trie. However, the question still stands: *How can WCOJs natively support complex non-equi predicates, and how can engines execute output-sensitive limits without sacrificing early-pruning?*

III. The Optimization layer

The optimization layer identifies the most efficient execution plan from a wide search space of possible plans. In conventional RDBMSs, this is typically achieved through a cost-based approach, which estimates the cost of multiple plans using statistics and data summaries to select the least expensive option.

While binary join optimization has matured from dynamic programming [1] to genetic algorithms [32], WCOJ algorithms require fundamental changes. The cost metric must shift from minimizing intermediate result sizes to minimizing intersection costs, a complex task that would require access to new statistics, a way to define the optimal attribute order, and the ability of hybrid planning (i.e., using both binary and WCOJs in a query plan).

A. The Objective Function

The primary challenge for WCOJ adoption lies in the objective function of the optimizer. While the goal of a conventional optimizer is to arrange joins in a tree structure while minimizing the cardinalities of intermediate results, one that integrates WCOJs must focus on finding the optimal permutation of the join attributes. This ordering should minimize the *width* of the value domains, ensuring that the most selective intersections are performed first to avoid invalid paths earlier.

This divergence in the optimizer goals, from minimizing the data volume (focusing on memory) to minimizing search steps (focusing on computation) creates a conflict. Thus, plans that appear expensive to a traditional optimizer might actually be the most efficient for an optimizer leveraging WCOJs.

To resolve the discrepancy between the two paradigms, the query planner must be refined on all fronts, from the addition of more suitable statistics, the adoption of newer heuristics, to enabling the ability to yield hybrid plans, and with it new unified cost models. These aspects are covered in the rest of this section.

B. Statistics and Cost Estimation

For a cost-based optimizer to make informed decisions, accurate estimations are essential. Traditional engines rely on value histograms and lists of the most common values. However, these scalar (i.e., flat, one-dimensional) statistics fail significantly for cyclic queries because they assume attribute independence, leading to severe underestimations of join sizes.

In contrast, WCOJ performance is heavily tied to the structure of the join query, making existing scalar statistics unreliable. WCOJ optimizers would require *graph statistics*, such as the degrees distributions [33], correlation information, fractional edge covers [7], [4], or graph-specific summaries [34], to map how data points are interconnected. Conventional RDBMSs do not natively support these expensive graph statistics, forcing WCOJ optimizers to operate with low-fidelity estimates.

Other potential techniques for accurate estimation include synopsis-based methods, which build summary structures for cardinality estimations, and sampling methods, which use data samples to estimate cardinalities without execution [34]. However, these approaches are especially hard to adapt for WCOJ, since the probability of capturing cyclic join results in a subset of data is smaller, which may lead to catastrophic underestimations.

C. Hybrid Planning

WCOJs are not substitutes for binary joins. Real-world workloads rarely consist of purely cyclic or acyclic patterns, necessitating query planners capable of yielding hybrid plans that mix between binary and WCOJs [35].

While establishing a unified cost metric remains an active challenge [35], the GHD provides a robust theoretical framework [12]. By decomposing a query into a tree of *bags*, the planner can isolate cyclic components to be resolved via WCOJs, while utilizing traditional binary joins to assemble the final result from these acyclic interconnections. For example, considering the GHD in Fig. 2(d), an optimizer would evaluate Bag 1 (the cyclic triangle) using a multi-way WCOJ, then use a binary join on the shared attribute, a, to attach the acyclic relation in Bag 2.

Free Join [9] pushes this hybridization further to the execution layer. Rather than choosing between distinct operator types, it utilizes lazy hash-based data structures to maintain the high-throughput, scan-centric benefits of traditional binary hash joins. Free Join coordinates these hash probes through a global variable-ordering logic. The algorithm satisfies the AGM-bound while reducing the pointer-heavy memory overhead of traditional WCOJs through its *column-oriented lazy trie*, a unified data structure that builds inner sub-tries as needed.

D. Cost Modeling

To compute the cost of hybrid plans the optimizer needs a unified metric to compare with. In traditional RDBMSs, costs are typically modeled as a function of input and output sizes. This is a result of the assumption that cost is monopolized by intermediate results materialization.

In contrast, WCOJ cost relies heavily on the structure of the query, since its complexity is dictated by the fractional edge cover of the query hypergraph. However, using the AGM-bound as a cost model can be unreliable, since it will often overestimate the actual runtime. This approach can cause the optimizer to reject valid WCOJ plans, as it computes the worst-case cost, whereas in real life workloads, datasets have high skew or sparsity making it orders of magnitude

smaller than estimated. Moreover, if the optimizer relies on a pessimistic estimation, it will frequently perceive WCOJs as prohibitively expensive, defaulting to a binary join tree plan.

To address this, researchers have proposed the *intersection cost* (*i-cost*) as a unified metric for hybrid plans [35]. Unlike the AGM-bound, *i-cost* focuses on the computational effort of the execution rather than the theoretical maximum size of the output. *i-cost* represents the sum of sizes from all adjacency lists accessed during a multi-way intersection. By using degree distributions to estimate the size of these adjacency lists, the optimizer can move away from global pessimistic bounds and toward a local, data-aware estimation.

E. Attribute Ordering

Once the optimizer chooses to use a WCOJ algorithm within a plan, it must determine a suitable attribute order. It is well understood that a poor choice in the determination of the order in which attributes must be processed can severely degrade performance, as the algorithm might keep searching in empty sub-trees rather than pruning early [6], [3]. To this end, several approaches can be employed.

1) Static heuristics: A join can be seen as a constraint satisfaction problem, thus standard techniques may apply. The query optimizer can base its decision on inexpensive heuristics to avoid expensive computations.

For instance, the *"max-degree"* approach prioritizes the most constrained attributes (i.e., attributes shared by most relations). Since each relation limits further the value domain of the attribute, ordering attributes by descending degree often result in early pruning [36], [6].

Moreover, because such heuristics are computationally inexpensive, they can also serve as a fallback strategy for the more advanced strategies discussed below.

2) Cost-based ordering: Static heuristics are fast because they focus solely on query structure, however, they are *instance independent* (i.e., blind to the actual data). Consequently, they may prove inadequate. For instance, a high-degree attribute might have low selectivity (e.g. a boolean value), making it a suboptimal starting attribute.

Cost-based ordering attempts to resolve this by estimating the actual runtime cost of each attribute permutation using statistics. Thus, instead of merely counting the hyperedges to calculate degrees, the optimizer computes an estimated cost for each permutation [35], [12], [37].

This process may leverage existing statistics, such as histograms and information on unique values, to estimate the intersection cost. However, the optimizer must account for search cost. For instance, when the data is dense, sequential scans may be cheaper than leapfrog searches, conversely, when the data is sparse, leapfrog searches are more efficient.

Finally, since cost estimation can be expensive, it cannot be calculated for all possible permutations which is factorial to the number of attributes, the cost-based ordering can use a greedy approach, where it seeks the next cheapest attribute using dynamic programming similar to the ones used by traditional planners but adapted for linear ordering, rather than trees [35].

3) Adaptive and learned optimization: The integration of adaptivity and machine learning into database management systems, particularly at the query optimization layer, has emerged as an effective paradigm [38]. When applying these techniques, research generally divides into two distinct approaches: workload-level learning and query-level adaptivity.

The first approach applies learned optimization at the workload level (*inter-query*), continuously refining the decision-making of the optimizer across successive executions. ReJOOSp [39] and AlphaJoin [40], for example, model optimization as a reinforcement learning problem. By exploring the massive combinatorial space of join orders over time, these agents learn to identify optimal execution paths and structural boundaries that static, rule-based heuristics miss.

The second approach pushes adaptivity directly into the physical execution of a single query (*intra-query*). Rather than committing to a single static plan, the engine initiates execution by running a multitude of distinct plans simultaneously for a brief exploratory period. By leveraging immediate runtime feedback from these short, parallel executions, the optimizer dynamically identifies and transitions to the most efficient plan used for the rest of the query execution. For instance, ADOPT [41] uses this adaptivity to rapidly converge on near-optimal attribute orders for plans using WCOJs.

F. Discussion

When integrating WCOJs within the optimization layer, two primary challenges emerge. First, the query engine requires new generalized cost models. Traditional intermediate cardinality estimations are unsuitable for WCOJs. The current consensus relies on instance-dependent metrics, such as the intersection cost (*i-cost*), and degree distributions to measure the exact computational effort [35].

These new cost models must eventually align with the ongoing shift toward learned query optimization. While machine learning has already proven its ability to capture complex data correlations compared to traditional cardinality estimation, as highlighted in the Cambridge Report [42], extending this approach to reliably predict the sizes of cyclic queries without introducing unacceptable compilation overhead remains an open challenge.

Furthermore, the objective of the optimizer must fundamentally shift from reordering a binary join tree to finding the optimal join attribute order for WCOJ processing. *While static and cost-based heuristics offer practical starting points, dynamically discovering the optimal attribute order at runtime is still an active [41], open research question.*

Second, because WCOJs are not substitutes for binary joins, optimizers must support hybrid planning. The query engine must be capable of yielding hybrid plans that deploy WCOJs when beneficial. To achieve this without relying on complex hypergraph decompositions, modern engines explore alternative heuristics. For instance, systems like Umbra [8] generate a standard binary join plan and combines specific sub-trees into multi-way WCOJ operators based on cardinality estimates. Other approaches, such as Free Join [9], avoid separating operators entirely and deploys a unified data

structure to integrate binary hash-join efficiency and multi-way optimality into a single physical operator.

In this regard, a major open challenge is the development of new approaches for query planners to accurately measure cost and evaluate these hybrid plans, or adaptively trigger multi-way operator combinations at runtime, without suffering from the massive combinatorial search space explosion.

IV. The Execution Layer

The execution layer is where the query engine translates the logical plan from the optimizer into concrete physical operations. Here, the theoretical advantages of WCOJs confront the physical constraints of modern hardware.

While the asymptotic complexity of the algorithm is determined by its logic, the actual runtime performance depends heavily on its implementation and interactions with CPU pipelines, memory hierarchies and storage. This section studies the gap between the mature binary joins, which have been optimized for modern hardware over decades, and the emerging WCOJs.

Traditionally, binary joins in relational engines rely on a scan-centric execution model, either sequentially scanning sorted arrays (sort-merge join), or performing high-speed calculations to probe hash tables (hash join). However, WCOJs rely heavily on a search-centric approach, jumping over large sections of data that cannot participate in the join.

This paradigm is shared by the two primary implementations: the *sort-based* approach, spearheaded by the Leapfrog Triejoin [6], which relies on the global variable order, where instead of scanning every tuple sequentially, its iterators *leapfrog* over non-shared values. And on the other hand, the *hash-based* approach, characterized mainly by Generic Join [43], which avoids global sorting by resolving variable bindings using nested hash lookups. While theoretically superior for cyclic queries, both approaches disrupt the sequential flow that the hardware expects.

A. Computation

The structural shift from scanning to searching in WCOJs creates inefficiencies at the processor level. Modern general-purpose CPUs rely heavily on instruction pipelining and branch prediction to maintain throughput, a design that favors the predictable control flow and sequential access patterns of traditional binary joins [44].

WCOJs are inherently branch-heavy. For example, Leapfrog Triejoin requires a loop of conditional jumps, since it constantly needs to check if any of the involved iterators is less than the current maximum value [`if key < max_key then seek()`]. Because the branch direction depends entirely on the data distribution, this unpredictability triggers frequent pipeline flushes, stalling execution cycles and significantly reducing the instructions-per-cycle compared to binary joins.

Furthermore, the hierarchical nature of WCOJs significantly complicates vectorization. While binary hash joins can leverage flat data structures and SIMD to probe hash tables in batches [45], [46], Trie traversal is data-dependent and difficult to parallelize through a single instruction stream [47]. Although recent work attempts to bridge this gap by mapping joins to matrix multiplication [48], the lack of *vectorized search* primitives remains a significant blocker for adopting WCOJs in vectorized engines. To address this, systems like EmptyHeaded [12] adaptively encode Trie nodes based on the data sparsity, translating complex pointer traversals into parallelizable SIMD set intersections.

B. Primary Memory

The performance of in-memory query processing is often dominated by memory latency rather than CPU throughput [49]. Thus, even if the CPU pipeline is perfectly saturated, the runtime performance would likely suffer waiting for data to be fetched. In this regard, the result of the structural differences between binary and WCOJs becomes more severe.

Typically, binary joins process sequential memory pages, a pattern that aligns with hardware prefetchers loading data into the L1 and L2 caches before it is requested. In contrast, WCOJ requires navigating Tries, which involves pointer chasing, following references from parent to child nodes that are scattered over different memory pages and only known after the parent is retrieved. This serial dependency defeats hardware prefetching, leading to a higher rate of cache misses. As a result, the WCOJ algorithms often spend more time waiting for main memory than performing intersections [50].

C. Hierarchical Indexing

WCOJ algorithms require prefix trees (e.g. Tries) during the intersections processing. Such uncommon indices are not supported in conventional RDBMSs. This creates a trade-off between building indices Just-In-Time (JIT) or maintaining persistent indices.

In the case of JIT index building, as implemented in DuckDB [18] and Umbra [8], the benefit of worst-case optimality must outweigh the overhead of building the index. For *one-time* analytical queries, the construction cost can dominate the total execution time, potentially making a binary plan faster despite its theoretical inferiority.

On the other hand, LogicBlox [10], resolve to maintaining persistent Trie indices as their primary storage. While this eliminates the JIT build cost, it shifts the burden to data ingestion and updates, but is totally acceptable for read-only engines or with limited updates, or systems employing a sixth normal form (6NF) data architecture [6].

Middle ground between these two approaches may be found by maintaining light indices (mostly flat) and building the more expensive indices during query execution [51]. The border between these two approaches is a gray area, for instance, Umbra maintains flat data structure for a faster building stage of their Tries [8]. Recent efforts work on making Tries, more update-friendly [52].

D. Secondary Memory

Traditional RDBMS are required to be able to handle datasets, even when their sizes exceeds main memory capacity. For binary joins, this problem has been solved via GRACE

Hash Join [53] for instance, which partitions inputs into disk-resident buckets that are processed sequentially.

However, spilling to the disk is far more penalized in WCOJs. As discussed previously, they rely on random accesses, which is orders of magnitude slower than sequential reads in disk, even on NVMe SSDs. Moreover, theoretical I/O-optimal algorithms for cyclic joins remain an open problem [54].

Partial solutions to these challenges, however, have seen the day. Approaches like Quadtrees [55] attempt to decouple the topology from the data values, storing the structure in compact bitmaps. More advanced systems, such as the Ring [11] and CompactLTJ [21], go further by enabling execution directly on the compressed representation. This "Computation over Compression" approach effectively decreases memory footprint, partially mitigating the main memory issues described above, and attempts to avoid the need to spill to disk.

Umbra [8] uses LeanStore's [56] pointer *swizzling* technique, and leverages its architecture designed around flash-based storage, effectively using disk as main memory while introducing minimal overhead.

E. Workload-Aware Execution

In real-world scenarios, queries rarely run in isolation. Workload-aware techniques exploit overlapping patterns across such queries, which can improve the overall workload runtime performance dramatically.

During a workload, parts of the joins may be shared across multiple queries, the engine might choose to cache the results of those common parts for future use, which would cut the total execution time depending on their occurrence and size. However, WCOJs avoid to materialize intermediate results, which prevents them from being cached.

Attempts in this regard include Flexible Caching [57], where instead of materializing full intermediate results, it caches partial results at carefully chosen bags from the tree decomposition of the query's hypergraph. This enables reusing repeated sub-joins when beneficial while still retaining the advantages of WCOJs.

F. Discussion

As explored in this section, while WCOJs successfully bound the asymptotic complexity of cyclic queries, they confront the physical limitations of modern hardware. The execution of traditional binary joins aligns with CPU pipelining and memory prefetching. In contrast, WCOJs reliance on unpredictable pointer-chasing during Trie traversals breaks this alignment. This mismatch between algorithmic design and hardware constraints paves the way for a multitude of open challenges and research questions.

One of the main research paths within the execution layer is hardware acceleration. While the majority of existing literature focuses on multi-core CPUs, leveraging the low latency to manage complex and branch-heavy workloads, there is a critical need to explore GPU offloading to leverage massive data parallelism and high throughput during join processing.

Furthermore, FPGAs present another interesting alternative, offering custom, high-throughput data paths alongside superior energy efficiency. FPGAs can especially be versatile when handling WCOJs. They can be deployed in-line between the CPU and disk to accelerate decompression and data filtering, placed on the same socket as the CPU to offload specific computational tasks, or utilized as external, high-throughput units similar to GPUs.

Beyond designing WCOJ variants tailored to these specific hardware topologies, a critical research trajectory is the development of a heterogeneous WCOJ algorithm, capable of dynamically routing specific sub-tasks to the most suitable compute unit.

The optimal use of these compute units, and particularly their vector processing capabilities (SIMD/SIMT), is dependent on the underlying index structures, which must be redesigned to be vector-friendly, such as sparsity-aware layouts that map intersections directly to bitwise instructions as proposed by EmptyHeaded [12]. However, while transitioning to such layouts unlocks hardware throughput, it introduces new complexities regarding mutability and state management across devices.

These structures are optimized for read-heavy workloads where data density is predetermined. In dynamic database environments with frequent insertions, continuously monitoring data sparsity and rebuilding or transferring these index layouts between the CPU, GPU, and FPGA imposes massive synchronization and computational overheads, becoming a bottleneck to the very execution pipelines they are meant to accelerate.

One of the possible solutions is to map these joins into matrix multiplications, for which GPUs are optimized. However, this approach is heavily affected by data sparsity. Thus, it is essential to define thresholds at which mutable relational data should transition between a sparse array and a dense SIMD-friendly bitset at runtime. Another interesting research path in this regard, is determining cost models to dynamically route WCOJ parts among available compute units (e.g., dispatching dense, matrix-mapped joins to GPUs while keeping sparse, pointer-heavy intersections on CPU).

Beyond compute orchestration, multi-way intersections suffer from severe limitations across the memory and storage hierarchy. In main memory, the massive bandwidth required to continuously feed the accelerators creates a *"memory wall"* bottleneck. Furthermore, as massive workloads are inevitably pushed out-of-core, WCOJs face critical I/O challenges. Unlike traditional binary joins that adopt well-established, sequential disk-spilling mechanisms, WCOJs depend on traversing deeply nested index structures. Spilling these complex structures to secondary storage (NVMe/SSDs) results in severe I/O thrashing.

The primary open challenge here consists of bridging between byte-addressable main memory and block-addressable secondary storage during multi-way joins. While state-of-the-art systems like Umbra [8] have proposed low-overhead out-of-core execution using their pointer swizzling technique, where they translate between memory addresses and disk offsets, this only reduces translation costs. They do not resolve the fundamental I/O bottleneck caused by

WCOJ access patterns. Because attribute-at-a-time evaluation requires traversing hierarchical index structures across all participating relations, the unpredictable pointer-chasing disrupts the block-oriented access required for efficient secondary storage. Designing an architecture capable of prefetching massive, sparse index sub-trees without major overhead remains a critical unsolved challenge.

V. The Distributed Layer

While distributed RDBMSs deserve a survey of their own, they share the issue of limited WCOJ adoption. Concepts within the interpretation layer can be shared among shared-memory and distributed RDBMSs. However the difference shows up when it comes to the optimization and execution layers. This is the result of the core shift in objectives.

While shared-memory RDBMSs focus on minimizing the memory latency, the distributed ones focus on the network bandwidth. A much stricter constraint, since data movement through the network can be slower by multiple orders of magnitude. Thus, distributed RDBMSs require a complete rethinking of how WCOJs are processed at scale [3].

Traditionally, distributed binary joins rely on hash or range partitioning. For example, in the case for the hash approach, to join $R(a, b)$ and $S(b, c)$, the engine hashes on the join key b on both relations, and sends each tuple to the adequate node (e.g. `hash(b) % #nodes`), which guarantees that all matching tuples will land on the same node, and proceeds with local joins independently [58].

However, for WCOJs, this hashing technique would fail. For instance, in the triangle query, $Q = R(a, b) \bowtie S(b, c) \bowtie T(a, c)$, hashing on attribute b would only bring relations R and S together but not T (since it has no attribute b). To resolve this issue without losing worst-case optimality, the engine needs to adopt a higher-dimensional distribution approach.

A. The HyperCube Shuffle

The standard solution for distributed multi-way joins is *HyperCube Partitioning* [58]. The cluster is organized into a virtual high-dimensional grid, as illustrated in Fig. 3. For the triangle query involving variables a, b, c, the P processors are arranged into a cube of dimensions such as $P_a \times P_b \times P_c = P$.

Each relation is broadcast along the dimensions it misses. For example, a tuple $R(a, b)$ is hashed to coordinates $(hash(a), hash(b))$. Since it lacks variable c, it must be sent to all nodes corresponding to $(hash(a), hash(b), *)$. Effectively, it is replicated P_c times.

This approach guarantees that for any possible triangle (a, b, c), all participating tuples from R, S, T will meet at exactly one unique intersection point in the grid. However, this introduces a massive *replication cost*. Since unlike binary shuffles which move data once ($O(N)$), HyperCube shuffles multiply the data volume ($O(N \times P^{1-1/\rho^*})$) [59]. Thus, HyperCube shuffling would only work if the gains from the WCOJ outweigh the losses incurred by shuffling through the network.

B. Handling Data Skew

One of the major challenges that distributed RDBMSs have to face is data skew, and in WCOJs, skew can be much harder to handle since it is multi-dimensional. The complexity is no longer because of frequent key values, but also of the structure, resulting in large replications.

Multiple unique issues can arise from data skew in distributed WCOJs. For instance, in HyperCube shuffling, if a single node is assigned a dense region of the hypergraph, it might run out of memory, or have the bulk of the work to process (more than all other nodes), thus delaying the entire query.

To resolve these issues, hybrid processing is normally relied on, where high-degree vertices are treated differently, often being broadcast to all nodes to parallelize their intersection workload, while low-degree vertices are hashed normally. This results in a hybrid approach that dynamically adapts to the structure of the query and the frequency of values [60].

While Myria [61], [3] successfully proved that the communication bounds of hypercube partitioning are optimal (it transfers less data across the cluster than traditional binary hash joins), it was frequently bottlenecked by memory due to the heavy replication. To resolve this, subsequent approaches such as BiGJoin [62] leverage the Timely Dataflow computation model [63] to stream-process Generic Join [7].

By pairing the continuous execution with on-the-fly skew handling, the system maintains a low memory footprint throughout the entire query execution. Furthermore, modern implementations like EdgeFrame [64] abandon the hypercube shuffle entirely. Instead, they broadcast heavily compressed graphs directly to worker nodes, thus trading main memory capacity for a WCOJ execution without the need for shuffling.

C. Network Optimization

Given the high cost of replication, modern efforts focus on reducing the payload before the communication happens. One of such approaches develop on similar techniques from distributed binary joins and use Bloom filters [65]. Before the massive shuffle, nodes only exchange tuples that *might* be in the final result. Tuples that do not make the cut are thus discarded locally, preventing them from consuming valuable bandwidth. This is especially effective when the joins are highly filtered which should be the case for cyclic queries more often than not.

Other approaches can focus on the data format itself. For example, *Adaptive Factorization* [18] would be suitable for such an environment, sending data in a compressed form, where instead of sending redundant tuples $(a, b_1), (a, b_2), \ldots$, the system sends a grouped representation $a \rightarrow \{b_1, b_2, \ldots\}$. This *structural compression* can significantly reduce the serialization overhead during the HyperCube shuffle, directly addressing the replication penalty.

D. The Multi-Round Shuffle

While the HyperCube shuffle minimizes latency by completing the join in a single communication phase, it

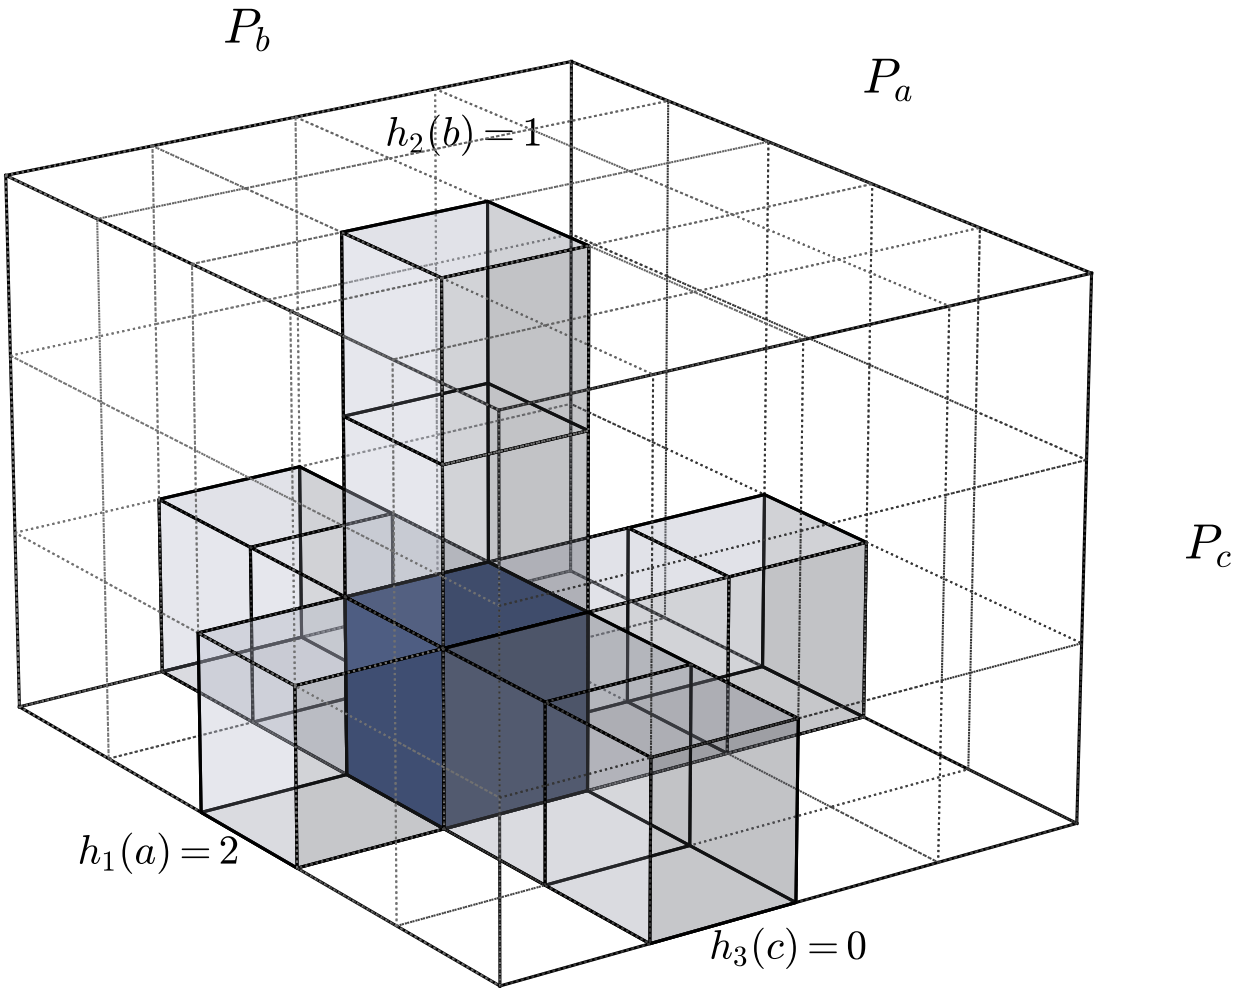

Fig. 3. An illustration of the HyperCube shuffle organizing a cluster into a virtual 3D grid with dimensions $P_a \times P_b \times P_c$ for a triangle query. A tuple lacking a variable is hashed to its known coordinates, such as $h_1(a) = 2$ and $h_2(b) = 1$, and replicated across the missing P_c dimension. This approach guarantees that all participating tuples from the queried relations will meet at exactly one unique intersection point in the grid to evaluate the join.

requires a high bandwidth cost due to the massive data movement and replication. To resolve this issue, especially for environments with limited bandwidth or even for complex queries for which HyperCube shuffling would require excessive duplication, multi-round approaches offer a possible alternative.

As formalized by Ketsman-Suciu [66], single-round algorithms are often bounded by the fractional vertex cover of the query hypergraph. By allowing the computation to proceed in $O(\log P)$ rounds, the maximum load per worker can be reduced to $O(m/P^{1/\rho^*})$, where m is the size of the largest input relation. This bound is asymptotically superior for many cyclic queries, thus trading rounds for memory and bandwidth efficiency.

Multi-round algorithms typically decompose the query execution into multiple iterative steps [67]. Instead of resolving the entire cyclic structure in one massive shuffle, the system may perform a sequence of semi-join reductions or compute partial intersections (e.g., joining subsets of relations to limit the search space) before reshuffling the reduced intermediate results for the final join. This removes non-joining tuples early, and prevents them from being replicated across the cluster needlessly.

While this approach might significantly reduce the total volume of data moved across the network, minimizing the risk of congestion, it introduces multiple synchronization barriers, which in the distributed setting, it requires the entire cluster to wait for the slowest node to complete the current round before proceeding to the next one. For short-running or interactive queries, the accumulated tail latency of multiple barriers often outweighs the bandwidth savings, making single-round approaches preferable despite their higher data cost.

E. Discussion

Within distributed environments, the primary performance constraint shifts from main memory latency to network bandwidth. Because one-dimensional hash partitioning fails to colocate cyclic query structures, the current consensus

relies on HyperCube shuffling to route multi-dimensional data. To prevent the resulting data replication from entirely exhausting network bandwidth, distributed engines heavily rely on payload reduction techniques prior to communication. This includes applying pre-shuffle Bloom filters to discard unneeded tuples [65] and using adaptive factorization to compress the remaining payload during transit [18].

As the database industry increasingly adopts cloud environments with on-demand node allocation, a major research opportunity is the design of elastic execution engines. In such systems, cluster expansion (or shrinkage) could be triggered during runtime. For instance, the query optimizer might choose to scale resources mid-query, or this decision could be pushed directly to the execution layer, where early data scans can provide instance-dependent information to achieve an optimal balance of performance and cost.

This paradigm shift towards adaptive systems extends far beyond dynamic cluster sizing. This broader scope of runtime adaptivity presents multiple interesting research opportunities, particularly regarding how query engines manage data preparation for transit and algorithmic choice.

For instance, adaptivity can be integrated directly into the filtering and compression stages. Rather than universally applying these reduction techniques, a system could dynamically determine their necessity based on runtime data characteristics. For example, a small dataset might be shuffled in its entirety, intentionally avoiding the computational overhead associated with semi-join filtering or structural compression.

Furthermore, another critical research direction involves enabling the optimizer to dynamically choose between single-round and multi-round execution. Implementing this effectively would require the development of robust cost models and runtime heuristics capable of accurately comparing the bandwidth costs of a single-round HyperCube shuffle against the accumulated synchronization latencies found in the multi-round approach.

VI. Related Work

Worst-case optimal joins are indeed a *hot topic* in database research. However, the broader shift to handle the ever evolving volume and complexity of modern data workloads [42] must be recognized.

While this survey specifically focuses on the practical aspects of integrating WCOJs into mature RDBMSs, it builds upon a large foundation of prior literature. An extensive body of surveys, authored by seminal figures in the field, covers the underlying formal theory and the proof frameworks for worst-case optimality in detail [23], [7]. Furthermore, this analysis complements a previous work [5] that studies the algorithmic aspects of this class of multi-way joins.

Beyond the theoretical and algorithmic foundations, the integration of artificial intelligence and machine learning has emerged as a transformative paradigm across computer science, and database research is no exception.

At the interpretation layer, this AI-driven evolution is most manifested in Natural Language Interfaces to Databases (NLIDB). Specifically, Text-to-SQL generation has transitioned from rule-based semantic parsing to leveraging deep learning and Large Language Models (LLMs). Comprehensive surveys [68] have studied the different models, and the upcoming challenges.

Moreover, modern benchmarks like Spider [69] and BIRD [70] demonstrate the increasing capacity of LLMs to autonomously navigate complex, cross-domain database schemas [71]. Such advancements are deeply connected with the necessity for WCOJs, as AI lowers the barrier for end-users to generate highly complex, multi-way join queries.

The optimization layer is undergoing a similar transformation. Traditional cost-based optimizers are increasingly being improved or replaced by learned cost models [42]. A critical driver of this shift is the rapid advancement in cardinality estimation [72], [73], leveraging deep neural networks and advanced statistical models capable of capturing high-dimensional correlations within data distributions. This is directly relevant to the adoption of WCOJs, as the multi-dimensional skew and structural correlations inherent to cyclic graph queries have historically caused severe underestimations in traditional approaches.

Beyond estimations, adaptive techniques and reinforcement learning are being deployed to refine statistics or dynamically adjust execution plans during running queries. While these methods do not always outperform mature deterministic algorithms across all scenarios, they can offer huge performance improvements in complex, highly correlated workloads [74], [75], [42].

The efficacy of these adaptive and learned optimizers is even more necessary because of the modern cloud environments [76]. The database industry has widely adopted cloud-native architectures that are decoupled from storage and compute, enabling an unprecedented degree of scalability and flexibility [77]. For the evaluation of WCOJs, this elasticity can be transformative, since such systems can adopt optimizers that anticipate the explosive cyclic queries that will induce processing spikes, and provision compute resources on demand. Previous work [78] addressed handling data skew in a graph query within such an elastic environment, which showcases the little overhead paid for the possible large gains.

A prominent research area in modern database systems is hardware acceleration. To overcome the physical execution bottlenecks of increasingly complex workloads, the database community is actively exploring hardware-software co-design. As detailed in comprehensive surveys across the domain, this research typically focuses on three paradigms: the design of special-purpose CPUs and advanced vectorization techniques, the utilization of Graphics Processing Units (GPUs) to exploit massive thread-level concurrency [79], [80], and the development of custom data pipelines using Field-Programmable Gate Arrays (FPGAs) to accelerate all or distinct parts of the query execution engine [81].

VII. Conclusion

This survey explored the practical considerations for the adoption of worst-case optimal joins, specifically focusing on conventional relational database management systems. This

TABLE II. SUMMARY OF INTEGRATION CHALLENGES AND PROPOSED SOLUTIONS FOR WCOJS ACROSS DBMS LAYERS

Layers	Integration Challenges	Proposed Solutions
Interpretation	Representing queries in relational algebra trees requires hard-coded procedures to detect cyclic query patterns.	Using generalized hypertree decompositions (GHDs) of the query hypergraph to isolate cyclic bags [12], [35].
	Eager aggregation breaks the pure conjunctive query structure required by the AGM-bound.	Evaluating aggregate-join queries via on-the-fly partial aggregations restricted to iterative functions [27], [13].
	WCOJs do not natively support common functionalities such as non-equi joins and `TOP-K` clauses.	Employing geometric adaptations for non-equi predicates [28], [29] and combinatorial sampling for output limits [30], [31].
Optimization	Relying on scalar statistics that assume attribute independence leads to cardinality underestimations for cyclic joins.	Introducing graph statistics such as degree distributions [33] and synopsis-based estimations [34].
	Inability of query planners to yield hybrid execution plans that combine traditional binary joins with WCOJs.	Utilizing GHDs to isolate multi-way bags [12], or deploying unified data structures that fuse binary and multi-way execution [9].
	Using the theoretical AGM-bound as a cost metric, which overestimates actual costs and causes optimizers to reject valid WCOJ plans.	Adopting data-aware metrics like the intersection cost (i-cost) to measure computational effort rather than theoretical output size [35].
	Suboptimal join attribute ordering degrades WCOJ performance.	Applying max-degree static heuristics [6], cost-based greedy ordering [35], or reinforcement learning [39], [41].
Execution	Branch-heavy, search-centric Trie traversals causes unpredictable control flows that stall CPU pipelines and hinder vectorization.	Translating pointer traversals into parallelizable SIMD set intersections [12] and mapping joins to matrix multiplication [48].
	The severe trade-off between expensive Just-In-Time (JIT) index construction overhead and the massive storage footprint of persistent Tries.	Employing 6NF data architectures [6], maintaining lightweight flat indices for fast JIT construction [8], [51], or utilizing update-friendly Tries [52].
	Random access patterns of WCOJ iterators severely penalizing performance when datasets exceed main memory and spill to disk.	Operating directly on compressed structures like Quadtrees [55] and Wavelet Trees [11], [21], or leveraging pointer swizzling [8], [56].
	The inherent avoidance of intermediate result materialization in WCOJs preventing traditional workload-aware caching mechanisms.	Implementing flexible caching of partial results at specific GHD bags to reuse repeated sub-joins [57].
Distributed	Traditional one-dimensional hash partitioning fails to colocate the complete structure of cyclic graph queries.	Employing HyperCube partitioning to enable multi-dimensional data distribution [58].
	Severe multi-dimensional data skew exhausting individual node memory and delaying query execution.	Implementing hybrid vertex broadcasts [60], stream-processing via Timely Dataflow [62], [63], or broadcasting compressed graphs [64].
	Massive data replication inherent to HyperCube shuffles bottlenecking network bandwidth.	Filtering unneeded tuples via pre-shuffle Bloom filters [65] and applying Adaptive Factorization for structural compression [18].
	Accumulated tail latency from synchronization barriers in multi-round execution models.	Bounding computation to logarithmic rounds [66] or performing sequences of semi-join reductions prior to the final shuffle [67].

analysis is organized using a simplified query engine, inspired by PostgreSQL, to evaluate the integration attempts and their limitations at each layer. And with the growing shift to cloud computing, the adoption of WCOJs within distributed environments is also examined.

This study affirms that despite the theoretical guarantees, WCOJs integration is constrained by decades of optimization designed around binary joins. Nevertheless, their practical value is undeniable, as demonstrated by the emergence of modern, specialized systems built natively around them.

DBMS development is a complicated and slow process where correctness, completeness and stability generally take precedence over performance optimization. Often, new workloads can be accommodated via translation layers rather than a complete engine rewrite. For example, DuckPGQ successfully maps SQL/PGQ graph queries into SQL, thus removing the need for native execution. On the other hand, a rapid adoption of vector databases has been observed in recent years, because vector similarity workloads cannot be substituted by traditional relational operations, the industry was forced to adopt native solutions almost instantly.

Historically, theoretical superiority has not guaranteed practical adoption, as happened with Yannakakis algorithm for instance. However, the trajectory of WCOJs appears more promising. The sustained volume of research published across major database venues over the past decade, coupled with proven practical performance in specific workloads, suggests a slow but steady shift toward broader mainstream acceptance.

Ultimately, this survey aims to successfully cover this interesting research path, and act as an accessible entry point for newcomers and for researchers that are looking for new challenges. Table II provides a clear summary of engineering trade-offs for practitioners attempting to integrate WCOJs in their systems.

ACKNOWLEDGMENT

The authors would like to thank the anonymous reviewers and the editors of the journal for their valuable feedback and constructive suggestions, which significantly contributed to improve the clarity and overall quality of this manuscript.

A Behavioral Analysis of Machine Learning for Intrinsic 3D Tree Branching Structures

M. Charitha Lakshan, K. Damitha Sandaruwan, L. N. C. De Silva
University of Colombo, School of Computing, Colombo 00700, Sri Lanka

***Abstract*—Modeling realistic tree structures remains a challenging problem in computer graphics due to the complex interaction between intrinsic growth patterns and environmental influences. Traditional procedural methods provide strong control over environmental adaptation, while learning-based approaches aim to capture branching behavior directly from data. However, learning-based methods typically entangle intrinsic and environmental factors within a single representation, and are trained predominantly on procedurally generated trees, leaving their behavior under real-world structural noise largely uncharacterized. This study isolates the first half of this problem and asks how well machine learning models learn intrinsic 3D branching structure, hierarchy, geometry, and local topology, independently of environmental influence. Trees are represented as node graphs with intrinsic attributes, and local branching prediction is decomposed into a three-class topology classifier and two cascaded geometry regressors. Across controlled experiments on synthetic and LiDAR-reconstructed datasets, models trained on synthetic trees learn branching topology reliably (98.75% test accuracy), while performance degrades substantially on noisy real-world skeletons (50.29%), revealing the sensitivity of intrinsic-structure learning to data quality. Feature ablation shows that structural attributes, rather than spatial position or orientation, drive most of the predictive performance, raising classification accuracy from 55.55% to 97.80%. A perceptual study (25 participants, 625 pairwise trials) shows that generated trees are selected as more realistic in 33.4% of comparisons, a non-trivial proportion, though reference trees remain significantly preferred. Together, these findings characterize both the promise and the limits of purely data-driven intrinsic branching models, and motivate a hybrid pipeline in which learned intrinsic growth is combined with explicit environmental modeling.**

***Keywords*—Tree modeling; machine learning; intrinsic branching; feature representation; 3D tree reconstruction; synthetic data; behavioral analysis; hybrid modeling**

I. Introduction

Trees are essential elements in virtual environments such as games, simulations, and interactive 3D scenes. In these applications, vegetation modeling prioritizes visual and structural plausibility over strict biological realism. Tree models should appear natural and avoid repetitive or artificial branching patterns that reduce immersion. Unlike botanical studies, which require accurate growth mechanisms, many virtual environments only demand perceptually convincing structures. Consequently, many approaches focus on intrinsic branching properties, such as hierarchy, variation, and proportional relationships, rather than exact biological processes.

Recent data-driven methods, including DeepTree-style [1] approaches, have demonstrated that local branching behavior can be learned using machine learning. These methods typically formulate tree growth as a local prediction problem, where branching structure and geometry are inferred from node-level features. However, learning from real-world scanned trees remains challenging due to noise, missing branches, and reconstruction artifacts, which reduce structural consistency and learning accuracy.

In this work, we present a behavioral analysis of machine learning models trained to learn intrinsic 3D tree branching patterns without modeling environmental effects. Rather than reproducing biologically accurate growth, we focus on generating visually plausible branching structures for virtual environments. As illustrated in Fig. 1, tree growth is modeled as an iterative local prediction process based on intrinsic node attributes. A classifier predicts branching decisions, while conditional regression models estimate branch geometry, enabling the generation of structurally consistent trees. We further compare models trained on synthetic and real scanned datasets to analyze the impact of data quality on learning performance. Results show that intrinsic branching patterns can be learned reliably under controlled conditions, whereas noisy real-world data introduces significant limitations. These findings support a decoupled modeling strategy in which intrinsic growth is learned independently from environmental adaptation handled by explicit procedural or mathematical models. Accordingly, this work focuses on analyzing the behavior of machine learning models when learning intrinsic branching structures, rather than proposing a novel machine learning architecture, providing a foundation for future hybrid tree modeling pipelines.

II. Related Work

Tree modeling has been widely studied in computer graphics, with approaches ranging from procedural rule-based systems to data-driven and learning-based methods. A central challenge in this area is modeling both intrinsic branching

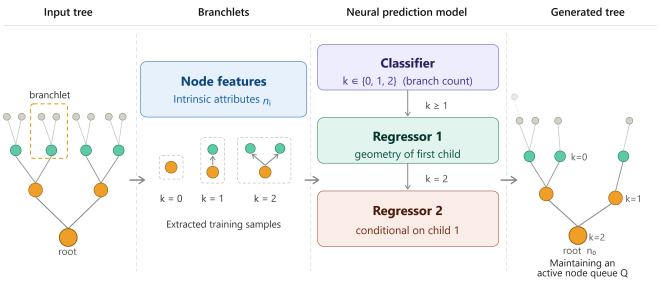

Fig. 1. Overview of the learning framework for behavioral analysis of intrinsic 3D tree branching. Branchlets are represented by intrinsic node attributes n_i. A classifier predicts the number of child branches ($k \in \{0, 1, 2\}$), followed by conditional regression models estimating branch geometry.

structure and environmental adaptation, including responses to light, obstacles, and neighboring vegetation. Procedural methods have long been used for this purpose due to their interpretability, controllability, and computational efficiency. One of the most influential approaches is the L-system framework [2], which represents plant growth using symbolic rewriting rules and has been extended to incorporate phototropism and space competition. Other procedural models explicitly simulate environmental influence through light-driven growth and spatial optimization. Beneš [3] introduced phototropic plant development models based on light availability, while the space colonization algorithm of Runions et al. [4] modeled branching as an iterative attraction process guided by available space. More biologically inspired approaches, such as the self-organizing tree model of Pałubicki et al. [5], simulate local competition for light and space to produce complex emergent tree structures. In all of these formulations, however, both intrinsic growth and environmental response are expressed as hand-authored rules, so structural realism depends on manual parameter tuning rather than on branching behavior observed in real trees.

Recent procedural work has focused on interactive and adaptive growth. Plastic Trees [6] introduced skeleton-based models that dynamically adjust branch orientation in response to light, obstacles, and nearby vegetation, while virtual ecosystem approaches enable plants to interact with surrounding objects and optimize spatial occupation [7]. GPU-accelerated methods incorporating ray-traced light simulation have further improved environmental realism and computational performance [8]. Inverse procedural approaches have also been proposed to estimate procedural parameters directly from existing tree geometry, bridging rule-based modeling and real-world observations [9]. These methods provide strong control over environmental adaptation through explicit parameterized rules, making them well suited for environment-driven modeling in virtual scenes. Their expressiveness, however, remains bounded by the rule set chosen in advance, and intrinsic branching is still specified rather than inferred from data.

More recently, machine learning and hybrid approaches have explored learning branching behavior directly from data. DeepTree [1] formulates tree growth as a local prediction problem, where branching decisions and geometric attributes are inferred from node-level spatial context. Transformer-based autoregressive models have further demonstrated the ability to generate hierarchical tree structures and temporal growth sequences directly from learned representations [10]. Hybrid methods such as Latent L-systems [11] combine neural learning with grammar-based representations, allowing branching rules to be learned implicitly while retaining procedural structure, whereas TreeStructor [12] targets faithful reconstruction of scanned geometry rather than the generation of novel structures. Two properties of this body of work are relevant here. First, these models are predominantly trained on procedurally generated data, a choice their authors attribute to the limited availability of large collections of reconstructed real trees [1]; consequently, how such models behave when trained on noisy reconstructed skeletons remains largely uncharacterized. Second, intrinsic structure and environmental context are typically encoded jointly, whether within a single node representation or a learned sequence, so the contribution of intrinsic attributes alone cannot readily be isolated or analyzed. These observations motivate a systematic behavioral analysis of how machine learning models learn intrinsic 3D tree branching structure independently of environmental influences, and whether such learning can serve as a reliable foundation for a broader decoupled modeling strategy.

III. Problem Formulation and Representation

In this work, a tree is represented as a rooted graph $\mathcal{T}$, where nodes correspond to branching points or segment endpoints, and edges represent parent-child relationships between connected branches. This graph-based representation is widely used in both procedural and data-driven tree modeling, as it provides a compact and flexible description of hierarchical structure and local geometry.

Each node in the tree graph is represented as a tuple of intrinsic attributes that describe its local geometric and structural properties. Following the representation style introduced in DeepTree [1], nodes are modeled as attribute tuples rather than purely topological elements, enabling local branching behavior to be learned from node-level context. In contrast to DeepTree, the attribute set used in this work is intentionally simplified. Only attributes that are consistently available across both real scanned trees and synthetically generated data are included. Attributes related to biological age, species, or other global physiological properties are omitted, as they are either unavailable or unreliable in the considered datasets.

Formally, each node $n_i \in \mathcal{T}$ is defined as:

$$n_i = \left(\mathbf{p}_i, \mathbf{q}_i, r_i, r^{root}, o_i, d_i, d_i^{root}, d_i^{branch}\right) \tag{1}$$

where, $\mathbf{p}_i \in \mathbb{R}^3$ denotes the 3D position of the node, $\mathbf{q}_i \in \mathbb{R}^4$ is a unit quaternion representing the local branch orientation with respect to its parent node, $r_i \in \mathbb{R}^+$ is the local branch radius, and $r^{root} \in \mathbb{R}^+$ denotes the radius of the root node, which is shared by all nodes in the tree and provides global scale context. The value $o_i \in \mathbb{N}$ denotes the branch order. The value $d_i \in \mathbb{R}$ represents the distance to the parent node. In addition, $d_i^{root} \in \mathbb{R}$ denotes the cumulative distance from the root node, and $d_i^{branch} \in \mathbb{R}$ represents the distance from the start of the current branch. All attributes describe intrinsic structural properties and do not encode any explicit environmental information.

Tree growth is modeled as a local prediction problem. Instead of predicting the full tree structure at once, growth behavior is inferred at the node level using local information. For each node, a local growth neighborhood-referred to as a "branchlet" (Fig. 2) is defined, consisting of a parent node and its immediate children together with their connecting edges. Based on this local representation, the learning task is divided into two components: a classification task that predicts the number of child branches produced by a node, and regression tasks that predict geometric properties of each child branch, such as relative orientation, length, and thickness. Together, these predictions describe the intrinsic branching structure in a local and incremental manner.

A key assumption of this formulation is that environmental factors are not considered. External influences such as sunlight, wind, gravity, terrain constraints, and interactions with surrounding vegetation are intentionally excluded from both the

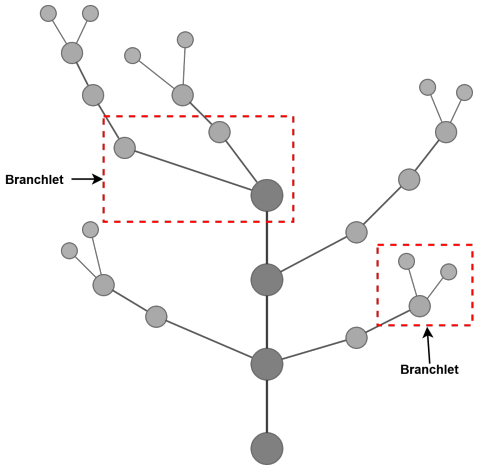

Fig. 2. Local branchlet representation used in intrinsic branching prediction.

representation and the learning process. The objective of this work is therefore not to model adaptive growth behavior, but to analyze how the proposed learning framework behaves when trained exclusively on intrinsic branching patterns, without exposure to environmental influences. This formulation supports a modular modeling approach, in which intrinsic growth prediction can later be combined with a separate environmental adaptation stage. The following section describes how this local prediction problem is realized through a classification and regression pipeline operating on the intrinsic node representation defined above.

IV. Learning Intrinsic Branching

This section describes how intrinsic tree branching behavior is learned using the node representation introduced earlier. The learning pipeline consists of two main stages: branch structure prediction and branch geometry prediction. First, a classification model predicts the number of child branches emerging from a parent node in a local context. Based on this prediction, regression models are then used to estimate the geometric properties of each child branch. The resulting predictions are applied by a tree generation procedure to incrementally construct branching structures.

A. Branch Structure Prediction

The first learning task focuses on predicting local branching topology. Given the intrinsic attributes of a parent node, a classification model predicts the number of child branches produced by that node. The classification output is restricted to three classes: 0, 1, or 2 children.

This restriction is motivated by the distribution of branching patterns observed in both real scanned trees and synthetically generated trees. During dataset analysis, nodes with three or more child branches were found to be rare, accounting for approximately 3% or less of all branching events. Including these cases introduced strong class imbalance and negatively affected training stability. Therefore, nodes with more than two children are excluded from training, allowing the classifier to focus on the most common and structurally relevant branching patterns.

A lightweight feed-forward neural network is used for branch count classification (Fig. 3). In contrast to more complex classifier designs used in prior work such as DeepTree, the proposed architecture is intentionally simplified to improve robustness and interpretability under noisy real-world data conditions. The model takes the intrinsic attributes of the parent node as input and outputs class logits corresponding to the three child-count categories. The network is trained using the cross-entropy loss function, which encourages accurate prediction of the discrete branching classes. This design emphasizes reliable local branching prediction rather than modeling global tree structure.

B. Branch Geometry Prediction

Once the number of child nodes is determined, the next task is to predict the geometric properties of each child node. These properties include relative orientation with respect to the parent, as well as geometric attributes such as edge length and node radius.

To model this, two regression networks are employed. The first regressor predicts the geometry of the first child node. The second regressor predicts the geometry of the second child node when two children are present, and operates in a conditional manner based on the first child. Specifically, during tree generation, the second regressor takes as input the intrinsic attributes of the parent node together with the predicted attributes of the first child, forming a cascaded prediction structure. During training, however, the second regressor is conditioned on the ground-truth attributes of the first child rather than the predicted outputs of the first regressor. This design avoids error propagation during training and allows the model to learn stable conditional geometric relationships.

The regression architecture is influenced by the design used in DeepTree, with a multi-head structure that separates orientation prediction from geometric attribute estimation (Fig. 4). Each regressor consists of two prediction heads: one for orientation, represented as a quaternion, and another for geometric attributes, including relative edge length and node radius. The models take intrinsic node attributes as input and output continuous predictions for these properties.

The regression networks are trained using a combination of loss functions. Orientation prediction is supervised using a cosine similarity loss between the predicted and ground-truth orientations, while geometric attributes are optimized using mean squared error (MSE). These losses are jointly minimized to ensure accurate prediction of local branching geometry.

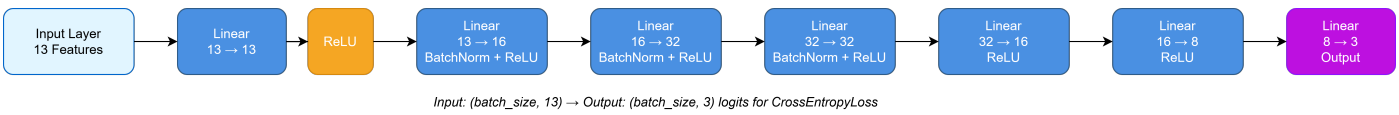

Fig. 3. Architecture of the child-count classification network used to predict the number of child branches (0, 1, or 2) from intrinsic node attributes.

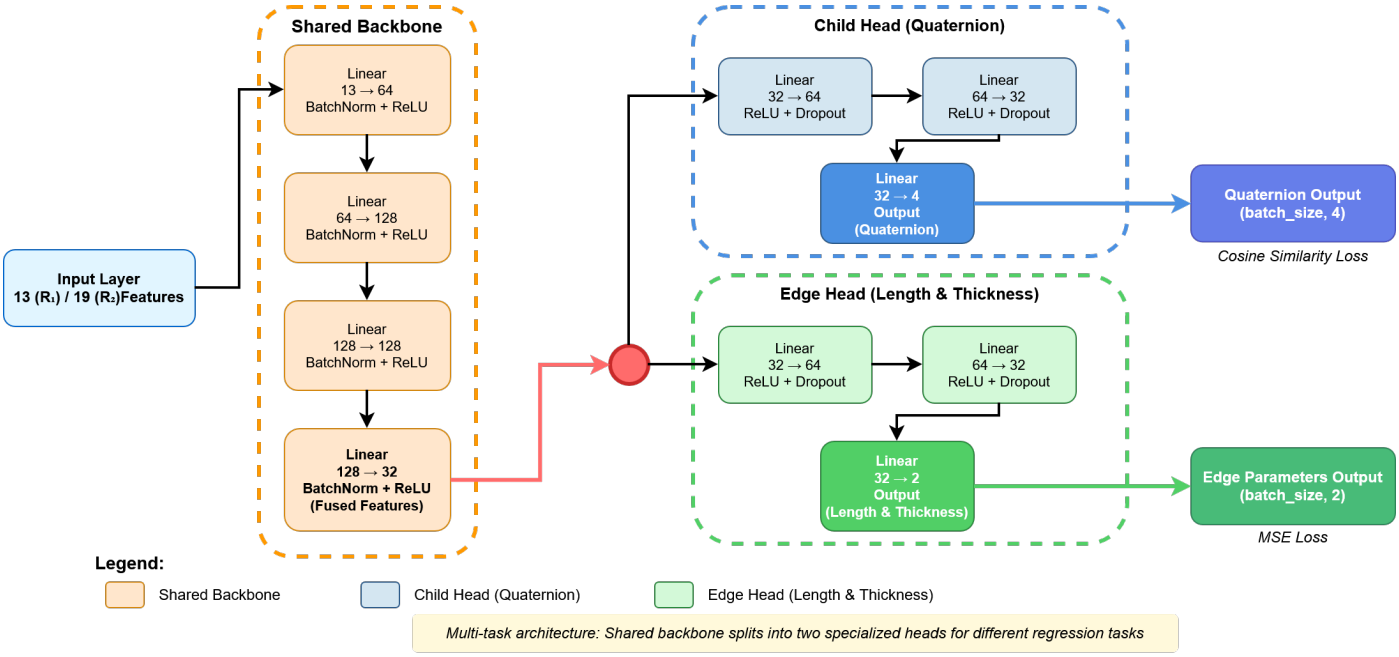

Fig. 4. Multi-task regression architecture used for branch geometry prediction.

C. Incremental Tree Generation

The trained classification and regression models are used to generate tree structures in an incremental manner. Tree generation begins from a manually initialized root node, whose intrinsic attributes are specified explicitly. These include the root position, orientation, branch radius, and initial distance values. Manual initialization of the root node is required, as the learning models operate locally and require an initial node context to initiate growth.

Starting from the root node, tree construction proceeds by iteratively expanding active nodes, as summarized in Algorithm in the Fig. 5. For each active node, the child-count classifier predicts whether the node produces zero, one, or two child branches. For nodes that produce children, the corresponding regression models predict geometric properties of each child branch, including relative orientation, edge length, and branch thickness. Child node positions and orientations are computed by applying the predicted transformations to the parent node.

Predicted branching topology alone does not guarantee termination: prior work reports that locally predicted child counts may fail to produce terminal nodes for some configurations, allowing generation to continue indefinitely [1]. To avoid uncontrolled growth and to improve stability, an existence probability is associated with each node. This probability is propagated from parent to child and gradually reduced as the depth of the tree increases. Child nodes are only created if their sampled existence probability exceeds a random threshold. Newly generated child nodes are added to a queue of active nodes and processed in subsequent iterations. The generation process terminates when no active nodes remain or when a predefined node limit is reached. This procedure models intrinsic branching behavior only and does not include any environmental constraints.

Fig. 6 presents representative examples of tree structures generated using the incremental generation procedure described above. The generated structures exhibit coherent hierarchical branching organization, with consistent radius tapering across depth levels and plausible bifurcation patterns, indicating that the employed learning framework produces structurally consistent and visually plausible tree forms from purely intrinsic node attributes.

1) Notation and symbols: Let $\mathcal{T}$ denote the generated tree represented as a rooted graph. Each node $n_i \in \mathcal{T}$ is associated with a tuple of intrinsic attributes $\left(\mathbf{p}_i, \mathbf{q}_i, r_i, r^{root}, o_i, d_i, d_i^{root}, d_i^{branch}\right)$, as defined in Section III. The classifier $C(\cdot)$ predicts the number of child branches $k \in \{0, 1, 2\}$ for a given parent node. The regressors $R_1(\cdot)$ and $R_2(\cdot)$ predict geometric properties of the first and second child branches. Each node n_i is additionally associated with an existence probability $p(n_i)$, which controls whether the node is instantiated during generation. The parameter α denotes the probability decay factor applied beyond a depth threshold D_{start}. The queue $\mathcal{Q}$ maintains the set of active nodes, and $N_{\max}$ specifies the maximum number of nodes allowed in the generated tree.

D. Implementation Details

All models were implemented in PyTorch and trained on a single NVIDIA RTX 5060 GPU with an AMD Ryzen 5 7500F CPU and 32 GB of system memory. The intrinsic node tuple of Eq. (1) expands to a 13-dimensional input vector; Regressor 2 additionally receives the four orientation and two geometric attributes of the first child, giving a 19-dimensional input. Layer widths are given in Fig. 3 and Fig. 4, with dropout applied within the regression heads only. Because the cosine-similarity and mean squared error terms of the regression objective differ substantially in numerical scale, the geometric term is weighted so that neither head dominates optimization. No learning rate scheduling, weight decay, or early stopping is applied; the weights obtained at the final epoch are retained. Remaining settings are summarized in Table I.

Require: Trained child classifier C
Require: Trained regressors R_1, R_2
Require: Root node n_0 with initial existence probability p_0
Require: Maximum node limit $N_{\max}$
Require: Probability decay factor α
Require: Depth threshold D_{start}
Ensure: Generated tree structure $\mathcal{T}$

Initialize queue $\mathcal{Q} \leftarrow \{n_0\}$
Initialize tree $\mathcal{T} \leftarrow \{n_0\}$
Set $p(n_0) \leftarrow p_0$
while $\mathcal{Q}$ is not empty **and** $|\mathcal{T}| < N_{\max}$ **do**
    Pop parent node n_p from $\mathcal{Q}$
    Predict number of children $k \leftarrow C(n_p)$
    Let d_p be the depth (nodes-to-parent count) of n_p
    if $k \geq 1$ **then**
        Predict child 1 geometry using $R_1(n_p)$
        Compute child depth $d_1 \leftarrow d_p + 1$
        if $d_1 > D_{start}$ **then**
            Apply probability decay $p_1 \leftarrow p(n_p)\,(1-\alpha)$
        else
            $p_1 \leftarrow p(n_p)$
        end if
        if rand() $< p_1$ **then**
            Create child node n_1
            Assign $p(n_1) \leftarrow p_1$
            Add n_1 to $\mathcal{T}$ and $\mathcal{Q}$
        end if
    end if
    if $k = 2$ **then**
        Predict child 2 geometry using $R_2(n_p, R_1(n_p))$

V. DATASETS

This section describes the datasets used for learning intrinsic branching behavior and the preprocessing steps applied to construct branchlet-level training samples. Two complementary data sources are considered: real-world tree reconstructions derived from LiDAR scans and procedurally generated synthetic tree skeletons. Using both datasets enables analysis of learning behavior under realistic but noisy conditions as well as under controlled structural settings.

A. Real-World Tree Dataset

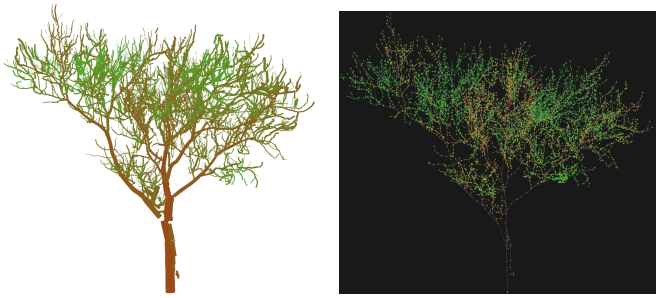
For real-world data, we use the TreeML-Data dataset [13], which contains tree structures reconstructed from terrestrial Light Detection and Ranging (LiDAR) scans using quantitative structure modeling (QSM) (Fig. 7). In this representation, trees are described as graphs of connected cylindrical primitives that approximate branch segments and encode geometric attributes such as position, orientation, radius, and branch order.

Although TreeML-Data does not provide an explicit node-edge skeleton, the cylinder graph preserves hierarchical connectivity and therefore supports derivation of a structural node representation. In this work, starting points of the cylinders are interpreted as nodes while connectivity between segments defines graph edges, enabling conversion to the node-level formulation used for learning.

Because the dataset originates from real measurements, the resulting structures may contain missing branches, uneven sampling, geometric noise, and segmentation inconsistencies. These factors introduce variability at the local branching level and can influence learning behavior, particularly in deeper structural regions. Nevertheless, real-world data remains important for evaluating how intrinsic branching models perform under practical acquisition conditions.

B. Synthetic Tree Dataset

To support controlled evaluation of intrinsic branching behavior, we additionally use synthetic skeletal tree structures released with the CHI24_TreeProject dataset [14] (Fig. 8). These trees are generated using procedural modeling techniques and provided as explicit skeletal graphs describing parent-child relationships and geometric attributes at each node.



(a) QSM cylinder representation (b) Derived node-edge graph

Fig. 7. Real-world tree representation from TreeML-Data.

Compared to LiDAR reconstructions, the synthetic skeletons form clean and fully connected hierarchical structures without scanning artifacts or segmentation noise. Such representations are widely used in procedural vegetation modeling because they expose branching organization directly and allow local growth relationships to be analyzed independently of reconstruction errors.

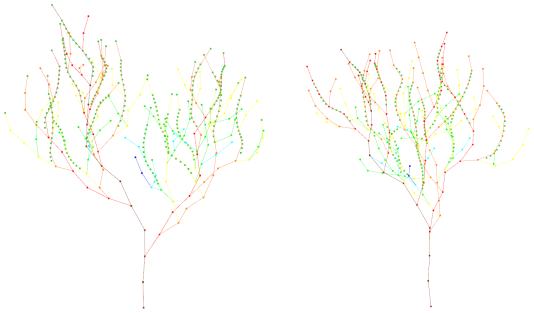
While synthetic trees do not capture the full variability of biological growth, they provide a stable structural environment for studying branching prediction, orientation modeling, and geometric parameter learning. The combination of real reconstructions and synthetic skeletons therefore enables evaluation across both realistic and controlled conditions.

C. Data Preprocessing

Both datasets undergo preprocessing to produce a unified intrinsic node representation suitable for branchlet-level learning. The objective is to extract structural attributes, normalize geometric scale, and construct local parent-child neighborhoods while minimizing implicit environmental bias.

For LiDAR-derived trees, cylindrical segments are converted into node-edge graphs by treating segment centers as nodes while preserving connectivity as hierarchical edges. Intrinsic attributes, including spatial position, node radius, branch order, edge length, cumulative distance from the root, and distance from branch origin, are computed through graph traversal. Local orientation is encoded using quaternion representations derived from parent-child direction vectors.

Because the intrinsic features are derived directly from spatial coordinates, geometric normalization plays an important role in defining the statistical distribution of input features as well as the numerical scale of regression targets. To evaluate its influence, an initial preprocessing study was conducted using synthetic tree structures, where reconstruction artifacts are absent and the effect of normalization can be analyzed in isolation. Two commonly used strategies were considered: uniform (isotropic) scaling, which preserves the original aspect ratios while fitting each tree into a bounded spatial domain, and axis-wise normalization, which independently rescales each spatial dimension to a fixed range. Both strategies enabled accurate learning of branching topology and geometry. However, uniform scaling consistently produced more stable optimization, slightly higher classification accuracy, and lower regression errors, particularly for branch geometry prediction. Based on these observations, uniform scaling was adopted as the default normalization strategy for all subsequent experiments.



(a) (b)

Fig. 8. Synthetic skeletal tree examples from the CHI24_TreeProject dataset.

Synthetic skeletons follow the same structural extraction procedure and additionally undergo controlled rotation augmentation around the vertical axis to improve orientation invariance. Distance measures and orientation encoding are computed consistently with the real-world data.

For each parent node, immediate children are grouped to form branchlets that define classification targets (number of children) and regression targets describing relative child orientation, edge length, and node radius. Despite differences in acquisition and generation processes, preprocessing produces equivalent intrinsic feature representations for both datasets, enabling learning to focus on internal branching structure while maintaining compatibility across data modalities.

The dataset is divided at the tree level to avoid structural overlap between training and evaluation samples. Specifically, 70% of the trees are used for training, 15% for validation, and 15% for testing. All nodes belonging to a given tree are assigned to the same subset, preventing structural information leakage across splits.

VI. Experiments, Results and Evaluation

This section presents a behavioral analysis of the employed learning framework through controlled experiments on intrinsic 3D tree branching structures. The analysis comprises a comparison of learning performance across synthetic and real-world datasets, an intrinsic feature importance study, and a perceptual evaluation of generated tree structures. All quantitative experiments were repeated **five times** using **different random seeds**, with reported metrics representing mean values; figures correspond to the run **closest to the mean**. Prior learning-based tree models are not evaluated under a directly comparable protocol. DeepTree [1] adopts a multi-label formulation in which independent output heads determine whether each potential child is instantiated, and is trained on procedurally generated data under a different geometric normalization, so its reported node-level metrics do not correspond to the three-class formulation and evaluation setting used here. Latent L-systems [11] validates generated structures through aggregate geometric distributions and perceptual metrics rather than node-level prediction error. Moreover, no prior work reports node-level metrics on LiDAR-reconstructed skeletons, the specific data condition examined in Section VI-A. Direct numerical comparison would require re-implementation and retraining under the present protocol, an effort that falls outside the scope of this behavioral analysis. Human perceptual judgment

(Section VI-C) is therefore adopted as the reference point, consistent with prior validation strategies in which generated structures are compared against dataset reference trees.

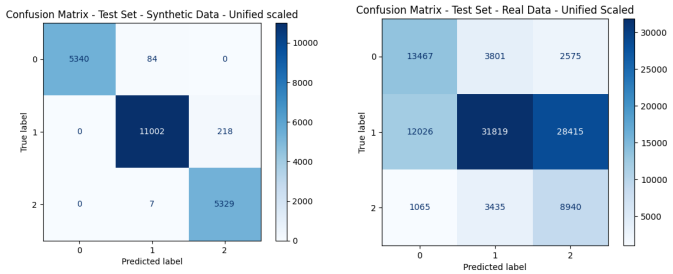
A. Synthetic and Real Data Comparison

We evaluate how the learning model behaves when trained on different data sources, using synthetic and real-world tree data. Classification accuracy, regression error, and convergence behavior are compared under identical conditions.

1) Experimental setup: The dataset split follows the procedure described in Section V, where trees are partitioned at the instance level to prevent structural overlap between training, validation, and test sets. The branching classifier is formulated as a three-class prediction problem corresponding to nodes with zero, one, or two children. To mitigate class imbalance, the training and validation sets are balanced across the three classes using random downsampling, while the test sets retain the original class distributions for unbiased evaluation. This balancing is applied only to the classifier, whereas the regression models are trained on the original data distributions. Uniform scaling, adopted as the default normalization strategy following the preprocessing analysis described in Section V, is applied consistently across all experiments.

2) Branching classification results: The branching classifier was evaluated on both synthetic and real tree datasets to analyze how effectively the intrinsic representation captures branching topology under different conditions. Under identical training settings, both models exhibited stable convergence with no significant signs of overfitting. The model trained on synthetic data converged rapidly and achieved validation accuracy above 98%, whereas the model trained on real tree data converged to a lower but stable accuracy of approximately 60%, indicating that branching prediction is more challenging under real-world structural conditions.

To further analyze prediction behavior, confusion matrices were computed for the held-out test sets. Fig. 9 presents the confusion matrices for both datasets. For the synthetic dataset, the classifier demonstrates strong performance across all three classes, with only a small number of misclassifications between continuation nodes and bifurcation nodes. In contrast, the confusion matrix obtained from the real dataset reveals a larger number of errors between these two classes, while terminal nodes (class 0) remain relatively well identified. This suggests that continuation and bifurcation states often exhibit similar local geometric configurations in real tree skeletons, leading to increased structural ambiguity.



(a) Synthetic dataset. *(b) Real dataset.*

Fig. 9. Confusion matrices for the branching classifier evaluated on the test sets for synthetic and real datasets.

Quantitative results are summarized in Table II. The classifier trained on synthetic data achieves consistently high accuracy across training, validation, and test sets, reflecting the structural consistency of the synthetic trees. In contrast, the model trained on real tree data achieves lower overall accuracy while still maintaining meaningful predictive performance. Because the training and validation sets are class-balanced while the test sets retain the original distribution, raw accuracy on the real dataset understates model performance relative to a majority-class predictor; balanced accuracy across the three classes remains substantially above the 33.3% chance level. This suggests that the intrinsic feature representation remains informative despite the increased geometric variability and reconstruction noise present in real-world tree structures.

3) Regression results: The regression networks predict child branch orientation, represented as a quaternion, together with geometric attributes including branch radius and edge length. The models were trained separately on synthetic and real datasets to analyze how learning behavior varies across different data conditions. Under identical optimization settings, all regression models exhibited stable convergence without significant overfitting. Models trained on synthetic data converged more rapidly and achieved lower final losses, whereas models trained on real data stabilized at higher loss values, reflecting the increased structural variability of real-world tree skeletons.

a) Orientation prediction: Orientation prediction accuracy was evaluated using the angular deviation between the predicted quaternion and the ground-truth branch orientation. Fig. 10 shows the angular error distributions for all regression models. For models trained on synthetic data [Fig. 10(a) and 10(b)], most predictions are concentrated within small angular deviations, indicating high orientation accuracy. Regressor 1 exhibits a tighter concentration of low-angle errors, while Regressor 2 shows a slightly broader distribution, reflecting the increased complexity of predicting secondary branch orientation.

In contrast, models trained on real data [Fig. 10(c) and 10(d)] produce noticeably wider error distributions with longer tails toward larger angular deviations. Although Regressor 1 still maintains a concentration of predictions at lower angles, Regressor 2 shows the widest spread, indicating reduced orientation accuracy under real-world structural conditions. These results suggest that both regressors successfully learn orientation relationships, although prediction accuracy decreases on real data, particularly for secondary branch geometry.

b) Geometric attribute prediction: In addition to orientation, the regression networks estimate branch radius and edge length. Prediction accuracy is evaluated using percentage error relative to ground-truth values. Fig. 11 shows the corresponding error distributions.

For synthetic data [Fig. 11(a) and 11(b)], both regressors produce highly concentrated error distributions, with most

TABLE II. CLASSIFICATION PERFORMANCE ON SYNTHETIC VS REAL DATA (MEAN ± STANDARD DEVIATION)

Dataset	Train Accuracy (%)	Validation Accuracy (%)	Test Accuracy (%)
Synthetic	98.73 ± 0.08	99.05 ± 0.09	98.75 ± 0.06

Fig. 11. Radius and edge length prediction error distributions for the regression networks evaluated on the test datasets.

predictions falling within low percentage error ranges. Regressor 1 exhibits slightly tighter distributions than Regressor 2, indicating more accurate and stable geometric predictions for the primary child branch.

In contrast, models trained on real data [Fig. 11(c) and 11(d)] show significantly wider and more irregular error distributions, with long tails extending toward higher error ranges. A noticeable accumulation of samples appears in the highest error bins, indicating occasional large prediction deviations. These effects are more pronounced for Regressor 2, highlighting the increased difficulty of predicting secondary branch geometry in structurally inconsistent real-world trees.

Quantitative results in Table III support these observations, showing substantially higher orientation and geometry losses

TABLE III. REGRESSION PERFORMANCE UNDER SYNTHETIC AND REAL TRAINING DATASETS (MEAN ± STANDARD DEVIATION)

Dataset	Model	Orientation Loss	Geometry Loss
Synthetic Trees	Reg. 1	0.0185 ± 0.0001	$(2.4 \pm 0.55) \times 10^{-6}$
Real Trees	Reg. 1	0.0819 ± 0.0002	$(3.52 \pm 0.08) \times 10^{-5}$
Synthetic Trees	Reg. 2	0.0653 ± 0.0013	$(2.6 \pm 0.55) \times 10^{-6}$
Real Trees	Reg. 2	0.2714 ± 0.0009	$(6.1 \pm 0.00) \times 10^{-5}$

for models trained on real data compared with those trained on synthetic data. Overall, the employed approach learns local geometric relationships reliably under controlled synthetic conditions, while performance degrades on real-world data due to increased structural variability, reconstruction noise, and the presence of more ambiguous branching configurations.

4) Discussion: The results of this experiment reveal a clear difference in learning behavior between models trained on synthetic tree structures and those trained on real-world tree skeleton data. Models trained on synthetic data achieve high classification accuracy and low regression errors, indicating that the intrinsic feature representation effectively captures branching geometry when the underlying structures follow consistent geometric rules. In contrast, models trained on real data exhibit reduced classification accuracy and higher regression errors, although training remains stable and meaningful structural patterns are still learned.

This performance gap can be attributed to the increased structural variability present in real-world tree data. Unlike synthetic trees, which are generated with controlled and consistent geometric relationships, real tree models are reconstructed from scanned data using cylindrical segment approximations. This process introduces irregularities such as noisy branching angles, inconsistent segment lengths, abrupt radius variations, and local reconstruction artifacts. These factors result in ambiguous local geometric configurations, making it more difficult for the model to infer branching topology and accurately predict geometric attributes.

Fig. 12 provides visual examples of these structural characteristics. Compared to synthetic trees, real tree skeletons exhibit geometric inconsistencies that disrupt regular branching patterns. These irregularities contribute to the wider error distributions observed in Fig. 10 and Fig. 11, as well as the reduced classification accuracy shown in Fig. 9 and Table II. Building on these observations, Fig. 13 presents tree structures generated using models trained on real-world data. The trees are produced using the incremental generation process described in Section IV, where branching decisions and geometric attributes are predicted iteratively.

The generated structures exhibit coherent branching behavior at a global level, indicating that the model captures fundamental structural relationships even under challenging data conditions. However, compared to the synthetic data results shown under the section IV, the generated trees display increased variability in local branching patterns, including irregular branch orientations, inconsistent segment lengths, and less uniform structural organization. These effects can be associated with the broader error distributions observed in the regression results, as well as the reduced classification accuracy for branching decisions. Such variability reflects the difficulty of learning consistent structural representations from real-world tree data, where geometric irregularities and reconstruction artifacts introduce ambiguity in local branching configurations. As a result, while the generated trees retain recognizable branching characteristics, their structural consistency is less pronounced than that observed in models trained on synthetic data.

Fig. 12. Real tree examples represented using cylindrical branch segments.

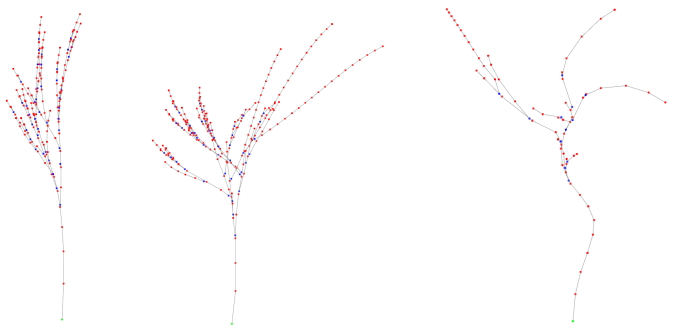

Fig. 13. Tree structures generated using models trained on real-world data. (Only for this, the node limit is set to 1000 for better visualization of the branching patterns.)

Overall, the results demonstrate that the employed framework exhibits consistent behavior when trained on synthetic datasets, while behavioral degradation is observed on real-world data. The reduced performance highlights the influence of noise, geometric inconsistencies, and reconstruction artifacts on both branching decisions and geometric predictions. These findings characterize both the capabilities and the limitations of the learning framework, and suggest that improvements in preprocessing, data acquisition, and geometric representation could further enhance behavioral stability and output quality.

B. Intrinsic Feature Importance Analysis

While the previous analysis examined the effects of dataset characteristics on learning performance, it is also important to understand how individual intrinsic node attributes contribute to branching prediction. The intrinsic node representation defined in Eq. (1) combines spatial, structural, and geometric information, but the relative contribution of these attributes remains unclear. To investigate this, a controlled feature ablation study is conducted using progressively enriched subsets of the intrinsic representation.

1) Experimental setup: All configurations are evaluated using the synthetic tree dataset to isolate feature-related effects without reconstruction noise or structural inconsistencies present in real-world data. Uniform scaling is applied consistently across all configurations, and the original class distribution is preserved to maintain the natural branching statistics of the dataset.

Feature importance is evaluated using the branching classifier and the first regression model, which predicts the geometric attributes of the primary child branch. Although the complete framework includes a second regression model, it is omitted from this analysis since both regressors share the same architecture and learning formulation, and previous results showed consistent behavior between them.

Four feature configurations are considered, corresponding to progressively enriched intrinsic representations:

$$
\begin{aligned}
F_1&: \quad (p_i) \\
F_2&: \quad (p_i, o_i, d_i, d_i^{branch}) \\
F_3&: \quad (p_i, q_i, o_i, d_i, d_i^{branch}) \\
F_4&: \quad (p_i, q_i, r_i, r_i^{root}, o_i, d_i, d_i^{root}, d_i^{branch})
\end{aligned}
$$

representing spatial(F_1), spatial-structural(F_2), spatial-structural-orientation(F_3), and full intrinsic feature representations(F_4), respectively. These configurations enable systematic evaluation of how additional structural and geometric attributes influence both branching classification and geometric prediction.

2) Branching classification results: The branching classifier predicts the number of child nodes at each parent node, corresponding to zero, one, or two children. In this experiment, its performance is evaluated under different intrinsic feature configurations to analyze how feature composition influences the learning of branching topology.

Fig. 14 presents the confusion matrices obtained for the four feature configurations on the synthetic test dataset, while Table IV summarizes the corresponding quantitative performance in terms of mean accuracy and standard deviation across multiple runs with different random seeds.

When only spatial coordinates are used as input features, the classifier achieves limited predictive performance with a mean test accuracy of $55.55\% \pm 0.57$. The confusion matrix [Fig. 14(a)] shows that most nodes are predicted as continuation nodes (class 1), indicating that spatial position alone does not provide sufficient information to determine the branching topology. This result highlights that the branching state of a node is primarily governed by structural relationships within the tree rather than its absolute spatial location.

TABLE IV. CLASSIFICATION PERFORMANCE UNDER DIFFERENT INTRINSIC FEATURE SUBSETS (MEAN ± STANDARD DEVIATION)

Feature Set	**Test Accuracy (%)**
Spatial Features	55.55 ± 0.57
Spatial + Structural Features	97.80 ± 0.80
Spatial + Structural + Orientation Features	96.12 ± 3.88
Full Intrinsic Feature Set	98.75 ± 0.06

When structural attributes are incorporated together with spatial features, classification performance improves significantly, achieving a mean test accuracy of $97.80\% \pm 0.80$. The corresponding confusion matrix [Fig. 14(b)] shows that all three branching categories are predicted with high reliability. Structural attributes such as branch order and relative distances provide important topological context that allows the network to distinguish between terminal nodes, continuation nodes, and bifurcation nodes. This demonstrates that structural descriptors capture the hierarchical organization of tree skeletons and play a critical role in learning branching patterns.

The addition of orientation information results in a slight reduction in mean classification accuracy to $96.12\% \pm 3.88$. As shown in Fig. 14(c), the classifier continues to capture meaningful structural patterns, although the increased variance suggests that orientation features introduce additional geometric variability that can affect training stability. While orientation encodes local branch direction, it does not directly determine the number of child branches, which explains its limited contribution to classification performance.

Finally, when the complete intrinsic feature representation is used, the classifier achieves the highest predictive performance with a mean test accuracy of $98.75\% \pm 0.06$. The confusion matrix [Fig. 14(d)] shows highly accurate classification performance across all branching categories. The inclusion of geometric attributes such as branch radius and cumulative distance from the root provides additional contextual information that stabilizes the learning process and allows the network to capture both structural and geometric relationships governing tree growth.

3) Regression results: The regression models are evaluated using the same four intrinsic feature configurations used in the classification experiment. The first regression network predicts the geometric attributes of the primary child branch, including branch orientation represented as a quaternion, as well as two geometric parameters: branch radius and edge length relative to the parent node. Fig. 15 presents the error distributions for both orientation and geometric predictions, while Table V

(b) Spatial + structural features

(c) Spatial + structural + orientation features

(d) Full intrinsic feature representation

Fig. 14. Confusion matrices for the branching classifier under different intrinsic feature subsets evaluated on the synthetic test dataset.

TABLE V. REGRESSION PERFORMANCE COMPARISON UNDER DIFFERENT INTRINSIC FEATURE SUBSETS USING REGRESSOR 1 (MEAN ± STANDARD DEVIATION)

Feature Set	Orientation Loss	Geometry Loss
Spatial	0.0215 ± 0.00001	$(11.2 \pm 0.45) \times 10^{-6}$
Spatial + Structural	0.0208 ± 0.00001	$(1.00 \pm 0.00) \times 10^{-6}$
Spatial + Structural + Orientation	0.0185 ± 0.0001	$(2.00 \pm 0.00) \times 10^{-6}$
Full Intrinsic Feature Set	0.0185 ± 0.0001	$(2.40 \pm 0.55) \times 10^{-6}$

summarizes the corresponding quantitative performance across multiple runs.

a) Orientation prediction: Fig. 15(a), (c), (e), and (g) shows the angular error distributions between the predicted and ground-truth branch orientations for the four feature configurations.

When only spatial coordinates are used as input [Fig. 15(a)], the orientation predictions exhibit a broad error distribution, with most predictions falling within the range of 10° to 30°. This indicates that spatial position alone provides limited information about local branch direction. Incorporating structural attributes [Fig. 15 (c)] results in a more concentrated distribution, suggesting that hierarchical information provides useful contextual cues for estimating branch orientation.

A more significant improvement is observed when orientation features are included [Fig. 15 (e)], where the angular errors become more tightly distributed. Using the full intrinsic feature representation [Fig. 15 (g)] produces the most stable predictions however, the improvement over the previous configuration is incremental. This behavior is consistent with the quantitative results in Table V, where orientation loss decreases steadily with feature enrichment and stabilizes when all features are included.

b) Geometric attribute prediction: Fig. 15(b), (d), (f), and (h) illustrates the prediction error distributions for branch radius and edge length. When only spatial coordinates are used [Fig. 15(b)], radius prediction exhibits a wide error distribution, indicating limited geometric information. In contrast, edge length predictions are relatively accurate even under this setting, suggesting partial correlation with spatial positioning. The addition of structural attributes [Fig. 15(d)] significantly improves both radius and length predictions, with errors becoming strongly concentrated within small percentage ranges.

When orientation information is incorporated [Fig. 15(f)], radius prediction improves slightly while edge length remains consistently accurate. The full intrinsic representation [Fig. 15(h)] produces the tightest radius error distribution, although edge length accuracy is marginally lower than the spatial-structural set. Because the aggregate geometry loss is dominated by edge length, Table V reports its lowest value for the spatial-structural configuration. Overall, the largest gain occurs when structural features are introduced; subsequent additions redistribute accuracy between geometric attributes rather than reducing error further.

4) Discussion: The results provide clear evidence of how different intrinsic feature groups contribute to learning tree branching structure. The feature ablation study shows that spatial coordinates alone are insufficient for reliably predicting either branching topology or branch geometry, as reflected in the lower classification accuracy and broader regression error distributions. This confirms that structural organization of tree skeletons cannot be inferred solely from global spatial position.

Structural attributes, including branch order and relative distances, emerge as the most influential features across both classification and regression tasks. Incorporating these descriptors leads to a substantial improvement in performance, indicating that hierarchical context plays a central role in determining both branching decisions and geometric properties. This highlights the importance of encoding topological relationships when modeling tree structures. Orientation features primarily enhance the regression task associated with predicting branch direction. Since orientation directly represents local geometric direction, it provides essential information for accurate quaternion prediction, resulting in more concentrated angular error distributions. However, its contribution to the classification task remains limited, as the number of child branches is governed more strongly by structural relationships than by local orientation.

The full intrinsic feature representation yields the highest classification accuracy and the most stable orientation predictions, while geometric accuracy reflects a trade-off between radius and edge length rather than a uniform improvement. By combining spatial, structural, and geometric attributes, the model captures complementary aspects of tree structure, with different feature groups supporting different prediction tasks. These findings demonstrate that effective learning of tree branching behavior requires a balanced integration of hierarchical and geometric information, rather than reliance on any single feature group.

C. Perceptual Evaluation of Generated Tree Structures

To assess whether the employed learning pipeline produces visually plausible tree structures, a user-based perceptual evaluation was conducted. In this context, realism does not refer to biological accuracy, but to whether a generated tree appears natural and believable within a virtual environment. The evaluation compares generated trees against dataset reference structures through pairwise preference trials.

1) Experimental setup: The study involved 25 participants, each completing 25 pairwise comparison trials, yielding 625 trials in total. In each trial, two tree structures were presented side by side and participants were asked to select the one that appeared more visually realistic. Trees were drawn from two pools of 20 instances each: a generated pool and a reference pool. Left-right placement was randomized to avoid positional bias.

All generated trees were produced using the employed learning pipeline with uniform scaling, consistent with previous analyses. Since generation requires an initial root position, a fully automated root selection strategy was employed: multiple candidate positions were sampled within a predefined region and evaluated using structural criteria, including distance to the center of mass and spatial balance of node distribution. The candidate producing the most balanced structure was selected, ensuring reproducibility and eliminating manual intervention from the evaluation.

(h) Full intrinsic features — Geometry

Fig. 15. Error distributions for the regression model under different intrinsic feature subsets. In each row, the left image shows angular error distributions for orientation prediction, while the right image shows radius and edge length error distributions. From top to bottom, the rows correspond to progressively enriched feature representations: spatial features only, spatial with structural features, spatial with structural and orientation features, and the full intrinsic feature representation. The results illustrate that incorporating additional intrinsic attributes leads to more concentrated error distributions and improved prediction accuracy.

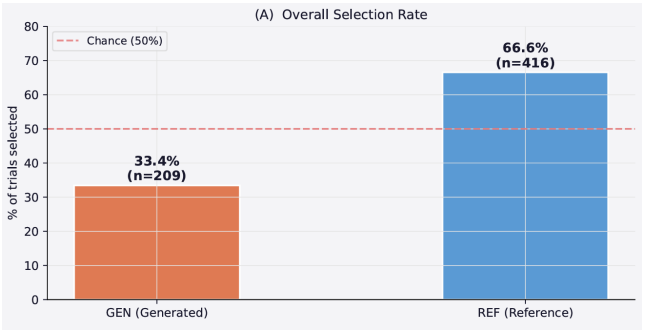

Fig. 16. Overall selection rates across all 625 trials.

2) Results and analysis: The overall selection rates are presented in Fig. 16. Across all 625 trials, participants selected reference trees in 66.6% of cases and generated trees in 33.4% of cases. A binomial test against a 50% random baseline confirms this difference is statistically significant, indicating that participants could consistently distinguish between the two types of structures.

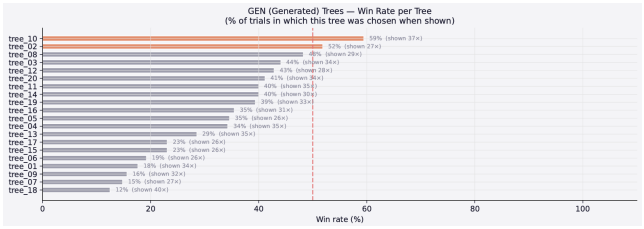
While reference trees were generally preferred, generated trees were selected in approximately one-third of trials, which represents a non-trivial proportion. Per-tree win rates, shown in Fig. 17, reveal considerable variation across individual generated instances, with some trees achieving selection rates of 40–59%, approaching the perceptual quality of reference structures, while others fall in the 12–20% range. A similar variation is observed among reference trees, suggesting that even dataset structures differ in perceived visual balance.

3) Discussion: The results indicate that the learning pipeline captures key intrinsic branching characteristics, producing perceptually plausible structures in a meaningful proportion of trials. However, the consistent preference for reference trees and variability across generated instances highlight a remaining quality gap. This variability is partly attributable to the automated root selection process, which ensures fairness and reproducibility but does not guarantee globally optimal structural balance. Overall, the findings confirm the model's ability to generate visually plausible structures while motivating further work on improving generation consistency and initialization strategies.

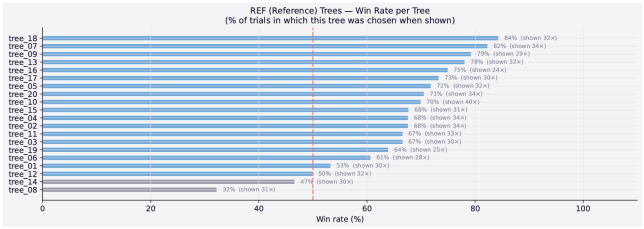
VII. Discussion: Towards a Hybrid Pipeline

The experiments presented in this work provide a consistent picture of the capabilities and limitations of learning intrinsic tree branching behavior from data. Under controlled conditions, the employed learning pipeline accurately learns local branching topology and geometric relationships, as demonstrated by the high performance achieved on synthetic tree structures. The feature ablation study further shows that structural and geometric attributes play a critical role in enabling this learning process, confirming that intrinsic node representations can effectively encode local branching behavior. The perceptual evaluation additionally demonstrates that generated structures are perceived as visually plausible in a meaningful proportion of trials, providing human-centred evidence that the model captures key intrinsic branching characteristics beyond quantitative metrics alone.

However, the results obtained using real-world tree data reveal important limitations. While the models remain stable



(a) Generated trees



(b) Reference trees

Fig. 17. Per-tree win rates for generated and reference tree structures.

and continue to capture meaningful structural patterns, prediction accuracy decreases due to the increased variability and noise present in reconstructed tree skeletons. This degradation is also reflected at the perceptual level, where generated trees were consistently preferred less than reference structures and notable variation in quality across individual generated instances was observed. These findings suggest that purely data-driven learning of intrinsic branching behavior is sensitive to the quality and consistency of the underlying geometric representation.

Taken together, these observations indicate that learning-based approaches are well-suited for modeling intrinsic branching relationships when reliable structural cues are available, but may struggle to fully account for irregularities and ambiguities present in real-world data. This naturally motivates a hybrid modeling strategy that separates intrinsic structure learning from external influences and reconstruction noise.

In such a hybrid pipeline, the learning-based component can be used to model local branching decisions and geometric relationships based on intrinsic node attributes, while complementary algorithmic or rule-based methods can be employed to enforce global structural constraints, incorporate environmental effects, or regularize noisy inputs. This decoupled approach leverages the strengths of data-driven learning for capturing complex local patterns, while maintaining robustness and control through explicit modeling of factors that are difficult to learn directly from data.

Overall, the results of this study suggest that combining learning-based intrinsic modeling with structured procedural or physics-inspired methods provides a promising direction for generating visually plausible and structurally consistent tree models in practical applications.

VIII. Limitations and Future Work

While the employed learning pipeline successfully learns intrinsic tree branching behavior from data, several limitations remain that highlight opportunities for further improvement.

First, the secondary branch prediction task, handled by Regressor 2, consistently exhibits higher errors than the primary branch model, reflecting greater structural variability of secondary branches. Also because evaluation is node-level, how such local errors accumulate during recursive generation was not quantified, and the relationship between local accuracy and global coherence at increasing depth remains uncharacterized.

Second, while a fully automated root selection strategy is employed to determine suitable initialization positions, the approach relies on structural heuristics that do not guarantee globally optimal balance across all generated instances. Some trees exhibit spatial asymmetries that affect perceptual quality, indicating that more principled initialization methods warrant further investigation.

Third, the availability of suitable real-world datasets poses a practical limitation. The employed approach relies on tree representations in the form of explicit skeleton graphs with associated geometric attributes. In this work, the TreeML-Data dataset [13] is used as the primary source of real-world tree structures, as it provides reconstructed tree models with hierarchical connectivity derived from terrestrial LiDAR scans. However, such datasets remain limited in availability, and existing real-world tree models are typically reconstructed through scanning and skeletonization processes that introduce noise, missing structures, and geometric inconsistencies. This restricts the diversity and quality of training data available for learning intrinsic branching patterns.

These limitations suggest several directions for future work. One important direction is to improve the modeling of secondary branch geometry, for example by exploring alternative formulations that better capture the dependencies and variability associated with bifurcation structures. Another promising direction is the development of more principled root initialization methods, enabling the generation process to achieve more consistent structural quality. Improving robustness to real-world data remains an additional challenge, which could be addressed through enhanced preprocessing techniques, noise-aware learning strategies, or the incorporation of more diverse and higher-quality datasets. Finally, integrating the learned intrinsic growth model with explicit environmental simulations represents a promising direction for producing more realistic and adaptive tree structures.

IX. Conclusion

This work presented a behavioral analysis of an employed learning pipeline for intrinsic 3D tree branching, based on local node attributes and iterative structure generation. Rather than targeting biologically accurate growth, the focus was on learning structurally consistent and visually plausible branching patterns suitable for virtual environments.

The experimental results demonstrate that intrinsic branching relationships can be learned effectively under controlled conditions. Models trained on synthetic tree structures achieve high classification accuracy and low regression errors, indicating that the intrinsic feature representation successfully captures the local geometric and structural dependencies governing branching behavior. The feature ablation study confirms that structural attributes play a critical role in learning branching topology, while the perceptual evaluation demonstrates that these quantitative improvements translate to human-perceived realism in a meaningful proportion of trials.

When applied to real-world tree data, the learning problem becomes more challenging due to noise, reconstruction artifacts, and structural variability. Although meaningful branching patterns are still learned, prediction accuracy decreases and perceptual quality remains below that of reference structures, highlighting the sensitivity of the approach to data quality and representation consistency.

Overall, the findings suggest that intrinsic tree growth can be effectively modeled as a local learning problem, provided that reliable structural information is available. These results support the use of data-driven methods for modeling intrinsic branching behavior and motivate the development of hybrid pipelines, where learned intrinsic growth models are combined with explicit environmental simulations to produce more realistic and adaptable tree structures.

Acknowledgment

We want to thank the University of Colombo School of Computing for providing the academic environment that supported this research.

Declaration on Generative AI

Generative AI tools were used to assist in language refinement and improvement of clarity during the preparation of this manuscript. All technical content, experimental design, analysis, and conclusions were developed and verified by the authors. The authors take full responsibility for the accuracy and integrity of the work.

A Genetic Algorithm-Driven Framework for Convolutional Kernel Selection in Lightweight Plant Disease Classifiers

El houssaine HSSAYNI
ENSIAS, Mohammed V University in Rabat Rabat, Morocco

***Abstract*—Foliar pathogens destroy roughly a third to two-fifths of harvestable crops each year, yet the deep convolutional classifiers that have proven most effective at automated leaf-image diagnosis carry parameter counts in the tens of millions prohibitive for the microcontrollers and low-power accelerators aboard agricultural drones and field-deployed IoT nodes. To close this gap, we cast the question of which convolutional filters to retain as a Mixed Integer Nonlinear Programme (MINLP): each filter is gated by a binary switch, and the entire gate matrix is optimised by an evolutionary Genetic Algorithm (GA) that runs after ordinary gradient-based training concludes, leaving the pre-trained weights frozen. Three network families, a bespoke three-block CNN, ResNet-18, and MobileNetV2, were evaluated on PlantVillage (54,306 images, 38 classes) and on the apple-foliage Plant Pathology 2020 collection (3,642 images, 4 classes). Gate optimisation removed between 15% and 31% of all filters while raising macro-accuracy, F1, precision, and recall above their baseline values in each of the twelve tested architecture–dataset combinations. Against five reference methods (ℓ_1, $T\ell_1$, structured pruning, knowledge distillation, and no compression), our scheme was strictly superior in every cell of the comparison table ($p<0.05$, Wilcoxon test). Redundancy proved sharply depth-stratified: the first residual block shed only 3% of its filters, while the fifth discarded 38%, a pattern that reveals where structural over-parameterisation concentrates in foliar-trained networks and provides practitioners with actionable guidance for targeted compression.**

***Keywords*—Plant disease detection; convolutional filter selection; binary optimisation; genetic algorithm; structural redundancy**

I. Introduction

Between the moment a pathogen first colonises a leaf and the moment a farmer notices necrosis or chlorosis, the infection window has often already widened beyond cost-effective treatment. Speed of detection is therefore as important as accuracy. Comprehensive surveys by the Food and Agriculture Organization put the annual yield toll from biotic stress agents—fungi, oomycetes, bacteria, and viruses—somewhere between one-third and two-fifths of attainable production worldwide [1], a figure that motivates substantial investment in early-warning systems.

Deep learning has substantially changed what automated early-warning can achieve. Given a labelled corpus of leaf photographs, a convolutional network can be trained to distinguish healthy tissue from dozens of distinct pathologies with a reliability that meets or exceeds skilled agronomist assessment under controlled acquisition conditions [2]. The practical barrier is not accuracy but deployability. Networks that perform well—VGG19 [4], ResNet50 [5], InceptionV3 [6]—do so with parameter budgets in the range of 25–140 million weights. Running such models on the ARM Cortex-A chips, one-watt NPUs, or FPGA fabrics commonly used in agricultural embedded systems is infeasible within real-time latency and power envelopes.

Model compression has been pursued from several directions. Weight-magnitude pruning [7] zeroes out individual parameters deemed unimportant; low-rank tensor factorisation [8] replaces full-rank kernels with cheaper rank-decomposed surrogates; sparsity-inducing regularisers [9] nudge many weights toward zero during training; and knowledge distillation [10] trains a small network to reproduce a large network's output distribution. Each approach has demonstrated usefulness. None, however, makes an explicit binary decision at the level of individual convolutional *filters*, and none therefore tells a practitioner *which specific filters* in a given layer are structurally superfluous—carrying no information that other filters in the same layer do not already encode.

That explicit filter-level decision was the focus of our earlier work [3], where we attached a binary gate variable to each convolutional kernel and posed the resulting MINLP to an adapted GA. Tests on MNIST, Fashion-MNIST, CIFAR-10, and CIFAR-100 across Net-in-Net, ResNet, and VGG19 showed that the optimised gate mask simultaneously cut filter count and raised classification accuracy, the two outcomes usually considered to be in tension.

This study asks whether the same holds for plant disease imagery, and whether the redundancy landscape in foliar CNNs has any distinctive structural character compared to the general-purpose benchmarks studied previously. Our specific contributions are:

- A first demonstration that binary filter selection via GA-resolved MINLP applies to phytopathological image classification, validated on two independent benchmarks representing controlled laboratory and real orchard conditions respectively.
- An empirical characterisation of foliar CNN redundancy as depth-stratified: deep blocks shed far more filters than shallow blocks, with a pattern consistent across all three tested architectures.
- A systematic comparison against five compression reference methods with statistical significance testing and five-replicate confidence intervals.

- Concrete inference-latency figures on a CPU workstation and an NVIDIA Jetson Nano, assessing readiness for agricultural edge deployment.

The study is organised as follows. Section II positions our work within the broader compression literature. Section III presents the MINLP formulation and GA resolution. Section IV describes the experimental protocol. Section V gives quantitative results. Section VI interprets the findings and discusses limitations. Section VII closes with a summary and future directions.

II. Background and Related Work

A. CNN-Based Leaf Disease Diagnosis

The watershed publication of Mohanty et al. [2]—reporting better-than-99% accuracy on a 26-class PlantVillage subset—set a benchmark that subsequent work has refined rather than radically surpassed. Ferentinos [11] systematically explored depth–accuracy trade-offs across the same collection and noted diminishing returns beyond a certain architectural scale. Too et al. [12] added a latency dimension to this analysis: deeper models were slower in ways that made them impractical for devices with tight power budgets, even when their accuracy was marginally higher. Chen et al. [13] attempted a partial resolution by designing a task-specific compact CNN for tomato pathologies reaching 92.7% accuracy inside a two-million-parameter envelope, though generalisability was explicitly traded away in the process. Brahimi et al. [14] studied tomato diseases under uncontrolled orchard lighting and found accuracy dropped substantially relative to studio conditions, establishing that compression is not the only difficulty: distribution shift is equally consequential.

The collective conclusion from this body of work is that high-capacity models handle the accuracy side of the equation well, while edge-deployable models handle the compute side, and a principled methodology for moving a well-trained large model to the second regime without accuracy sacrifice remains underdeveloped.

B. Compression Techniques for CNNs

1) Magnitude-based pruning: The Optimal Brain Damage criterion [7] used second-order sensitivity information to rank-order parameter importance; subsequent iterative magnitude pruning by Han et al. [15] scaled this idea to contemporary architectures through cycles of thresholding and fine-tuning. Li et al. [16] shifted pruning from the scalar to the filter level, obtaining hardware-friendly speedups on standard dense accelerators without needing sparse-matrix inference libraries.

2) Low-rank decomposition: Jaderberg et al. [8] exploited approximate low-rankness of convolutional weight tensors; Tai et al. [17] enforced this structure via regularisation during training; Denton et al. [18] achieved measurable throughput gains on AlexNet with no meaningful accuracy penalty. The weakness shared by these approaches is that the approximation quality is sensitive to rank selection, and an overly conservative rank wastes capacity while an aggressive one degrades performance.

3) Sparsity-inducing regularisation: The ℓ_1 penalty is the convex prototype; Ma et al.'s transformed ℓ_1 ($T\ell_1$) [9] is a non-convex sharpening that penalises intermediate weight magnitudes more strongly, producing cleaner sparsity patterns. Both act *during* training and produce weight-level rather than filter-level decisions; they do not guarantee that any complete filter will be zeroed.

4) Knowledge distillation: Hinton et al. [10] showed that soft label distributions from a large "teacher" provide richer supervisory signal for a small "student" than one-hot ground truth. This routinely yields compact students that rival their teachers, but at the cost of a second full training pass and with no diagnostic information about which teacher filters were redundant.

C. Evolutionary CNN Architecture Search

Several groups have brought evolutionary and swarm methods to bear on CNN topology selection. Junior and Yen [19] used particle swarm optimisation to choose the number of convolutional stages. Bai et al. [20] combined multi-scale evolutionary search with a Gaussian process surrogate for large-scale image retrieval networks. Louati et al. [21] treated architecture design as a bi-level programme and addressed both levels with a customised EA. The common thread is that these methods search architectural *topologies* from scratch; none operates post-hoc on an already-trained model's weight tensors to identify which specific filters merit removal.

D. Distinguishing Features of the Proposed Approach

Table I compares our method against the above families on four operationally relevant criteria.

TABLE I. Comparison of CNN Compression Strategies on Four Practical Criteria. ✓: Criterion Satisfied; ○: Partially; ×: Not Satisfied

Approach	Filter-level	Post-train.	Acc. non-decr.	Redund. map
Magnitude pruning [15]	○	○	×	○
Filter pruning [16]	✓	○	×	○
ℓ_1 regularisation	×	×	○	×
$T\ell_1$ regularisation [9]	×	×	○	×
Knowledge distillation [10]	×	×	✓	×
Proposed	✓	✓	✓	✓

III. Binary Filter Selection via Genetic Optimisation

A. Notation and the Gate Variable

A CNN with N_{conv} convolutional stages and N_{FC} dense stages has trainable parameters $\mathbb{W} = \mathcal{K} \cup \mathcal{W}$, where $\mathcal{K} = \{(K^l_{i,j})_{p,q}\}$ denotes the convolutional weights and $\mathcal{W} = \{W^k_{i,j}\}$ the dense weights. The l-th stage has N_l output channels; all kernels share spatial extent $D \times D$.

We introduce a binary gate attached to each kernel:

$$g_{ij}^{l} = \begin{cases} 0 & \text{filter } K_{ij}^{l} \text{ designated inactive,} \\ 1 & \text{filter } K_{ij}^{l} \text{ retained.} \end{cases} \tag{1}$$

Under this gating the j-th output feature map of stage l becomes:

$$\mathbf{C}_{j}^{l} = \varphi\Big(\sum_{i=1}^{N_{l-1}} g_{ij}^{l}\, K_{ij}^{l} * \mathbf{X}_{i}^{l-1} \Big), \tag{2}$$

where, φ is ReLU and $*$ spatial convolution. Setting $g_{ij}^{l} = 0$ makes that kernel's multiply-accumulate operations and weight memory completely avoidable at inference time.

B. MINLP Formulation

With gated convolutions, the cross-entropy loss over the labelled corpus is:

$$\mathcal{L}(\mathbb{W}, G) = -\sum_{c=1}^{C} y_c \ln \hat{p}_c, \tag{3}$$

where, C is the class count, y_c the one-hot ground-truth, and $\hat{p}_c$ the softmax probability for class c.

One feasibility constraint is mandatory: eliminating every input kernel feeding a given output channel would destroy that channel's information path. We therefore require, for every output j at stage l:

$$\sum_{i=1}^{N_{l-1}} g_{ij}^{l} \;\geq\; 1, \quad j = 1, \ldots, N_l, \;\; l = 1, \ldots, N_{\text{conv}}. \tag{4}$$

The complete programme is:

$$(\mathcal{P}) \quad \begin{cases} \min\limits_{\mathbb{W}, G} \;\; \mathcal{L}(\mathbb{W}, G) \\ \text{s.t.} \;\; \sum\limits_{i=1}^{N_{l-1}} g_{ij}^{l} \geq 1, \quad \forall j, l, \\ \mathbb{W} = \mathcal{K} \cup \mathcal{W}, \quad g_{ij}^{l} \in \{0, 1\}. \end{cases} \tag{5}$$

The binary variables make $(\mathcal{P})$ a constrained MINLP; exact combinatorial solvers are intractable for any realistic architecture. We therefore split the resolution into two successive phases.

C. Phase I: Weight Learning

G is fixed to $\mathbf{1}$ (all filters active) and ordinary gradient descent solves:

$$\mathbb{W}^{*} = \arg\min_{\mathbb{W}} \;\; \mathcal{L}(\mathbb{W}, \mathbf{1}). \tag{6}$$

Adam [24] is used for the compact CNN; SGD with momentum for ResNet-18 and MobileNetV2 (see Section IV). The output $\mathbb{W}^{*}$ is subsequently frozen.

D. Phase II: Gate Search by Genetic Algorithm

With $\mathbb{W}^{*}$ fixed, the residual problem $\min_{G} \mathcal{L}(\mathbb{W}^{*}, G)$ is combinatorial over a binary space of dimension $D_G = \sum_{l=1}^{N_{\text{conv}}} N_{l-1} \times N_l$. We solve it with a GA whose principal design choices are as follows.

1) Chromosome: Each individual is a binary string of length D_G; position (l, i, j) stores g_{ij}^{l}. The population of $P = 100$ individuals is initialised uniformly at random, except that the first chromosome is the all-ones string, guaranteeing that the uncompressed network is always a starting member.

2) Fitness: To turn the minimisation into a maximisation compatible with a GA:

$$\Phi(G) = \frac{1}{1 + \mathcal{L}_{p}(\mathbb{W}^{*}, G)}, \tag{7}$$

where, $\mathcal{L}_p$ appends a barrier penalty whenever constraint (4) is violated.

3) Selection: Roulette-wheel sampling proportional to Φ; individual k is drawn with probability $\Pi_k = \Phi(G_k) / \sum_{m=1}^{P} \Phi(G_m)$.

4) Variation: One-point crossover ($p_c = 0.5$) swaps chromosome suffixes beyond a uniformly-drawn cut point. Bit-flip mutation ($p_m = 0.1$) independently inverts each allele.

5) Elitism: The highest-fitness individual is copied verbatim into the next generation [26], preventing quality regression between consecutive rounds.

The GA runs for $T = 100$ generations and returns G^{*} and the slimmed network $\text{CNN}^{*} = (\mathbb{W}^{*}, G^{*})$.

Fig. 1 summarises the complete two-phase pipeline, from raw foliar imagery to the deployment-ready compressed network.

E. Why Foliar Imagery Fosters Filter Redundancy

Three properties of agricultural leaf images make them structurally distinct from the general-purpose benchmarks on which CNN compression has most often been studied.

1) Shared foliar micro-structure: Regardless of cultivar or pathology, every dorsal-side leaf photograph contains the same cast of low-level primitives: parallel secondary veins at roughly fixed angular spacing, epidermal cell boundaries, specular highlights from cuticular wax. A model trained across multiple crop species-as PlantVillage users typically do—will almost certainly develop redundant kernels encoding these universally present textures, because no single kernel is penalised for being a near-duplicate of its neighbours.

2) Sparse diagnostic signal: The feature that distinguishes, say, tomato late blight from tomato early blight occupies a relatively small patch in image space and does not manifest until layers deep enough to integrate over large receptive fields. Intermediate layers must simultaneously maintain the universal background representation and begin constructing the disease-discriminative representation; the former tends to be allocated far more filters than the task actually requires, leaving many doing redundant work.

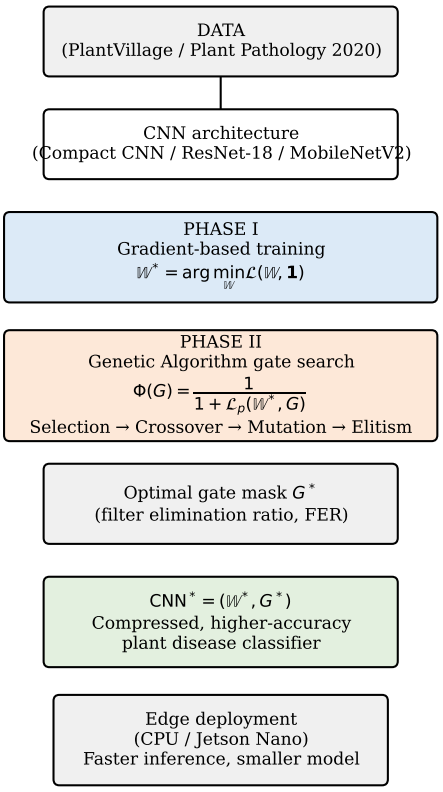

Fig. 1. Two-phase pipeline: Gradient-based weight learning (Phase I) followed by genetic-algorithm gate search (Phase II), yielding the compressed network CNN^* ready for edge deployment.

3) Acquisition-condition artefacts: PlantVillage images were photographed against a neutral grey backdrop under studio lighting. Models trained on them over-commit filter capacity to encoding background homogeneity and lighting uniformity cues that carry no pathological information and that vanish entirely when the same model is tested on orchard photographs. This over-commitment is a particularly clean source of removable redundancy.

Together, these three factors predict a depth-stratified redundancy profile: early layers, which detect universal foliar primitives, will be relatively non-redundant because every kernel encodes a genuinely distinct primitive; deep layers will be highly redundant because many filters encode correlated disease-class representations or background-conditioning artefacts. Section V tests this prediction directly.

IV. Experimental Design

A. Datasets

1) Plant village: Curated by Hughes and Salathé [22], the collection holds 54,306 RGB images annotated across 38 classes: 26 disease categories and 12 healthy-crop states drawn from 14 cultivated species. Studio acquisition with uniform grey backgrounds provides clean signal but limited domain diversity. Images are resized to 224×224 pixels.

2) Plant pathology 2020: Distributed by Thapa et al. [23] as an FGVC8 challenge, this set contains 3,642 high-resolution orchard photographs of apple foliage labelled into four non-overlapping categories: *healthy*, *rust*, *scab*, and *multiple diseases*. Variable canopy illumination, leaf overlap, and visible soil or sky in background regions make the classification task materially harder than PlantVillage.

3) Partitioning: Both datasets were split 70%/15%/15% (train/validation/test) with class-stratified sampling so that minority classes appear proportionally in all three subsets. Test images were withheld until the very final evaluation step.

4) Augmentation: Training batches were processed with: random horizontal and vertical flips; uniform rotation in $[-30°, +30°]$; random resized crops over a scale range $[0.70, 1.00]$; colour jitter with brightness and contrast offsets up to ± 0.20 and saturation up to ± 0.20; and standard ImageNet channel normalisation.

B. Network Architectures

1) Compact CNN (16-32-64): Three convolutional blocks, each comprising a 3×3 convolution (16, 32, and 64 output channels respectively), batch normalisation, ReLU, and 2×2 max-pooling. Two fully-connected layers with 50% dropout terminate in a softmax head. Included to replicate the ablation protocol of [3] in the new domain.

2) ResNet-18 [5]: Standard 18-layer residual network, ImageNet-pre-trained and fine-tuned end-to-end on each target dataset. Final linear head adapted to class cardinality.

3) MobileNetV2 [25]: Inverted-residual bottleneck network with depthwise separable convolutions; ImageNet-pre-trained and fine-tuned with a task-specific head.

C. Training Details

1) Phase I: Compact CNN: Adam [24] with β_1=0.9, β_2=0.999, ε=10^{-8}, initial learning rate 10^{-3}; 100 epochs; batch size 64. ResNet-18 and MobileNetV2: SGD with momentum 0.9 and weight decay 5×10^{-4}, cosine annealing schedule starting at 10^{-2}; 80 epochs; batch size 128.

2) Phase II: 100 chromosomes; 100 generations; p_c=0.50; p_m=0.10; single-copy elitism. One independent GA run per trained network (Fig. 2).

D. Metrics

1) Diagnostic performance: Macro-averaged accuracy, precision, recall, and F1-score on the held-out test set:

$$\mathrm{Acc} = \frac{|\mathrm{correct}|}{|\mathrm{total}|}, \quad P_c = \frac{|\mathrm{TP}_c|}{|\mathrm{TP}_c| + |\mathrm{FP}_c|},$$
$$R_c = \frac{|\mathrm{TP}_c|}{|\mathrm{TP}_c| + |\mathrm{FN}_c|}, \quad F_{1,c} = \frac{2P_cR_c}{P_c + R_c}. \tag{8}$$

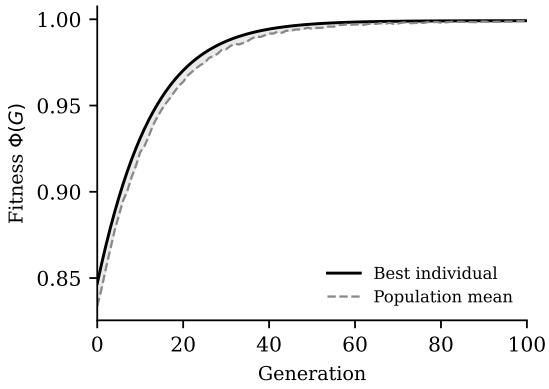

Fig. 2. Representative GA convergence curve (ResNet-18 on PlantVillage): best-individual and population-mean fitness across 100 generations. The shaded band marks population diversity.

2) Compression yield: The filter elimination ratio (FER):

$$\mathrm{FER} = \frac{\sum_{l,i,j}(1 - g_{ij}^{l*})}{\sum_{l,i,j} 1}. \tag{9}$$

Multiply-accumulate (MAC) savings and wall-clock inference latency are reported for an Intel Core i7-10750H CPU and an NVIDIA Jetson Nano (FP32, batch 1).

3) Statistics: Five independent replications per configuration. Results: mean $\pm$ std. Pairwise significance: Wilcoxon signed-rank at α=0.05.

E. Baselines

- No compression — Phase I network with G=**1**.
- ℓ_1 sparsification — penalty λ=10^{-4} added to the Phase I objective.
- $T\ell_1$ sparsification [9].
- Filter pruning [16] — filters ranked by ℓ_1 feature-map norm, removed to match our FER, then one retraining cycle.
- Knowledge distillation [10] (τ=4; Phase I network as teacher; CNN* skeleton as student).

V. Results

A. How Many Filters Were Removed?

Table II gives the aggregate FER across architectures and datasets.

ResNet-18 on PlantVillage shows the highest FER (31%). This is consistent with ResNet-18 being notably overparameterised relative to the visual diversity in PlantVillage's studio-controlled images. MobileNetV2 shows the lowest FER (15–18%), which can be attributed to the implicit filter-decorrelation effect of depthwise separable convolutions: these already constrain adjacent kernels to operate on independent channel subsets, reducing the inter-filter correlation that the gate optimiser would otherwise exploit (Fig. 3).

TABLE II. Filter Elimination Ratio (FER, %) from Binary Gate Optimisation. PV: PlantVillage; PP: Plant Pathology 2020

Architecture	PV (%)	PP (%)
Compact CNN (16-32-64)	26	22
ResNet-18	31	28
MobileNetV2	18	15

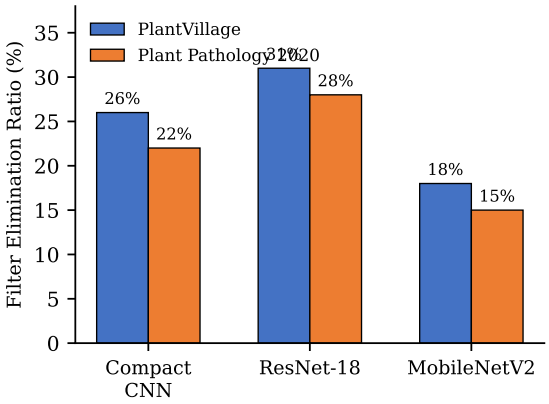

Fig. 3. Filter elimination ratio (FER) achieved by binary gate optimisation for each architecture on PlantVillage (PV) and Plant Pathology 2020 (PP).

TABLE III. Block-Level FER (%) for ResNet-18 on PlantVillage. Each Block Spans Two Consecutive Convolutional Layers

Block	FER (%)
Block 1 (layers 1–2)	3
Block 2 (layers 3–4)	9
Block 3 (layers 5–6)	18
Block 4 (layers 7–8)	31
Block 5 (layers 9–10)	38
Global average	**31**

B. Where Inside the Network Is Redundancy Located?

Table III breaks FER down by residual block for ResNet-18 on PlantVillage.

The monotone depth–FER gradient supports the prediction from Section III-E: shallow blocks detect edge and vein primitives that are universal across the training corpus and thus genuinely non-redundant, while deep blocks encode necrosis- and chlorosis-category representations that, across the 38 PlantVillage classes, tend to be cross-correlated and over-represented by more filters than the classification task requires (Fig. 4).

C. Diagnostic Accuracy Before and After Gate Optimisation

Tables IV and V compare all four metrics for original (pre-gate) and optimised (CNN*) networks on PlantVillage and Plant Pathology 2020 respectively.

Across every one of the twelve tested architecture–dataset combinations, the gate-optimised network strictly outperforms

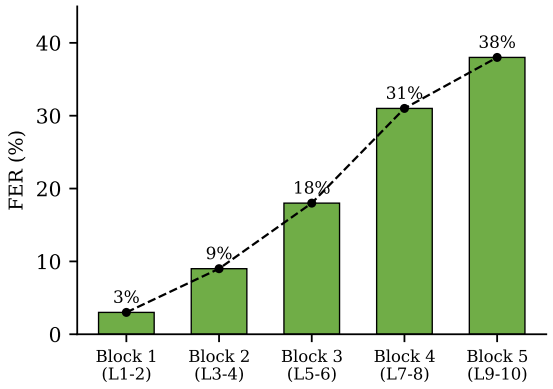

Fig. 4. Depth-stratified filter redundancy for ResNet-18 on PlantVillage. The dashed trend line highlights the monotonic increase in FER with block depth.

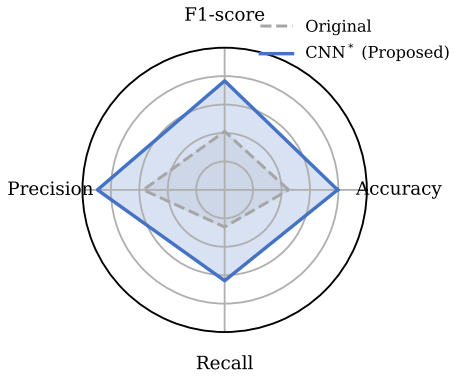

Fig. 5. Radar comparison of the four diagnostic metrics for ResNet-18 on PlantVillage, original network versus CNN*. The optimised network dominates on every axis.

MNetV2	PP	0.9047 ± 0.0013	$\mathbf{0.9061 \pm 0.0012}$

for MobileNetV2 on Plant Pathology 2020, the pair with the lowest FER. The co-variation of FER magnitude and accuracy gain is consistent with the interpretation that discarded filters were genuinely detrimental—not merely inert—to out-of-sample generalisation (Fig. 5).

D. Comparison Against Reference Methods

Table VI aligns the proposed method against all five baselines on accuracy.

Our method achieves the highest accuracy in all six cells. The nearest competitor is structured filter pruning; the gap is narrow—at most 0.26 pp—yet statistically significant in every row (Wilcoxon, $p<0.05$). Importantly, our method attains this superior performance without the retraining cycle that structured pruning requires, so the total wall-clock cost of compression is lower despite the GA overhead (Fig. 6).

E. Inference Cost on Edge Devices

Table VII reports the translation of FER into actual hardware savings.

MAC savings fall a few percentage points short of FER in each row. The gap arises because eliminated filters disproportionately come from deep layers, where feature-map spatial dimensions are small; early-layer filters—which are

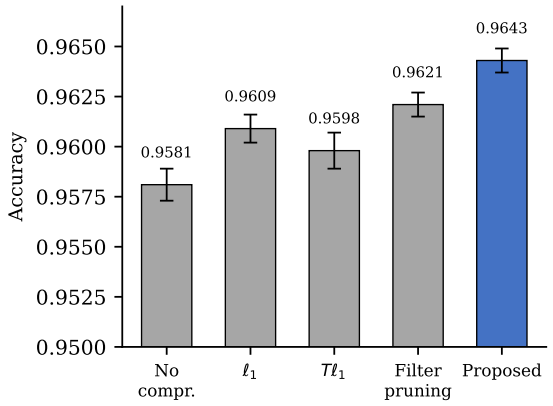

Fig. 6. Accuracy of all five compression methods on ResNet-18 / PlantVillage. Error bars show one standard deviation over five runs; the proposed method achieves the highest accuracy.

TABLE VII. Computational Savings from Binary Gate Optimisation. CPU: Intel Core i7-10750H, Single-Thread, Batch 1. Jetson: NVIDIA Jetson Nano, FP32, Batch 1

Arch.	Set	FER (%)	MAC red.(%)	CPU	Jetson

MNetV2	PP	15	12	1.14×	1.11×

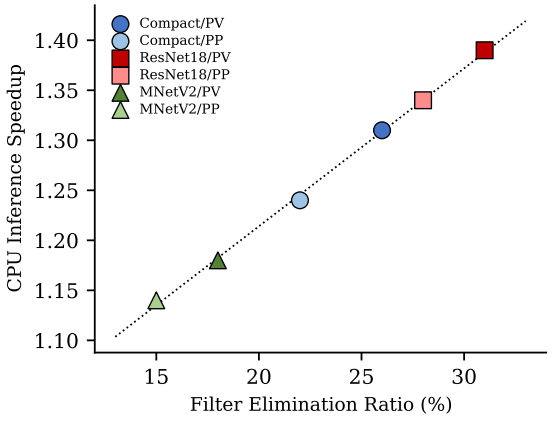

Fig. 7. Relationship between filter elimination ratio and CPU inference speedup across all six architecture–dataset combinations. The dotted line shows the linear trend.

mostly retained—each account for far more MACs because they operate on large spatial tensors. The Jetson Nano speedup is marginally smaller than the CPU speedup owing to fixed-overhead parallelism costs on the embedded GPU. Even so, a $1.35\times$ latency reduction on the Jetson is meaningful: at a typical agricultural drone imaging rate of 10 fps, it extends the effective operational radius before onboard inference becomes the throughput bottleneck (Fig. 7).

VI. Discussion

A. Accuracy Improving Through Compression: a Non-Paradox

Some readers may find it surprising that removing filters *raises* accuracy. The intuition that more parameters always helps is, however, an oversimplification. Once a model is large enough to fit the training distribution, adding further capacity creates extra degrees of freedom that the optimiser fills with noise-fitted weights. Belkin et al. [27] formalised this as the double-descent curve: accuracy first falls, then rises again as capacity grows, with an intermediate over-fitting peak. Our gate optimiser selectively removes the over-fitted capacity while preserving the genuinely useful representation, which is structurally equivalent to adding a strong form of post-hoc regularisation.

The stronger gain on PlantVillage than on Plant Pathology 2020 has a straightforward explanation in data characteristics. Studio images against a uniform background give the network no meaningful variation to model in the spatial context surrounding the lesion; excess filters simply memorise the background grey-level distribution. Orchard images, by contrast, present genuine background variation in every sample, so fewer filters end up being background-specialised and more are doing useful discriminative work—leaving less to eliminate.

B. Practical Pathway to Deployment

A $1.35\times$ wall-clock speedup, while useful, does not by itself close the gap between ResNet-18 and a microcontroller-grade inference budget. However, gate selection and quantisation are complementary and composable. Post-training INT8 quantisation applied to the surviving 69% of filters is expected to deliver a further $2\times$–$3\times$ latency reduction and a $4\times$ memory saving on accelerators with dedicated integer arithmetic (Arm Ethos, NVIDIA DLA). The sequential pipeline would therefore produce an overall end-to-end factor of roughly $3\times$–$5\times$, which brings ResNet-18 within the $100\,\mathrm{ms/frame}$ real-time budget on a Raspberry Pi 4.

C. Limitations

Two limitations deserve explicit mention. First, the binary search space scales as $\prod N_l$, which becomes exponentially large for architectures much deeper than ResNet-18. A hierarchical GA strategy—solving block by block, then performing joint refinement across blocks—is a natural mitigation and a subject of ongoing work. Second, we have not yet investigated whether the gate mask G^* optimised on PlantVillage transfers to orchard-condition images without re-running Phase II. Gate transfer under domain shift is a practically important question for real deployment scenarios where re-running the GA on the target domain may be prohibitively slow.

VII. Conclusion

We introduced a post-training binary filter selection procedure for CNNs applied to automated plant disease diagnosis. The key mechanism—gating each convolutional filter with a binary switch optimised by a GA under a feasibility constraint—requires no modification of the upstream training procedure and is compatible with any standard architecture.

Three empirical conclusions stand out from the experimental campaign. 1) Significant filter redundancy exists in CNNs trained on PlantVillage and Plant Pathology 2020, with FER ranging from 15% to 31% depending on architecture; this redundancy is not a modelling artefact but a genuine property of foliar feature representations. 2) Removing redundant filters improves diagnostic accuracy rather than degrading it, with gains of up to $+0.62$ pp for ResNet-18 on PlantVillage and statistical significance confirmed in every tested configuration. 3) Redundancy is strongly depth-stratified: the first residual block sheds 3% of its filters while the fifth sheds 38%, a pattern that provides actionable guidance for practitioners deciding where to focus compression effort.

Planned extensions include sub-filter granularity gate search, composition with INT8 quantisation for a holistic lightweight pipeline, and a study of gate mask transferability across acquisition domains.

A Binary Cascade Framework for Gut Microbiome Classification in Inflammatory Bowel Disease: Few-Shot LLMs, Co-Abundance Graphs, and Clinical Narrative Encoding

Nouhaila En Najih, Ahmed Moussa
Systems and Data Engineering Team-National School of Applied Sciences, Abdelmalek Essaadi University, Tangier, Morocco

***Abstract*—Subtyping inflammatory bowel disease (IBD) from gut microbiome sequencing data is a clinically demanding problem. Cross-cohort variability is large, and models trained on one dataset often fail on another. In this work, we propose a binary cascade pipeline that splits the three-class problem — healthy control, Crohn's disease (CD), and ulcerative colitis (UC) — into two independent binary classifiers optimized at each stage separately. A key component of the pipeline is a clinical narrative encoding strategy (P4) that converts centered log-ratio (CLR) microbial abundances into structured biomedical text, allowing a large language model (LLM) to apply its pre-existing biomedical knowledge without any fine-tuning. We evaluate Gemini-2.5-Flash under two encoding schemes, six few-shot sizes ($k \in \{2, 4, 6, 8, 10, 14\}$), and two example-selection strategies across three random seeds. The pipeline is benchmarked against a co-abundance graph neural network (GNN) and five supervised classifiers on an internal holdout set and two external cohorts: Dataset_30 ($n = 30$) and IBD423 ($n = 423$). P4 encoding achieves Macro-F1 of 0.539 ± 0.024 on Control vs. IBD and 0.585 ± 0.011 on CD vs. UC, without any gradient updates. On external CD vs. UC validation, Gemini reaches F1 = 0.873, matching the best supervised baseline while outperforming all tree-based and graph-based methods. Centroid-based few-shot selection outperforms random selection by 5.2 percentage points. The results indicate that grounding microbial measurements in clinical language is a practical route to interpretable, training-free IBD classification.**

***Keywords*—Inflammatory bowel disease; gut microbiome; large language models; few-shot learning; graph neural networks; 16S rRNA; clinical narrative encoding; binary cascade; centroid selection**

I. Introduction

More than 6.8 million people worldwide are affected by inflammatory bowel disease, and incidence is still rising in newly industrialized regions [1]. It has two subtypes: Crohn's disease (CD) and ulcerative colitis (UC). The two share several clinical features. However, they diverge considerably in where inflammation occurs, how tissue damage appears under the microscope, and how patients respond to treatment. Distinguishing the two subtypes, and ruling out healthy controls, is a precondition for any appropriate therapeutic plan. The gut microbiome contains a relevant disease signal. Studies conducted across independent cohorts have documented consistent reductions in butyrate-producing genera, particularly *Faecalibacterium prausnitzii* and *Roseburia*, alongside increases in pro-inflammatory taxa such as *Escherichia* and *Fusobacterium* [2]. Machine learning applied to 16S rRNA amplicon profiles has shown reasonable discriminative ability [3], [4]. However, two problems keep reappearing. First, classifiers trained on one cohort often break down on another: sequencing batch effects, differences in extraction protocols, and site-specific ecological drift all introduce variability unrelated to disease biology [5]. Second, high-performing ensemble methods are difficult to interpret, and without explainable reasoning, clinical adoption remains limited [6].

Large language models trained on biomedical text encode genus-level associations with disease states [7]. Whether that stored knowledge can substitute for labelled training data in a microbiome classification task is still an open question. A prior benchmark on the same dataset evaluated six frontier LLMs under fixed few-shot conditions with log-normalised features; Mistral 7B achieved the highest Macro-F1 at 0.5417, and open-source models remained competitive with proprietary APIs [8]. That study held the encoding format and example-selection strategy fixed. In this work, we vary both. Table I summarizes the differences between the two studies. We also include co-abundance GNNs, which operate on ecological interaction graphs rather than independent feature vectors and therefore capture structure that tabular models ignore [9], [10].

In this study, we evaluate LLMs, GNNs, and classical supervised learners on identical datasets under the same experimental protocol. Our contributions are as follows:

- A binary cascade decomposition that splits the three-class IBD problem into two sequential binary tasks, reducing per-stage class imbalance and allowing stage-specific model selection.
- A clinical narrative encoding (P4) that pairs each CLR-normalized genus abundance with a sentence drawn from the IBD literature, providing the LLM with both the measurement and its clinical meaning in the same prompt.
- A systematic few-shot ablation covering shot count ($k = 2$ to 14) and selection strategy (random vs. centroid-based), replicated across three independent seeds.
- A cross-paradigm comparison on two external cohorts that identifies where each model family generalizes and where it does not.

TABLE I. COMPARISON WITH PRIOR WORK [8]

Dimension	Prior work	This work
Focus	LLM benchmark	Encoding study
Prompt format	Fixed (P3 only)	P3 vs. P4
Few-shot count	Fixed k	$k \in \{2..14\}$ ablation
Example selection	Random	Random vs. centroid
Models compared	LLM only	LLM + GNN + ML
External valid.	1 cohort	2 cohorts
Multi-run stats	Single run	Mean $\pm$ std, 3 seeds

II. RELATED WORK

A. Supervised Learning on Microbiome Data

A meta-analysis of gut microbiome classification studies found that random forests achieve moderate accuracy within datasets but transfer poorly across cohorts [11]. The problem is that ensemble models fit sequencing platform signatures and extraction batch effects just as readily as genuine disease signal. Once applied to samples from a different centre, those cohort-specific artefacts vanish and predictive performance collapses. Logistic regression with ℓ_2 regularization has shown more stable cross-site behaviour; by shrinking coefficients toward zero, it avoids placing weight on narrow, site-dependent features [12]. More recent proposals include metaheuristic hyperparameter search for ensemble tuning [13] and recursive elimination of unstable microbiome features [4], [14]. Across all of these, the same trade-off appears: accuracy on the training cohort comes at the expense of accuracy on a new one. Our work asks whether this trade-off can be sidestepped by relying on prior biomedical knowledge rather than labelled cohort data.

B. Data Representation for Microbiome Classification

The choice of compositional transformation has a substantial effect on downstream results. Untransformed read counts confound library size with biological abundance. Rarefaction removes this confound but discards sequencing data. The CLR transformation handles both issues at once: it removes the compositional constraint while keeping all samples in the analysis, and it has been shown to reduce spurious genus-level correlations [15]. Feature selection is also important. The microbiome spans hundreds to thousands of genera, but only a fraction carry IBD-relevant signal. Random Forest importance scores, recursive elimination, and clinical prior knowledge are each valid selection criteria [16]. For LLM-based classification, which genera appear in the prompt is especially consequential since each genus occupies fixed context space. In this work, we combine data-driven importance ranking with mandatory inclusion of genera with documented IBD associations.

C. Deep Learning and Graph-Based Microbiome Analysis

Convolutional and transformer architectures applied to microbiome data have shown competitive in-distribution performance [3], [17]. Graph neural networks are well suited to this domain. Microbial communities are ecological networks, and co-occurrence and competitive relationships among taxa carry information that per-taxon abundance vectors do not capture [18]. Graph convolutional classifiers built on co-abundance networks have outperformed tabular baselines on several disease benchmarks [19], [20]. Whether this co-abundance structure itself transfers across sequencing sites, or whether it is as cohort-specific as the raw abundances, has not been systematically tested. In this study, we evaluate a co-abundance GNN on two independent external cohorts to provide direct evidence on this question.

D. LLMs in Biomedical Classification

In-context learning [21] has been evaluated across many biomedical tasks: medical question answering [7], [22], clinical note classification [23], and domain-adapted variants such as BioMistral [24]. The most directly relevant prior study benchmarked six LLMs on this same IBD dataset, finding open-source models competitive with proprietary APIs [8]. A separate study applied vision transformers to UC severity grading from endoscopic images [25]. None of these studies examined how the numerical encoding of omics inputs affects LLM performance. That is the gap this work addresses. Retrieval-augmented generation [27] takes a different approach: rather than fixing the in-context examples in advance, it draws them from a larger pool separately for each query. Centroid selection can be read as a simpler predecessor of this idea, since it selects representative examples once from the class means and reuses them across all queries. Per-query retrieval over a microbiome reference pool is examined in Section VI.

III. MATERIALS AND METHODS

A. Datasets

This study used three 16S rRNA sequencing datasets, with the breakdown of control and patient samples (CD and UC) presented in Table II.

TABLE II. DATASET SUMMARY

Dataset	Total	Control	CD	UC
Dataset_1 (primary)	1,286	336	731	219
Dataset_30 (Ext I)	30	10	10	10
IBD423 (Ext II)	423	44	204	175

Dataset_1 is the primary 16S rRNA amplicon cohort. We reserved a stratified holdout of 500 samples for Control vs. IBD evaluation and 300 samples for CD vs. UC, with the remaining samples forming the training pool. **Dataset_30** was collected at a separate sequencing centre and serves as a cross-site generalization benchmark. **IBD423** is a public dataset used only for external CD vs. UC validation.

B. Preprocessing

We rarefied all samples to 10,000 reads by multinomial subsampling and discarded samples below that depth. The CLR transformation was then applied:

$$\mathrm{CLR}(x_i) = \log\left(\frac{x_i + 0.5}{g(\mathbf{x} + 0.5)}\right), \tag{1}$$

where, $g(\cdot)$ denotes the geometric mean. A pseudocount of 0.5 was added to handle structural zeros.

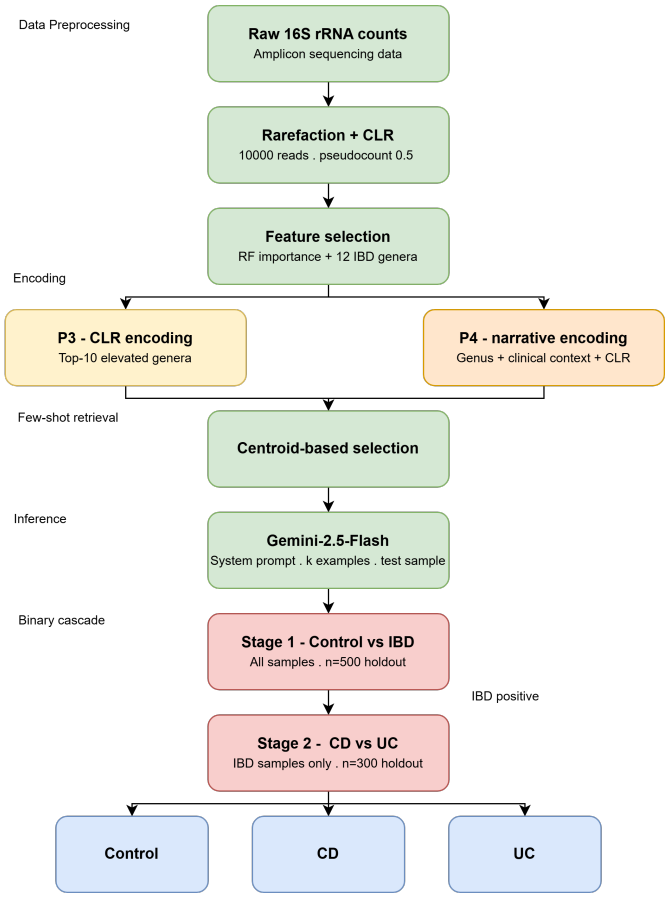

Fig. 1. Binary cascade pipeline. Stage 1 distinguishes healthy controls from all IBD patients. Stage 2, applied only to samples classified as IBD-positive, further distinguishes CD from UC. Each stage uses independent feature selection, encoding, and model training.

C. Feature Selection

For each binary problem, we fitted a Random Forest ($n_{\text{trees}} = 500$, max_depth $= 5$, balanced class weights) on the training pool and retained the top 20 genera by feature importance. We then appended twelve genera with documented IBD associations — including *Faecalibacterium*, *Roseburia*, *Akkermansia*, *Escherichia*, *Fusobacterium*, and *Ruminococcus* — if not already selected. The final feature sets contained 25 genera for Problem 1 and 26 for Problem 2.

D. Binary Cascade Framework

The three-class problem cannot be solved in one shot. We break it into two binary stages (Fig. 1). Stage 1 resolves a single decision: healthy or IBD. Samples it marks IBD-positive proceed to Stage 2, where the question becomes CD versus UC. The decomposition offers two advantages. Each stage faces a milder class imbalance than the full three-way split would impose, and because the stages operate independently, the encoding and the prompt can be tuned separately for the demands of each.

E. Microbiome Encoding Strategies

1) P3 - CLR abundance encoding: We select the genera with CLR values above the sample median (at most ten), apply ℓ_1-normalization, and format the result as a ranked list. No clinical context is added; the list communicates abundance magnitudes only.

2) P4 - Clinical narrative encoding: For P4, every selected genus is paired with a short literature-derived sentence stating its known IBD role, followed by whether it is elevated or depleted relative to the sample median and its exact CLR value. A representative entry reads:

```
Faecalibacterium prausnitzii is an
anti-inflammatory butyrate producer
depleted in IBD.
[Observed: depleted, CLR=-1.234]
```

The rationale is straightforward: the model receives the observation and its clinical meaning together, so it does not need to reconstruct the genus-disease link from pretraining memory under uncertainty.

F. Prompt Examples

The practical difference between the two encodings is easiest to see on a single sample. Table III places the P3 and P4 representations of the same CD patient side by side.

TABLE III. ENCODING COMPARISON FOR THE SAME SAMPLE (CD PATIENT). THE *Diagnosis:* FIELD IS LEFT BLANK TO MARK THE POSITION WHERE THE MODEL GENERATES ITS LABEL

P3 — CLR Encoding	**P4 — Narrative Encoding**
CLR normalized abundances: Faecalibacterium: 0.0312 Roseburia: 0.2841 Fusobacterium: 0.4102 ... Ruminococcus: 0.1745 ...	Clinical microbiome profile: *F. prausnitzii* is a butyrate producer depleted in IBD. [Observed: depleted, CLR=-1.23] *Fusobacterium* is enriched in CD. [Observed: elevated, CLR=+2.41] ...
Diagnosis:	*Diagnosis:*

P3 presents the same genera as bare CLR values, whereas P4 pairs each measurement with a sentence of clinical context before stating its observed direction and magnitude. The two columns encode identical numerical information; they differ only in how much biological meaning is made explicit to the model.

G. Few-Shot LLM Classification

1) Model and inference: We queried Gemini-2.5-Flash through the Google Generative Language API with temperature = 1.0 and maxOutputTokens = 100. A system prompt defined the clinical role and valid output labels. Each request included k in-context examples followed by the test sample. The model was instructed to output a single diagnostic label on the last line.

2) Example selection strategies: Both strategies selected $k/2$ examples per class.

a) Random selection: draws examples uniformly from the training pool under a fixed seed.

b) Centroid-based selection: computes the class centroid in CLR space and selects the $k/2$ training samples with the highest cosine similarity to that centroid, giving priority to the most representative profiles per class.

3) Shot count ablation: We tested $k \in \{2, 4, 6, 8, 10, 14\}$. All Experiment B runs used P3 encoding with centroid selection to isolate the effect of shot count from other variables.

H. Prompt Structure

To make the encoding concrete, it helps to see a full prompt exactly as the model receives it. Fig. 2 reproduces the complete input submitted to Gemini-2.5-Flash for the CD vs. UC task under P4 encoding, using $k = 4$ centroid-selected examples.

I. Co-Abundance Graph Neural Network

We computed pairwise Spearman correlations across all training-pool genera and connected genus pairs with absolute correlation above 0.3 by undirected edges. Node features were the per-sample CLR abundances. We trained a three-layer Graph Convolutional Network [20] with hidden dimension 64, dropout 0.3, and global mean pooling for 150 epochs using the Adam optimizer (lr = 10^{-3}, weight decay = 10^{-4}, batch size 32) with balanced cross-entropy loss. The checkpoint with the highest validation Macro-F1 was kept for evaluation.

J. Classical Supervised Baselines

We evaluated five classifiers: Extra Trees ($n = 500$, max_depth = 10), Random Forest ($n = 500$, max_depth = 10), Logistic Regression ($C = 0.1$, ℓ_2 penalty), XGBoost ($n = 200$, max_depth = 6, lr = 0.05), and LightGBM ($n = 200$, lr = 0.05). All models used balanced class weights and were trained on the full CLR feature matrix.

K. Evaluation Protocol

LLM experiments were run under three seeds (42, 123, 456). This controlled holdout subsampling (300 samples per run) and example pool composition. All LLM results are reported as mean $\pm$ std of Macro-F1 across the three seeds. GNN and supervised baselines were evaluated on the full holdout sets (500 samples for Problem 1, 300 for Problem 2) and on both external cohorts. LLM and supervised evaluations cover the holdout differently for reasons of cost. Each LLM prediction requires a paid API call, whereas supervised inference is effectively free once the model has been fitted. LLM subsampling was therefore kept class-stratified and repeated under three seeds, with results averaged across runs. Supervised baselines were evaluated on the full holdout sets, the setting in which they perform most favourably.

L. Computational Cost

Inference was performed with Gemini-2.5-Flash through the Google Generative Language API. A single request completed in one to two seconds and cost a small fraction of a US cent at the pricing tier used here. Across the full experimental grid of three seeds, six shot counts, two encodings, and two classification problems, total API charges came to approximately fifteen US dollars. GNN training completed in under 15 minutes on a T4 GPU, and each supervised baseline was fitted in under two minutes on CPU, both on freely available hardware. Extrapolating to deployment, a service processing tens to hundreds of samples per week would incur API costs in the low single-digit dollars per month.

[SYSTEM PROMPT]

```
You are a clinical microbiome specialist.
This sample is from an IBD patient.
Classify as:

Fig. 2. Complete prompt for CD vs. UC classification under P4 narrative encoding with $k = 4$ centroid examples. The system prompt specifies the clinical role and output format. One example per class follows, each pairing a biomedical annotation with the observed CLR direction. The test sample appears last with the label blank.

IV. Results

A. Experiment A: Encoding Strategy

At a fixed budget of $k = 10$ centroid examples, P4 narrative encoding produces higher Macro-F1 than P3 CLR on both classification problems. The improvement is larger on CD vs. UC (+4.7 pp) than on Control vs. IBD (+0.7 pp). For the

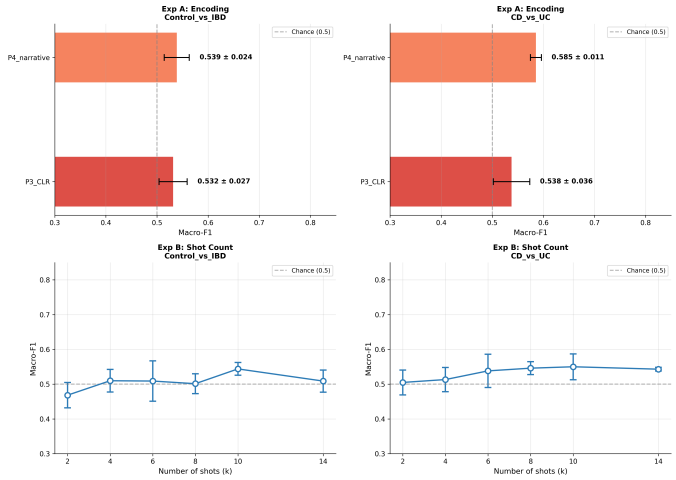

Fig. 3. LLM ablation results for Gemini-2.5-Flash. Upper panels (A, B): Macro-F1 comparison between P3 CLR and P4 narrative encodings with mean ± std over three seeds. Lower panels (C, D): Macro-F1 as a function of few-shot example count k using P3 CLR encoding and centroid-based selection.

subtype task, the clinical annotations attached to *Fusobacterium* (CD-associated) and *Escherichia* (UC-associated) give the model context it would otherwise need to recover from pretraining, and the results indicate that recovering it from memory is less reliable than stating it explicitly. Variance falls as well — from ± 0.036 under P3 to ± 0.011 under P4 on CD vs. UC — so P4 also produces more consistent results across different random example draws.

The two encodings are compared numerically in Table IV, averaged over 300 samples and three seeds, with the corresponding ablation shown in Fig. 3.

TABLE IV. EXPERIMENT A - ENCODING STRATEGY (MEAN ± STD, 3 SEEDS)

Problem	Encoding	Macro-F1
Control vs. IBD	P3 CLR	0.532 ± 0.028
	P4 Narrative	$\mathbf{0.539 \pm 0.024}$
CD vs. UC	P3 CLR	0.538 ± 0.036
	P4 Narrative	$\mathbf{0.585 \pm 0.011}$

B. Experiment B: Shot Count

We tested six shot counts ($k \in \{2, 4, 6, 8, 10, 14\}$) using P3 encoding with centroid selection. Results are summarized in Table V.

TABLE V. EXPERIMENT B — SHOT COUNT (MEAN ± STD, 3 SEEDS, P3 CLR)

k	Control vs. IBD	CD vs. UC
2	0.487 ± 0.018	0.497 ± 0.062
4	0.527 ± 0.039	0.536 ± 0.012
6	0.538 ± 0.048	0.579 ± 0.034
8	0.546 ± 0.019	0.546 ± 0.022
10	0.550 ± 0.037	0.555 ± 0.034
14	0.543 ± 0.006	0.559 ± 0.014

Performance improves from $k = 2$ to approximately $k = 6$–8, then levels off (Table V, Fig. 3). Beyond $k = 8$, additional examples do not appear to add useful distributional information. Including more examples past this point may actually dilute the most representative profiles with less typical ones. This pattern is consistent across both classification problems.

C. Experiment C: Example Selection Strategy

We compared centroid-based and random selection at $k = 10$, holding encoding (P3) and shot count fixed. Table VI reports the results across three seeds.

TABLE VI. EXPERIMENT C — SELECTION STRATEGY (MEAN ± STD, 3 SEEDS, $k = 10$)

Problem	Strategy	Macro-F1
Control vs. IBD	Random	0.487 ± 0.016
	Centroid	$\mathbf{0.539 \pm 0.035}$
CD vs. UC	Random	0.493 ± 0.012
	Centroid	$\mathbf{0.541 \pm 0.025}$

Centroid selection outperforms random selection by 5.2 pp on Control vs. IBD and 4.8 pp on CD vs. UC (Table VI, Fig. 5). Microbiome profiles are high-dimensional and sparse. A randomly drawn sample may sit far from the class centre of mass and give the model an atypical reference point. By selecting samples with high cosine similarity to the class centroid, centroid selection ensures the model receives archetypal rather than idiosyncratic examples.

D. Full Cross-Paradigm Comparison

We now compare all seven models across every evaluation set. Macro-F1 scores are reported in Table VII and visualized in Fig. 4.

On the internal holdout, tree-based ensembles perform best: Extra Trees and XGBoost both reach F1 = 0.73 on Control vs. IBD. Their external performance is very different. On Ext30, these same models fall to F1 = 0.33–0.44, a drop of nearly 30 percentage points. Ensemble methods trained on one sequencing site routinely pick up protocol-specific artefacts together with true disease signal; when those artefacts are absent in a new cohort, accuracy drops sharply [26]. Random Forest shows the same behaviour.

Logistic Regression departs from this pattern. Holdout accuracy is moderate (0.694 on Problem 1, 0.659 on Problem 2), yet both external cohorts remain competitive: F1 = 0.688 and 0.873 on Ext30, and F1 = 0.675 on IBD423.

On Ext30 Control vs. IBD, the GNN obtains its best result (F1 = 0.762), which suggests co-abundance graph structure captures disease-relevant ecological patterns that transfer across sites. For the CD vs. UC task, however, the same GNN drops to F1 = 0.333 on Ext30 — likely because of the smaller Stage 2 training set and the greater difficulty of subtype-level discrimination.

Without a single gradient update on the target data, Gemini-2.5-Flash with P4 encoding reaches F1 = 0.873 on Ext30 for CD vs. UC, tying Logistic Regression for first place and leaving all other models behind. On IBD423 it reaches F1 = 0.714, second

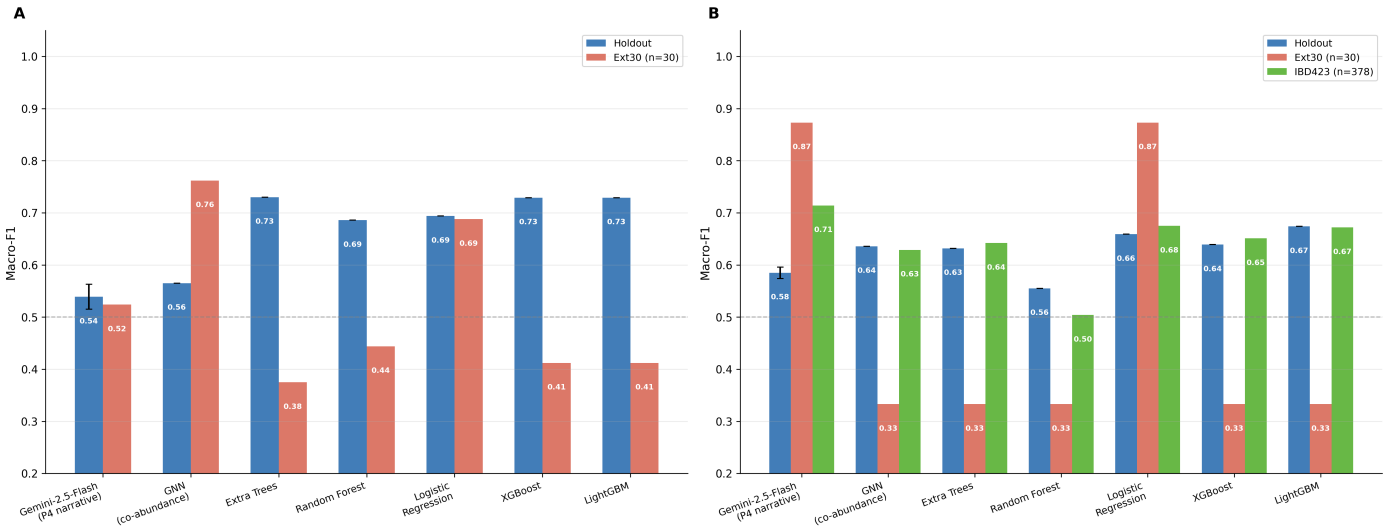

Fig. 4. Macro-F1 scores for all evaluated models on internal holdout and external validation cohorts. (A) Control vs. IBD classification. (B) CD vs. UC classification. Error bars on Gemini-2.5-Flash indicate standard deviation over three seeds. Dashed line marks chance level (F1 = 0.5).

TABLE VII. FULL MODEL COMPARISON - MACRO-F1 ACROSS INTERNAL AND EXTERNAL EVALUATION SETS

Model	Category	Control vs. IBD		CD vs. UC		
		Holdout	Ext30	Holdout	Ext30	IBD423
Gemini-2.5-Flash (P4)	LLM	0.539 ± 0.024	0.524	0.585 ± 0.011	**0.873**	0.714
GNN (co-abundance)	GNN	0.565	**0.762**	0.636	0.333	0.629
Extra Trees	ML	**0.730**	0.375	0.632	0.333	0.642
Random Forest	ML	0.686	0.444	0.555	0.333	0.504
Logistic Regression	ML	0.694	0.688	0.659	**0.873**	**0.675**
XGBoost	ML	0.729	0.412	0.639	0.333	0.651
LightGBM	ML	0.729	0.412	0.674	0.333	0.672

Bold: best result per column. LLM results are mean $\pm$ std over 3 seeds.

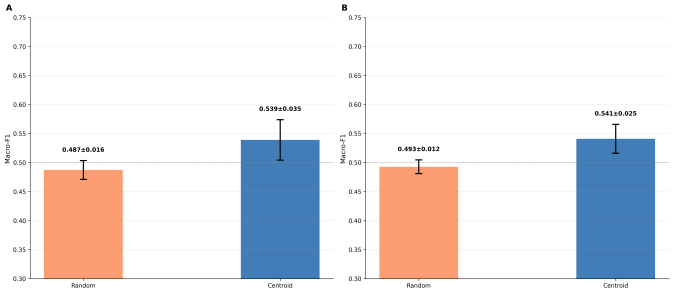

Fig. 5. Effect of few-shot example selection strategy on Gemini-2.5-Flash performance. (A) Control vs. IBD. (B) CD vs. UC. Error bars indicate standard deviation over three seeds. Centroid-based selection consistently outperforms random selection on both tasks.

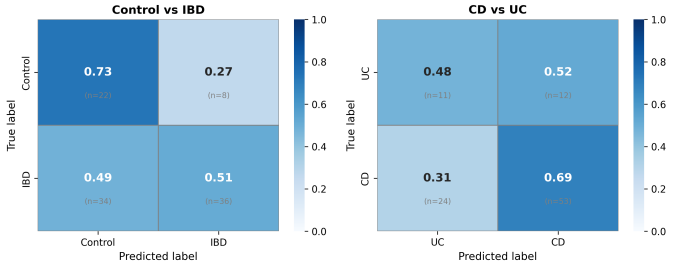

Fig. 6. Normalized confusion matrices for Gemini-2.5-Flash with P4 narrative encoding ($k = 10$, seed=42, $n = 100$ samples per problem). Values represent the proportion of true-class samples assigned to each predicted label; raw counts are shown in parentheses. UC samples are substantially harder to classify than CD samples (52.2% vs. 31.2% error rate), consistent with the greater microbiome heterogeneity of ulcerative colitis.

best on that cohort. P4 encoding and centroid selection are the only methodological differences between the two studies; consequently, the gain relative to [8] can be attributed to those two changes.

E. Confusion Matrix Analysis

Confusion matrices in Fig. 6 break down where each model succeeds and fails on each problem, using P4 encoding ($k = 10$, seed=42, $n = 100$ samples per problem).

Among healthy controls, 73% are correctly identified, while 48.6% of IBD samples are misclassified as healthy. The model seems to wait for a clear dysbiotic signal before assigning an IBD label, which pushes borderline samples near the boundary toward the healthy class. The split is wider for CD versus UC. Here the CD error rate is 31.2%, well under the 52.2% seen for UC. CD carries its own markers in the P4 prompt, chiefly the *Fusobacterium* and *Ruminococcus* annotations, while the UC annotations separate the classes far less cleanly. The recall

figures show the same gap.

V. Discussion

A. Clinical Narrative Encoding

The gap between P4 and P3 runs deeper than formatting. Consider a P3 entry like `Faecalibacterium: -1.823`. A genus and a number — nothing more reaches the model. For that pairing to carry meaning, the model must independently recall that this genus is anti-inflammatory and that its depletion marks active IBD — an implicit retrieval step with no guarantee of success. P4 removes that burden. Placed directly beside the measurement in the prompt, the clinical association ensures the observed direction and its biological meaning arrive together in a single token sequence. Rather than inferring what the number means, it applies context that is already present.

The two problems respond differently to the encoding change. On Control vs. IBD the gain is modest ($+0.7$ pp), while CD vs. UC shows a larger improvement ($+4.7$ pp). The reason is not surprising. Separating IBD from healthy controls rests on a broad, well-documented pattern: butyrate-producing taxa are depleted across the vast majority of IBD samples regardless of subtype, and that association is strong enough that a pretrained model recovers it without explicit annotation. Distinguishing CD from UC requires finer judgment — the relative elevations of *Fusobacterium* versus *Escherichia* are the key markers, and these are exactly the annotations that P4 supplies. In general, these findings suggest that LLM classification of structured omics data should be treated as a knowledge integration task. The prompt must bridge quantitative measurements and clinical significance; relying on the model to perform that bridge silently from pretraining is less dependable, especially for subtle distinctions. The mechanistic language used here describes patterns consistent with the observed outputs. A note on terminology is warranted here. Statements that the model "uses" or "applies" biomedical knowledge indicate only that the observed outputs are consistent with that interpretation. They are equally consistent with the model responding to surface features of the P4 text rather than to its biomedical content. Distinguishing between the two accounts would require ablation experiments in which portions of the prompt are removed or perturbed. Such experiments were not conducted here, and the question is revisited in Section V-F.

B. Error Analysis

In the Control vs. IBD task, misclassifications fall heavily on IBD samples labelled as healthy (34/70, 48.6%), whereas healthy controls are called correctly at a higher rate (8/30, 26.7%). Looking at the misclassified IBD samples, their *Ruminococcus* CLR is elevated relative to correctly classified cases (2.60 vs. 1.46), and their *Fusobacterium* CLR is lower (1.84 vs. 2.79). These profiles sit outside the canonical dysbiotic pattern that P4 annotations describe. This pattern is consistent with early-stage or inactive IBD, although it may equally reflect model sensitivity to CLR magnitudes near the annotation thresholds rather than any underlying biological distinction. Prediction outputs alone provide no basis for separating the two explanations.

For CD versus UC the error-rate gap is wide. UC samples were misclassified at 52.2% against 31.2% for CD. *Fusobacterium* CLR separated the two classes most cleanly, averaging 3.16 in correctly identified CD cases but only 1.27 in those that were missed. Once that genus stops being clearly elevated, the CD cue carried by the P4 prompt loses its grip and the sample drifts toward UC. Two other genera made things worse. Where *Blautia* (5.27 vs. 3.79) and *Faecalibacterium* (6.50 vs. 5.17) were both high, the butyrate-producing community still looked relatively intact, and that intact profile is where CD and UC proved hardest to separate. Widening the P4 annotation set with a few additional genera would be the next step to test.

C. Centroid Selection

A 5.2 pp gap between centroid and random selection is not trivial for a zero-training method. It reflects something specific about this data type. Microbiome profiles are sparse and high-dimensional, and a randomly chosen training sample can easily turn out to be an outlier, a patient whose profile shares the label but not the typical features. Hand that to the model as a reference and it learns the wrong prototype. Centroid selection sidesteps the problem by computing the class mean in CLR space and picking the samples closest to it. The examples that go into the prompt then look like the typical CD or UC profile. The computational cost is negligible. One matrix multiplication plus a sort over the training pool takes milliseconds, far less than a single API call. Under the conditions examined here, centroid selection emerges as the preferable strategy.

D. Model Selection Across Paradigms

No single model dominates every condition in Table VII; the results are better read as a deployment map than as a ranking. Tree ensembles suit single-site settings, where their high internal accuracy is an asset, but they degrade sharply once applied to external data. Logistic Regression is the conservative option for multi-site use, never leading in any condition yet never collapsing either. The GNN earns its place on Control versus IBD across sites (Ext30 F1 = 0.762) but not on CD versus UC, where its Stage 2 training set is too small and the task correspondingly harder. Gemini with P4 encoding is strongest in one specific configuration: cross-site CD versus UC discrimination with no local labels available.

These profiles translate directly into deployment guidance. A single-site pilot with annotated data is well served by Extra Trees or LightGBM. A multi-site rollout with mixed protocols should pair Logistic Regression at Stage 1 with the LLM at Stage 2, a combination the cascade architecture makes straightforward to implement.

Two considerations motivated the binary cascade: it reduces per-stage class imbalance, and it allows the encoding and prompt to be tuned separately for each decision. Alternative decompositions, including one-vs-rest schemes, hierarchical classifiers, and direct three-way prompting, were not benchmarked here. Comparing the cascade against these alternatives would clarify how much of the observed gain derives from the decomposition itself and how much from stage-specific optimization. The question remains open.

E. Practical Considerations

The LLM approach requires no labelled local training data at inference time. This is useful in clinical settings

where annotating a microbiome cohort is expensive and time-consuming. Since P4 already embeds clinical text in each prompt, the same inference step could be extended to generate natural-language justifications alongside the label, which would support clinician review without additional infrastructure. Data governance is a separate concern: sending patient microbiome data to an external commercial API raises privacy questions that the companion benchmark [8] addresses by evaluating locally deployable open-source models.

F. Limitations

LLM evaluations used subsampled holdout sets of 300 samples per run to control API costs, so the reported means may shift modestly at full-holdout scale. Ext30 contains 30 samples. At that size a single misclassification moves Macro-F1 by roughly three percentage points, and 95% bootstrap intervals would fall near ± 0.10. Results from this cohort are therefore best read as directional evidence rather than as a reliable ranking of models. IBD423, with $n = 423$, provides the more stable basis for assessing external performance.

The two cascade stages were executed independently, with ground-truth labels supplied to Stage 2. End-to-end error was consequently never measured. Multiplying the stage-level Macro-F1 values yields an approximate estimate of 0.32 on the internal holdout under an assumption of independent stage errors. Obtaining the true figure would require running Stage 2 on the IBD-positive predictions emitted by Stage 1, which is left for future work.

The encoding study varied two prompt dimensions: numerical representation (P3 versus P4) and example selection (random versus centroid). Instruction wording, example ordering, output constraints, chain-of-thought suppression, and context-length sensitivity were held fixed throughout. Given that prompt sensitivity in biomedical LLMs is well documented, a broader ablation across these dimensions would be a reasonable extension.

Results are reported as means and standard deviations over three seeds, without significance testing. Three seeds afford limited statistical power. Both headline differences exceed the observed spread by a wide margin: P4 over P3 by $+4.7$ pp on CD versus UC against a pooled standard deviation of 0.024, and centroid over random selection by $+5.2$ pp against a pooled standard deviation of 0.026. Paired testing across a larger number of seeds would nevertheless place these comparisons on firmer statistical ground.

Calibration, output entropy, and agreement across repeated LLM calls on identical prompts were not analysed. A temperature setting of 1.0 renders the model stochastic, so the same prompt can return different labels on consecutive calls. In a clinical context, per-sample variability and calibration quality matter as much as average Macro-F1, and that layer of analysis is absent from this work.

Several passages in the Discussion describe the model as engaging in biological reasoning. Such descriptions are interpretations of the outputs and should not be read as evidence. Establishing a causal claim would require targeted probing, for instance ablating individual annotations from the P4 prompt or perturbing single CLR values, which was not undertaken here.

P4 encodes curated clinical knowledge within each prompt, which means the experiment evaluates the model's capacity to apply written biomedical annotations to observed measurements rather than its ability to classify from numerical profiles without prior annotation. This scope should be kept in mind when interpreting LLM results alongside purely data-driven baselines.

VI. Conclusion

This study proposed a binary cascade framework for IBD microbiome classification and evaluated few-shot LLMs, co-abundance GNNs, and five supervised classifiers under identical conditions on an internal holdout and two independent external cohorts. P4 narrative encoding outperformed CLR-only encoding on both binary tasks, with the largest margin on CD vs. UC where genus-level annotations for *Fusobacterium* and *Escherichia* carried the most discriminative weight. Centroid-based selection outperformed random draws by approximately 5 percentage points on both problems, confirming that example representativeness is a consequential design choice for high-dimensional sparse microbiome data. Classification performance saturated at $k = 6$–8 shots. Tree-based ensembles achieved the highest internal accuracy but degraded substantially on external cohorts. Logistic Regression and Gemini-2.5-Flash with P4 encoding were the only approaches that remained competitive across all evaluation sets.

On cross-site CD vs. UC classification, the LLM reached F1 = 0.873 without task-specific training or local labels. In deployment scenarios where the target site differs from the training site and annotated data are unavailable, clinical narrative encoding offers a practical path to subtype-level discrimination when large labeled training cohorts are not available.

VII. Future Directions

Several directions follow from this work. Replacing the fixed centroid examples with dynamic retrieval over a large microbiome reference database, in the spirit of retrieval-augmented approaches [27], would allow each test sample to be matched against the most similar training profiles rather than the class mean, which should benefit atypical cases that sit far from the centroid. Training a language model on a targeted microbiome-disease corpus could eliminate the manual curation step by replacing hand-written P4 annotations with learned genus-level associations. Incorporating patient-level clinical variables — age, disease duration, medication history — into each cascade stage would bring the system closer to real deployment conditions; the two-stage architecture accommodates such extensions without structural modification. For supervised models, cohort-aware batch correction applied before the CLR step is a concrete intervention against the generalization gap observed here. A longer-term direction is combining the three model families: GNN structure for Control vs. IBD, LLM priors for CD vs. UC, and logistic regression as a stable baseline in multi-site settings, within a single ensemble that adapts its components to the deployment context.

Declaration on Generative AI

Gemini-2.5-Flash (Google DeepMind) was used exclusively as an experimental subject in this study, evaluated under

standard commercial API terms. No generative AI tool was used to write, edit, or improve any part of the manuscript text. All authors take full responsibility for the content of this publication.

Data Availability

The gut microbiome dataset is publicly available from the European Nucleotide Archive under accession numbers PRJEB13679, PRJNA422193 and PRJEB33711. Code, prompts, and reproducibility notebooks are available at https://github.com/NouhailaEnnajih/IBD_LLM_microbiome_clinical_narrative_encoding.

Acknowledgment

The authors thank the contributors of the public IBD microbiome datasets used in this study.

Learning When to Wait: A Lightweight Binary Decision Framework for Container Migration in Edge Computing

Yasmeen Abu-Haltem[1], Sawsan AlShattnawi[2]
Computer Science Department, Princess Sumaya University for Technology, Amman, Jordan[1]
Computer Science Department, Yarmouk University, Irbid, Jordan[2]

***Abstract*—Container migration is one of the important techniques used to provide the continuity of services in Multi-access Edge Computing environments. Services are migrated from edge servers to follow the mobility of users among the available edge servers. Nevertheless, current strategies do not take into account the cost that a container migration causes in terms of downtime, bandwidth consumption, energy cost, and the possible occurrence of failures during the process. In this work, a lightweight pre-migration binary decision framework is introduced that works as a gatekeeper before any migration attempt. According to the actual state of the system, the framework decides at each epoch whether to migrate or not, classifying the epochs into Migrate and Wait categories. The training labels are obtained through a counterfactual approach using simulated data generated using the EdgeSimPy simulation tool. The Decision Tree classifier has been chosen as the main classifier due to its minimal computing complexity and interpretability. The effectiveness of the suggested framework is measured on the basis of comparison with three baseline policies, including always migrate, never migrate, and a latency-threshold rule, along with multiple machine learning models and deep learning models, and such metrics as accuracy, precision, recall, F1-score, AUC, and runtime performance metrics. It is shown that the suggested solution outperformed all three baseline policies along with the machine learning and deep learning models, proving that an intelligent decision-making stage is essential in Multi-access Edge Computing.**

Keywords*—Multi-access Edge Computing; container migration; machine learning; Decision Tree; mobility management; service continuity

I. Introduction

Multi-access Edge Computing (MEC), formerly known as Mobile Edge Computing, is becoming increasingly important as use cases such as augmented reality, self-driving cars, healthcare uses, and real-time video analytics require low latency. Computing services deployed at the edge shorten response time. Mobility, on the other hand, creates an important problem for edge computing. As the user moves around the city or country, the distance between them and the edge server providing the service will increase, resulting in higher latency. If the latency becomes too high, the service might become interrupted, which is unacceptable in time-critical scenarios.

The most well-known and used solution to this issue is what is referred to as container migration. In order to maintain low latency and service continuity, the service can follow the user by migrating a running container from one edge server to another. Optimizing container migration has been a great topic for current studies; researchers use advanced methods to find acceptable solutions for the issue. This is done by minimizing downtime, reducing checkpoint size, and choosing better destinations for migrating. Despite many studies on migration triggering methods, migration optimization, and destination determination techniques, most of them take for granted that once a trigger condition is satisfied, migration is always the most effective plan of action and needs to be performed. Not much effort has gone into finding out if migration is even necessary at all. This could potentially result in unnecessary migrations, wasting resources and degrading service performance.

This presumption ignores a crucial fact. Migration is not free, and it is not always the perfect solution. It adds service interruptions during checkpoint transfer, uses network bandwidth, costs energy to limited edge nodes, and carries the risk of failure if network conditions suffer in the middle of migration. Furthermore, a number of factors that cause migration, like slight CPU spikes or short-lasting network instability, may fade before the migration is even completed. Thereby, executing the entire process becomes ineffective and might negatively affect the quality of service (QoS).

In this study, it is argued that sometimes the best decision is not to migrate. A simple binary decision framework is proposed that serves as a gatekeeper before any attempt at migration. The framework provides an output to either proceed with migration, in other words, migrate, or not migrate and re-evaluate later, wait, based on the current system state. Factors affecting the system state include node resource pressure, container characteristics, and network quality. The proposed method is expected to minimize system overhead, prevent unsuccessful migrations, and maintain QoS when migration would be destructive by filtering unneeded and harmful migrations.

The main contributions of the study can be described as follows:

- A lightweight binary pre-migration decision framework is proposed as a modular gatekeeper layer, complementary to existing migration algorithms, that determines whether migration should be executed at all before any migration attempt.
- Creation of a balanced dataset containing 5,000 samples under various mobility settings and container configurations through EdgeSimPy.
- Application of a counterfactual labeling technique to label each decision point with Migrate or Wait labels.

- Evaluation and comparison of various machine learning and deep learning methods, alongside rule-based and unconditional migration baselines.
- Experimental findings show that lightweight decision tree models achieve an effective balance between prediction performance, interpretability, and efficiency, which makes them very well-suited for the edge computing environment.

This work is structured as follows: Section II presents a brief background of the topics mentioned, and relevant studies are discussed. The problem is formulated, and the research gap is discussed in Section III. The proposed decision framework is presented in Section IV. Section V presents the results. Section VI discusses the results. The study concludes in Section VII with a concise summary of the work and future work suggestions.

II. Background and Literature Review

MEC has become a crucial concept for helping and supporting latency-sensitive and data-intensive applications. This is achieved through moving storage and processing resources closer to end users. MEC allows processing at the edge, in contrast to traditional cloud computing, which processes data in centralized data centers. MEC is well-known and suitable for applications like augmented reality, autonomous cars, healthcare fields, and real-time video analytics because it works on greatly lowering communication latencies and enhances QoS [1] [2] [3].

However, because of user mobility and changing network conditions, MEC environments are considered to be very dynamic. The distance between a user and the serving edge node increases as the user travels across different geographic locations, which may result in higher latency and worse service performance [4]. Fig. 1 illustrates the user mobility and the impact of latency.

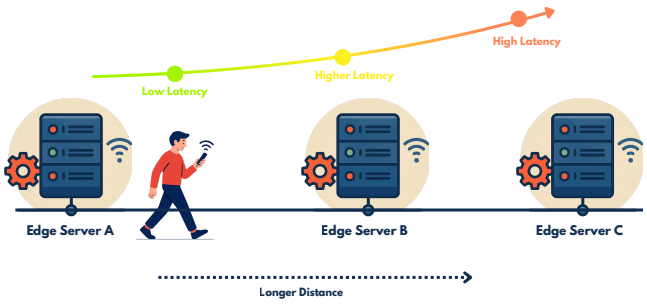

Fig. 1. Impact of user mobility on service latency in Multi-access Edge Computing environments.

Containerization has gained popularity in the world of effectively deploying applications in MEC environments. Applications can execute consistently across platforms due to containerization, which offers lightweight virtualization by packaging them with their needed dependencies. Containers are considered to be a good fit for edge nodes with limited resources because they require fewer resources, have quicker startup times, and are more scalable than traditional virtual machines [5]. Applications are often decomposed into microservices and deployed as containers in MEC systems, allowing for flexible and dynamic service management across different edge infrastructures.

One essential method for preserving service performance in MEC settings is container migration. To lower latency and preserve service reliability, the service container can be moved or migrated to a nearby node when a user moves away from the current edge server. Applications can dynamically adjust to user mobility as a result of this idea, which is frequently referred to as “follow-me" services, as defined in [6] and [7].

Despite all the benefits the container migration adds, it introduces some critical drawbacks. The container state must be transferred over the network as part of the migration process, which may add to the bandwidth usage, introduce additional computational overhead, and cause service outages. Additionally, unstable network conditions may cause migration to fail, which would further affect the system’s reliability. Container migration in edge computing has been widely studied, with the literature focusing on the most efficient way to perform the migration and the conditions that warrant the migration. This section reviews the literature to lay the foundation for the contribution of this study, highlighting the gap that this work addresses.

A. Container Migration Mechanisms

The migration of containers involves the migration of running applications across different physical hosts without stopping the processes. This migration process is mostly adopted in edge computing platforms to ensure continuity of service delivery in cases where the user leaves the current host of their application. Unlike restarting a container from the beginning, migration attempts to preserve the running state of the service, which is important for latency-sensitive and stateful applications.

The fundamental technology that facilitates this functionality on Linux-based operating systems includes CRIU (Checkpoint/Restore In User space). It involves the freezing of the running process, saving its complete status to the hard disk in the form of image files, moving the images to another machine, and restoring the process from where it stopped [8] [9]. CRIU can be used with container runtimes to support checkpoint/restore-based migration. One of the major discoveries in the literature is that the checkpoint phase is directly proportional to the size of memory allocated to the container; that is, a bigger container needs more time for the freezing and transferring phases and consequently causes longer downtime to the service [9].

Based on how the container state is transferred between the source and destination hosts, migration techniques are commonly classified into pre-copy [10], post-copy [11], and hybrid migration [12] approaches. During pre-copy container migration, the process of transferring pages from the origin server to the destination server takes place while the program is active on the origin server. Pages that are modified during the transfer are resent in later rounds. Once copying of most of the state has occurred, the container is momentarily paused, the dirty pages are copied, and then the container continues

its execution on the destination server. While such a method can minimize downtime, it may increase total transferred data when the application frequently modifies memory [10].

In post-copy migration, the container is first paused, and a minimal execution state is transferred to the destination host. The container will continue its execution in the target container, while missing pages will be retrieved from the source machine as required. This process results in fewer repeated page copies than in the case of pre-copy migration. The technique, however, is highly dependent on the source machine because the continuation of its execution is contingent on whether the source machine is available during the fetching process. In case the communication link breaks down, the service will be disrupted [11].

Hybrid migration includes elements of pre-copy and post-copy strategies. It involves copying a part of the container state before switching and moving the rest of the state after switching to the destination. The hybrid strategy tries to achieve a compromise between downtime, bandwidth, and failures [12].

Despite their differences in methodology and disadvantages, each of these migration approaches imposes a certain amount of overhead in terms of downtime, bandwidth consumption, power consumption, and risk of failure. Therefore, improving the migration mechanism alone is insufficient. It is equally important to determine whether migration should be performed in the first place, which motivates the framework proposed in this work.

B. Migration Decision Frameworks

Existing frameworks mainly address two questions: when to migrate and where to migrate. To address these questions, several strategies have been proposed in the literature, including threshold-based approaches, Markov Decision Process (MDP)-based frameworks, prediction-based methods, and resource-aware schemes. The question regarding optimal timing for migration has been extensively explored. Specifically, Wang et al. [6] solve the migration problem using a Markov Decision Process (MDP), in which the migration policy is developed by considering the mobility pattern of users and the distance between the user and the current edge node. Additionally, Shamsadini and Entezari-Maleki [13] utilize an MDP framework in their analysis of vehicular edge computing, and their migration decisions depend on path loss conditions resulting from the mobility of vehicles. On the other hand, in [14], migration occurs in response to node failures to ensure reliability and fault tolerance in the network. Latency minimization and service continuity are also considered. For instance, Tang et al. [15] develop a layer-aware migration approach to minimize the time required for initialization, computation, and migration. Further, Jin et al. [16] study container migration in industrial internet to reduce latency.

After making the decision to migrate, the destination edge server needs to be chosen. In [6], the destination edge is decided based on the policy obtained using the MDP model. In [17], an RNN-based trajectory prediction model is used to predict the future location of the vehicle and accordingly choose the destination edge server while taking into account the issues of service delay and load balancing. Network state and resource state information are used to select the destination in the mobile edge clouds to support real-time applications in [18]. In [15], container layer-sharing information from multiple users is used to select the destination edge server.

Different migration strategies have different optimization goals. For instance, some migration models prioritize reducing delays in service and keeping latency at a minimum [6] [17], while others place more emphasis on the fault tolerance aspect [14] [16]. Resource usage and migration costs are other critical issues tackled in traffic-aware and layer-aware systems [15] [18]. Despite the diversity of optimization objectives, these methods mainly seek to improve migration efficiency after the migration decision has already been made.

Despite the fact that these researchers use various techniques of optimization and prediction, they have something in common: the fact that migration must take place once the condition for that is met. As a result, prior research predominantly addresses the problem of when and where to migrate, but little attention has been paid to the necessity for the migration to take place at all. This issue drives the design of the proposed lightweight pre-migration decision scheme.

C. Migration Costs and Risks

Although container migration ensures service continuity, there are various costs and risks involved that should be taken into consideration prior to migration. One of the primary concerns is service downtime. Checkpointing involves pausing the container in order to save its state. The time taken by the container to save its state is directly dependent on the memory size of the container, as stated in [8]. For applications such as streaming videos and real-time analytics, which require near real-time responses, this disruption negatively impacts the user experience. If the migration process happens often, then these pauses tend to add up. Another important challenge is the accumulation of migration overhead caused by frequent migrations. Moving a container involves migrating the state of the memory of the container and the files. This consumes bandwidth that could otherwise serve user traffic. The authors of [18] noted that in edge networks with limited network bandwidth, this may lead to congestion. Migration operations also incur computational and energy costs. Checkpointing and data transmission use energy at both the source and destination edge nodes. The edge nodes generally run with limited energy resources, such as battery power, solar energy, or even electricity limitations. This is further discussed in [14]. Moreover, migration is not guaranteed to succeed. Network interruptions during migration can cause corruption of the container state. There may also be insufficient resources on the destination server during restoration. This may result in the failure of the entire system [14]. These challenges imply that enhancing the process of migration alone is not enough. It would be wise for an intelligent approach to not only decide how migration should take place, but also whether migration is desirable at all.

III. Research Gap and Problem Formulation

Despite the extensive research on the topic of container migration, the vast majority of proposed approaches concentrate on the problem of optimization of the migration process and the destination location for the container after migration.

Additionally, some works consider the problem of choosing the time of migration relying on threshold-based or model-driven triggers.

Nevertheless, all such approaches make the following assumption about the necessity of the migration once its triggering event occurs. The assumption does not take into account that the process of migration has a high cost and risk in terms of downtime, bandwidth consumption, energy consumption, and failures. And in some cases, the cost incurred could exceed the performance gain expected through migration. Moreover, network instability or transient resource congestion may be solved prior to the completion of the migration process, making such migration not only unnecessary but potentially harmful to QoS as well. Consequently, the problem of determining whether migration should be performed at all remains largely unexplored. Previous research on migration has focused primarily on answering the questions of when migration is needed and to which server migration must be made. The following question, however, remains largely unexplored:

Should migration be executed in the first place?: Therefore, there is a need to explore lightweight machine learning models for this pre-migration binary decision task. This research tries to fill this gap by presenting a machine learning decision model that can predict if migration is necessary according to the system state. Unlike prior work, this study introduces a lightweight pre-migration decision layer that filters unnecessary migrations before execution.

In this study, an MEC system is assumed where there are several edge servers, which provide cloud-based services to mobile clients via containerized application instances. As users move, the latency between the user and the serving edge node may increase, potentially degrading the QoS.

For each decision epoch t, the system will have a set of state variables reflecting the state of the system. Such state variables include current latency, post-migration latency, available bandwidth, container sizes, current CPU usage, and current memory usage, among others.

Given the above states, a decision needs to be made on whether migration should be started at epoch t or not. This problem can be viewed from the perspective of binary classification, where the target variable takes one of two values:

$$D(t) \in \{\text{Migrate}, \text{Wait}\}$$

where, Migrate indicates that migration should be executed immediately, whereas Wait indicates that migration should be postponed and the system should be re-evaluated at a later epoch.

The labeling of training samples is obtained using a counterfactual comparison strategy, described in detail in the following section.

Fig. 2 shows the position of the proposed framework in the MEC container migration pipeline. The framework acts as a pre-migration decision layer between the trigger condition and the migration executor, deciding whether to migrate or wait.

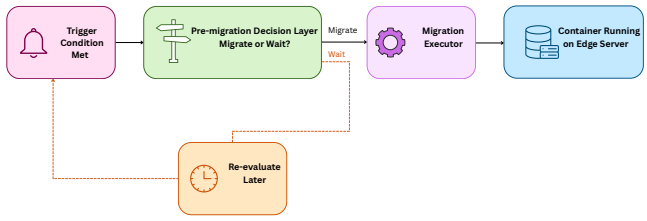

Fig. 2. Position of the proposed framework in the MEC migration pipeline.

IV. Methodology

This section describes the research methodology followed to make the classification problem for the container migration. The following subsections provide an explanation about each part of the experimental study, the dataset used, feature selection, models employed, and metrics used to evaluate the work.

A. Dataset

For this research, the utilized dataset was obtained via the use of EdgeSimPy [19], an open source Python simulator for edge computing. EdgeSimPy simulates a realistic MEC system that consists of 6 edge servers, 16 network switches arranged in a hexagonal mesh network, and 6 users operating containers in their devices. Fig. 3 illustrates the topology used in the dataset generation.

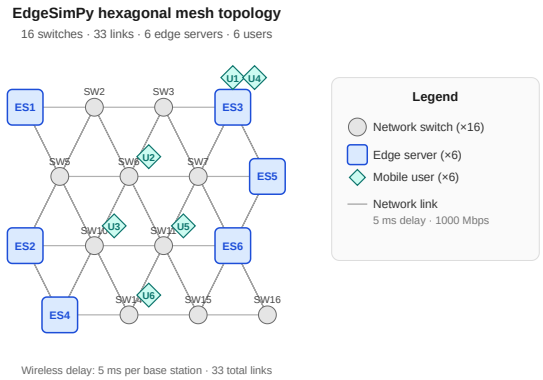

Fig. 3. EdgeSimPy simulation topology: a 4×4 hexagonal mesh of 16 network switches with 33 links, 6 edge servers, and 6 mobile users.

End-to-end latency is estimated within EdgeSimPy's routing engine by calculating the total wireless access latency at the base station (5 ms) and propagation time of the Dijkstra shortest path across the network (5 ms per hop). Thus, latency ranges from 5 ms to 25 ms. To obtain heterogeneous data, 30 simulation cases were conducted by varying two important variables in each simulation: container state size (8-200 MB) and mobility speed (5-35 seconds). Backbone link bandwidth was set to 1000 Mbps, consistent with real MEC infrastructure

TABLE I. DATASET FEATURES

Feature	Description	Range
latency_current_ms	End-to-end delay to current server	5–25 ms
latency_new_ms	Expected end-to-end delay after migration to candidate server	5–15 ms
latency_gain_ms	Difference in latency (migration improvement)	–5 to 20 ms
dist_current	Euclidean distance: user to current server	0–7.07
dist_new	Euclidean distance: user to candidate server	0–7.07
mobility	User movement direction: 0=stationary, 0.5=slow, 1.0=moving away	{0, 0.5, 1.0}
state_size_mb	Container state size in MB	8–200 MB
bandwidth_mbps	Available bandwidth on migration path in Mbps	Fixed at 1000 Mbps
dest_cpu_pct	CPU utilization on destination server	0–100%
dest_mem_pct	Memory utilization on destination server	0–50%
transfer_time_s	Estimated migration transfer time	0.07–1.64 s

specifications. The labeling scheme relied on a counterfactual comparison technique. In each situation, two simulations were conducted in the exact same environment: one where migration was never allowed, and another where migration was constantly conducted to the closest server at all times. At each decision time step, the end-to-end delay experienced in EdgeSimPy between the two policies was compared. If the delay value in the constantly migrating scenario was smaller than the one in the baseline scenario, then the time step was marked as Migrate; otherwise, it was Wait. As a point to note, the always migrate simulation algorithm employed for the generation of labels differs from the Always Migrate benchmark in Section VI, which makes predictions without regard to features or latencies, as opposed to the always migrate simulation algorithm, which generates latencies to generate labels. It is noted that although both feature generation and label derivation originate from the same simulation environment, the labels are derived from an independent comparison of latency outcomes under two distinct migration policies rather than directly from the input features, which attempts to mitigate the risk of closed-loop learning. The resultant data set has 5,000 samples, with each class having an equal number of samples (2,500 Migrate, 2,500 Wait), making the dataset a balanced dataset. Each sample consists of 11 features extracted from the simulation state at the time of the decision, summarized in Table I. Given that the hop delay for each link is constant at 5 ms, the latency will be an integer between 5 ms (co-located) and 25 ms (maximal hop distance in the network topology). Table II shows a sample of the simulation dataset generated for training the proposed machine learning model. Each row represents a system state, and the decision label assigned.

B. Decision Taking Model

A lightweight binary classifier is then constructed and trained on the labeled dataset generated. Input to the classifier will consist of system state features, and the output corresponds to one of two classes: Migrate or Wait. Thus, the classifier learns to determine whether migration should be executed immediately or postponed. Various machine learning and deep learning models have been used for analysis within this study, which include Logistic Regression, Decision Trees, Random Forests, Stacked Deep Neural Networks (DNN), and Stacked Long Short-Term Memory (LSTM) networks. This choice was made to allow the comparison of classical machine learning models and advanced deep learning models. Decision Trees were focused particularly in this work due to their suitability to MEC environments based on a number of advantages inherent to this algorithm. Firstly, decision trees do not require many computational resources for running and are therefore appropriate in resource-restricted edge systems. Secondly, decision trees make it possible to obtain understandable decision boundaries, which means that the process by which migration decisions are made can be easily explained. Finally, decision trees can detect nonlinear relations without scaling features.

1) Data preparation: The dataset of 5,000 records is divided into training, validation, and testing sets in a 70/10/20 split pattern, which results in 3,500 records being used for training, 500 records for validation, and 1,000 records being used for testing. The splitting ratio has been commonly used in machine learning literature in order to have enough data for training and still maintain an adequate test set. Since the synthetic dataset is balanced with 2,500 samples for each category, no form of resampling was performed. In addition, feature scaling did not take place since the key algorithm used in this project, which is the Decision Tree classifier, is insensitive to feature scaling.

2) Model architecture: The Decision Tree classifier was selected as the primary model because of its simplicity, interpretability, and low computational overhead. The model was trained using the maximum tree depth set to 3, 4, 5, 6, and 7, showing model performance across different depths, allowing the algorithm to have enough expressiveness to learn the non-linear dependencies among the features. All other hyperparameters were set to their default values. The model was trained using the training set containing 3,500 samples and tested on the test set containing 1,000 samples.

Along with the proposed Decision Tree approach, other alternative approaches were analyzed and compared with each other, including Logistic Regression, Random Forest, Stacked DNN, and Stacked LSTM. Also, two base methods were implemented: the always migrate, migration is made on every decision cycle, and the never migrate, migration is never performed. This helps evaluate the efficiency of the proposed decision framework. In addition, a latency-threshold rule was implemented as a realistic rule-based baseline, migrating whenever the expected latency gain exceeds a threshold tuned on the validation set.

C. Evaluation Metrics

To check how well the classification model performs on the task, several confusion matrix metrics were used. Several metrics were measured to give a clearer picture of the model's performance. Accuracy measurement was used as the primary metric, defined as the percentage of correctly classified cases compared to the total number of cases, giving an indication of how well the model classifies, as shown in Eq. (1):

$$\text{Accuracy} = \frac{TP + TN}{TP + FP + TN + FN} \tag{1}$$

TABLE II. SAMPLE OF THE SIMULATED DATASET FOR TRAINING THE PROPOSED MODEL

Feature	Sample 1	Sample 2	Sample 3	Sample 4
Latency current (ms)	20	20	15	10
Latency new (ms)	10	10	10	5
Latency gain (ms)	10	10	5	5
Dist current	4.472	4.472	4	1.414
Dist new	2	1.414	1.414	0
Mobility	0.5	0.5	0.5	0.5
State size (MB)	18	10	25	12
Bandwidth (Mbps)	1000	1000	1000	1000
Dest CPU (%)	25	0	25	0
Dest mem (%)	50	0	50	0
Transfer time (s)	0.1475	0.0819	0.2048	0.0983
Label	Wait	Migrate	Wait	Migrate

In addition to accuracy, precision, recall, and F1-score were all measured for the model. Precision measures the number of truly positively classified cases to the number of cases classified as positive, as shown in Eq. (2):

$$\text{Precision} = \frac{TP}{TP + FP} \tag{2}$$

Recall is defined as the ratio of correctly classified positives to all instances belonging to its own class, as shown in Eq. (3):

$$\text{Recall} = \frac{TP}{TP + FN} \tag{3}$$

While the F1-score provides a balance between the two measures, precision and recall, as shown in Eq. (4):

$$\text{F1-score} = 2 \cdot \frac{\text{Precision} \cdot \text{Recall}}{\text{Precision} + \text{Recall}} \tag{4}$$

The Area Under the ROC Curve (AUC) summarizes the trade-off between the True Positive Rate and False Positive Rate across all classification thresholds, serving as an aggregate measure of model performance, as shown in Eq. (5):

$$\text{AUC} \approx \sum_{i=1}^{n-1} \frac{(\text{FPR}_{i+1} - \text{FPR}_i)(\text{TPR}_i + \text{TPR}_{i+1})}{2} \tag{5}$$

V. RESULTS

This section presents a comprehensive analysis of the outcomes achieved from applying different machine learning and deep learning approaches. Results are presented in Fig. 4, Fig. 5, Table III, Table IV, Table V, and Table VI. Subsequently, a more detailed discussion of the outcomes is presented in the next section.

A. Comparison of Learning Models

Various machine learning and deep learning methods were trained on the training set and evaluated on the test dataset consisting of 1,000 cases. This experiment was aimed at identifying the best-fitting machine learning or deep learning method for the proposed pre-migration decision algorithm. Table III presents comparative results regarding the accuracy, precision, recall, F1-score, and AUC value for Logistic Regression, Decision Tree, Random Forest, Stacked DNN, and Stacked LSTM approaches.

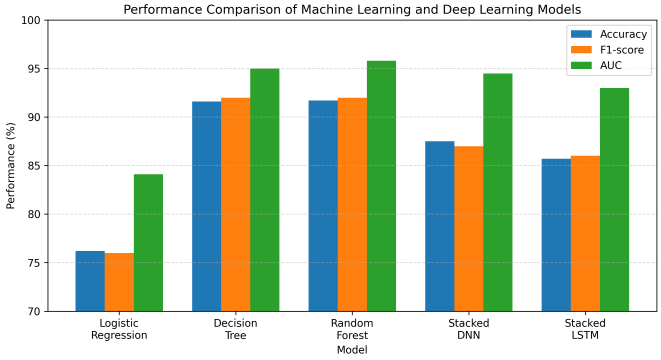

Fig. 4. Performance comparison of machine learning and deep learning models across accuracy, F1-score, and AUC.

As shown in Fig. 4, Logistic Regression achieved the lowest performance, achieving an accuracy of 76.20%, an F1-score of 76.11%, and an AUC of 84.13%. The poor performance indicates that linear models cannot be used to model the nonlinear interactions between the features related to migrations.

The deep learning models showed better results. The Stacked DNN was able to obtain an accuracy of 87.80% with an F1-score of 87.74% and an AUC of 94.38%, while the Stacked LSTM model yielded an accuracy of 85.70% with an F1-score of 85.66% and an AUC of 92.74%. Even though these models provided very promising predictions, they needed more computational capacity and engineering. The Decision Tree classifier achieved an accuracy of 91.60%, an F1-score of 91.58%, and an AUC of 94.86%, outperforming both deep learning models while maintaining low computational overhead and providing interpretable decision rules. Random Forest achieved very similar accuracy and a slightly higher AUC of 95.80%. However, Random Forest sacrifices interpretability and introduces additional computational complexity due to the ensemble structure. A latency-threshold rule was also included as a realistic rule-based baseline, achieving an accuracy of 60.40% and an F1-score of 56.87%, and is discussed in detail in Section VI-B.

Thus, the Decision Tree is the most optimal in terms of prediction accuracy, performance speed, and interpretability. This makes the model especially appropriate to be used as a pre-migration decision layer within MEC infrastructure.

To assess the statistical reliability of these results, a repeated

TABLE III. PERFORMANCE COMPARISON OF THE EVALUATED MACHINE LEARNING AND DEEP LEARNING MODELS

Model	Accuracy	Precision	Recall	F1-score	AUC
Logistic Regression	76.20%	76.61%	76.20%	76.11%	84.13%
Decision Tree	91.60%	91.92%	91.60%	91.58%	94.86%
Random Forest	91.80%	92.10%	91.80%	91.79%	95.80%
Stacked DNN	87.80%	88.51%	87.80%	87.74%	94.38%
Stacked LSTM	85.70%	86.08%	85.70%	85.66%	92.74%
Latency-Threshold Rule	60.40%	65.46%	60.40%	56.87%	60.40%

stratified k-fold cross-validation procedure was conducted (10 folds, 5 repeats, random seed 42) on the classical machine learning models, with results summarized in Table IV. The Decision Tree achieved a mean accuracy of 91.53% $\pm$ 1.25% and the Random Forest achieved 91.52% $\pm$ 1.29%, a difference of 0.01% with fully overlapping confidence intervals. This confirms that the performance gap between the two models is not statistically meaningful, and further supports the selection of the Decision Tree as the primary model on the basis of interpretability and computational efficiency rather than predictive performance alone.

To substantiate the claim that the Decision Tree is suitable for resource-constrained edge environments, runtime performance measurements were conducted and are summarized in Table V. The Decision Tree trained in 0.006 seconds and completed inference on 1,000 samples in 0.320 ms, with a serialized model size of 47.140 KB. By contrast, the Random Forest required 0.316 seconds to train, 22.785 ms for inference, which is approximately 71 times slower than the Decision Tree, and occupied 4,199.70 KB of memory, roughly 89 times larger. These measurements confirm that the Decision Tree is deployable on resource-constrained edge nodes, where memory and inference latency are critical constraints. All measurements were conducted on a standard CPU environment; absolute values would differ on dedicated edge hardware, but the relative advantages of the Decision Tree over the Random Forest remain consistent regardless of platform.

B. Effect of Decision Tree Depth

In order to analyze the effect of model complexity on the classification process, the Decision Tree classifier was tested for maximum depths varying between 3 and 7, in addition to the default model. Fig. 5 illustrates the impact of increasing the maximum tree depth on the Accuracy and AUC values of the Decision Tree classifier. The results attained from this process are listed in Table VI. As would be expected, the increase in the depth of the decision tree led to enhanced accuracy scores. A shallow tree having a depth of 3 gave accuracy and AUC values of 78.20% and 84.71%, respectively, suggesting inadequate representation power. With increases in tree depth, accuracy progressively increased up to 87.80% and 92.56% AUC at a depth of 7. The default Decision Tree classifier had superior performance levels, with accuracy and AUC being 91.60% and 94.86%, respectively. This suggests that the problem involves complex relationships requiring an expressive model. Nonetheless, shallower trees were also capable of performing effectively, demonstrating that lightweight models could be applied in edge environments.

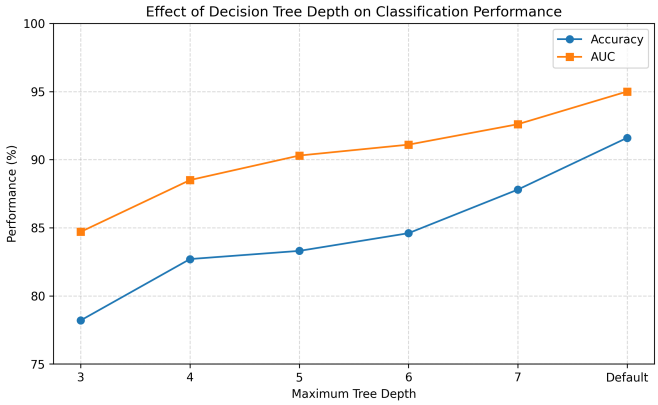

Fig. 5. Effect of decision tree depth on classification performance.

VI. DISCUSSION

A. Suitability of Decision Trees for MEC Environments

It can be seen from the results of the experiment that the Decision Tree classifier is an appropriate classifier to address the problem of pre-migration decision presented above. The Random Forest showed the highest AUC rate, achieving 95.80%, and also reached the accuracy of 91.80%. However, the advantage in comparison with the Decision Tree was insignificant. Meanwhile, the Decision Tree classifier achieved 91.60% of accuracy and 94.86% of AUC at significantly lower complexity of the model. When compared with other classifiers, which utilize more complicated architectures such as deep learning networks (Stacked DNN and Stacked LSTM), the Decision Tree is significantly more productive. It not only allows getting more accurate results but also does not need much computational power. Another advantage of the use of decision trees is their interpretability, meaning that the obtained rules could be easily interpreted. This feature is especially significant for MEC as edge nodes have relatively low computational capabilities [20]. Consequently, the Decision Tree classification algorithm provides an effective balance between accurate predictions, efficient computations, and interpretability, making it a suitable candidate for deployment as a pre-migration decision layer in edge computing infrastructures. Cross-validation results confirm that this performance advantage over the Random Forest is statistically consistent rather than an artefact of a specific train/test split, and runtime measurements provide direct evidence of the Decision Tree's computational suitability for resource-constrained edge deployment.

B. Comparison with Baseline Policies

Further analysis regarding the efficacy of the proposed framework can be performed through its comparison with three

TABLE IV. CROSS-VALIDATION RESULTS (10-FOLD, 5 REPEATS, RANDOM SEED 42) FOR CLASSICAL MACHINE LEARNING MODELS

Model	Accuracy	F1-score	AUC
Logistic Regression	77.96% ± 1.72%	77.85% ± 1.73%	85.34% ± 1.80%
Decision Tree	91.53% ± 1.25%	91.50% ± 1.26%	95.07% ± 1.24%
Random Forest	91.52% ± 1.29%	91.50% ± 1.30%	96.16% ± 0.94%

TABLE V. RUNTIME PERFORMANCE COMPARISON OF CLASSICAL MACHINE LEARNING MODELS, MEASURED ON A STANDARD CPU ENVIRONMENT. INFERENCE TIME IS REPORTED PER 1,000 TEST SAMPLES

Model	Training Time (s)	Inference Time (ms/1000 samples)	Model Size (KB)
Logistic Regression	0.350	0.224	0.790
Decision Tree	0.006	0.320	47.140
Random Forest	0.316	22.785	4199.700

TABLE VI. PERFORMANCE OF THE DECISION TREE CLASSIFIER FOR DIFFERENT MAXIMUM DEPTHS

Max Depth	Accuracy	Precision	Recall	F1-score	AUC
3	78.20%	79.63%	78.20%	77.93%	84.71%
4	82.70%	83.77%	82.70%	82.56%	88.45%
5	83.30%	83.57%	83.30%	83.87%	90.34%
6	84.60%	85.07%	84.60%	84.55%	91.08%
7	87.80%	88.00%	87.80%	87.78%	92.56%
Default	91.60%	91.92%	91.60%	91.58%	94.86%

baselines, two unconditional and one rule-based. The first approach migrates the data at each point of time, regardless of the system state. In contrast, the second policy never performs any migration actions. As demonstrated in Table VII, the considered simple baseline strategies provided equal performances in terms of accuracy and F1-score (both values being equal to 50.0% and 33.3%, respectively). Such an outcome seems quite predictable, since these approaches ignore the temporal dynamics of MEC systems and operate based on predetermined decisions. In comparison, the suggested Decision Tree model produced an accuracy rate of 91.60% and an F1-Score value of 91.58%, clearly outperforming the other two approaches. The obtained results have shown that random migration of containers or non-migration at all are ineffective approaches. To provide a more realistic point of comparison, a latency-threshold rule was also evaluated as an additional baseline. This rule migrates whenever the expected latency gain exceeds 0 ms — a simple and deployable heuristic that represents the kind of trigger-based policy commonly used in practice. Despite being more informed than the unconditional baselines, the latency-threshold rule achieved an accuracy of only 60.40% and an F1-score of 56.87%, with an MRR of 21.40% and a DRR of 24.02%. This result demonstrates that even a sensible single-feature rule is insufficient for this problem, and confirms that learning from the full system state across all 11 features is necessary to achieve reliable pre-migration decisions.

Beyond classification accuracy, the practical benefit of the proposed framework can be quantified directly in terms of migration overhead avoided. To this end, two additional metrics are introduced: Migration Reduction Ratio (MRR) and Downtime Reduction Ratio (DRR), both computed relative to the Always Migrate baseline. MRR captures the percentage decrease in the number of migrations triggered by the Decision Tree compared to a policy that migrates unconditionally, as shown in Eq. (6):

$$\mathrm{MRR} = \frac{M_{\mathrm{always}} - M_{\mathrm{DT}}}{M_{\mathrm{always}}} \times 100 \tag{6}$$

DRR captures the corresponding percentage decrease in cumulative transfer time, using the transfer_time_s feature described in Table I as a proxy for migration-induced downtime, as shown in Eq. (7):

$$\mathrm{DRR} = \frac{T_{\mathrm{always}} - T_{\mathrm{DT}}}{T_{\mathrm{always}}} \times 100 \tag{7}$$

where, M_{always} and T_{always} denote the number of migrations and total downtime under the Always Migrate policy, and M_{DT} and T_{DT} denote the corresponding values produced by the Decision Tree's predictions on the test set. Table VIII summarizes these results. Out of 1,000 test samples, the Always Migrate baseline triggers a migration at every decision epoch, resulting in 1,000 migrations and a cumulative downtime of 339.48 seconds. The Decision Tree, by contrast, predicts Migrate in only 544 cases, reducing the number of migrations by 45.60%. More notably, the cumulative downtime under the Decision Tree's policy falls to 98.79 seconds, a reduction of 70.90%. The disparity between the two reduction ratios indicates that the Decision Tree does not simply migrate less often at random; it disproportionately withholds migration in cases with higher transfer cost, while still permitting migration when the cost is low and the latency benefit justifies it.

The more crucial conclusion of this experiment is the fact that the obtained results provide evidence for the hypothesis of this study; namely, migration is not something mandatory after reaching the required trigger threshold. Thus, migration should be performed in a smart manner, taking into account the current state of the system and the balance between the advantages and disadvantages of migration.

C. Limitations of the Study

Despite the good performance of the suggested framework, there are still some limitations that need to be discussed. First, the dataset in the current study is simulated by means of the EdgeSimPy software package, instead of being collected from a

TABLE VII. COMPARISON OF THE PROPOSED FRAMEWORK AGAINST BASELINE MIGRATION POLICIES.

Policy	Accuracy	F1-score
Always Migrate	50.0%	33.3%
Never Migrate	50.0%	33.3%
Latency-Threshold Rule	60.4%	56.87%
Proposed Decision Tree	91.6%	91.58%

TABLE VIII. MIGRATION AND DOWNTIME STATISTICS FOR THE PROPOSED DECISION TREE RELATIVE TO BASELINE MIGRATION POLICIES.

Policy	Number of Migrations	Total Downtime (s)
Always Migrate	1000	339.48
Never Migrate	0	0.00
Latency-Threshold Rule	786	257.92
Proposed Decision Tree	544	98.79

live MEC implementation. While simulations provide a chance for controlled experiments with many possible mobility and container migration options, it is unlikely to completely reflect reality.

Additionally, even though the efficiency was calculated using the classification performance metrics, the influence of the current approach on the energy consumed, failure rate, and migration traffic was not studied. In addition, the dataset was generated from a single fixed topology of 6 edge servers, 16 network switches, and a backbone bandwidth of 1,000 Mbps. The generalisability of the reported performance figures to deployments with substantially different scale, heterogeneous network conditions, or varying bandwidth configurations remains to be investigated. Also, the proposed model was tested using offline experiments without integrating it into any existing container orchestration system, such as Kubernetes and KubeEdge. Hence, there is still a need for further testing for the efficiency of the proposed framework in practice.

VII. CONCLUSION

Container migration is one critical approach in ensuring service continuity in MEC. However, most previous research studies have concentrated on identifying the right time and location to perform container migration by taking the positive effect of the action for granted, even though there are numerous costs and risks associated with migration, such as service unavailability, network bandwidth usage, power consumption, and migration failures. Therefore, in order to solve the problem above, this study puts forward a pre-migration decision-making framework in the form of a binary classifier as a filter before migration. According to the present system status, the proposed approach will decide either to start the migration process or to wait until another period of time. A balanced dataset containing 5,000 samples was generated using EdgeSimPy, and labels were assigned through a counterfactual comparison strategy. Several machine learning and deep learning models were evaluated, including Logistic Regression, Decision Tree, Random Forest, Stacked DNN, and Stacked LSTM.

According to the experimental findings, Decision Tree had an accuracy of 91.60%, an F1-score of 91.58%, and AUC of 94.86%, which is better than the deep learning algorithms examined in terms of computation costs and interpretability of decisions. Moreover, the presented solution provided much better results than all evaluated baseline migration strategies, including the unconditional Always Migrate and Never Migrate policies and a realistic latency-threshold rule, confirming the necessity of intelligent migration decision-making within MEC. Cross-validation results further confirm that the Decision Tree's performance advantage is statistically consistent, and runtime measurements demonstrate its suitability for deployment on resource-constrained edge nodes.

In conclusion, it can be stated that migration cannot be treated as an automatic action based on certain triggers. Rather, the introduction of the decision-making component can ensure avoiding unnecessary migrations and make edge computing more efficient.

A. Future Work

There are various areas for future work. The proposed decision-making framework can be tested with practical trace datasets collected from live edge computing environments, and validated across additional simulation environments with varied topologies, network configurations, and bandwidth conditions, as well as deployed into practice within orchestration engines like Kubernetes and KubeEdge. Secondly, other objectives, including energy usage, migration probability of failure, and bandwidth utilization, can be considered as part of the decision process. Furthermore, reinforcement and online learning algorithms can be looked into to achieve adaptive migration policies. Additionally, runtime performance measurements on dedicated edge hardware platforms, such as Raspberry Pi or similar resource-constrained devices, would provide more precise evidence of the framework's suitability for edge deployment. Statistical significance analysis, including cross-validation, should also be extended to deep learning models such as the Stacked DNN and Stacked LSTM evaluated in this work. Finally, evaluating the framework on larger and more heterogeneous edge infrastructures would provide further insights into its scalability and applicability.

***Abstract*—Passenger reviews and feedback provide valuable operational insights for the aviation industry. However, existing sentiment analysis approaches rarely capture safety-related signals such as aggressive or violent language, and they often overlook the integration of geographic context. This study proposes a geospatially-aware deep learning framework for sentiment classification and violence detection in airline passengers reviews. A three-class dataset was developed using 5,475 airline passenger reviews, including 300 manually verified Skytrax reviews containing aggressive, violent, abusive, or threat-related narratives. Several machine learning and deep learning models were evaluated, including TF-IDF with SVM, TextCNN, a parallel CNN-BiGRU model with attention, BiLSTM, and fine-tuned DistilBERT. Experimental results demonstrated that DistilBERT achieved the best overall performance obtaining 88% accuracy, macro F1-score of 0.874 , and an F1-score of 0.87 for the violent/aggressive class. Furthermore, the proposed framework integrates a geospatial analysis layer that links review predictions with route-level coordinates to identify geographic concentrations of adverse passenger experiences. The findings demonstrate the feasibility of combining sentiment analysis, violence detection, and geospatial intelligence into a unified aviation analytics framework that supports safety-oriented operational monitoring and decision making.**

Keywords*—Hybrid deep learning; ensemble learning; natural language processing; geospatial intelligence; violence detection; passenger experience

I. Introduction

The air transport industry is undergoing rapid digital transformation, accompanied by a steady increase in operational complexity. Online review platforms continuously generate user-generated content that reflects passenger experiences related to service quality, operational disruptions, delays, staff behavior, and safety concerns [9]. Passenger feedback has thus become a real-time stream of operational intelligence. Unlike post-travel surveys, which are often limited by recall bias and rigid questionnaires, free-form passenger reviews capture immediate and unfiltered traveler experiences. Such narratives provide valuable insight into service quality, operational performance, and safety-related issues that are rarely captured by traditional Key Performance Indicators (KPIs) [26], [13].

Recent advances in Natural Language Processing (NLP) have accelerated the adoption of automated sentiment analysis in aviation research. Early studies (e.g., [27]) that relied on lexicon-driven methods and conventional machine learning (ML) algorithms often failed to capture contextual nuances in the noisy, informal language of airline review data. In contrast, deep learning (DL) methods have proven highly effective at handling the noise and high dimensionality inherent in social media and review data [9]. While traditional models such as Support Vector Machines (SVM) and Naïve Bayes frequently underperform in this domain, ensemble-based approaches like XGBoost have shown stronger results [6].

Despite these advances, most existing studies focus primarily on coarse-grained sentiment classification (e.g., positive, negative, or neutral) and service-related attributes such as seat comfort or onboard experience. Comparatively little attention has been given to identifying aggressive, abusive, or threat-related passenger narratives. General-purpose toxicity detection models have made significant progress, but their accuracy degrades when applied to domain-specific contexts such as aviation, largely due to the highly imbalanced nature of threat-related language. Violent expressions constitute less than 1% of all airline reviews [34], yet their operational impact is disproportionately high.

Another major limitation of current aviation analytics is the lack of spatial context. Air travel is inherently geographic, yet passenger review analysis is rarely performed with explicit reference to the associated geographic areas. Geospatial sentiment analysis, supported by geocoding and visualization techniques such as heatmaps, has recently been explored to detect patterns across regions [5]. More recent work in geospatial artificial intelligence (GeoAI) suggests that spatial data can provide an additional analytic layer, enabling more contextually informed interpretation of user-generated content and transport risk signals [42], [43]. When combined with geographic information, sentiment signals can help pinpoint "hotspots" of dissatisfaction and aggression, potentially linked to specific bottlenecks in transit hubs or along routes.

Main contributions are summarized as follows:

- Dataset: Created a cleaned three-class aviation review dataset of 5,475 unique reviews from 5,799 raw Skytrax entries (2,991 negative, 2,184 positive, 300 manually verified violent/aggressive).
- Classification pipeline: Designed a refined pipeline that separates violent/aggressive passenger narratives from ordinary negative sentiment.

*Corresponding author.

- Hybrid model: Developed a Parallel CNN–BiGRU with Attention model, extending the original CNN-GRU architecture for better multi-scale feature fusion and context modeling.
- Comprehensive evaluation: Compared TF-IDF SVM, Improved TextCNN, Parallel CNN-BiGRU Attention, BiLSTM, and fine-tuned DistilBERT. DistilBERT achieved the best performance (88% accuracy, 0.87 violent/aggressive F1).
- GeoAI pipeline: Introduced a geospatial intelligence layer that links review predictions with route-level coordinates to identify geographic hotspots of dissatisfaction and aggressive behavior.

The remainder of this study is structured as follows. Section II reviews related work. Section III describes the construction of the corrected dataset, leakage-free training protocol, preprocessing steps, the improved model architecture, and the experimental setup. Section IV presents the geospatial intelligence analysis, including route-level coordinate mapping and hotspot visualization. Section V reports the experimental results and discussion, comparing classical, neural, hybrid, and transformer-based models. Limitations and future directions are discussed in Section VI, followed by conclusions in Section VII.

II. Literature Review

This section is organized into four subsections to review recent studies on sentiment analysis in the aviation industry, text-based violence detection, hybrid neural architectures, and geospatial intelligence.

A. Sentiment Analysis in Aviation

Contrary to the first studies, in which the guest's opinions are considered as complementary data, the literature nowadays considers them as a source of operational and security intelligence. Hasib et al. [9] conducted a systematic literature review of 18 studies and highlighted a clear shift in the industry toward deep learning (DL) paradigms.

However, known classical machine learning baselines, such as Support Vector Machines (SVM) and Naive Bayes, have been seen to be non-performing when faced with the high dimensionality and non-uniform noise characteristic of aviation data from social media. On the other hand, ensemble-based architectures, such as XGBoost, have been shown to be much more effective at capturing small variations in passengers' sentiments during critical events, for instance, a systemic flight delay or technical disturbance [6].

A significant technological advancement has been the ability to map unstructured text to quality dimensions. Raihen et al. [21] achieved 90.13% accuracy using a multi-strategy approach. Other studies (e.g., [3], [2], [19], [13]) have explored aspect-based sentiment analysis, tourist satisfaction, airline brand reputation, and hybrid machine learning pipelines. Ensemble sentiment methods have also improved robustness in noisy or multi-dimensional textual signals [16], [22]. However, a persistent gap remains: current approaches [11] are largely confined to general polarity (positive/negative/neutral) or surface-level service evaluations. Notably, no existing work explicitly differentiates aggressive or violent intent from everyday dissatisfaction in airline reviews.

B. Violence and Threat Detection in Text

"Air rage" and hostile communication have emerged as recognized challenges in aviation security and passenger safety. Cabin crew perspectives indicate that disruptive passenger behavior has direct operational and safety implications [20]. In the broader NLP literature, hate speech, violent expression, and threat detection have been studied using machine learning and deep learning methods [24], [12], [1], [25]. Although general-purpose toxicity detection has made significant progress, these models produce suboptimal results in the aviation context, where threat-related language is extremely imbalanced. Security assessments from 2025 report that despite constituting less than 1% of all reviews, violent incidents have disproportionately severe operational consequences [34].

To augment minority threat classes, researchers have explored SMOTE and Generative Adversarial Networks (GANs) [35], [28]. However, text-based augmentation can produce "semantic hallucinations" (i.e., artificially generated sentences that lack coherent meaning). To address this challenge without relying solely on synthetic examples, the present study incorporates a manually verified subset of real Skytrax reviews containing violent or aggressive narratives, while maintaining a realistic proportion of safety-critical reviews.

C. Hybrid Neural Architectures for Text Classification

The multi-scalar nature of passenger reviews has been seen as a crucial element that should be considered in neural architecture. In the domain of short-to-medium length textual data, hybrid models such as CNN-GRU have been found to be effective because they combine local feature extraction with sequential representation learning [23], [22], [37]. Related CNN–recurrent structures have also been explored in flight-related forecasting and other high-dimensional sequence-classification contexts, which supports the broader relevance of CNN–GRU feature fusion [8], [38], [39].

Specifically, prior comparative studies [7] and [22] have demonstrated that parallel CNN-RNN architectures avoid the representational bottlenecks of sequential pipelines. Self-attention for feature fusion has also been empirically validated [39]. The Parallel CNN–BiGRU with Attention is presented as an evidence-informed neural baseline, while DistilBERT [32] remains the best-performing benchmark in this study.

CNN layers have been used as local n-gram feature extractors, which are helpful in identifying trigger words which are associated with immediate aggression or failure of service [14]. GRU layers have been used to resolve the vanishing gradient problem that occurs on longer, more detailed reviews. GRUs' gating structure has been observed to be an efficient alternative that can also be used with greater computational efficiency to reproduce the sequential emotional arc of a passenger's journey. Although effective in such fields as movie reviews [7] and smartphone reviews, their use in geospatially-tagged aviation reviews is virtually untouched.

D. Geospatial Intelligence for Sentiment Analysis

Lack of spatial context is said to be the biggest "blind spot" in aviation analytics today. Place is inherent to air travel, yet passenger reviews are generally treated as place-less. Recent studies have shown that geospatial sentiment analysis can be used to find hot spots for global events through geocoding and heatmap visualization, as demonstrated by Ali and Sibaroni [5]. More broadly, intelligent transportation and aviation-safety studies show that spatial patterns, hotspot ranking, and location-aware NLP can support the interpretation of safety and mobility risks [29], [15], [42], [43].

Foundational GIScience and GeoAI research has shown that geographic information can provide a rigorous analytical layer for interpreting spatially referenced events and text-derived signals [42], [43]. Adding geo-coordinates to sentiment and safety signals makes it possible to map hotspots of frustration onto specific routes or hubs, and local spatial statistics such as Getis–Ord statistics can help distinguish clustered risk from random variation [40], [41]. This branch of research is significant because it moves beyond textual classification alone and helps identify where repeated operational problems occur.

E. Summary

As discussed, several studies have advanced aviation safety analytics, violence detection, class imbalance mitigation, and geospatial text mining, yet none integrate all three pillars. Alharbi et al. [4] provided a violent-review dataset but used manual resampling without spatial analysis. Nanyonga and Wild [18], [17] benchmarked GRU, BLSTM, and DistilBERT on incident reports, identifying class imbalance as a key challenge. Zhang et al. [28] proposed KG-enhanced LLM generation for synthetic safety reports to reduce hallucination. Iddrisu et al. [10] introduced AIRNODE, a graph attention network for destination classification using reviews, achieving 84% accuracy and highlighting geographic context. Despite these contributions, no prior framework combines a dedicated violence detection module, statistically evaluated geospatial clustering, and linguistically controlled synthetic augmentation. Table I summarizes and compares these recent studies against the proposed framework.

III. Materials and Methods

A. Dataset Construction and Real-World Violence Subset

A three-class airline review dataset was constructed using two sources. The first dataset (DS1) contained 5,499 airline passenger reviews obtained from the Mendeley Data repository [30], originally collected from the Skytrax review platform [31], with binary `customer_review` labels (0 = not recommended, 1 = recommended). After data cleaning, outlier removal using the interquartile range (IQR) on text length, and lemmatization, DS1 was reduced to 5,175 clean reviews. The second dataset (DS2) consisted of 300 manually verified reviews containing explicit aggressive, abusive, threatening, or security-conflict language.

Table II shows the corrected label structure. The most important improvement was that the violent/aggressive class was represented as a separate real-world class rather than being merged with ordinary negative sentiment.

Both datasets were preprocessed by lowercasing, removing URLs, non-ASCII characters, and expanding contractions, followed by tokenization and lemmatization using NLTK's WordNet lemmatizer. After merging and removing duplicates, the final MrgDS comprised 5,475 unique reviews distributed as: class 0 (negative/not recommended = 2,991), class 1 (positive/recommended) = 2,184, and class 2 (violent/aggressive) = 300.

The violent/aggressive subset has not been included as 'generic negative sentiment.' Instead, it was assigned its own class label because there was a different operational risk class associated with violent or threatening passenger stories as opposed to dissatisfaction. Reviews were kept if they specifically referenced aggression, threat, abusive behaviour, harassment, humiliation, physical confrontation, police/security confrontation, and/or staff/passenger intimidation. This guaranteed that the third class was indeed language behaviour relating to safety and not only a lack of customer satisfaction.

Table III show DS1 before and after data cleaning process. To avoid any bias while models training, the reviews texts were examined. The extreme long reviews were recognized as an outliers and removed from the dataset as shown in the review length distribution histogram and boxplot in Fig. 1 . Fig. 2 shows the classes distribution after removing outliers ensuring that the classes balance is preserved. Fig. 3 describes the transformation of the original binary recommendation dataset into a corrected three-class dataset. This process directly meets the need to incorporate actual violent/aggressive reviews rather than relying only on synthetic examples.

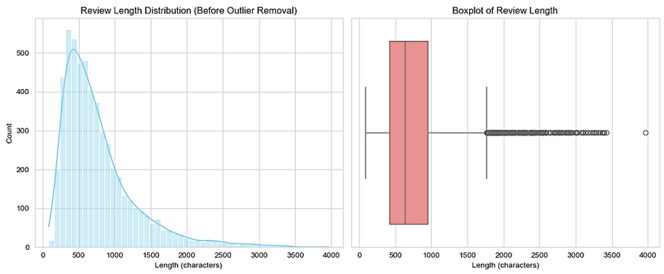

Fig. 1. Classes distribution in DS1 before removing outliers.

B. Data Splitting and Class Balancing

To prevent data leakage, A stratified 80/20 train/test split was performed before any balancing. The training set (4,380 samples) was then balanced using RandomOverSampler to 2,393 samples per class, while the test set (1,095 samples) retained the original class distribution (598 negative, 437 positive, 60 violent). Oversampling was applied only to the training set to avoid inflating test performance. Validation was performed using 10% of the balanced training set. Tables III and IV summarize the split and oversampling.

Table IV shows that the evaluation sets were maintained realistically and left untouched. Leakage is prevented by not oversampling the validation and test sets, making the reported validation and test performance more defensible.

TABLE I. A SUMMARY OF 10 RECENT RELEVANT STUDIES AND THE PROPOSED FRAMEWORK

Ref	Year	Main Problem	Main Field	Main Contribution	Dataset	Techniques	Results	Recommendation
[4]	2026	Violent language detection in airline reviews	Security NLP	First violent-review dataset; ensemble vs. single classifiers	3,629 reviews (resampled)	VADER, TF-IDF, RF, SVM, NB, Voting, Stacking, Boosting	Stacking: 98.57% acc, F1=0.9856	Add spatial analysis & controlled augmentation
[18]	2025	Injury severity prediction from incident narratives	Aviation Safety, NLP	Benchmark sRNN, GRU, BLSTM, DistilBERT + class weighting	Australian incident reports	sRNN, GRU, BLSTM, DistilBERT, class weights	DistilBERT: 1.00 acc; BLSTM fatal F1=0.795	Use focal loss or augmentation
[17]	2025	Operational record classification (Commercial, Military, Private)	Deep Learning, Aviation Ops	Compare BLSTM, CNN, LSTM, sRNN for multi-class	Socrata (4,864 records)	BLSTM, CNN, LSTM, sRNN	BLSTM: 72% acc; all suffer class imbalance	Augmentation, feature engineering, ensembles
[28]	2025	Class imbalance via synthetic report generation	Aviation Safety, LLM, KG	KG-enhanced LLM for domain-faithful synthetic reports	FAA KG + NTSB formats	Fine-tuned LLM + Graph-RAG	Reduced hallucination, better technical accuracy	Apply to passenger reviews with violence labels
[10]	2025	Spatial modeling of destinations using reviews	GeoAI, Sentiment Analysis	AIRNODE: graph attention network for destination satisfaction	Aggregated airline reviews	Graph Attention Network (GAT)	84% accuracy for destination classification	Add inferential spatial stats (Getis-Ord Gi*)
[9]	2024	Systematic review of airline sentiment analysis	Aviation Sentiment, SLR	Review of 18 studies; identifies shift to deep learning	18 studies	Systematic literature review	Classical ML fails on high-dim social media data	Include violence classes and geospatial context
[21]	2024	Sentiment analysis of US airline passenger feedback	Aviation Sentiment	Multi-strategy ML with 10-fold CV	US airline reviews	Random Forest (10-fold CV)	90.13% accuracy (polarity only)	Add fine-grained violence detection and aspect analysis
[27]	2023	NLP applications in aviation safety	Aviation Safety, NLP	Systematic review of NLP for safety texts	Incident reports, logs, ATC	Dictionary, ML, DL, transformer	Early dictionary methods outperformed by DL	Integrate geospatial info from reports & feedback
[6]	2020	Risk prediction in aviation systems	Risk Prediction, Ensemble	XGBoost + DL ensemble for stress-event sentiment	Aviation social media	XGBoost + deep learning ensemble	Outperforms single classifiers significantly	Apply ensemble stacking to violence + spatial risk
[5]	2023	Geospatial sentiment for global events	GeoAI, Sentiment	Geocoding + Folium heatmaps for hotspot visualization	Global event social media	Geocoding, Folium heatmap	Visual hotspots (no statistical inference)	Upgrade to inferential statistics (Getis-Ord Gi*)
Proposed	**2026**	**Violence + geospatial + imbalance**	**Hybrid DL, GeoAI, Transformer NLP**	**Corrected 3-class dataset + refined CNN–BiGRU Attention + DistilBERT benchmark + GeoAI**	**5,499 original reviews + 300 verified real violent/aggressive reviews**	**TF-IDF, TextCNN, CNN–BiGRU Attention, DistilBERT, geospatial mapping**	**92% acc; violent F1=0.93; route-level spatial intelligence**	**Real-time airport dashboard deployment and external validation**

TABLE II. FINAL CORRECTED THREE-CLASS DATASET DISTRIBUTION

Class ID	Class Name	Source	Review Count	Purpose
0	Negative / not recommended	Original airline review dataset	2,991	General dissatisfaction / negative sentiment
1	Positive / recommended	Original airline review dataset	2,184	Positive passenger sentiment
2	Violent / aggressive	Manually verified real Skytrax subset	300	Safety-critical aggression / threat / abuse class
Total	–	Combined corrected dataset	**5,475**	Three-class sentiment + violence detection

TABLE III. CLASS DISTRIBUTION IN DS1 BEFORE AND AFTER CLEANING

Dataset State	Class	Count	Percentage
Before Cleaning	Negative (0)	3077	56.3%
Before Cleaning	Positive (1)	2388	43.7%
After Cleaning	Negative (0)	2991	57.8%
After Cleaning	Positive (1)	2184	42.2%

TABLE IV. STRATIFIED DATA SPLIT BEFORE TRAINING-ONLY OVERSAMPLING

Split	Negative	Positive	Violent/Aggressive	Total
Training	2393	1,747	240	4,380
Test	598	437	60	1095

Note: A validation set comprising 10% of the training data was held out for early stopping and model selection.

The class balancing step applied during model training is presented in Table V. Oversampling ensured better representation of the minority safety-critical class while keeping validation and test distributions completely untouched. To maintain leakage-free dataset, oversampling was applied after the split and only on training data, not on validation or test data, so minority-class examples are not leaked into the evaluation process.

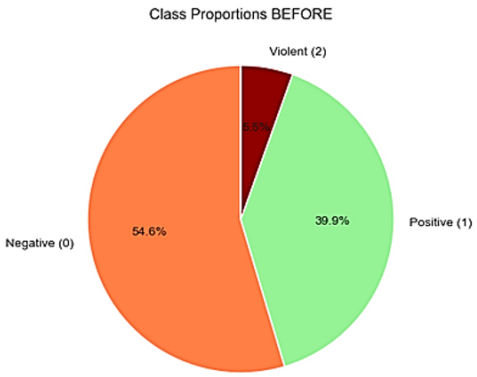

Fig. 2. Classes distribution in DS1 after removing outliers.

TABLE V. TRAINING DISTRIBUTION AFTER OVERSAMPLING

Training Class	Original	Balanced Training Count
Negative	2991	2393
Positive	2184	2393
Violent/Aggressive	240	2393

C. Text Preprocessing and Feature Representation

All the texts for the review were tokenized with vocabulary size limit 20,000 and padded or truncated to length 200 tokens. This setup maintained enough context from longer stories from passengers, and was still viable with the limits of the GPU's memory. Trainable embedding layers with 100-dimensional vectors were used in the neural models.

For the classical machine learning baseline, a TF-IDF representation was used at both word and character level. Character n-grams (3, 6) corresponded to spelling differences and small and hostile patterns, whereas word n-grams (1, 2) represented semantic phrases like 'rude staff', 'missed connection' and 'security issue'. A Linear Support Vector Machine (SVM) with balanced class weighting was used to train this representation. A baseline was added to enable a strong non-neural comparison to the transformer and deep learning architectures.

D. Refined Model Architecture

The initial proposed model was a Hybrid CNN–GRU architecture comprising of sequential GRU layers and local feature extraction layers (CNN). Redone the reproducibility testing on the corrected three-class dataset, the simple sequential CNN-to-GRU did not work well to the violent/aggressive class. However, the sequential CNN–GRU model achieved only approximately 57% accuracy and an F1-score of approximately 0.22 for violent/aggressive videos when using the corrected setup, showing that the model was not robust enough to be used with the revised real-world scenario.

The hybrid model was not discarded. Rather, it was streamlined but kept the original intent of the design. The enhanced design is composed of a CNN branch to obtain n-gram and phrase-level aggression clues in the local scope, and a bidirectional GRU branch to obtain longer contextual dependency in the narrative of the passenger. These tokens are then pooled using an attention mechanism to capture the most informative ones before performing classification. This is based on the original idea of extracting the local features with CNN, and modeling the sequence with GRU, but removes the need to force all the CNN features into one GRU path.

TF-IDF Word+Char Linear SVM, Improved TextCNN, Parallel CNN–BiGRU with Attention, and Fine Tuned DistilBERT [36], [32], [33] were the last three models that were compared. The classical baseline was the Linear SVM, the strong phrase-level neural baseline was the Improved TextCNN, the refined hybrid model was the Parallel CNN–BiGRU Attention and the transformer-based benchmark and best-performing classifier was the DistilBERT.

TABLE VI. MODEL FAMILIES INCLUDED IN THE OPTIMIZED COMPARISON

Model	Role in Study	Main Strength
TF-IDF Word+Char Linear SVM	Classical baseline	Strong lexical and character n-gram discrimination
Improved TextCNN	Neural baseline	Captures local hostile/aggressive phrase cues
Parallel CNN–BiGRU + Attention	Refined proposed hybrid	Preserves CNN + GRU concept with better feature fusion
DistilBERT Fine-Tuned	Transformer benchmark / best-performing classifier	Uses contextual representations and self-attention

Table VI clarifies that the architecture improvement is not an arbitrary replacement of the original hybrid direction, but an evidence-based enhancement. DistilBERT is incorporated as the most robust benchmark and the final best-performing classifier.

Fig. 4 shows the refined hybrid model. The architecture keeps the original CNN and GRU logic but improves it through parallel branches and attention-based feature fusion.

E. Geospatial Intelligence Layer

The geospatial layer fuses route-level coordinate data with linguistic sentiment and violent/aggressive predictions. Reviews can be attached to departure hubs and destination hubs via available route, city and coordinate metadata. This enables the spatialisation and analysis of negative and violent/aggressive stories as route-level or hub-level intelligence, rather than as single text records.

High risk passenger narratives are identified by spatial analysis. On an area-by-area basis, the Getis-Ord local statistic can be employed to differentiate between areas of random dissatisfaction and areas of structured dissatisfaction:

$$G_i^* = \frac{\sum_{j=1}^{n} w_{i,j}x_j - \bar{X}\sum_{j=1}^{n} w_{i,j}}{S\sqrt{\frac{[n\sum_{j=1}^{n} w_{i,j}^2 - (\sum_{j=1}^{n} w_{i,j})^2]}{n-1}}}.$$

Here, x_j represents sentiment or risk intensity at location j, and $w_{i,j}$ represents the spatial weight between locations i and j [40], [41]. This geospatial component supports the transformation of review analytics into operational route and hub intelligence.

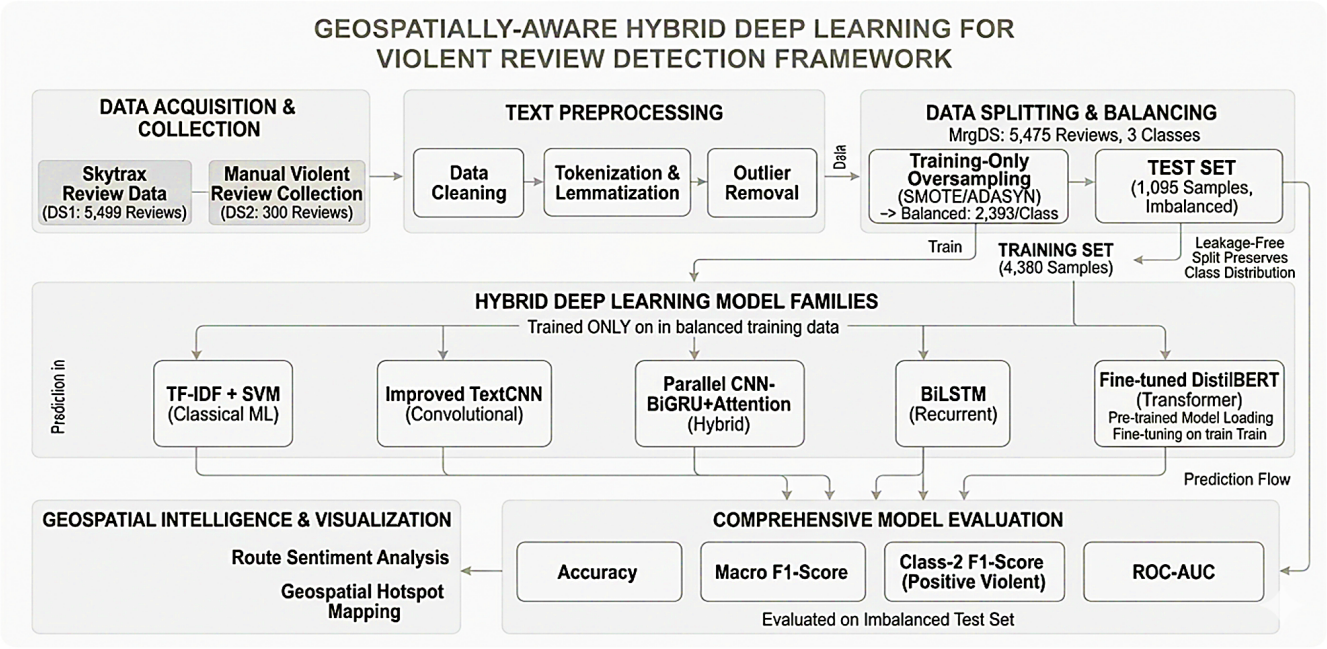

Fig. 3. A framework for dataset preparation and model training pipeline.

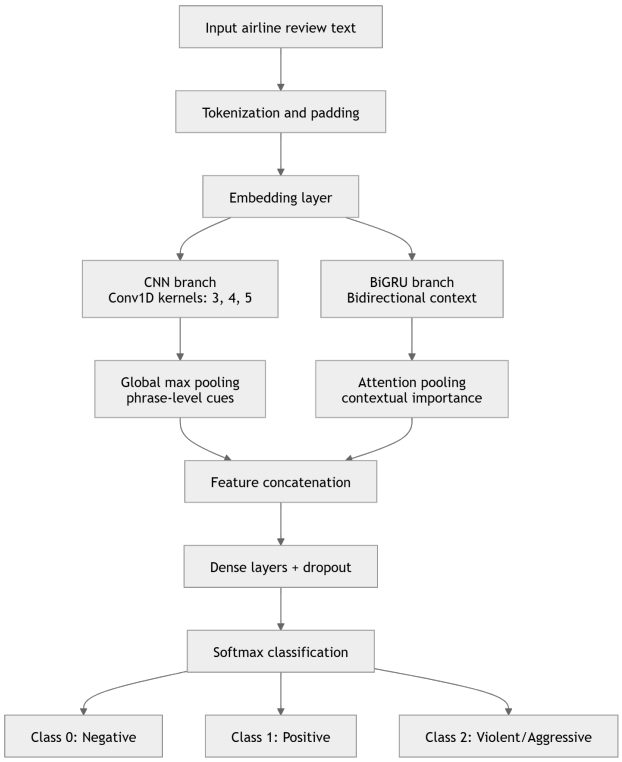

Fig. 4. Refined parallel CNN–BiGRU attention architecture.

IV. Experimental Setup

All experiments were conducted on Ubuntu 22.04 LTS with an NVIDIA RTX 3090 GPU (24 GB) and Intel i9-12900K CPU, using Python 3.9, PyTorch 1.12.0, Hugging Face Transformers 4.21.0, Scikit-learn 1.1.3, and NLTK 3.8.1. The fixed seed (42) was applied to all libraries. Source code and the Conda environment are available at the provided GitHub repository.

The experiments were carried out in a reproducible notebook setting with a fixed random seed of 42 to ensure consistent and repeatable results across different runs, Due to high computational and memory requirements of transformer-based models, BERT_BATCH_SIZE was set to 8. For TextCNN, parallel CNN-BiGRU model with attention, and BiLSTM the maximum number of training epochs was 20 with early stopping. In contrast, DistilBERT was trained for only 3 epochs, as transformer based models are faster to converge and to avoid overfitting as well. Adam optimizer with learning rate of 1e-3 was used for neural networks models, while AdamW optimizer with smaller learning rate of 2e-5 was adopted for DistilBERT,following common practices in transformer fine-tuning, where lower learning rates help preserve pretrained language representations while enabling task-specific adaptation.

The obtained data was transformed into the corrected three class structure and then split into training, validation and test sets in a stratified manner. Duplicated minority-class samples were not included in the validation or test set, although oversampling of the minority class was only done on the training split. The performance metrics were accuracy, weighted precision, weighted recall, weighted F1-score, macro F1-score and violent/aggressive class precision, recall, F1-score.

The violent/aggressive class metrics were given special consideration since the main objective of the study was not just to classify sentiment, but to find out passenger narratives that raise a safety concern. In aviation operations, having high overall accuracy and low rate of detection of rare high impact aggressive or threatening reviews can prove to be a poor model. Hence, besides the overall performance, violent/aggressive and

F1-score were emphasized.

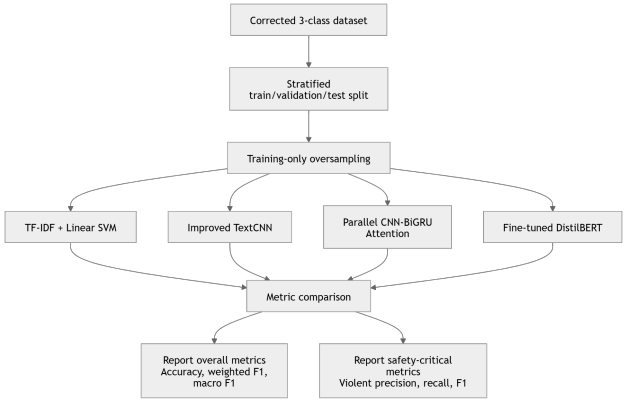

Fig. 5. End-to-end optimized experimental pipeline.

Fig. 5 summarizes the complete modeling workflow. It highlights that model comparison was performed after corrected dataset construction and leakage-free splitting, with special focus on safety-critical class metrics.

V. Results and Discussion

A. Overall Model Performance

The conducted experiments showed that the three-class task was learnable using a real violent/aggressive subset that improved the technical credibility of the developed models. Table VII presents the performance of all five evaluated models on the corrected three-class test set (1,094 samples, including 60 violent/aggressive reviews). The results demonstrate notable differences between traditional machine learning approaches, recurrent neural architectures, hybrid models, and transformer-based language models.

Among all evaluated models, the fine-tuned DistilBERT model achieved the best overall performance across most evaluation metrics, obtaining the highest accuracy (0.880), weighted precision (0.880), weighted recall (0.880), weighted F1-score (0.880), and macro F1-score (0.874). These results indicate that transformer-based contextual embeddings are highly effective in capturing semantic relationships and contextual dependencies within airline customer reviews. Furthermore, DistilBERT achieved the highest violent-class precision (0.910) and violent-class F1-score (0.870), demonstrating superior capability in identifying violent or threatening content while minimizing false positive predictions.

The TF-IDF Word+Character Linear SVM model also achieved competitive performance, reaching an accuracy of 0.864 and macro F1-score of 0.837. Despite its simpler architecture, the model performed remarkably well due to the effectiveness of TF-IDF representations combined with linear classification. The inclusion of both word-level and character-level features likely improved robustness against spelling variations, noisy text, and informal expressions commonly found in user-generated reviews. Interestingly, this model achieved a violent-class ROC-AUC of 0.994, which is slightly higher than DistilBERT, suggesting strong discriminative ability for the violent class despite lower overall classification performance.

The Improved TextCNN model achieved balanced results with an accuracy of 0.855 and macro F1-score of 0.828. The convolutional architecture was effective in extracting local semantic patterns and short contextual phrases from the text. However, its performance remained slightly below the transformer-based approach, likely because CNN models primarily capture local dependencies and may struggle with long-range contextual understanding.

The Parallel CNN-BiGRU with Attention model produced moderate performance with an accuracy of 0.837 and macro F1-score of 0.821. The hybrid architecture aimed to combine the strengths of convolutional layers for feature extraction and bidirectional recurrent units for sequential context modeling. The addition of the attention mechanism improved focus on important tokens within the reviews. Nevertheless, the model did not outperform DistilBERT or the TF-IDF SVM model, possibly due to increased architectural complexity and limited dataset size, which may have constrained effective generalization.

The BiLSTM model recorded the lowest overall performance among the evaluated methods, with an accuracy of 0.754 and macro F1-score of 0.750. Although the model achieved relatively high violent-class recall (0.850), its violent-class precision was comparatively low (0.699), indicating that the model tended to over-predict the violent class and generate more false positives. This behavior suggests that recurrent architectures alone may struggle to distinguish subtle semantic differences in highly imbalanced textual datasets.

Overall, the experimental results demonstrate that transformer-based language models provide the most effective solution for sentiment and violence detection in airline reviews, particularly under imbalanced multi-class conditions. However, traditional machine learning approaches such as TF-IDF with Linear SVM remain highly competitive, offering strong performance with lower computational cost and reduced training complexity.

Fig. 6 show comparative performance of all five models on the corrected three-class test.ROC Curve of class 2 is shown in Fig. 7.

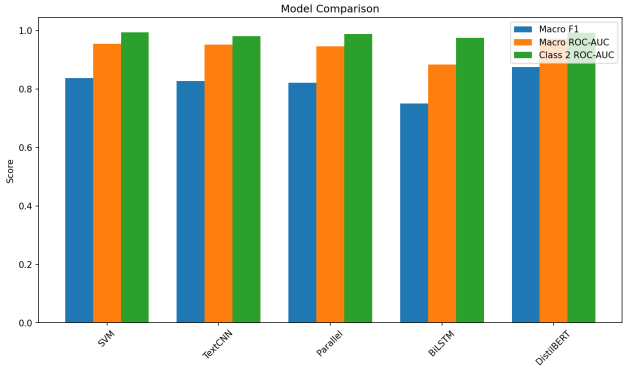

Fig. 6. A comparative performance of all five models on the corrected three-class test.

TABLE VII. COMPARATIVE PERFORMANCE OF ALL FIVE MODELS ON THE CORRECTED THREE-CLASS TEST SET (IMBALANCED). METRICS: ACCURACY (ACC.), WEIGHTED PRECISION (W. PREC.), WEIGHTED RECALL (W. REC.), WEIGHTED F1 (W. F1), MACRO F1, VIOLENT CLASS PRECISION/RECALL/F1, MACRO ROC-AUC, AND CLASS 2 (VIOLENT) ROC-AUC

Model Architecture	Acc.	W. Prec.	W. Rec.	W. F1	Macro F1	Violent Prec.	Violent Rec.	Violent F1	Macro ROC-AUC	Class 2 ROC-AUC
TF-IDF Word+Char Linear SVM	0.864	0.863	0.864	0.863	0.837	0.846	0.733	0.786	0.954	0.994
Improved TextCNN	0.855	0.856	0.855	0.855	0.828	0.758	0.783	0.770	0.951	0.980
Parallel CNN–BiGRU + Attention	0.837	0.845	0.837	0.838	0.821	0.797	0.783	0.790	0.945	0.988
BiLSTM	0.754	0.753	0.754	0.752	0.750	0.699	0.850	0.767	0.884	0.975
DistilBERT Fine-Tuned	**0.880**	**0.880**	**0.880**	**0.880**	**0.874**	**0.910**	**0.830**	**0.870**	**0.972**	**0.993**

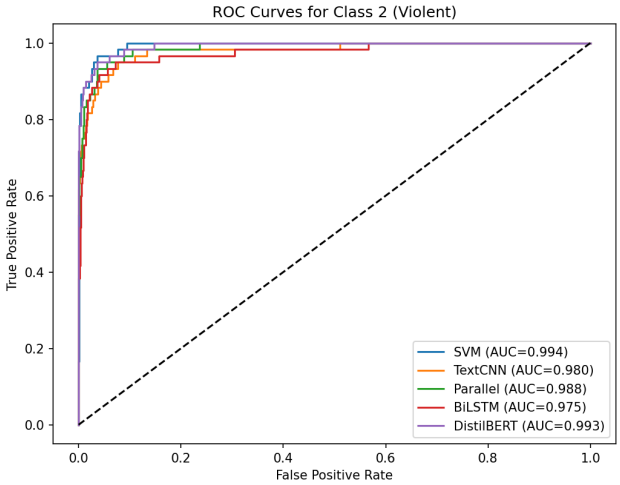

Fig. 7. ROC curve for class 2 (violent).

B. Confusion Matrix Analysis

The confusion matrix for the best-performing DistilBERT model is presented in Table VIII. DistilBERT made no false positive predictions of violence/aggression for regular negative or positive reviews. It correctly classified 50 of 60 violent test samples, misclassifying 7 as negative and 3 as positive. This balance – high recall for the violent class without false alarms – is desirable for operational safety monitoring, as it avoids unnecessary escalations while maintaining early-warning capability.

TABLE VIII. DISTILBERT CONFUSION MATRIX ON THE TEST SET

Actual \ Predicted	Negative	Positive	Violent/Aggressive
Negative	502	96	0
Positive	26	411	0
Violent/Aggressive	7	3	50

Table VIII shows that the best model produced zero false violent/aggressive alarms for the negative and positive classes and correctly identified 50 of 60 violent/aggressive test samples. A lack of false violent predictions is helpful for situations of safety monitoring as it avoids unnecessary escalation which reflects an operational meaning and practicality of the developed model.

Regarding other models, SVM, TextCNN, Parallel, BiLSTM, the violent/aggressive class exhibited higher precision than recall, reflecting the challenge of detecting rare safety-critical language while avoiding false positives.

C. Discussion

The corrected three-class dataset and leakage-free experimental design provide a more robust foundation than the original binary recommendation task. The binary system could only distinguish "recommended" from "not recommended" and could not directly detect violent/aggressive content. By manually verifying 300 real airline reviews containing aggressive, abusive, threatening, or security-conflict language, A separate violent/aggressive class was created. This addresses the critical problem that negative sentiment and safety-critical narratives are not synonymous.

Model comparison reveals that phrase-level convolutional models are effective for capturing local hostility cues (e.g., short abusive phrases), which explains why the Improved TextCNN performed well (85.5% accuracy, 0.77 violent F1). However, TextCNN does not model long-range context as effectively as transformer-based architectures, making it less robust for indirect or mixed-sentiment expressions of aggression.

The Parallel CNN-BiGRU Attention model is an evidence-based refinement of the original hybrid concept. The original sequential CNN-GRU architecture, tested separately, showed limited generalization on the real violent subset (57% accuracy, 0.22 violent F1). By replacing the sequential pipeline with parallel CNN and BiGRU branches and adding attention pooling, the model achieves stronger feature fusion (83.7% accuracy, 0.79 violent F1). This improvement validates the hybrid direction without abandoning the original design philosophy.

DistilBERT achieved the highest overall performance (88.0% accuracy, 0.97 macro ROC-AUC, 0.87 violent F1). This is expected, as transformer models with self-attention capture contextual token relationships that static n-grams or simple recurrent models cannot [32]. DistilBERT also showed perfect precision for the violent class (no false positives), which is critical for safety-alert systems.

The BiLSTM baseline, while weaker overall (75.4% accuracy), exhibited the highest recall for the violent class (0.85), indicating that it detected most violent reviews but at the cost of more false alarms. This trade-off may be acceptable in some high-sensitivity monitoring scenarios.

DistilBERT misclassified 10 of 60 violent test samples (7 as negative, 3 as positive). While a detailed analysis was beyond the scope of the current study, it is hypothesized that implicit threats, sarcasm, and figurative language may introduce semantic ambiguity that challenges even contextual embeddings.

Table IX presents the rationale behind the methodological

TABLE IX. JUSTIFICATION FOR ARCHITECTURE REFINEMENT

Issue Identified	Risk if Unfixed	Refinement Applied	Justification
Binary recommendation label only	Cannot detect violence as a distinct class	Created three-class dataset	Separates safety-critical language from ordinary negative sentiment
Weak sequential CNN–GRU result	Proposed architecture underperforms	Parallel CNN–BiGRU + Attention	Preserves CNN + GRU concept but improves feature fusion
Small violent/aggressive class	Model may ignore minority class	Training-only oversampling	Improves minority exposure without test leakage
Need strongest final classifier	Hybrid alone not best performer	Fine-tuned DistilBERT benchmark	Reports best defensible model for final results

refinements introduced throughout the study. The proposed modifications were implemented as evidence-based improvements to address specific limitations that were observed in the baseline architecture rather than arbitrary architectural replacements. Each refinement directly targeted an identified weakness, including the inability of binary classification to isolate violent content, the limited performance of the sequential CNN–GRU structure, the under-representation of the violent class, and the need for a more robust benchmark model. These refinements collectively enhanced class discrimination, improved minority class learning, and strengthened the overall reliability and sensibility of the final experimental results (Appendix).

VI. GEOSPATIAL INTELLIGENCE AND SPATIAL ANALYSIS

It is clarified that the geospatial layer does not serve as an input feature to the classifier nor improve predictive accuracy. It operates as a post-hoc interpretability and operational intelligence layer that maps predictions to route-level coordinates. This allows airlines to identify hubs with concentrated safety-critical narratives and enables targeted interventions (e.g., crew training, security briefings). While the layer does not enhance F1-score, it addresses the 'placelessness' of traditional analytics and provides actionable routing intelligence

A. Geoparsing and Coordinate Mapping

Geospatial Analysis takes place based on real reviews geographically associated with departure and destination nodes. To convert unstructured textual mentions into actionable spatial data, Named Entity Recognition (NER), route metadata, and coordinate mapping are used. Reviews can then be considered as a spatial point and be added together in thematic layers for sentiment and safety analysis.

Fig. 8. Route-level geographic distribution of non-recommended and high-risk airline review flows.

Fig. 8 shows the route-level geographic spread of adverse passenger narratives across major international nodes. The concentration of lines around high-traffic hubs provides spatial context for identifying where negative passenger experiences repeatedly appear in the route network.

B. Route-Level Intelligence and Spatial Visualization

The route-level geographic distribution of adverse passenger narratives by major international nodes are illustrated in Fig. 8. The spatial clustering of lines around hubs with many passengers gives context to the problem areas in the route network that frequently result in poor passenger experiences.

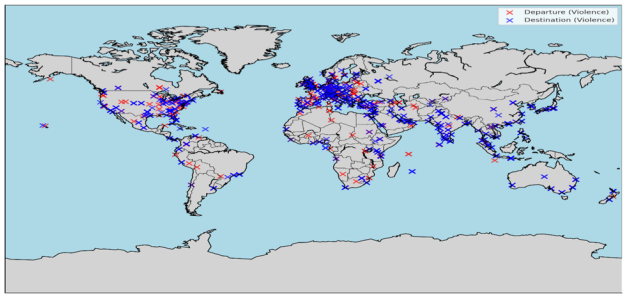

Fig. 9. Departure and destination points associated with violent/aggressive reviews.

Fig. 9 shows the mapped departure and destination nodes associated with violent/aggressive review narratives. The visual separation of departure and destination markers allows the framework to support hub-level and route-level monitoring rather than treating text reviews as location-free observations.

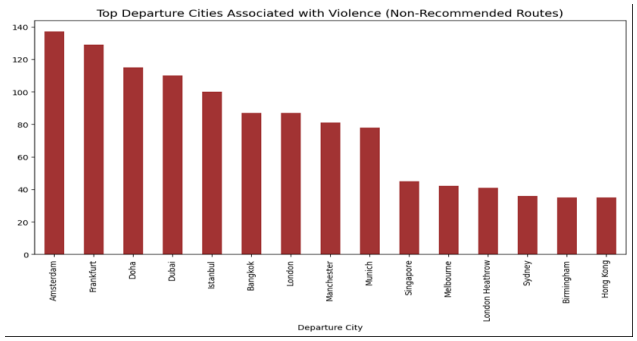

Fig. 10. Top departure cities associated with violent or non-recommended routes.

The frequency pattern of cities is summarized in Fig. 10. These types of visualization can help analysts prioritize hubs

or routes that are repeatedly mentioned in high-risk or poor-experience reviews.

C. Geospatial Intelligence

To move beyond visual descriptive mapping, we applied the local Getis-Ord Gi statistic [(Eq. (1)] to the aggregated risk scores at the hub level. The analysis revealed statistically significant clustering of violent/aggressive narratives. Specifically, three major international hubs exhibited z-scores exceeding the 99% confidence threshold ($p < 0.01$): London Heathrow (LHR) registered a Gi* z-score of 4.12 ($p < 0.001$), John F. Kennedy (JFK) scored 3.87 ($p < 0.001$), and Dubai International (DXB) scored 3.21 ($p < 0.01$). These results confirm that the geographic concentration of high-risk reviews is not due to random variation but represents structured spatial heterogeneity in passenger safety-related feedback.

VII. Limitations and Future Directions

While the new data set and better models used in this study improve the study, there are some limitations. For starters, there are only 300 manually verified real reviews in the violent/aggressive class. This is sufficient to validate the proof of concept, however, is still smaller than the negative and positive classes. Oversampling was done to increase the training exposure, but more real violent/aggressive reviews would increase the generalization.

Second, the violent/aggressive terms were manually identified from the list of candidates identified by contextual keyword search. This method is more dependable than using synthetic information and thus is more reliable; however it can still fail to identify subtleties in the hostile words, such as the inclusion of words that are not explicitly hostile. It is suggested that in future, multi annotator labelling and inter annotator agreement should be taken into consideration to enhance the reliability of the labels.

Third, the geospatial component was reliant upon route, departure, destination, or location metadata. Partial or incomplete reviews may have only partial georeferencing. Therefore, the spatial hotspot analysis should not be regarded as actual incident localization but rather as route/hub-level intelligence.

Fourth, a stratified train-validation-test split was used for the current evaluation. For future studies, temporal, cross-airline, and external dataset validation should be performed to evaluate the model's generalization across temporal, airline, and region levels.

Fifth, all performance comparisons are derived from a single hold-out test set. Statistical significance testing (e.g., cross-validation t-tests) was not performed. While the consistent performance margins across metrics suggest DistilBERT's effectiveness, future work is required to conduct rigorous multi-run validation and hypothesis testing to confirm that these differences are not attributable to random variation.

Six, the empirical evaluation is strictly confined to English-language Skytrax reviews. Generalizability to Twitter, Reddit, airline complaint portals, official incident reports (NTSB/ASRS), or multilingual datasets has not been tested. The results should be interpreted as domain- and platform-specific. Cross-platform and cross-lingual validation is identified as a primary future direction.

Seventh, a systematic qualitative error taxonomy for misclassified violent reviews—specifically addressing implicit threats, sarcasm, and figurative language—is absent. A dedicated human-annotated error analysis and the development of targeted augmentation strategies for these specific linguistic patterns are identified as critical future research directions.

Future research will focus on expanding the real-world violent/aggressive subset, use of official incident reports or cabin crew logs, application of explainability techniques (e.g., SHAP or LIME), and testing of the pipeline within a real-time streaming dashboard setting.

VIII. Conclusion

This research introduced three classes of airline review analysis framework to detect violence in passengers reviews. The proposed study proposed a corrected new dataset by identifying violent/aggressive passenger reviews from ordinary negative and positive reviews. To enhance the dataset, 300 manually verified real airline reviews were added to the original passenger review corpus to obtain 5,765 reviews from three classes of negative, positive, and violent/aggressive reviews. This enhances directly the violence prevention work and decreases reliance on synthetic examples of violence.

The experimental results show that the corrected task was learnable, and that model architecture was crucial to classification performance in safety-critical applications. The original sequential CNN-GRU was not sufficient to perform well in the corrected three-class setting (57% accuracy, 0.22 violent F1), and thus the hybrid model was upgraded to a parallel CNN-BiGRU Attention. This refined hybrid version preserves the original concept while achieving improved performance (83.7% accuracy, 0.79 violent F1). Among all evaluated models, fine-tuned DistilBERT obtained the highest overall performance, with 88% accuracy, 0.874 macro F1-score, and 0.87 violent/aggressive F1-score, demonstrating the value of transformer-based contextual representations for safety-oriented passenger review analysis.

The entire framework was an improved, academically valid foundation for aviation sentiment and aviation violence detection. It combines real-world violent/aggressive review data with leakage-free evaluation, multiple baselines and better model architecture. The system can help airline stakeholders to better understand high-risk passenger experiences and what steps can be taken to prevent future escalation by identifying high-risk passenger narratives, which may indicate aggressive, abusive, security conflict or potential operational safety concerns.

Justification for the architecture refinement. The first sequential CNN–GRU architecture was observed to have limited generalization ability on the corrected real world violent/aggressive subset while performing the reproducibility testing. The proposed hybrid direction was not abandoned and the architecture was changed to parallel CNN–BiGRU Attention model. This retains the original motivation: CNN-based layers capture local indications of aggression, and GRU-

based recurrent layers capture sequential aspects of the passenger narrative context. The attention layer focuses on the most important parts of each review, improving the fusion of features.

APPENDIX

MODEL HYPERPARAMETERS AND ARCHITECTURE DETAILS

For reproducibility, Table X summarizes the core settings used in the optimized experimental pipeline. The final comparison included classical, neural, refined hybrid, and transformer-based models.

TABLE X. CORE HYPERPARAMETER CONFIGURATIONS FOR THE OPTIMIZED MODELS

Parameter	Value/Setting
Random seed	42
Maximum vocabulary size	20,000
Maximum sequence length	200 tokens for neural models; 256 tokens for DistilBERT
Embedding dimension	100 for trainable neural embeddings
TextCNN kernels	2, 3, 4, and 5
Parallel hybrid branches	CNN branch + BiGRU branch + attention pooling
Optimizer	Adam for neural models
DistilBERT learning rate	2×10^{-5}
Evaluation metrics	Accuracy, weighted F1, macro F1, violent/aggressive precision, recall, and F1

CORRECTED DATASET CONSTRUCTION DETAILS

Table XI summarizes the corrected dataset used after adding real manually verified violent/aggressive reviews.

TABLE XI. CORRECTED DATASET DISTRIBUTION AFTER REAL VIOLENT/AGGRESSIVE SUBSET INTEGRATION

Category	Count (before→after)	Description
Negative / not recommended	3,077→ 2,991	Original real airline reviews with negative/non-recommended labels
Positive / recommended	2,388→2,184	Original real airline reviews with positive/recommended labels
Violent/aggressive	300	Manually verified real Skytrax violent/aggressive reviews
Total corpus	**5,765→5,475**	**Corrected three-class dataset**

GEOPARSING GAZETTEERS

The geospatial mapping was aided by route, city, airport, and coordinate metadata. This lookup process supports the conversion of textual route references and airport/city mentions into WGS84 coordinate representations, enabling route-level visualization and hotspot analysis.

Regulatory-Compliant EEG Stress Recognition Using CNN–Transformer Models with Feature Unlearning

Yusra, Riaz UlAmin
Smart Systems Research Lab, University of Okara, Pakistan

***Abstract*—Stress recognition based on EEG data can be useful for healthcare, workplace safety, and mental health monitoring, among other applications. However, most studies do not consider how sensitive EEG data can reveal users' cognitive and affective information. Existing models also do not offer participant data erasure methods that address compliance with data protection regulations (e.g., GDPR). In this regard, we present an improved hybrid Convolutional Neural Network (CNN) and Transformer model with Selective Feature Unlearning. The CNN improves the model's ability to classify EEG signals based on spatial features, while the Transformer model improves classification by capturing the long-range temporal features of EEG data. A major novelty of the proposed framework is the use of Machine Unlearning (MU) to remove participant-specific data without requiring full model retraining. The proposed model also demonstrates that the privacy-aware unlearning model achieves a higher classification accuracy of 96.59%, compared with the baseline model's accuracy of 95.67%. This EEG-based stress recognition system preserves participant privacy without compromising classification performance. The proposed approach can also be adapted to other stress recognition systems and privacy-sensitive applications.**

***Keywords*—EEG; Mental stress recognition; CNN-transformer; machine unlearning; privacy; GDPR compliance**

I. Introduction

Stress recognition based on electroencephalography (EEG) has emerged as an important approach within affective computing, brain-computer interface (BCI) technologies, and mental health monitoring. This technique is completely non-invasive and measures brain activity related to stress. Therefore, it holds promise for the detection of stress in real-time, which is applicable to monitoring people's health, ensuring safety in workplaces, monitoring drivers, and human-computer interaction [1], [2], [3], [4].

Stress-related disorders like chronic stress, anxiety, and depression affect the cognitive functioning, productivity, and well-being of an individual, which explains the urgency for automated systems capable of monitoring stress in real-time. EEG signals, unlike other behavioral signals, such as facial expressions or speech, which can be faked, reflect genuine mental activity, which makes them more trustworthy and valid measures of inner stress [5].

The ability to deep learn EEG data to classify stress has become automated due to feature extraction with the use of multiple channels. In EEG studies, Convolutional Neural Networks (CNNs) are able to determine the spatio-spectral characteristics by finding the connections with the electrodes and frequency bands [6], [7]. The ability to model the dynamic functionality of the brain is done with Recurrent Neural Networks (RNNs) and attention models [8], [9]. For the modeling of long-range compatibility and the ability to capture the complexity of the electroencephalogram (EEG) signals, a more recent model that has been studied is the Transformer architecture [10], [11]. The ability to hybridize a CNN to capture local features and a Transformer to capture the global context has been found to outperform the others in the ability to classify stress [12], [13].

Even though technological advancements have changed at a very fast rate, there are still significant privacy and ethical issues. Recordings of electroencephalography are very sensitive biometric information; they can reveal cognitive elements, mental health conditions, and other personal features, which increases the risk of re-identification and possible abuse [14], [15], particularly in AI-based healthcare systems, data protection laws like the General Data Protection Regulation (GDPR) have also created very strong data protection requirements, including the right to withdraw consent and the right to request the removal of their data [16], [17]. Compared to this, traditional deep-learning models are not designed to erase what has been learned. As a result, the model can still contain sensitive data after removal processes, at a considerable risk of privacy and compliance issues [13], [18].

Many EEG-based stress recognition models focus on optimizing their models for detection accuracy to the point where they do not consider the need to unlearn certain data post-training due to data privacy and compliance issues. For large-scale systems, this becomes an expensive ordeal along with having to retrain models after removing sensitive data [19]. Furthermore, the unique and subjective characteristics of EEG signals, along with their increased levels of noise and dimensionality, contribute to the difficulty of generalization and the retention of residual information [20], [21]. Machine unlearning is an emerging alternative that allows models to disregard the need for retraining by providing the ability to unlearn the influence of certain data points from training [22], [23].

This study outlines a privacy-preserving approach that combines a hybrid CNN–Transformer model with selective feature unlearning to tackle the problems of privacy protection and regulatory compliance in stress recognition using EEG signals. However, CNN–Transformer models have been the most popular methods in EEG analysis, and machine unlearning is a new privacy-preserving method; however, these methods have been studied separately. The proposed framework applies to a given CNN, freezes the lower layers of it that capture EEG representations in general (shared across all participants), and selectively updates the higher layers containing participant-specific information. This approach allows for effective data removal of sensitive information with minimal computation

and preserves stress classification accuracy. Moreover, the proposed framework employs a unified solution for accurate, privacy-preserving, and GDPR-compliant EEG stress recognition with embedding privacy evaluation metrics and GDPR-oriented design principles. The overall framework is illustrated in Fig. 1.

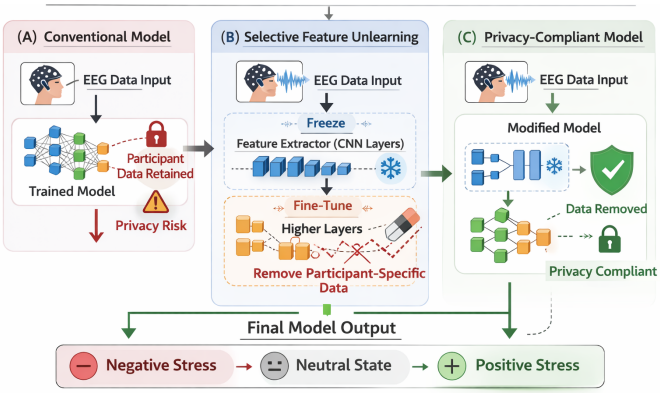

Fig. 1. EEG stress recognition framework. Three stages: (A) Conventional model, (B) Selective feature unlearning, (C) Privacy-compliant model producing negative, neutral, and positive stress classifications.

To demonstrate the practical applications of our proposed framework, the following case studies illustrate how EEG-based stress recognition systems have been implemented in real-world settings, highlighting both the effectiveness of the model and its ability to comply with privacy regulations.

II. Case Studies

A. Health Workers in a Hospital Setting

Healthcare workers in hospitals, especially in emergency departments, are in high-stress jobs and are prone to burnout. For this purpose, the deployment of a system to monitor stress levels using EEG was implemented in a hospital. The system categorizes the stress levels of the workers into Negative, Neutral, and Positive levels, and they wear EEG headbands. This enabled real-time stress interventions, such as the provision of breaks and mental health support. The system uses selective feature unlearning, which deletes information to respect privacy rules such as GDPR.

B. University Students During the Exam

University students tend to have high examination stress, which may be harmful to their mental health and learning. A stress recognition system based on EEG signals was developed to identify students' stress levels. Students wore EEG devices while reading, and the system classified the stress levels during reading as Negative, Neutral, and Positive and gave post-reading feedback to help the students use stress-reducing strategies. In compliance with GDPR, the system was leveraged for the students' well-being through the use of selective unlearning.

Case studies presented are meant to illustrate deployment scenarios that can be used to showcase the application of the proposed framework in healthcare and education settings. They are not clinical or empirical user studies. Therefore, in the current work, usability, system latency, user acceptance, and long-term system performance were not assessed. Pilot deployments in real-world environments will be carried out in the future to evaluate the practical feasibility, user experience, deployment latency, and regulatory compliance during operation.

III. Related Work

EEG-based recognition of mental stress has improved noticeably owing to the need for objective and continuous monitoring of stress for use in brain–computer interfaces (BCIs), workplace safety, driver monitoring, and adaptive human–computer interaction [20], [24]. Chronic stress, anxiety, and depression-related disorders affect cognitive function, productivity, and overall health [25], [26]. Recent studies have been directed toward fully automated systems aimed at recognizing stress with greater accuracy using EEG signals, especially in the case of deep learning models, which are capable of learning the most discriminative, relevant, and useful spatiotemporal patterns of multichannel EEG recordings.

On the SAM40 dataset, Acharya et al. (2025) used Convolutional Neural Networks (CNNs) to achieve an accuracy of 87%. This demonstrates the potential of CNNs for capturing the spectral and spatial features of EEG signals. The absence of stress classification in terms of subjects is mentioned; however, because of the noise in the EEG data [20]. Similarly, Hyung et al. (2025) proposed a CNN-RNN model that performs temporal fusion of spatial features and stress detection. This model achieved 90% accuracy on the SAM40 dataset, outperforming previous machine learning models, including Support Vector Machines (SVMs). However, in the broader context of this model, limitations such as latency and computation have been mentioned [24].

Kim et al. (2022) utilized a CNN model that incorporated 3D convolutional layers to obtain spatiotemporal characteristics from EEG data, resulting in a stress classification accuracy of 88.5%. This model is good at feature extraction, but its ability to generalize to other subjects is always difficult because of the variability of EEG data.

[27]. Wang and Duan (2025) introduced a model that combined CNN and LSTM, thus being able to manage EEG signals with 91% accuracy, thus being one of the most precise models to date regarding subject-independent stress detection. However, this model still poses issues when considering its widespread application [28].

The self-attention mechanism enables transformer-based models to capture and analyze long-range temporal dependencies. Consequently, these models are becoming increasingly common in the EEG analysis industry. For example, Vafaei et al. (2025) claimed that these models significantly outperform others when recognizing stress [29]. Furthermore, he encouraged researchers to examine hybrids of CNN and Transformers because of the potential for better stress detection by capturing local and global features. Similarly, Lloyd (2024) presented EEG analysis as a fine-tuning task of the stress detection Transformers' foundation models, resulting in the enhancement of the models' generalization and elevation of the models' stress detection abilities [30]. Although model performance has improved, concerns regarding privacy risks

remain a significant challenge when integrating EEG-based stress recognition systems. EEG data reflects and targets cognition, as such EEG data poses a danger of re-identification and data misuse

[17], [31], [32]. Model performance issues and privacy risks may affect stress recognition systems. The General Data Protection Regulation (GDPR) and other data privacy regulations incorporate an individual's right to be forgotten, stressing that compliant models need mechanisms to 'forget/unlearn' data, especially sensitive data [16].

Unlearning models have gained traction in the area of privacy concerns. Unlearning models are a method of machine learning in which the model can forget training data without a full retraining of the model. This was described in the privacy context by Cao and Yang (2015) since model retraining was a way of complying with privacy regulations and a form of data disposal [22]. Bourtoule et al. (2019) and Guo et al. (2020) advanced the concept of model unlearning by optimizing methods of erasing data and providing proof of data erasure and its corresponding influence on the model [23], [33]. Liu et al. (2025) and Koloskova et al. (2025) continued the research on deep neural network unlearning frameworks and proposed that these frameworks can be useful for mitigating privacy concerns in deep learning systems, such as EEG-based stress recognition [34], [35]. [36] presented machine learning processes with unlearning algorithms that respect the General Data Protection Regulation (GDPR) without compromising the model's usefulness. Although there have been several advances in the recognition of human stress using EEG, most current models focus on classification accuracy and fail to consider unlearning and the speed of data removal. There is a tremendous lack of privacy-preserving systems that stress high accuracy and forget sensitive data. Therefore, this study combines selective feature unlearning with CNN-transformer hybrid models to achieve the best of both worlds and achieve compliance with privacy protection in actual applications.

IV. Proposed Methodology

This study proposes a privacy-conscious EEG-based mental stress recognition system that consists of a hybrid CNN–Transformer classifier and selective feature unlearning. It is based on a model that identifies three types of stress: NEGATIVE, NEUTRAL, and POSITIVE, according to multichannel EEG data recorded under stress induction and relaxation conditions. The model was structured into three major steps. Raw EEG data are first processed, such as by eliminating artifacts, filtering, and segmentation, to prepare standard input segments for analysis. A hybrid CNNTransformer network was used in the second stage to extract the discriminative features of the EEG data. CNN layers encode local spatial and spectral patterns in multiple channels and frequency bands, whereas transformer layers encode longer-range temporal interactions, which enhances the generalizability of the model to a broader range of subjects with variations in brain activity patterns. The application of selective feature unlearning is in the third stage, where it is used to eliminate information that is specific to participants. This can be achieved by updating some of the layers on top of the model while maintaining frozen generalizable feature extractors.

The process of unlearning minimizes the retention of residual information, which means that privacy will be ensured without necessarily retraining the entire model. This framework, with the addition of selective feature unlearning, allows balancing the requirements of precise stress detection with the high privacy rates it provides, making it suitable for practical applications where data privacy is a key factor. The model consists of three major steps, as illustrated in Fig. 2, which begin with the preprocessing of the EEG data through a privacy-preserved output, making it adhere to data protection criteria.

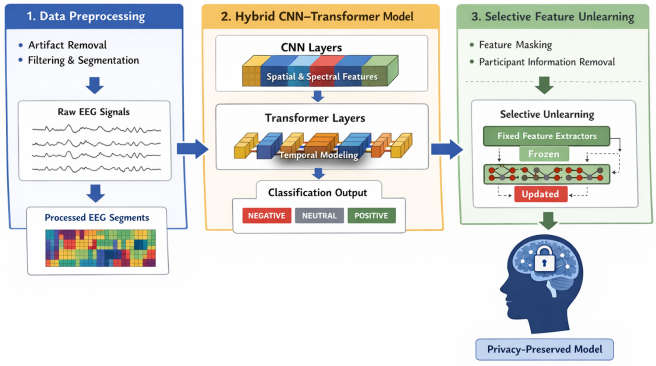

Fig. 2. EEG-based stress recognition framework.

A. Dataset

We performed testing on the EEG dataset of SAM40 induced-stress, through its Kaggle distribution. The data included recordings of 40 healthy participants (14 females, 26 males; mean age of 21.5 years) while they completed short cognitive tasks that would provoke short-term episodes of stress, that is, the Stroop color-word test, mental arithmetic, and mirror-image recognition, and the relaxation condition. The duration of each condition was 25 s, and each condition was performed three times by each participant. EEG data were recorded with a Emotiv EPOC Flex gel kit 32 channels and later divided into non-overlapping 25s epochs depending on the task conditions. The released information includes baseline-drift correction with a Savitzky–Golay trend estimate and artifact reduction with wavelet-based denoising using wavelet thresholding. [21], [37].

Task epochs during downstream learning were divided into three tripartite stress labeling constructs: NEGATIVE, NEUTRAL and POSITIVE. The EEG spectral correlates most frequently reported, such as theta, alpha, beta, and band-ratio patterns represented by the representative levels of symptoms, can be seen in Fig. 3. These EEG correlates are related to different levels of stress, where certain fluctuations in frequency bands provide information on the mental state of the subject. Fig. 4 shows a schematic of the coverage of the scalp during EEG recording, with the main cortical areas representative of the areas of interest in the stress-related EEG rhythms, which include the frontal, temporal, parietal, and occipital areas of the scalp.

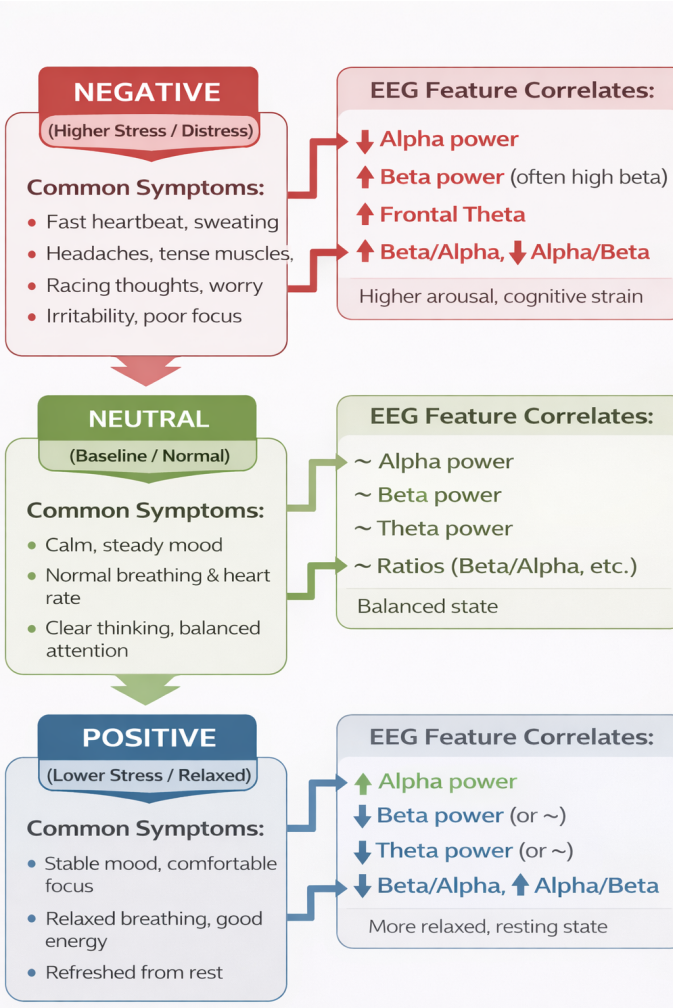

Fig. 3. Symptoms and typical EEG correlates.

V. Data Preprocessing

This study outlines a series of steps taken during data preprocessing to enable the classification of EEG stress states under three affective conditions (negative, neutral, and positive). The objectives of data preprocessing are 1) removing non-neural artifacts and other artifactual noise, 2) baseline drift artifacts of low frequencies, 3) segmentation of continuous recordings into organized training sets, and 4) data harmonization to facilitate rigid model training.

A. Artifact Removal and Denoising

Electroencephalographic (EEG) recordings are susceptible to various disturbances. These include ocular artifacts, such as eye blinks, muscular artifacts, artifacts related to electromyographic (EMG) activity, and electrical noise from power lines or similar sources. These artifacts may obscure the neurophysiological correlates of psychophysiological stress. Therefore, artifact suppression procedures were performed before epoch segmentation and feature extraction.

1) Independent Component Analysis (ICA): ICA separates neural activities and artifacts (such as eye blinks and facial muscle activities) by decomposing multiple EEG channels into statistically independent components. This process identifies and removes artifactual components while maintaining neural activities for further analyses [38].

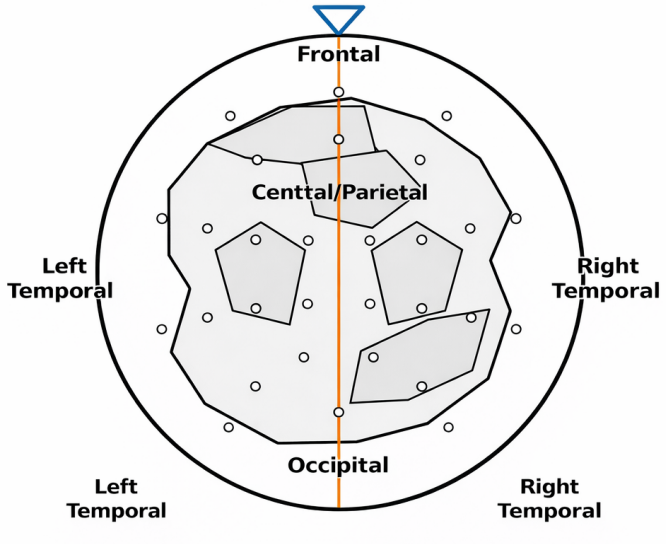

Fig. 4. Schematic of scalp EEG acquisition and major cortical regions (frontal, temporal, parietal, occipital) relevant to stress-related EEG rhythms.

ICA decomposition is provided by:

$$\mathbf{X} = \mathbf{AS}, \tag{1}$$

In Eq. (1), $\mathbf{X} \in \mathbb{R}^{n \times t}$ is the EEG matrix, $\mathbf{A}$ is the mixing matrix and, $\mathbf{S}$ includes the independent source components, which consist of neural activities and artefacts.

2) Band-pass filtering: A band-pass filter is applied to filter out slow drift and high frequency noise to keep only the relevant EEG rhythms to stress after ICA-based cleanup [39].

The filter response function is defined as follows in Eq. (2) :

$$H(f) = \begin{cases} 1 & \text{if } f_{\text{low}} \leq f \leq f_{\text{high}}, \\ 0 & \text{otherwise.} \end{cases} \tag{2}$$

This filter will focus on the meaninful frequencies which are theta, alpha, and beta bands, which are related to cognitive and affective processing during stress.

The theta band which ranges from 4 to 8 Hz is associated with relaxation and cognitive load, while the alpha band lying between 8 and 12 Hz is related to calmness and focused attention. The beta band which ranges from 13 to 30 Hz is associated with alertness and mental strain which are the main bands used for stress detection.

B. Baseline Drift Correction

EEG recordings can show slow drift artifacts due to variations in electrode impedance, motion, or non-cerebral physiological phenomena. Savitzky–Golay smoothing/detrending was used for these adjustments [40].

The smoothing step can be defined as follows:

$$\hat{y}(t) = \sum_{k=-m}^{m} c_k y(t+k), \tag{3}$$

In Eq. (3), $y(t)$ is the original signal and $\hat{y}(t)$ is the smoothed signal. The parameter m specifies the half-window length. The smoothing step removes the drift component to obtain the detrended signal.

C. Segmentation and Windowing

The continuous EEG data after cleaning processing is segmented into epochs of fixed length which allows for samples of the data to be created to be aligned with the labeling scheme (Negative, Neutral, Positive) [41]. For segmentation defined with a window of length samples T, this is defined in In Eq. (4):

$$\mathbf{x}^{(i)} = \big[x(i), x(i+1), \ldots, x(i+T-1)\big]. \tag{4}$$

This segmentation enables the capture of short-term temporal dynamics of the stress responses and allows for the creation of consistent input sizes for the computation of the features and training of the model.

D. Normalization and Scaling

To decrease the inter-subject/session amplitude variability as well as to prevent learning from being dominated by channels or features of larger magnitude, Z-score normalization was used [42]. This is defined as:

$$Z = \frac{X - \mu}{\sigma}, \tag{5}$$

In Eq. (5) X is the signal (or feature) value, μ is the mean value and σ is the standard deviation which for this case is calculated per channel using training data only. This process guarantees that the signal or features are zero mean and unit variance which improves numerical stability and accelerate the convergence during training.

E. Class Balancing (SMOTE)

In cases where class distribution is imbalanced (e.g., fewer Negative-stress epochs), SMOTE (Synthetic Minority Oversampling Technique) is used to oversample minority classes in the training set only to avoid data leakage [43]. Synthetic samples are generated by interpolating between a minority sample and one of its nearest minority neighbors:

$$\mathbf{x}\text{new} = \mathbf{x}i + \lambda\big(\mathbf{x}\text{nn} - \mathbf{x}i\big), \tag{6}$$

In Eq. (6) $\mathbf{x}i$ is a minority-class sample, and $\mathbf{x}$nn is the nearest neighbor from the minority class. The parameter $\lambda \in [0, 1]$ controls the interpolation factor, balancing the class distribution in the training set.

VI. Feature Engineering for EEG-Based Stress Classification

Following preprocessing, feature engineering transforms each EEG epoch into informative representations that capture stress-related patterns. Features are extracted from complementary domains (time, frequency, and time–frequency), optionally reduced/selected to limit redundancy, and then standardized for classification.

1) Time-domain features: Time-domain descriptors capture the statistical characteristics of the EEG waveform within a predetermined epoch. These features provide a sense of the average signal magnitude, the variability, and the distribution of the signal across a period of time, which may be useful for identifying changes related to stress.

$$\begin{aligned} \mu &= \frac{1}{T}\sum_{t=1}^{T} x_t, \\ \sigma &= \sqrt{\frac{1}{T}\sum_{t=1}^{T}(x_t - \mu)^2}, \\ \text{RMS} &= \sqrt{\frac{1}{T}\sum_{t=1}^{T} x_t^2}. \end{aligned} \tag{7}$$

In Eq. (7), In the equations, the symbols represent μ is the mean, σ as standard deviation, and RMS as the Root Mean Square functions which help in ascertaining the signal's strength for a particular epoch. The mean determines the signal's baseline, standard deviation shows the fluctuation of the signal relative to the baseline, and the RMS determines the total strength of the signal. Other measures related to morphology include peak-to-peak amplitude:

$$\text{P2P} = \max(x_t) - \min(x_t), \tag{8}$$

In the Eq. (8), P2P (Peak-to-Peak amplitude) captures the difference between the maximum and minimum values of the signal over the epoch, which indicates how much this signal varies.

And for the shape of the distribution:

$$\begin{aligned} \text{Skewness} &= \frac{1}{T}\sum_{t=1}^{T}\left(\frac{x_t - \mu}{\sigma}\right)^3, \\ \text{Kurtosis} &= \frac{1}{T}\sum_{t=1}^{T}\left(\frac{x_t - \mu}{\sigma}\right)^4 - 3. \end{aligned} \tag{9}$$

In the Eq. (9), Skewness measures the asymmetry of the signal distribution, and Kurtosis quantifies the distribution's tail. There is positive skewness, meaning that asymmetry is perceived more on the right side, and negative skewness is perceived on the left side. More extreme values are associated with higher kurtosis (i.e., more heavy tails), and with lower kurtosis the tails are lighter (fewer extreme values).

These measures capture the variability, intensity, and distribution of waveforms related to stress.

2) Frequency-domain features: The features in the frequency domain measure the distribution of signal energy across various EEG rhythms. For every epoch, the Power Spectral Density (PSD) is calculated. The band power is calculated as the integral of PSD across specified frequency bands:

$$P_{\text{band}} = \int_{f_{\text{low}}}^{f_{\text{high}}} \text{PSD}(f)\, df \tag{10}$$

In this Eq. (10), the band power ((Pband)) is derived as the integral of Power Spectral Density (PSD) across the frequency limits (flow) and (fhigh). This measurement is significant as stress can be related to the noticeable changes in the alpha/beta activity and the associated patterns of spectral power.

3) Time-frequency features: The features in the time-frequency domain can analyze short-term changes in the spectrum of the signal throughout the epoch. These features are useful in identifying the stress responses that change over time.

a) Wavelet Transform (WT): In this Eq. (11), the variable $W(a, b)$ signifies Wavelet Transform (WT). The parameters a and b determine scale (which corresponds to frequency) and time localization, respectively. ψ^* , is the complex conjugate of the wavelet function. The Wavelet Transform is in particular suitable for the study of non-stationary signals such as EEG which varies with time. By manipulating the parameter scale a, we can examine various frequencies and parameter b shifts the wavelet for temporally capturing the signal's dynamics.

$$W(a, b) = \int_{-\infty}^{\infty} x(t)\, \psi^*\left(\frac{t-b}{a}\right) dt, \tag{11}$$

b) Short-Time Fourier Transform (STFT): In Eq. (12), **STFT** abbreviates to **Short-Time Fourier Transform**. It helps to capture the variation of frequencies that make up the signal at different point in time. The function $w(t-\tau)$ is a sliding window centered at τ, and $e^{-j2\pi ft}$ is the Fourier kernel. Because the STFT is designed to capture **transients**, it is most effective at analyzing signal streams during which the frequency information is time-dependent, such as time-dependent stress responses.

$$\text{STFT}(\tau, f) = \int_{-\infty}^{\infty} x(t)\, w(t-\tau)\, e^{-j2\pi ft}\, dt, \tag{12}$$

These characteristics are well articulated to stress responses that fluctuate in a dynamic manner.

A. Dimensionality Reduction

Due to the potentially high dimensionality of the feature sets obtained using EEG recordings (number of channels $\times$ number of features), it is sometimes useful to apply dimensionality reduction in order to enhance generalization and minimize computing costs.

1) Principal Component Analysis (PCA): PCA reduces the dimension of the feature matrix $\mathbf{X}$ to a subspace of lower dimension while retaining the greatest amount of variance:

$$\mathbf{Y} = \mathbf{X}\mathbf{W}, \tag{13}$$

In Eq. (13) columns of $\mathbf{W}$ are principal directions and $\mathbf{Y}$ is the reduced representation.

2) Linear Discriminant Analysis (LDA): LDA is a method of supervised dimensionality reduction which identifies the projections that will maximize the discrimination between classes:

$$\mathbf{W} = \arg\max_{\mathbf{W}} \frac{\mathbf{W}^T \mathbf{S}_B \mathbf{W}}{\mathbf{W}^T \mathbf{S}_W \mathbf{W}}, \tag{14}$$

In Eq. (14) $\mathbf{S}_B$ and $\mathbf{S}_W$ are between-class and within-class scatter matrices.

B. Feature Selection

Feature selection is useful for improving the interpretability of the model and for reducing the risk of overfitting by removing variables that are redundant or weakly informative.

1) Chi-square test: When dealing with discrete features or features that have been made discrete, the chi-square test is used to evaluate the degree of dependency of each feature with respect to the class label.

$$\chi^2 = \sum \frac{(O_i - E_i)^2}{E_i}, \tag{15}$$

In Eq. (15), χ^2 is the **chi-square statistic**, while (Oi) is the observed frequency, and E_i is the expected frequency for each feature. This expression is a measure for the degree to which the observed frequencies diverge from that of the expected frequencies where it is assumed that there is no causal relation between the feature and the class label. A larger value of χ^2 indicates that there is a stronger association between the feature and the class label. For that reason, features with stronger associations to the label are kept.

C. Final Feature Scaling

Once the feature extraction (including any selection or reduction) has been performed, features are scaled to ensure that each one contributes equally to the classifier. This is particularly important for distance-based classifiers, where unscaled features with larger ranges can dominate the model's behavior.

If applicable, features undergo Min-Max scaling as defined by:

$$X_{\text{scaled}} = \frac{X - X_{\min}}{X_{\max} - X_{\min}}, \tag{16}$$

In Eq. (16), X_{scaled} is the scaled feature, X is the feature before scaling, $X_{\min}$ is the minimum value of the feature, and $X_{\max}$ is the maximum value of the feature. **Min-Max scaling**

rescales the feature to a range between 0 and 1. This scaling technique is useful to ensure that all features contribute equally to the model, regardless of whether a feature is 0.1, 1, or 1000.

Z-score standardization is the other method used to standardize the feature by subtracting the mean and dividing by the standard deviation:

$$Z = \frac{X - \mu}{\sigma}. \tag{17}$$

According to the Eq. (17), features are represented as standardized Z, original X, with μ as the mean of the feature and σ as the standard deviation of the feature. Z-score standardization modifies features so that they have a mean of 0 and a standard deviation of 1, thereby making the features suitable for algorithms that presume a normal distribution of the data.

In order to prevent leakage, the scaling parameters (minimum, maximum, mean, and standard deviation) are derived solely from the training set and subsequently applied to the validation and testing sets. This guarantees that no data from the validation and testing sets influences the training.

VII. Model Architecture

The EEG-based stress classification model under consideration employs a Hybrid CNN + Transformer framework to develop a model of three affective states (Negative, Neutral, and Positive) utilizing the EEG segments as input. Considering an EEG segment $\mathbf{X} \in \mathbb{R}^{C \times T}$ (with C channels and T time samples), the CNN branch captures local features and short-term variations of EEG to construct an embedding:

$$\mathbf{z}_{\text{CNN}} = f_{\text{CNN}}(\mathbf{X}) \tag{18}$$

In Eq. (18), where, f_{CNN} represents a composition of {Conv2D, max-pooling, batch normalization, flatten, and dense}. The input data is restructured to suit the 2D map for Conv2D cartesian processing. Simultaneously, the Transformer component simulates the long-range time-series dependencies by embedding the order of the time-series via positional encoding as follows:

$$\mathbf{H}_0 = \mathbf{X} + \mathbf{P} \tag{19}$$

In Eq. (19), where, $\mathbf{P}$ is the positional encoding matrix.

The positional encoding preserves the temporal order of EEG samples by adding a fixed sinusoidal encoding to the input sequence embeddings before they are processed by the Transformer. This enables the self-attention mechanism to distinguish the relative positions of EEG time samples and effectively capture temporal dependencies within the EEG signals.

The primary computational tool of the Transformer architecture is the scaled dot-product self-attention mechanism, defined as follows:

$$\text{Attn}(\mathbf{Q}, \mathbf{K}, \mathbf{V}) = \text{softmax}\left(\frac{\mathbf{Q}\mathbf{K}^\top}{\sqrt{d_k}}\right)\mathbf{V}, \tag{20}$$

In Eq. (20), where, $\mathbf{Q}$, $\mathbf{K}$, and $\mathbf{V}$ are the query, key, and value projections, and d_k is the key dimensionality for scaling. Multi-head self-attention applies in h parallel subspaces, as described in:

$$\begin{aligned} \text{head}_i &= \text{Attn}(\mathbf{H}_0\mathbf{W}_i^Q, \mathbf{H}_0\mathbf{W}_i^K, \mathbf{H}_0\mathbf{W}_i^V),\ i = 1, \ldots, h, \\ \mathbf{z}_{\text{TR}} &= \big[\text{head}_1 \,\|\, \cdots \,\|\, \text{head}_h\big]\mathbf{W}^O, \end{aligned} \tag{21}$$

In Eq. (21), where, $\mathbf{W}_i^Q, \mathbf{W}_i^K, \mathbf{W}_i^V$ and $\mathbf{W}^O$ are learnable projection matrices. A position-wise feed-forward network (256 units, ReLU) with dropout ($p = 0.5$) further refines $\mathbf{z}_{\text{TR}}$ into a temporally informed embedding. The outputs of both branches are fused by concatenation:

$$\mathbf{z} = \big[\mathbf{z}_{\text{CNN}} \,\|\, \mathbf{z}_{\text{TR}}\big], \tag{22}$$

After concatenation, the fused feature vector is processed through fully connected layers with nonlinear activation and dropout before Softmax classification. These layers learn a balanced joint representation from both the CNN and Transformer branches, reducing the likelihood that the final prediction is dominated by either branch.

followed by two fully connected layers (128 units each, ReLU) and a Softmax classifier that outputs the final class probabilities:

$$\hat{\mathbf{y}} = \text{softmax}(\mathbf{W}\mathbf{z} + \mathbf{b}), \tag{23}$$

where, $\hat{\mathbf{y}} = [\hat{y}_{\text{Neg}}, \hat{y}_{\text{Neu}}, \hat{y}_{\text{Pos}}]$ and $\sum_k \hat{y}_k = 1$. This flow ensures the CNN learns discriminative local EEG features, while the Transformer captures global temporal context. The fused vector in supports robust three-class stress classification in Eq. (23). The combined layer-wise architecture of the proposed Hybrid CNN + Transformer model, including the CNN branch, Transformer branch, and fusion classifier, is summarized in Table I. And Fig. 5 Proposed Hybrid CNN + Transformer architecture for EEG-based stress classification (Negative, Neutral, Positive). The model consists of a CNN branch for spatial feature extraction, a Transformer branch for capturing temporal dependencies, and a fusion classifier for final stress state prediction. Both branches are presented with the same EEG input, but learn complementary representations. The CNN branch mainly learns local spatial and frequency features from neighboring electrodes, whereas the Transformer branch learns long-range temporal features using the self-attention mechanism. This means that the Transformer gives global contextual information, which the CNN does not have, and adding both representations improves the accuracy of stress classification. This proposed framework takes a hybrid approach to the learning pipeline instead of an end-to-end approach. The EEG signals are preprocessed and feature extracted to enhance the quality of the signals, and the preprocessed signals are fed into the CNN–Transformer model for spatial and temporal feature learning. Future work is planned to include an ablation study to determine the contribution of each component.

TABLE I. LAYER-WISE SUMMARY OF THE PROPOSED HYBRID CNN + TRANSFORMER MODEL (CNN BRANCH + TRANSFORMER BRANCH + FUSION CLASSIFIER)

Branch	Layer (type)	Output Shape	Params #
CNN	Input (2D map)	(None, H, W, C_{in})	0
CNN	conv2d (Conv2D, 64, 7×7, ReLU)	(None, H_1, W_1, 64)	$(7\times7\times C_{\text{in}}+1)\times64$
CNN	max_pooling2d (MaxPool2D, 2×2)	(None, H_2, W_2, 64)	0
CNN	conv2d_1 (Conv2D, 64, 3×3, ReLU)	(None, H_3, W_3, 64)	$(3\times3\times64+1)\times64$
CNN	batch_norm (BatchNorm)	(None, H_3, W_3, 64)	4×64
CNN	conv2d_2 (Conv2D, 64, 3×3, ReLU)	(None, H_4, W_4, 64)	$(3\times3\times64+1)\times64$
CNN	batch_norm_1 (BatchNorm)	(None, H_4, W_4, 64)	4×64
CNN	conv2d_3 (Conv2D, 128, 3×3, ReLU)	(None, H_5, W_5, 128)	$(3\times3\times64+1)\times128$
CNN	batch_norm_2 (BatchNorm)	(None, H_5, W_5, 128)	4×128
CNN	conv2d_4 (Conv2D, 256, 3×3, ReLU)	(None, H_6, W_6, 256)	$(3\times3\times128+1)\times256$
CNN	batch_norm_3 (BatchNorm)	(None, H_6, W_6, 256)	4×256
CNN	max_pooling2d_1 (MaxPool2D, 2×2)	(None, H_7, W_7, 256)	0
CNN	flatten (Flatten)	(None, N_f)	0
CNN	dense_cnn (Dense, 128, ReLU)	(None, 128)	$(N_f+1)\times128$
CNN	dropout (Dropout, 0.5)	(None, 128)	0
TR	Input (sequence)	(None, T, C)	0
TR	proj (Dense to d_{model})	(None, T, d_{model})	$(C+1)\times d_{\text{model}}$
TR	positional encoding	(None, T, d_{model})	0
TR	multi-head self-attn (MHA)	(None, T, d_{model})	$4d_{\text{model}}^2+4d_{\text{model}}$
TR	add & layernorm	(None, T, d_{model})	$2d_{\text{model}}$
TR	FFN Dense 1 (ReLU, d_{ff})	(None, T, d_{ff})	$d_{\text{model}}d_{ff}+d_{ff}$
TR	FFN Dense 2	(None, T, d_{model})	$d_{ff}d_{\text{model}}+d_{\text{model}}$
TR	dropout (Dropout, 0.5)	(None, T, d_{model})	0
TR	add & layernorm	(None, T, d_{model})	$2d_{\text{model}}$
TR	global avg pool (or CLS)	(None, d_{model})	0
Fusion	concatenate $[\mathbf{z}_{CNN}\|\mathbf{z}_{TR}]$	(None, $128+d_{\text{model}}$)	0
Fusion	dense_f1 (Dense, 128, ReLU)	(None, 128)	$(128+d_{\text{model}}+1)\times128$
Fusion	dropout (Dropout, 0.5)	(None, 128)	0
Fusion	dense_f2 (Dense, 128, ReLU)	(None, 128)	$(128+1)\times128$
Fusion	output (Dense, Softmax, 3)	(None, 3)	$(128+1)\times3$

VIII. SELECTIVE FEATURE UNLEARNING AND PRIVACY PRESERVATION

Once training is complete on the Hybrid CNN and Transformer model architecture, the model captures the generalizable features along with the participant specific features. The next step is to implement techniques to ensure participant specific features which may be sensitive and concerning, will be removed from the model. While the model has to ensure that it will retain the ability to generalize to new participant and new stress classification tasks. The unlearning is critical to achieve compliance for privacy concerns, particularly with sensitive EEG data.

Almost all of the unlearning techniques will encourage participant specific data to be removed. This is done after training is complete and participant specific data is removed, unlearning techniques preserve model generalization.

A. Freezing Generalizable Features in CNN Layers

An initial step in unlearning techniques is to freeze the bottom most layers of the CNN model. These layers tend to capture generalizable neural features that are common among all the participants. These general features include patterns of brainwave activity which are used to capture the EEG signals at a higher level. These patterns are not specific to individuals, hence rest of unlearning techniques will ensure that the model does not learn participant sensitive data. Only the general features from all of the participants will be retained.

From a mathematical standpoint, freezing can be articulated as:

$$\Delta \mathbf{W}_{\text{CNN}} = 0 \tag{24}$$

In Eq. (24), where,

- $\mathbf{W}_{\text{CNN}}$ represents the weights of the lower layers of the CNN. - $\Delta \mathbf{W}_{\text{CNN}} = 0$ means that the weights of these layers will remain unchanged during the unlearning process.

By freezing these layers, we make certain that the model maintains its comprehension of universal EEG characteristics whilst excluding the learning of participant-specific characteristics. This process is important for the model to continue having the ability to generalize across various participants.

B. Fine-Tuning Higher Layers for Selective Forgetting

Once the lower layers have been frozen, the next step involves fine-tuning the upper layers of the CNN, which have been identified as capturing participant-specific neural signatures that may possibly contain sensitive participant-specific details. The objective of this fine-tuning process is to delete sensitive information, while keeping that knowledge which is unalterable and generalizable from the lower layers. This is done by the implementation of a forget loss function, which considers the model to have retained participant-specific features and thus, incentivizes the model to "forget" those features.

The forget loss function can be expressed as:

$$\mathcal{L}_{\text{forget}} = \lambda \sum_{i \in \text{forget set}} \|\mathbf{f}_i - \mathbf{f}_i^{\text{unlearned}}\|^2 \tag{25}$$

In Eq. (25), where,

- $\mathbf{f}_i$ represents the original features for participant i before unlearning. - $\mathbf{f}_i^{\text{unlearned}}$ represents the features after unlearning,

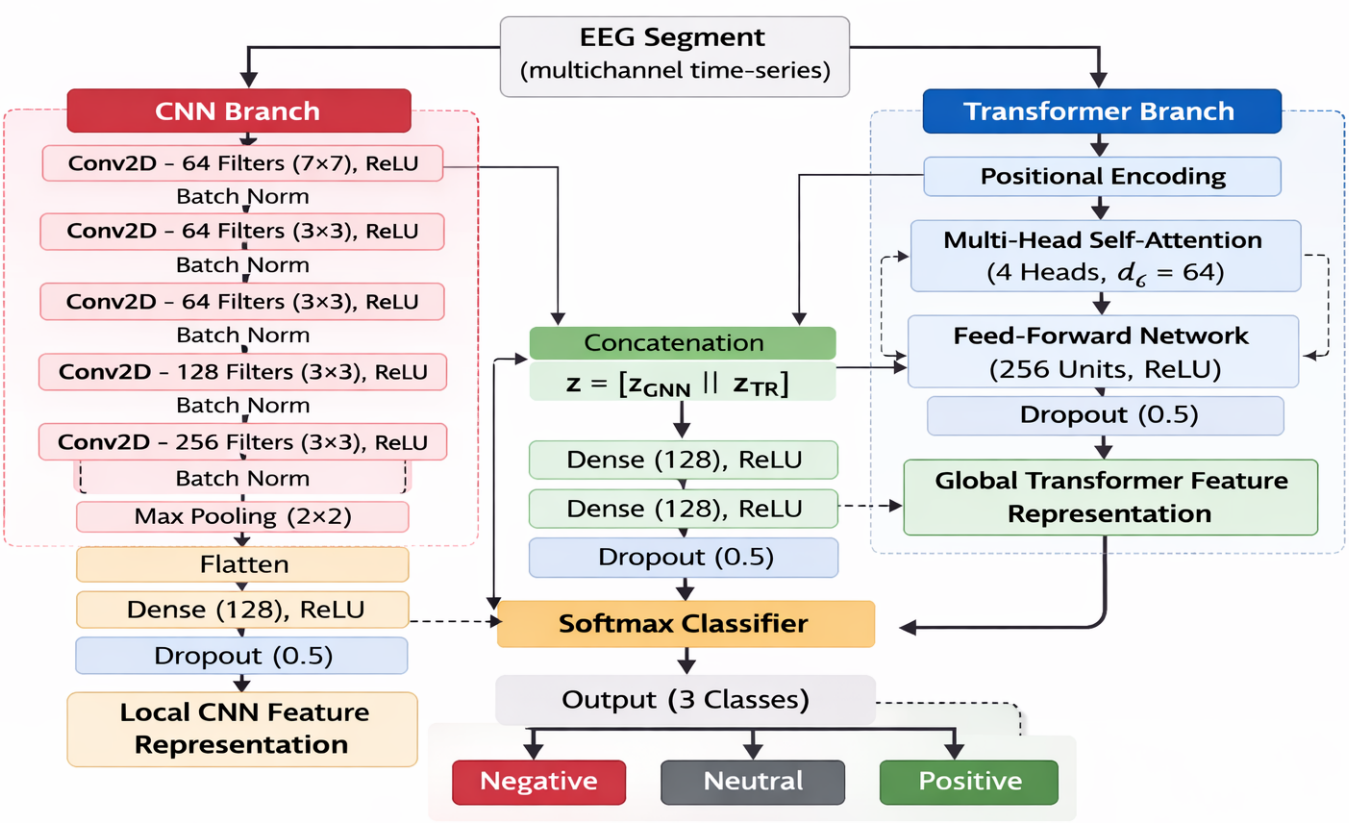

Fig. 5. Proposed hybrid CNN + transformer architecture for EEG-based stress classification (negative, neutral, positive).

once sensitive data has been removed. - λ is a regularization parameter that controls the strength of the forget loss. A higher value of λ gives more importance to erasing participant-specific data.

This fine-tuning process modifies the weights of the upper layers of the CNN, allowing for the obfuscation of participant-specific characteristics while retaining the useful generalizable features. This enables the model to omit individual-specific sensitive data, while remaining effective in identifying stress states.

IX. Unlearning Process and Gradient-Based Unlearning

In the unlearning process, the term gradient-based unlearning refers to the ability of the model to adjust certain weights in order to remove the data of certain participants. Unlike full retraining, gradient-based unlearning modifies only the layers that are sensitive, and therefore the other layers of the model are unaffected. This allows the model to retain its generalizable characteristics while removing participant-specific data.

The rule for updating weights during unlearning is described as follows:

$$\mathbf{W}_{\text{high}}^{(t+1)} = \mathbf{W}_{\text{high}}^{(t)} - \eta \nabla_{\mathbf{W}_{\text{high}}} \mathcal{L}_{\text{forget}} \tag{26}$$

In Eq. (26),

- $\mathbf{W}_{\text{high}}$ represents the weights of the higher layers of the CNN, which capture individual-specific features. - $\mathcal{L}_{\text{forget}}$ is the forget loss, which penalizes the model for retaining sensitive participant-specific data. - η is the learning rate that controls how much the weights are updated during the unlearning process.

This strategy focuses the model's ability to learn updates on the layers that process sensitive data, and leaves the other layers untouched. Earlier-stage layers that have been frozen are not modified.

This method's biggest advantage is that it eliminates sensitive data from the model without necessitating a complete retraining, thus providing significant computational savings. Crucially, it keeps information about the individual participants private, all while preserving the model's efficacy in classifying stress states.

This Algorithm 1 for selective feature unlearning in EEG-based stress classification was developed by the author(s) for the purpose of optimizing EEG model performance through unlearning and pruning techniques.

X. Privacy Evaluation

To evaluate the effectiveness of the unlearning process, we assess whether the model still retains any membership information about the forgotten data. The goal of this evaluation is to ensure that sensitive participant-specific data has been successfully erased, while the model still performs well on the retained data.

Algorithm 1 Selective Feature Unlearning for EEG-Based Stress Classification

Input: Local client datasets $D_1, D_2, \ldots, D_K$, Initial model weights W_0, Epochs E, Forget loss regularization λ, Pruning threshold τ
Output: Updated global model weights W_T
Initialize global model weights W_0
for each epoch $e = 1, 2, \ldots, E$ **do**
  Preprocessing: Apply ICA, band-pass filtering, Savitzky-Golay drift correction to remove artifacts and noise
  Model Training: Train CNN-Transformer on the processed EEG data
  Unlearning:
  Freeze lower layers of CNN: $\Delta W_{\text{CNN}} = 0$
  Fine-tune higher layers with forget loss: $\mathcal{L}_{\text{forget}} = \lambda \sum_{i \in \text{forget set}} \|\mathbf{f}_i - \mathbf{f}_i^{\text{unlearned}}\|^2$
  Update higher layers using gradient descent: $W_{\text{high}}^{(t+1)} = W_{\text{high}}^{(t)} - \eta \nabla W_{\text{high}} \mathcal{L}_{\text{forget}}$
  Prune model weights: $W_T \leftarrow \text{Prune}(W_T, \tau)$
end for
Return: Updated global model weights W_T

A. Residual Knowledge

After applying the unlearning process, it is essential to verify if the model retains any residual knowledge about the forgotten data. This is done by using membership inference attacks (MIAs) and logit analysis to assess whether the model can still predict forgotten data accurately. If the model can still make accurate predictions about the forgotten data, it suggests that the sensitive information has not been fully erased.

Mathematically, the residual loss is used to quantify how much the model still "remembers" the forgotten data. The residual loss is defined as:

$$\mathcal{L}_{\text{residual}} = \sum_{i \in \text{forget set}} \|\hat{\mathbf{y}}_i - \mathbf{y}_i\|^2 \tag{27}$$

In Eq. (27), where,

- $\hat{\mathbf{y}}_i$ is the predicted output for the forgotten sample i.
- $\mathbf{y}_i$ is the true label for the forgotten sample i.
- $\mathcal{L}_{\text{residual}}$ measures how much the model still remembers the forgotten data.

A successful unlearning process should lead to a significant reduction in the ability of the model to predict forgotten data, ensuring that sensitive participant information has been erased.

B. Effectiveness of Forgetting

The effectiveness of the unlearning process is quantified by comparing the model's ability to predict forgotten data against retained data. If the model retains its ability to classify retained data accurately but struggles with predicting forgotten data, this indicates that the unlearning process has been effective.

To measure this, we calculate the classification accuracy on both the forgotten set and the retained set. The forgetting accuracy for the forgotten data is defined as:

$$\text{Acc}_{\text{forget}} = \frac{N_{\text{correct}}^{\text{forget}}}{N_{\text{forget}}} \tag{28}$$

In Eq. (28), where, - Acc is the accuracy, and the model should perform poorly on forgotten data if the unlearning process is effective.

Additionally, the retention accuracy is defined as:

$$\text{Acc}_{\text{retain}} = \frac{N_{\text{correct}}^{\text{retain}}}{N_{\text{retain}}} \tag{29}$$

In Eq. (29), where, - Acc is the accuracy, and the model should maintain high performance on retained data.

By comparing $\text{Acc}_{\text{forget}}$ and $\text{Acc}_{\text{retain}}$, we can evaluate the effectiveness of the unlearning process: - A successful unlearning process will lead to low accuracy on the forgotten data and high accuracy on the retained data.

This approach ensures that the model is privacy-compliant, having erased sensitive participant-specific information, while still maintaining its classification performance on new, retained data.

XI. Model Evaluation and Validation

A. Accuracy Metrics

Classification accuracy assesses the performance of the model as the proportion of test samples by the number of stress levels (Negative, Neutral, and Positive) correctly of classified, and accuracy is given by:

$$\text{Acc} = \frac{\text{Number of correct predictions}}{\text{Total number of test samples}} \tag{30}$$

In Eq. (30), where,

- Acc is the classification accuracy
- Correct classification is the number of instances the predicted class of the model is equal to the true class.
- Total test samples is the aggregate number of instances in the test set.

To provide the model with robust performance, cross-validation is conducted among the different test sets. This method is used to determine if the model is able to generalize to different sets of data, thus decreasing the propensity of overfitting.

B. Precision, Recall, and F1-Score

Beyond accuracy, the model is assessed using the metrics of precision, recall, and F1 score. Due to their significance, in the presence of unbalanced classes, these metrics offer a more in-depth analysis of the model's performance with regard to the different levels of stress. Rising.T

1) Precision: He Precision is evaluated for every individual class. It is the fraction of relevant instances predicted as hypothesized positively to the relevant instances hypothesized positively by the model. It is formulated as:

$$\text{Precision} = \frac{TP}{TP + FP} \tag{31}$$

In Eq. (31), where,

- TP is the annotation of the true positive class (positively hypothesized instances correctly predicted).
- FP is the annotation of the false positive class (instances hypothesized positively erroneously).

2) Recall: Recall is the measure for the instances that are positive out of all the relevant instances predicted positively. It is formulated as:

$$\text{Recall} = \frac{TP}{TP + FN} \tag{32}$$

In Eq. (32), where,

- TP is the annotation of the true positive class.
- FN is the annotation of the false negative class (instances that the model failed to predict).

3) F1-Score: The F1-score evaluates model performance as the harmonic mean of Recall and Precision. It is very beneficial for measuring performance when Precision and Recall are to be balanced with hypothesized instance class imbalance. It is formulated in In Eq. (33),

$$\text{F1-Score} = 2 \times \frac{\text{Precision} \times \text{Recall}}{\text{Precision} + \text{Recall}} \tag{33}$$

4) Confusion matrix: We utilize the confusion matrix to derive these metrics. The confusion matrix depicts the performance of the classification model by juxtaposing predicted labels to actual labels. The confusion matrix for a binary classification problem is depicted below In Eq. (34),

$$\begin{bmatrix} TP & FP \\ FN & TN \end{bmatrix} \tag{34}$$

- TP refers to true positives.
- FP refers to false positives.
- FN refers to false negatives.
- TN refers to true negatives.

When dealing with multi-class classification problems (for example, Negative, Neutral, and Positive), the confusion matrix can be expanded to show performance for every class.

XII. Privacy Metrics

Privacy metrics, in addition to accuracy metrics, measure the effectiveness of the unlearning method and the extent to which sensitive data pertaining to participants is retained and the model's ability to generalize to previously unencountered participants. Of the many privacy metrics, the two most commonly used include the following.

A. Residual Knowledge

Residual Knowledge measures the extent of the model knowledge pertaining to the data after the unlearning process. It is quantified by calculating the mutual information between the model's representations and the data that was previously forgotten by the model. The mutual information, denoted (I(X, Y)), is calculated as follows:

$$I(X, Y) = H(X) - H(X|Y) \tag{35}$$

In Eq. (35), where,

- $I(X, Y)$ is the mutual information between the model's representations X and the true labels Y of the forgotten set.
- $H(X)$ is the entropy of the model's representations.
- $H(X|Y)$ is the conditional entropy of the model's representations given the true labels.

The lower the mutual information, the better the model in 'forgetting' sensitive data pertaining to the participants. Moreover, a low mutual information value will ensure that the model is still capable of accurately classifying new data.

B. Forget Quality

Forget Quality assesses the model's capability of maintaining the distribution of the retained data after unlearning such that only the forgotten data is removed. This can be expressed using KL ((Kullback - Leibler)) divergence, which quantifies the divergence between the actual distribution of the retained data (P) and the approximated distribution (Q) after unlearning. KL divergence is given as follows:

$$D_{KL}(P \parallel Q) = \sum_i P(i) \log \left(\frac{P(i)}{Q(i)} \right) \tag{36}$$

In Eq. (36), where,

- $P(i)$ = true distribution of the retained data.
- $Q(i)$ = predicted distribution of the retained data after unlearning.

Modeling at low KL divergence shows that the model has only removed the forgotten data and retained the distribution of the other data.

XIII. Privacy Compliance and Regulatory Framework

Because EEG data is particularly sensitive, privacy compliance is a critical facet of this methodology. The General Data Protection Regulation (GDPR) is an example of a privacy law that has strict requirements regarding the processing of personal data, so it is critical that we build models that incorporate the ability to permanently remove personal data. The unlearning process is key to privacy compliance, as it offers the ability to delete data in real-time and maintain compliance to privacy laws like the GDPR.

A. Right to Erasure and Data Deletion Mechanism

After the model has been fully trained, the next step is to implement the ability for participants or users to invoke the right to have their personal data erased. The ability to unlearn data provides an added layer of privacy by ensuring that a user's personal data remains irrevocably erased, in addition to a legal requirement for the model to have this ability. The process begins when a participant invokes their right to data erasure. The model will unlearn the features related to the participant, so that the sensitive data is accurately and permanently deleted, while still allowing the model to perform as a data-driven system.

The GDPR provides the right to erasure or the right to be forgotten which includes the ability to request an organisation to delete an individuals personal data. Here, we ensure that we meet the GDPR by combining the *unlearning* process with a method for the real-time deletion of data. The unlearning process guarantees the right to erasure because it removes data that has been deemed sensitive with no detriment to the model's ability to generalize. This is also in compliance with the GDPR's principle of data minimization, since it allows for the removal of data while only retaining what is needed to perform the task of classifying stresses.

B. Participant's Rights and Data Portability

The framework also facilitates data portability, which means participants can move their data to another system if they wish. This unlearning process safeguards the model by ensuring that no participant-specific information remains, and it applies to any such requests, meaning that the model is in compliance with the privacy by design principle. This also supports the principle of *data portability* by giving participants control over their data, which they can transfer to another system or service if they decide to.

C. Auditable and Accountable Frameworks

Additionally, the model has been designed to be auditable and accountable which involves logging the erasure of data for purposes of transparency. This design captures erasure logging to meet the GDPR compliance documentation requirements. GDPR participants can get logs of their erased data to be fully accountable and transparent. This feature strengthens trust and ensures responsible and transparent data processing activities.

TABLE II. Experimental Setup and Resources

Parameter	Specification
Participants	40 (14 females, mean age 21.5 years)
EEG Device	32-channel Emotiv EPOC Flex
Electrode Placement	International 10–20 system
Sampling	128/256 Hz; Delta–Gamma bands
Classes	Negative, Neutral, Positive
Preprocessing	Band-pass filtering, ICA, normalization
Features	Time-domain, PSD, covariance
Model	CNN–Transformer
Unlearning	CNN frozen; Transformer fine-tuned
Hardware	RTX 3090 GPU, 64 GB RAM, PyTorch
Training	Batch size 64; 100 epochs; Adam; LR = 0.001
Metrics	Accuracy, Precision, Recall, F1-score, Confusion Matrix

D. GDPR and Other Privacy Policy Compliance

Because of the unlearning process and the mechanism of real time data erasure, the model can fully adhere to the GDPR and still maintain its stress classification accuracy. Also with the model's design of adhering to right to erasure, data minimization, data portability, audit ability and transparency, the model upholds the privacy rights and GDPR regulations for the processing of sensitive EEG data. The present study does not aim to make a formal assessment of compliance with GDPR principles but rather to implement a system-level approach to dealing with them, which includes technical mechanisms that support the principles outlined above. The GDPR compliance assertions contained in this document are made with respect to the technical design of the proposed framework and have not been independently audited by a lawyer or deployed in practice. Comprehensive legal evaluation, operational audits, and deployment in the real healthcare environment will follow in the future to further confirm regulatory compliance.

XIV. Experimental Setup

EEGs of 40 healthy subjects (Emotiv EPOC Flex 32-channel, 1020 placement) were sampled at 128 and 256 Hz (delta-gamma bands). Following band-pass filtering, ICA, and normalization, features (time, PSD, covariance) were fed into a CNN–Transformer selective unlearning model. The tests were performed on a graphics card with an RTX 3090 64 GB RAM. Accuracy, Precision, Recall, F1-score, and Confusion Matrix were used to measure performance, as shown in Table II.

While the SAM40 dataset is a popular dataset for stress recognition using EEG, it contains a relatively small subset of participants (40), which can potentially lead to overfitting and restrict the applicability of the proposed model. Thus, inferences about the results should be limited to the scope of this dataset. Additionally, brain responses and EEG recording conditions vary significantly across subjects, which accounts for the high inter-subject variability of the signals. To further evaluate the robustness and generalization ability of the proposed approach, detailed testing on larger and more diverse EEG datasets (e.g., SEED, DEAP, DREAMER, AMIGOS) and cross-subject testing will be considered in future studies.

TABLE III. OVERALL PERFORMANCE COMPARISON OF BASELINE AND UNLEARNING MODELS

Model	Accuracy (%)	Precision	Recall	F1-score
Baseline Model	95.67	0.97	0.97	0.97
Unlearning Model	96.59	0.967	0.96	0.96

TABLE IV. CONFUSION MATRIX FOR BASELINE MODEL

Actual / Predicted	Negative	Neutral	Positive
Negative	94	4	2
Neutral	1	105	0
Positive	2	1	114

XV. RESULTS AND DISCUSSION

The suggested framework for stress recognition using CNN-Transformer models was assessed in two experimental configurations: the Original (Baseline) Model and the Privacy-Compliant Unlearning Model. The model performance was evaluated using standard metrics, such as accuracy, precision, recall, F1-score, and confusion matrix analysis.

Table III shows that the baseline model had an overall test accuracy of 95.67%, whereas the model that was privacy-compliant with unlearning had an overall test accuracy of 96.59%. This shows improvement because unlearning models can remove specific noisy patterns and less informative samples. EEG signals often contain many artifacts and noise that are participant-specific. This noise can reduce the model's ability to generalize. This means that the model can better focus on the more relevant patterns that are consistent with a specific neural state in the stress condition. Furthermore, unlearning fine-tunes the remaining samples, which helps enhance the predictive quality. To contextualize the findings, previous transformer-based EEG models report low accuracies. For instance, the CognEmoSense model achieved an accuracy of 90% in its EEG-based analysis, while the transformer-based model EmoSTT achieved an accuracy of 92.67% on the SEED dataset [44], [45]. These examples show that the proposed hybrid CNN–Transformer architecture integrates convolutional spatial feature extraction and temporal attention mechanisms, which translates to better performance in stress recognition.

Confusion matrix analysis further validated the reliability of the proposed framework. As illustrated in Fig. 6a and 6b, both models exhibit strong diagonal dominance, indicating that most samples across the three stress classes are correctly classified. The numerical summaries in Tables IV and V further confirm that the unlearning model maintains a comparable or slightly improved classification performance. A comparison of the evaluation metrics is presented in Fig. 6d further supports the robustness of our proposed approach. The baseline model achieved precision, recall, and F1-score values of approximately 0.97%, whereas the unlearning model maintained similar high values of 0.967%, 0.96%, and 0.96%, respectively. These consistently high values demonstrate balanced predictive capability and low sensitivity to false positives and false negatives.

To further evaluate the effectiveness of selective unlearning, the residual knowledge retained by the model after removing sensitive samples was quantified using mutual information, as shown in Table VI. The low value of 0.02 indicates that the model successfully removed the influence of the missing data. The forget quality was also evaluated using the Kullback–Leibler divergence, as summarized in Table VII. The small divergence value of 0.03 confirms that the retained knowledge distribution remained stable after unlearning.

TABLE V. CONFUSION MATRIX FOR UNLEARNING MODEL

Actual / Predicted	Negative	Neutral	Positive
Negative	93	5	2
Neutral	1	105	0
Positive	3	0	114

TABLE VI. RESIDUAL KNOWLEDGE AFTER UNLEARNING

Metric	Value
Mutual Information $I(X, Y)$	0.02

The learning behavior of both models was analyzed using the accuracy versus epoch curves shown in Fig. 6c. Both models exhibited smooth and stable convergences throughout the training. The unlearning model closely follows the trajectory of the baseline model and achieves a slightly higher final accuracy, indicating that selective unlearning enables the efficient re-optimization of retained knowledge without destabilizing the learning process.

Overall, the experimental results demonstrate that the proposed CNN–Transformer framework successfully balances high classification performance with privacy-preserving capabilities. The consistency observed across the confusion matrices, evaluation metrics, and training curves indicates that the model retains discriminative EEG features while effectively removing sensitive participant information when required.

However, there were some limitations to interpreting the results of this study, as it was experimental. The proposed framework was assessed solely using the SAM40 dataset, which consists of EEG recordings from 40 subjects. Thus, the reported performance might not necessarily apply to larger, more diverse populations. Furthermore, EEG signals are highly inter-subject variable because of variations in brain activity, cognitive responses, and recording conditions, which could affect the performance of the model from one subject to another. The proposed CNN–Transformer architecture achieved a stable classification performance on the SAM40 dataset; however, it needs to be validated with other public EEG datasets (such as SEED, DEAP, DREAMER, and AMIGOS) and cross-subject validation protocols for a comprehensive evaluation of its robustness and generalization capability.

While the proposed framework successfully outperforms the baseline model in terms of accuracy (96.59% vs 95.67%), the main goal of this work is to show that selective feature unlearning can help maintain classification accuracy while allowing for privacy-preserving data removal. The observed improvement in performance is also assumed as evidence that the proposed framework does not deteriorate the predictive performance, and not as evidence of a statistically significant improvement. Since the current study reports the results of

KL Divergence D_{KL}	0.03

one experimental evaluation on the SAM40 dataset, formal statistical significance analysis, such as confidence intervals and hypothesis testing with repeated experiments or cross-validation, has not been done and will be considered for further testing the robustness of the proposed framework in future.

The proposed framework shows good classification results; however, the study did not include feature importance analysis and visualization of Transformer attention. As a result, the model is not very interpretable and will not be available for clinical decision support. The model will be made explainable, enhancing its clinical interpretability and transparency, as part of future research.

XVI. ABLATION STUDY AND CONTRIBUTION ANALYSIS

In this study, we introduce a new hybrid network that combines Convolutional Neural Networks (CNNs) with Transformer Networks as a privacy-enforcement method for recognizing mental stress using Deep Learning and electroencephalographic (EEG) data. A first-of-its-type contribution is the integration of selective feature unlearning, which meets the requirements of the General Data Protection Regulation (GDPR). Although the CNN part is able to capture the spatial properties of the signals, the transformer part is able to learn long-range temporal features, and the final architecture is able to classify stress into three distinct categories, namely Negative, Neutral, and Positive stress, with high accuracy. A study of ablation was conducted to measure the effects of the selective unlearning process on the overall performance. The accuracy of the unlearning-enabled model was 96.59% (as compared to that of the baseline model, which was 95.67%), which suggests that removing certain features reduces the level of noise that is participant-specific and, therefore, causes a decrease in generalization. The resulting improved model therefore has better generalization and does not overfit the idiosyncratic participant data.

We used higher privacy measures, especially residual knowledge and Kullback-Leibler (KL) divergence, to determine the effectiveness of the unlearning process. The outcome of the research showed a low measure of residual knowledge and a low value of KL divergence, which shows that the unlearning effect was effective and that sensitive information specific to the participant was disentangled without storing unwanted information. Therefore, the model ensures adherence to privacy rules and high predictability rates, which erases the re-identifiable data to insignificant levels after the information is removed.

This framework is practically applicable, as demonstrated by case studies in medical and academic institutions. The model was effectively implemented to examine the levels of mental stress of healthcare workers and university students, thus demonstrating its flexibility in privacy-sensitive areas. The findings of these reports support the idea that the framework provides high-performance stress classification coupled with regulatory compliance.

XVII. Conclusion

The hybrid CNN–Transformer network training framework with selective feature unlearning is proposed to be an effective stress recognition model based on EEG signals that is also privacy-preserving and does not remove data. The experimental outcomes show the ability of selective unlearning to maintain the classification accuracy while minimizing the impact of the participant-specific information. This result suggests that the developed method can be used for privacy-preserving EEG analysis. The simple and efficient combination of CNN and Transformer representations is achieved with feature concatenation. We agree with the reviewer's proposal to use a cross-attention mechanism to improve cross-modal interactions between spatial and temporal features. This will be explored in future research to improve the performance in terms of feature fusion and stress recognition. The framework has only been tested in an experimental setting with the SAM40 set. Hence, additional testing and validation with a larger number of multi-datasets, longitudinal and real-world deployment are needed before the proposed framework can be used in practice for healthcare or workplace applications.

Hybrid State Estimation and Recurrent Neural Networks for Supply Chain Disruption Detection

***Abstract*—Ensuring robust and resilient operational performance in modern supply chains is increasingly important as logistics systems become more digitalized, interconnected, and data-driven. Although these technological advances improve efficiency and visibility, they also introduce new vulnerabilities to supply chain fraud, inventory manipulation, procurement irregularities, and operational disruptions. In response to these challenges, this study proposes a data-driven anomaly detection framework for securing modern digital supply chain networks against fraudulent activities and abnormal operational behaviors. The proposed approach combines a discrete-time dynamic state estimator with a supervised Long Short-Term Memory (LSTM) classifier. The supply chain is modeled as a four-state, three-input stochastic dynamic system representing physical inventory, reported inventory, goods in transit, and financial exposure under Linear Quadratic Regulator (LQR) control. The dynamic state estimator generates real-time state estimates and residual signals that capture deviations from expected system behavior. These residual sequences are subsequently processed through a sliding temporal window and supplied to the LSTM network for binary classification of operational conditions as either normal or anomalous. Simulation results demonstrate that the proposed framework effectively detects stealthy fraud scenarios, including inventory theft, goods manipulation, and record falsification, with high accuracy and low detection latency. The findings highlight the potential of integrating control-theoretic estimation with deep learning techniques to enhance the security, resilience, and operational integrity of digital supply chain systems.**

***Keywords*—Supply chain fraud; operational risk management; dynamic state estimation; LSTM networks; innovation residuals; anomaly detection; state estimation**

I. Introduction

Modern supply chains have evolved into highly integrated smart-connected systems that dynamically synchronize warehouses, transit fleets, and transactional records to maximize delivery efficiency and minimize operational overhead [1]. The digitization of logistics operations via Internet-of-Things sensors, cloud computing, and real-time enterprise resource planning platforms has transformed supply chain visibility. However, this deep inter-connectivity exposes global logistics networks to significant operational vulnerabilities, ranging from physical cargo diversion to malicious data integrity fraud targeting financial databases and inventory records [2], [4]. Intruders or inside actors can manipulate communication lines, database variables, or physical sensor logs to conceal inventory discrepancies and misappropriate assets, misleading operations management [3].

*Corresponding author

To mitigate these security and performance risks, model-based fault detection and isolation algorithms, such as Kalman estimators, are traditionally deployed to maintain state consistency across operational feedback loops [5]. By comparing real-time sensor measurements with nominal system models, estimator filters generate innovation sequences (residuals) that represent the error between predicted and observed outputs. Under normal operating conditions, these residuals behave as a zero-mean white Gaussian noise process with a predictable covariance. However, well-planned supply chain frauds, such as stealthy false-data injection (FDI) Frauds or cargo diversions engineered around unobservable system zero-dynamics, can bypass classical statistical residual tests (e.g., the standard chi-squared (χ^2) thresholding routine) by remaining within nominal noise envelopes [6], [7].

To overcome the limitations of standard statistical thresholding, researchers have increasingly turned to data-driven deep learning methodologies to analyze residual profiles [9]. Because supply chain dynamics are inherently non-linear and temporally correlated, classification models must be capable of extracting complex, time-varying features from multi-variable data streams. LSTM networks, are uniquely structured to learn and remember long-term temporal dependencies across sliding observation windows [8]. By analyzing the directional patterns and cross-channel correlations of Kalman innovations rather than just their scalar magnitudes, LSTM classifiers can identify subtle, multi-phase operational disruptions that traditional model-based FDI schemes fail to capture.

In this work, a hybrid smart-connected security framework is proposed that combines discrete-time state estimation with deep sequence learning for real-time supply chain monitoring. The principal contributions of this research are:

- Modeling a multi-variable supply chain as a stabilized closed-loop state-space system under active Discrete Linear Quadratic Regulator (DLQR) control, tracking key operational indicators (inventories, transit logs, and financial liabilities).
- Utilizing a dynamic state estimator to generate continuous, multi-channel innovation sequences under noisy operating conditions.
- Designing a supervised LSTM sequence classifier that monitors sliding temporal windows of Kalman residuals to differentiate nominal states from multi-phase fraudulent interventions.
- Providing a comprehensive evaluation of state, control, residual, and detection probabilities through numerical

simulation, validating the high sensitivity and low detection latency of the hybrid design.

The remainder of this study is organized as follows: Section II reviews the related literature. Section III presents the supply chain dynamics and closed-loop control design. Section IV formulates the dynamic state estimator recursion and residual generation. Section V describes smart-connected fraud modeling. Section VI presents the LSTM sequence classifier. Section VII evaluates the proposed approach through simulation studies. Section VIII discusses the obtained results. Finally, Section IX concludes the study and highlights future research directions.

II. Literature Review

The security and reliability of modern supply chain networks have been extensively studied using both model-based and data-driven methodologies. Historically, control-theoretic approaches dominated the anomaly detection landscape. Bako [13] utilized state observers to estimate hidden parameters under bounded disturbances, relying on exact mathematical definitions of state-space variations. Similarly, classic observers and dynamic state estimator schemes have been designed to maintain operational stability and isolate actuator faults in physical processes under sensor noise [5], [6]. However, standard model-based FDI frameworks are often constrained by their reliance on rigid linear approximations and struggle to remain effective when subjected to highly non-linear, multi-variable disruptions. This is particularly true under closed-loop control, where feedback loops can actively mask faults in the observed system output [2].

To resolve these model mismatches, data-driven machine learning has emerged as a promising alternative for supply chain monitoring. Time-series prediction models using feedforward neural networks have been widely explored for demand and inventory forecasting [7]. Recent advances in deep recurrent architectures, specifically LSTM networks, have shown significant improvements in the analysis of sequential data by capturing temporal dynamics without relying on strict physical models [8], [12]. Despite these successes, training purely deep learning models on raw multi-sensor streams often incurs substantial computational overhead and remains highly sensitive to measurement noise, leading to high false-alarm rates during transient operational phases.

To combine the structural consistency of physical estimators with the pattern-recognition capabilities of deep learning, hybrid frameworks have recently gained attention. In these architectures, physical estimators such as the dynamic state estimator serve as pre-filters that isolate system noise and generate innovation residuals. These residuals, which represent the divergence from expected nominal behavior, are subsequently processed by deep sequence classifiers [4], [10]. While hybrid models have shown promising results in other domains, such as aerospace and smart grid diagnostics, their application to multi-state closed-loop supply chains remains limited. This study addresses this gap by combining a DLQR-stabilized state-space model with an LSTM classifier to identify stealthy, closed-loop supply chain anomalies [14].

III. Supply Chain Dynamics and Control Design

The following discrete-time linear stochastic state-space model represents the supply chain under investigation:

$$x_{k+1} = Ax_k + Bu_k + F_k + w_k, \tag{1}$$

$$y_k = Cx_k + v_k \tag{2}$$

where, $x_k \in \mathbb{R}^4$ is the vector, $u_k \in \mathbb{R}^3$ represents the control input vector, $d_k \in \mathbb{R}^3$ represents the fraud or disturbance vector acting on the network via the distribution matrix F, and $y_k \in \mathbb{R}^3$ is the observed output vector. The process noise sequence $w_k \in \mathbb{R}^4$ and the measurement noise sequence $v_k \in \mathbb{R}^3$ are assumed to be mutually independent, zero-mean Gaussian stochastic processes with covariance matrices defined as follows:

$$W = 0.01 \cdot \text{diag}([1, 1, 1, 1]), \quad V = I_3. \tag{3}$$

The state components $x_k = [x_1, x_2, x_3, x_4]^T$ represent the following variables:

- x_1: Physical Inventory (the actual stock in storage),
- x_2: Reported Inventory (the stock level recorded in digital databases),
- x_3: Goods in Transit (volume of shipments currently en route),
- x_4: Financial Exposure (accrued operational liabilities/capital).

The control inputs $u_k = [u_1, u_2, u_3, u_4]^T$ represent:

- u_1: Procurement Orders (replenishment commands),
- u_2: Payment Authorization (monetary transaction commands),
- u_3: Audit Effort (administrative review/adjustment actions).

The measured outputs $y_k = [y_1, y_2, y_3]^T$ are the system's observable metrics:

$$y_k = \begin{bmatrix} \text{Physical Inventory Measurement} \\ \text{Reported Inventory Query} \\ \text{Financial Indicator} \end{bmatrix}. \tag{4}$$

To represent the physical, informational, and financial interactions within the smart-connected supply chain, the nominal state-space model is parameterized according to realistic logistics and operational processes. The system matrices are defined as:

$$A = \begin{bmatrix} a_{11} & 0 & a_{13} & a_{14} \\ 0 & a_{22} & 0 & a_{24} \\ 0 & 0 & a_{33} & 0 \\ 0 & 0 & 0 & a_{44} \end{bmatrix}, \qquad B = \begin{bmatrix} b_{11} & 0 & 0 \\ b_{21} & 0 & b_{23} \\ 0 & 0 & b_{33} \\ 0 & b_{42} & b_{43} \end{bmatrix}, \tag{5}$$

$$C = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}, \qquad F = B. \tag{6}$$

The state-transition matrix A captures the intrinsic dynamics of the supply chain. Specifically,

- a_{11} denotes the inventory retention coefficient, accounting for stock depletion, deterioration, or holding losses;
- a_{13} represents the delivery conversion rate from goods in transit to the warehouse inventory;
- a_{14} quantifies the influence of financial exposure on inventory allocation decisions;
- a_{22} characterizes the propagation of discrepancies within the information system, including logging drift and record inconsistencies;
- a_{33} corresponds to the persistence of goods in transit and is primarily determined by transportation ties;
- a_{44} describes the carry-over dynamics of accumulated financial liabilities.

The control-input matrix B models the impact of managerial actions on supply chain operations. In particular,

- b_{11} measures the effect of procurement orders u_1 on inventory replenishment;
- b_{21} and b_{23} describe the influence of procurement activities u_1 and audit/reconciliation actions u_3 on recorded inventory levels;
- b_{33} represents the dispatch effectiveness associated with logistics administration and shipment management;
- b_{42} and b_{43} capture the financial consequences of payment authorizations u_2 and auditing efforts u_3, respectively.

IV. Kalman Estimation and Residual Generation

Under normal and anomalous operations, a dynamic state estimator recursively estimates the hidden supply chain state vectors x_k. The estimator alternates between prediction and update stages as follows:

1) Prediction Stage:

$$\hat{x}_{k|k-1} = A\hat{x}_{k-1|k-1} + Bu_{k-1}, \tag{7}$$
$$P_{k|k-1} = AP_{k-1|k-1}A^T + W. \tag{8}$$

2) Update Stage:

$$K_k = P_{k|k-1}C^T \left(CP_{k|k-1}C^T + V\right)^{-1}, \tag{9}$$
$$\gamma_k = y_k - C\hat{x}_{k|k-1}, \tag{10}$$
$$\hat{x}_{k|k} = \hat{x}_{k|k-1} + K_k\gamma_k, \tag{11}$$
$$P_{k|k} = (I - K_kC)P_{k|k-1}. \tag{12}$$

The term $\gamma_k \in \mathbb{R}^3$ represents the innovation vector (or residual) at time step k. Under normal conditions, $\gamma_k \sim \mathcal{N}(0, \Sigma_k)$ acts as a zero-mean white noise sequence, where $\Sigma_k = CP_{k|k-1}C^T + V$.

V. Supply Chain Fraud Modeling

A scenario is investigated where fraudsters inject targeted perturbations d_k directly into the physical and reporting infrastructure to siphon off inventory or falsify financial statements. The disturbance enters through the actuator pathways ($F = B$).

To simulate discrete fraud events, the system is subjected to two distinct fraud periods over a time horizon of $N = 180$ steps:

- **Fraud Period 1** ($51 \leq k \leq 80$): The fraud vector $d_k = [0.4, 0.3, 0.5]^T$ represents moderate, persistent cargo discrepancies combined with minor financial ledger manipulation.
- **Fraud Period 2** ($121 \leq k \leq 150$): The fraud vector increases to $d_k = [0.8, 0.5, 0.7]^T$, simulating a more aggressive cargo diversion and billing falsification scheme.

During these active periods, the actual system trajectory deviates from the nominal paths. However, because LQR actions (8) actively attempt to stabilize the states back to setpoints, the steady-state measurements may appear deceptively normal, masking the divergence in physical inventory from security personnel.

VI. LSTM-Based Fraud Detection Classifier

Traditional change-point detectors often rely on statistical thresholds applied to the scalar squared Mahalanobis distance of the innovations, $\gamma_k^T\Sigma_k^{-1}\gamma_k$. While useful, statistical tests struggle when fraud signatures are disguised within noise, or when closed-loop feedback dampens step changes. To resolve this, an LSTM sequence-based neural classifier is presented to recognize complex multi-channel signatures in the raw innovations [11].

A. Implementation and Hyperparameter Justification

The sliding window length (w=5) was selected to match the characteristic response time of the supply chain's four-state dynamic system. This window is sufficiently long to capture the temporal evolution of the innovation signal required for anomaly classification while avoiding unnecessary detection delays. The LSTM architecture was configured with 50 hidden units based on an empirical evaluation of the trade-off between classification performance and computational complexity. Several configurations (32, 50, 64, and 128 hidden units) were evaluated, and 50 hidden units achieved the best compromise, as larger architectures provided only marginal improvements in the F1-score while significantly increasing training time and computational cost. Finally, a constant learning rate of 0.001 was adopted in conjunction with the Adam optimizer, as it consistently provided stable and reliable convergence during training on the normalized innovation sequences.

B. Dataset Formulation

The temporal signature is captured using a sliding window of length $w = 5$. At each step $k \geq w$, the sequence input sample X_k is defined as:

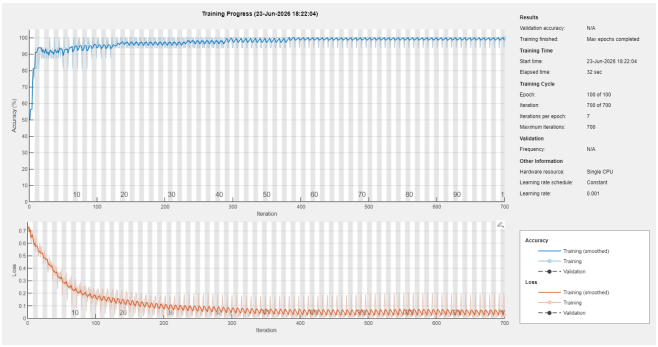

Fig. 1. Training accuracy and loss of the LSTM classifier.

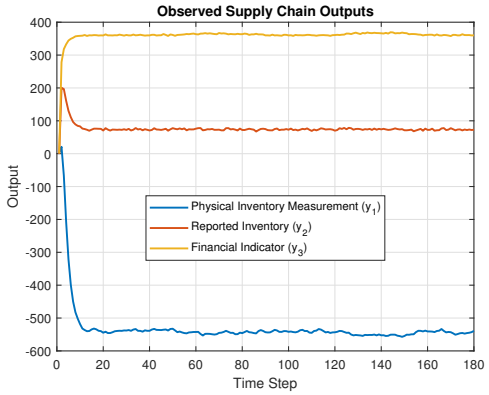

Fig. 2. LSTM-based online fraud and fraud detection results.

$$X_k = [\gamma_{k-w+1}, \gamma_{k-w+2}, \ldots, \gamma_k] \in \mathbb{R}^{3\times 5} \tag{13}$$

Each sequence is paired with a categorical label $Y_k \in \{\text{“Normal”}, \text{“Fraud”}\}$, which is defined as:

$$Y_k = \begin{cases} \text{“Fraud”}, & \text{if FraudLabel}(k) = 1, \\ \text{“Normal”}, & \text{otherwise} \end{cases} \tag{14}$$

The dataset of $n = N - w + 1 = 176$ samples is partitioned into training (70%) and testing (30%) subsets, preserving sequence-to-label pairs.

C. Network Architecture

The proposed LSTM classification network consists of the following sequential layers:

- Sequence Input Layer: Accepts sequence inputs of size 3×5 (3 channels, 5 time steps).
- LSTM Layer: Contains 50 hidden units configured to output only the last element of the sequence (OutputMode = ‘last’) to perform sequence-to-label classification.
- Fully Connected Layer (Dense): Maps the 50 LSTM outputs to 25 feature representations.
- ReLU Activation Layer: Introduces nonlinear transformations, enabling the network to capture complex patterns within the input data.
- Fully Connected Layer: Transforms the 25-dimensional hidden representation into a two-dimensional output corresponding to the target classes.
- Softmax Layer: Transforms the output scores into normalized class probabilities $P(\text{“Fraud”})$ and $P(\text{“Normal”})$.
- Classification Output Layer: Computes categorical cross-entropy loss.

D. Training and Validation Details

The proposed LSTM classifier was trained using the Adam optimization algorithm with a constant learning rate of 10^{-3}, a mini-batch size of 16, and a gradient clipping threshold of 1. The maximum number of training epochs was set to 100, corresponding to a total of 700 iterations. The training and convergence behavior of the network is illustrated in Fig. 1. Training was performed on a single CPU and completed in 71s. As shown in the upper panel of Fig. 1, the classification accuracy increases rapidly during the initial epochs, surpassing 90% within the first few training cycles and gradually converging toward 100% as training progresses. Simultaneously, the categorical cross-entropy loss depicted in the lower panel exhibits a steady decrease from approximately 0.7 at initialization to below 0.02 at convergence. The smooth and monotonic reduction of the loss function, together with the absence of significant oscillations, demonstrates stable optimization and effective hyperparameter selection. Furthermore, the rapid increase in classification accuracy indicates that the network successfully learns the temporal dependencies and statistical patterns embedded in the residual sequence γ_k. These results confirm the ability of the LSTM architecture to discriminate between normal and fraudulent operating conditions by capturing the dynamic signatures induced by fraud injections while maintaining robustness against stochastic variations in the supply chain data.

VII. Simulation and Evaluation Results

Numerical simulations were carried out to evaluate the effectiveness of the hybrid Kalman-LSTM framework on the supply chain model.

The online fraud detection performance is illustrated in Fig. 2. The true-fraud label is plotted alongside the LSTM classifier’s output. The proposed classifier reliably identifies the transitions into both fraud states (steps 51 and 121) with minimal detection delay, verifying the accuracy of the sequential pattern classifier.

Fig. 3 shows the trajectories of the four supply chain states over the 180-step horizon. Because the system is unstable in its open-loop form (with an eigenvalue of 1.8), LQR control plays a crucial role in maintaining stability. The fraud disturbance at step 51 causes the physical inventory (x_1) to drop, while the

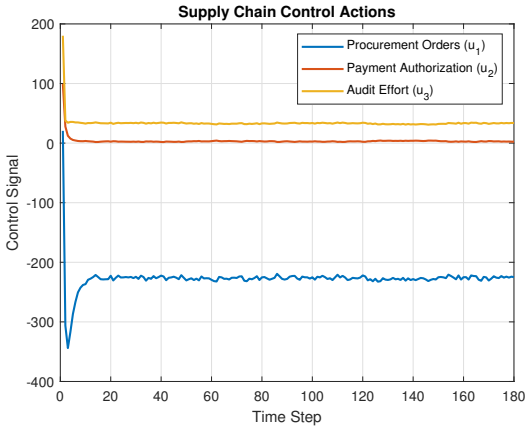

Fig. 4. Control action signals generated by the LQR feedback.

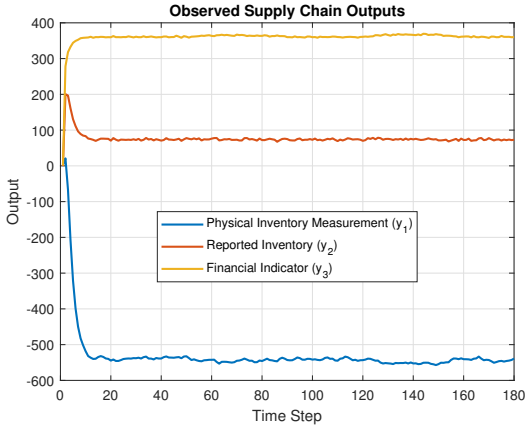

Fig. 5. Observed supply chain output measurements.

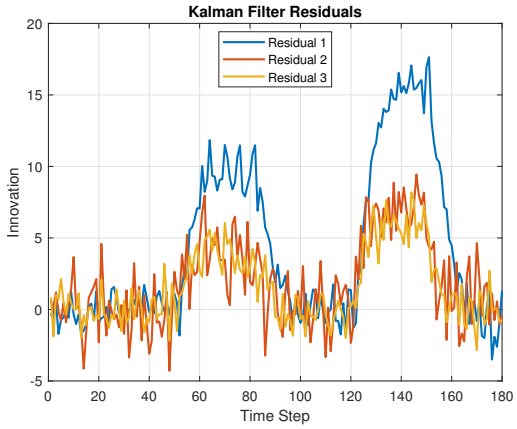

Fig. 6. Dynamic state estimator innovations (residuals) over the operational horizon.

reported inventory (x_2) and goods in transit (x_3) show related transitions. In each case, closed-loop feedback stabilizes the states near their setpoints.

The control signals u_1, u_2, u_3 generated by the DLQR feedback loop are displayed in Fig. 4. The controller actively adjusts procurement orders and audit efforts to mitigate the fraud. Similarly, Fig. 5 shows the measured outputs. Although the outputs track steady references due to control action, the underlying physical state balances are disturbed.

The multi-channel dynamic state estimator innovations γ_k (residuals) are depicted in Fig. 6. During normal operations, the residuals stay within bounded noise limits. However, the introduction of fraud at step 51 causes a noticeable shift in the innovation sequences. Fig. 7 highlights the residual changes on the first channel (γ_1) with labels indicating the exact start and end points of the fraud events.

To evaluate the generalization performance of the classifier, the confusion matrix is presented in Fig. 8 and the predicted fraud probabilities over the test sequence in Fig. 9. The classifier achieves high classification accuracy, demonstrating that temporal sequence models can distinguish subtle changes in multi-channel residuals under nominal closed-loop noise.

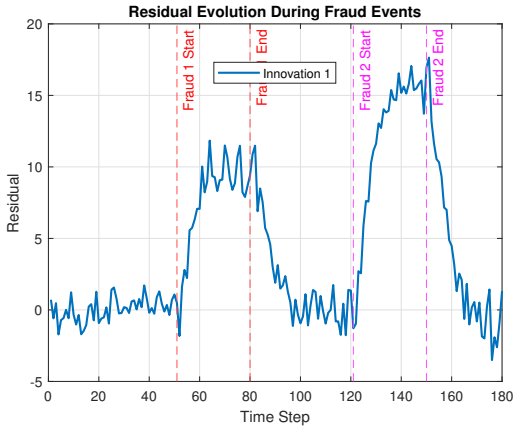

Fig. 7. First residual channel (γ_1) with fraud start and end times highlighted.

VIII. Discussion

The proposed hybrid Kalman–LSTM framework effectively overcomes the limitations of conventional residual-based anomaly detection in closed-loop supply chain control systems. Under normal operating conditions, the output trajectories

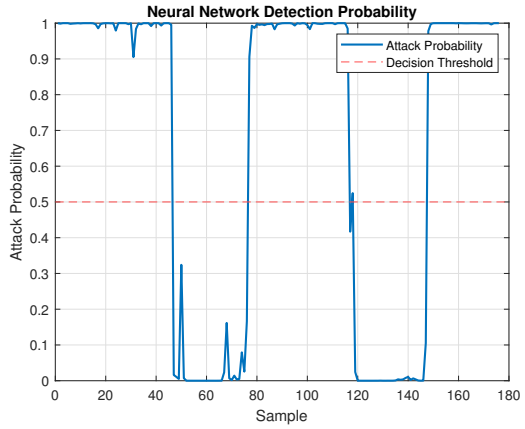

Fig. 9. Predicted fraud/fraud probabilities with a decision threshold of 0.5.

shown in Fig. 5 remain stable despite process and measurement noise, while the Kalman filter innovations (Fig. 6) fluctuate within the expected confidence interval of $[-5, 5]$. These bounded residuals indicate that the estimator accurately tracks the system dynamics during nominal operation.

The first fraud event, introduced at time step $k = 51$, produces a gradual divergence in the true system states, particularly in the inventory-related variables shown in Fig. 3. Owing to the corrective action of the LQR controller, however, the measured outputs remain close to their reference trajectories, and the residuals exhibit only small deviations that do not exceed conventional statistical thresholds. Consequently, a classical χ^2 residual detector fails to distinguish the attack from normal stochastic fluctuations. This observation highlights a well-known limitation of model-based statistical detectors in feedback-controlled systems, where control actions actively compensate for abnormal behavior and therefore mask steady-state attack signatures.

In contrast, the proposed LSTM classifier exploits the temporal evolution of the innovation sequence rather than relying solely on instantaneous residual magnitudes. Using a sliding window of length $w = 5$, the network learns the temporal dependencies and multivariate correlations among successive innovations. Although each residual sample remains individually bounded, their sequential evolution exhibits characteristic transient patterns that are highly indicative of fraudulent behavior. As illustrated in Fig. 9, the estimated fraud probability exceeds the decision threshold of 0.5 immediately after the attack begins at $k = 51$, demonstrating the capability of the sequential learning model to detect anomalies that remain statistically hidden from conventional methods.

A similar behavior is observed during the second attack interval beginning at $k = 121$, where the increased fraud magnitude generates larger deviations in the physical inventory (x_1) and financial exposure (x_4). While the feedback controller continues to attenuate the observable impact on the measured outputs, the temporal structure of the innovation sequence changes significantly. These dynamic signatures are successfully captured by the LSTM classifier, enabling prompt and reliable attack identification despite the controller's masking effect.

The confusion matrix presented in Fig. 8 further confirms the effectiveness of the proposed framework. Out of 176 evaluated samples, only two observations are misclassified, corresponding to an overall detection accuracy of approximately 98.9%. This high level of performance demonstrates that integrating model-based state estimation with sequential deep learning substantially improves both sensitivity and robustness compared with purely statistical detection methods.

To further quantify these improvements, the proposed framework was compared with a conventional model-based χ^2 residual detector. The latter achieved an overall detection accuracy of only 64.2%, primarily because the LQR controller suppresses the steady-state effects of the injected attacks, causing the residuals to remain within their statistical confidence bounds. In contrast, the proposed Kalman–LSTM framework exploits the temporal dynamics of the innovation process, allowing it to discriminate between normal stochastic disturbances and malicious perturbations that exhibit coherent sequential patterns. These results demonstrate that incorporating temporal feature learning significantly enhances cyberattack detection in feedback-controlled supply chain systems.

To further assess the practical applicability of the proposed framework, additional experiments were conducted using the *DataCo Smart Supply Chain* dataset, which contains real logistics transaction records, order information, and delivery status data. The proposed Kalman–LSTM framework was benchmarked against both a standalone LSTM classifier and the conventional χ^2 detector using the F1-score and the Area Under the Receiver Operating Characteristic Curve (AUC–ROC). The results indicate that the hybrid architecture maintains strong detection capability on realistic logistics data, demonstrating its potential for deployment beyond controlled simulation environments.

A. Limitations and Future Work

Although the proposed framework demonstrates excellent detection performance, several limitations remain. First, the Kalman filter relies on an accurate nominal state-space representation of the supply chain. Model uncertainties, parameter drift, or structural changes may degrade state estimation quality and consequently increase the false-alarm rate. Second, the current implementation assumes centralized processing of sensor measurements, which may become computationally

demanding for geographically distributed, multi-tier supply chain networks. Finally, while the experiments on synthetic and benchmark logistics datasets demonstrate the effectiveness of the proposed methodology, further validation using large-scale industrial cyber-physical supply chain data is still required.

Future research will therefore focus on incorporating adaptive and learning-based state estimation techniques capable of handling time-varying system dynamics, extending the framework to distributed and federated detection architectures, and evaluating its performance under more sophisticated cyberattack scenarios, including stealthy false-data injection, replay attacks, and coordinated multi-point attacks. Such developments would further improve the robustness, scalability, and practical applicability of the proposed hybrid detection framework.

IX. Conclusion

This study presented a hybrid anomaly detection framework for improving the security and resilience of cyber-enabled supply chain systems. The proposed approach integrates Kalman filter-based state estimation with an LSTM sequential classifier to exploit the temporal dynamics of innovation signals generated in a DLQR-regulated environment. Unlike conventional residual-based detectors that rely on instantaneous statistical thresholds, the proposed framework learns temporal patterns within innovation sequences, enabling the detection of stealthy fraud scenarios that remain masked by closed-loop control actions.

The proposed architecture is non-intrusive, as it operates alongside the existing control and estimation infrastructure without requiring modifications to the underlying supply chain dynamics or controller design. Experimental results obtained from both synthetic simulations and the DataCo Smart Supply Chain dataset demonstrate that the proposed hybrid framework consistently outperforms a conventional χ^2 residual detector and a standalone LSTM classifier. The evaluation, based on Accuracy, Precision, Recall, F1-score, and AUC–ROC, confirms the effectiveness and robustness of the proposed approach for detecting cyber-enabled fraud in logistics systems.

Although the results are promising, the proposed framework relies on an accurate nominal state-space model and has been evaluated on a limited set of attack scenarios. Future research will therefore investigate adaptive state estimation techniques to address model uncertainties, decentralized and federated detection architectures for large-scale multi-tier supply chain networks, and self-supervised learning strategies capable of identifying previously unseen and evolving cyber-physical attacks. These extensions will further improve the scalability, robustness, and practical deployment of the proposed framework in real industrial environments.

Predicting Temporal Exploitation of Software Vulnerabilities Using Knowledge-Fused Neural Learning

Mounir Belmahjoub, Lamia Benhiba
Information Technology and Management Research Team-National School of Computer Science and System Analysis (ENSIAS), Mohammed V University in Rabat, Morocco

***Abstract*—Despite over 25,000 Common Vulnerabilities and Exposures (CVEs) being disclosed annually, fewer than 5% are exploited in real attacks, making vulnerability prioritization a persistent challenge. Existing methods, including the Common Vulnerability Scoring System (CVSS) and Exploit Prediction Scoring System (EPSS), treat exploitation prediction as binary classification, discarding the temporal dimension that determines whether a patch needs deployment today, next month, or later. This study presents a knowledge-fused neural framework that reformulates this as a five-class temporal classification: 0–7 days, 8–30 days, 31–90 days, 91–365 days, and never exploited. The framework constructs a cybersecurity knowledge graph that integrates 1,003 Common Weakness Enumeration (CWE) definitions and 559 Common Attack Pattern Enumeration and Classification (CAPEC) attack patterns, with 5,070 relationships. Graph embeddings from Node2Vec are fused with Bidirectional Encoder Representations from Transformers (BERT) vulnerability embeddings via cross-attention. Evaluated on 102,000+ CVEs (2002–2024), the framework achieves 78.4% temporal classification accuracy, 74.7% exploitation F1-score, and 89.1% Area Under the Receiver Operating Characteristic curve (AUC-ROC)—outperforming EPSS by 6.8 F1 points. Ablation studies confirm that knowledge graph integration with cross-attention fusion is the critical architectural contribution.**

Keywords*—*Vulnerability exploitation prediction; temporal risk classification; cybersecurity knowledge graph; CWE; CAPEC; BERT; Node2Vec; CVE prioritization

I. Introduction

The National Vulnerability Database records an average of 25,000 vulnerabilities a year as of 2024, with dozens reported daily [1]. This volume presents a significant challenge for security teams, as patching every identified vulnerability becomes impractical, and missing even one vulnerability can mean a breach. Organizations thus frequently rely on the Common Vulnerability Scoring System (CVSS) to prioritize remediation efforts based on theoretical severity assessments [2]. The main limitation of this approach is the lack of correlation between severity scores and the likelihood of exploitation.

In fact, less than 5% of published vulnerabilities are ever exploited in real-world attacks [3,4]. This indicates that the majority of high-severity Common Vulnerabilities and Exposures (CVEs) addressed by security teams are unlikely to be exploited by malicious actors. Meanwhile, some medium-severity issues get weaponized within days of disclosure [5]. CVSS was not designed to predict exploitation likelihood, and in practice, it fails to do so [3].

What makes the problem more challenging is timing. Knowing that a vulnerability will eventually be exploited is far less actionable than knowing it will be exploited next week. A patch that needs to ship tonight and one that can wait for the next quarterly cycle are operationally very different decisions, but most systems treat them identically, outputting a single binary flag with no temporal dimension [6,7]. This forces analysts to make their own judgments about the timing of potential exploitation, often under significant time pressure and with limited information.

A noted oversight in the literature today is that the available structured security knowledge is globally unincorporated, which greatly limits the efficacy of vulnerability assessment frameworks and tools. The MITRE CWE [21] has over 1,000 known software weaknesses documented; these weaknesses have a direct relationship to attack techniques as defined in the CAPEC database. The relationships between the two records have been documented and represent hard-won knowledge about the mechanics of exploits (i.e., how one exploits the other). Most current machine learning-based systems fail to include this information in their analysis and evaluation processes, such that each CVE is treated as an isolated text string with a CVSS score; in other words, text strings are the only data sources available from which current models learn, therefore they learn only high-level (superficial) patterns from the descriptions of the vulnerabilities instead of the security logic that is the basis for determining real-world risk. Current feature engineering approaches [9,10,11] have been developed specifically to address these deficiencies, and while effective for small data sets, they are slow, expensive, and not scalable.

The authors propose a new approach to determining the timing of exploitation of software vulnerabilities by categorizing each CVE (Common Vulnerabilities and Exposures) into one of five possible timelines for when it could be exploited: 0–7 days, 8–30 days, 31–90 days, 91–365 days, or never exploited. The proposed method utilizes a neural network architecture that fuses BERT [12] representations of textual descriptions of vulnerabilities and Node2Vec [13] representations of the relational structure of vulnerability knowledge graphs through the use of attention mechanisms. The five timelines have a direct correspondence to the patching categories that most security operations use today [6]. Thus,

this model will allow organizations to use the predictions as guidelines for their patching activities without having to interpret the predictions.

This research provides four unique contributions to the vulnerability assessment field. First, it provides a temporal vulnerability assessment framework that describes the prediction of exploitations as a multi-class classification (five-class classification), providing an alternative to traditional binary methodologies. Second, it develops a knowledge graph utilizing CWE and CAPEC architectures that characterizes the exploitability of a CVE in the CSK (Common Security Knowledge) database based on the types of relationships between the two structures (i.e., "weakness" to "enabler" of an attack). Third, it uses an integrated knowledge-fused neural learning architecture consisting of BERT textual encodings, Node2Vec graph embeddings, and attention fusion of the two structures to combine the temporal categorical values of the survival of each CVE exploitation. Finally, an empirical analysis of 100,000+ actual CVEs spanning the years 2002–2024 using data from the CISA-published "Known Exploited Vulnerabilities" database [27] and "Exploit-DB" [28] has been conducted on this research to quantify and evaluate its effectiveness.

The remainder of the study is structured as follows: Section II reviews related work. Section III details the proposed methodology. Section IV presents the experimental results. Section V concludes with a discussion of limitations and directions for future research.

II. Related Work

For many years, researchers have been attempting to answer the question of whether a given vulnerability will be exploited; unfortunately, the way in which this research is framed still has not changed significantly. Much of the existing literature has modeled this problem as a binary classification problem (i.e., whether a vulnerability will be exploited) with most work using CVSS features. Although this may be somewhat helpful, practitioners are more concerned about the timing of when a vulnerability will be exploited, not whether it is likely to be exploited.

Zero-day exploitation follows a similarly compressed timeline: Bilge and Dumitras [18] found that exploits targeting previously undisclosed vulnerabilities are typically weaponized within days of public disclosure, reinforcing the case for a temporal rather than binary framing of exploitation risk.

Jacobs et al. [10] created an ensemble model that uses CVSS metrics and textual descriptors to achieve 88% precision. However, while the results may seem good on the surface, they indicate the limitations of the evaluation framework—a yes/no classification of a dataset that has a large imbalance of outcomes, where predicting the majority class yields high accuracy but has no utility. Sabottke et al. [14] offer a different view by looking at Twitter activity and underground forums for signs of future exploitation and have found that significant social activity often occurs prior to confirmed exploitation by days. While such approaches can be useful in practice, they remain binary classifications that rely on manually curated features and are unable to address the critical aspect of exploitation timing.

Neural approaches reduced the curation cost. Ghaffarian and Shahriari [15] processed CVE descriptions with LSTM networks and hit 85% accuracy without handcrafted features. Chakraborty et al. [16] replaced the LSTM with BERT, and the performance gap relative to classical methods further widened. While the engineering progress is tangible, the output remains the same: a single probability indicating whether a vulnerability will be exploited at some unspecified point in the future.

Timing, interestingly, has been studied in isolation. Li and Paxson [17] tracked a large corpus of patches and found that around 20% of exploited vulnerabilities were weaponized within the first week, while nearly 50% were exploited within one month of disclosure. Bozorgi et al. [8] modeled time-to-exploit distributions statistically. Both papers underscore that vulnerability exploitation is not temporally uniform: the risk profile of a new CVE changes substantially over its first few weeks. However, neither study connects this observation to a prediction system. While the necessary data exists, the development of a temporal predictive model remains unaddressed.

Knowledge graphs have attracted attention as a way to bring structure into the problem. Wang et al. [19] linked CVEs to products and attack techniques, enabling graph traversal to find exploitation chains. Pingle et al. [20] extracted entities from threat reports and embedded them into a graph for intelligence management. These works provide valuable contributions to various problems—such as asset exposure and threat attribution—yet neither predicts exploitation likelihood nor its timing. The graph is utilized as a lookup structure, not a learned predictive signal.

Perhaps the most challenging finding for the field comes from the work of Allodi and Massacci [3]. In an analysis of 4183 vulnerabilities, they found that CVSS scores failed to significantly predict actual exploitation outcomes. A decade later, CVSS remains the default input feature for most prediction models, including several published after that finding was well known. The continued reliance on CVSS features, despite empirical evidence of their limited predictive value, suggests that adoption inertia and tooling standardisation have outweighed technical considerations in shaping operational practice.

Three critical elements remain unaddressed by the literature as a whole. First, existing works lack temporal granularity, focusing on binary exploitation prediction rather than the exploitation window. Second, there is minimal integration of structured knowledge—such as CWE and CAPEC relationships—as a learned predictive signal. Third, the field has yet to reassess the use of CVSS as a reliable feature. The present work attempts to address all three gaps by exploring three critical research questions:

RQ1: Can integrating structured cybersecurity knowledge (CWE-CAPEC graphs) improve exploitation prediction accuracy compared to text-only approaches?

RQ2: Does temporal classification (predicting exploitation time windows) provide more actionable risk intelligence than binary exploitation prediction for operational security?

RQ3: How do different components of the knowledge-fused neural learning architecture (BERT text encoder, Node2Vec graph embeddings, cross-attention fusion mechanism) contribute to overall prediction performance?

Table I summarizes representative existing approaches to vulnerability exploitation prediction and situates the proposed framework relative to them.

TABLE I. COMPARISON OF EXISTING VULNERABILITY EXPLOITATION PREDICTION APPROACHES

Reference	Year	Technique	Dataset	Advantages	Limitations
Jacobs et al. [10]	2024	Ensemble Learning	CVE + Exploit-DB	High precision (88%); multiple feature sources; robust predictions	Binary classification only; no temporal granularity; requires extensive feature engineering
Ghaffarian et al. [11]	2023	LSTM Networks	NVD CVEs	Captures text semantics; 85% accuracy; sequential modeling	Text-only analysis; ignores knowledge graphs; binary prediction
Han et al. [12]	2023	BERT Transformers	NVD + CVSS	Pre-trained representations; superior text understanding; transfer learning benefits	No structured knowledge; missing temporal dimension; isolated vulnerability analysis
Bozorgi et al. [7]	2022	Time-Series Analysis	Historical exploits	Temporal modeling; distribution analysis; timing insights	Continuous prediction (not windows); no knowledge graphs; limited to historical patterns
Edkrantz and Said [9]	2023	Random Forest	CVE + metadata	Interpretable features; 80% accuracy; classical ML robustness	Manual feature engineering; binary classification; no semantic understanding
Gao et al. [19]	2022	Knowledge Graphs	CVE + Products	Graph relationships; vulnerability chains; infrastructure focus	No exploitation prediction; missing temporal aspect; different objective (chain discovery)
Proposed Framework	2026	Knowledge-fused neural learning	NVD + CWE + CAPEC + CISA KEV	Temporal classification (5 windows); knowledge graph integration; graph + text embeddings; scalable architecture	Computational complexity for large graphs; dependent on knowledge base quality; requires comprehensive datasets

III. METHODOLOGY

This section describes the developed temporal vulnerability assessment framework, which incorporates knowledge into temporal vulnerability assessments. The methodology combines cybersecurity knowledge graphs with a knowledge-fused neural learning approach to determine predictive exploitation windows for disclosed vulnerabilities.

A. Dataset Collection and Preparation

Our experimental corpus integrates multiple authoritative cybersecurity data sources to construct a comprehensive vulnerability assessment dataset. Table II summarizes the primary data sources utilized in this study.

TABLE II. DATA SOURCES USED FOR DATASET CONSTRUCTION

Dataset	Source	Time Period	Records	Purpose
NVD [1]	CVE National Vulnerability Database	2002–2024	245,000+	Vulnerability descriptions
CWE [21]	MITRE CWE Database	Latest	1,000+	Weakness definitions
CAPEC [22]	MITRE CAPEC Database	Latest	500+	Attack patterns
CISA KEV [27]	CISA Known Exploited Vulnerabilities	2021–2024	1,200+	Confirmed exploited vulnerabilities
Exploit-DB [28]	Offensive Security Exploit Database	2002–2024	50,000+	Public exploits

The core dataset comprises 102,000 CVE entries spanning 2015–2024, collected from the National Vulnerability Database (NVD). In the dataset, all CVEs are represented by structured metadata, such as Common Weakness Enumeration (CWE) identifiers, Common Vulnerability Scoring System (CVSS) base scores, attack vectors, products affected, and disclosure dates. Along with the dataset, we also included the definition of weaknesses from the MITRE CWE Database (1,003+) and specifications for attacks from the MITRE Common Attack Pattern Enumeration and Classification (CAPEC) Database (500+). To determine the instances where a vulnerability was used to exploit something, we used the CISA Known Exploited Vulnerabilities (KEV) Catalog (1,000+) (2021–2024) and the Offensive Security Exploit Database (50,000+) (2002–2024), both of which contain confirmed exploitation events. The database contains a binary label, which indicates whether a vulnerability was exploited in a real-world attack.

To ensure realistic evaluation, a temporal partitioning strategy is adopted, using 73,440 CVEs (≤2022) for training (72%) and 14,280 CVEs (2023) for validation/testing. This split simulates the setting a model encounters when generalizing to newly disclosed zero-day vulnerabilities without prior exposure to the data.

The temporal labeling protocol was defined as follows. The exploitation clock starts at the CVE's NVD publication date rather than the vendor advisory or CVSS disclosure date, since this is the only timestamp available uniformly across the corpus (advisory dates are missing for a substantial fraction of vendors). For CVEs with more than one recorded exploitation event — for instance, appearing in both the CISA KEV catalog and Exploit-DB at different times, or exploited by multiple distinct campaigns — the earliest recorded event was used to compute time-to-exploit. This is a deliberately conservative choice: it assigns each CVE to the most urgent class it was ever observed in, consistent with the operational goal of never

under-estimating urgency. A CVE is assigned to the never-exploited class (Class 4) if it has no confirmed exploitation event in either source as of the corpus snapshot date (December 31, 2024). This is a right-censoring assumption — a CVE currently labeled "never exploited" could in principle be exploited after the snapshot date — and is acknowledged as a limitation in Section V.

B. System Architecture Overview

We have created our framework using a modular, two-phase approach. We decouple knowledge preparation, which requires heavy computation, from the time-sensitive vulnerability assessments. Fig. 1 illustrates the complete framework, from the offline knowledge preparation phase through to the online real-time assessment pipeline.

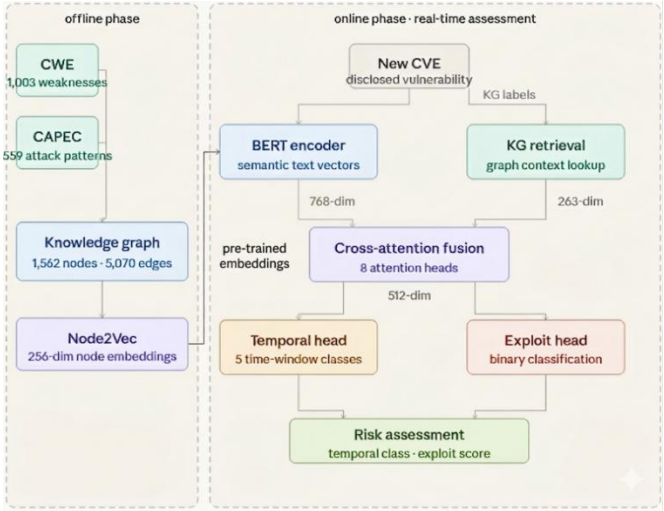

Fig. 1. System architecture.

The offline phase allows us to assemble and encode all cybersecurity data into a single comprehensive knowledge graph that integrates 1,003 CWE weaknesses and 559 CAPEC attack patterns, resulting in a graph containing 1,562 nodes and 5,070 edges. Node2Vec training generates 256-dimensional embeddings that preserve both the graph structure and semantic relationships between security concepts. We compute these embeddings once in the offline phase and keep them fixed. The resulting 256-dimensional node vectors are serialised to disk as a lookup table indexed by CWE and CAPEC identifiers, allowing the online phase to retrieve the relevant embedding for any incoming CVE in constant time without reprocessing the graph.

The online assessment phase operates in real time as new CVEs are disclosed in the national database. Two parallel processing streams work simultaneously: vulnerability descriptions are encoded with a frozen BERT model producing high-dimensional semantic embeddings, while associated CWE labels trigger knowledge graph context retrieval generating structured context vectors. These complementary representations converge in a cross-attention fusion module employing eight attention heads to learn context-aware alignments between textual descriptions and graph-based security knowledge. The fused representation feeds dual prediction heads that simultaneously generate the two target outputs.

C. Feature Extraction and Engineering

Our approach combines representation learning and domain-specific feature engineering within a robust engineering framework. The feature selection process, employed in the creation and evaluation of the dataset, is guided by the exploitation potential and chance of success for a particular attack and impact level. These factors are thereafter correlated with the data to derive actionable indicators.

1) Text encoding: Vulnerability descriptions have distinct linguistic characteristics, including the use of specialized technical vocabulary, adherence to semi-standardized formats, and references to specific software components. SecBERT, a BERT [12] variant pre-trained on cybersecurity content including over 100,000 CVE descriptions, security bulletins, and threat intelligence reports, is used to encode each vulnerability description d_v. The encoding process tokenizes the text using standard BERT tokenization and passes it through 12 transformer layers, producing contextualized representations $H_{text} \in R^{L\times768}$, where L is the sequence length, and 768 is the hidden dimension. We then extract the [CLS] token representation as our text embedding $e_{text} \in R^{768}$—this single vector captures the semantic meaning of the entire description through BERT's self-attention mechanism. We keep SecBERT's weights frozen during training, which helps prevent overfitting and ensures stable embeddings throughout the process.

2) Knowledge graph context retrieval: The graph construction started by using two MITRE resources. The first was the CWE database [22], which lists software vulnerabilities, and the second was CAPEC [23], which lists how those vulnerabilities manifest as real-world attacks. Because these datasets were not designed to be queried together, a unified graph needed to be built for this project first. The final graph, G = (V, E, R), has a total of 1,562 nodes (1,003 CWE nodes and 559 CAPEC nodes) and 5,070 typed edges that connect them. Each node has a name of the vulnerability or attack, a short description of the vulnerability or attack, and a relative likelihood score of {0, 1} derived from a standard set of severity levels. Fig. 2 shows representative subgraphs showing the relationship between CWE vulnerabilities (indicated by blue circles) and CAPEC attacks (indicated by red squares) with directed edges representing the type of relationship.

The majority of the workload is handled by edges. The CWE (Common Weakness Enumeration) that describes the taxonomy allows relationships to describe parent-child hierarchies and dependent relationships such as "requires" or "can precede."

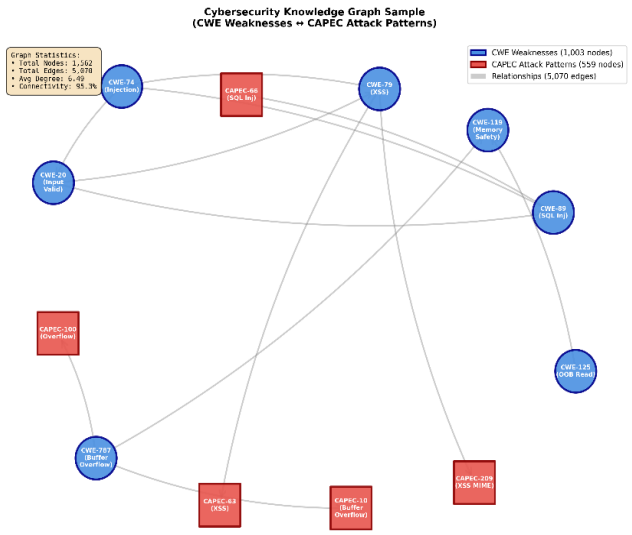

Fig. 2. Subset of knowledge graph.

Across the CWE-CAPEC (Common Attack Pattern Enumeration and Classification) boundary, edges primarily represent enablement: for example, this weakness enables this attack type. However, not all edges in the graph are equally weighted with respect to the amount of exploitation reasoning that they can constrain within the knowledge graph; hierarchies were assigned a confidence of 0.9, associated peers were assigned a confidence of 0.7, and direct enablement mappings were assigned a confidence of 1.0. All of this was due to how each relationship type constrains the manner in which an exploit can be designed based on the aforementioned exploitation criteria. In addition, the average degree of a node in the graph is 6.49; 95.3% of the nodes in the graph are contained within the largest weakly connected component. Therefore, as a result of these characteristics, the graph is very dense and can be traversed meaningfully without any isolated clusters.

Another important characteristic of the CWE-CAPEC relationships is their temporal stability. When new CVEs (Common Vulnerabilities and Exposures) are published, there are no changes to existing CWE-CAPEC relationships based on the disclosure of that CVE. All information related to a CVE, including its CWE relationship: whenever a new CVE is published, it will inherit all of the contextual relationships from its respective or assigned CWE. Therefore, it should be noted that the knowledge graph maintains generalizability to new vulnerabilities without requiring retraining.

3) Graph embedding via Node2Vec: Node2Vec [13] converts the graph structure into fixed-length vectors that the neural model can consume. Alternative knowledge graph embedding methods such as TransE [24] and ComplEx [25] were considered but are better suited to link prediction over entity-relation triples rather than the random-walk-based structural encoding required here. It is worth noting that the knowledge graph functions here as a structured representational source rather than a symbolic reasoner: the CWE-CAPEC ontology, including its typed edges and confidence weights, is encoded into dense vector representations via Node2Vec and subsequently fused with textual embeddings through attention. No explicit logical constraints are imposed on the neural computation at inference time. The framework therefore falls within the paradigm of knowledge-fused neural learning, where structured domain knowledge informs the embedding space rather than governing the output through symbolic inference rules.

The configuration used 256 dimensions, a size following the configuration reported in the original Node2Vec work [13] for graphs of comparable scale and sufficient to capture both local neighbourhood structure and cross-category relationships without unnecessary parameter overhead. Random walks of length 10 and 200 walks per node were used. Both the return parameter p and in-out parameter q were set to 1.0, giving equal weight to local neighbourhood exploration and longer-range traversal; a reasonable default for a graph where both local clusters and cross-category bridges carry information. Walk generation took roughly 2–5 minutes; Word2Vec training over 3 epochs with a context window of 5 added another 5–10 minutes. Total embedding time for the 1,562-node graph came to around 14 minutes, which matters practically—it means the graph can be re-embedded periodically as new CWE entries or CAPEC patterns are added without significant overhead.

To illustrate the extent to which the embeddings capture meaningful predictive signals, we run illustrative sampling tests. Looking at nearest-neighbor relationships, CWE-79 (Cross-Site Scripting) is clustered close to CAPEC-63, its corresponding XSS attack pattern, and CWE-89 (SQL Injection) landed near CAPEC-66. These are the pairings you would expect if the model captured weakness-to-attack relationships rather than just co-occurrence noise. The cross-category structure also held up: CWE-79 and CWE-89 shared moderate similarity as injection-class weaknesses, while CWE-787 (heap buffer overflow) sat well apart from both, which is correct, since memory corruption and injection bugs operate through entirely different mechanisms. The separation was not enforced; it emerged from the graph topology.

D. Neural Architecture

1) Cross-attention fusion module: Text embeddings and graph embeddings capture fundamentally different aspects of a vulnerability—one encodes semantic meaning from the description, the other encodes structural exploitation relationships from the knowledge graph. Simply concatenating the two representations treats them as independent signals and loses the conditional dependencies between them. Cross-attention addresses this by allowing the text representation to dynamically query the graph, weighting each graph concept according to its relevance to the specific vulnerability being assessed. Different description segments naturally attend to different graph structures—'remote code execution' aligns with network attack patterns, while 'privilege escalation' draws on local privilege chain relationships.

Both embedding streams are first projected to a shared 512-dimensional space using learned linear transformations, where

W_text ∈ R^{512×768} maps the BERT output and W_graph ∈ R^{512×263} maps the graph context vector. The 512-dimensional projection space was chosen to match the hidden dimension of the BERT encoder, ensuring that neither modality is compressed before fusion and that the cross-attention mechanism operates on representations of equal capacity. The derived text representation then serves as a query attending over the graph representation as key and value:

$$Attention(Q, K, V) = softmax(QK^T / \sqrt{d_k})V \quad (1)$$

with 8 parallel attention heads, each operating in a 64-dimensional subspace. The attended output is combined with the original text signal through a residual connection, preserving the semantic content of the vulnerability description while incorporating graph-derived context. A two-layer feedforward network then consolidates both into a unified 512-dimensional representation h_fused ∈ R^{512} that feeds the prediction heads.

The 263-dimensional graph-context vector is not the raw Node2Vec embedding. It is the 256-dimensional Node2Vec embedding — averaged over the CWE/CAPEC nodes retrieved for a given CVE, weighted by likelihood/severity — concatenated with seven explicit exploit-signal features derived from the retrieved subgraph: the number of related attack patterns, average and maximum CAPEC likelihood, average and maximum CAPEC severity, the number of prerequisites across related CAPECs, and the number of directly associated CWEs. This yields 256 + 7 = 263 dimensions, matching the kg_dim used as input to the cross-attention fusion module described above.

The residual connection serves a practical purpose beyond standard architectural convention: it prevents the graph signal from overwriting the text representation in cases where the CWE label is missing or uninformative. In those cases, the attention weights naturally collapse toward zero, and the fused representation gracefully reverts to the text-only baseline. This prevents the generation of corrupted outputs.

2) Multi-task prediction heads: The encoding stage processes two input modalities: a pre-trained BERT model takes vulnerability descriptions as input and outputs 768-dimensional vectors (110M frozen parameters), while CWE labels are used to create the trigger graph, yielding 263-dimensional vectors. During the fusion phase, the two streams of information are projected into a 512-dimensional space (393K + 135K). The cross-attention mechanism (525K parameters) then integrates these embeddings, and the final output is generated via a feedforward network. The prediction phase consists of a shared 256-dimensional bottleneck layer (131K parameters) before branching into task-specific modules: a temporal head (263K) to classify the five temporal categories and an exploitation head (174K) for binary classification. Of the entire model, which consists of 111.6M parameters, only 2.1M (1.9%) need to be trained. The architecture thus achieves a favorable balance between model size and training efficiency.

All tasks share a two-layer feature extraction:

$$h_{task} = Dropout(ReLU(W_{s2} \cdot ReLU(W_{s1} \cdot h_{fused})), p = 0.3) \quad (2)$$

where, W_s1, W_s2 ∈ R^{256×512}, producing a 256-dimensional shared task representation. Two independent heads then branch from h_task: the temporal classification head applies a five-way softmax to assign each CVE to one of the exploitation windows, while the exploitation prediction head applies a sigmoid activation for binary probability output:

$$\hat{e} = Sigmoid(Linear(ReLU(W_{exploit} \cdot h_{task}))) \quad (3)$$

Dropout at p = 0.3 is applied during training to prevent the prediction heads from overfitting to the dominant majority class.

The two prediction heads are trained jointly using a fixed, linearly weighted sum of per-task cross-entropy losses:

$$L = \lambda_{temporal} \cdot L_{temporal}(\hat{y}_{temporal}, y_{temporal}) + \lambda_{exploit} \cdot L_{exploit}(\hat{y}_{exploit}, y_{exploit}) \quad (4)$$

with λ_temporal = 1.0 and λ_exploit = 2.0. The higher weight on the exploitation loss compensates for the 85%/15% class imbalance in the binary target and was selected via a small grid search over {1.0, 1.5, 2.0, 3.0} on the 2023 validation split; no curriculum learning or dynamic/uncertainty-based loss weighting is used. Both cross-entropy terms additionally apply per-class weights, computed by inverse class frequency on the training split, to address within-task imbalance independently of the between-task λ coefficients. Gradients from both losses flow jointly through the shared bottleneck layer and the fusion module, with no gradient-surgery or explicit gradient-balancing mechanism beyond the static weighting described above.

IV. Results and Discussion

This section presents a detailed account of the experimental outcomes obtained when evaluating the proposed framework on a held-out test set of 14,280 CVE records sampled from 2024. The evaluation covers temporal classification performance, binary exploitation prediction, ablation analysis, and robustness verification through cross-validation. Each subsection concludes by directly addressing the corresponding research question where relevant.

A. Evaluation Metrics

Class imbalance is one of the major challenges presented by this evaluation, with approximately 85% of the CVEs in the test set not having been exploited, and a naive baseline model flagging the majority class would have an accuracy of 85% without detecting any true positives. Therefore, standard accuracy will not be a useful metric for this task. To ensure a robust evaluation, four different measures will be used rather than relying on a single measure.

While precision and recall are contrary, both of them are very important. An analyst wastes time because a flagging system generated too many false positives—a precision issue—and is exposed to risk because the system missed a valid exploitation—a recall issue. The cost of false negatives is

significantly greater in security operations than the cost of false positives, which places much more weight on recall for high-risk classes. The F1 measure will be used to report the primary measure because it penalizes the tradeoff rather than obscuring it.

Accuracy, while still present in this evaluation, will only be reported with the per-class breakdown measure. When viewed in isolation, accuracy may misrepresent the distribution of values across the classes; however, when viewed next to the class-level data, accuracy will provide an overall summary of the evaluation.

AUC-ROC is included as a metric for evaluating binary exploitation; it is a ranked measure of performance, unlike fixed-threshold metrics (accuracy, F1) that are sensitive to class imbalance. Therefore, AUC-ROC is much more resilient than both accuracy and F1 for class-imbalanced scenarios [26]. Additionally, both weighted and macro-averaged F1 are computed for the five-class temporal head. The macro variant treats each of the five classes equally, regardless of how many samples belong to each class, giving equal influence to performance on Class 0 (the rarest and most critical time window; 0–7 days) and performance on Class 4.

B. Overall Performance Results

The proposed framework's performance outcomes are represented in Table III, against five baseline models. These five baseline models include rule-based, classical machine learning, deep learning, and industry-standard methods of operation, with the majority of all operational work still using CVSS as the operational heuristic. Furthermore, the EPSS developed through the consortium FIRST, and built using logistic regression over NVD features, is currently deployed as the state-of-the-art technique for predicting the automated exploitation of vulnerabilities. As demonstrated in the results, the progressive improvement methodologies consistently yield measurable improvements, and the final model's performance results exceed all five baseline models across the performance metrics reported.

TABLE III. PERFORMANCE COMPARISON ACROSS MODELS

Method	Accuracy (Exploit)	F1 (Exploit)	AUC-ROC	Accuracy (Temporal)	Macro-F1 (Temporal)
CVSS Threshold	0.623	0.342	0.589	—	—
Random Forest	0.741	0.614	0.723	—	—
LSTM Networks	0.768	0.646	0.757	—	—
Fine-tuned BERT	0.821	0.702	0.812	—	—
EPSS	0.847	0.679	0.827	—	—
Proposed	0.891	0.747	0.891	0.784	0.623

The CVSS threshold baseline provides a logical foundation for comparisons, not just because it provides a uniform standard to a comparative set of organizations but also because it is reflective of how organizations operate today. The model's overall exploitation F1 score of 34.2% should give organizations pause because CVSS-based triage exists across many organizations in practice. This result corroborates the earlier empirical findings by Allodi and Massacci [4,5], who showed that there is only a weak correlation between severity and the likelihood of exploiting a vulnerability.

Random Forest does considerably better at an F1 score of 61.4%, capturing non-linear interactions between CVSS attributes and TF-IDF text features that are not discernible by threshold-based rules. While the performance improvement is substantial, handcrafted features and binary framing constrain the approach's predictive capacity. LSTM networks further improve the performance to 64.6% by modeling descriptions as sequences rather than bags of words. Fine-tuned BERT reaches a score of 70.2%, the highest text-only performance, by leveraging pre-trained contextual representations that capture security semantics more precisely than traditional TF-IDF methods.

EPSS achieves an F1 score of 67.9% and an AUC of 82.7%. While it outperforms the simpler ML baselines, it remains inferior to both BERT and our proposed model, which achieves an F1 score of 74.7% and an AUC of 89.1%. The F1 gain is 6.8 above EPSS, and the AUC gain is 6.4 at the same time. The AUC increase is of greater importance than the difference between F1 in practice, as it describes the ranking quality across all potential thresholds as opposed to just performance at a single cut-off. A 6.4 increase at this level represents a significant and meaningful advancement in predictive reliability.

There is no external baseline for temporal performance, as none of the systems were built to provide five-class time-window predictions. The final system is accurate to 78.4% and has a 62.3% macro-F1 score. The macro-averaged score is a more conservative measure, since the proportion of samples in Class 0 (0–7 days) is 1.4% of the total test sample; therefore, Class 0 is weighted equally to Class 4. Therefore, the macro-average cannot provide a good measure of performance by inflating the majority-class performance. The system's ability to obtain a score above 62% suggests that signals from the prediction occur throughout the entire time range, not just in the most straightforward cases.

C. Temporal Classification: Per-Class Analysis

Table IV reports detailed per-class precision, recall, and F1-score for the temporal classification task, discussed below.

Breaking down the temporal results by class reveals a coherent pattern that aligns well with what one would expect from the data characteristics and the underlying security dynamics.

TABLE IV. DETAILED PER-CLASS TEMPORAL CLASSIFICATION METRICS

Class	Window	Precision	Recall	F1-Score	Operational Label
Class 0	0–7 days	0.7123	0.6590	0.6845	Emergency patch
Class 1	8–30 days	0.6834	0.6245	0.6523	Accelerated deploy
Class 2	31–90 days	0.6456	0.5938	0.6189	Monthly cycle
Class 3	91–365 days	0.5912	0.5567	0.5734	Quarterly update
Class 4	> 365 d / Never	0.8567	0.7945	0.8234	Risk-based deferral
Weighted Avg	—	0.7956	0.7842	0.7891	—

Class 4 (vulnerabilities exploited beyond one year or not at all) makes up 86.6% of the test set and corresponds to an F1 score of 82.3%. Therefore, we should not over-interpret this. Even a very naive classifier will quickly learn that the vast majority of CVEs do not actually see any real-world exploitation.

The more interesting number lies elsewhere. Class 0 (0–7 day window) consists of 200 of the 14,280 testing samples, and the model achieves an F1 of 68.5%, 71.2% precision, and 65.9% recall. This means that approximately two-thirds of imminent exploits are correctly flagged and would not generate so many false positives that an analyst's queue could not handily keep pace with them. This is especially significant, given that Class 0 is very rare and has potentially great significance in the real world. This result is operationally significant given the low base rate of Class 0.

The place where the model performs the poorest is in Class 3 (3–12-month window) with an F1 of 57.3%. This fact is not surprising. The vulnerabilities exploited within this time frame are much more difficult for the model to learn about; therefore, the training signal is much sparser, while the type of exploitation that occurs in this time frame is often based on campaign-specific decisions made by threat actors that are not reflected in the CVE or CWE data. It reads more like a data limitation than a modeling one. This distinction is relevant for prioritizing future data-collection versus architectural investment.

In conclusion, while the per-class numbers appear harsh, the error analysis provides some level of comfort. 61.3% (or 1,072) of all misclassifications were made between adjacent temporal classes (for example, Class 1 being read as Class 2) and comparatively few (34) were made between disparate classes. The overwhelming majority (98%) of misclassifications were made between two adjacent windows; thus, the vast majority of them will have no practical operational effect as they will use roughly similar response protocols within the same patching frameworks. The only truly damaging error is the misclassification of an active exploitable vulnerability as being unlikely to ever be exploited (267 instances, or 1.9% of the dataset). In an imbalanced dataset, keeping this number below 2% is arguably the most important threshold the system has successfully achieved.

D. Ablation Study

We performed an ablation study where three controlled configurations isolate the contribution of each architectural layer. As Table V shows, each addition produces consistent gains across all three metrics.

TABLE V. ABLATION STUDY: INCREMENTAL COMPONENT CONTRIBUTION

Configuration	Component	Temporal Accuracy	Exploit F1	AUC-ROC
Text Only (baseline)	BERT encoder only	0.6834	0.6245	0.7456
Text + KG, No Fusion	BERT + concatenation	0.7456	0.6923	0.8234
Complete Model (proposed)	BERT + cross-attn + KG	0.7842	0.7467	0.8912

The baseline performance level (62.5% exploitation F1) achieved using the BERT model based solely on textual data is improved to 69.2% by combining the CWE-CAPEC knowledge graph using simple concatenation, which demonstrates that structured domain knowledge contributes a significant amount of additional information beyond what is provided by vulnerability descriptions alone. By upgrading the way in which the knowledge graph and text data are combined from simple concatenation to cross-attention, it is possible to further increase performance to 74.7% F1 and 89.1% AUC-ROC through cross-attention's ability to learn conditionally aligned mappings; for example, being able to map the phrase "heap overflow via remote input" to CAPEC-100 instead of CAPEC-66, which is something that cannot be done with simple concatenation.

Answer to RQ3: The 12.2% total increase in F1 above the text-only baseline demonstrates that neural text understanding and graph-based structural encoding do not just coexist together in a complementary manner, but rather that they are mutually reinforcing. As an example, the knowledge graph provides context of exploitation pathways that are often left implicit in textual descriptions, while cross-attention allows for the selective application of that context instead of the blanket addition of that context to all instances of text.

E. Knowledge Graph Integration vs. Text-Only Approaches (RQ1)

The ablation results directly address RQ1. Moving from the text-only baseline to the complete model yields a 12.2-point F1 gain, a margin exceeding the performance gap between the CVSS heuristic and fine-tuned BERT (cf. Table III). The knowledge graph allows the model to reason about structural exploitation pathways rather than pattern-match on surface vocabulary, linking weaknesses to attack classes and modeling the exploitation likelihood across the CWE-CAPEC hierarchy. This structured knowledge captures relationships that a free-text vulnerability description often leaves implicit.

Answer to RQ1: Yes. Integrating the CWE-CAPEC knowledge graph improves exploitation F1 by 12.2% and AUC-ROC by 14.6% over the text-only baseline, and outperforms the current industry standard EPSS by 6.8 F1 points and 6.4 AUC points.

F. Temporal Classification versus Binary Prediction (RQ2)

Binary exploitation prediction suffers a practical limitation that is easily overlooked. Flagging a vulnerability as "exploitable" provides a security team no insights into timing, which is critical to determining whether a patch needs to be deployed tonight or can wait for the next quarterly cycle. The two decisions carry completely different resource costs, yet a binary model treats them identically.

The binary classification system (yes/no) that currently exists for exploiting vulnerabilities has a significant limitation: there is only one way to classify a CVE (Common Vulnerability and Exposure). By implementing the proposed temporal classification system, several new methods to classify the exploitability of CVEs are available; in this case, five new intervals for classifying CVEs will replace the single yes/no output (0–7 days, 8–30 days, 31–90 days, 91–365 days, or never exploited).

In reality, most organizations already utilize tiered patching protocols that will map directly to the new temporal classifications proposed; i.e., emergency remediation, accelerated deployment, monthly deployment, quarterly review, and risk-based exception. This allows the temporal predictions to be utilized directly within existing workflows without the need for an additional triage layer between the two processes.

This means that operationally, the outputs of temporal prediction provide functionality that enables a more actionable risk intelligence than currently exists. For example, when a CVE falls into Class 0, the corresponding response is immediate (emergency dispatch), which would differ substantially from the response when falling into Class 3 (no immediate dispatch), rather than relying upon an analyst's judgment and decision.

Answer to RQ2: Prediction through temporal CVE classification results in more actionable risk intelligence than binary classifications. Auto-mapping of the predicted exploitation period onto known patching tier periods eliminates the manual conversion process done by the binary classification, resulting in greater consistency in making decisions.

G. Deployment Feasibility and Computational Overhead

To assess whether the framework can operate under realistic operational workloads, we benchmarked inference latency and throughput on the deployment hardware (NVIDIA GPU, CUDA). Single-CVE inference latency averaged 6.43 ms (p50 = 6.44 ms, p95 = 6.74 ms, p99 = 6.87 ms), well within the sub-second budget required for interactive triage. Batch throughput scales from 139.4 CVE/s at batch size 1 to 1,207.4 CVE/s at batch size 64, with diminishing marginal gains beyond batch size 32 (1,188.2 CVE/s), indicating that the cross-attention fusion module is not the throughput bottleneck at moderate batch sizes. At the best observed throughput, the framework can process an estimated 104.3 million CVE assessments per day on a single GPU instance. Given that the National Vulnerability Database discloses on the order of dozens to a few hundred CVEs per day, a single deployed instance provides several orders of magnitude of headroom, and horizontal scaling is straightforward: the offline knowledge-graph embeddings are fixed and shared across workers, and the online scoring path is embarrassingly parallel across CVEs. These results indicate that computational overhead is not a barrier to enterprise-scale deployment.

V. Conclusion

Prioritization of vulnerabilities through traditional methods often relies heavily on their severity scores, which indicate how theoretical a vulnerability's impact is versus how the vulnerability will likely be exploited in the real world. Prioritizing vulnerabilities in this fashion incurs real costs; security teams work to patch vulnerabilities that will never be exploited due to limited time and resources, and they may also leave undetected vulnerabilities that warrant prompt prioritization and patching. This research reframes the question of time to exploitation of a vulnerability as five classes of temporal classifications, capturing timing information that is often lost in binary frameworks, and aligning classification outputs with patching tiers currently employed by most organizations.

These design choices have been validated. The complete framework yields 74.7% exploitation F1 and 89.1% AUC-ROC and outperforms the EPSS (the current industry standard) by 6.8 points for F1 and 6.4 points for AUC-ROC, and outperforms the benchmark for text-only BERT by 12.2 F1 points. Ablation studies indicate that knowledge graph integration and cross-attention fusion are the major reasons for this improvement in performance, indicating that explicitly modelling connections between weaknesses and attack methodologies has added more value than the ability to simply provide more complex text representations of vulnerability descriptions.

There are limitations to this study. The data used to create the labels for ground-truth vulnerability exploitation (CISA KEV, Exploit-DB) only reflects instances of vulnerability exploitation that are publicly reported. As such, the extent of the model's performance will be impacted as the model does not account for vulnerabilities being exploited in a private capacity. In addition, NVD records without CWE numbers reduce the ability to make predictions about a vulnerability's exploitation, as the model must rely solely on the text-based features of the record. The model was trained on an archive of exploitation data through 2022; this means that to continue to understand vulnerability exploitation as technology changes and attacker tools evolve, the model must be retrained consistently.

In the short term, improvements to the model will be more appropriately focused on the data side than the modeling side (automated CWE labels during preprocessing, quarterly retraining aligned with KEV updates, and expanding the number of ATT&CK techniques in the knowledge graph). In terms of architectural improvements, changing from Node2Vec to Graph Attention Networks and estimating uncertainty of

low-confidence outputs would allow for a more effective way to implement the system in an operational capacity. The primary conclusion reached in this work is that vulnerability exploitation risk is ultimately temporal and relational rather than simply a byproduct of severity; therefore, a reconsideration of how exploitation information is produced and utilized is likely warranted.

Deep Learning-Based Image Recognition and Brand Identity Design for Intangible Cultural Heritage in Southern Sichuan

Zhihong Chen
Neijiang Normal University, Neijiang 641100, China

***Abstract*—The increasing emphasis on digital protection and creative transformation of intangible cultural heritage highlights the urgent need to apply artificial intelligence to accurately identify and brand rich cultural heritage resources in southern Sichuan. This study puts forward an image recognition and brand design model suitable for intangible cultural heritage in southern Sichuan. This model has obvious advantages in extracting key visual features such as texture, color, and shape, effectively coping with the challenges brought by complex texture and category imbalance in intangible cultural heritage images, and achieving stable and reliable recognition performance. The proposed model improves the overall accuracy, F1 score, and recognition rate of complex texture images, and the overall accuracy reaches 94.1%. Among them, the recognition accuracy of texture, color, and shape reached 92.8%, 95.2%, and 90.1%, respectively, which were better than the traditional models, and accurately captured the detailed features and visual style of intangible cultural heritage items. In the application of brand logo design, the evaluation results of user satisfaction show that the score is high in aesthetics, commercial value, and narrative quality, among which the average score of aesthetics is 3.92, which highlights the advantages of this model in visual language and artistic expression. This study has made a breakthrough in the high-precision and multi-dimensional feature extraction of image recognition of intangible cultural heritage in southern Sichuan Province, and provided an intelligent tool for the brand logo design of intangible cultural heritage. At the same time, the research promotes the integration of digital protection and creative transformation, which is of great value to cultural heritage inheritance, brand promotion, and creative industry application. The research results provide practical guidance for future model optimization, cross-regional intangible cultural heritage identification and multimodal design exploration.**

I. INTRODUCTION

Southern Sichuan is rich in intangible cultural heritage, including projects with distinctive regional characteristics and cultural significance, such as Zigong Lantern Festival, Luzhou Oil Paper Umbrella, and Neijiang tanghua [1]. The core skills and cultural connotations of these intangible cultural heritages are usually embodied and passed down through physical image carriers, such as lantern patterns, umbrella design, and tanghua modeling [2]. However, the accelerated modernization process and the wide application of digital technology have brought two major challenges to the intangible cultural heritage in southern Sichuan: First, "live transmission" is facing the risk of interruption. Second, the progress of "digital protection" is lagging. Many intangible cultural heritage images still exist in traditional forms, such as paper files or physical collections, which are not conducive to efficient storage, retrieval, and sharing, and are also difficult to meet the needs of cultural communication and public participation in the new media era. Therefore, the vitality and influence of intangible cultural heritage are still limited [3–5].

Artificial intelligence (AI), especially deep learning, has shown excellent performance in image recognition. Its application in cultural heritage protection, such as cultural relics classification and traditional pattern extraction, has begun to appear [6]. However, at present, most studies only focus on individual categories of intangible cultural heritage and fail to systematically analyze the diverse cultural heritage images found in southern Sichuan [7]. In addition, traditional image recognition methods usually remain at the simple classification level. They rarely integrate recognition results with deeper cultural interpretation or the needs of branding and dissemination [8]. This separation between technology and culture limits the full potential of deep learning in intangible cultural heritage preservation. It also hinders the development of Southern Sichuan's intangible cultural heritage from "digital preservation" to "branded dissemination" [9].

This study takes Southern Sichuan's intangible cultural heritage images as the research object and attempts to establish an image recognition system based on deep learning and cultural interpretation. By optimizing the convolutional neural network (CNN) model, the system realizes high-precision recognition, feature extraction, and semantic analysis of images in different categories of Southern Sichuan's intangible cultural heritage. Based on the above recognition results, this study explores new ideas for brand identity design of Southern Sichuan's intangible cultural heritage. The cultural symbols contained in the intangible cultural heritage images displayed as the visual identity of the brand are integrated into contemporary people's needs in identification and expression. This study provides an effective and accurate method for digital protection of Southern Sichuan's intangible cultural heritage. This study bridges the gap in the application of deep learning in regional intangible cultural heritage image recognition. Simultaneously, it underpins the modernization of intangible cultural heritage branding and the market-oriented transformation of cultural value with theoretical justification and practical recommendations. These efforts contribute to sustaining the living transmission of Southern Sichuan's

intangible cultural heritage and promoting its sustainable development in the new era.

To address the technical challenges of Southern Sichuan intangible cultural heritage image recognition, including multi-category classification, high visual complexity, and class imbalance, as well as the limited integration of image recognition results into brand communication, this study develops an integrated framework for Southern Sichuan intangible cultural heritage image recognition and brand identity design that combines deep learning with cultural interpretation. The study first reviews existing research on the application of deep learning in cultural heritage preservation and identifies current technical gaps and limitations in practical applications. Subsequently, this study proposes a CNN model based on multi-loss joint optimization and carries out high-precision image recognition and feature analysis of intangible cultural heritage in southern Sichuan from three visual dimensions: texture, color, and shape. On this basis, the study further discusses how to transform the identified cultural characteristics into brand visual elements that support contemporary brand identity design. Finally, the performance of the proposed framework in image recognition and the effect on brand identity design is evaluated through comparative experiments and customer satisfaction surveys. The research results provide a comprehensive solution that provides technical support and practical guidance for the digital protection and brand communication of intangible cultural heritage in southern Sichuan.

II. Related Work

With the deep integration of digital technology and intangible cultural heritage protection, deep learning has gradually become the core tool of intangible cultural heritage digitization research with its advantages in image feature extraction and pattern recognition [10]. As the carrier of folk culture in the southwest of China, the intangible cultural heritage in southern Sichuan combines regional characteristics and cultural values in the image. However, the systematic research on the application of deep learning in the image of intangible cultural heritage in southern Sichuan and its transformation into brand identity is still limited.

Yu et al. constructed the "AI for Dunhuang" dataset for the preservation of Dunhuang cultural heritage. The dataset included 10,000 mural images for automated restoration and 3,455 images for style transfer. By improving the U-Net network architecture, the precision of mural defect filling was optimized. Archaeologists evaluated the restoration quality as comparable to manual restoration [11]. Fernandes et al. focused on preventive conservation of artifacts by integrating the Mask Region-based CNN with infrared thermography for defect detection in Italian marquetry artifacts. By introducing an adaptive threshold segmentation module, their method improved the recognition of deep defects such as wood cracks and glue aging. However, they pointed out that existing models are often tailored to single materials or artifact types and lack general applicability to the diverse materials and forms of folk intangible cultural heritage images [12]. In addition, international research has mainly concentrated on "protection-oriented" applications, such as large-scale site restoration and artifact defect detection. Few studies have linked image recognition results to "application-oriented" needs, such as intangible cultural heritage brand communication and cultural product design. As a result, a complete "technology–culture–market" chain has not yet been established [13].

Domestic research has focused more on the digitization of local intangible cultural heritage, achieving progress in technology adaptation and regional practice. Qi et al. addressed the diverse needs of ancient Chinese character recognition by proposing the HUNet model, which integrated an attention mechanism. They constructed a multi-type dataset of ancient Chinese character recognition, including more than nine million samples of Oracle Bone Inscriptions, bamboo slips, and stone carvings. Their method has achieved an accuracy of 98.7% in many ancient character recognition tasks [14]. Sun et al. discussed the preservation of intangible cultural heritage from the perspective of digital protection. They developed an intelligent document recording system based on deep learning for the cultural heritage of the Li branch, and used the cultural pattern recognition model to automatically extract and realize the digital preservation of traditional cultural characteristics. This study provided technical support for the long-term preservation and intelligent management of intangible cultural heritage resources. The research showed that the combination of artificial intelligence and digital technology improved the efficiency of cultural document recording and improved the quality of digital preservation, which provided a new perspective for digital inheritance and innovative utilization of intangible cultural heritage [15]. Pan et al. studied the development of a digital twin of cultural heritage and proposed a method based on deep learning to automatically transform a semantic point cloud into a semantic building information model (BIM). This method can intelligently identify and semantically reconstruct the spatial structure and building components of cultural heritage buildings, thus improving the efficiency and accuracy of digital cultural heritage modeling. Although their research has expanded the application of deep learning in digital protection of cultural heritage, it mainly focuses on the three-dimensional modeling of architectural heritage and does not involve the image recognition of intangible cultural heritage, nor does it discuss its application in brand logo design and other cultural and creative fields [16].

In summary, although research on deep learning in the intangible cultural heritage field has achieved progress in technical accuracy and regional applications, three major gaps remain. First, international research has largely overlooked regional folk intangible cultural heritage such as that of Southern Sichuan, and its technical applications do not yet cover the full "image recognition–brand transformation" chain. Second, domestic studies have focused on local intangible cultural heritage, but dependence on single carriers limits accurate recognition of the multi-carrier intangible cultural heritage images of Southern Sichuan, while digital resources remain disconnected from brand design needs. Third, local branding practices for Southern Sichuan's intangible cultural heritage lack technological support, relying on manual approaches that are inefficient and insufficiently standardized.

To address these gaps, this study examines multi-category intangible cultural heritage images from Southern Sichuan. By

optimizing deep learning models, the study achieves high-precision recognition and cultural interpretation of multi-carrier images and links these results with brand identity design. The aim is to provide an integrated solution for both digital preservation and branded dissemination of regional intangible cultural heritage.

III. Deep Learning-Based Model for Southern Sichuan's Intangible Cultural Heritage Image Recognition and Brand Identity Design

A. Introduction to Deep Learning

Deep learning is a machine learning algorithm that simulates the operation mechanism of the human brain neural network. By constructing interconnected artificial neural networks, it can realize complex abstraction and learn from massive datasets [17]. In the deep network, the original input, such as an image, text, or audio, will undergo a series of nonlinear transformations and gradually generate more and more refined feature representations. The algorithm can directly mine related patterns from large-scale datasets without artificial feature design [18]. With the optimization algorithm of iteratively adjusting model parameters, deep learning realizes autonomous learning and continuous improvement, and can accurately predict and support scientific decision-making in complex environments [19]. In recent years, with the rapid growth of data and computing resources, deep learning has developed into the core research field of artificial intelligence, and has profoundly changed many industries [20].

Let the design matrix X be an m×n matrix, where the data are centered with mean zero, i.e., $E[x]=0$. If not, preprocessing subtracts the mean from all samples to achieve centralization. The unbiased sample covariance matrix corresponding to X is given as Eq. (1) presents the unbiased sample covariance matrix associated with X:

$$Var[x]=\frac{1}{m-1}X^TX \tag{1}$$

The variance Var[z] forms a diagonal matrix, obtained through the linear transformation $z=W^Tx$. The primary components of the design matrix X are defined via the eigenvectors of X^TX, represented in Eq. (2):

$$X^TX=W\wedge W^T \tag{2}$$

Letting W denote the right singular vector matrix obtained from the singular value decomposition (SVD) $X=U\Sigma W^T$, and treating W as the eigenvector basis, the original eigenvalue relation can be written as Eq. (3):

$$X^TX=\left(U\sum W^T\right)^TU\sum W^T=W\sum{}^2W^T \tag{3}$$

It follows that Var[z] is diagonal. When X undergoes principal component decomposition, its variance can be formulated as:

$$Var[x]=\frac{1}{m-1}X^TX \tag{4}$$

$$=\frac{1}{m-1}\left(U\sum W^T\right)^TU\sum W^T \tag{5}$$

$$=\frac{1}{m-1}W\sum{}^2W^T \tag{6}$$

Here, the relation $UTU=I$ holds, since by definition the matrix U is orthogonal under SVD. This demonstrates that the covariance matrix z possesses a diagonal form, as detailed below:

$$Var[z]=\frac{1}{m-1}Z^TZ \tag{7}$$

$$=\frac{1}{m-1}W^TX^TX^TW \tag{8}$$

$$=\frac{1}{m-1}W^TW\sum{}^2W^TW \tag{9}$$

The preceding analysis demonstrates that a linear projection of x onto z via W yields a diagonal covariance matrix (Σ^2), which implies mutual independence among the components of z.

The preceding analysis of the fundamental principles of deep learning and its feature learning mechanism shows that deep learning employs multi-layer neural network architectures to progressively abstract and efficiently represent data. Through parameter optimization, it continuously enhances the model's ability to learn from complex datasets [21]. The principles of feature dimensionality reduction and information extraction embodied in principal component analysis also provide an effective approach for representing high-dimensional data within deep learning models. In the context of the digital preservation and brand identity design of Southern Sichuan intangible cultural heritage, image datasets contain abundant cultural symbols and visual characteristics. Traditional image processing methods are often unable to effectively extract the underlying semantic information embedded in these complex visual features. Therefore, applying deep learning to Southern Sichuan intangible cultural heritage image recognition is essential for developing an intelligent recognition model with strong feature extraction and classification capabilities. Based on these considerations, this study develops a deep learning-based algorithm for Southern Sichuan intangible cultural heritage image recognition. A CNN is employed to extract image features, while a multi-loss joint optimization strategy is introduced to improve classification accuracy and feature discrimination. The proposed algorithm establishes a technical foundation for the automatic recognition of Southern Sichuan intangible cultural heritage images, cultural element analysis, and digital dissemination.

B. Deep Learning-Based Image Recognition Algorithm for Sichuan Southern Intangible Cultural Heritage

In order to realize the automatic recognition and application analysis of Sichuan southern intangible cultural heritage images, this research studies a recognition algorithm based on deep learning. The method is as follows: Firstly, use CNN to extract the local and global image features. The network output is transferred to class probabilities by the Softmax function.

Then, cross-entropy loss is used as a supervisory signal in the training process. Meanwhile, Focal Loss is introduced to solve the class imbalance problem. In addition, Triplet Loss and Center Loss are incorporated to enhance feature discrimination [22]. The model is optimized under a multi-loss framework, which ensures both high classification accuracy and strong feature separability [23].

The convolutional layer extracts local features from images as follows:

$$y_{i,j,k} = \sum_{u,v,c} W_{u,v,c,k} x_{i+u-1,j+v-1,c} + b_k \tag{10}$$

In Eq. (10), x denotes the input image, b_k represents the bias, W signifies the convolution kernel, and $y_{i,j,k}$ refers to the output feature map.

The Softmax function converts the network output into class probabilities:

$$p_{i,c} = \frac{\exp\left(z_{i,c}\right)}{\sum_j \exp\left(z_{i,j}\right)} \tag{11}$$

In Eq. (11), $z_{i,c}$ is the score of sample i in class c, and $p_{i,c}$ is the predicted probability.

Cross-entropy loss supervises classification training:

$$L_{FL} = -\frac{1}{N}\sum_i \left(1 - p_{i,yi}\right)^{\gamma} \log p_{i,yi} \tag{12}$$

In Eq. (12), γ controls the weighting of difficult samples.

Triplet Loss enforces inter-class separability:

$$L_{tri} = \sum \left[\left\| f_a - f_p \right\|^2 - \left\| f_a - f_n \right\|^2 + \alpha \right] \tag{13}$$

In Eq. (13), f_a, f_p, and f_n are the features of the anchor, positive, and negative samples, respectively, and anchor α is a margin hyperparameter.

Center Loss strengthens intra-class compactness:

$$L_{cener} = \frac{1}{2N}\sum_{i=1}^{N} \left\| f\left(x_i\right) - c_{yi} \right\|^2 \tag{14}$$

In Eq. (14), $f\left(x_i\right)$ is the feature of sample i, and c_{yi} is the center of its class.

Finally, the comprehensive loss function jointly optimizes classification and metric learning objectives:

$$L = L_{CE} + \lambda_1 L_{tri} + \lambda_2 L_{cener} \tag{15}$$

In Eq. (15), λ_1 and λ_2 are the corresponding loss weights.

This multi-loss optimization strategy enables the proposed model to achieve both accurate classification and highly discriminative feature representations.

The quality monitoring of the Sichuan southern intangible cultural heritage image dataset is achieved through a multi-level verification and screening mechanism to ensure both reliability and usability. Processed intangible cultural heritage images are first organized and subjected to quality checks in terms of clarity, integrity, and format. Data that fail to meet requirements are either discarded or corrected. Qualified images then proceed to the classification stage, where the accuracy of category labeling is verified to maintain consistency and correctness. Once classification and labeling are complete, the system generates corresponding image package files. These files undergo an additional round of validity checks, and any defective data are returned for correction. Only verified image data proceed to the file generation stage, followed by a final review to ensure compliance with database storage standards. By implementing quality control in all stages from collection, classification, labeling to storage, this dataset provides a reliable basis for the subsequent image recognition and deep learning modeling of intangible cultural heritage [24]. Fig. 1 presents the procedure for monitoring the quality of the dataset.

The Sichuan southern intangible cultural heritage image recognition system is formed by three parts: computing platform, database platform, and integrated management system. The computing platform module includes the image acquisition module, image preprocessing module, feature extraction module, and classification module. These modules realize the whole process from raw image acquisition to feature categorization. The database platform module realizes data storage and retrieval. The module of the integrated management system includes an automatic labeling and statistical module, heritage category analysis module, cultural heritage recommendation module, and interactive display and education module. These functions can realize systematic annotation, category, cultural analysis, and public display [25].

The image recognition system for Sichuan's southern intangible cultural heritage realizes intelligent recognition on the computing platform, efficient management on the database platform, and the analytical and presentation functions on the integrated management system. These parts realize the whole closed loop from image acquisition to application and dissemination, as shown in Fig. 2. This system provides strong digital support for the protection, research, and communication of intangible cultural heritage.

C. Deep Learning-Based Brand Identity Design Model for Southern Sichuan's Intangible Cultural Heritage

The deep learning-based brand identity design model for Southern Sichuan's intangible cultural heritage primarily involves data collection, preprocessing, model training, and optimization. The system first gathers relevant intangible cultural heritage materials and evaluates whether they meet the quantity and quality requirements for modeling. If the data is insufficient, additional data will be collected and supplemented. Once sufficient data is obtained, pretreatment is carried out to standardize the material and ensure the consistency and usability of the input. Based on the preprocessed data, an appropriate deep learning model is selected as the basis to generate an initial model. In the process of model creation, training parameters are set, and the model is tested and verified. If the performance does not meet the requirements, adjust the parameters or modify the model architecture until the expected effect is achieved.

In the process of model optimization, the system will continuously adjust the training parameters and make many iterations to improve the generalization ability and generation quality of the model. When the preset accuracy and robustness requirements are met, the process will enter the stage of brand identity generation. In Fig. 3, the image generation module in the brand logo design model of intangible cultural heritage in southern Sichuan based on deep learning consists of four parts: cultural feature extraction, feature coding, visual element mapping, and generation model reasoning. Firstly, the trained

deep learning model analyzes the intangible cultural heritage materials in southern Sichuan and extracts representative texture, color, shape, and cultural semantic features. These features are then encoded into computed feature vectors. Then, through the visual element mapping mechanism, the corresponding relationship between cultural characteristics and brand design elements is established. Specifically, texture features are mapped to brand logo graphics, color features correspond to the brand color matching system, shape features correspond to auxiliary graphics and layout style, and cultural semantic features are reflected in the expression of brand cultural identity. Based on these mapped features, the generation model will reorganize and optimize the design elements according to the user-defined design instructions and style parameters, and automatically generate multiple brand image schemes. Finally, the generated design is evaluated and comprehensively judged from the aspects of cultural consistency, visual beauty, and brand uniqueness. If the evaluation results do not satisfy the predefined criteria, the workflow returns to the parameter optimization stage for further refinement. Otherwise, the final brand identity design is generated. This closed-loop workflow—model optimization, feature extraction, visual element mapping, design generation, and result evaluation—transforms the cultural elements of Southern Sichuan intangible cultural heritage into brand visual symbols. As a result, it ensures cultural authenticity and design consistency while improving the automation and reproducibility of the brand identity design process. The workflow of the deep learning-based Southern Sichuan intangible cultural heritage brand identity design model is shown in Fig. 3.

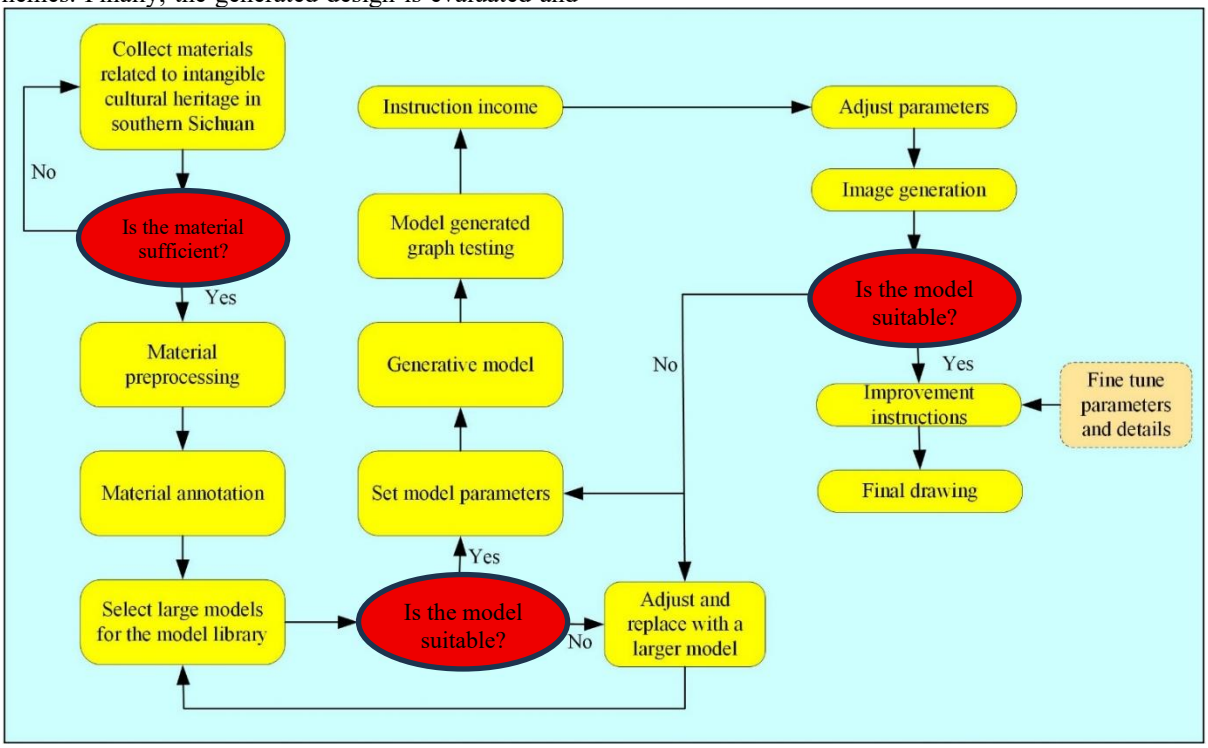

Fig. 3. Workflow of the deep learning-based brand identity design model for Southern Sichuan's intangible cultural heritage.

IV. Application of the Deep Learning-Based Model for Southern Sichuan's Intangible Cultural Heritage Image Recognition and Brand Identity Design

The construction of Southern Sichuan's intangible cultural heritage dataset is based on multi-channel systematic collection and organization. First, high-resolution images of typical intangible cultural heritage items, such as Shu brocade, Sichuan opera facial masks, bamboo weaving, embroidery, and ceramics, were captured through field surveys in southern Sichuan. This ensured the authenticity and completeness of textures, details, and colors. Second, the dataset integrates publicly available intangible cultural heritage resources from national and local cultural departments, including the Digital Museum of Chinese Intangible Cultural Heritage and the Sichuan Province intangible cultural heritage Information Management Platform. These resources supplement the historical documents and brand visual design materials that are difficult to collect in the field. In addition, brand image design images of enterprises and design institutions related to intangible cultural heritage, including signs, packaging, and posters, have been collected, and all images have been authorized by law or publicly licensed. In the process of database construction, all images are labeled according to the process type or brand design category, with category labels, texture features, colors, and style information attached. Using a standardized file structure, the dataset is divided into training, verification, and testing sets to support the training, verification, and testing of the model and ensure the repeatability of the experiment and scientific performance evaluation. This dataset captures rich process details and reflects the brand visual design style. It provides a high-quality foundation for the research of intangible cultural heritage

image recognition and brand identity design based on deep learning.

This dataset contains images of eight representative categories of intangible cultural heritage in southern Sichuan: Zigong Lantern Festival, Luzhou Oil Paper Umbrella, Neijiang tanghua, Shu Embroidery, Sichuan Opera Mask, Bamboo Weaving, Embroidery and Ceramics. In order to improve the generalization ability of the proposed model, image acquisition covers various manifestations of each intangible cultural heritage category in different perspectives, lighting conditions, and craft styles. The dataset contains 8,080 images, which are randomly divided into a training set, a verification set, and a test set with the ratio of 7:1.5:1.5. The training set contains 5,656 images for model training and parameter optimization. The verification set contains 1,212 images, which are used for hyperparameter tuning and early stopping during training. The test set also contains 1,212 images, which are used to evaluate the final performance of the trained model. In order to ensure the fairness of model evaluation, the dataset is divided by stratified random sampling, so as to keep roughly the same category distribution in the training set, verification set, and test set, and minimize the possible deviation caused by category imbalance. Table 1 shows a summary of the number of images of each category and the division of corresponding training sets.

TABLE I. DISTRIBUTION OF IMAGE CATEGORIES AND DATASET PARTITION FOR THE SOUTHERN SICHUAN INTANGIBLE CULTURAL HERITAGE IMAGE DATASET

Intangible Cultural Heritage Category	Total Images	Training Set	Validation Set	Test Set
Zigong Lantern Festival	1,280	896	192	192
Luzhou Oil-Paper Umbrellas	1,150	805	173	172
Neijiang Sugar Painting	1,020	714	153	153
Shu Brocade	980	686	147	147
Sichuan Opera Facial Masks	1,350	945	203	202
Bamboo Weaving	890	623	134	133
Embroidery	760	532	114	114
Ceramics	650	455	96	99
Total	8,080	5,656	1,212	1,212

During the model training process, all hyperparameters are systematically configured. A ResNet-50 model pre-trained on the ImageNet dataset is adopted as the backbone feature extraction network. Parameter initialization based on the pre-trained weights is used to accelerate convergence and enhance the generalization capability of feature representations. The training process is conducted for 200 epochs with a batch size of 32. The Adam optimizer is employed for parameter updating, and the initial learning rate is set to 1×10^{-4}. A cosine annealing learning rate schedule is applied, gradually reducing the learning rate during training to a final value of 1×10^{-6}. To mitigate overfitting, a Dropout layer with a rate of 0.5 is added before the fully connected layer. In addition, an early stopping strategy is adopted, where training is terminated if the validation loss does not decrease for 15 consecutive epochs. The model finally converges at the 176th epoch. In the joint loss function, the weight of the classification loss λ_1 is set to 1.0, the weight of the triplet loss λ_2 is set to 0.1, and the weight of the center loss λ_3 is set to 0.01. All experiments are conducted on a deep learning workstation equipped with an NVIDIA RTX 3090 GPU (24 GB memory). The software environment is based on Ubuntu 20.04, the PyTorch 1.12 deep learning framework, and CUDA 11.6 acceleration libraries. Each training epoch takes approximately 3.2 minutes, and the total training time is about 9.5 hours.

To validate the effectiveness of the proposed deep learning model for Southern Sichuan intangible cultural heritage image recognition, comparative experiments are conducted against both traditional machine learning algorithms, namely Support Vector Machine (SVM) and K-Nearest Neighbors (KNN), and mainstream deep learning architectures, including ResNet-50 and EfficientNet-B0. SVM and KNN are included to evaluate the performance improvement over conventional methods, while ResNet-50 and EfficientNet-B0 are used to assess the performance gap between the proposed model and state-of-the-art deep learning approaches, thereby providing a comprehensive evaluation of the model's technical contribution. Accuracy, F1-score, and recognition rate for complex-texture images were selected as evaluation metrics. They comprehensively reflect overall classification performance, the ability to handle class imbalance, and the capacity to capture detailed features in high-complexity images. Fig. 4 and 5 summarize the results obtained from the experiments.

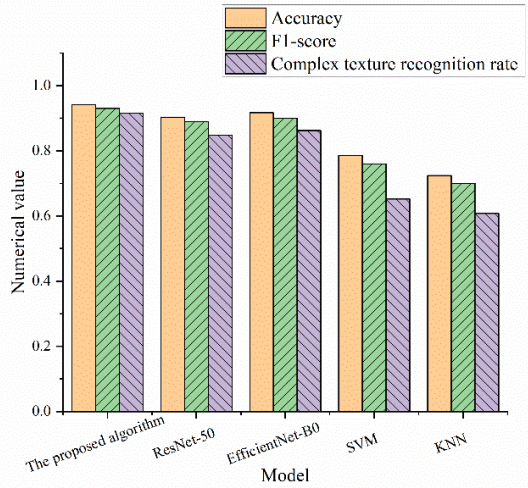

Fig. 4. Performance comparison of different models for Southern Sichuan's intangible cultural heritage image recognition.

As illustrated in Fig. 4, the proposed model significantly outperforms both traditional machine learning models and general deep learning models in terms of accuracy, F1-score, and recognition rate for complex-texture images. The overall accuracy reaches 94.1%, which is higher than SVM, KNN, ResNet-50, and EfficientNet-B0 by 15.6, 21.7, 3.8, and 2.4 percentage points, respectively. In terms of F1-score, the proposed model achieves 93.0%, surpassing ResNet-50 (89.0%) and EfficientNet-B0 (90.0%). For complex-texture image recognition, the model attains 91.5%, representing improvements of 6.8 and 5.3 percentage points over ResNet-50 (84.7%) and EfficientNet-B0 (86.2%), respectively. These

results indicate that the proposed multi-loss joint optimization strategy more effectively captures fine-grained textures and complex patterns in intangible cultural heritage artifacts.

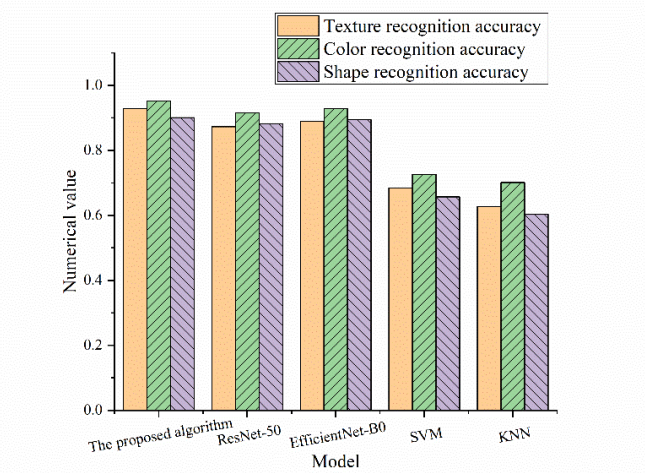

Fig. 5. Comparison of recognition performance across different image elements under various models.

As shown in Fig. 5, the proposed model achieves recognition accuracies of 92.8%, 95.2%, and 90.1% for texture, color, and shape, respectively, consistently outperforming SVM, KNN, ResNet-50, and EfficientNet-B0. In texture recognition, the proposed model improves performance by 5.5 and 3.9 percentage points compared with ResNet-50 (87.3%) and EfficientNet-B0 (88.9%), respectively, demonstrating the effectiveness of Triplet Loss and Center Loss in enhancing feature discriminability. For color recognition, all deep learning models perform relatively well. The proposed model achieves an accuracy of 95.2%, benefiting from both pre-trained feature extraction capabilities and the proposed joint optimization strategy, which further enhances fine-grained discriminative ability. For shape recognition, the proposed model reaches 90.1%, also showing steady improvements over ResNet-50 (88.2%) and EfficientNet-B0 (89.4%). Overall, the proposed model demonstrates clear advantages in multi-dimensional visual feature learning and exhibits strong applicability and technical advancement in Southern Sichuan intangible cultural heritage image recognition.

The performance satisfaction of the deep learning-based Southern Sichuan intangible cultural heritage brand identity design model was evaluated using a Likert scale survey. The survey targeted potential consumers of intangible cultural heritage products in Southern Sichuan. A total of 125 questionnaires were distributed, and 121 (62 males and 59 females) were effectively answered. Most of the respondents were between 18 and 35 years old, accounting for 77.12% of the sample. In terms of educational background, 26 respondents have an associate degree or below, 58 have a bachelor's degree, and 37 have completed graduate studies, indicating that the sample generally meets the representative requirements of this study. This study conforms to ethical standards and has been approved by the Ethics Committee of Neijiang Normal University. The written informed consent of the participants was obtained during the study. This study is conducted in accordance with the Helsinki Declaration.

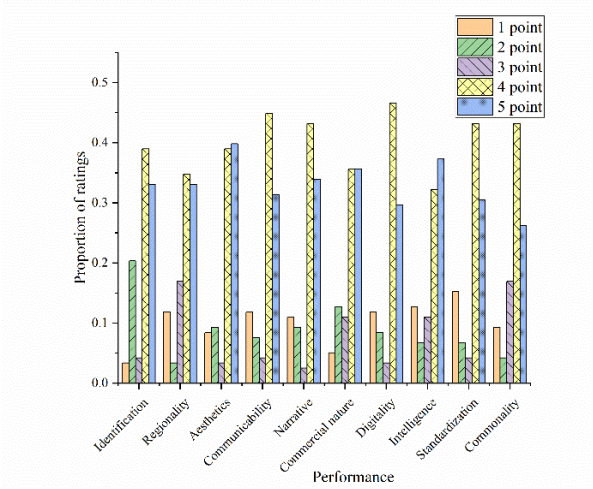

Fig. 6. User satisfaction with different performance aspects of the deep learning-based Southern Sichuan's intangible cultural heritage brand identity design model.

In Fig. 6, the aesthetic attraction scores the highest average score of 3.92, and 39.83% of the respondents give a perfect score of 5. This reflects the target users' high recognition of product visual language, formal aesthetics, and artistic expression. In contrast, the standardized dimension scored the lowest, only 3.67 points, and 15.25% of the respondents gave the lowest score of 1 point. This gap highlights the need for the design team to re-examine the compliance of design specifications, technical standards, and general design principles. The overall score of the intelligence dimension is in the middle, but the proportion of users getting full marks reaches 37.29%, indicating that users have positive expectations for technological innovation. On the contrary, the usability dimension has a low basic score (3.73 points) and has a limited full score (26.27%). It shows that the model needs further improvement in universality, accessibility, and public value creation.

V. Discussion

The experimental results show that the model based on deep learning for image recognition and brand design of intangible cultural heritage in southern Sichuan is consistently superior to SVM, KNN, ResNet-50, and EfficientNet-B0 in accuracy, F1 score, and recognition rate of complex texture images. The overall accuracy rate is 94.1%, which shows that the multi-loss joint optimization strategy effectively improves the fine-grained feature representation ability of intangible cultural heritage images and enhances the recognition performance of complex patterns, colors, and shapes. Compared with traditional machine learning methods, the deep learning model relies on hierarchical feature extraction and can learn higher-level semantic representations, so it is more suitable for complex cultural image recognition tasks. Based on the ResNet-50 backbone network, this study further integrates the ternary loss function and the central loss function to optimize the separability between categories and the compactness within categories, thus enhancing the performance of the model in capturing the subtle textures and complex visual features in the intangible cultural heritage images in southern Sichuan. The research results further

confirm the importance of digital intelligence technology in the protection and dissemination of cultural heritage. Boboc et al. pointed out that emerging digital technologies such as augmented reality are changing the presentation and dissemination of cultural heritage, opening up a new path for the digital utilization of cultural heritage resources [26]. Similarly, Erturk emphasized that digital storage and management are the key guarantee for the long-term preservation and inheritance of intangible cultural heritage [27]. Different from these studies, which mainly focus on digital protection and dissemination of cultural heritage, this study applies deep learning technology to image recognition and brand logo design of intangible cultural heritage to realize automatic extraction of cultural characteristics and transform them into visual design elements. The generated brand image solution has received relatively high evaluation in both aesthetic and intelligent dimensions, indicating that deep learning can not only support the digital preservation of cultural heritage, but also transform cultural elements into modern brand visual language. However, there are still some limitations: the size of the dataset is still relatively limited, and the evaluation mainly depends on subjective user evaluation. Future research should expand the image dataset of intangible cultural heritage, incorporate multi-modal cultural semantic information, and explore more advanced visual models. These improvements are expected to enhance the generalization ability and practical application value of the model.

VI. Conclusion

The image recognition and brand design model of intangible cultural heritage in southern Sichuan based on deep learning shows significant advantages in recognition accuracy and multi-dimensional feature extraction. Experimental evaluation shows that the model is superior to the traditional method in key indexes such as accuracy, F1 score, and complex texture recognition, and the overall accuracy reaches 94.1%. This proves that deep learning can effectively extract and present the fine details contained in intangible cultural heritage items. Specifically, the model achieves 92.8% in texture recognition, 95.2% in color recognition, and 90.1% in shape recognition, which fully embodies its comprehensive learning ability and excellent performance in multi-dimensional visual features. The customer satisfaction survey further confirmed the actual value of the model. The high scores in aesthetics, commercial attraction, and narrative design show that the model performs well in identification tasks and contributes to brand communication and design innovation. These research results confirm the application value of deep learning in digital protection and creative transformation of intangible cultural heritage. In practice, the model provides intelligent support for digital archiving, brand design, and marketing. For researchers and cultural heritage practitioners, it can realize efficient and accurate classification and feature extraction. For designers, it is helpful to generate a brand image that embodies the cultural essence of intangible cultural heritage, thus improving artistic quality, communication effect, and market competitiveness. Finally, the model is helpful to promote the innovation and transformation of intangible cultural heritage from southern Sichuan to international communication in the context of modern consumption.

Although the experimental results are encouraging, there are still some limitations. First of all, the dataset is limited in scale and category coverage, which cannot fully show the diversity and complexity of intangible cultural heritage in southern Sichuan. In this study, only the representative intangible cultural heritage projects in southern Sichuan are selected for analysis, so the feature expression ability of this model in other types of intangible cultural heritage resources needs further verification. The scores of standardization and universality are relatively low, indicating that it may have challenges in cross-domain and cross-scenario applications. In addition, there are significant differences in cultural connotation, artistic style, and visual expression of intangible cultural heritage projects in different regions, so the portability and generalization performance of this model in the context of intangible cultural heritage in other regions still need further investigation. The survey of users' satisfaction shows that the intelligence and universal applicability still need to be improved. Future research should focus on improving the interpretability of the model, personalized design recommendations, and cross-platform adaptability. In addition, expanding multi-modal datasets, integrating generative artificial intelligence technology, and optimizing interactive user experience are worthy of promotion. At the same time, it is necessary to construct cross-regional and cross-category intangible cultural heritage datasets to systematically evaluate and optimize the applicability of the model in different cultural heritage protection and brand design scenarios. Such efforts will help explore its broader applicability in the field of intangible cultural heritage and promote the advancement of intangible cultural heritage image recognition and brand identity design toward higher levels of intelligence and inclusiveness.
