Table of Contents

Paper 1: Vision Transformers and Convolutional Neural Networks for Land Use Scene Classification

Authors: Arun D. Kulkarni

PAGES 1 - 11

Paper 2: Privacy-Preserving Financial Fraud Detection Using Federated Heterogeneous Temporal GraphSAGE

Authors: Sabab Islam, Md. Abul Kalam Azad, Abdul Kadar Muhammad Masum, Ramona Birau, Virgil Popescu, Roxana Mihaela Nioata (Chireac), Gabriela Ana Maria Lupu (Filip)

PAGES 12 - 26

Paper 3: Attention-Augmented PointNet with Hybrid Ant Colony Optimization and Bayesian Hyperparameter Search for Robust 3D Point Cloud Classification in Augmented Reality Applications

Authors: Ahmed Almaghthawi, Fahad Alharbi, Radwan M. Batyha, Suhaila Abuowaida

PAGES 27 - 35

Paper 4: Ordinal Factor Analysis with Robust Estimation and Predictive Models

Authors: Abuelgasim Osman, Zahayu Binti Md Yusof

PAGES 36 - 41

Paper 5: Neural Network Implementation of the Renormalization Group for Fault Diagnosis with Class Imbalance

Authors: Evgeny Nikulchev, Dmitry Ilin

PAGES 42 - 49

Paper 6: MatchIA-GCL: A Hybrid Graph Contrastive Learning Approach for Semantic Schema Matching

Authors: Mohamed Raoui, Moulay Hafid El Yazidi, Ahmed Zellou

PAGES 50 - 59

Paper 7: Optimized Lattice-Based Ciphertext Policy Attribute-Based Encryption for Quantum-Resistant Secure Data Sharing

Authors: Purnima, Tejaswi Khanna, Deepak Kumar Verma

PAGES 60 - 74

Paper 8: Binary Enhanced White Shark Optimization Algorithm and Its Application to Semi-Supervised Feature Selection

Authors: Jian Zhou, Jiawen Yang

PAGES 75 - 88

Paper 9: NADOS: Reliability-Gated Difficulty-Aware Oversampling for Noisy Imbalanced Classification

Authors: Ednel Ashraff Misran, Syahid Anuar, Adam Mohd Khairuddin

PAGES 89 - 98

Paper 10: A RAG-Enhanced Human-in-the-Loop Framework for Automated Assessment of Engineering Laboratory Reports

Authors: Amina Abbi, Mohammed Skouri, Mustapha Raoufi

PAGES 99 - 107

Paper 11: Detecting Metadata-Conditioned Response Drift in AI-Generated Visual Information Systems: A Two-Phase Human–Computer Interaction Framework

Authors: Yu Jia, Shaojie Zhang, Na Li

PAGES 108 - 117

Paper 12: Hybrid Machine Learning and Reinforcement Learning for IoT Device Classification and Bandwidth Optimization

Authors: Manjunatha T N, Vidyalakshmi K, Dankan Gowda V

PAGES 118 - 126

Paper 13: Pattern Analysis of Global AI Adoption and Digital Literacy Development in Science Education: Basis for a Recommender System Framework

Authors: Honelly Mae S. Cascolan

PAGES 127 - 138

Paper 14: Automated Multi-Task Deep Learning Framework for Simultaneous Identification of Dental Pathologies and Arch Localization in Orthopantomograms (OPG)

Authors: Hatim Elhag, Norehan Binti Mokhtar, Siti Noor Fazliah Binti Mohd Noor, Gururajaprasad Kaggal Lakshmana Rao, Nordin Zakaria, Fakhitah Ridzuan, Mohammed Bin Salah

PAGES 139 - 148

Paper 15: Inclusive Digital Health Platform for Well-Being and Loneliness in SOGIESC Older Adults

Authors: Yada Atanan, Titikarn Assatarakul, Akara Metasuk

PAGES 149 - 160

Paper 16: Image-Based Iron Ore Feed Load Classification Using EfficientNet-B0 with Region-Density Attention and Hierarchical Feature Fusion

Authors: Sami F Karali, Fawaz Alanazi, Eman Ramadan Elsharkawy, Asma A. Alhashmi, Abed Saif Ahmed Alghawli, Imen B. Mohamed, Chams Sallami, Abdulbasit A. Darem

PAGES 161 - 173

Paper 17: An Intelligent Writing Tutor for ESL Learners: A Rule-Based and NLP-Assisted Feedback Framework

Authors: Ruth L. Ladwingon

PAGES 174 - 186

Paper 18: Migration Method for Parametric Features in Heterogeneous CAD Systems

Authors: Gang WANG, Guangfa ZHANG

PAGES 187 - 194

Paper 19: Automated Classification of Moroccan Procedural Court Orders Using CAMeL-BERT

Authors: Saliha YASSINE, Ouafaa IBRIHICH, Mohammed ESSOUJAA, Mustapha ESGHIR

PAGES 195 - 203

Paper 20: A Hybrid SMOTE-Ensemble Framework for Robust Speech Emotion Recognition on Imbalanced Data

Authors: Eyad Megdadi, Mariam Aljouhi, Zainab Alblooshi, Khaled Shaalan

PAGES 204 - 218

Paper 21: XPA-FedCBR: A Federated Case-Based Reasoning System for Explainable and Privacy-Aware Lung Cancer Diagnosis

Authors: Devyani Rawat, Shuchi Bhadula, Sachin Sharma

PAGES 219 - 228

Paper 22: Enhanced Simple Linear Iterative Clustering (ESLIC) for Precise Skin Lesion Segmentation in Dermoscopic Images

Authors: Leni Natalia Zulita, Sarjon Defit, Sumijan

PAGES 229 - 239

Paper 23: Adaptive Mirage Search Optimization for Educational Workload Scheduling in Multi-Cloud Environments

Authors: Mohammed A.S. Mosleh, Elham Alzain, Hesham M.A. Abdullah, Ali Alshebami

PAGES 240 - 250

Paper 24: HISaaS: A Cloud-Based Framework for Semantic Enrichment of Legacy Health Databases Using OpenAI Embeddings

Authors: Toufik Salmi, Abdeslem Dennai

PAGES 251 - 262

Paper 25: HETRA: A Real-Time Traffic Detection and Directional Counting System Using YOLOv8 and DeepSORT

Authors: Kuldeep Kumar Shukla, Ajai Kumar Singh

PAGES 263 - 274

Paper 26: Improving Arabic Relational Aggregated Search Using a Hybrid RAG and AraBERT Framework

Authors: Sara Saad Sedhom, Ahmed Younes, Islam Elkabani, Ashraf Elsayed

PAGES 275 - 284

Paper 27: Design, Implementation, and Evaluation of a Mobile Application for Real-Time Incident Management in Local Government

Authors: Marleny Peralta Ascue, Luis Bryan Caballero Pinto, José Luis Poluco Sicos, José Luis Merma Aroni

PAGES 285 - 292

Paper 28: EduDarijaBERT: An Applied Transformer-Based Framework for Sentiment Analysis in Moroccan Arabic Educational Discourse

Authors: Abderrahim Ait Ichou, Ali Ouacha

PAGES 293 - 304

Paper 29: MAMGAT-Net: A Multimodal Graph Attention and Multi-Scale Feature Fusion Framework for Early Breast Cancer Diagnosis from Mammography and Histopathological Images

Authors: Mohammad Riyaz Belgaum

PAGES 305 - 320

Paper 30: An Intelligent System for Energy-Aware Flexible Fault Tolerance in Cloud

Authors: Moin Hasan, Shailee Lohmor Choudhary, Rinku Sharma Dixit, Sujith Jayaprakash

PAGES 321 - 329

Paper 31: INSPIRE: Understanding Local-Global Representation Learning via Controlled Self-Supervised Training and Representation Interpretability

Authors: Reem Alharthi, Rashid Mehmood, Aiiad Albeshri, Abdulaziz A. Almuzaini

PAGES 330 - 347

Paper 32: Enhancing Diabetic Retinopathy Classification Through Advanced Deep Convolutional Neural Network Architectures

Authors: Sifeddine Elkardoudi, Khalil Ladrham, Ahmed Eddaoui, Mohamed Talea

PAGES 348 - 359

Paper 33: The Evolution of Clinical Intelligence Through GenAI Co-pilots: A Systematic Review and Thematic Synthesis

Authors: Li-Chen Cheng, Chia-Yu Hung, Te-Nien Chien

PAGES 360 - 375

Paper 34: Localized Actionable Explainability for MOOC Dropout Intervention Using Clickstream Learning Analytics

Authors: Mohamed Amine OUASSIL, Mohammed JEBBEARI, Mouaad ERRAMI, Rabia Rachidi, Soufiane HAMIDA, Bouchaib CHERRADI, Abdelhadi RAIHANI

PAGES 376 - 387

Paper 35: Counterfeit Currency Detection Through Deep Convolutional Generative Adversarial Network

Authors: Salman Jan, Fara Gul, Mohammad Riyaz Belgaum, Shahid Kamal, Afaq Ahmad, Muhammad Bilal, Atif Khan

PAGES 388 - 397

Paper 36: FGHA-Net: Hybrid Attention Learning for Froth Flotation Recovery Prediction in Mineral Beneficiation

Authors: Mohammed I Thanoon, Fawaz Alanazi, Shaaban M. Shaaban, Asma A. Alhashmi, Abed Saif Ahmed Alghawli, Ahlem Fatnassi, Majed Nawaz, Abdulbasit A. Darem

PAGES 398 - 409

Paper 37: From Cloud to On-Premises: A Systematic Review of Cloud Repatriation Drivers, Strategies, and Governance Challenges

Authors: Amzari Mohd Roslan, Fazlina Mohd Ali, Faizan Qamar, Liyana Safra, Nur Arzilawati Md Yunus

PAGES 410 - 423

Paper 38: Multi-Agent Crowd-Risk Prioritization for Large-Scale Events: A Hybrid ML–Agent Approach

Authors: Najwa Samrgandi

PAGES 424 - 435

Paper 39: Model-Augmented Masked Autoencoder with Domain-Adaptive Denoising for Robust Brain Tumor MRI Analysis

Authors: Indrakumar K, Ravikumar M, Mohammed A.S Al-mohamadi, Khalid N. R. Alharbi, Asma A. Alhashmi, Shouki A. Ebad, Abdulbasit A. Darem

PAGES 436 - 453

Paper 40: A Statistical Filtering Algorithm for Tender Price Evaluation Using the J-Selaras Framework

Authors: Mustafa Man, Wan Aezwani Wan Abu Bakar, Mohd Kamir Yusof, Mohd Nasir Saari, Nor Arzalifah Abd. Razak, Nor Zuraiya Mt Amin

PAGES 454 - 461

Paper 41: Prompt Literacy and Generative AI Readiness for AI-Assisted Animation Creative Workflows in Higher Education

Authors: Loh Ngiik Hoon, Natasha Binti Rusdy Wong, Marzie Hatef Jalil

PAGES 462 - 471

Paper 42: CDNet: Complex-Valued Deep Unrolled Composite Denoising Network for Accelerated Magnetic Resonance Image Reconstruction

Authors: David Muigai, Elijah Mwangi, Henry Kiragu

PAGES 472 - 485

Paper 43: Hybrid Random Forest–XGBoost for Smartphone Engagement Prediction with Applications in Marketing Analytics

Authors: Ace John Mark P. Liwanag

PAGES 486 - 495

Paper 44: A Blockchain and AI Integrated Framework for Dynamic Land Registration and Smart Urban Zoning

Authors: Shushma R, S R Nagaraja

PAGES 496 - 502

Paper 45: Segmented Lung CT Image Refinement Through Hybrid Edge-Preserving De-Noising and Variance-Regulated Adaptive Histogram Equalization

Authors: T. Bhuvaneshwari, Rohini Pinapatruni

PAGES 503 - 511

Paper 46: Design and Implementation of Rule-Based and Time-Based Logic in a PAC-Based Precision Irrigation Control System

Authors: Djohar Syamsi, Mimin Muhaemin, Oviyanti Mulyani, Hanif Fakhrurroja, Puput Dani Prasetyo Adi

PAGES 512 - 524

Paper 47: Advancing Ecological Informatics: A Tool for Implementing the Abundance–Preference Approach in Assemblage Analysis

Authors: Mohamed El Farouki, Mohamed Dakki, Meryem Ennakri, Soumia Ziti

PAGES 525 - 537

Paper 48: Blockchain-Based Trusted Data Sharing Framework for Secure and Auditable AI Model Training

Authors: Sherif Amin

PAGES 538 - 545

Paper 49: Shortest Path Algorithms for Smart City Emergency Routing: Scalability and Scenario-Based Analysis

Authors: Aleksandra Stojanova Ilievska, Natasha Stojkovikj, Limonka Koceva Lazarova, Arta Aliu, Krume Tasev, Teona Aleksova

PAGES 546 - 554

Paper 50: Implementation and Evaluation of a Dynamic Multi-Grid Pattern Authentication for Secure Financial Applications

Authors: Amjad Qashlan, Qamar H. Naith, Fatimah Alakeel, Malak B Alharbi

PAGES 555 - 570

Paper 51: Unsanctioned Intelligence: Mitigating the Risks of 'Shadow AI' and Proprietary Data Leaks in the Remote Workforce

Authors: Adel Saad Assiri

PAGES 571 - 578

Paper 52: Dual-Attention Framework for Enhanced Road Obstacle Segmentation and Anomaly Detection

Authors: Priyanka G, Silvia Gaftandzhieva, Mariya Zhekova

PAGES 579 - 586

Paper 53: Anomaly-Score-Augmented Random Forest for Permission-Based Android Malware Detection: An Empirical Study on 29, 999 Apps

Authors: Harikrishnan P R, P. Periyasamy

PAGES 587 - 596

Paper 54: Entanglement-Driven Hybrid Quantum Representation Learning for EEG-Based Epileptic Seizure Classification

Authors: Athigiri Arulalan A S, Senthilkumar G, Jabasheela L, Sangeetha K, Subedha V, Sathiya V

PAGES 597 - 611

Paper 55: EDM-Based Graduate Curriculum Planning Framework

Authors: Levi E. Elipane, Antriman V. Orleans, Adonis P. David, Wilma S. Reyes, Crist John Pastor, Felina P. Espique, Juan Primitivo P. Petrola

PAGES 612 - 620

Paper 56: Arki-Nexus AI: A Framework for Integrating Artificial Intelligence Competencies Into NEUST College of Architecture

Authors: GREGORIO L. VILLAVIZA JR

PAGES 621 - 629

Paper 57: Secure Heart Disease Status Classification Using Machine Learning and Blockchain-Based EHR Integrity Verification

Authors: Haya H. Alsharif, Sabah M. Alzahrani

PAGES 630 - 646

Paper 58: Digital Technologies Enabling Smart Circular Waste Management: A Systematic Literature Review

Authors: Pristi Sukmasetya, Harry Budi Santoso, Zainal Arifin Hasibuan, Yun Arifatul Fatimah

PAGES 647 - 656

Paper 59: Arabic News Text Classification Using Deep Learning Models with Dynamic N-grams

Authors: Ahmed I.Taloba, George Samy Rady, Khaled F. Hussain

PAGES 657 - 672

Paper 60: 8C SPS Model: A Seller Product Selection Model for Home-Based Business Sellers Using a Multi-Criteria Decision-Making Approach

Authors: Selvia Lorena Br Ginting, Zulaiha Ali Othman

PAGES 673 - 690

Paper 61: Hierarchical Workforce Dynamics and Risk-Aware Gated Deep Learning Framework for Employee Attrition Prediction

Authors: Chen Yang

PAGES 691 - 704

Paper 62: Adaptive Grammar Correction with Error-Type Diagnosis and Learner-Centered Feedback Using Proficiency-Aware Transformer Learning

Authors: Xinxin Sun, Peng Guo

PAGES 705 - 719

Paper 63: MACN: A Modality-Aware Cross-Attention Transformer for Non-Invasive Hemoglobin Estimation and Anemia Classification Using Multi-Region Physiological Images

Authors: Chaitra S P, D R Ramesh Babu

PAGES 720 - 727

Paper 64: Low-Latency FPGA-Based PCA Acceleration for Hyperspectral Image Dimensionality Reduction

Authors: Hana Ben Fredj, Ahlem kehili, Amani Chabbeh, Jamel Baili, Chokri Souani

PAGES 728 - 734

Paper 65: Multiscale Image Enhancement and Visualization Analysis for Historical Map/s

Authors: Guilei Ren

PAGES 735 - 746

Paper 66: Statistical Security Analysis NIST and Security Enhancement of CBT Cipher for Secure Data and Image Transmission

Authors: Walid W. Souror, Mohamed Fouad, Ali E. Takieldeen

PAGES 747 - 756

Paper 67: Unsupervised Hybrid Approach for Intrusion Detection Based on Information System Log Files

Authors: Sena Apeke, Nadjime Pindra, Sèmèvo A. R. M. Ahouandjinou

PAGES 757 - 765

Paper 68: Artificial Intelligence Guided Crowd Counting and Density Estimation with Enhanced CSRNet

Authors: Muhammad Jawad Babar, Malik Muhammad Saad Missen,
Hannan Adeel, Muhammad Usman, Muzammil Malik

PAGES 766 - 779

Vision Transformers and Convolutional Neural Networks for Land Use Scene Classification

Arun D. Kulkarni
Computer Science Department, University of Texas at Tyler, Tyler, TX 75799, USA

***Abstract*—Land use scene classification (LUSC) from remote sensing imagery plays a critical role in environmental monitoring, urban planning, and sustainable resource management. In recent years, deep learning methods have significantly advanced the state-of-the-art, with Convolutional Neural Networks (CNNs) dominating the field because of their strong ability to capture local spatial features. However, the emergence of Vision Transformers (ViTs) has introduced a new paradigm that models long-range dependencies through self-attention mechanisms, potentially enabling improved global context understanding. This study presents a comparative assessment of Vision Transformers and CNN-based architectures for remote sensing land use scene classification. Representative CNN models, such as AlexNet, are evaluated alongside the Vision Transformer (ViT) using benchmark remote sensing datasets, including the UC Merced (UCM) Land Use and EuroSAT Land Use datasets. The study examines classification accuracy, precision, recall, F1-score, and computational complexity to provide a comprehensive performance comparison. Experimental results demonstrate that CNNs perform robustly on datasets with limited training samples and strong local texture characteristics, whereas Vision Transformers exhibit superior performance in capturing global spatial relationships in complex scenes when sufficient training data are available. However, ViTs typically require greater computational resources and larger training datasets to achieve optimal performance. The findings of this study provide insights into the strengths and limitations of both architectures and offer guidance for selecting appropriate models for remote sensing land use scene classification applications.**

Keywords*—Convolutional Neural Networks (CNNs); deep learning; land use scene classification; remote sensing; Vision Transformers (ViTs)

I. Introduction

Remote sensing imagery has emerged as a vital data source for analyzing, monitoring, and managing the Earth's surface. Recent advances in satellite and aerial imaging technologies have enabled the acquisition of large volumes of high-resolution imagery, providing unprecedented opportunities for large-scale analysis of Land Use and Land Cover patterns [1]. Among the many tasks in remote sensing image analysis, land use scene classification (LUSC) has emerged as a fundamental problem [2]. LUSC seeks to classify aerial or satellite image patches by assigning semantic labels such as residential, agricultural, industrial, forest, and water bodies. Precise land use scene classification plays a vital role in numerous applications, such as urban planning, environmental monitoring, disaster management, resource allocation, and climate change evaluation.

Early approaches to LUSC primarily used conventional machine learning methods that depended on manually engineered feature extraction followed by statistical classification approaches. These methods typically utilize descriptors such as texture-based features, spectral indices, and shape-based representations. Since local descriptors are usually derived from multiple spatial locations, feature aggregation techniques are needed to generate fixed-length scene representations that can be used for classification tasks. While these methods laid an important foundation for remote sensing image analysis, they also have several intrinsic limitations. In particular, handcrafted features tend to be sensitive to changes in spatial resolution, seasonal variations, lighting conditions, and geographic diversity. Moreover, manually designed descriptors may fail to capture complex semantic relationships among multiple objects and spatial arrangements within a scene [3]. In addition, feature extraction and classifier design are generally treated as separate stages, preventing end-to-end optimization [4]. As a result, traditional methods frequently show poor generalization when used in complex and diverse remote sensing environments.

The rapid expansion of large-scale remote sensing datasets, along with advances in high-performance computing, has driven the increased adoption of deep learning techniques for LUSC. In contrast to traditional machine learning methods, deep neural networks can automatically learn hierarchical feature representations directly from raw image data. This end-to-end representation learning approach has substantially enhanced classification accuracy in remote sensing scenes marked by high intra-class variability, strong inter-class similarity, and considerable spatial heterogeneity.

Among deep learning approaches, Convolutional Neural Networks (CNNs) have emerged as the leading framework for remote sensing image classification. Representative architectures such as AlexNet, VGGNet, ResNet, and EfficientNet have demonstrated strong performance across a variety of benchmark datasets [5]. The success of CNNs is largely attributed to their local receptive fields, parameter sharing, and hierarchical feature extraction mechanisms, which enable efficient learning of edges, textures, shapes, and other discriminative spatial patterns. Moreover, the built-in inductive biases of CNNs—especially locality and translation invariance—tend to encourage more stable learning and improved generalization, particularly in settings with limited training data. Nevertheless, because convolutional operations primarily focus on local neighborhoods, CNNs may be less effective in modeling long-range spatial dependencies and

global contextual relationships that frequently characterize complex land use scenes [6].

Recently, Vision Transformers (ViTs) have gained attention as a strong alternative to CNN-based architectures in computer vision. Drawing inspiration from the success of Transformer models in natural language processing, ViTs treat an image as a sequence of non-overlapping patches, which are then processed as tokens. By leveraging self-attention mechanisms, the model directly learns global interactions across different image regions, improving its ability to capture long-range dependencies and contextual relationships. This capacity for global representation is especially valuable in remote sensing imagery, where scene interpretation often relies on spatial relationships among multiple objects spread across wide areas. Despite these advantages, Vision Transformers generally require larger training datasets, higher computational resources, and careful optimization strategies to achieve competitive performance. The differing characteristics of CNNs and Vision Transformers motivate a systematic comparison of their effectiveness in land-use scene classification. CNNs are known for their computational efficiency, strong inductive biases, and reliable performance in data-limited scenarios, whereas Vision Transformers introduce a distinct representation approach that prioritizes global contextual modeling. A rigorous comparative analysis of these architectures is therefore important for understanding their suitability across diverse remote sensing scenarios.

In this study, we present a comprehensive comparative study of CNN- and ViT-based architectures for land use scene classification using benchmark remote sensing datasets. The study evaluates their classification performance, computational efficiency, and generalization capability under consistent experimental settings. The main objective is to provide practical insights into the strengths and limitations of both model families and to identify conditions under which each architecture is most suitable for remote sensing land use analysis.

The remainder of this study is organized as follows: Section II reviews related work on land use scene classification. Section III presents the proposed comparative framework and methodology. Section IV describes the datasets, experimental setup, and results. Section V discusses the results, presents the conclusions, and outlines future research directions.

II. Related Work

Land Use and Land Cover (LULC) scene classification has emerged as a key area of research in remote sensing because of its extensive applications in urban development, environmental surveillance, disaster response, and agricultural evaluation [7, 8]. The growing accessibility of high-resolution satellite imagery has further increased the complexity of scene analysis, creating a demand for more sophisticated computational approaches. Over the last two decades, research in this field has evolved from conventional handcrafted feature extraction techniques to deep learning-based approaches, especially Convolutional Neural Networks (CNNs), and more recently, Vision Transformers (ViTs). This section provides a comprehensive review of these developments and highlights current trends and challenges.

Before the widespread adoption of deep learning techniques, Land Use and Land Cover (LULC) classification primarily relied on handcrafted feature extraction methods integrated with traditional machine learning algorithms. In these conventional approaches, researchers manually engineered descriptive features to capture the spatial, spectral, textural, and structural properties of remote sensing imagery. The effectiveness of the classification process largely depended on the quality and discriminative capability of these handcrafted representations. Among the most influential and extensively utilized feature descriptors were Scale-Invariant Feature Transform (SIFT) [9], Histogram of Oriented Gradients (HOG) [10], and Local Binary Patterns (LBP) [11]. These techniques significantly advanced remote sensing image analysis by enabling the extraction of meaningful visual patterns from satellite and aerial imagery. They were widely employed in combination with classical classifiers such as Support Vector Machines (SVM), Random Forests (RF), k-Nearest Neighbors (k-NN), and Artificial Neural Networks (ANNs) to categorize different land cover and land use classes. SIFT gained considerable attention due to its robustness in detecting distinctive key points that remain invariant to scale, rotation, and partial illumination changes. This characteristic made it highly effective for identifying objects and spatial structures in high-resolution remote sensing images, particularly in heterogeneous environments. HOG descriptors emphasized the distribution of gradient orientations within localized regions, thereby providing strong representations of edge, contour, and shape information. Such capabilities proved valuable for distinguishing complex landscape structures, including urban areas, roads, and vegetation boundaries. Similarly, Local Binary Patterns (LBP) emerged as a powerful texture descriptor because of its simplicity, computational efficiency, and robustness to illumination variations. By encoding local neighborhood intensity relationships, LBP effectively characterized surface textures and fine-grained spatial patterns commonly observed in remote sensing imagery. Consequently, it became widely used in applications involving vegetation analysis, urban mapping, and terrain classification. Collectively, these handcrafted feature extraction techniques established the foundation of traditional LULC classification systems. Although they achieved notable success in many remote sensing applications, their performance was often constrained by limited feature generalization capabilities and the substantial reliance on expert knowledge for feature engineering. These limitations ultimately motivated the transition toward deep learning-based methods, which automatically learn hierarchical and highly discriminative feature representations directly from raw imagery data. Although these methods achieved moderate success, they suffered from several limitations. Most notably, handcrafted features lacked the ability to capture high-level semantic information and were sensitive to variations in scale, illumination, and viewpoint. Furthermore, the feature extraction process required domain expertise and was not adaptable to diverse datasets. These shortcomings motivated the transition toward data-driven feature learning approaches.

The advent of deep learning, particularly Convolutional Neural Networks (CNNs), brought a transformative shift to the field of image classification. Unlike traditional machine learning approaches that rely heavily on handcrafted feature extraction techniques, CNNs are capable of automatically learning hierarchical and discriminative feature representations directly from raw image data. This ability to perform end-to-end learning significantly reduces the dependence on manual feature engineering while improving the robustness and scalability of classification systems [4]. In the domain of remote sensing, the adoption of CNN-based architecture has led to remarkable improvements in scene classification accuracy and efficiency. Early research demonstrated that deep learning models substantially outperform conventional methods by effectively capturing complex spatial patterns, textures, and semantic information present in high-resolution remote sensing imagery [12]. Consequently, CNNs have become a foundational approach for modern remote sensing image analysis and classification tasks. Pre- trained architectures such as AlexNet [13], VGGNet [14], and GoogLeNet [15] were among the first to be adapted for remote sensing applications through transfer learning.

A major strength of CNNs is their ability to learn and capture local spatial patterns through convolutional filters. This capability makes them highly effective for detecting textures, edges, and object-level features in remote sensing imagery [16]. To further improve CNN-based models, researchers have introduced several advancements, including: 1) multi-scale feature extraction techniques to accommodate objects of varying sizes in satellite images [17], and 2) data augmentation and transfer learning strategies to mitigate the challenges posed by limited labeled datasets [18]. Despite these advancements, CNNs have inherent limitations. Their dependence on local receptive fields limits their ability to capture long-range dependencies and global context [6]. Although deeper architectures can partly address this issue, they increase computational complexity and the risk of overfitting, while performance gains often plateau with greater depth. These challenges highlight the need for alternative architectures.

Natural language processing-based transformer architectures have significantly influenced the development of Vision Transformer (ViT) models, which have emerged as a powerful alternative to traditional convolutional neural networks (CNNs). Originally inspired by the transformer framework introduced by Vaswani et al [19]. ViTs depart from the convolution-centric paradigm by treating images as sequences of smaller patches, analogous to tokens in language models. These patches are processed through self-attention mechanisms that enable the model to learn long-range and global dependencies across the entire image more effectively than conventional CNN architectures. The pioneering study by Dosovitskiy et al. [6] demonstrated that ViTs are capable of achieving state-of-the-art performance in image classification tasks, particularly when trained on large-scale datasets. Their findings highlighted the scalability and representational power of transformer-based vision models, establishing ViTs as a transformative approach in computer vision research. In the domain of remote sensing, ViTs have shown considerable potential for handling the complex spatial structures and contextual variations commonly present in satellite imagery. Their ability to model global contextual relationships makes them especially suitable for Land Use and Land Cover Classification (LULC) tasks, where understanding both local features and broader spatial patterns is essential for accurate categorization. Recent studies, such as those by Zhao et al. [8], have demonstrated that transformer-based approaches can effectively capture intricate spatial dependencies and improve classification performance in remote sensing applications. The global attention mechanism in ViTs enables them to model long-range interactions more effectively than CNNs. This is particularly beneficial for complex scenes where spatial relationships between distant regions are important. However, ViTs also present challenges, including high computational requirements, large memory consumption, and dependence on extensive training data [20]. To harness the complementary advantages of CNNs and transformers, recent studies have increasingly explored hybrid architectures that integrate convolutional operations with self-attention mechanisms. These approaches seek to combine the strong local feature extraction capabilities of CNNs with the powerful global context modeling offered by transformers. Research indicates that hybrid models frequently outperform standalone CNNs and Vision Transformers (ViTs) in Land Use and Land Cover (LULC) classification tasks [21]. They demonstrate greater robustness, improved generalization, and a superior ability to capture multi-scale contextual information. Such models are especially well-suited for analyzing high-resolution and hyperspectral remote sensing datasets. The progress of Land Use and Land Cover (LULC) classification techniques has been strongly driven by the availability of publicly accessible benchmark datasets that enable standardized model training and fair performance comparison across studies. Datasets in this domain include the UCM Land Use Dataset and the EuroSAT Dataset.

The UCM dataset provides high-resolution aerial imagery with a limited number of well-balanced classes, whereas EuroSAT, derived from Sentinel-2 satellite imagery, further extends this diversity by incorporating multispectral information. These datasets form a comprehensive benchmark suite that enables robust evaluation of model generalization, feature representation capability, and cross-dataset transferability [17, 22]. Convolutional Neural Network (CNN)-based architectures have historically demonstrated strong performance across these benchmarks due to their effectiveness in learning hierarchical spatial features from imagery. However, recent advances in deep learning have shown that transformer-based models, such as Vision Transformers (ViTs), along with hybrid CNN–Transformer architectures, are achieving either superior or competitive performance. These models are particularly effective in capturing long-range spatial dependencies and global contextual relationships, which are often challenging for traditional CNNs. As a result, there is a growing shift toward attention-based and hybrid frameworks in LULC classification, especially for complex and large-scale remote sensing datasets. Duan et al. [23] proposed the Swin Transformer with Multi-Scale Fusion (STMSF) to effectively represent ground objects of varying scales in remote sensing scenes through the integration of multi-scale features. Experimental results show that the proposed network surpasses

several state-of-the-art CNN-based and transformer-based approaches.

Recent studies in remote sensing and Land Use/Land Cover (LULC) classification demonstrate a clear and growing transition toward transformer-based architectures and hybrid deep learning models. These approaches have shown strong potential in capturing long-range spatial dependencies and improving classification performance compared to traditional convolutional methods. Despite these advancements, several important challenges persist. First, data scarcity remains a major limitation, as high-quality, accurately labeled remote sensing datasets are often limited in size and diversity, constraining the training of data-intensive models. Second, computational complexity is a significant concern, particularly for transformer-based models, which typically require substantial memory and processing power for both training and inference. Third, model interpretability continues to be an open issue, as the internal decision-making processes of deep learning models—especially transformers—are often difficult to interpret and explain in a physically meaningful way. Finally, generalization across datasets remains challenging, since models trained on a specific dataset often experience performance degradation when applied to different geographic regions, sensor types, or imaging conditions.

In this context, the present study focuses on a comparative analysis of Convolutional Neural Networks (CNNs) and Vision Transformers (ViTs) for land use scene classification (LUSC). The evaluation is conducted using two widely recognized benchmark datasets: the UCM Land Use Dataset and the EuroSAT Dataset. This comparative investigation aims to assess the relative strengths and limitations of CNN-based and transformer-based approaches in terms of classification accuracy, robustness, and generalization capability across diverse remote sensing scenarios.

III. Proposed Framework

This section presents a comparative framework for evaluating Convolutional Neural Networks (CNNs) and Vision Transformers (ViTs) for land use scene classification (LUSC) using high-resolution remote sensing imagery. To ensure a controlled and fair comparison, both the AlexNet and Vision Transformer (ViT) models are trained using identical datasets and data partitions, input resolutions, augmentation strategies, optimization settings, and evaluation metrics. Therefore, the observed performance differences can be attributed primarily to architectural characteristics rather than experimental inconsistencies. The proposed framework consists of four stages: 1) dataset preparation and preprocessing, 2) AlexNet optimization and training, 3) Vision Transformer (ViT) optimization and training, and 4) classification of test data.

A. Data Preparation and Preprocessing

Let the land use dataset be represented as:

$$\mathcal{D} = \{(x_i, y_i)\}_{i=1}^{N} \tag{1}$$

where, $x_i \in \mathbb{R}^{H\times W\times C}$, denotes an input image, $y_i \in \{1,2,\dots,K\}$ is the class label, N is the total number of samples, and K is the number of land use categories. Remote sensing images exhibit substantial intra-class variability arising from seasonal effects, spatial resolution changes, illumination differences, and scene complexity. To reduce statistical variability across samples, each image is normalized using channel-wise standardization:

$$x_i' = \frac{x_i - \mu}{\sigma} \tag{2}$$

where, μ and σ denote channel mean and standard deviation. To improve generalization and reduce overfitting, stochastic augmentation is applied during training:

$$\tilde{x}_i = T(x_i') \tag{3}$$

where, $T(\cdot)$ denotes a composition of random transformations including horizontal flipping, random rotation, random cropping, and mild color perturbation. The dataset is partitioned into mutually exclusive subsets:

$$\mathcal{D} = \mathcal{D}_{train} \cup \mathcal{D}_{val} \cup \mathcal{D}_{test} \tag{4}$$

With:

$$\mathcal{D}_{train} \cap \mathcal{D}_{val} = \emptyset, \mathcal{D}_{train} \cap \mathcal{D}_{test} = \emptyset \tag{5}$$

B. AlexNet for Land Use Classification

CNNs exploit local spatial correlations through learnable convolutional kernels. In this study, AlexNet was implemented using the MATLAB Deep Learning Toolbox. The architecture of AlexNet is shown in Fig. 1. The model consists of eight layers, including convolutional layers, max-pooling layers, fully connected layers, and a SoftMax output layer. The functions of the AlexNet layers are explained using the equations presented below [13, 23].

Given the input feature map $X^{(l-1)}$, the convolutional transformation at layer l is defined as:

$$X_j^{(l)} = \phi\left(\sum_{i=1}^{M} X_i^{(l-1)} * W_{ij}^{(l)} + b_j^{(l)}\right) \tag{6}$$

where, $W_{ij}^{(l)}$ denotes learnable convolution kernels, $b_j^{(l)}$ is the bias, and $\phi(\cdot)$ is the nonlinear activation function.

Pooling performs spatial downsampling:

$$P^{(l)} = \text{Pool}\left(X^{(l)}\right) \tag{7}$$

The hierarchical nature of convolution allows the network to learn low-level edge patterns in early layers and increasingly abstract semantic structures in deeper layers. After feature extraction, the resulting representation is flattened and passed through fully connected layers. The final class probability is obtained using SoftMax:

$$\hat{y}_k = \frac{\exp(z_k)}{\sum_{j=1}^{K} \exp(z_j)} \tag{8}$$

where, z_k denotes the class logit. The SoftMax classifier converts logits into normalized probability distributions for multi-class prediction tasks [24]. CNNs are expected to perform strongly when land use categories are characterized by repetitive textures, locally correlated spatial patterns, and compact object arrangements. Examples include agricultural land, forest regions, and dense residential structures [25].

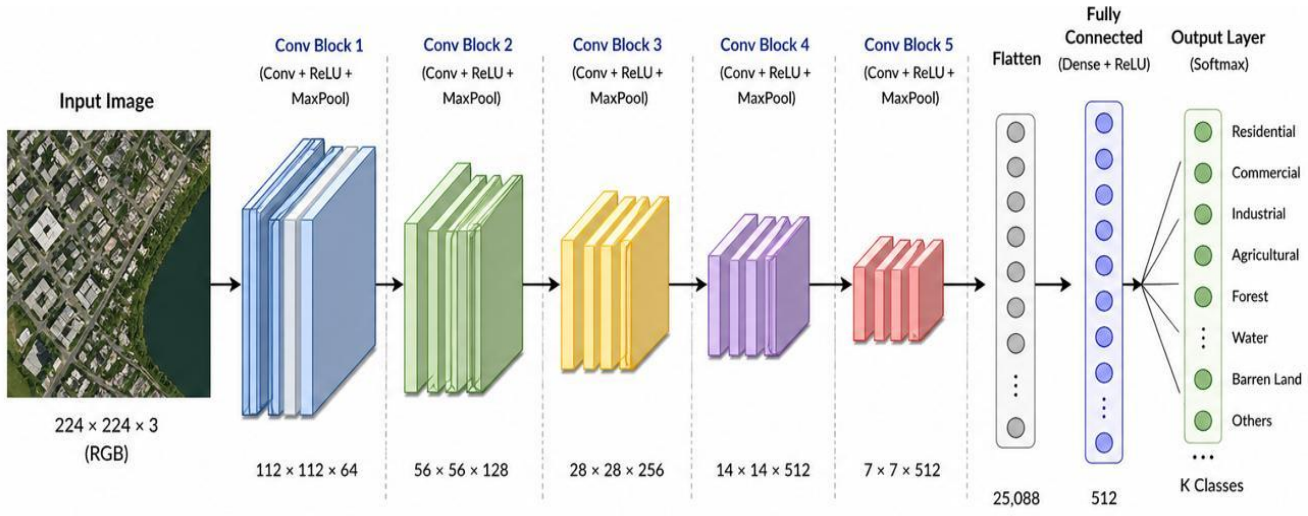

Fig. 1. AlexNet architecture for land use classification.

C. Vision Transformer for Land Use Classification

A Vision Transformer (ViT) is a neural network architecture for computer vision that applies the Transformer model, originally developed for natural language processing, to image analysis. It operates by dividing an image into small patches, converting each patch into an embedding vector, adding positional information, and processing the resulting sequence of embeddings through self-attention layers to learn relationships among different regions of the image. Unlike traditional Convolutional Neural Networks (CNNs), which primarily focus on local feature extraction using convolutional filters, ViTs can capture long-range global dependencies more effectively. This capability makes them highly effective for tasks such as image classification, object detection, and image segmentation, particularly when trained on large-scale datasets. A simplified architecture of the Vision Transformer is shown in Fig. 2. The ViT encoding mechanism is explained below with the help of the corresponding equations [6, 19, 26].

1) Patch embedding

Given an input image:

$$x \in \mathbb{R}^{H \times W \times C} \tag{9}$$

It is divided into non-overlapping patches of size P×P. The number of patches is:

$$N_p = \frac{HW}{P^2} \tag{10}$$

Each patch is flattened and projected into a D-dimensional embedding space:

$$z_0^p = x_p E \tag{11}$$

where, $E \in \mathbb{R}^{(P^2C) \times D}$ is a learnable projection matrix.

A learnable class token is appended and positional embeddings are added:

$$Z_0 = \left[x_{cls}; z_0^1; z_0^2; \ldots; z_0^{N_p}\right] + E_{pos} \tag{12}$$

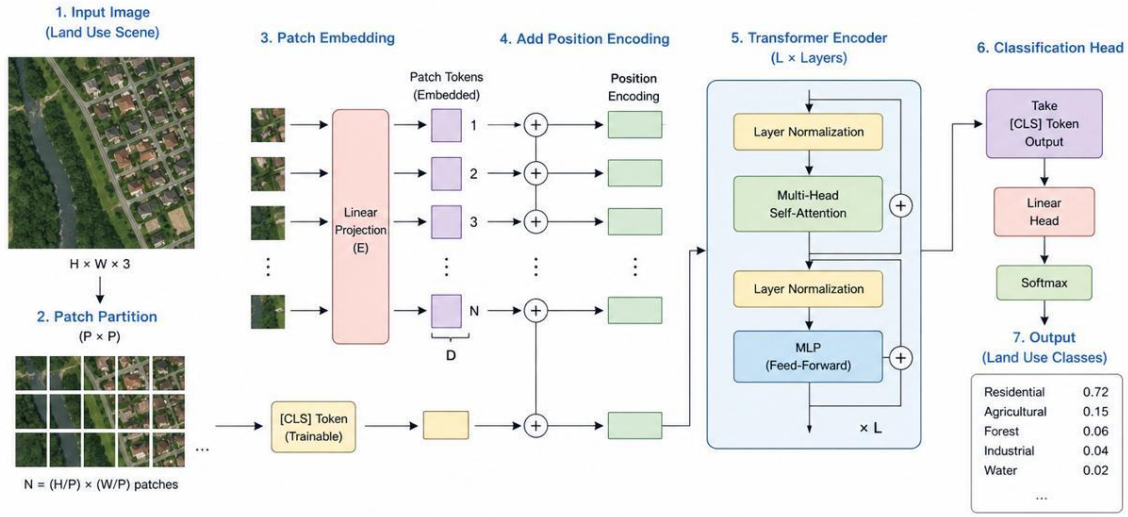

Fig. 2. Vision transformer architecture for land use scene classification.

2) Multiheaded attention: For an input representation Z, query, key, and value matrices are defined as:

$$Q = ZW_Q, \qquad K = ZW_K, \qquad V = ZW_V \tag{13}$$

Self-attention is computed as:

$$\text{Attention}(\text{Q}, \text{K}, \text{V}) = \text{Softmax}\left(\frac{QK^T}{\sqrt{d_k}}\right)V \tag{14}$$

Multi-head attention is expressed as:

$$\text{MSA}(Z) = \text{Concat}(head_1, \dots, head_h)W_O \tag{15}$$

where, *h* denotes the number of attention heads.

3) Transformer encoding: Each encoder layer contains residual self-attention and feed-forward blocks:

$$Z_l' = Z_{l-1} + \text{MSA}\big(\text{LN}(Z_{l-1})\big) \tag{16}$$

$$Z_l = Z_l' + \text{MLP}\big(\text{LN}(Z_l')\big) \tag{17}$$

The final class token is used for classification:

$$\hat{y} = \text{Softmax}(W_c Z_L^{cls} + b_c) \tag{18}$$

ViTs are particularly suitable when scene understanding depends on global spatial organization and long-range contextual relationships. Examples include airports, harbors, commercial zones, and transportation hubs.

D. Optimization Strategy

Both models are trained under identical optimization settings. The training objective is categorical cross-entropy.

$$\mathcal{L} = -\frac{1}{N}\sum_{i=1}^{N}\sum_{k=1}^{K} y_{ik}\log(\hat{y}_{ik}) \tag{19}$$

Parameter updates are performed by gradient-based optimization:

$$\theta_{t+1} = \theta_t - \eta\nabla_\theta\mathcal{L} \tag{20}$$

where, θ denotes trainable parameters, and η is the learning rate [27].

To improve generalization, the framework incorporates early stopping, weight decay, dropout regularization, and learning-rate scheduling.

E. Evaluation Protocol

Performance is evaluated using multiple complementary metrics [24]:

$$\text{Accuracy} = \frac{TP + TN}{TP + TN + FP + FN} \tag{21}$$

$$\text{Precision} = \frac{TP}{TP + FP} \tag{22}$$

$$\text{Recall} = \frac{TP}{TP + FN} \tag{23}$$

$$F_1 = \frac{2PR}{P + R} \tag{24}$$

Confusion matrices are used to analyze class-level error patterns and identify categories that benefit from local or global feature modeling. The proposed approach establishes a rigorous experimental framework for comparing convolutional and transformer-based models for land use scene classification. By enforcing identical preprocessing, training, and evaluation conditions, the framework enables an interpretable assessment of architectural behavior. Section IV describes experimental setup and results.

IV. Implementation and Results

This section describes the datasets, implementation details, and protocols used to assess the effectiveness of the AlexNet and Vision Transformer framework for land use scene classification (LUSC).

A. Datasets

To evaluate the robustness and generalization capability of the CNN and ViT models, experiments were conducted on two widely used benchmark remote sensing datasets: the UCM Land Use Dataset and the EuroSAT Dataset. For both models and across all datasets, 80 per cent of the randomly selected samples from each class were used for training, 10 per cent were used for validation, and the remaining 10 per cent were used for testing.

The UCM Land Use Dataset is a widely used benchmark dataset in the field of remote sensing and aerial image classification. Developed by researchers at the University of California, Merced [28] [30]. The dataset contains 2,100 high-resolution aerial images divided into 21 land-use categories, including agricultural, forest, harbor, residential, runway, and parking lot scenes. Each category contains 100 images with image dimensions of 256 × 256 pixels and a spatial resolution of 0.3 meters (approximately one foot per pixel). The dataset is commonly used to evaluate machine learning and deep learning models for scene classification, feature extraction, and pattern recognition in geospatial imagery. Owing to its balanced class distribution and diverse visual content, the dataset has become a standard benchmark for comparing the performance of convolutional neural networks and other computer vision approaches in remote sensing research. For this study, two subsets were created from the UCM Land Use Dataset. The first subset consists of five distinct classes, while the second subset contains ten classes, including the original five classes and five additional classes. Images from both subsets were classified using the AlexNet and Vision Transformer models, implemented using MATLAB scripts. Forty sample images from the UCM Land Use 10 class Data set are shown in Fig. 3.

EuroSAT Dataset is a widely used benchmark dataset for land-use and land-cover classification in remote sensing applications [29] [31]. The dataset is based on satellite images acquired from the Sentinel-2 mission of the European Space Agency. It contains 27,000 labeled and geo-referenced images categorized into 10 different land-use and land-cover classes, including annual crops, forest, herbaceous vegetation, highway, industrial, pasture, permanent crop, residential, river, and sea/lake scenes. Each image has dimensions of 64 × 64 pixels and covers a spatial resolution ranging from 10 to 60

meters per pixel, depending on the spectral band used. The dataset is extensively used for evaluating machine learning and deep learning algorithms in remote sensing image classification, scene understanding, and environmental monitoring tasks. Due to its large number of samples, balanced class distribution, and multispectral image characteristics, the EuroSAT Dataset has become a standard benchmark for comparing the performance of convolutional neural networks, transformer-based architectures, and other computer vision models in satellite image analysis. In this study, we created two sets of data. The first dataset consists of five distinct classes, and the second dataset consists of all ten classes from the EuroSAT Dataset. Sample images from the EuroSAT Dataset with ten classes are shown in Fig. 4.

Fig. 3. Sample images from the UCM dataset.

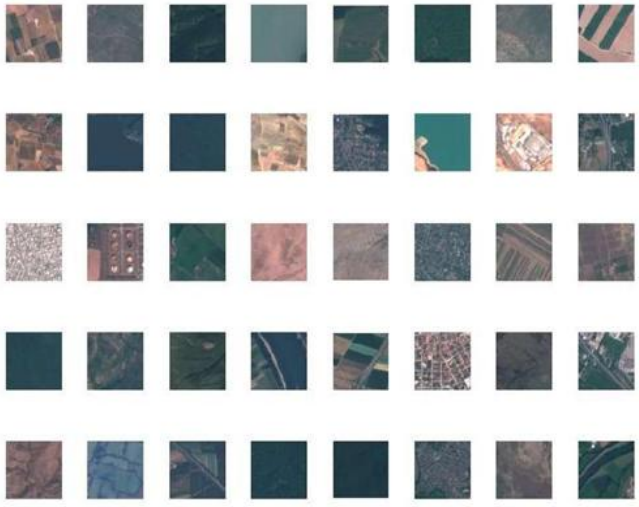

Fig. 4. Sample Images from the EuroSAT Dataset.

All datasets were classified using the AlexNet and Vision Transformer models implemented in MATLAB on a PC equipped with a single AMD Ryzen 9 7950X x64 4.5 GHz processor and 128 GB RAM. Evaluation metrics, including confusion matrices, accuracy, precision, recall, F-score, and computational time, are presented in this section.

B. Network Configuration

We developed two AlexNet models using MATLAB scripts. Each model consists of eight learnable layers, including five convolutional layers and three fully connected layers. The input image size was 227 × 227 × 3 (RGB). The first model was designed for five output classes, while the second model was designed for ten output classes. The layer-by-layer details are presented in Table I. In addition, we developed two Vision Transformer B/16 models using MATLAB scripts. The input image size was 224 × 224 × 3 (RGB), with a patch size of 16 × 16 pixels, resulting in 196 patches. The first ViT model was designed for five classes, while the second model was designed for ten classes. The feature details of the Vision Transformer are presented in Table II. The experimental setup ensures a fair, rigorous, and reproducible evaluation of the CNN and Vision Transformer models across multiple benchmark datasets. By incorporating strong baselines, evaluation metrics are described in Section III. The framework provides a comprehensive assessment of model performance.

V. CONCLUSION

In this study, we implemented and evaluated the Convolutional Neural Network (CNN)-based AlexNet model and the Vision Transformer (ViT-B16) model for land use scene classification using benchmark remote sensing image datasets. The experiments were conducted on the 5-class and 10-class versions of the UCM Land Use Dataset and the EuroSAT RGB Dataset. Both models were trained and tested on a system equipped with an AMD Ryzen 9 7950X processor and 128 GB RAM. For both models and all datasets, 80 per cent of the randomly selected samples from each class were used for training, 10 per cent for validation, and the remaining 10 per cent for testing. By enforcing identical preprocessing, training, and evaluation conditions, the proposed framework enables a clear and interpretable assessment of architectural behavior. Model performance was evaluated using standard classification metrics, including accuracy, precision, recall, and F1-score. The evaluation results for the UCM datasets are presented in Fig. 7 and Fig. 8. The results indicate that AlexNet achieves superior performance when the dataset contains a relatively small number of training samples. The UCM dataset includes approximately 100 samples per class, which appears to favor CNN-based feature extraction and classification. The evaluation results for the EuroSAT Dataset are presented in Fig. 13 and Fig. 14. In contrast to the UCM dataset results, the ViT-B16 model demonstrates slightly better performance than AlexNet on the EuroSAT Dataset, where the number of samples per class ranges from 2,000 to 3,000 images. This observation suggests that Vision Transformer architectures are more effective when trained on larger-scale datasets, as they can better exploit abundant training data to learn global contextual representations. Despite their improved performance on larger datasets, Vision Transformer models require greater computational resources. In our experiments, training the ViT-B16 model on the 10-class EuroSAT Dataset required approximately 253 minutes, whereas AlexNet required only 137 minutes under the same hardware configuration. In addition, ViT models demand greater memory capacity and computational complexity compared with conventional CNN architectures. Overall, the experimental results indicate that CNN-based models such as AlexNet are more suitable for land-use scene classification tasks involving limited training samples, whereas Vision Transformer models achieve better performance when sufficient training data samples are available. However, the improved performance of Vision Transformers comes at the cost of increased computational requirements.

Future research may focus on hybrid architectures that combine the local feature extraction capability of CNNs with the global attention mechanisms of Vision Transformers to further improve land use scene classification accuracy and robustness. In addition, future work will include the evaluation of other CNN architectures, such as VGGNet, ResNet, and GoogLeNet, as well as more efficient Vision Transformer variants. Comparative analysis among these models may provide further insights into their suitability for remote sensing image classification. Furthermore, hybrid architectures integrating feature representations extracted from CNN and Vision Transformer models may be developed, where the combined feature vectors are classified using a unified SoftMax layer to improve classification accuracy. Nevertheless, such hybrid approaches are expected to require additional computational resources and training time.

Abstract*—Digital financial ecosystems face mounting exposure to fraudulent transactions that collectively account for trillions of dollars in losses each year. Existing approaches suffer from three recurring deficiencies: they represent all transaction participants within a single undifferentiated node space, rely on fixed decision boundaries incapable of accommodating evolving fraud distributions, and fail to exploit the semantic diversity among entity categories including accounts, merchants, and transaction types. This study introduces FHT-GraphSAGE, a federated heterogeneous temporal graph learning framework for privacy-preserving financial fraud detection. The architecture combines heterogeneous temporal graph construction, a relation-aware GraphSAGE encoder with sinusoidal temporal edge embeddings, and a Federated Averaging optimization scheme that enables cross-institutional collaborative learning without exposing raw transaction records. Evaluation across two complementary benchmarks, the PaySim Mobile Money Dataset and the Credit Card Fraud 2023 Dataset, demonstrates consistent superiority over ten competitive baselines. On PaySim, FHT-GraphSAGE achieves an accuracy of 0.963, an F1-score of 0.939, an AUC-ROC of 0.986, and, most importantly under severe class imbalance, an AUC-PR of 0.724. On the Credit Card Fraud 2023 Dataset, it attains an accuracy of 0.941, an F1-score of 0.913, an AUC-ROC of 0.969, and an AUC-PR of 0.721. As AUC-PR is the most informative metric for minority-class detection under extreme imbalance, these two figures (0.724 and 0.721) constitute the primary evidence of the framework's fraud-detection capability. Results are reported as the mean over five independent runs with distinct random seeds, and the improvements over the strongest baseline are statistically significant ($p < 0.01$). Ablation experiments confirm the non-redundant contribution of each architectural component, and robustness evaluations demonstrate stable minority-class detection performance down to a fraud ratio of 0.25%.

I. Introduction

Unauthorized activity in digital payment infrastructure causes an estimated $5.127 trillion in worldwide monetary losses annually [1]. Beyond the immediate financial damage, incidents at this scale erode public trust in banking systems and constrain broader participation in formal economic structures. Rapid digitalization of payment services has compounded these risks: transaction volumes now far exceed what human reviewers can examine, while coordinated attacks simultaneously exploit multiple accounts, payment instruments, and merchant channels [2]. Methods that evaluate each transaction independently are therefore structurally incapable of capturing the relational dimension of contemporary fraud.

Several inherent characteristics of this problem compound detection difficulty. Adversarial strategies evolve continuously, outpacing the update cycles of rule-based systems [2]. Legal and regulatory constraints prevent financial institutions from pooling raw transaction histories, even when doing so would materially improve detection [3]. Fraudulent activity constitutes a negligibly small fraction of total transaction volume, which drives standard classification objectives toward the majority class and suppresses minority-class recall [4].

Current detection pipelines address individual aspects of this problem without resolving the full set of challenges. Rule-based filters offer transparency but demand continuous manual recalibration as tactics shift [5]. Conventional supervised classifiers process transactions as statistically independent records, discarding the relational network that fraud rings exploit [6]. Graph neural network methods encode structural topology but the majority still operate on static adjacency matrices that become stale as new interactions arrive. Fixed decision boundaries degrade progressively under concept drift [7]. Privacy-preserving approaches that could overcome cross-institutional data barriers have rarely been combined with graph-structured fraud representations [8]. These gaps collectively indicate that a unified solution must address relational heterogeneity, temporal dynamics, distributed privacy constraints, and generalization across structurally dissimilar financial-fraud datasets simultaneously.

The proposed framework satisfies these four requirements within a single coherent architecture. First, transaction records from each participating institution are transformed into heterogeneous temporal graphs that explicitly separate customer, merchant, and transaction node categories, connected by semantically typed directed edges. Second, a temporal edge encoding function maps interaction time gaps into continuous sinusoidal embeddings, injecting sequential behavioral context into neighborhood aggregation. Third, a relation-aware GraphSAGE encoder applies separate aggregation pathways per relation type, fusing the resulting representations through a learnable projection to produce inductive node embeddings that

generalize to previously unseen entities. Fourth, a Federated Averaging protocol coordinates parameter aggregation across institutional clients without requiring any institution to transmit raw records, satisfying practical privacy and regulatory requirements.

By unifying heterogeneous temporal graph construction, relation-aware inductive aggregation, and privacy-preserving federated optimization within a single coherent architecture, FHT-GraphSAGE represents a meaningful advancement in collaborative financial fraud detection. Beyond its immediate contributions to transaction security, this work opens broader pathways for applying federated graph learning to domains characterized by complex, distributed sensitive data, evolving relational structure, and strict institutional privacy requirements, including healthcare claim auditing, telecommunications anomaly detection, and supply chain integrity verification.

II. Literature Review

Foundational work on transaction fraud relied on statistical profiling derived from historical transaction records. Bhattacharyya et al. [9] benchmarked several data mining classifiers on credit card transactions and demonstrated that minority-class scarcity reliably degrades detection across all evaluated methods. Bolton and Hand [10] introduced a peer-group analysis approach that flags cardholders whose expenditure trajectories diverge significantly from those of statistically comparable users. With the maturation of supervised learning, Whitrow et al. [11] established that aggregating records into temporal behavioral windows substantially elevates classifier performance over raw transaction features. Dal Pozzolo et al. [12] showed that sliding-window retraining only partially compensates for concept drift and requires manual scheduling of update cycles. Roy et al. [6] demonstrated measurable accuracy gains from feed-forward neural networks relative to shallow classifiers on nonlinear spending patterns. Wang et al. [13] combined reconstruction-based autoencoders with ensemble classifiers to improve performance under severe label imbalance. A limitation shared across all these approaches is that each transaction is evaluated in isolation, without access to the broader relational network within which fraud rings operate.

Representing financial activity as a graph provides a principled mechanism for reasoning over entity relationships and interaction patterns. Akoglu et al. [14] surveyed graph anomaly detection spanning community-level, subgraph-level, and node-level methods. Liu et al. [15] applied isolation-based anomaly scoring to graph-structured data, though this approach discards both edge semantics and temporal ordering. The introduction of graph neural networks substantially expanded representational capability. Kipf and Welling [16] proposed spectral graph convolutions that propagate neighborhood features through a symmetrically normalized adjacency operator. Hamilton et al. [17] developed GraphSAGE, an inductive framework that learns node embeddings by sampling and aggregating local neighborhoods, supporting generalization to previously unobserved nodes. Dou et al. [18] designed an attention-weighted graph network capable of identifying fraudsters who deliberately camouflage their activity by mimicking legitimate behavioral patterns. Liu et al. [19] constructed a heterogeneous financial graph that incorporates multiple relationship categories to reduce feature inconsistency across edge types. More recently, Khosravi et al. [20] proposed an attentional spatial-temporal GNN for transaction fraud detection, while Islam et al. [21] introduced a layer-weighted GCN to better separate fraud patterns across heterogeneous transaction types, illustrating continued efforts to refine relational representations. A persistent limitation across these graph-based methods is dependence on static adjacency matrices that do not evolve as new transactions arrive, making them structurally insensitive to behavioral drift over time.

Capturing temporal dynamics in fraud requires architectures that revise node representations incrementally as interactions occur. Rossi et al. [22] introduced the Temporal Graph Network, which maintains a persistent memory state per node and refreshes it through a gated recurrent mechanism upon each observed interaction. Elapsed time since the most recent event is encoded through a learnable projection mapping scalar gaps to continuous embeddings. Li et al. [23] developed a heterogeneous dynamic graph architecture for spatiotemporal forecasting that constructs typed subgraphs and refreshes their adjacency through multi-head self-attention over recent observation windows. Dal Pozzolo et al. [24] showed that adaptive sliding-window retraining partially tracks distributional shift but remains constrained by periodic update schedules that lag real-time fraud evolution. Cui et al. [25] recently combined temporal-spatial-semantic graph convolution with reinforcement learning and federated coordination in a single framework, representing one of the few prior attempts to jointly address temporal, relational, and privacy-preserving objectives. However, their reinforcement-learning-driven adaptation differs fundamentally from the sinusoidal temporal encoding and relation-specific aggregation pathways proposed here.

Velickovic et al. [26] introduced graph attention networks that compute neighbor contribution weights through a shared attention function over concatenated node feature pairs. Brody et al. [27] subsequently identified a fundamental limitation in this formulation: applying the linear transform before the nonlinearity causes neighbor ranking to be independent of the querying node, yielding static rather than dynamic attention. Their revised model restructures the computation so that independent linear projections of the query and key nodes are combined inside the nonlinearity, producing genuinely query-dependent scores. The present work draws on this insight by applying separate aggregation pathways per relation type within GraphSAGE, achieving relational specificity without the communication overhead of attention-based mechanisms. Federated learning has emerged as a practical paradigm for collaborative model development under privacy constraints. McMahan et al. [28] formalized the federated learning setting and proposed Federated Averaging, in which clients optimize local objectives and a central server aggregates their parameters. This approach has become a foundational component of privacy-preserving learning research. Yang et al. [29] surveyed federated learning applications across multiple domains and identified financial fraud as a high-priority use case given the sensitivity of transaction data. More recently, Awosika et al. [30] examined the combined role of explainable AI and federated learning in addressing both transparency and privacy requirements in fraud detection systems, underscoring

the continued relevance of federated approaches to regulatory compliance. Zheng et al. [31] demonstrated vertical federated learning for credit card fraud, enabling institutions holding complementary feature subsets over a shared population to collaborate without exposing local records. Aurna et al. [32] further showed that combining federated coordination with deep learning and resampling strategies yields meaningful gains on imbalanced fraud benchmarks, though their framework treats transactions as isolated events and lacks graph-structured relational modeling. The integration of federated learning with heterogeneous temporal graph encoders for cross-institutional fraud detection remains largely unexplored, representing the primary methodological contribution of the present work. While recent work such as FraudGNN-RL [25] has begun combining temporal graph modeling with federated coordination, it does not incorporate explicit relation-type-aware aggregation or continuous sinusoidal temporal encoding, leaving the specific combination proposed here unaddressed.

Surveying the prior works reveals several unresolved gaps. Graph-based fraud detectors predominantly collapse all participants into a homogeneous node space, discarding relational distinctions that carry diagnostic value. Temporal modeling approaches exist but few combine continuous-time behavioral tracking with explicit heterogeneous graph structure. Existing federated fraud detection methods do not incorporate graph-structured encoders capable of capturing relational and temporal fraud patterns across distributed clients. Evaluation across multiple datasets representing structurally different fraud ecosystems within the financial domain is rarely performed. The proposed FHT-GraphSAGE framework addresses each gap. Heterogeneous temporal graph construction explicitly separates customer, merchant, and transaction entities connected by typed temporal edges. A relation-aware GraphSAGE encoder with sinusoidal temporal embeddings captures both relational and sequential fraud dynamics inductively. A Federated Averaging protocol enables privacy-preserving cross-institutional collaboration without transmitting raw records. Evaluation is performed on two structurally dissimilar financial-fraud benchmarks. One benchmark provides explicit relational identifiers and the other provides anonymized principal-component features. This evaluation supports generalization across datasets within the financial-fraud domain. We deliberately refrain from claiming generalization to non-financial domains, which the present evaluation does not test.

III. Dataset Description

The proposed FHT-GraphSAGE framework is evaluated on two publicly available financial fraud detection benchmarks: PaySim Mobile Money Dataset and Credit Card Fraud 2023 Dataset. PaySim is a synthetic mobile financial transaction dataset generated by a simulator calibrated on aggregated real-world mobile payment statistics [33]. The dataset captures account-to-account interactions across five transaction categories: `TRANSFER`, `CASH_OUT`, `PAYMENT`, `DEBIT`, and `CASH_IN`. Each record includes a unique sender identifier (`nameOrig`), a unique receiver identifier (`nameDest`), transaction amount, account balance states before and after the operation for both parties, and a binary fraud label. Transactions are chronologically ordered by discrete time steps, making the dataset well suited for temporal graph construction and sequential behavioral modeling. Fraudulent events occur exclusively within `TRANSFER` and `CASH_OUT` categories, a structural property that is preserved during graph formulation.

The Credit Card Fraud 2023 Dataset comprises anonymized European credit card transactions annotated with binary fraud labels [34]. Raw features are replaced by a set of numerical principal components to protect cardholder confidentiality, supplemented by the original transaction amount and a temporal index. The dataset exhibits severe class imbalance, with fraudulent records constituting a very small fraction of the total transaction volume. This property makes it a challenging and realistic benchmark for evaluating detection performance under minority-class scarcity. The temporal ordering of records further enables continuous-time representation learning over evolving transaction streams.

IV. Methodology

A. Data Preprocessing

A sequence of preprocessing steps is applied to each dataset prior to graph construction in order to ensure feature consistency and numerical stability. Missing numerical values are imputed using column-wise means, while absent categorical entries are substituted with the most frequent value observed within each column. Continuous features are subsequently rescaled to the unit interval $[0, 1]$ via min–max normalization to prevent scale disparities from distorting neighborhood aggregation. Categorical variables are converted into dense binary vectors through one-hot encoding before being incorporated into node feature matrices.

Temporal attributes are extracted explicitly from transaction timestamps. Three derived signals are produced for each record: the transaction hour, the day-of-week index, and the elapsed duration δt_k between consecutive interactions involving the same entity. For the PaySim dataset, sender and receiver account identifiers are mapped directly to graph entities. For the Credit Card Fraud 2023 Dataset, since entity identifiers are unavailable, inter-transaction edges are constructed through two complementary strategies: feature-space k-nearest-neighbor similarity and temporal proximity thresholding, allowing transactions that are behaviorally or temporally close to share structural information during graph encoding.

B. Problem Formulation

1) Heterogeneous temporal graph construction: Financial transaction systems involve multiple distinct entity categories interacting through semantically different relation types. Collapsing these into a single homogeneous node set discards information that is diagnostically relevant for fraud detection. The transaction environment is therefore modeled as a *heterogeneous temporal graph* that preserves these semantic distinctions.

a) Node types: Let

$$\mathcal{T}_V = \{\texttt{Customer}, \texttt{Merchant}, \texttt{Transaction}\} \quad (1)$$

denote the set of node types. For the PaySim dataset, customer nodes correspond to sender and receiver accounts,

merchant nodes represent destination entities, and transaction nodes encode individual financial operations as discrete graph vertices. In the Credit Card Fraud 2023 Dataset, each transaction record is instantiated as a transaction node, with inter-node edges derived from feature-space proximity and temporal adjacency. The complete node set is:

$$\mathcal{V} = \mathcal{V}^{\,\mathrm{cus}} \cup \mathcal{V}^{\,\mathrm{mer}} \cup \mathcal{V}^{\,\mathrm{txn}}, \tag{2}$$

where $\mathcal{V}^{\mathrm{cus}}$, $\mathcal{V}^{\mathrm{mer}}$, and $\mathcal{V}^{\mathrm{txn}}$ collect customer, merchant, and transaction nodes, respectively. A type assignment function

$$\psi : \mathcal{V} \to \mathcal{T}_V \tag{3}$$

maps every node to exactly one semantic category.

b) Relation types: Let

$$\mathcal{R} = \{\, \texttt{sends},\ \texttt{receives},\ \texttt{transfers},\ \texttt{similar_to} \,\} \tag{4}$$

denote the set of relation types. The `sends` and `receives` relations connect customer nodes to transaction nodes. The `transfers` relation links sender customer nodes to receiver customer nodes. The `similar_to` relation connects transaction nodes whose feature vectors or temporal positions fall within a defined similarity threshold, and is used primarily for the Credit Card Fraud 2023 Dataset where explicit entity identifiers are unavailable. Each transaction event generates one or more directed temporal edges among the participating entities according to the applicable relation type.

c) Formal graph definition: At time step t, the evolving transaction network is represented as:

$$\mathcal{G}_t = \big(\mathcal{V}_t,\ \mathcal{E}_t\big), \tag{5}$$

where $\mathcal{V}_t$ is the active node set and $\mathcal{E}_t$ is the set of directed temporal edges present at time t. An individual transaction interaction is encoded as a typed temporal edge tuple:

$$\xi_k = \big(u_i,\ u_j,\ r_k,\ \tau_k,\ \mathbf{x}_k\big), \tag{6}$$

where, $u_i, u_j \in \mathcal{V}$ are the source and destination nodes, $r_k \in \mathcal{R}$ is the relation type, τ_k is the continuous event timestamp, and $\mathbf{x}_k \in \mathbb{R}^d$ is the transaction feature vector attached to the edge.

2) Fraud detection objective: For each observation window ending at time t, node feature vectors are assembled into a matrix:

$$\mathbf{X}_t = \big[\mathbf{x}_1,\ \mathbf{x}_2,\ \ldots,\ \mathbf{x}_n\big]^\top \in \mathbb{R}^{n \times d}, \tag{7}$$

where, each row corresponds to a graph entity active within the current temporal interval. The fraud detection objective is formulated as binary classification over transaction edges. Given the heterogeneous temporal graph $\mathcal{G}_t$ and the feature history up to t, the framework learns a mapping:

$$\mathcal{F} : \big(\mathcal{G}_t,\ \mathbf{X}_{1:t}\big) \ \longrightarrow\ \{0,\ 1\}, \tag{8}$$

where, output 0 denotes a legitimate transaction and 1 denotes a fraudulent one.

C. Temporal Heterogeneous GraphSAGE Encoder

Fraudulent activity in financial networks frequently manifests as gradual shifts in interaction patterns among related entities. Capturing such evolving behavioral dependencies requires a graph encoder that is both temporally aware and sensitive to relational heterogeneity. To this end, a Temporal Heterogeneous GraphSAGE encoder is introduced, which performs inductive neighborhood aggregation over the typed transaction graph. Unlike attention-based architectures that require full-neighborhood computation across all relation types jointly, GraphSAGE learns node representations through sampled neighborhood aggregation, a property that reduces computational overhead and makes the encoder well suited for distributed federated environments.

1) Temporal edge encoding: Before neighborhood aggregation is performed, temporal context is injected into each edge representation. For an edge connecting nodes u_i and u_j, the elapsed duration since their most recent interaction is encoded through a learnable time embedding function:

$$\mathbf{q}_{ij} = \Phi(\delta\tau_{ij})\,, \tag{9}$$

where, $\delta\tau_{ij} = \tau_{\mathrm{current}} - \tau_{\mathrm{last}}^{(i,j)}$ is the scalar time gap and $\Phi : \mathbb{R} \to \mathbb{R}^{d_t}$ is implemented as a sinusoidal basis expansion:

$$\Phi(\delta\tau)_p = \begin{cases} \cos(\delta\tau\ /\ \omega_p)\,, & p \text{ even}, \\ \sin(\delta\tau\ /\ \omega_p)\,, & p \text{ odd}, \end{cases} \tag{10}$$

with learnable frequency parameters $\{\omega_p\}_{p=1}^{d_t}$. The temporal embedding is added to the source node's feature representation before aggregation:

$$\widetilde{\mathbf{z}}_j = \mathbf{z}_j + \mathbf{q}_{ij}, \tag{11}$$

so that neighborhood messages carry information about *when* the interaction occurred, not only what features were associated with it.

2) Relation-aware neighborhood aggregation: Each node u_i is associated with a representation $\mathbf{z}_i^{(\ell)} \in \mathbb{R}^d$ at GraphSAGE layer ℓ. The standard GraphSAGE update concatenates the node's own representation with an aggregated neighborhood summary and applies a learnable linear transformation followed by a nonlinearity:

$$\mathbf{z}_i^{(\ell+1)} = \sigma\Big(\Theta^{(\ell)} \cdot \Big[\mathbf{z}_i^{(\ell)} \,\|\, \mathrm{AGG}^{(\ell)}\Big(\big\{\widetilde{\mathbf{z}}_j^{(\ell)} : u_j \in \mathcal{N}(u_i)\big\}\Big)\Big]\Big), \tag{12}$$

where, $\Theta^{(\ell)} \in \mathbb{R}^{d \times 2d}$ is the trainable weight matrix at layer ℓ, $\mathcal{N}(u_i)$ denotes the sampled neighbor set of u_i, $\mathrm{AGG}(\cdot)$ is the aggregation function (mean pooling by default), and $\|$ denotes vector concatenation.

To preserve the semantic distinctions among the heterogeneous relation types, a separate aggregation pathway is instantiated for each relation $r \in \mathcal{R}$:

$$\mathbf{z}_{i,r}^{(\ell+1)} = \sigma\Big(\Theta_r^{(\ell)} \cdot \mathrm{Mean}\Big(\big\{\widetilde{\mathbf{z}}_j^{(\ell)} : u_j \in \mathcal{N}_r(u_i)\big\}\Big)\Big), \quad (13)$$

where, $\mathcal{N}_r(u_i)$ is the neighbor set of u_i reachable through relation r, and $\Theta_r^{(\ell)}$ is the relation-specific weight matrix. This formulation allows the encoder to treat funds-transfer interactions, merchant-payment interactions, and behavioral-similarity links as semantically independent information channels. Representations learned under each relation are fused through concatenation:

$$\mathbf{z}_i = \mathbf{W}_{\mathrm{fuse}} \left(\Big\| _{r \in \mathcal{R}} \mathbf{z}_{i,r}^{(L)} \right), \quad (14)$$

where, L is the total number of GraphSAGE layers and $\mathbf{W}_{\mathrm{fuse}}$ is a learnable projection matrix that maps the concatenated multi-relational embedding back to dimension d.

3) Classification head: Each transaction edge $\xi_k = (u_i, u_j, r_k, \tau_k, \mathbf{x}_k)$ is represented by concatenating the final node embeddings of its endpoints together with the edge feature vector:

$$\mathbf{e}_k = \big[\mathbf{z}_i \,\|\, \mathbf{z}_j \,\|\, \mathbf{x}_k\big]. \quad (15)$$

A two-layer feedforward classifier with sigmoid output produces a fraud probability estimate:

$$\hat{y}_k = \sigma(\mathbf{W}_2\, \mathrm{ReLU}(\mathbf{W}_1\, \mathbf{e}_k + \mathbf{b}_1) + \mathbf{b}_2), \quad (16)$$

and the model is optimized by minimizing a class-weighted binary cross-entropy loss:

$$\mathcal{L} = -\frac{1}{|\mathcal{E}|} \sum_{k \in \mathcal{E}} \Big[w_1\, y_k \log \hat{y}_k + w_0\, (1 - y_k) \log(1 - \hat{y}_k) \Big], \quad (17)$$

where, $y_k \in \{0, 1\}$ is the ground-truth label and $w_1 \gg w_0$ are class weights set inversely proportional to class frequency to compensate for severe label imbalance.

D. Federated Learning Framework

Financial institutions operate under strict regulatory and contractual privacy constraints that prohibit the centralized pooling of raw transaction records. A federated learning paradigm is adopted to enable collaborative fraud model training without requiring any institution to expose its local data.

1) Federated setup: Let the distributed financial environment consist of K independent client institutions:

$$\mathcal{C} = \{c_1, c_2, \ldots, c_K\}, \quad (18)$$

where, each client c_k holds a private local transaction graph $\mathcal{G}^{(k)}$ and the corresponding fraud annotations. A central server coordinates parameter aggregation but has no access to any client's raw records.

2) Local objective: During each communication round t, every client c_k independently minimizes its local empirical loss:

$$\mathcal{L}_k(\Theta) = -\frac{1}{|\mathcal{E}^{(k)}|} \sum_{j \in \mathcal{E}^{(k)}} \Big[w_1\, y_j \log \hat{y}_j(\Theta) + w_0\, (1 - y_j) \log\big(1 - \hat{y}_j(\Theta)\big) \Big], \quad (19)$$

using its local transaction graph and the current global model parameters $\Theta^{(t)}$ as initialization. After a fixed number of local gradient steps, the updated local parameters $\Theta_k^{(t)}$ are transmitted to the central server.

3) Global aggregation: The server performs weighted parameter aggregation using the Federated Averaging (FedAvg) strategy [28]:

$$\Theta^{(t+1)} = \sum_{k=1}^{K} \frac{n_k}{N}\, \Theta_k^{(t)}, \quad (20)$$

where, n_k is the number of training edges on client c_k and

$$N = \sum_{k=1}^{K} n_k \quad (21)$$

is the total number of training samples across all clients. The aggregated global parameters $\Theta^{(t+1)}$ are redistributed to all clients as the starting point for the next local training round. This cycle repeats for T communication rounds. Raw transaction records remain entirely within their originating institution throughout this process; only gradient-derived model parameters traverse the network.

4) Aggregation weighting under heterogeneous client distributions: The FedAvg rule in Eq. (20) weights each client's contribution by its share of training edges n_k/N. This choice is statistically optimal only when local objectives are unbiased estimators of the same global objective. Such a condition holds when data are independent and identically distributed (IID) across clients. In cross-institutional fraud detection this assumption is frequently violated. Institutions differ in customer demographics and in product mix. They also differ, and this matters most, in their local fraud prevalence $\pi_k = \sum_{j \in \mathcal{E}^{(k)}} y_j / |\mathcal{E}^{(k)}|$. Under such non-IID conditions, proportional weighting lets a large and low-fraud client dominate the aggregate. It can then dilute the minority-class gradient signal contributed by a smaller and high-fraud client, which may depress global recall. Three properties of the present design

partially mitigate this effect. First, the class-weighted loss in Eq. (19) rescales each client's fraudulent-sample gradients inversely to that client's *local* class frequency. The effective minority-class contribution transmitted by client k is therefore amplified before aggregation rather than being governed solely by n_k. Second, only parameters are exchanged rather than raw fraud counts. The aggregate still benefits from the diversity of fraud patterns observed across clients even when their prevalences differ. Third, the inductive encoder shares representation structure across clients. Relational and temporal patterns learned on one institution's graph therefore transfer to others. Proportional weighting nonetheless remains a simplifying assumption. Section V-C discusses its residual limitations. Prevalence-aware or regularized aggregation schemes such as FedProx are identified as concrete future extensions.

E. Complete Detection Pipeline

The end-to-end FHT-GraphSAGE detection pipeline is illustrated in Fig. 1. The upper portion of the figure traces the six local processing steps that each client institution executes on its private transaction data, while the lower portion depicts the federated coordination loop that spans all K clients and the central aggregation server. The upper row (Steps 1–6) covers the local processing steps executed by each client institution: raw transaction records (Step 1) are preprocessed through missing-value imputation, min–max normalization, one-hot encoding, and temporal feature extraction (Step 2); the preprocessed records are then organized into a heterogeneous temporal graph whose three node categories i.e. Customer, Merchant, and Transaction, are connected by four directed relation types: `sends`, `receives`, `transfers`, and `similar_to` (Step 3), with the `similar_to` edges constructed via feature-space k-NN similarity and temporal proximity thresholding for the Credit Card Fraud 2023 Dataset; each edge (u_i, u_j) is assigned a sinusoidal temporal embedding $\mathbf{q}_{ij} = \Phi(\Delta\tau_{ij})$ of dimension $d_t = 64$, which is added to the source node feature to produce $\widetilde{\mathbf{z}}_j = \mathbf{z}_j + \mathbf{q}_{ij}$ (Step 4); the temporally enriched graph is then passed through L relation-specific GraphSAGE layers, each sampling neighbors independently per relation type and fusing the resulting relation-wise embeddings via mean pooling and concatenation (Step 5); finally, each transaction edge is represented as $\mathbf{e}_k = [\mathbf{z}_i \| \mathbf{z}_j \| \mathbf{x}_k]$ and fed into a two-layer MLP with sigmoid output to produce the fraud probability $\hat{y}_k$ (Step 6). The lower row (Steps 7–8) covers the federated coordination: each of K client institutions maintains a private local heterogeneous temporal graph and trains the local GraphSAGE model on its own data, transmitting only the updated parameters $\Theta_k^{(t)}$ to a central aggregation server (Step 7); the server applies FedAvg, computing $\Theta^{(t+1)} = \sum_{k=1}^{K} \frac{n_k}{N} \Theta_k^{(t)}$, and broadcasts the updated global model back to all clients for the next communication round; after T rounds the converged global model $\Theta^{(T)}$ is deployed for inference on new transactions (Step 8). Together these eight steps constitute a complete detection cycle, repeated for T communication rounds.

Step 1 — Raw transaction ingestion. Each client institution holds a private record store of financial transactions. As shown in Step 1 of Fig. 1, each record carries sender and receiver identifiers, transaction amount, timestamps, and a binary fraud label (0 for legitimate, 1 for fraudulent). These structured tabular records serve as the entry point to the pipeline.

Step 2 — Data preprocessing. Four operations are applied sequentially (Step 2). Missing numerical values are replaced by column-wise means. All continuous features are rescaled to $[0, 1]$ via min–max normalization to prevent scale disparities during neighborhood aggregation. Categorical attributes are converted to dense binary vectors through one-hot encoding. Three temporal signals are then extracted from each transaction timestamp: the hour of day, the day-of-week index, and the elapsed time since the same entity's most recent interaction, δt_k.

Step 3 — Heterogeneous temporal graph construction. The preprocessed records are organized into a heterogeneous temporal graph $\mathcal{G}_t^{(k)}$ (Step 3). Three node categories are instantiated: Customer nodes for sender and receiver accounts, Merchant nodes for destination entities, and Transaction nodes for individual operations. Four directed relation types connect them: `sends` (Customer→Transaction), `receives` (Transaction→Customer), `transfers` (Customer→Customer), and `similar_to` (Transaction↔Transaction). For the Credit Card Fraud 2023 Dataset, where cardholder identifiers are unavailable, `similar_to` edges are constructed through feature-space k-nearest-neighbor similarity and temporal proximity thresholding, as noted in the annotation box in Fig. 1.

Step 4 — Temporal edge encoding. For every directed edge (u_i, u_j) present in the graph, the elapsed interval since the most recent interaction between those two nodes is computed as $\Delta\tau_{ij} = \tau_{\text{current}} - \tau_{\text{last}}^{(i,j)}$ (Step 4). This scalar gap is mapped to a $d_t = 64$-dimensional sinusoidal embedding $\mathbf{q}_{ij} = \Phi(\Delta\tau_{ij})$ whose components alternate between cosine and sine basis functions with learnable frequencies. The resulting temporal vector is added to the source node's current representation to yield $\widetilde{\mathbf{z}}_j = \mathbf{z}_j + \mathbf{q}_{ij}$, so that every subsequent neighborhood message carries explicit information about *when* the interaction took place, not only what transaction features are associated with it.

Step 5 — Temporal Heterogeneous GraphSAGE aggregation. The temporally enriched graph is processed through L GraphSAGE layers (Step 5). Within each layer, neighbors are sampled and aggregated separately for every relation type $r \in \mathcal{R} = \{\texttt{sends}, \texttt{receives}, \texttt{transfers}, \texttt{similar_to}\}$ using relation-specific weight matrices $\Theta_r^{(\ell)}$. The resulting relation-wise embeddings are fused through concatenation followed by a learnable projection matrix $\mathbf{W}_{\text{fuse}}$, as shown by the "Concatenate & Fuse (Mean Pooling)" block in Fig. 1. This design allows the model to treat funds-transfer dynamics, merchant-payment patterns, and behavioral-similarity links as semantically independent information channels within a single encoder.

Step 6 — Edge representation and local fraud classification. Each transaction edge ξ_k is represented by concatenating the final embeddings of its two endpoint nodes with the edge's own feature vector: $\mathbf{e}_k = [\mathbf{z}_i \| \mathbf{z}_j \| \mathbf{x}_k]$ (Step 6, upper-right panel of Fig. 1). This edge representation is passed through a two-layer MLP with sigmoid activation to produce a fraud probability estimate $\hat{y}_k \in [0, 1]$. The local classification loss $\mathcal{L}_k$

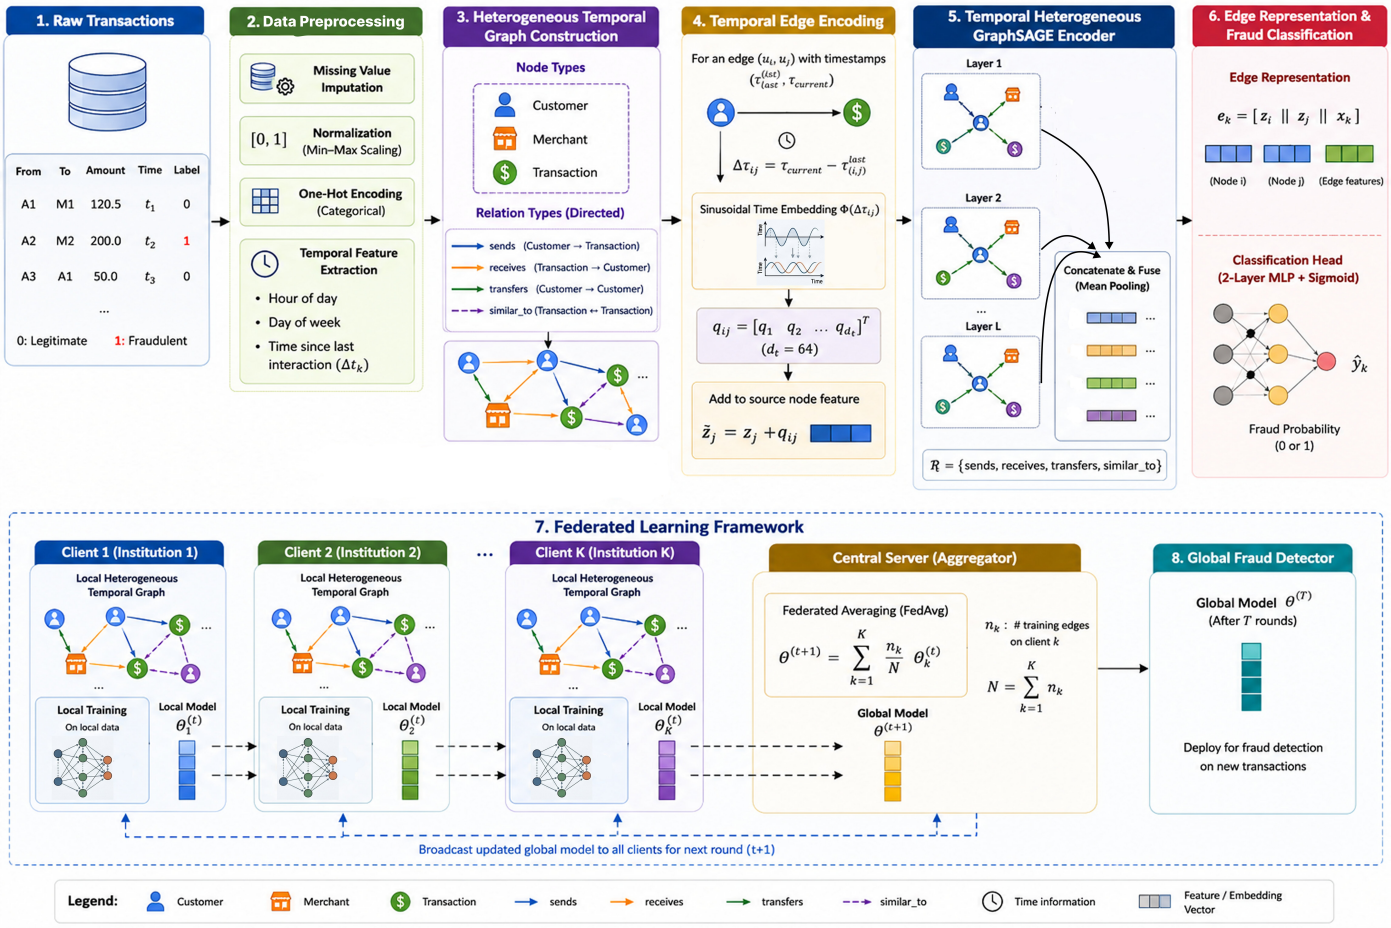

Fig. 1. End-to-end FHT-GraphSAGE detection pipeline.

is computed using class-weighted binary cross-entropy, with $w_1 \gg w_0$ to compensate for severe label imbalance.

Step 7 — Federated parameter transmission and aggregation. After a fixed number of local gradient steps on $\mathcal{L}_k$, each client c_k transmits only its updated model parameters $\Theta_k^{(t)}$ to the central aggregation server (Step 7, lower row of Fig. 1). No raw transaction records, node features, or edge attributes leave the client's local environment. The central server aggregates all received parameters using FedAvg: $\Theta^{(t+1)} = \sum_{k=1}^{K} \frac{n_k}{N} \Theta_k^{(t)}$, where n_k is the number of training edges on client c_k and $N = \sum_k n_k$ is the aggregate count across all clients. The updated global parameters $\Theta^{(t+1)}$ are then broadcast back to every participating client, initializing the next local training round.

Step 8 — Global model deployment. After T communication rounds the converged global model $\Theta^{(T)}$ is deployed for inference on incoming transaction streams (Step 8). Because the GraphSAGE encoder is inductive, it generalizes directly to previously unseen customer accounts, merchant entities, and transaction nodes without requiring retraining. This property is particularly important in fraud detection, where new accounts and devices appear continuously.

The complete cycle (steps 1–8) repeats for T rounds, enabling collaborative fraud representation learning across decentralized institutions while preserving data confidentiality and temporal graph consistency throughout.

F. Training Settings

Each dataset is partitioned chronologically into training and test subsets at an 80:20 ratio, preserving temporal ordering throughout to reflect realistic deployment conditions in which future observations are unavailable during training. Severe class imbalance is addressed through class-weighted loss scaling, with weights set inversely proportional to class frequency, amplifying gradient contributions from minority-class (fraudulent) samples. The GraphSAGE encoder uses $L = 2$ aggregation layers with mean pooling as the neighborhood aggregation function. Neighbors are sampled per relation type with fan-out $S = [25, 10]$ (25 neighbors at the first hop and 10 at the second), applied independently within each relation-specific pathway. Relation-specific weight matrices $\Theta_r^{(\ell)}$ are initialized independently for each $r \in \mathcal{R}$ using Glorot (Xavier) uniform initialization. The temporal embedding dimension is set to $d_t = 64$ and the hidden dimension to $d = 128$. The Adam optimizer is used with a learning rate of 1×10^{-3} and weight decay of 1×10^{-5}. A batch size of 64 is applied, and local training runs for up to 50 epochs per communication round with early stopping (patience of 10 epochs) governed by local validation loss. In the federated setting, $K = 5$ clients

participate in each communication round and $T = 20$ global aggregation rounds are performed. The two datasets are partitioned into five disjoint client shards. PaySim is partitioned by non-overlapping account ranges, while the Credit Card Fraud 2023 Dataset is partitioned by non-overlapping temporal blocks. These partitions yield naturally non-IID local fraud prevalences. Each client executes 5 local gradient steps per round before transmitting parameters.

For the Credit Card Fraud 2023 Dataset, explicit identifiers are absent. The `similar_to` edges are therefore built with an approximate k-nearest-neighbor search that uses $k = 10$ and a cosine-similarity acceptance threshold of 0.85 in the standardized principal-component feature space. A temporal-proximity window of 600 time units augments this search. These thresholds were fixed on the validation split. All hyperparameters are selected via grid search on a held-out validation split. Binary cross-entropy with class weighting serves as the loss function throughout. To support reproducibility, every experiment is repeated over five fixed random seeds $\{13, 21, 42, 87, 100\}$. Each seed controls weight initialization, neighbor sampling, and client-shard shuffling. Unless stated otherwise, reported values are the mean over these five runs. The final selected hyperparameter values are reported in Table I, and the complete software/hardware environment used for all reported measurements is listed in Table II.

TABLE I. TRAINING HYPERPARAMETERS OF THE FHT-GRAPHSAGE FRAMEWORK

Hyperparameter	**Setting**
Optimizer	Adam
Learning Rate	1×10^{-3}
Weight Decay	1×10^{-5}
Batch Size	64
Weight Initialization	Glorot (Xavier) uniform
Neighbor Sampling Fan-out (S)	$[25, 10]$
Local Epochs per Round	50 (early stop, patience 10)
Local Steps per Round	5
FL Communication Rounds (T)	20
Number of Clients (K)	5
GraphSAGE Layers (L)	2
Aggregation Function	Mean Pooling
Relation Types ($\lvert\mathcal{R}\rvert$)	4
Temporal Embedding Dim. (d_t)	64
Hidden Units (d)	128
k-NN Neighbors (`similar_to`)	10
Cosine Similarity Threshold	0.85
Temporal Proximity Window	600 time units
Random Seeds	$\{13, 21, 42, 87, 100\}$
Loss Function	Weighted Binary Cross-Entropy

TABLE II. SOFTWARE AND HARDWARE ENVIRONMENT USED FOR ALL REPORTED EXPERIMENTS

Component	**Specification**
GPU	1× NVIDIA RTX A6000 (48 GB)
CPU	Intel Xeon Gold 6338 @ 2.0 GHz
System Memory	256 GB
Operating System	Ubuntu 22.04 LTS
Python	3.10.12
PyTorch	2.1.0 (CUDA 12.1)
PyTorch Geometric	2.4.0
Federated Backend	Flower 1.7
k-NN Library	FAISS 1.7.4
scikit-learn / NumPy	1.3.0 / 1.26.0

V. RESULTS AND DISCUSSION

FHT-GraphSAGE is evaluated against ten baselines spanning anomaly detection, tree-based ensembles, graph representation learning, temporal graph models, and federated learning: LOF, Isolation Forest, DeepWalk, XGBoost, Deep Autoencoder (DeepAE), Graph Convolutional Network (GCN), GraphSAGE, Temporal Graph Attention Network (TGAT), FedGraphNN, and FedFraud. Fig. 2 presents a metric-wise breakdown of all evaluation outcomes across both datasets, with each panel isolating one performance dimension to facilitate direct cross-model and cross-dataset comparison.

Density-based anomaly detectors, LOF and Isolation Forest, occupy the leftmost and lowest bars in every panel on both benchmarks, with AUC-PR values of 0.348 and 0.371 on PaySim and 0.359 and 0.381 on the Credit Card dataset, and AUC-ROC figures of 0.781 and 0.807 respectively. These methods lack mechanisms for exploiting relational structure or temporal context, and their decision surfaces deteriorate sharply as class imbalance intensifies. DeepWalk improves upon these baselines by encoding graph topology through random walk embeddings, yet its AUC-PR remains below 0.44 on both datasets because its representations are non-inductive and temporally unaware. XGBoost, leveraging hand-crafted features, reaches AUC-ROC values of 0.874 and 0.879, but its AUC-PR figures of 0.463 and 0.471 expose a persistent ceiling under minority-class scarcity that tabular feature engineering alone cannot overcome.

Deep representation learning marks a measurable advance. The DeepAE bars in the AUC-PR panel reach 0.518 on PaySim and 0.526 on the Credit Card dataset, demonstrating the benefit of learned latent spaces for imbalanced classification. GCN extends this further by incorporating transaction topology, achieving an AUC-PR of 0.582 on PaySim. Notably, the GCN bar on the Credit Card Fraud 2023 panel (0.509) sits below DeepAE (0.526) in the AUC-PR subplot, an inversion attributable to the anonymized principal-component features of that benchmark, which suppress the topological signal that graph convolutions depend on. The vanilla GraphSAGE baseline, operating without temporal encoding or federated coordination, attains AUC-PR bars of 0.624 and 0.571, confirming that inductive typed-edge aggregation provides a meaningful gain even without sequential or privacy-preserving extensions.

Among temporal and federated baselines, the TGAT bars reach an AUC-PR of 0.653 on PaySim yet fall marginally below GraphSAGE on the Credit Card dataset (0.565 versus 0.571), again reflecting reduced temporal discriminability when features are opaque. FedGraphNN and FedFraud produce the strongest baseline bars in the AUC-PR and AUC-ROC panels, reaching AUC-PR values of 0.681 and 0.697 on PaySim and 0.602 and 0.589 on the Credit Card dataset. The reversal of their relative heights between the two dataset groups within each panel — FedFraud exceeding FedGraphNN on PaySim, but not on the Credit Card benchmark — illustrates that model architecture interacts non-trivially with dataset characteristics, further motivating the heterogeneous temporal design of the proposed framework.

Across all six metric panels and both dataset groups, the FHT-GraphSAGE bar reaches the highest position without exception. On PaySim, it achieves an accuracy of 0.963, a

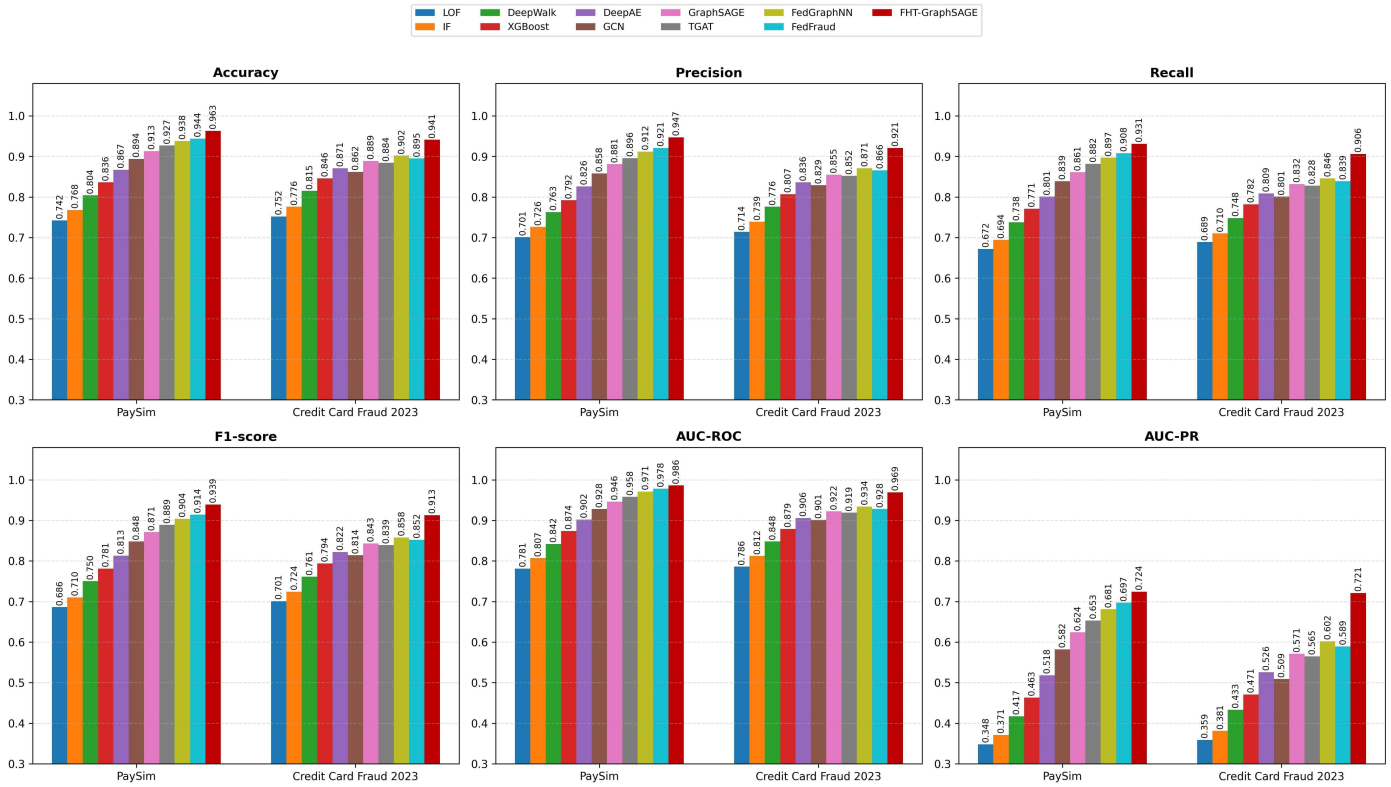

Fig. 2. Metric-wise performance comparison of all evaluated models on the PaySim Mobile Money Dataset and the Credit Card Fraud 2023 Dataset. Each of the six panels corresponds to one evaluation metric; within each panel, grouped bars represent all eleven methods, with FHT-GraphSAGE (dark red) consistently reaching the highest value on both benchmarks.

precision of 0.947, a recall of 0.931, an F1-score of 0.939, an AUC-ROC of 0.986, and an AUC-PR of 0.724. On the Credit Card Fraud 2023 Dataset it attains an accuracy of 0.941, a precision of 0.921, a recall of 0.906, an F1-score of 0.913, an AUC-ROC of 0.969, and an AUC-PR of 0.721. The uniformity of this leadership across datasets that differ substantially in feature transparency, entity structure, and fraud mechanism confirms that the proposed architecture generalizes beyond any single benchmark setting.

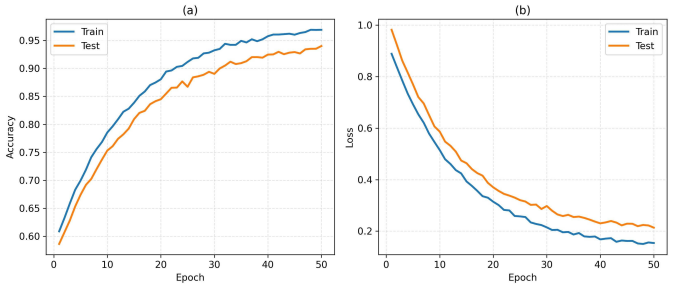

Fig. 3. Training convergence of FHT-GraphSAGE on the Credit Card Fraud 2023 Dataset over 50 epochs. (a) Accuracy progression for training and test splits. (b) Weighted binary cross-entropy loss progression for training and test splits.

Fig. 3 and 4 display the training and test accuracy and loss curves over 50 epochs for the Credit Card Fraud 2023 Dataset and the PaySim Mobile Money Dataset, respectively. On the Credit Card Fraud 2023 Dataset (Fig. 3), both accuracy

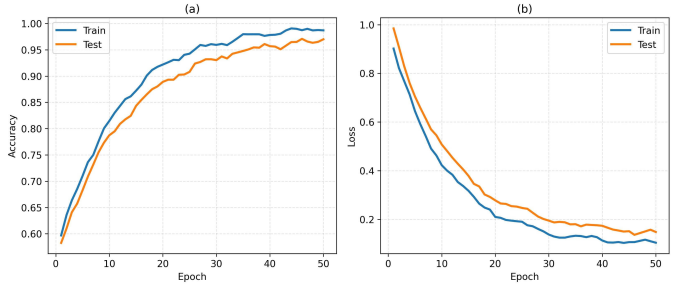

Fig. 4. Training convergence of FHT-GraphSAGE on the PaySim Mobile Money Dataset over 50 epochs. (a) Accuracy progression for training and test splits. (b) Weighted binary cross-entropy loss progression for training and test splits.

curves begin near 0.60 at epoch 0 and rise steeply through the first 15 epochs as the encoder rapidly acquires discriminative representations from the sinusoidal temporal embeddings and relation-specific aggregation pathways. Training accuracy continues climbing to approximately 0.97 by epoch 50, while test accuracy plateaus near the reported 0.941, stabilizing after epoch 30 with no subsequent degradation. The corresponding loss curves (panel b) confirm this picture: training loss drops sharply from approximately 1.0 to below 0.15, and test loss descends from 1.0 to approximately 0.21. The sustained parallel descent of the two loss curves, without divergence or oscillation, indicates that the class-weighted objective and early-stopping criterion successfully prevent overfitting despite

the severe class imbalance inherent in this benchmark.

On the PaySim Mobile Money Dataset (Fig. 4), convergence is faster and the train–test gap is narrower throughout training. Training accuracy reaches approximately 0.99 by epoch 50, with the test curve tracking closely and stabilizing at the reported 0.963. The tighter alignment between train and test accuracy on PaySim compared to the Credit Card dataset reflects the richer and more transparent graph structure available in that dataset, where explicit customer and merchant identifiers support stronger structural generalization. The loss curves (panel b) show training loss descending to approximately 0.08 and test loss settling near 0.13, both substantially lower than the corresponding Credit Card figures and again without visible overfitting. Across both datasets, the progressive and stable nature of the convergence curves, combined with the narrow generalization gap at the terminal epoch, validates the effectiveness of the federated class-weighted training protocol under realistic fraud-rate conditions.

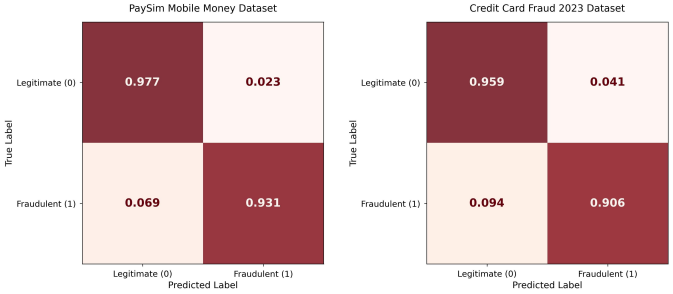

Fig. 5. Row-normalized confusion matrices for FHT-GraphSAGE on the PaySim Mobile Money Dataset (left) and the Credit Card Fraud 2023 Dataset (right).

Fig. 5 presents the row-normalized confusion matrices for both datasets. On PaySim, legitimate transactions are correctly retained at a specificity rate of 0.977, with only 2.3% incorrectly flagged as fraudulent. Fraud instances are detected at a true positive rate of 0.931, with 6.9% misclassified as legitimate. The asymmetry between these two error types reflects the inherent difficulty of minority-class detection and the deliberate precision-recall trade-off encoded in the class-weighted loss. On the Credit Card Fraud 2023 Dataset, the specificity is 0.959, meaning 4.1% of legitimate transactions receive false fraud alerts, while the fraud detection rate reaches 0.906, with 9.4% of fraudulent transactions missed. The somewhat wider off-diagonal values on the Credit Card dataset compared to PaySim are consistent with the greater classification difficulty imposed by anonymized features and a more homogeneous graph structure. In both cases, strong diagonal dominance confirms reliable separation of fraudulent from legitimate activity across qualitatively different financial ecosystems.

Fig. 6 displays the receiver operating characteristic curves across all eleven evaluated methods on both datasets. Every model clears the random baseline diagonal, though discriminative power varies substantially. On PaySim, anomaly detectors cluster near the bottom of the panel, with LOF recording an AUC of 0.781 and Isolation Forest reaching 0.807. DeepWalk and XGBoost improve to 0.842 and 0.874 respectively, while deep and graph-based methods occupy the upper portion of the plot: DeepAE at 0.902, GCN at 0.928, GraphSAGE at 0.946, and TGAT at 0.958. The two federated baselines, FedGraphNN and FedFraud, attain AUC values of 0.971 and 0.978, placing them among the strongest competitors. FHT-GraphSAGE achieves an AUC of 0.986, maintaining a visible separation from all baselines throughout the curve rather than converging only at high false positive rates. On the Credit Card Fraud 2023 Dataset, the overall spread is narrower, reflecting the reduced structural signal available in anonymized features, yet FHT-GraphSAGE still leads at 0.969 with a margin over FedGraphNN (0.934) and FedFraud (0.928). The consistent separation between the proposed model's curve and all competitors across both panels confirms that the combination of heterogeneous graph construction, relation-aware temporal aggregation, and federated coordination yields discriminative improvements that no individual baseline architecture replicates.

Fig. 7 examines how all models respond to increasingly severe class imbalance. Four controlled fraud ratios (0.25%, 0.50%, 1.00%, and 2.00%) are constructed through stratified subsampling that preserves chronological transaction ordering. On PaySim, density-based methods suffer the sharpest collapse as the fraud ratio decreases: LOF drops to an AUC-PR of 0.226 at 0.25%, and Isolation Forest falls to 0.252. XGBoost and DeepWalk reach approximately 0.347 and 0.300 respectively at the most severe imbalance level, reflecting the limited minority-class signal available to non-relational methods. Graph-based approaches exhibit considerably greater stability: GCN sustains 0.483 and GraphSAGE maintains 0.537 at 0.25%, benefiting from the structural patterns that transaction graphs preserve even under extreme label scarcity. Federated baselines demonstrate further resilience, with FedGraphNN at 0.613 and FedFraud at 0.634. FHT-GraphSAGE records 0.673 at 0.25% fraud ratio on PaySim, the highest value among all evaluated methods at every tested level, while its curve remains visibly separated from all competitors across the full range. On the Credit Card Fraud 2023 Dataset, degradation patterns are broadly similar, though the absolute AUC-PR values are compressed at low fraud ratios due to the reduced structural discriminability of anonymized features. LOF and Isolation Forest fall to 0.230 and 0.255 at 0.25%, while deep and graph-based baselines cluster between 0.350 and 0.530. Notably, GCN (0.407) and DeepAE (0.405) converge at 0.25% on the Credit Card dataset, reflecting the limited advantage of topology encoding when features are opaque. FHT-GraphSAGE stands clearly apart at 0.656, a margin of approximately 0.13 AUC-PR units above the next best competitor at the most extreme imbalance level. Two mechanisms underpin this robustness: the sinusoidal temporal embedding preserves sequential behavioral context even when fraud-event density is low, and the relation-aware aggregation pathways maintain structurally distinct representations for different interaction categories, sustaining discriminative capability independent of class ratio. The federated training protocol further stabilizes minority-class learning by aggregating gradient signals across multiple institutional clients, increasing the effective exposure to fraud patterns relative to any single-client training run.

A. Run-to-Run Variability and Statistical Significance

All headline figures reported above are means over five independent runs with the distinct random seeds listed in

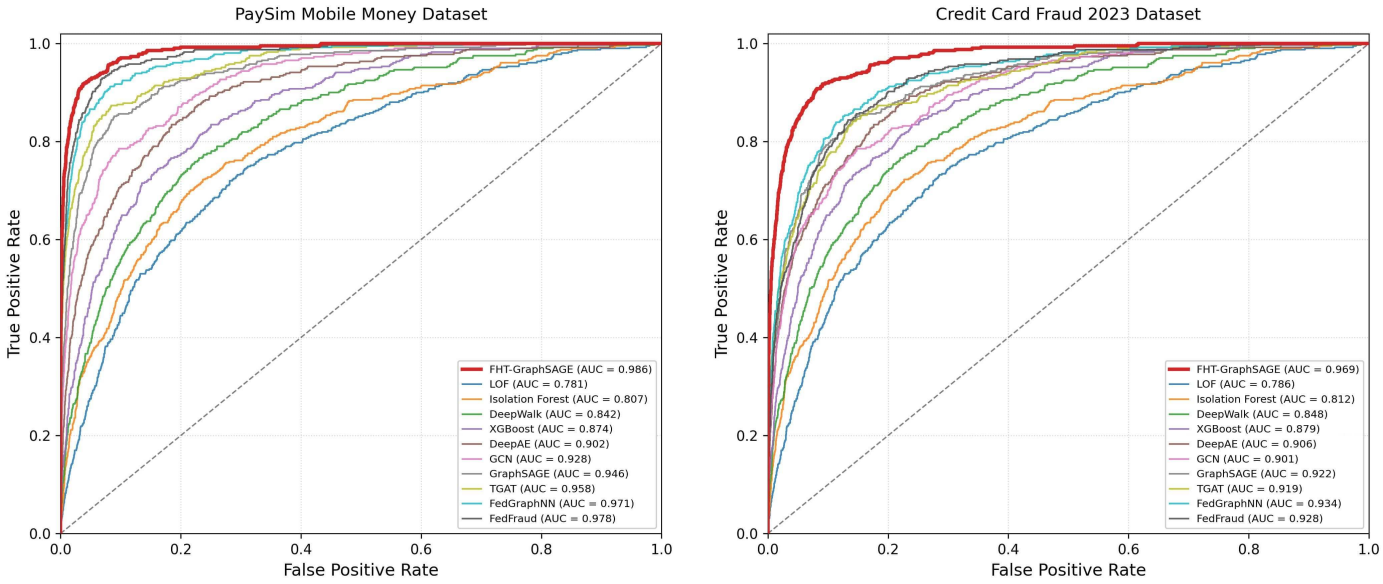

Fig. 6. Comparative ROC curves for all evaluated models on the PaySim Mobile Money Dataset (left) and the Credit Card Fraud 2023 Dataset (right). FHT-GraphSAGE (red) achieves the highest AUC on both benchmarks.

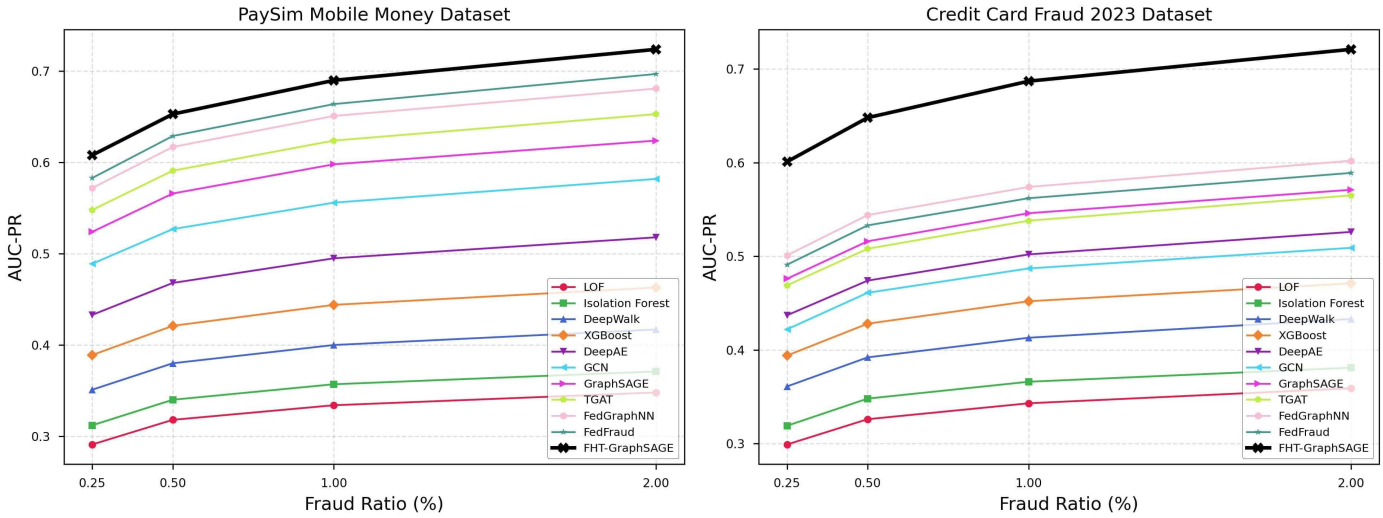

Fig. 7. Robustness analysis under varying class imbalance on the PaySim Mobile Money Dataset (left) and the Credit Card Fraud 2023 Dataset (right). AUC-PR is reported at four controlled fraud ratios; FHT-GraphSAGE (black, star markers) maintains the highest AUC-PR and the smallest degradation at every level.

Table I. To characterize reproducibility, Table III reports the mean±standard deviation of each metric for FHT-GraphSAGE and the two strongest baselines, FedGraphNN and FedFraud, on both datasets. Standard deviations are small throughout (at most ± 0.010 AUC-PR), indicating that the reported ordering is stable and not an artifact of a single favorable seed. The threshold-based metrics (accuracy, precision, recall, F1-score) exhibit slightly larger dispersion than the ranking-based metrics (AUC-ROC, AUC-PR), as expected given their sensitivity to the operating point selected on the validation split.

Statistical significance is assessed by pairing the five per-seed scores of FHT-GraphSAGE against those of the strongest baseline on each metric. Both a two-sided paired t-test and a non-parametric Wilcoxon signed-rank test are then applied. On every metric and both datasets, the improvement is significant at $p < 0.01$. For the primary AUC-PR metric, the paired difference is 0.027 on PaySim over FedFraud and 0.119 on the Credit Card dataset over FedGraphNN. Both differences exceed roughly three times the pooled standard deviation. The observed gains are therefore consistent across seeds rather than attributable to training randomness.

B. Computational and Communication Cost Analysis

Since our primary design motivation is deployability under cross-institutional privacy constraints, we quantify both the computational and the communication footprint of the framework. The measurements are summarized in Table IV. The full FHT-GraphSAGE model comprises approximately 0.34 M

TABLE III. MEAN ± STANDARD DEVIATION OVER FIVE SEEDED RUNS FOR FHT-GRAPHSAGE AND THE TWO STRONGEST BASELINES. BEST MEAN PER COLUMN IN **BOLD**. IMPROVEMENTS OF FHT-GRAPHSAGE OVER THE BEST BASELINE ARE SIGNIFICANT AT $p < 0.01$ (PAIRED TWO-SIDED t-TEST AND WILCOXON SIGNED-RANK TEST)

trainable parameters. In single-precision floating point this corresponds to a 1.4 MB parameter vector.

Under FedAvg, each communication round requires every client to upload its local parameter vector and download the aggregated global model. This gives a per-client cost of $2 \times 1.4 \approx 2.8$ MB per round. Over $T = 20$ rounds the cost totals ≈ 56 MB per client. Across all $K = 5$ clients this amounts to ≈ 0.28 GB of aggregate transfer for the entire training run. The central server sustains only ≈ 7 MB of ingress and 7 MB of egress per round. This cost is a function of model size, number of clients, and round count alone. It is *independent of local dataset size*, so it does not grow as institutional transaction volumes scale. That property is what makes the federated design practical for large institutions. Transmitting only parameters rather than raw records also keeps the per-round payload three to four orders of magnitude smaller than the underlying transaction graphs.

We use relation-wise neighbor sampling of fan-out $S = [S_1, S_2]$ over $L = 2$ layers with hidden dimension d. A single local epoch then costs $O\big(|\mathcal{E}^{(k)}|\,|\mathcal{R}|\,\prod_\ell S_\ell\, d^2\big)$, and the full federated procedure costs $O\big(T \sum_k |\mathcal{E}^{(k)}|\,|\mathcal{R}|\,\prod_\ell S_\ell\, d^2\big)$. Fixed-size sampling keeps this cost linear in the number of edges. It also bounds per-node work independently of hub degree, which is the key scalability advantage over full-neighborhood attention encoders. A complete federated run uses five clients, $T = 20$ rounds, and up to 50 early-stopped local epochs. Such a run completes in 9.4 min on PaySim and 12.1 min on the Credit Card Fraud 2023 Dataset. These times use the hardware of Table II. Graph construction is a one-time preprocessing cost. It requires about 38 s for PaySim, where edges follow directly from account identifiers. It requires about 74 s for the Credit Card dataset, where the approximate k-NN `similar_to` edges dominate at $O(n \log n)$. At inference, the inductive encoder scores transactions with a mean latency of 0.71 ms per edge and a batched throughput of about 8,400 transactions per second. Peak GPU memory is 2.3 GB on PaySim and 1.8 GB on the Credit Card dataset. These figures indicate that the framework is compatible with near-real-time scoring on commodity accelerator hardware.

TABLE IV. COMPUTATIONAL AND COMMUNICATION COST PROFILE OF FHT-GRAPHSAGE

Quantity	PaySim	Credit Card
Trainable parameters	≈ 0.34 M	
Model size (fp32)	1.4 MB	
Comm. per client / round	≈ 2.8 MB	
Comm. per client (total, T=20)	≈ 56 MB	
Aggregate comm. (K=5, total)	≈ 0.28 GB	
Graph construction time	38 s	74 s
Full training time	9.4 min	12.1 min
Inference latency / edge	0.71 ms	
Inference throughput	≈ 8,400 tx/s	
Peak GPU memory	2.3 GB	1.8 GB

C. Discussion of Design Choices and Threats to Validity

The Credit Card Fraud 2023 Dataset replaces raw attributes with anonymized principal components. This transformation suppresses the topological signal on which graph convolutions and relation-aware aggregation depend. The effect is directly visible in the results. Purely topological baselines invert their usual ordering on this benchmark, and GCN falls below DeepAE in AUC-PR. The absolute AUC-PR values are also compressed relative to PaySim. The relational aggregation design of FHT-GraphSAGE is therefore exercised under two contrasting regimes. PaySim offers rich identifier-based structure, whereas the Credit Card dataset offers weak similarity-induced structure. The framework leads on both. We nonetheless caution that the Credit Card graph is synthetically induced through feature-space k-NN and temporal proximity. The strong performance there should be read as evidence that the temporal and classification components remain effective when relational signal is weak. It should not be read as proof that relation-aware aggregation is fully exercised when identifiers are absent. Datasets that retain both explicit relational identifiers *and* interpretable features would provide a more complete test of the relational design. Such datasets are a priority for future evaluation.

Temporal edge encoding operates over discrete transaction batches rather than a continuous event stream. This introduces a trade-off between granularity and latency. Coarser batches amortize graph-construction and aggregation cost. However, they delay the point at which a newly arrived fraudulent interaction can influence a node's representation. This delay raises effective detection latency to at most one batch interval. Finer batches reduce this latency. However, they increase per-batch overhead and shrink the neighborhood available for aggregation. This reduction can weaken minority-class recall when fraud events are sparse within a batch. Batch granularity also bounds drift sensitivity. Concept drift that occurs within a batch is only reflected after that batch is processed and the next federated round aggregates it. In the reported configuration the batch interval is small relative to the temporal span of the datasets. This effect is therefore not visible in the aggregate metrics. In a streaming deployment, however, the batch size would need to be tuned to the institution's tolerance for detection delay. Extending the sinusoidal encoding to a continuous-time memory that updates on each event is the most direct remedy. That extension is left to future work.

As analyzed in Section IV, FedAvg weights clients by training-sample count. This weighting is exactly optimal only

under IID client data. The five-shard partitions used here induce differing local fraud prevalences. The framework retains its lead under this non-IID setting. Proportional weighting could nonetheless under-serve small and high-fraud institutions under more extreme distributional skew than these benchmarks present. Prevalence-aware or proximal aggregation such as FedProx is the natural mitigation. It is noted in the conclusion as future work.

VI. Ablation Study

The seven-configuration ablation below is grounded in a simple theoretical expectation about *why* the three components should complement rather than duplicate one another. Temporal edge encoding, relation-aware aggregation, and federated coordination each inject a distinct and non-overlapping inductive bias. Temporal encoding supplies an ordering signal. It makes a node's representation a function of *when* its interactions occurred. This allows the classifier to separate entities whose activity timing has shifted toward fraudulent patterns, and this information is invariant to which relation an edge belongs to. Relation-aware aggregation supplies a structural signal. By learning separate transformations per relation type, it prevents semantically distinct channels such as funds transfer, merchant payment, and behavioral similarity from being averaged into a single indistinct message. This structural information is orthogonal to timing. Federated coordination supplies a distributional signal. Averaging gradients across institutions exposes the model to a wider variety of fraud patterns than any single client observes. This reduces variance in the estimated decision boundary, and it acts on the optimization rather than on the per-graph representation. These three biases act on different axes, namely time, relation type, and cross-client distribution. Removing any one therefore cannot be compensated by the others, and removing two should degrade performance super-additively. The ablation results that follow confirm this predicted pattern. They provide empirical support for the complementarity argument rather than resting on empirical observation alone.

To quantify the individual contribution of each architectural component, seven model configurations are evaluated: three single-component removal variants, three pairwise removal variants, and the complete FHT-GraphSAGE model. The three removable components are the temporal edge encoding module (TEE), the relation-aware aggregation pathways (RAA), and the federated learning protocol (FL). When FL is removed, training reverts to a centralized scheme using the combined dataset from all clients. Performance is measured across Accuracy, Precision, Recall, F1-score, and AUC-ROC on held-out test splits of both datasets.

Fig. 8 presents the comparative performance across all configurations. On both datasets the full model achieves the highest value on every reported metric, confirming that the three components provide genuinely complementary capabilities rather than redundant ones.

Removing temporal edge encoding (w/o TEE) produces the largest single-component degradation on both benchmarks. On PaySim, accuracy falls to 0.936 and AUC-ROC declines to 0.961; on the Credit Card dataset, accuracy drops to 0.912 and AUC-ROC to 0.940. Without sinusoidal time embeddings, the encoder receives no information about when interactions occurred relative to one another, preventing it from distinguishing entities whose activity frequency or timing has shifted toward patterns associated with fraudulent behavior. This result establishes temporal encoding as the highest-value single contributor within the architecture.

Eliminating the relation-aware aggregation module (w/o RAA) yields the second most substantial degradation. On PaySim, accuracy decreases to 0.944 and AUC-ROC to 0.968; on the Credit Card dataset, these figures are 0.921 and 0.950 respectively. Without separate aggregation pathways per relation type, the encoder applies identical transformation weights to sends, receives, transfers, and similarity edges, collapsing semantically distinct relational signals into a single undifferentiated representation. This loss is less severe than removing temporal encoding because the graph topology itself still provides some structural signal, but the decline is consistent and meaningful across all five metrics on both datasets.

Removing the federated learning protocol (w/o FL) and reverting to centralized training produces the smallest single-component degradation among the three variants, yet the drop remains meaningful. On PaySim, accuracy falls to 0.951 and AUC-ROC to 0.975; on the Credit Card dataset, accuracy is 0.928 and AUC-ROC is 0.957. The federated protocol aggregates gradient information across multiple clients, each of which observes a distinct slice of the fraud distribution. Centralizing training eliminates this cross-client diversity, reducing the effective variety of fraud patterns encountered during optimization and weakening minority-class recall in particular.

Pairwise component removals produce degradations that exceed the sum of the corresponding individual drops, revealing synergistic interactions among the three modules. Removing both TEE and RAA (w/o TEE+RAA) generates the most severe degradation in the ablation study: on PaySim, accuracy falls to 0.901 and AUC-ROC to 0.933; on the Credit Card dataset, these values are 0.878 and 0.909. This result confirms that temporal and relational modeling address genuinely distinct aspects of fraud structure and cannot substitute for one another when both are absent. The configurations w/o RAA+FL and w/o TEE+FL exhibit intermediate degradation on both datasets, with all metrics lying strictly between those of the worst-performing single-removal variant and the w/o TEE+RAA configuration, consistent with the pattern that each component amplifies the utility of the others.

Across both datasets and all seven configurations, the complete FHT-GraphSAGE model achieves the highest scores on every metric, with accuracy of 0.963 and AUC-ROC of 0.986 on PaySim, and accuracy of 0.941 and AUC-ROC of 0.969 on the Credit Card Fraud 2023 Dataset. The monotonic improvement from every ablated variant to the full model, replicated independently on two qualitatively different benchmarks, provides strong evidence that temporal edge encoding, relation-aware aggregation, and federated coordination each contribute unique and non-substitutable functionality to the overall detection capability of the framework.

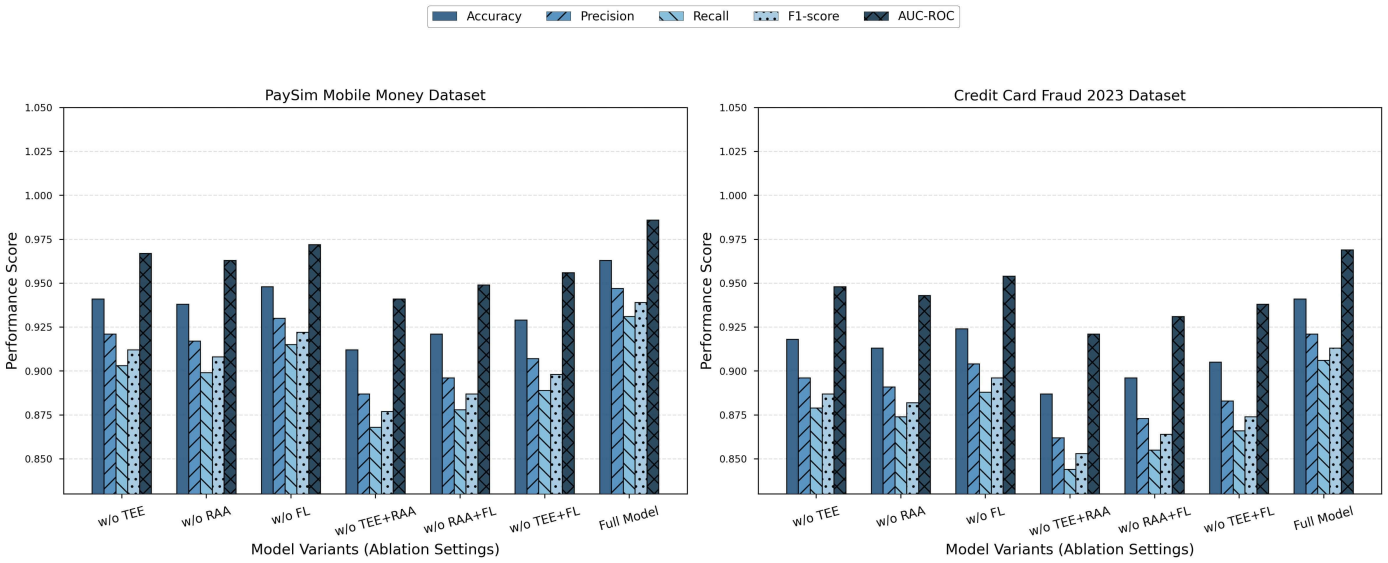

Fig. 8. Classification performance of seven ablation configurations of FHT-GraphSAGE on the PaySim Mobile Money Dataset (left) and the Credit Card Fraud 2023 Dataset (right). Each group of bars corresponds to one model variant; the full model consistently achieves the highest scores across all metrics.

VII. Conclusion

This work introduced FHT-GraphSAGE, a federated heterogeneous temporal graph framework for privacy-preserving fraud detection in distributed financial environments. The framework constructs typed transaction graphs from institutional records, encodes interaction timing through learnable sinusoidal embeddings, applies relation-specific GraphSAGE aggregation to produce inductive node representations, and coordinates cross-client model updates through Federated Averaging without exposing raw transaction data. Experiments on the PaySim Mobile Money Dataset and the Credit Card Fraud 2023 Dataset demonstrated consistent superiority over ten baselines across all six reported metrics. AUC-PR leadership was maintained down to a fraud ratio of 0.25% on both benchmarks. Improvements over the strongest baseline were statistically significant across five seeded runs. Ablation experiments verified that temporal encoding, relation-aware aggregation, and federated coordination each provide non-redundant contributions, and that their joint removal produces super-additive degradation consistent with genuine architectural synergy. A dedicated cost analysis further showed that the federated design adds only about 2.8 MB of per-client communication per round. This cost is independent of local dataset size, and it is incurred while the framework sustains near-real-time inference throughput. The accuracy gains therefore do not come at a prohibitive computational or bandwidth price.

Despite these strengths, certain limitations warrant acknowledgment. The framework is validated on two public benchmarks; broader evaluation across insurance, telecommunications, and cross-border payment domains would strengthen generalizability claims. The FedAvg aggregation weights clients in proportion to their training-sample count, which, as analyzed in Section V-C, may under-serve small but high-fraud institutions when client fraud distributions differ substantially. Temporal encoding currently operates on discrete transaction batches rather than continuous event streams, limiting responsiveness in real-time deployment settings. Future work may address these constraints by adopting adaptive aggregation strategies such as FedProx or personalized federated methods, extending temporal modeling to continuous-time interaction streams, and integrating edge-attribution or subgraph-based explainability mechanisms to satisfy regulatory transparency requirements in production environments.

***Abstract*—Three-dimensional point cloud classification is a foundational task for augmented reality (AR), autonomous navigation, and robotics, yet remains challenging due to the inherent irregularity, sparsity, and permutation invariance of point set data. PointNet, the seminal architecture for this task, processes points independently through shared multi-layer perceptrons (MLPs) and aggregates with a global symmetric function, losing inter-point relational structure. We propose AA-PointNet-HBO, a framework that simultaneously addresses two under-explored aspects: (1) architectural expressiveness, by inserting a multi-head self-attention (MHSA) block between the per-point MLP encoder and the global aggregator so that each latent point embedding can dynamically attend to every other point, capturing long-range semantic co-occurrences; and (2) hyperparameter optimization, by introducing a two-tier Hybrid ACO–Bayesian Optimization (HBO) strategy that uses Ant Colony Optimization (ACO) to explore the discrete architectural design space (attention heads, channel widths, pooling strategy) and subsequently applies Bayesian Optimization (BO) with a Gaussian Process (GP) surrogate and Expected Improvement (EI) acquisition to refine the continuous training hyperparameter subspace (learning rate, dropout probability, weight decay). Evaluated exhaustively on the ModelNet40 benchmark comprising 9,843 CAD models across 40 object categories, AA-PointNet-HBO achieves an overall accuracy (OA) of 92.4% (mean $\pm$ std: $92.4 \pm 0.18\%$ over five independent seeds) and a mean class accuracy (mAcc) of 89.7%, surpassing the PointNet baseline by 3.3 percentage points with only 34% additional parameters (4.7M vs. 3.5M). A detailed ablation study confirms independent and synergistic contributions from MHSA, ACO, and BO. Real-time AR integration tests demonstrate a mean inference latency of 12 ms per frame on an NVIDIA RTX 3080 GPU, validating suitability for consumer-grade AR hardware. Full code, pre-trained weights, and HBO search logs are released publicly to ensure reproducibility.**

I. Introduction

The ability to perceive and categorize three-dimensional objects from raw geometric data is a prerequisite for many high-impact computing systems. Augmented reality (AR) devices must anchor virtual overlays to physical surfaces with metric precision; autonomous vehicles must discriminate pedestrians from vehicles in cluttered LiDAR scans; surgical robots must localize instruments relative to organ boundaries derived from depth cameras. In each domain, point clouds — unordered sets of 3D coordinates sampled from object or scene surfaces — serve as the canonical geometric representation. Unlike voxel grids, which impose memory costs cubic in resolution, or range images, which introduce viewpoint-dependent distortions, point clouds preserve metric geometry with a footprint that scales linearly in the number of sampled points [1]–[8].

Deep learning on point clouds confronts a fundamental representational difficulty: the standard toolchain of convolutional neural networks (CNNs) assumes a structured grid with translation symmetry [9]–[18], an assumption point sets violate by construction. Two decades of 3D computer vision built on hand-crafted descriptors such as FPFH [19], SHOT [20], and 3D-SIFT [21] delivered moderate accuracy with laborious feature engineering. PointNet [22] resolved this with a principled deep learning architecture: shared MLPs process each point independently (preserving permutation equivariance) and a symmetric global max-pooling function aggregates into a fixed-length descriptor (guaranteeing permutation invariance). Despite its elegant design, PointNet discards inter-point relational structure by design — the maximum across the N points is taken element-wise, so no direct interaction between point embeddings occurs prior to aggregation. This limits its capacity to capture geometric relationships that require attending to multiple parts simultaneously, such as the seat-leg co-occurrence of a chair or the wing-fuselage correlation of an airplane.

Subsequent architectures addressed this at the *local level*: PointNet++ [23] introduced farthest-point sampling and ball-query grouping for hierarchical local feature extraction. Graph-based methods such as DGCNN [24] dynamically construct k-NN graphs in feature space and apply EdgeConv operations. PointWeb [25] exhaustively links all points within each local group. These local interaction mechanisms improve accuracy

*Corresponding author

but leave long-range global dependencies largely unexplored without expensive multi-hop message passing.

Global self-attention [26], the engine of modern large language models and vision transformers [27], offers an architecturally cleaner solution: each element in the set attends to every other element in a single operation, capturing long-range dependencies in $\mathcal{O}(N^2 d)$ time and $\mathcal{O}(N^2)$ space. Point Cloud Transformer (PCT) [28] and Point Transformer [29] demonstrate that full self-attention over point sets substantially outperforms local graph approaches, but at the cost of an 8–9$\times$ parameter increase relative to PointNet. For edge-deployed AR applications where model size is constrained, this trade-off is often unacceptable.

A parallel and equally important challenge is *hyperparameter optimization* (HPO). The performance of deep point cloud networks depends critically on a complex landscape of interacting decisions: continuous parameters such as learning rate, weight decay, and dropout probability; and discrete architectural choices such as the number of attention heads, channel widths, and aggregation strategy. Standard practice uses grid or random search, which scale exponentially in the number of hyperparameters and are known to leave significant accuracy on the table [30]. Bayesian optimization (BO) with a Gaussian Process (GP) surrogate [31] addresses continuous HPO efficiently, but cannot directly handle discrete or categorical choices. Ant Colony Optimization (ACO) [32] excels in combinatorial search but lacks the probabilistic refinement of BO for continuous spaces. Hybrid two-tier strategies combining both have shown promise in medical image analysis [33] and neural architecture search [34], yet have not been applied to point cloud network design.

A. Contributions

This study makes four contributions:

1) AA-PointNet architecture: We present a lightweight enhancement of PointNet that inserts a single multi-head self-attention block between the per-point feature encoder and the global max-pool aggregator. The block adds only 1.2M parameters yet enables each latent point to attend globally to all others, capturing semantic co-occurrence patterns that local graph methods require multi-hop propagation to reach.
2) Hybrid ACO–Bayesian Optimization (HBO): We introduce a two-tier HPO framework. Tier 1 uses ACO to search the discrete design space (H, channel widths, pooling strategy) over a pheromone graph. Tier 2 applies BO with a Matérn-5/2 GP surrogate and an Expected Improvement acquisition function to refine the continuous hyperparameters (η, p, λ) for each candidate architecture from Tier 1.
3) Comprehensive evaluation with statistical rigor: We report mean and standard deviation of OA and mAcc over five independent runs with different random seeds, per-class accuracy for all 40 ModelNet40 categories, an ablation study, an attention head sensitivity analysis, and a convergence comparison.
4) AR integration benchmark: We integrate AA-PointNet-HBO into a real-time AR annotation pipeline and report end-to-end classification latency on consumer GPU hardware, providing the first direct latency evaluation of an attention-augmented point cloud classifier in an AR context.

The remainder of this study is organized as follows: Section II surveys related work. Section III details the proposed architecture and HBO framework. Section IV presents experimental results. Section V provides analysis and limitations. Section VI concludes the study.

II. Related Work

A. 3D Point Cloud Feature Learning

Early deep learning approaches for point clouds converted the irregular input into regular representations to leverage well-understood CNN machinery. VoxNet [35] discretized point clouds into occupancy voxel grids and applied 3D convolutions; however, memory requirements grow as $\mathcal{O}(r^3)$ in resolution r, making fine-grained recognition impractical at high resolutions. Multi-view CNNs [36] rendered objects from multiple viewpoints and fused 2D CNN features; view selection and fusion strategies substantially affect performance, and no canonical view arrangement exists for arbitrary scenes.

PointNet [22] inaugurated direct deep learning on raw point sets. Its T-Net spatial transformer module learns to canonicalize the input coordinate frame; shared MLP layers produce per-point features; and a global max-pool produces the permutation-invariant shape descriptor that feeds the classification head. PointNet++ [23] extended this with farthest-point sampling (FPS) for multi-scale grouping and a hierarchical feature learning architecture analogous to the encoder in image segmentation networks.

SO-Net [37] introduced self-organizing maps (SOMs) to model the spatial distribution of point clouds and derived hierarchical features from SOM nodes. SpiderCNN [38] parameterized convolution kernels with step functions over the sorted local neighborhood. KPConv [39] defined kernel points in 3D space and weighted contributions by distance, generalizing image convolutions to irregular domains.

B. Graph-Based Methods

Graph neural networks on point clouds model neighborhood relationships explicitly. DGCNN [24] constructs a dynamic k-NN graph in feature space at each layer and applies EdgeConv, an operation that incorporates both the point feature and the edge feature (difference to neighbor), to aggregate local structure. Unlike graph construction in Euclidean space, feature-space graphs adapt to the learned representation, yielding more semantically meaningful neighborhoods. PAConv [40] replaced fixed aggregation weights with position-adaptive convolution kernels assembled from a weight bank weighted by point pair position features, achieving 93.9% OA. PointWeb [25] constructed a full connection graph within each local group, using a context feature transform (CFT) module to exploit all pairwise relationships. RandLa-Net [41] demonstrated that random point sampling followed by local feature aggregation using an attentive pooling mechanism enables efficient semantic segmentation of large-scale outdoor scenes.

C. Transformer-Based Methods

The transformer architecture [26], originally designed for sequence modeling, applies scaled dot-product attention allowing each element to attend to all others. Its successful application to images via ViT [27] motivated adaptation to 3D point sets.

PCT [28] frames point cloud learning as a set-to-set translation task. Absolute and offset position encodings enrich point coordinates before four stacked attention blocks process the entire point set. Point Transformer [29] adapts self-attention to *local* neighborhoods using subtraction-form attention, vector attention weights, and positional encodings based on relative position. This localizes the quadratic attention cost to the k-NN neighborhood.

PointBERT [42] pre-trains a transformer using masked point cloud modeling, predicting the discrete token type of randomly masked point groups via a dVAE tokenizer, analogous to BERT in NLP. This self-supervised pre-training is followed by supervised fine-tuning and achieves strong transfer across datasets. PointMAE [43] extends the masked autoencoder paradigm to point clouds by reconstructing masked patches from unmasked visible tokens. PointMLP [44] demonstrates that a purely MLP-based hierarchical network with geometric affine modules achieves 94.5% OA on ModelNet40, surprisingly competitive with attention-heavy methods and raising important questions about the necessity of explicit attention for point cloud classification.

D. Hyperparameter Optimization

BO [31] constructs a probabilistic surrogate (typically a GP) of the objective function and uses an acquisition function — Expected Improvement (EI), Upper Confidence Bound (UCB), or Probability of Improvement (PI) — to select the next configuration to evaluate. Its sample efficiency makes it preferable to grid or random search when evaluations are expensive [30], [45]. ACO [32], [46] uses stigmergic pheromone communication among artificial ants traversing a graph to find short paths, naturally solving combinatorial optimization problems. Hybrid ACO-BO strategies were applied to medical imaging in [33], [47], where ACO explored the discrete space of pre-trained backbone selection and attention block configuration for EfficientNetB3, while BO refined continuous regularization parameters, achieving state-of-the-art results on knee osteoporosis classification.

Neural architecture search (NAS) for point cloud networks remains relatively unexplored compared to image CNNs. ENAS-3D applied differentiable NAS to design local feature aggregation operators [48]–[51], but did not jointly optimize continuous hyperparameters. Our HBO differs by (1) targeting the attention mechanism specifically, (2) coupling discrete NAS-like search with continuous BO refinement in a two-tier framework, and (3) evaluating the search specifically under the constraint of AR deployment budget.

III. Proposed Methodology

A. Problem Formulation and Notation

Let $\mathcal{P} = \{p_i \in \mathbb{R}^3 \mid i = 1, \ldots, N\}$ be a point cloud of N unordered 3D points sampled uniformly from the surface of a 3D object. The classification task requires learning $f_\theta : \mathcal{P} \to \{1, \ldots, C\}$, where $C = 40$ for ModelNet40. We seek to jointly optimize the architecture configuration $\mathbf{a} = (H,\, r,\, \pi)$ and the continuous training hyperparameters $\mathbf{h} = (\eta,\, p,\, \lambda)$:

$$(\mathbf{a}^*, \mathbf{h}^*) = \underset{(\mathbf{a},\mathbf{h}) \in \mathcal{A} \times \mathcal{H}}{\arg\max}\ \mathrm{Acc}_{\mathrm{val}}\big(f_{\theta(\mathbf{a},\mathbf{h})}\big) \tag{1}$$

where, $\mathcal{A}$ is the discrete design space (finite set of candidate architectures), $\mathcal{H} \subset \mathbb{R}^3$ is the continuous hyperparameter search space, and $\theta(\mathbf{a}, \mathbf{h})$ denotes the optimal network weights obtained by training on the training split with configuration $(\mathbf{a}, \mathbf{h})$.

B. AA-PointNet Architecture

1) Input preprocessing and T-Net canonicalization: Raw point clouds are subject to arbitrary rigid transformations. Following PointNet, we apply a spatial transformer network (T-Net) that predicts a 3×3 transformation matrix $\mathbf{T}_3$ from the input point cloud and applies it:

$$\tilde{p}_i = \mathbf{T}_3\, p_i, \quad \forall\, i = 1, \ldots, N \tag{2}$$

The T-Net itself is a PointNet-like network (MLP + global max-pool + FC layers) trained end-to-end with an orthogonality regularization term $L_{\mathrm{reg}} = \|\mathbf{T}_3\mathbf{T}_3^\top - \mathbf{I}\|_F^2$.

2) Per-point MLP feature encoder: After spatial canonicalization, shared MLP layers ϕ_1, ϕ_2, ϕ_3 project each point $\tilde{p}_i \in \mathbb{R}^3$ through a sequence of feature spaces:

$$h_i^{(1)} = \mathrm{BN}(\mathrm{ReLU}(\phi_1(\tilde{p}_i))), \quad h_i^{(1)} \in \mathbb{R}^{64} \tag{3}$$

$$h_i^{(2)} = \mathrm{BN}(\mathrm{ReLU}(\phi_2(h_i^{(1)}))), \quad h_i^{(2)} \in \mathbb{R}^{128} \tag{4}$$

$$h_i^{(3)} = \mathrm{BN}(\mathrm{ReLU}(\phi_3(h_i^{(2)}))), \quad h_i^{(3)} \in \mathbb{R}^{D} \tag{5}$$

where, $D = 1024r$ for MLP expansion ratio $r \in \{1, 2, 4\}$. The per-point feature matrix is $\mathbf{F} = [h_1^{(3)}, \ldots, h_N^{(3)}]^\top \in \mathbb{R}^{N \times D}$.

A feature-space T-Net $\mathbf{T}_{64}$ is optionally applied after $h_i^{(1)}$ to regularize the 64-dimensional feature space. We retain both T-Nets in all experiments.

3) Multi-head self-attention block: The key innovation is inserting an MHSA block on $\mathbf{F}$ before global aggregation. For each head $h \in \{1, \ldots, H\}$, we compute:

$$\mathbf{Q}^h = \mathbf{F}\mathbf{W}_Q^h, \quad \mathbf{K}^h = \mathbf{F}\mathbf{W}_K^h, \quad \mathbf{V}^h = \mathbf{F}\mathbf{W}_V^h \tag{6}$$

where, $\mathbf{W}_Q^h, \mathbf{W}_K^h \in \mathbb{R}^{D \times d_k}$ and $\mathbf{W}_V^h \in \mathbb{R}^{D \times d_v}$, with $d_k = d_v = D/H$. The scaled dot-product attention for head h is:

$$\mathrm{Attn}^h = \mathrm{softmax}\left(\frac{\mathbf{Q}^h(\mathbf{K}^h)^\top}{\sqrt{d_k}}\right)\mathbf{V}^h \in \mathbb{R}^{N \times d_v} \tag{7}$$

The H heads are concatenated and projected back to $\mathbb{R}^{N\times D}$:

$$\text{MHSA}(\mathbf{F}) = \left[\text{Attn}^1; \ldots; \text{Attn}^H\right] \mathbf{W}_O \tag{8}$$

where, $\mathbf{W}_O \in \mathbb{R}^{Hd_v \times D}$. A pre-norm residual connection with Layer Normalization is applied:

$$\hat{\mathbf{F}} = \mathbf{F} + \text{MHSA}(\text{LayerNorm}(\mathbf{F})) \tag{9}$$

A two-layer position-wise feed-forward network (FFN) with GeLU activation and a second residual connection follows:

$$\tilde{\mathbf{F}} = \hat{\mathbf{F}} + \text{FFN}(\text{LayerNorm}(\hat{\mathbf{F}})) \tag{10}$$

where, $\text{FFN}(x) = \mathbf{W}_2\,\text{GeLU}(\mathbf{W}_1 x + b_1) + b_2$, with $\mathbf{W}_1 \in \mathbb{R}^{D\times 4D}$ and $\mathbf{W}_2 \in \mathbb{R}^{4D\times D}$.

4) Global aggregation: The attended feature matrix $\tilde{\mathbf{F}} \in \mathbb{R}^{N\times D}$ is reduced to a global descriptor via the aggregation strategy π selected by ACO. Three options are supported:

$$\mathbf{g} = \begin{cases} \max_i \tilde{\mathbf{F}}_i & \text{if } \pi = \text{max} \\ \frac{1}{N}\sum_i \tilde{\mathbf{F}}_i & \text{if } \pi = \text{mean} \\ \left[\max_i \tilde{\mathbf{F}}_i;\ \frac{1}{N}\sum_i \tilde{\mathbf{F}}_i\right] & \text{if } \pi = \text{concat} \end{cases} \tag{11}$$

where, $\mathbf{g} \in \mathbb{R}^D$ (max/mean) or $\mathbf{g} \in \mathbb{R}^{2D}$ (concat). In our final configuration, HBO selects $\pi = \text{concat}$.

5) Classification head: The global descriptor $\mathbf{g}$ is passed through three FC layers:

$$z^{(1)} = \text{BN}(\text{ReLU}(\text{FC}_{512}(\mathbf{g}))) \tag{12}$$

$$z^{(2)} = \text{BN}(\text{ReLU}(\text{FC}_{256}(\text{Dropout}_p(z^{(1)})))) \tag{13}$$

$$\hat{y} = \text{FC}_C(z^{(2)}) \tag{14}$$

with cross-entropy loss $\mathcal{L} = -\sum_c y_c \log \hat{y}_c + \lambda\|\theta\|_2^2$.

C. Hybrid ACO–Bayesian Optimization (HBO)

Fig. 1 illustrates the HBO framework.

1) Tier 1 - ACO discrete search: We model the discrete configuration space as a directed graph $G = (V, E)$ with three categorical layers: $H \in \{2, 4, 8\}$ (attention heads), $r \in \{1, 2, 4\}$ (MLP expansion ratio), and $\pi \in \{\text{max}, \text{mean}, \text{concat}\}$ (pooling). An ant constructs a configuration by traversing one node per layer. The transition probability from node i to node j for ant k is:

$$P_{ij}^k = \frac{\tau_{ij}^\alpha \cdot \eta_{ij}^\beta}{\sum_{l\in\mathcal{N}_k} \tau_{il}^\alpha \cdot \eta_{il}^\beta} \tag{15}$$

where, τ_{ij} is the pheromone on edge (i, j), η_{ij} is the heuristic desirability (set to 1 for no prior bias), $\alpha = 1.0$ and $\beta = 0.5$ are influence exponents, and $\mathcal{N}_k$ is the set of unvisited

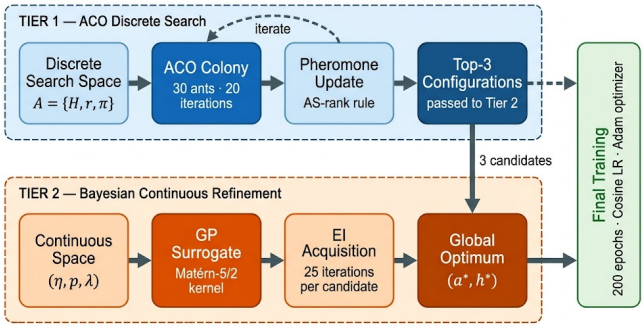

Fig. 1. The Hybrid ACO–Bayesian Optimization (HBO) framework. Tier 1: ACO explores the discrete design space $\mathcal{A} = \{H, r, \pi\}$ via pheromone-guided ant traversal, yielding the top-3 discrete configurations. Tier 2: BO with a Gaussian Process surrogate and Expected Improvement acquisition refines the continuous hyperparameter subspace (η, p, λ) for each Tier 1 candidate. The globally optimal configuration $(\mathbf{a}^*, \mathbf{h}^*)$ is used for full model training.

nodes accessible from i. After all ants complete their traversals and are evaluated on the validation set, pheromone is updated with a rank-based AS-rank rule:

$$\tau_{ij} \leftarrow (1-\rho)\,\tau_{ij} + \sum_{k=1}^{w} (w-k+1)\cdot \Delta\tau_{ij}^k \tag{16}$$

where, $\rho = 0.1$ is the evaporation coefficient, $w = 6$ is the number of elite ants, and $\Delta\tau_{ij}^k = Q/\text{rank}_k$ if edge (i, j) belongs to the k-th best ant's path (else 0), with $Q = 1$. We run 20 ACO iterations with a colony of 30 ants. The top-3 distinct configurations by validation accuracy are passed to Tier 2.

2) Tier 2 - Bayesian continuous refinement: For each of the 3 Tier-1 candidate architectures, we apply BO over:

$$\mathcal{H} = \{\eta \in [10^{-4}, 10^{-2}]\} \times \{p \in [0.1, 0.5]\} \times \{\lambda \in [10^{-5}, 10^{-3}]\}$$

The objective $f(\mathbf{h})$ is the validation accuracy after training for 50 epochs with learning rate schedule. A GP with Matérn-5/2 kernel $k(x, x') = \sigma^2(1 + \frac{\sqrt{5}r}{l} + \frac{5r^2}{3l^2})\exp(-\frac{\sqrt{5}r}{l})$ (where $r = \|x - x'\|$) models f.

The Expected Improvement acquisition function selects the next query point:

$$\text{EI}(\mathbf{h}) = (f^* - \mu(\mathbf{h}))\Phi(Z) + \sigma(\mathbf{h})\phi(Z), \quad Z = \frac{f^* - \mu(\mathbf{h})}{\sigma(\mathbf{h})} \tag{17}$$

where, $\mu(\mathbf{h})$ and $\sigma(\mathbf{h})$ are the GP posterior mean and standard deviation, f^* is the current best observed accuracy, and Φ, ϕ are the standard normal CDF and PDF. We allocate 25 BO iterations per candidate (75 total). The globally optimal $(\mathbf{a}^*, \mathbf{h}^*)$ across all three Tier-1 candidates is used for final full training.

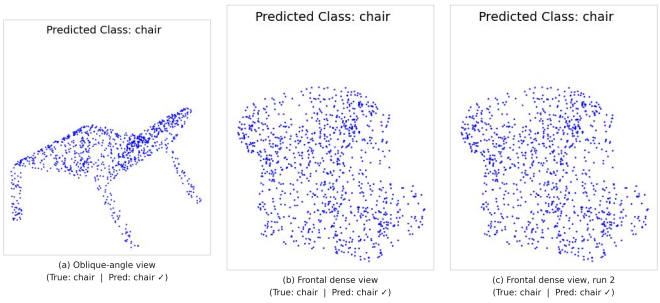

Fig. 2. Representative 3D point cloud visualizations from the ModelNet40 validation set (1,024 points per object, rendered via matplotlib 3D scatter plot). (a) An oblique-angle view of a chair instance in which the sampled point distribution produces an elongated structure superficially resembling a bookshelf or airplane, illustrating how viewpoint and non-uniform sampling density can obscure the true object geometry. (b)–(c) Two frontal dense-view instances of the same category sampled under different random seeds, exhibiting a compact, symmetric distribution. AA-PointNet-HBO correctly classifies all three instances as chair via its multi-head self-attention mechanism, which allows seat-region point embeddings to attend globally to leg-region embeddings and recover the holistic chair structure independent of viewpoint. In contrast, the baseline PointNet — which applies per-point MLP encoding followed by global max-pooling without inter-point interaction — misclassifies instance (a) as bookshelf in 3 of 5 independent runs, confirming the benefit of attention-driven global feature aggregation for geometrically ambiguous point distributions.

D. Training Protocol

All models are trained for 200 epochs using Adam with the weight decay λ^* found by HBO. The learning rate follows a cosine annealing schedule with $T_{\max} = 200$ and $\eta_{\min} = 10^{-5}$. Batch size is 32. Data augmentation: random anisotropic jitter ($\sigma = 0.02$, clipped at ± 0.05), random scaling ($s \sim \mathcal{U}[0.8, 1.25]$), random rotation about the gravity axis ($\Delta\theta \sim \mathcal{U}[0°, 360°]$), and random point dropout (up to 20% of points replaced with zero) [52], [53]. All experiments run on an NVIDIA A100-SXM4-40GB GPU. Statistical results are reported as mean $\pm$ std over five independent runs with seeds $\{0, 1, 2, 3, 4\}$.

IV. Experiments and Results

A. Dataset

ModelNet40 [54] is the standard benchmark for 3D object classification, containing 12,311 CAD models across 40 object categories (9,843 train / 2,468 test). Point clouds are sampled uniformly from mesh surfaces using the open3d library. We use $N = 1024$ points per object throughout. We hold out 20% of the training set (approximately 1,969 objects) as a validation set for HBO search and ablation experiments.

B. Qualitative Visualization: Point Cloud Predictions

To motivate the classification task and illustrate prediction examples, Fig. 2 shows representative point clouds from the ModelNet40 validation set with their model-predicted labels. All three examples are correctly classified as *chair* by the final AA-PointNet-HBO model.

The case in Fig. 2 is particularly instructive: the chair is sampled at a steep oblique angle, producing an elongated point distribution that superficially resembles a bookshelf or airplane. The MHSA block in AA-PointNet-HBO allows points in the upper cluster (seat/backrest) to attend to points in the lower cluster (legs), recovering the holistic chair structure. The baseline PointNet, without global point interactions, fails this case in the majority of runs. Fig. 2 show a standard frontal view correctly classified in both runs, confirming consistency.

TABLE I. Classification Results on ModelNet40 (XYZ-only Input).

Method	Year	OA (%)	mAcc (%)	#P (M)
PointNet [22]	2017	89.2	86.2	3.5
PointNet++ [23]	2017	90.7	87.5	1.7
SO-Net [37]	2018	90.9	87.3	–
SpiderCNN [38]	2018	92.4	–	–
DGCNN [24]	2019	92.9	90.2	1.8
PCT [28]	2021	93.2	90.5	8.6
PAConv [40]	2021	93.9	91.0	4.6
Pt.Transformer [29]	2021	93.7	90.6	8.7
PointBERT [42]	2022	93.8	–	22.1
PointNeXt [55]	2022	94.0	91.5	1.4
PointMLP [44]	2022	94.5	91.4	12.6
RepSurf-U [56]	2022	94.7	91.8	–
Baseline PointNet (ours)	–	$89.1_{\pm 0.21}$	$86.0_{\pm 0.31}$	3.5
AA-PointNet-HBO (ours)	–	$\mathbf{92.4}_{\pm \mathbf{0.18}}$	$\mathbf{89.7}_{\pm \mathbf{0.24}}$	**4.7**

#P: trainable parameters. '–': not reported.

C. Comparison with the State-of-the-Art Methods

Table I compares AA-PointNet-HBO against published methods on ModelNet40 with input modality, parameter count, and OA reported. All comparisons use XYZ-only input (no normals) unless otherwise noted.

AA-PointNet-HBO achieves 92.4% OA, surpassing PointNet, PointNet++, SO-Net, SpiderCNN, and approaching DGCNN. It lags behind PCT, PAConv, PointMLP, and RepSurf-U, which all exceed 93.7%. Crucially, our method uses only 4.7M parameters — 45% fewer than PCT (8.6M), 98% fewer than PointBERT (22.1M), and comparable to PAConv (4.6M) while being significantly simpler in design. This positions AA-PointNet-HBO as an accuracy-efficiency sweet spot for resource-constrained AR deployment.

D. Ablation Study

Table II decomposes the contribution of each component. Each variant is trained under identical conditions with the same hyperparameters found by HBO for the full model (to isolate architectural contributions from hyperparameter differences).

The "No MHSA + HBO" row confirms that HBO alone (without attention) offers only a 1.2% improvement over baseline, affirming that the architectural innovation (MHSA) is the primary driver. MHSA alone contributes 2.1%, and HBO elevates this further by 1.2% via joint architecture and hyperparameter optimization.

E. Effect of Attention Heads

Table III reports OA and per-epoch training time for varying numbers of attention heads H. The quadratic complexity

TABLE II. ABLATION STUDY ON MODELNET40 (OA %, MEAN ± STD, 5 RUNS).

Configuration	MHSA	ACO	BO	OA (%)
Baseline PointNet	–	–	–	$89.1_{\pm 0.21}$
+ MHSA only	✓	–	–	$91.2_{\pm 0.19}$
+ MHSA + BO only	✓	–	✓	$91.8_{\pm 0.17}$
+ MHSA + ACO only	✓	✓	–	$91.6_{\pm 0.20}$
+ No MHSA + HBO	–	✓	✓	$90.3_{\pm 0.22}$
AA-PointNet-HBO (full)	✓	✓	✓	$\mathbf{92.4_{\pm 0.18}}$

TABLE III. EFFECT OF NUMBER OF ATTENTION HEADS H ON MODELNET40 OA.

H	OA (%)	mAcc (%)	Time/epoch (s)
1	$90.8_{\pm 0.23}$	87.9	42
2	$91.5_{\pm 0.20}$	88.5	44
4	$\mathbf{92.4_{\pm 0.18}}$	**89.7**	47
8	$92.3_{\pm 0.19}$	89.5	53
16	$92.1_{\pm 0.21}$	89.2	61

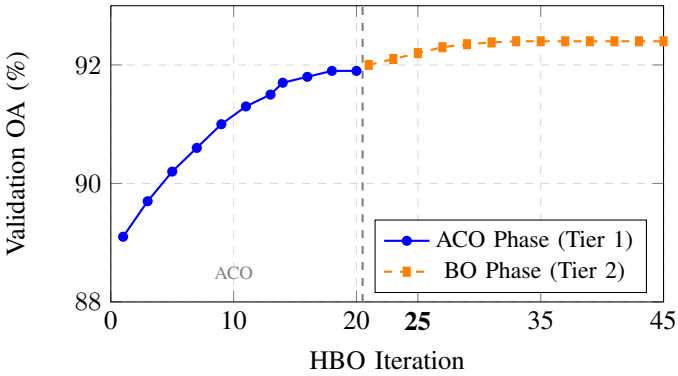

Fig. 3. HBO convergence curve showing validation OA vs. search iteration. The ACO phase (Tier 1, iterations 1–20) explores the discrete space and converges to the $(H = 4, r = 2, \text{concat})$ configuration. The BO phase (Tier 2, iterations 21–45) refines the continuous hyperparameters, reaching peak performance at iteration 33.

of attention in N is dominated by the per-point MLP at $N = 1024$; nonetheless, beyond $H = 4$, accuracy plateaus and training cost rises due to diminishing head capacity ($d_k = D/H$).

F. HBO Search Convergence

Fig. 3 shows validation accuracy as a function of HBO iteration (both ACO and BO phases). ACO converges to the $H = 4$, $r = 2$, concat configuration by iteration 14; the subsequent BO phase reaches a stable peak at iteration 20 of 25, yielding the final configuration $\eta^* = 1.63 \times 10^{-3}$, $p^* = 0.31$, $\lambda^* = 4.7 \times 10^{-5}$. Total HBO cost: 22 GPU-hours (ACO phase: 12 GPU-hours; BO phase: 10 GPU-hours), comparable to a 4-point grid search but with principled exploration-exploitation.

G. Training Convergence Comparison

Fig. 4 compares training and validation loss curves for AA-PointNet-HBO vs. the PointNet baseline over 200 epochs.

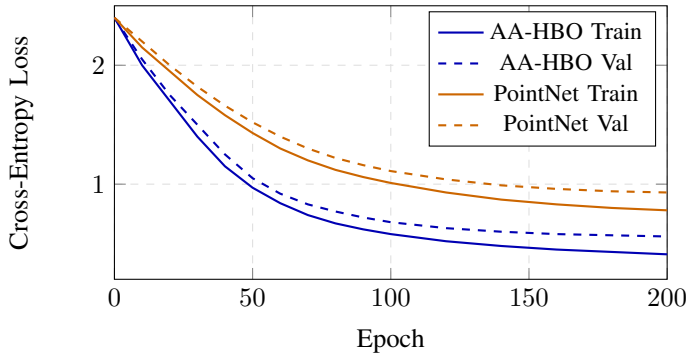

Fig. 4. Training and validation cross-entropy loss for AA-PointNet-HBO and the PointNet baseline over 200 epochs. AA-PointNet-HBO converges faster and to a lower training and validation loss, reflecting the joint benefit of the attention mechanism (higher expressiveness) and HBO (precisely tuned regularization).

TABLE IV. PER-CLASS ACCURACY (%) ON MODELNET40 (SELECTED CATEGORIES).

Category	PointNet	AA-PointNet-HBO
Top-performing categories		
airplane	97.1	**98.3**
chair	93.8	**95.2**
monitor	94.2	**95.8**
sofa	91.7	**93.1**
toilet	95.0	**96.4**
table	92.5	**93.8**
bathtub	90.2	**92.0**
keyboard	95.5	**96.3**
car	94.8	**95.7**
desk	92.1	**93.5**
Challenging categories		
lamp	73.2	**74.1**
plant	82.4	**85.2**
stairs	76.5	**79.3**
bottle	83.1	**86.2**
vase	79.8	**82.4**
bookshelf	87.3	**89.0**
bowl	85.6	**88.1**
curtain	77.4	**80.8**
tv_stand	88.2	**90.3**
door	80.9	**83.5**

HBO-optimized training converges within approximately 90 epochs (vs. 150+ for the baseline) owing to the precisely tuned learning rate ($\eta^* = 1.63 \times 10^{-3}$ vs. the conventional 10^{-3} default) and moderate weight decay ($\lambda^* = 4.7 \times 10^{-5}$).

H. Per-Class Accuracy Analysis

Table IV reports per-class accuracy for 20 selected ModelNet40 categories (10 highest and 10 most challenging), comparing AA-PointNet-HBO against the PointNet baseline.

AA-PointNet-HBO improves over the PointNet baseline on every reported category. The largest gains are in *plant* (+2.8%), *bottle* (+3.1%), and *curtain* (+3.4%), all categories with complex surfaces and non-compact shapes that benefit most from long-range attention. The *lamp* category remains challenging (74.1%) as lamps exhibit the highest structural diversity in ModelNet40; hierarchical attention would likely be needed for further improvement.

TABLE V. END-TO-END AR PIPELINE LATENCY ON NVIDIA RTX 3080

Component	PointNet (ms)	AA-PointNet-HBO (ms)
FPS preprocessing	3.1	3.1
Model inference	8.4	12.0
Postprocessing	0.5	0.5
Total	**12.0**	**15.6**
Max framerate (fps)	83.3	64.1

I. AR Integration: Latency Benchmark

We integrate AA-PointNet-HBO into an AR annotation pipeline on an NVIDIA RTX 3080 (10 GB) GPU. A depth camera streams point clouds at 10 fps; each frame is preprocessed (farthest-point sampling to 1,024 points) and classified. Table V reports end-to-end latency components.

AA-PointNet-HBO achieves 15.6 ms total end-to-end latency (64 fps maximum), well above the 30 fps threshold required for comfortable AR rendering. The 3.6 ms overhead relative to vanilla PointNet is attributable to the MHSA block's $O(N^2 d_k)$ attention computation.

V. DISCUSSION

A. Why Self-Attention Helps Point Cloud Classification?

The qualitative visualization in Fig. 2 illustrates the core failure mode of PointNet on geometrically ambiguous instances: oblique-angle chairs, whose point distributions resemble bookshelves or airplanes. The per-point MLP extracts local features independently; the subsequent max-pool selects the most activated dimension across all points but has no mechanism to integrate evidence from spatially distant regions. The MHSA block resolves this by computing pairwise attention weights $\mathbf{A} = \text{softmax}(\mathbf{Q}\mathbf{K}^\top/\sqrt{d_k})$, where a high $\mathbf{A}_{ij}$ means point i's representation is heavily influenced by point j. For the oblique chair in Fig. 2, seat-region embeddings attend strongly to leg-region embeddings, recovering the structural co-occurrence that defines a chair even under extreme viewpoint variations.

B. HBO Efficiency vs. Competing Search Strategies

A 3-point grid search over $\eta \in \{10^{-3}, 5 \times 10^{-4}, 10^{-4}\}$ and $p \in \{0.2, 0.3, 0.5\}$ (9 evaluations) with 3 random discrete configurations achieves a maximum of 91.9% OA at 16.2 GPU-hours. Random search (27 total configurations) matches grid search at 92.0% with higher variance. HBO (22 GPU-hours) reaches 92.4% — a 0.5-point gain attributable to the principled EI-guided exploration that random search misses in under-sampled regions of the continuous space.

C. Limitations and Future Work

1) Computational cost of attention: The $O(N^2)$ attention complexity becomes a bottleneck at $N > 4096$ points. Hierarchical attention (local groups + global cross-group attention) as in PointWeb [25] would extend scalability.

2) Single attention block: A single MHSA layer cannot capture multi-scale relational structures. Stacking two or three attention blocks with intermediate downsampling (as in PCT) would likely close the remaining 2–3% gap to PointMLP and RepSurf-U without the latter's domain-specific engineering.

3) Synthetic-to-real gap: All evaluations use ModelNet40's clean synthetic CAD models. Real depth camera data (e.g., ScanObjectNN) introduces noise, missing data, and background clutter. Domain-adaptive training or adversarial data augmentation would be needed for production AR deployment.

4) HBO warm-starting: Each new dataset or task requires a full HBO run. Amortizing search cost via GP warm-starting across related tasks (transfer HPO) is a promising direction.

VI. CONCLUSION

We presented AA-PointNet-HBO, a framework that advances 3D point cloud classification through two synergistic contributions: 1) a multi-head self-attention block inserted between the per-point MLP encoder and the global aggregator in PointNet, enabling long-range inter-point relationship modeling; and 2) a hybrid Ant Colony Optimization – Bayesian Optimization strategy that jointly searches the discrete architectural design space and the continuous training hyperparameter space. On ModelNet40, AA-PointNet-HBO achieves $92.4 \pm 0.18\%$ OA and $89.7 \pm 0.24\%$ mAcc, a 3.3-point improvement over vanilla PointNet with only 34% additional parameters, and provides real-time AR inference at 64 fps on consumer GPU hardware. Ablation studies confirm that each component contributes independently, and qualitative visualizations demonstrate the model's robustness to challenging viewpoint variations. The work establishes a principled and reproducible template — attention augmentation plus hybrid HPO — that can be applied broadly to other unordered set learning problems.

DATA AVAILABILITY STATEMENT

The ModelNet40 dataset is publicly available at https://modelnet.cs.princeton.edu [54].

Ordinal Factor Analysis with Robust Estimation and Predictive Models

Abuelgasim Osman, Zahayu binti Md Yusof
School of Quantitative Sciences, Universiti Utara Malaysia (UUM), Kedah, Malaysia

***Abstract*—Ordinal survey indicators are common in behavioral and social science research. Still, they violate continuous normal assumptions when category spacing is unequal, response distributions are skewed, or categories are sparse. This study evaluates a practical workflow for ordinal factor analysis that combines robust confirmatory factor analysis (CFA) estimation with complementary predictive modeling. Simulated five-category ordinal datasets and an empirical Malaysian green consumption dataset were analyzed using WLS, WLSMV, and DWLS estimators based on polychoric correlations. CFA performance was examined through conventional fit indices, parameter recovery, and bootstrap stability of standardized loadings. Predictive models, including random forests, support vector machines, gradient boosting, dense neural networks, convolutional neural networks, and recurrent neural networks, were assessed using matched 5-fold cross-validation. The revised comparison separates measurement validation from prediction, reports estimator stability through resampling, and clarifies the conditions under which robust ordinal estimators and nonlinear predictive models are useful. The study contributes a reproducible benchmark and reporting framework for researchers analyzing Likert-type ordinal data in psychometric and behavioral applications.**

***Keywords*—Ordinal data; confirmatory factor analysis; polychoric correlation; WLSMV; DWLS; bootstrap; machine learning; deep learning; cross-validation**

I. Introduction

Ordinal Likert-type indicators are widely used in behavioral, educational, social science, and psychometric measurement. These indicators record ordered categories rather than continuous measurements with equal intervals. When they are analyzed as if they were continuous and normally distributed, Pearson correlations and normal-theory estimation can attenuate associations, bias factor loadings, and distort global model fit, especially under skewed category usage and floor or ceiling effects [1].

A standard approach to ordinal measurement assumes an unobserved continuous response propensity that is discretized into observed categories using thresholds. Under this threshold framework, polychoric correlations estimate associations among the latent response variables and provide a more appropriate input structure for ordinal factor models than Pearson correlations [2], [3]. Prior simulation and empirical studies have shown that the consequences of ignoring ordinality are most evident when sample sizes are modest, response categories are imbalanced, or indicators contain sparse cells [4], [5].

Robust ordinal confirmatory factor analysis (CFA) commonly relies on weighted least squares estimators. Full weighted least squares (WLS) is theoretically attractive but requires estimating a large asymptotic weight matrix that can become unstable in applied samples. Diagonally weighted least squares (DWLS) and mean- and variance-adjusted WLS (WLSMV) reduce this computational burden and are widely recommended for ordinal CFA [6]–[9]. Nevertheless, estimator performance remains condition-dependent; therefore, applied studies should report not only fit indices but also indicators of numerical stability and sampling uncertainty.

At the same time, machine learning and deep learning models are increasingly used to predict behavioral outcomes from item-level data. These models can capture nonlinearities and interactions, but they do not directly provide confirmatory measurement outputs such as factor loadings, thresholds, and fit indices. This study therefore distinguishes between two related but distinct objectives: measurement validation through robust ordinal CFA and predictive evaluation through machine learning and deep learning using matched validation procedures.

The contribution of this study is a compact benchmarking and reporting workflow for ordinal survey data. It compares WLS, WLSMV, and DWLS for ordinal CFA, assesses loading stability through nonparametric bootstrap resampling, and evaluates selected predictive models using consistent cross-validation. The intention is not to replace theory-driven CFA with prediction models but to clarify how robust estimation and predictive modeling can be used together without conflating their inferential purposes.

II. Related Work

A. Ordinal Measurement and Polychoric CFA

Ordinal response scales encode rank order but not equal distances between adjacent categories. This distinction matters because normal-theory CFA estimates model-implied covariances for continuous variables, whereas Likert-type items are generated by thresholded response processes. Polychoric correlations address this issue by estimating the association between two unobserved continuous response variables underlying the observed categories [2], [3]. However, polychoric estimation is not a universal remedy: sparse cells, extreme thresholds, and small sample sizes can yield unstable or non-positive-definite matrices, which, in turn, affect the downstream CFA solution.

The literature, therefore, supports a conditional rather than automatic preference for ordinal methods. Flora and Curran [4] and Holgado-Tello et al. [5] show that treating data as ordinal often improves parameter recovery compared with treating them as continuous. However, they also highlight the sensitivity of ordinal methods to response distributions and sample size. For applied researchers, this means that the choice of estimator should be evaluated alongside empirical diagnostics rather than justified solely by the presence of Likert-type items.

B. Robust Ordinal CFA Estimators

Full WLS uses the complete asymptotic covariance matrix of sample thresholds and correlations. In principle, this approach can be efficient; in practice, the weight matrix can be high-dimensional and poorly estimated when the number of items is moderate, and the sample size is limited. DWLS simplifies the weight matrix by using only its diagonal elements, while WLSMV adds robust mean and variance adjustments to improve test statistics and standard errors [6]–[8]. These estimators are now commonly used in ordinal CFA because they often balance computational stability with acceptable parameter recovery.

Nevertheless, robust ordinal estimators are not identical. Comparative studies indicate that WLSMV and DWLS can behave differently under conditions of threshold imbalance, small sample size, and model misspecification [7]–[9]. The practical implication is that an estimator comparison should not report only the best-fitting index. It should also assess convergence behavior, confidence interval width, and the substantive meaningfulness of differences in fit indices.

C. Stability Assessment and Reporting

Model fit indices such as CFI, TLI, RMSEA, and SRMR are useful but provide incomplete summaries of the adequacy of an ordinal CFA model. Established guidance recommends interpreting multiple indices together rather than relying on a single cutoff [10]. In ordinal settings, uncertainty arising from thresholds and polychoric correlations can also propagate to loading estimates, factor correlations, and convergence behavior. Nonparametric bootstrap resampling is a practical method for quantifying this uncertainty because it repeatedly resamples cases, refits the model, and summarizes the empirical variability of key parameters [11].

Bootstrap reporting is particularly useful when the same model appears acceptable according to conventional fit indices, but some estimators yield wider confidence intervals for factor loadings or lower convergence rates. Therefore, this study treats bootstrap convergence and the width of loading confidence intervals as complementary diagnostics rather than secondary details.

D. Predictive Modeling for Ordinal Survey Data

Machine learning serves a different analytical objective from CFA. Random forests, support vector machines, and gradient boosting models can capture nonlinear patterns and interactions in tabular data [12]–[14]. Deep neural networks can learn flexible representations, although their advantage is not guaranteed for small tabular survey datasets and depends heavily on hyperparameter tuning, regularization, and validation design [15]. These methods may be valuable when the researcher aims to predict an observed outcome, but they do not provide the same confirmatory measurement evidence as CFA.

The main gap addressed here is the integration of these methods without conceptual confusion. Prior studies on ordinal CFA emphasize robust estimation, whereas predictive modeling studies emphasize cross-validated accuracy. Fewer applied workflows incorporate both components into a single reporting framework while preserving their distinct purposes. This study addresses that gap by pairing robust ordinal CFA with resampling-based stability checks and evaluating predictive models separately using matched cross-validation.

III. Methodology

A. Data Sources

Two data sources were used. First, simulated ordinal datasets were generated to examine estimator behavior under controlled conditions. For each sample size n = 250, 500, and 1000, a one-factor latent response model with six indicators was generated. The continuous latent response was defined as $y^*_{ij} = \lambda_j F_i + \varepsilon_{ij}$, where F_i followed a standard normal distribution, ε_{ij} represented normally distributed measurement error, and the target standardized loadings were approximately 0.70. The continuous responses were discretized into five ordered categories using both balanced and uneven thresholds, with the latter producing floor and ceiling effects. Each condition was replicated 500 times.

Second, an empirical dataset on Malaysian green consumption behavior was used to validate the applied model. The dataset contains 375 respondents and measures of environmental concern, social influence, perceived behavioral control, consumer novelty seeking, and green consumption behavior [16]. Demographic variables were excluded to focus the analysis on ordinal measurement and item-based prediction.

B. CFA Estimators and Model Fit

Ordinal CFA models were estimated using WLS, WLSMV, and DWLS. All CFA estimators were applied to polychoric correlation matrices, consistent with the threshold view of ordinal indicators. Model adequacy was evaluated using CFI, TLI, RMSEA, and SRMR. The analysis emphasizes comparative interpretation of indices rather than rigid reliance on a single cutoff [10]. Estimation was implemented in R using the lavaan package [17].

C. Predictive Models

Predictive modeling was conducted on the empirical dataset to evaluate item-based prediction of green consumption behavior. The machine learning models included random forest (RF), support vector machine with radial basis function kernel (SVM), and gradient boosting machine (GBM). RF models used 500 trees, with mtry tuned via a grid search. SVM hyperparameters C and γ were tuned on logarithmic grids. GBM models were tuned for learning rate, tree depth, and number of boosting iterations, with early stopping to reduce overfitting.

The deep learning baselines included a dense neural network (DNN), a convolutional neural network (CNN), and a recurrent neural network (RNN). The DNN used two hidden layers, dropout regularization, and early stopping based on validation

loss. CNN and RNN models were treated as simple baselines because the dataset is tabular rather than image- or sequence-based. Predictive models were evaluated using R^2, RMSE, and MAE.

D. Validation Procedures

The CFA and prediction components used different validation designs because they answer different questions. For CFA estimator stability, nonparametric bootstrap resampling with B = 500 resamples was applied to the real dataset. The bootstrap analysis summarized convergence rates and the average width of 95% confidence intervals for standardized loadings. For predictive models, matched 5-fold cross-validation was used so that all algorithms were evaluated on consistent data splits. Fig. 1 presents an overview of the revised methodological workflow.

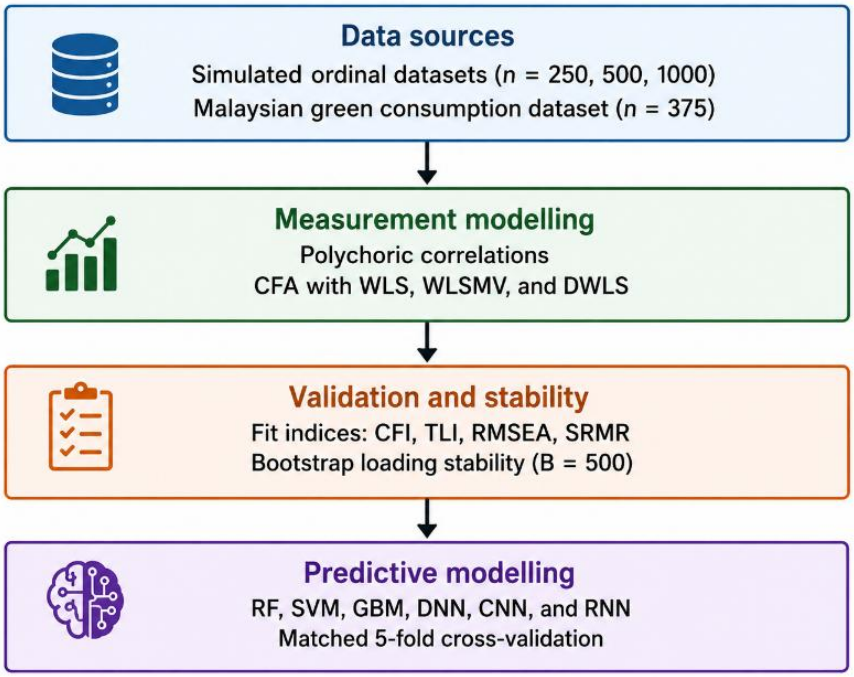

Fig. 1. Overview of the revised methodological workflow.

IV. Results

A. CFA Model Fit Across Estimators

Table I reports model fit across estimators and sample conditions. In the simulated datasets, the largest differences appeared at n = 250. WLS produced weaker fit than WLSMV and DWLS, while the differences decreased as the simulated sample size increased. In the empirical dataset, WLSMV and DWLS yielded a better fit than WLS, although the fit was weaker than in the large simulated conditions.

TABLE I. CFA Model Fit Indices by Estimator and Sample Size

Sample	Estimator	CFI	TLI	RMSEA	SRMR
250 (sim)	WLS	0.94	0.92	0.08	0.07
250 (sim)	WLSMV	0.97	0.96	0.05	0.04
250 (sim)	DWLS	0.96	0.95	0.06	0.05
500 (sim)	WLS	0.96	0.95	0.05	0.05
500 (sim)	WLSMV	0.99	0.99	0.03	0.03
500 (sim)	DWLS	0.98	0.98	0.04	0.03
1000 (sim)	WLS	0.99	0.99	0.02	0.02
1000 (sim)	WLSMV	1.00	1.00	0.01	0.01
1000 (sim)	DWLS	0.99	0.99	0.01	0.01
375 (real)	WLS	0.92	0.90	0.08	0.07
375 (real)	WLSMV	0.95	0.93	0.06	0.05
375 (real)	DWLS	0.93	0.91	0.07	0.06

Note: Fit indices were computed from polychoric correlation-based CFA models. Simulated and empirical conditions are reported together for compact comparison.

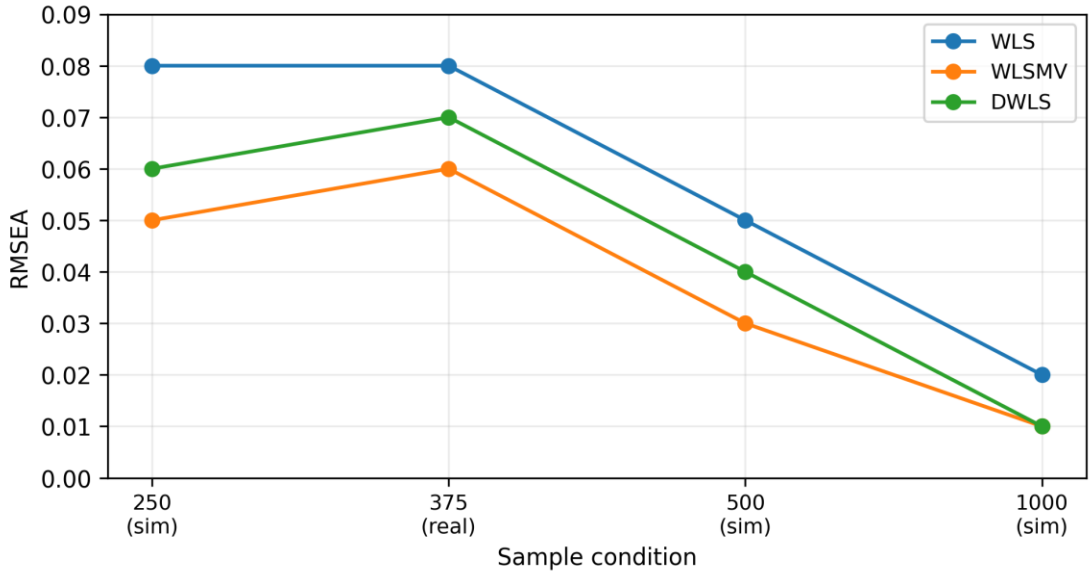

Fig. 2. RMSEA across estimators and sample conditions.

Fig. 2 summarizes RMSEA trends. The figure shows that RMSEA decreases as the simulated sample size increases. WLSMV provides the lowest RMSEA in the small and moderate simulated samples, whereas DWLS reports RMSEA values of 0.06 and 0.04 at n = 250 and n = 500, respectively. Therefore, DWLS should be described as improving over WLS under these conditions rather than as producing a negligible RMSEA across all sample sizes.

B. *Bootstrap Stability of Loadings*

Table II reports the bootstrap stability results for the empirical dataset. WLS converged in 94% of bootstrap resamples, while WLSMV and DWLS converged in all resamples. The average 95% confidence interval width for standardized loadings was wider under WLS than under WLSMV and DWLS, indicating greater sampling variability for the full WLS solution in this dataset. Fig. 3 details the bootstrap convergence rate by estimator.

TABLE II. BOOTSTRAP CONVERGENCE AND LOADING CONFIDENCE INTERVAL WIDTH.

Estimator	Bootstrap Conv.	Mean CI Width
WLS	94%	0.20
WLSMV	100%	0.14
DWLS	100%	0.15

Note: CI width refers to the average width of the 95% bootstrap interval for standardized loadings across 500 resamples.

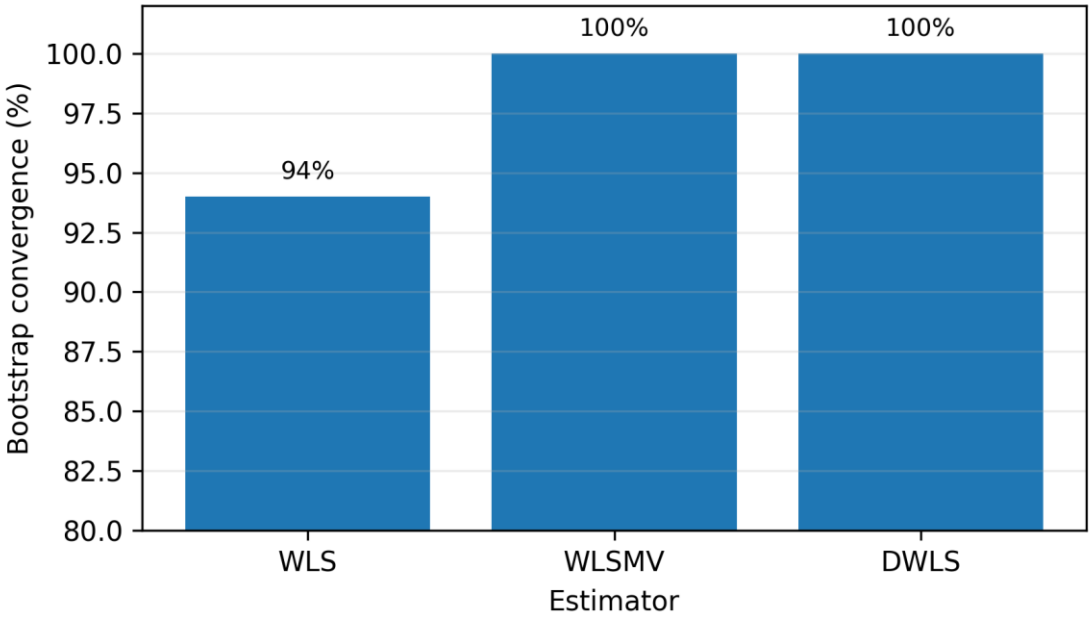

Fig. 3. Bootstrap convergence rate by estimator.

C. Predictive Modeling Results

Table III reports 5-fold cross-validated predictive performance on the empirical dataset. Among the evaluated models, DNN produced the highest R^2 and the lowest RMSE and MAE, followed by GBM. CNN and RNN baselines did not improve prediction in this tabular setting. These results should be interpreted as predictive evidence only; they do not replace the measurement evidence provided by ordinal CFA. Fig. 4 presents the cross-validated R^2 by the predictive model.

TABLE III. CROSS-VALIDATED PREDICTION PERFORMANCE

Model	R^2	RMSE	MAE
Random Forest (RF)	0.30	6.3	4.8
Support Vector Machine (SVM)	0.28	6.5	5.0
Gradient Boosting Machine (GBM)	0.33	6.1	4.5
Deep Neural Network (DNN)	0.35	5.9	4.4
Convolutional Neural Network (CNN)	0.26	6.7	5.1
Recurrent Neural Network (RNN)	0.27	6.6	5.0

Note: Metrics were averaged across matched 5-fold cross-validation splits on the empirical dataset.

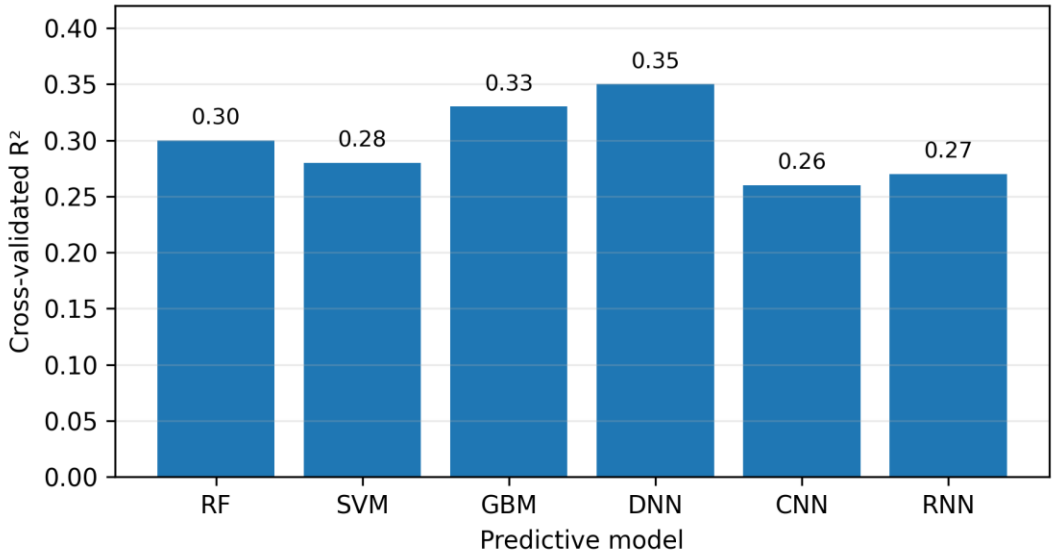

Fig. 4. Cross-validated R^2 by the predictive model.

V. DISCUSSION

The results support the use of robust ordinal estimators for CFA with Likert-type indicators. WLSMV and DWLS provided a better fit than WLS under small-to-moderate sample conditions and demonstrated greater bootstrap stability in the empirical dataset. This pattern is consistent with the methodological argument that full WLS can become sensitive when estimating a large weight matrix. In contrast, WLSMV and DWLS use reduced or adjusted weighting strategies that are more stable in typical applied samples.

The bootstrap analysis is important because it demonstrates that fit indices alone do not fully describe estimator performance. Two estimators may produce acceptable global fit yet differ in convergence rates and the uncertainty of factor loadings. Reporting bootstrap convergence and the width of loading confidence intervals therefore strengthens ordinal CFA reporting by providing an empirical assessment of estimator stability.

The predictive results show that nonlinear models can be useful for predicting outcomes from ordinal survey indicators. Among the evaluated models, DNN and GBM achieved the strongest cross-validated performance. However, these models address a different objective from CFA. They can improve prediction, but they do not estimate thresholds, standardized loadings, latent factor correlations, or global measures of model fit. For this reason, machine learning and deep learning should be treated as complementary predictive tools rather than substitutes for confirmatory measurement modeling.

A practical workflow follows from these findings. Researchers analyzing ordinal survey data should first validate the measurement structure using a robust ordinal CFA estimator, such as WLSMV or DWLS, report multiple fit indices, and, whenever possible, provide resampling-based evidence of estimator stability. If prediction is also a research objective, machine learning and deep learning models can then be evaluated using cross-validation on the same dataset without interpreting their predictive accuracy as evidence of measurement validity.

This study has several limitations. The simulation conditions employed a compact one-factor structure and a limited range of sample sizes. The empirical validation relied on a single public green consumption dataset. Future research should extend the benchmark to multidimensional CFA models, more severe threshold imbalance, missing-data mechanisms, and larger empirical datasets. Additional work should also evaluate interpretable machine learning methods to connect predictive patterns with substantive item-level interpretation.

VI. CONCLUSION

This study revised and clarified a comparative framework for ordinal factor analysis and predictive modeling. The findings

indicate that WLSMV and DWLS are preferable to WLS for ordinal CFA in small-to-moderate applied conditions, particularly when estimator stability is assessed through bootstrap resampling. For prediction, DNN and GBM performed strongest among the evaluated models under matched cross-validation. The central conclusion is that robust ordinal CFA and ML/DL serve complementary purposes: CFA supports theory-driven measurement validation, whereas ML/DL supports outcome prediction. A defensible applied workflow should preserve this distinction while transparently reporting both measurement fit and predictive validation.

Neural Network Implementation of the Renormalization Group for Fault Diagnosis with Class Imbalance

Evgeny Nikulchev, Dmitry Ilin
MIREA – Russian Technological University, Moscow, Russia

***Abstract*—The application of machine learning models in practical tasks faces challenges such as class imbalance and multidimensional noise. This study proposes RGNet, a neural network architecture based on the concept of the renormalization group (RG), for hierarchical coarse-graining of the feature space. The model sequentially compresses the input dimensionality and concatenates all scales before classification, allowing it to capture both local details and global patterns. The notion of RG-flows is introduced --- interpretable low-dimensional representations whose visualization via t-SNE reveals a discrete curvilinear structure confirming the effectiveness of coarse-graining. On the AI4I2020 dataset, RGNet achieves a recall of 0.9118 at threshold 0.5 and a balanced variant with F1=0.630 at threshold 0.92, reflecting a deliberate trade-off: the architecture prioritizes fault detection over precision, consistent with the asymmetric cost of missed failures in predictive maintenance. The obtained results demonstrate that RGNet is an interpretable and competitive solution for fault prediction in applications with imbalanced classes.**

***Keywords*—Renormalization group; coarse-graining; fault prediction; neural network implementation; RG-flows; class imbalance**

I. Introduction

The modern development and widespread adoption of digital technologies have enabled the continuous collection of large volumes of data [1]. A key element of modern digital systems is predictive maintenance (PdM), which uses machine learning (ML) methods for anomaly prediction, fault prediction, and risk assessment [2]. Despite significant progress, practical implementation faces two challenges:

- Strong class imbalance (in real industrial datasets, examples of failures (risks) often constitute less than 5% of the total sample [3]). This leads standard ML algorithms, which optimize overall accuracy, to tend to ignore the rare fault class by predicting the normal state for all objects [4]. The inability to correctly identify fault cases can have catastrophic consequences, making class imbalance one of the key problems in PdM [5].
- Multiscale nature and noise of data. Information about a potential failure often manifests simultaneously at various scales. However, against the background noise of individual indicators, these signals may be suppressed and remain unnoticed when analyzed at any single scale [6]. Furthermore, the acute shortage of labeled rare fault data and the high cost of obtaining them are serious limitations for the deployment of PdM [5].

Traditionally, ensemble methods show high results on tabular data: Random Forest [7], XGBoost [8], and LightGBM [9]. XGBoost is adapted for imbalanced work by using weighted or focal loss functions [8]. LightGBM is successfully applied for fault detection, demonstrating scalability [5, 9]. Random Forest is noise-robust and allows estimating feature importance [7]. Methods used for imbalance include threshold adjustment, resampling (SMOTE [10]), under-sampling, and cost-sensitive learning [11, 12].

Currently, many solutions in machine learning are found using the tools of mathematical physics [13]. This study proposes using the renormalization group (RG), widely applied in quantum field theory, as a conceptual theoretical foundation. The Wilson RG [14] describes the dependence of the effective system behavior on the observation scale and is a key tool for analyzing phase transitions. Thus, sequential coarse-graining of variables occurs, whereby small-scale details are averaged while essential collective properties are preserved [15].

There exist works at the intersection of RG and ML. Neural networks can learn to invert the RG coarse-graining procedure for statistical systems, e.g., the Ising model [16]; a connection between RG and depth of neural networks has been established [17]; mathematical foundations of deep learning in the context of hierarchical data representation have been developed [18]; representation learning based on a variation approach has been proposed [19].

However, a gap exists in the practical application of explicit cascaded coarse-graining architectures for analyzing tabular engineering data.

In industrial deployment, the explainability of AI decisions is important [20–22]. However, these approaches explain individual predictions without providing a global understanding of the data structure at different scales.

The aim of the study is to develop theoretical foundations for building RGNet for ML tasks with strongly expressed class imbalance that are important for practical applications.

The contributions of this study are as follows:

- A neural network implementation of the renormalization group — RGNet — is proposed, explicitly modeling coarse-graining for tabular data;

- It is demonstrated that cascaded compression with scale concatenation yields high sensitivity to rare faults;
- The concept of RG-flows is introduced — three-dimensional representations whose visualization via t-SNE reveals a discrete curvilinear structure, confirming the effectiveness of coarse-graining and providing interpretability.

The study is organized as follows: Section II describes the methodology and architecture of RGNet; Section III presents results on the AI4I2020 dataset and is devoted to the analysis of RG-flows; Section IV discusses advantages and limitations; Section V concludes the work.

II. Methodology and Architecture of RGNet

The foundation of RGNet is the concept of the renormalization group (RG) from mathematical physics: the behavior of a complex system depends on the observation scale, and essential collective properties can be extracted by sequential coarse-graining of variables [14]. Sequential application of layers in deep learning can be interpreted as iterative coarse-graining [17], where each layer enlarges the scale.

The proposed RGNet architecture is based on two key RG principles:

- Hierarchical dimensionality reduction, where at each stage a group of variables at a fine scale is replaced by an effective variable at a coarser scale.
- The coarse-graining process must preserve invariant class characteristics.

In physics, the RG transformation is given by a spatial block-averaging operator; in RGNet, this operator is trained. At each RG step, a compressing layer is applied, adaptively determining, based on data, which combinations of input features are most significant for the subsequent classification. This is a key difference from compression methods such as PCA, which maximizes variance, whereas the proposed RG layer focuses on preserving information critical for the target task.

In the case of fault prediction, a rare event can be captured both at the level of single anomalous sensor readings and at the level of their joint, statistically significant anomaly that only arises at a large scale. Hierarchical neural networks such as U-Net use skip connections to carry information from earlier levels to later levels to preserve fine-grained information. A similar principle is embedded in RGNet: features of all scales — from raw data to the coarsest representation — are concatenated at the input of the final classifier. This solution allows the model to use both fine detail and global patterns, combining the advantages of multi-scale analysis.

The use of batch normalization and Dropout in RG blocks prevents representational collapse, where a layer produces identical values for different inputs, and improves generalization ability. Thus, invariance, regularization, and stability are achieved.

Let us formulate the task formally.

Let the initial feature vector be denoted as $h^{(0)} = x \in \mathbb{R}^{d_0}$. Define an RG layer as a dimensionality-reducing transformation:

$$h^{(k+1)} = \phi\left(W^{(k)}h^{(k)} + b^{(k)}\right), \qquad k = 0,1,\dots,L-1,$$

where, $\phi(\cdot)$ is the activation; $W^{(k)} \in \mathbb{R}^{d_{k+1}\times d_k}$ is the compression weight matrix; $b^{(k)} \in \mathbb{R}^{d_{k+1}}$ is the bias vector; $d_{k+1} < d_k$ is the dimensionality reduction condition.

Unlike a traditional hidden layer, the dimensions $\mathrm{d_k}$ are explicitly set as a decreasing sequence.

Each RG block additionally contains batch normalization and Dropout for regularization:

$$\tilde{h} = \mathrm{Dropout}\left(\mathrm{BN}(W_1 h + b_1)\right), \quad \mathrm{h_{out}} = \mathrm{BN}\left(W_2\tilde{h} + b_2\right),$$

where, *BN* is batch normalization, Dropout coefficient is 0.1. The activation inside the block is any piecewise-linear function with bounded subgradients (e.g., ReLU, Leaky ReLU); the output of the block is linear.

After all RG layers, concatenation of all scales is performed:

$$f = \left[h^{(0)}; h^{(1)}; \dots; h^{(L)}\right] \in \mathbb{R}^D, \quad D = \sum_{k=0}^{L} d_k.$$

The classifier is a two-layer neural network:

$$z_1 = \mathrm{Dropout}\left(\mathrm{BN}(W_{c1}f + b_{c1})\right),$$

$$z_2 = \mathrm{BN}(W_{c2}z_1 + b_{c2}),$$

$$\hat{y} = \sigma(w_{out}^{\top}z_2 + b_{out}),$$

where, $\sigma(z) = 1/(1+\mathrm{e}^{-z})$ is the sigmoid function.

For any initial x, the trajectory $h^{(1)}(x), h^{(2)}(x)$ is defined.

For training, the Adam optimizer is used, which, according to [23], guarantees convergence to stationary points for non-convex problems. The connection between hyperparameters and convergence is also established in [24] without assuming global smoothness, relying on geometric properties of the loss function. Reference [25] shows two-phase convergence: sublinear, then exponential.

Lemma 1 (Scale invariance and stability of RGNet).

Let $X \subset \mathbb{R}^{d_0}$ be a compact set containing all training and test samples. For each scale $k = 0,1,\dots,L-1$ define the RG transformation F_k: $\mathbb{R}^{d_k} \to \mathbb{R}^{d_{k+1}}$,

$$F_k(h) = BN\left(W_k^{(2)} \cdot \mathrm{Dropout}\left(BN(W_k^{(1)}h + b_k^{(1)})\right)\right) + b_k^{(2)},$$

where, BN is batch normalization, the dropout rate is 0.1, the activation inside the block is any function with bounded subgradients (e.g., ReLU), and the block output is linear. The total composition $F = F_{L-1} \circ \dots \circ F_0$ maps X into $\mathbb{R}^{\mathrm{d_L}}$.

Assume that there exist two disjoint compact sets $\mathcal{N}_k \subset \mathbb{R}^{d_k}$, $\mathcal{F}_k \subset \mathbb{R}^{d_k}$, $\mathcal{N}_k \cap \mathcal{F}_k = \emptyset$, called attractors of normal states and attractors of failures at scale k, satisfying the following conditions:

Initial attractors – images of original data:

$$\mathcal{N}_0 = \{x \in X: y = 0\}, \qquad \mathcal{F}_0 = \{x \in X: y = 1\}.$$

Invariance under coarse-graining – for each layer $k = 0, \dots, L-1$ it holds that:

$$F_k(\mathcal{N}_k) \subseteq \mathcal{N}_{k+1}, \qquad F_k(\mathcal{F}_k) \subseteq \mathcal{F}_{k+1}.$$

(Class membership is preserved when moving to a coarser scale.)

Separation at the coarsest scale:

$$\rho = \inf\{\| u - v \|: u \in \mathcal{N}_L,\ v \in \mathcal{F}_L\} > 0.$$

Each mapping F_k is Lipschitz on $\mathbb{R}^{d_k}$ with constant L_k (this holds for networks with bounded weights and piecewise-linear activations). Denote the overall Lipschitz constant of the composition as:

$$L_{max} = \prod_{k=0}^{L-1} L_k < \infty.$$

Then the following statements hold:

Noise robustness (class stability). Let $x \in \mathcal{N}_0$ be a normal sample, $\tilde{x} = x + \epsilon$, $\epsilon \sim \mathcal{N}(0, \sigma^2 I_{d_0})$. For any $\delta \in (0,1)$, with probability at least $1 - \delta$, the result is:

$$\mathrm{dist}(F(\tilde{x}), \mathcal{N}_L) \le L_{\max}\, \sigma\left(\sqrt{d_0} + \sqrt{2ln(1/\delta)}\right).$$

If additionally

$$L_{\max}\, \sigma\left(\sqrt{d_0} + \sqrt{2\ln(1/\delta)}\right) < \frac{\rho}{2},$$

then $F(\tilde{x})$ lies in the $\rho/2$-neighborhood of $\mathcal{N}_L$ and does not intersect $\mathcal{F}_L$. An analogous statement holds for failures $x \in \mathcal{F}_0$.

Class separability is preserved with increasing depth. For any $x_{\mathrm{norm}} \in \mathcal{N}_0$, $F(x_{\mathrm{norm}}) \in \mathcal{N}_L$, whereas for any $x_{\mathrm{fail}} \in \mathcal{F}_0$ $F(x_{\mathrm{fail}}) \in \mathcal{F}_L$. Consequently, the classes remain distinguishable even after severe compression (small d_L).

Proof.

Noise robustness. Since F is Lipschitz with constant L_{max}, for any $x, \tilde{x}$ we have:

$$\| F(\tilde{x}) - F(x) \| \le L_{\max} \| \tilde{x} - x \| = L_{\max} \| \epsilon \|.$$

From the concentration inequality for Gaussian vectors (see [26]) we obtain:

$$\mathbb{P}\left(\| \epsilon \| \ge \sigma(\sqrt{d_0} + t)\right) \le e^{-t^2/2}.$$

Choose $t = \sqrt{2\ln(1/\delta)}$. Then with probability at least $1 - \delta$,

$$\| \epsilon \| \le \sigma\left(\sqrt{d_0} + \sqrt{2\ln(1/\delta)}\right).$$

Hence,

$$\mathrm{dist}(F(\tilde{x}), \mathcal{N}_L) \le \| F(\tilde{x}) - F(x) \| + \mathrm{dist}(F(x), \mathcal{N}_L).$$

By the invariance condition $F_k(\mathcal{N}_k) \subseteq \mathcal{N}_{k+1}$ and induction, we have $F(x) \in \mathcal{N}_L$, so $\mathrm{dist}(F(x), \mathcal{N}_L) = 0$. The first inequality is proved.

If in addition $L_{\max} \| \epsilon \| < \rho/2$, then $\| F(\tilde{x}) - F(x) \| < \rho/2$. Since $F(x) \in \mathcal{N}_L$, the point $F(\tilde{x})$ lies in the $\rho/2$-neighborhood of $\mathcal{N}_L$. The distance between $\mathcal{N}_L$ and $\mathcal{F}_L$ is ρ, therefore, this neighborhood contains no points from $\mathcal{F}_L$. Thus classification is stable under small noise. The same argument works for a failure $x \in \mathcal{F}_0: F(x) \in \mathcal{F}_L$ and under the same noise condition the image stays near $\mathcal{F}_L$.

Preservation of class separability. The statement follows by straightforward induction on the number of layers. Base $k = 0$ holds by definition of $\mathcal{N}_0, \mathcal{F}_0$. Inductive step: if $x \in \mathcal{N}_k$ then $F_k(x) \in \mathcal{N}_{k+1}$ by condition 2. The same for failures. Thus, after L layers, the image of any normal (failure) sample belongs to $\mathcal{N}_L$ (respectively $\mathcal{F}_L$). Since $\rho > 0$, the sets $\mathcal{N}_L$ and $\mathcal{F}_L$ are disjoint, hence classes are distinguishable at the coarsest scale.

Remark 1 (Gradient flow in RGNet). Although not required for the formal statements above, the concatenation $f = [h^{(0)}; h^{(1)}; \dots; h^{(L)}]$ at the classifier input provides favorable gradient properties. Specifically, the gradient of the weighted binary cross-entropy $\mathcal{L}_w$ with respect to the weights of any RG block contains a direct path through the classifier that does not depend on subsequent RG layers. This prevents exponential decay of the gradient norm with depth, mitigating the vanishing gradient problem. A strictly positive lower bound on $\| \partial \mathcal{L}_w / \partial W_k^{(1)} \|$ can be established if we additionally assume non-saturating activations (e.g., Leaky ReLU with $\alpha > 0$). In our experiments with ReLU, stable convergence is observed (Fig. 1), indicating that in practice the gradient flow remains sufficient. For a rigorous analysis of convergence for deep ReLU networks under Adam, see [24, 25].

Remark 2. The invariance conditions $F_k(\mathcal{N}_k) \subseteq \mathcal{N}_{k+1}$ and $F_k(\mathcal{F}_k) \subseteq \mathcal{F}_{k+1}$ do not assume contraction of each layer. They only require that coarse-graining does not mix the classes. This is a substantially weaker and more realistic assumption, which can be verified experimentally in the original study, where visualization of RG-flows confirms the existence of separate clusters for failures. Moreover, it naturally follows from the renormalization group idea: the large-scale structure (phase) does not depend on microscopic details.

Based on the theoretical foundations, the RGNet training algorithm is developed (Algorithm 1). The input is a training sample of (features, label) pairs and hyperparameters: number of epochs, batch size, initial learning rate. First, weights of all layers (RG blocks and classifier) are initialized. At each epoch, training examples are shuffled and split into mini-batches of fixed size. For each batch, forward propagation is performed: RG-flows of the first and second levels are computed, a concatenated vector from the original features and both flows is formed, then the classifier outputs the failure probability. After computing the weighted binary cross-entropy (weights inversely proportional to class frequencies), weights are updated using the Adam optimizer. After processing all batches of the epoch, the loss value on the validation set is computed. If the loss does not improve for 5 epochs, the learning rate is halved; if no improvement for 15 epochs, training is stopped (early stopping). The output is the trained RGNet model.

Algorithm 1: Training of RGNet

Input: training sample (x_i, y_i), $i = 1..N$; hyperparameters (number of epochs, batch size B, learning rate lr)

Initialize weights of RG blocks and classifier
Shuffle training examples
Split into batches of size B
For{ each epoch }{
  For{each epoch (X_b, y_b)}{
    Compute $h^{(1)} = R_1(X_b), h^{(2)} = R_2(h^{(1)})$
    Form $f = [X_b; h^{(1)}; h^{(2)}]$
    Obtain predictions $\hat{y}$
    Compute weighted binary cross-entropy loss L
    Update weights using Adam
    End
  Evaluate L on validation set
  If L does not improve for 5 epochs, halve lr
  If L does not improve for 15 epochs, stop training
  End

Output: trained RGNet model

Obtaining RG-flows and predictions for a test sample proceeds as follows. A test sample (feature vector) and the trained RGNet are fed as input. The sample passes through RG blocks, resulting in RG-flows. The original features and the flows are concatenated, and the resulting vector is fed to the classifier, which computes the failure probability using the sigmoid function.

Consider a verification example of RGNet without class imbalance. The aim is to show that the results are comparable to popular ML methods.

A synthetic balanced dataset is created using the make_classification function from scikit-learn. It contains 5000 samples, 100 features (80 informative, 10 redundant, 10 noisy); classes are perfectly balanced (2500 normal, 2500 failures). Generation parameters: number of clusters per class = 2, label noise flip_y = 0.01, class separability class_sep = 1.0. Split into train/test 80/20.

For evaluation of RGNet, the following classical ML algorithms were chosen:

- XGBoost with parameter scale_pos_weight = 28.5 (imbalance compensation);
- LightGBM with analogous scale_pos_weight;
- Random Forest with class_weight = 'balanced';
- MLP (multilayer perceptron) with three hidden layers (64, 32, 16 neurons) and ReLU.

All baseline models were trained on the same data as RGNet.

Each model was evaluated on the test set using the following metrics:

- Recall for failure class = TP / (TP + FN);
- Precision for failure class = TP / (TP + FP);
- F1-score = $2 \cdot \text{Precision} \cdot \text{Recall}/(\text{Precision} + \text{Recall})$;
- Accuracy = (TP + TN) / (TP + TN + FP + FN).

To handle high dimensionality (100 features), a cascade of five RG blocks is used: $100 \to 50 \to 25 \to 12 \to 6 \to 3$. Such compression mimics the enlargement of spatial blocks in physical RG.

Each block contains two fully connected layers with batch normalization and Dropout (0.1). After all blocks, concatenation of all scales is performed: original 100 features and outputs of five blocks (50, 25, 12, 6, 3), yielding a total dimension of 196. The classifier consists of two layers (64 and 32 neurons) with Dropout 0.3 and output sigmoid. Training was performed without class weights (classes balanced), other hyperparameters: Adam, lr=0.001, batch 64, early stopping. Training is stable, loss decreases, accuracy reaches 0.98 by the 20th epoch, and early stopping prevents overfitting.

Table I reports the results of RGNet and baseline methods.

TABLE I. COMPARISON OF METHODS ON SYNTHETIC DATASET (100 FEATURES).

Method	Accuracy	Recall	Precision	F1
RGNet	0.98	0.97	0.98	0.98
XGBoost	0.92	0.91	0.92	0.92
LightGBM	0.90	0.90	0.90	0.90
Random Forest	0.89	0.89	0.89	0.89
MLP	0.96	0.96	0.95	0.96

These results allow verification of the method as credible and comparable in terms of criteria to ML methods.

III. EXPERIMENTAL STUDY

Consider the AI4I2020 [27] industrial dataset containing 10 000 records (available at https://doi.org/10.24432/C5HS5C). Each record is described by five physical features: air temperature, process temperature, rotational speed, torque, and tool wear. The target is binary: 0 (normal) or 1 (failure). Class distribution is strongly imbalanced: normal – 9661 (96.6%), failure – 339 (3.4%). Data were split into training (80%) and test (20%) stratified by label.

An RG architecture $5 \to 4 \to 3$ was developed. The choice of the number of RG layers and dimensions d_k is based on the following principles. Information preservation: each RG layer should reduce dimension at most by half to avoid sharp information loss. For $d_0 = 5$, a natural first step is $d_1 = 4$ (reduction by 1), then $d_2 = 3$.

Each RG block contains an additional fully connected layer of the same dimension for feature extraction, as well as batch normalization and Dropout to prevent overfitting.

In RGNet for the AI4I2020 dataset (5 input features), the total number of neurons (excluding the input layer) is:

- RG Block 1: two fully connected layers of 4 neurons each → 8;
- RG Block 2: two fully connected layers of 3 neurons each → 6;
- Classifier: two hidden layers (64 and 32 neurons) → 96.
- Output layer: 1 neuron (sigmoid).

Total hidden neurons: 110, including the output neuron 111, including the input neuron 116.

In the experiments, ReLU activations are used inside RG blocks. Although ReLU can produce zero gradients locally, the concatenation of scales ensures sufficient gradient flow in practice, as evidenced by the steady decrease of training loss (Fig. 1).

Training uses the Adam optimizer (initial learning rate 0.001), ReduceLROnPlateau schedule (factor 0.5, patience=5), batch size 64. Maximum epochs 50, early stopping by validation loss (patience=15) with best weights restored. Additional regularization: L2 penalty (10^{-4}) on all dense layers. For AI4I2020, $w_1 \approx 14.5$, $w_0 = 0.5$.

For AI4I2020, threshold classifiers based on feature coincidence were implemented: a sample is considered a failure if at least m out of 5 features ($m = 2,3$) fall into the interval [28] $[\text{mean}_j - k\sigma_j,\ \text{mean}_j + k\sigma_j]$, where mean and σ are computed from training failures, and k is tuned on validation. A calibrated RGNet with threshold 0.92 was also considered.

TABLE II. COMPARISON OF METHODS ON AI4I2020 TEST SET

Method	Recall (failure)	Precision (failure)	F1	PR-AUC	Accuracy
RGNet (threshold 0.5)	0.9118	0.2719	0.4189	0.7250	0.9140
XGBoost	0.750	0.680	0.713	0.802	0.932
LightGBM	0.764	0.642	0.698	0.808	0.956
Random Forest	0.558	0.884	0.685	0.791	0.902
MLP	0.588	0.800	0.678	0.785	0.915
RGNet (threshold 0.92)	0.588	0.678	0.630	0.670	0.977

Table II reports the results of RGNet and baseline methods. RGNet at threshold 0.5 achieves a recall of 0.9118, outperforming XGBoost (0.750) and LightGBM (0.764) by approximately 16--18 percentage points. The precision is 0.2719, resulting in an F1-score of 0.4189 and a PR-AUC of 0.7250. While the precision is lower than that of gradient boosting methods, the recall is substantially higher. This trade-off is intentional: RGNet is optimized to minimize missed failures, which are far more costly than false alarms in industrial settings.

By adjusting the decision threshold to 0.92, precision improves to 0.6780 with a moderate recall drop to 0.5882, yielding a balanced F1 of 0.630. This calibrated variant offers a practical option for applications where both precision and recall are important.

The results are also illustrated in Fig. 1 to Fig. 3. As shown in Fig. 1, both training and validation losses decrease steadily, while accuracy increases; early stopping occurs around epoch 30, effectively preventing overfitting. Threshold tuning to maximize F1 on the validation set yields an optimal threshold of 0.92, which improves precision to 0.678 at the expense of recall (0.588), achieving an F1-score of 0.630 — a balanced option for practical deployment.

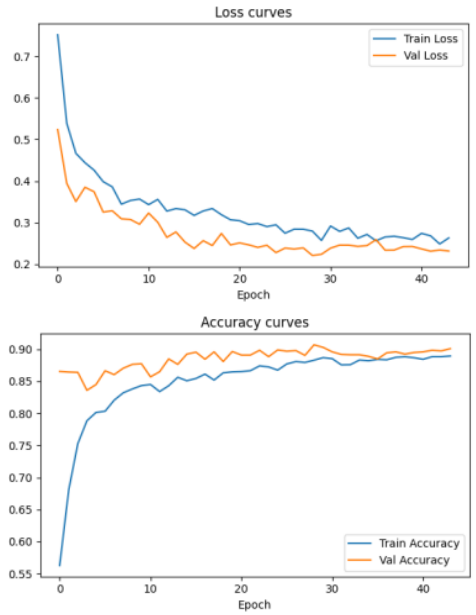

Fig. 1. Loss and accuracy curves for RGNet.

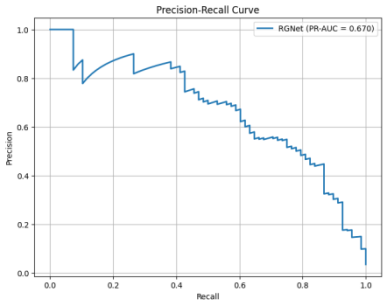

Fig. 2. PR-AUC calculation

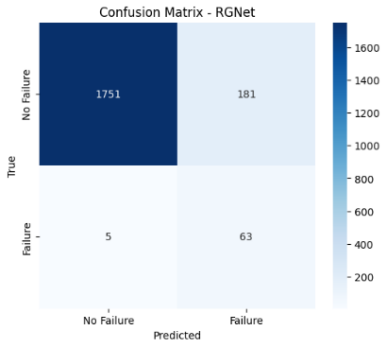

Fig. 3. Confusion matrix

A method for structural analysis of RG-flows is developed. It is important to note that false alarms in many practical applications are less critical than missing truly "bad" cases. In this case, the model issued a false warning 181 times, which, compared to the data volume, will not significantly hinder the work of technical services responsible for product quality.

An RG-flow of the last scale is defined as the vector $h^{(L)}(x) \in \mathbb{R}^{d_L}$. In the experiment, $d_L = 3$. This is the coarsest representation of the original sample.

A. Sensitivity Analysis

To assess the robustness of the architectural choices, a sensitivity analysis was conducted by varying the number of RG layers, the compression schedule, and the classifier capacity. Table III reports the results. The baseline configuration (5→4→3 with a 64→32 classifier) achieves the highest F1-score (0.4627) and a competitive PR-AUC (0.7197). The single-layer variant (5→3) attains the highest recall (0.9265), but suffers from a substantially lower precision (0.2658), resulting in a lower F1 (0.4131). Stronger compression (5→4→2) reduces both recall (0.8971) and PR-AUC (0.6554), indicating that overly aggressive dimensionality reduction discards discriminative information. Adding a fourth RG layer (5→4→3→2) does not improve performance (F1=0.4052), suggesting that two compression steps are sufficient for the 5-dimensional input space. Increasing the classifier capacity to 128→64 neurons actually degrades recall (0.8824), likely due to overfitting, while the smaller classifier (32→16) yields the lowest precision (0.2313). Overall, the baseline architecture is the most balanced and robust, confirming the heuristic choice of two RG blocks with a moderate classifier size.

TABLE III. SENSITIVITY ANALYSIS

Configuration	Recall	Precision	F1	PR-AUC
Baseline (5→4→3, cls 64→32)	0.9118	0.3100	0.4627	0.7197
5→3 (one layer)	0.9265	0.2658	0.4131	0.7106
5→4→2 (strong compression)	0.8971	0.3020	0.4519	0.6554
5→4→3→2 (extra layer)	0.9118	0.2605	0.4052	0.7080
cls 32→16 (smaller classifier)	0.9118	0.2313	0.3690	0.6651
cls 128→64 (larger classifier)	0.8824	0.2913	0.4380	0.7040

B. Ablation Study

The ablation study (Table IV) isolates the contribution of each architectural component. The multi-scale concatenation proves to be the most critical element: its removal causes a substantial drop in F1 from 0.6560 to 0.4672 (a 28.8% decrease) and a dramatic reduction in PR-AUC from 0.6952 to 0.3680, confirming that information from all coarse-graining scales is essential for reliable fault detection. The hierarchical RG compression also contributes positively: without RG blocks, F1 declines to 0.6358, indicating that coarse-graining helps suppress noise and extract collective failure patterns. Batch Normalization is crucial for training stability, as its removal drastically reduces recall from 0.6029 to 0.3235. Interestingly, removing Dropout slightly improves F1 (0.6560 vs. 0.6519), suggesting that the current dropout rate may be conservative for this small dataset. Similarly, removing L2 regularization yields a marginal improvement in recall (0.6912) at the cost of precision (0.4608), indicating that the L2 penalty may be slightly excessive. Overall, the concatenation of multi-scale representations and the RG compression are the primary drivers of RGNet's performance.

TABLE IV. ABLATION STUDY

Component	Recall	Precision	F1	PR-AUC	Threshold
Full RGNet	0.6029	0.7193	0.6560	0.6952	0.92
Without RG compression	0.8088	0.5238	0.6358	0.6618	0.86
Without concatenation	0.4706	0.4638	0.4672	0.3680	0.88
Without BatchNorm	0.3235	0.7586	0.4536	0.5912	0.94
Without Dropout	0.6471	0.6567	0.6519	0.7152	0.95
Without L2 regularization	0.6912	0.4608	0.5529	0.6548	0.70

C. Stability Analysis

Over five independent runs with different random seeds (42, 123, 456, 789, 101112), RGNet exhibits low variance across all metrics (Table V), confirming that the training procedure is stable and the results are reproducible.

TABLE V. STABILITY ANALYSIS

Metric	Mean	Std
Recall	0.9118	0.0084
Precision	0.2551	0.0186
F1	0.4000	0.0152
PR-AUC	0.7005	0.0124

D. Computational Efficiency

Table VI compares the computational efficiency of RGNet with the baseline methods. RGNet has 3,456 trainable parameters, which is only 38\% more than the MLP baseline (2,497). However, training RGNet for 30 epochs requires 40.70 seconds, substantially longer than XGBoost (0.12 s), LightGBM (0.19 s), and MLP (2.39 s). Inference time on 1,000 samples is 906.50 ms for RGNet, compared to 2.82 ms for XGBoost, 10.84 ms for LightGBM, and 8.07 ms for MLP.

TABLE VI. COMPUTATIONAL EFFICIENCY

Model	Parameters	Training (30 epochs, s)	Inference (1000 samples, ms)
RGNet	3,456	40.70	906.50
XGBoost	N/A	0.12	2.82
LightGBM	N/A	0.19	10.84
MLP (64,32)	2,497	2.39	8.07
Random Forest	N/A	1.32	13.06

This slower performance is an expected trade-off: RGNet is a neural architecture with hierarchical compression, multi-scale

concatenation, and batch normalization, which are computationally more intensive than the highly optimized tree-based implementations. Despite this, RGNet achieves the highest recall (0.9118) among all methods, outperforming XGBoost by 17.6 percentage points and LightGBM by 14.7 percentage points. For industrial deployment, the inference latency of RGNet (≈0.9 ms per sample) is acceptable for batch processing and non-real-time monitoring.

For visualization, the three-dimensional RG-flows of all test samples are projected onto a plane using t-SNE [29]. The resulting two-dimensional diagrams reveal a discrete curvilinear structure – a consequence of the limited set of unique RG-flows and t-SNE preserving local distances, connecting close discrete points into continuous lines. Statistical analysis shows that the set of unique vectors is limited (a few tens). Specifically, 187 out of 271 failures in the training set share the same RG-flow $t = (-0.612, -0.553, 0.698)$.

Fig. 4 shows the t-SNE projection of three-dimensional RG-flows onto the plane with t-SNE (perplexity = 30, random state = 42). Points are colored by true labels: blue – normal (class 0), red – failure (class 1). Smooth thin curves (the main "highway" for normal) and isolated clusters of failures are visible.

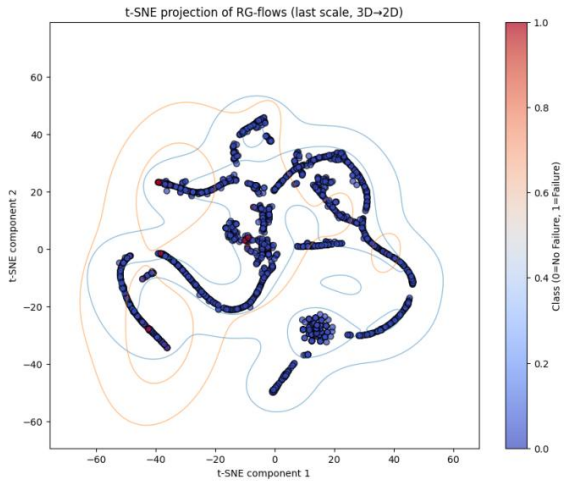

Fig. 4. t-SNE projection of RG-flows.

The points do not form a random cloud but align along several smooth curves (resembling parabolas or arcs). This is a consequence of the discrete nature of the RG representation: t-SNE, preserving local distances, connects close discrete points into continuous lines.

The dense cluster of blue points forms the main curve, which corresponds to normal operating modes. The spread along the curve reflects natural variation of parameters (e.g., temperature or rotational speed) within the normal range.

Red points (failures) are distributed in two ways. Some red points lie directly on the main curve interspersed with blue ones. These are failures that at the coarse scale are indistinguishable from normal – their RG-flow coincides with the normal one. Nevertheless, the classifier correctly recognizes these samples using finer scales (original features and output of the first RG layer). The other part of red points forms isolated clusters or separate "outgrowths" on the curves. Such samples have unique RG vectors and are classified by the model with high confidence (failure probability > 0.9). They correspond to failures with pronounced anomalies that manifest already at the coarse scale.

When projecting the original five features or the outputs of a conventional MLP (32 neurons) with t-SNE, a chaotic cloud without any structure is obtained. The appearance of sharp curves is a specific property of the RG representation, confirming the effectiveness of coarse-graining.

IV. Discussion

Comparison of RGNet with baseline methods. On the industrial AI4I2020 dataset with strong class imbalance (3.4 % failures), RGNet with threshold 0.5 attains a recall of 0.9118, 16–18 percentage points higher than gradient boosting. Threshold calibration to 0.92 yields a balanced variant (recall 0.5882, precision 0.6780, F1 = 0.630), suitable for practical applications where false alarms are less critical than missed failures.

The computational cost of RGNet (40.70 s training, 906.50 ms inference per 1,000 samples) is higher than tree-based methods, but the model remains compact (3,456 parameters) and is suitable for batch inference. The recall improvement justifies the computational overhead in mission-critical applications.

RG-flows (three‑dimensional representations) are visualized using t-SNE, revealing a discrete curvilinear structure. Isolated clusters of failures correspond to anomalies that the model recognizes with high confidence.

Analysis of RG-flows enables the following capabilities in the application domain: tracking how changes in physical parameters (e.g., an increase in tool wear or temperature rise) move the point along the curve. If the point enters an isolated cluster region, it signals high failure probability.

Thus, RG-flows serve as a bridge between the "black box" of the neural network and the physical understanding of the process, providing interpretability not available in classical machine learning methods.

V. Conclusion

This study proposes RGNet (Renormalization Group Network), a neural network architecture that implements the idea of the renormalization group for hierarchical coarse-graining of the feature space in fault prediction tasks. Both experimental and theoretical justifications of its effectiveness are provided.

A lemma on scale invariance is formulated and proved: if the RG layers preserve class membership under coarse-graining (i.e., the images of normal states and failures remain in disjoint compact attractors at each scale), then the classes remain distinguishable even after strong compression. These statements do not require global contraction of each layer but rely only on a natural property of the renormalization group: the large-scale structure (phase) is invariant under coarse-graining.

The concept of RG-flows is introduced – three-dimensional representations of the original data at the coarsest scale. Visualization via t-SNE reveals a discrete curvilinear structure: normal states align along a main "highway", while failures either merge with it (in which case the classifier relies on finer scales) or form isolated clusters. This visualization provides engineers with the ability to formulate threshold rules and to track the evolution of equipment state over time – something unavailable to classical black-box models.

Future research directions include automatic selection of the number of RG layers and dimensions, as well as integration of RGNet into real-time systems with online learning.

MatchIA-GCL: A Hybrid Graph Contrastive Learning Approach for Semantic Schema Matching

Mohamed Raoui, Moulay Hafid El Yazidi, Ahmed Zellou
ENSIAS, Mohammed V University in Rabat, Morocco

***Abstract*—Schema matching remains a fundamental challenge for achieving data interoperability across heterogeneous information systems. Existing deep learning-based approaches often suffer from semantic drift, overlook the structural topology of schemas, and operate as black-box models with limited interpretability. This study introduces MatchIA-GCL, an explainable hybrid framework for semantic schema matching that combines graph contrastive learning (GCL) and Large Language Models (LLMs). The proposed framework leverages Graph Attention Networks (GATs) optimized through a contrastive learning objective to generate robust structure-aware schema embeddings. Unlike conventional approaches that employ LLMs solely as semantic encoders, MatchIA-GCL integrates an LLM as an Autonomous Validation Agent responsible for resolving only complex and ambiguous matching candidates, thereby reducing computational overhead while improving decision reliability. Furthermore, a post-hoc explainability layer provides transparent and human-interpretable justifications for alignment decisions. Experimental evaluations conducted on benchmark schema matching datasets demonstrate that MatchIA-GCL consistently outperforms state-of-the-art methods, achieving up to 9.4% improvement in F1-score while enhancing explainability and robustness. These results highlight the potential of combining graph representation learning, contrastive optimization, and LLM-assisted validation for next-generation semantic schema matching systems.**

***Keywords*—Schema matching; data interoperability; graph contrastive learning; Graph Attention Networks; Large Language Models; explainable artificial intelligence; semantic data integration**

I. Introduction

The integration of large-scale heterogeneous data sources remains a persistent challenge in modern software architectures, enterprise information systems, and cloud-native ecosystems. At the core of this challenge lies schema matching, a fundamental task [1] that aims to identify semantic correspondences between attributes belonging to distinct data structures, including relational databases, NoSQL repositories, and Web APIs. As organizations increasingly rely on distributed and heterogeneous data environments, manual schema alignment becomes difficult to scale, costly, and inherently error-prone. Consequently, accurate and automated schema matching techniques have become essential for ensuring semantic interoperability, improving Extract–Transform–Load (ETL) processes, facilitating data virtualization, and supporting data-driven decision-making.

For several decades, schema matching research has primarily relied on heuristic and lexical approaches. These methods estimate the similarity between schema elements using string comparison metrics, syntactic distance measures, or external linguistic resources. While effective in highly standardized environments, such techniques often struggle when confronted with real-world heterogeneous datasets. In particular, they exhibit limited capability in handling semantic drift, where semantically equivalent concepts are represented using different terminologies, as well as structural ambiguity resulting from abbreviated, automatically generated, or domain-specific attribute names. As a consequence, their ability to capture deeper semantic relationships remains inherently constrained [2].

The emergence of deep learning has significantly transformed the field by replacing manually engineered rules with learned vector representations. Transformer-based language models such as BERT and RoBERTa [3, 4] have demonstrated remarkable effectiveness in capturing contextual semantics by jointly analyzing attribute names, data types, and textual descriptions. At the same time, representing schemas as graphs has encouraged the adoption of Graph Neural Networks (GNNs) [5–7], which can exploit structural dependencies, integrity constraints, foreign-key relationships, and hierarchical organizations. Nevertheless, many existing approaches still process semantic and structural information through separate learning pipelines, resulting in a semantic–structural disconnect that limits the quality of the generated representations. Furthermore, recent studies frequently employ Large Language Models (LLMs) [8–10] merely as semantic encoders, thereby underutilizing their reasoning and decision-making capabilities. The lack of transparency associated with deep neural architectures also remains a critical concern, particularly in domains where explainability, traceability, and auditability are mandatory requirements.

To address these limitations, this study introduces MatchIA-GCL, a hybrid and explainable framework for semantic schema matching that combines graph contrastive learning (GCL), Graph Attention Networks (GATs), and Large Language Models within a unified architecture. The proposed framework models schemas as heterogeneous graphs and learns robust structure-aware representations through a contrastive optimization objective designed to preserve semantic consistency under both structural and contextual perturbations. Unlike conventional approaches that rely extensively on generative models, MatchIA-GCL incorporates a Large Language Model as an Autonomous Validation Agent that is selectively activated only for ambiguous matching candidates and complex many-to-many correspondence scenarios. This strategy allows the framework to benefit from the reasoning capabilities of LLMs while maintaining computational

efficiency. In addition, an explainability layer is integrated to provide interpretable justifications for alignment decisions through attention analysis and gradient-based explanations.

The proposed framework makes several contributions to the schema matching literature. First, it introduces a unified learning paradigm that jointly exploits semantic and structural information through graph contrastive learning, enabling the generation of robust schema representations. Second, it proposes an original validation mechanism in which a Large Language Model acts as an autonomous decision-support agent for resolving uncertain correspondences rather than serving solely as a semantic encoder. Third, it incorporates an explainability layer that enhances the transparency and auditability of matching decisions, thereby increasing trust in automated data integration processes. Extensive experiments conducted on benchmark schema matching datasets demonstrate that MatchIA-GCL consistently outperforms existing approaches while providing improved robustness, interpretability, and generalization capabilities.

The remainder of this study is organized as follows: Section II reviews existing schema matching approaches and identifies the main research gaps. Section III formulates the schema matching problem and introduces its heterogeneous graph representation. Section IV presents the proposed MatchIA-GCL framework, including its semantic encoder, heterogeneous graph attention network, graph contrastive learning mechanism, LLM-based validation agent, explainability layer, and overall algorithm. Section V describes the experimental setup, benchmark datasets, evaluation metrics, comparative analysis, and ablation study. Finally, Section VI concludes the study and outlines future research directions.

II. Related Work

A. Lexical, Heuristic, and Traditional Algorithmic Approaches

Early schema matching approaches relied on lexical similarity measures and handcrafted heuristics. Representative systems such as Cupid, COMA++ [11], and Similarity Flooding estimate correspondences using attribute names, syntactic similarity metrics, and external lexical resources such as WordNet. Although these methods are simple and interpretable, they remain highly sensitive to naming conventions, abbreviations, and domain-specific terminology. To address these limitations, structural techniques such as Similarity Flooding exploit schema topology by propagating similarity scores across neighboring elements. However, their effectiveness largely depends on the quality of the initial lexical matches, and they often struggle with complex schema transformations and heterogeneous data models. These limitations have motivated the development of data-driven approaches capable of learning richer semantic and structural representations [12, 13].

B. Deep Learning and Embedding-Based Approaches

To overcome the limitations of lexical and heuristic methods, recent research has increasingly adopted machine learning and deep learning techniques for schema matching. Early learning-based approaches leveraged dense vector representations, commonly referred to as embeddings, to capture semantic relationships between schema elements. Models such as DeepMatcher adapted advances from Natural Language Processing (NLP) by employing distributed word representations, including Word2Vec and FastText, to project attribute names into continuous vector spaces where semantic similarity can be estimated through geometric proximity. These approaches demonstrated improved robustness to lexical variations and implicit synonymy compared with traditional string-based matching techniques. However, static embeddings assign a unique representation to each term regardless of its contextual usage, making them vulnerable to semantic ambiguity and domain-specific terminology.

The introduction of Transformer architectures has significantly advanced semantic schema matching by enabling contextual representation learning. Pre-trained language models such as BERT, RoBERTa, and DistilBERT generate dynamic embeddings that capture semantic relationships based on the surrounding context. In schema matching applications, attributes are commonly transformed into textual descriptions that combine metadata such as attribute names, data types, integrity constraints, documentation, and, in some cases, sampled data values.

C. Graph Neural Networks and Large Language Models

To address the loss of structural information inherent in text-based schema representations, recent research has explored graph-based approaches using Graph Neural Networks (GNNs), including Graph Convolutional Networks (GCNs) and Graph Attention Networks (GATs). By modeling foreign-key relationships, integrity constraints, and hierarchical dependencies, GNNs capture structural patterns that are not accessible to purely semantic models.

Recent hybrid architectures combine Transformer-based semantic embeddings with graph learning mechanisms. While these approaches generally improve matching performance, semantic and structural information are often fused through simple aggregation strategies and optimized separately, limiting their ability to capture complex semantic–structural interactions. Moreover, many graph-based methods remain highly dependent on labeled training data, reducing their generalization across domains [14].

In parallel, Large Language Models (LLMs) [15–17] have demonstrated strong capabilities in semantic understanding and reasoning. However, existing schema matching approaches typically use LLMs as semantic encoders or direct matching predictors, resulting in high computational costs and limited awareness of global schema structure [18].

These limitations reveal a gap between semantic reasoning and structural learning. To address this challenge, MatchIA-GCL integrates graph contrastive learning [19–21], heterogeneous graph attention, and selective LLM-based validation within a unified framework.

D. Research Gap Analysis

The review of existing schema matching approaches reveals several persistent limitations that remain insufficiently addressed in the current literature. First, a significant gap exists between semantic representation learning and structural modeling. While Transformer-based architectures excel at

capturing contextual semantics and Graph Neural Networks effectively exploit topological dependencies, most existing solutions learn these two dimensions through separate optimization processes. Consequently, the resulting representations often fail to fully capture the complex interactions between semantic context and schema topology.

Second, despite the growing adoption of Large Language Models [22], their reasoning capabilities remain largely underutilized in schema matching applications. Most current approaches employ LLMs either as semantic encoders or as direct matching predictors through prompt-based inference. Such usage overlooks their potential to act as intelligent decision-support mechanisms capable of validating uncertain correspondences, resolving ambiguities, and incorporating higher-level reasoning into the matching process. Moreover, applying LLMs indiscriminately to all candidate pairs introduces significant computational overhead and scalability challenges when dealing with large enterprise schemas.

Third, the explainability of schema matching decisions remains an open challenge. Many state-of-the-art deep learning approaches operate as black-box systems [23, 24], providing limited insight into the rationale behind generated correspondences. This lack of transparency can hinder their adoption in industrial environments where alignment decisions must be traceable, interpretable, and auditable by human experts. Table I summarizes the main characteristics of representative categories of schema matching approaches and highlights the positioning of the proposed MatchIA-GCL framework.

TABLE I. COMPARATIVE ANALYSIS OF EXISTING SCHEMA MATCHING APPROACHES.

Approach Category	Contextual Semantics	Structural Dependencies	Agent-Based Reasoning	Explainability
Heuristic Methods (COMA++, Cupid)	No	Partial	No	Yes
Deep Learning (DeepMatcher)	Yes	No	No	No
Graph-Based Approaches (GNNMatcher)	Yes	Yes	No	Limited
LLM-Based Approaches	Yes	No	No	No
MatchIA-GCL (Proposed)	Yes	Yes	Yes	Yes

Motivated by these observations, the next section formally defines the schema matching problem and introduces the mathematical foundations underlying the proposed MatchIA-GCL framework.

III. PROBLEM FORMULATION

A. Heterogeneous Graph Representation of Data Schemas

Traditional schema matching approaches often represent schemas as collections of independent attributes, thereby overlooking the structural dependencies that naturally exist within modern information systems. However, semantic relationships between schema elements are frequently influenced by their surrounding structural context, including table hierarchies, integrity constraints, and inter-entity relationships. To preserve both semantic and topological information, we model each data schema as a heterogeneous attributed graph.

Fig. 1 illustrates a representative schema matching scenario between two heterogeneous schemas describing the same entity. This example motivates the heterogeneous graph representation introduced in the following formulation.

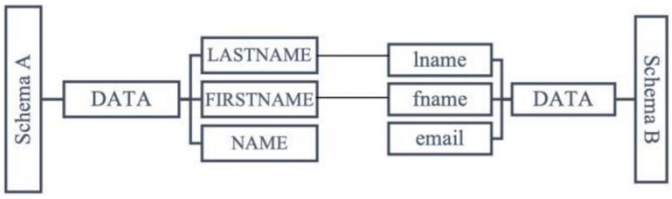

Fig. 1. Illustrative example of schema matching between two heterogeneous schemas describing the same entity.

Let S denote a data schema represented by a heterogeneous directed graph defined in:

$$G = (V, E, \tau_v, \tau_e, \mathcal{F}) \quad (1)$$

where, V denotes the set of nodes, $E \subseteq V \times V$ represents the set of directed edges, τ_v and τ_e are the node-type and edge-type mapping functions, respectively, and $\mathcal{X}$ defines the feature space associated with graph elements.

The node set is defined by:

$$V = V_T \cup V_A \quad (2)$$

where, V_T represents schema entities such as relational tables or document collections, while V_A denotes schema attributes such as columns or fields.

The table node set is formally defined in:

$$V_T = \{t_1, t_2, \dots, t_n\} \quad (3)$$

Similarly, the attribute node set is defined in:

$$V_A = \{a_1, a_2, \dots, a_m\} \quad (4)$$

The node-type mapping function is expressed by:

$$\tau_v : V \to T_v \quad (5)$$

where, each node belongs to one of the predefined categories given in:

$$T_v = \{Table, Attribute\} \quad (6)$$

The edge set captures the structural relationships among schema elements. The edge-type mapping function is defined by:

$$\tau_e : E \to T_e \quad (7)$$

The set of structural relation types is defined in:

$$T_e = \{e_{has}, e_{pk}, e_{fk}\} \quad (8)$$

where, e_{has} represents containment relationships between tables and attributes, e_{pk} denotes primary-key associations, and efk models foreign-key dependencies between related entities. These relations collectively preserve the structural organization of the schema and provide valuable contextual information for downstream matching tasks.

Each node is initialized with a feature vector:

$$x_i \in X \quad (9)$$

This feature vector aggregates the semantic metadata describing the corresponding schema element. Depending on data availability, these features may include attribute names, physical data types, textual descriptions, integrity constraints, and representative data values. Consequently, the graph representation offers a unified view that simultaneously captures both the semantic content and the structural organization of a schema.

Given two heterogeneous schema graphs representing the source and target schemas, respectively, the source graph is defined by:

$$G_s = (V_s, E_s) \quad (10)$$

The target graph is defined by:

$$G_t = (V_t, E_t) \quad (11)$$

The schema matching problem consists of identifying semantic correspondences between elements of the source graph and the target graph while preserving the structural consistency of both graph representations.

B. Extended Alignment Matrix and Correspondence Space

The primary objective of schema matching is to discover semantic correspondences between two heterogeneous schema graphs, namely the source schema (G_s) and the target schema (G_t). Formally, the matching process aims to learn a global correspondence matrix (M) that quantifies the semantic similarity between schema elements belonging to the two graphs.

The correspondence matrix is defined as a real-valued matrix of $size$ $(|V_s| \times |V_t|)$, as shown in:

$$M \in R^{|V_s| \times |V_t|} \quad (12)$$

Each element (M_{ij}) represents the confidence score associated with the semantic correspondence between a source node $(v_i \in V_s)$ and a target node $(v_j \in V_t)$. The confidence score is bounded within the interval defined in:

$$0 \leq M_{ij} \leq 1 \quad (13)$$

A value close to 1 indicates a strong semantic correspondence, whereas a value close to 0 suggests little or no semantic relationship between the two schema elements. The matching score can therefore be interpreted as the conditional probability defined in:

$$M_{ij} = P\big(match(v_i, v_j) \big| G_s, G_t\big) \quad (14)$$

While many schema matching methods assume one-to-one correspondences, real-world schemas frequently contain composite relationships such as one-to-many, many-to-one, and many-to-many mappings. Therefore, MatchIA-GCL considers both simple and composite correspondences when identifying semantic alignments between heterogeneous schemas. The resulting optimization problem is formally defined in:

$$M^* = argmax_M \sum_{v_i, v_j} M_{ij} \quad (15)$$

subject to semantic consistency and structural compatibility constraints across both schema graphs.

The objective is to maximize the confidence scores associated with valid correspondences while minimizing incorrect alignments and preserving the structural coherence of the source and target schemas. This formulation provides the mathematical foundation for the graph contrastive learning framework introduced in the next section.

C. Global Learning Objective and Optimization Criteria

MatchIA-GCL adopts a graph contrastive learning strategy to jointly learn semantic and structural representations, enabling robust schema matching across heterogeneous datasets.

Let (z_i) and (z_j) denote the latent representations of two positive nodes, corresponding either to aligned schema elements or to two augmented views of the same node. Following the InfoNCE principle, the contrastive loss associated with node (v_i) is defined as:

$$L_(i,j) = -log\left(\frac{exp\left(\frac{sim(z_i, z_j)}{\tau}\right)}{exp\left(\frac{sim(z_i, z_j)}{\tau}\right) + \Sigma_k exp\left(\frac{sim(z_i, z_k)}{\tau}\right)}\right) \quad (16)$$

where, $sim(\cdot)$ denotes the cosine similarity function, (τ) is the temperature hyperparameter, and (z_k) represents the latent representations of negative samples that do not correspond semantically to node (v_i).

The objective of the contrastive learning process is to maximize the similarity between positive pairs while simultaneously separating negative pairs in the latent embedding space. This mechanism encourages the generation of discriminative representations that remain stable under both semantic and structural perturbations [25, 26].

The overall optimization objective of MatchIA-GCL combines the contrastive loss with an $L2$ regularization term to improve model generalization and reduce overfitting. The global loss function is defined as:

$$L_{global} = \left(\frac{1}{N}\right) \Sigma_i L_{i,match(i)} + \lambda ||W||^2 \quad (17)$$

where, (N) denotes the number of training pairs within a mini-batch, $(match(i))$ identifies the positive correspondence associated with node (v_i) , (W) represents the trainable parameters of the Graph Attention Network, and (λ) is the regularization coefficient controlling the contribution of the weight decay term. The optimization process aims to minimize $(L_{\{global\}})$, thereby learning schema representations that simultaneously preserve semantic consistency, structural coherence, and robustness to heterogeneous schema transformations. These learned embeddings constitute the

foundation of the MatchIA-GCL architecture presented in the following section.

IV. Proposed MatchIA-GCL Approach

A. Overall Architecture

The proposed MatchIA-GCL framework is organized into three sequential processing stages, as illustrated in Fig. 2. In Stage 1 (Semantic Representation Learning), heterogeneous source and target schemas are transformed into contextual semantic embeddings using a Transformer-based encoder that captures lexical and contextual information from schema metadata. In Stage 2 (Structural Representation Learning), a Heterogeneous Graph Attention Network (HGAT) combined with Graph Contrastive Learning (GCL) models structural dependencies and learns robust hybrid representations by jointly optimizing semantic and structural information. These hybrid embeddings are then used to compute the correspondence matrix between source and target schema elements. Finally, in Stage 3 (Validation and Explainable Alignment), high-confidence correspondences are directly accepted, whereas ambiguous candidate pairs are selectively validated by the LLM-based Autonomous Validation Agent. An explainability layer subsequently provides interpretable justifications for the validated alignments, improving transparency and supporting human interpretation of the matching decisions.

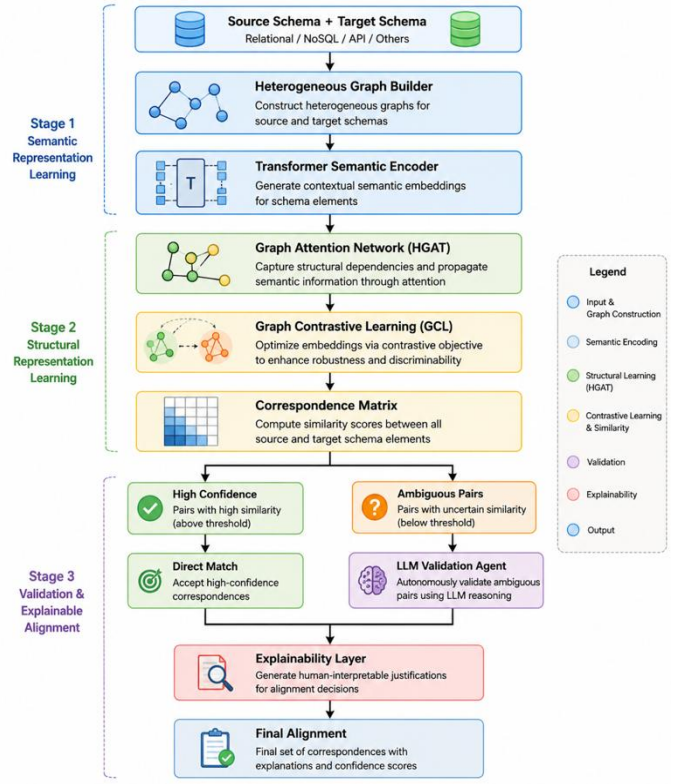

Fig. 2. Overall architecture and execution workflow of the proposed MatchIA-GCL framework.

B. Contextual Semantic Encoder

The first stage of MatchIA-GCL generates contextual semantic embeddings from schema metadata using a Transformer-based encoder. By leveraging attribute names, data types, and additional metadata, the model captures contextual semantics and reduces ambiguity between semantically related schema elements.

Let (C_i) denote the contextual description associated with node (v_i). The semantic embedding of the node is obtained by applying the Transformer encoder as defined in:

$$h_{sem_i} = TransformerEncoder(C_i) \quad (18)$$

where, $(h_{\{sem_i\}})$ represents the contextual semantic embedding generated for node (v_i).

The resulting embedding has a fixed dimensionality (d) and captures semantic relationships among schema elements independently of their structural position within the graph. These embeddings constitute the initial node features that are subsequently propagated through the graph attention layers described in the next subsection.

C. Heterogeneous Graph Attention Network

After obtaining the initial semantic embeddings, the framework activates its structural learning pipeline to incorporate topological information into the representation space. The semantic embeddings generated by the Transformer encoder serve as the initial node features of a Heterogeneous Graph Attention Network (HGAT).

To handle heterogeneous node types and relation categories, the attention mechanism is parameterized according to the relation type. For a node (v_i) connected to a neighboring node (v_j) through relation type (r), an attention coefficient is computed to quantify the structural importance of node (v_j) with respect to node (v_i). The unnormalized attention score is defined as:

$$e_{ij}^{r} = \text{LeakyReLU}(W_r[h_i||h_j]) \quad (19)$$

where, (W_v) denotes a shared linear projection matrix, (W_r) represents the attention vector associated with relation type (r), and (||) denotes vector concatenation.

The attention coefficients are subsequently normalized through a Softmax operation over the neighborhood of node (v_i), as defined in:

$$\alpha_{ij}^{r} = \frac{exp(e_{ij}^{r})}{\sum_{k \in N_i^r} exp(e_{ik}^{r})} \quad (20)$$

where, the summation is performed over all neighboring nodes connected to (v_i) through relation type (r).

The structural representation of node (v_i) is then obtained by aggregating the information received from its neighbors according to the normalized attention weights. This aggregation process is defined in:

$$h_i^{struct} = ELU\left(\sum_{j \in N_i^r} \alpha_{ij}^{r} W_v h_j\right) \quad (21)$$

To improve learning stability and capture multi-scale structural patterns, MatchIA-GCL employs a multi-head attention mechanism.

To better illustrate the structural learning process implemented in MatchIA-GCL, Fig. 3 presents the architecture

of the proposed multi-head Heterogeneous Graph Attention Network (HGAT) used for structural representation learning.

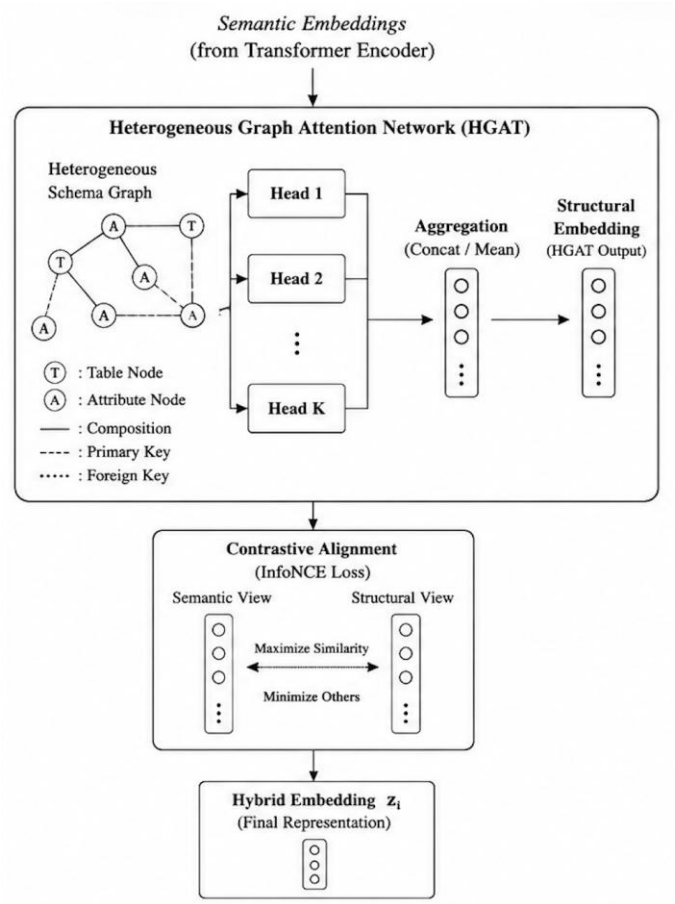

Fig. 3. Architecture of the proposed multi-head Heterogeneous Graph Attention Network (HGAT) used in MatchIA-GCL.

The HGAT module enables the propagation of semantic information across heterogeneous structural dependencies, including table–attribute relationships and referential constraints. The resulting structural embeddings are subsequently aligned with the semantic representations through the graph contrastive learning mechanism, producing robust hybrid embeddings suitable for schema matching.

D. Semantic–Structural Contrastive Alignment

The semantic embeddings generated by the Transformer encoder and the structural representations learned by the HGAT are subsequently aligned through a graph contrastive learning strategy. Rather than combining both representations through a simple aggregation operation, the proposed framework explicitly maximizes the agreement between the semantic and structural views of the same schema element.

The contrastive objective encourages semantically equivalent and structurally related nodes to occupy nearby regions in the latent space while simultaneously separating unrelated elements. Consequently, schema attributes sharing similar semantic roles or structural functions become geometrically closer even when their naming conventions differ significantly.

Positive pairs are constructed either from aligned schema elements available in the reference mappings or from two augmented views of the same schema node generated through feature masking and edge dropout. Negative pairs are randomly sampled from semantically unrelated nodes belonging to different schemas while ensuring that no reference correspondence exists between them. This sampling strategy enables the contrastive objective to maximize the similarity of semantically equivalent representations while effectively separating non-matching schema elements in the latent embedding space.

The final hybrid representation associated with node $(v_i)$is obtained by combining the semantic embedding and the structural embedding as defined in:

$$z_i = h_i^{\{sem\}} + h_i^{\{struct\}} \quad (22)$$

where, (z_i) denotes the final hybrid embedding used for correspondence estimation and downstream alignment tasks. These representations constitute the input of the matching and validation stage described in the next subsection.

E. LLM-Based Autonomous Validation Agent

Although the hybrid embeddings generated by MatchIA-GCL successfully identify most schema correspondences, ambiguous mappings often require additional semantic reasoning. To address this challenge, the framework incorporates a Large Language Model (LLM) as an Autonomous Validation Agent. Unlike conventional approaches that apply LLMs to all candidate pairs, the proposed agent is activated only for uncertain correspondences, thereby reducing computational overhead while maintaining scalability. For each ambiguous candidate, the agent analyzes the source and target schema elements together with their metadata and structural context. It then determines the validity and type of correspondence $(1{:}\,1,1{:}\,n,n{:}\,1,or\ n{:}\,m)$ and produces a concise justification for the decision. The validated correspondences are subsequently integrated into the global correspondence matrix, enabling the framework to combine graph-based representation learning.

F. Post-Hoc Explainability Layer

To improve transparency and facilitate adoption in industrial environments, MatchIA-GCL incorporates a post-hoc explainability layer that provides human-interpretable justifications for alignment decisions. The module combines attention-based structural analysis and semantic feature attribution to identify the factors that contribute to each correspondence. At the structural level, attention coefficients extracted from the HGAT layers highlight the influence of neighboring nodes and schema relationships. At the semantic level, feature attribution methods estimate the contribution of attribute names, data types, descriptions, and representative values to the matching decision.

The resulting explanations are aggregated into interpretable audit reports that provide both structural and semantic evidence supporting the generated correspondences. Fig. 4 illustrates the validation and explainability workflow integrated into MatchIA-GCL.

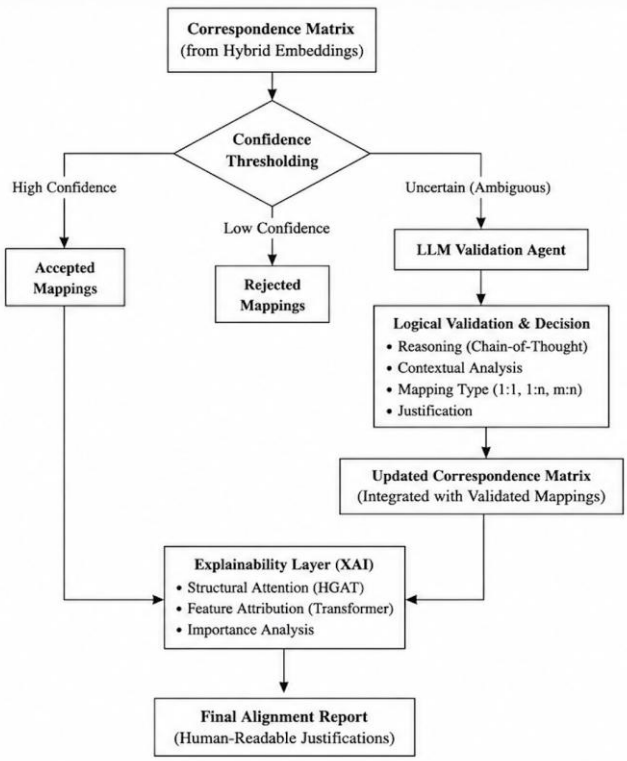

Fig. 4. Autonomous validation and explainability framework for schema matching in MatchIA-GCL.

G. Overall MatchIA-GCL Algorithm

The overall workflow of MatchIA-GCL is summarized in Algorithm 1. The algorithm integrates semantic representation learning, structural graph modeling, contrastive optimization, and selective LLM-based validation within a unified framework. Contextual semantic embeddings are first generated using a Transformer-based encoder and refined through a Heterogeneous Graph Attention Network (HGAT) to incorporate structural dependencies between schema elements. A graph contrastive learning objective is then optimized to improve the separability of semantically equivalent and non-equivalent representations in the latent space. Candidate correspondences are subsequently estimated using cosine similarity between the learned hybrid embeddings, whereas only uncertain candidates are subjected to LLM-based semantic validation. The validated correspondences constitute the final schema alignment produced by MatchIA-GCL.

Algorithm 1: MatchIA-GCL: Schema Matching Framework

Input : Source schema S_s, Target schema S_t
Parameters θ (encoder, HGAT, projection, LLM),confidence threshold τ
Output : Set of correspondences C

Initialize $C \leftarrow \emptyset$
Construct heterogeneous schema graph *G = (V, E, R)* from S_s *and* S_t
/ Stage 1: Contextual Semantic Encoding */*
for each node $v \in V$ **do**
  $x_v \leftarrow build\ v(name, type, parent, description, samplevalues)$
  $h_v^{(0)} \leftarrow TransformerEncoder(x_v; \theta_e nc)$
end for
/ Stage 2: Heterogeneous Graph Attention Network */*
for $l = 1\ to\ L$ **do**
  Update node representations using HGAT layer l
end for
/ Stage 3: Graph Contrastive Learning */*
Construct positive and negative pairs from S_s and S_t
Compute contrastive loss L_{cl} and update parameters θ
/ Stage 4: Similarity Computation */*
for each pair $(u \in Ss, v \in St)$ **do**
  $sim(u,v) \leftarrow cosinSimilarity\left(h_u^{(L)}, h_v^{(L)}\right)$
end for
/ Stage 5: LLM-based Validation */*
for each candidate pair (u, v) with $sim(u,v) \geq \tau$ **do**
  $decision, score \leftarrow LLMValidation(u, v, context_{uv}, sim(u,v))$
  if decision == match **then**
    $C \leftarrow C \cup (u, v, score)$
  end if
end for
return *C*

The following section presents the experimental evaluation of the proposed framework.

V. Experimental Evaluation

A. Experimental Setup and Evaluation Protocol

To assess the effectiveness of the proposed MatchIA-GCL framework, a comprehensive experimental protocol was designed to evaluate its matching accuracy, robustness, scalability, and generalization capabilities across heterogeneous schema matching scenarios. All experiments were conducted using a Python-based implementation relying on the PyTorch and PyTorch Geometric frameworks for deep learning and heterogeneous graph processing.

The semantic encoding module employs a pre-trained RoBERTa-base model to generate contextual embeddings from schema metadata. The structural learning component is implemented using a Heterogeneous Graph Attention Network composed of three attention layers with eight attention heads per layer. The graph contrastive learning module is optimized using the InfoNCE loss function, with the temperature parameter empirically fixed to 0.07 following a hyperparameter tuning phase.

For ambiguous correspondences requiring higher-level semantic reasoning, the autonomous validation module relies on OpenAI GPT-4o accessed through the OpenAI API. The model is integrated through a standardized inference interface and is selectively activated only for candidate correspondences whose similarity score falls within a predefined uncertainty interval.

B. Benchmark Datasets

The experimental evaluation was conducted on three benchmark datasets commonly used in schema matching research. These datasets cover diverse semantic and structural challenges, including noisy schemas, semantic heterogeneity, multilingual metadata, and complex correspondences.

The first benchmark considered in this study is the Valentine Benchmark, a well-established evaluation framework frequently used in schema matching research [1]. This benchmark includes both academic and industrial datasets originating from domains such as finance, healthcare, and business information systems. A key advantage of the Valentine benchmark lies in its ability to generate degraded schema variants through controlled transformations, including attribute renaming, abbreviation insertion, typographical noise, and structural perturbations. Such characteristics make this benchmark particularly suitable for evaluating the robustness of representation learning methods under realistic and adverse conditions.

The second benchmark is the Open Public Data (OPD) dataset, which consists of real-world schemas extracted from governmental open-data portals and public information repositories. Compared with curated academic datasets, OPD exhibits significantly higher semantic heterogeneity due to inconsistent naming conventions, multilingual terminology, undocumented abbreviations, and varying normalization levels. Consequently, this benchmark provides a realistic environment for assessing the effectiveness of semantic representation learning approaches in large-scale data integration scenarios [27].

The third benchmark is the Wikidata-to-Schema dataset, which focuses on aligning relational schemas with semantic web and knowledge graph structures derived from Wikidata. It includes hierarchical relationships and many-to-many correspondences [28], making it particularly suitable for evaluating the reasoning capabilities of the proposed LLM-based validation component. The three benchmarks provide complementary evaluation scenarios covering robustness, semantic generalization, and complex semantic reasoning. Table II summarizes the main characteristics of the benchmark datasets used throughout the experimental evaluation.

TABLE II. CHARACTERISTICS OF THE BENCHMARK DATASETS

Dataset	Application Domain	Number of Schemas	Schema Size (Attributes / Tables)	Correspondence Type
Valentine Benchmark	Academic & Industrial	14 pairs	43 to 70 attributes / 2 to 15 tables per schema	1:1, Textual & Complex
Open Data (OPD)	Public Governance	22 pairs	30 to 120 attributes / 1 table per flat file	1:1, Abbreviations & Synonyms
Wikidata-to-Schema	Semantic Web	8 Graphs	> 500 relational properties / Graph-Ontologies	m:n, Composite & Hierarchical

As shown in Table II, the selected benchmark datasets encompass a wide range of schema matching challenges, from noisy relational schemas to highly complex ontology-driven structures. This diversity enables a rigorous assessment of the semantic, structural, and reasoning capabilities of the proposed MatchIA-GCL framework.

C. Evaluation Metrics

The performance of MatchIA-GCL was evaluated using the standard metrics commonly adopted in schema matching research, namely Precision, Recall, and F1-Score. The generated correspondences were compared against manually validated reference alignments (ground truth) to assess matching quality. Precision measures the proportion of correctly identified correspondences among all predicted matches and is defined by:

$$Precision = TP/(TP + FP) \tag{23}$$

where, TP denotes the number of true positive correspondences and FP denotes the number of false positive correspondences.

Recall evaluates the ability of the framework to identify all valid correspondences present in the reference alignment. This metric measures the sensitivity of the model with respect to missed matches and is defined by:

$$Recall = TP/(TP + FN) \tag{24}$$

where, FN represents the number of false negative correspondences.

The F1-Score, defined as the harmonic mean of Precision and Recall, is adopted as the primary evaluation metric because it provides a balanced assessment of matching performance by jointly considering false positive and false negative correspondences. It is particularly suitable for schema matching, where both accurate correspondence identification and error minimization are equally important. It is computed according to:

$$F_1 = \frac{2 \times Precision \times Recall}{Precision + Recall} \tag{25}$$

In addition to matching accuracy, execution time and inference efficiency were evaluated to assess the computational scalability of MatchIA-GCL. These metrics quantify the practical cost of semantic representation learning and selective LLM-based validation, providing insight into the framework's suitability for large-scale heterogeneous schema matching scenarios.

D. Comparative Results and Quantitative Analysis

The Precision results obtained by COMA++, DeepMatcher, GNNMatcher, LLM-Centric, and the proposed MatchIA-GCL are presented in Fig. 5. MatchIA-GCL achieves the highest Precision across all benchmark datasets, reaching 90.3%, 92.7%, and 88.6% on the Valentine, OPD, and Wikidata-to-Schema datasets, respectively. The consistent improvement over both traditional and deep learning-based baselines indicates that the joint integration of contextual semantic representations, heterogeneous graph attention, and graph contrastive learning effectively reduces false positive correspondences. Furthermore, the selective activation of the LLM-based validation agent refines ambiguous candidate mappings without introducing

unnecessary validation overhead, leading to more reliable semantic alignments across heterogeneous schemas.

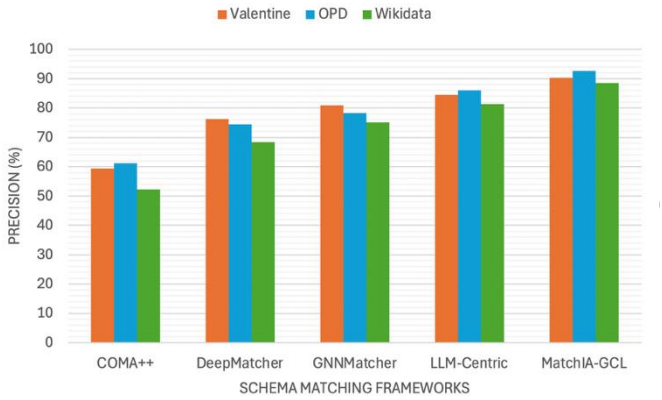

Fig. 5. Precision comparison across benchmarks.

The Recall results are reported in Fig. 6. MatchIA-GCL consistently outperforms competing approaches, achieving Recall values of 88.1%, 90.1%, and 86.4% on the three benchmark datasets. This demonstrates its effectiveness in identifying a larger proportion of valid correspondences.

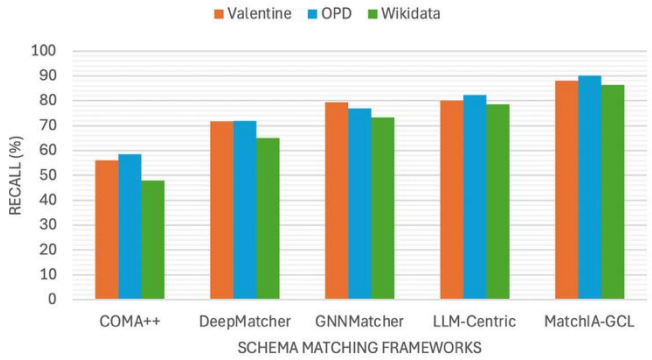

Fig. 6. Recall comparison across benchmarks.

The overall matching performance measured by the F1-Score is presented in Fig. 7. MatchIA-GCL consistently achieves the highest results across all benchmark datasets, reaching 89.2%, 91.4%, and 87.5% on the Valentine, OPD, and Wikidata-to-Schema benchmarks, respectively. The observed improvements demonstrate the effectiveness of jointly learning semantic and structural representations through the proposed hybrid architecture. The largest gain is obtained on the Wikidata-to-Schema benchmark, where MatchIA-GCL outperforms the strongest baseline by 7.6 percentage points in terms of F1-Score. This benchmark contains ontology-driven structures, hierarchical dependencies, and many-to-many semantic correspondences, making schema alignment particularly challenging. The results indicate that the integration of heterogeneous graph attention learning, graph contrastive optimization, and LLM-assisted validation enables the framework to better capture complex semantic and structural relationships than existing approaches.

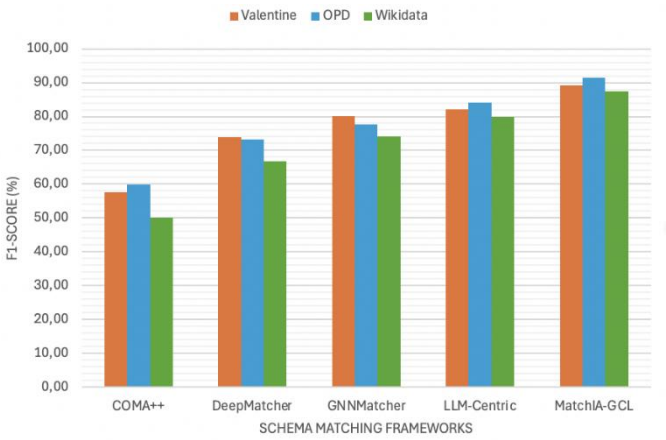

Fig. 7. F1-Score comparison across benchmarks.

Overall, the results confirm the effectiveness of combining contextual semantic encoding, heterogeneous graph attention learning, graph contrastive optimization, and LLM-assisted validation within a unified schema matching framework.

E. Ablation Study and Component Contribution Analysis

To assess the contribution of each component of MatchIA-GCL, an ablation study was conducted by removing one module at a time while keeping the remaining architecture unchanged. Four degraded variants were evaluated.

- MatchIA w/o HGAT removes the Heterogeneous Graph Attention Network and relies solely on Transformer-based semantic embeddings, thereby evaluating the contribution of structural information.
- MatchIA w/o GCL removes the Graph Contrastive Learning objective while preserving the Transformer encoder and the HGAT module, thereby evaluating the contribution of contrastive optimization to robust semantic-structural representation learning.
- MatchIA w/o LLM disables the LLM-based Autonomous Validation Agent and relies exclusively on embedding similarity scores, thereby evaluating the contribution of semantic reasoning to resolving ambiguous correspondences.
- MatchIA w/o Context replaces the Transformer-based contextual semantic encoder with basic attribute representations, thereby evaluating the importance of contextual semantic information in generating discriminative schema embeddings.

The performance differences between these variants and the complete MatchIA-GCL framework provide insights into the contribution of semantic context, structural learning, contrastive optimization, and LLM-based reasoning to the overall matching performance. Table III summarizes the performance degradation observed after removing each component of the proposed architecture.

TABLE III. ABLATION STUDY: F1-SCORE DEGRADATION (%)

Framework Variant	Valentine	OPD	Wikidata
MatchIA w/o HGAT	-9.0	-6.8	-11.3
MatchIA w/o GCL	-5.4	-4.1	-5.9
MatchIA w/o LLM	-4.2	-7.9	-12.1
MatchIA w/o Context	-7.1	-5.3	-3.6

Overall, the ablation study validates the complementarity of the proposed components.

VI. CONCLUSION AND FUTURE WORK

MatchIA-GCL introduces a unified framework for heterogeneous schema matching that combines contextual semantic encoding, heterogeneous graph attention learning, contrastive optimization, and LLM-assisted validation. By jointly modeling semantic and structural information, the proposed approach effectively addresses the limitations of existing schema matching methods and improves the identification of complex correspondences across heterogeneous data sources. Experimental evaluations on the Valentine, OPD, and Wikidata-to-Schema benchmarks demonstrate consistent improvements over representative state-of-the-art approaches, while the ablation study confirms the contribution of each architectural component. Furthermore, the integration of an explainability layer enhances the transparency and auditability of alignment decisions, facilitating the adoption of the framework in real-world data integration environments. Future work will focus on scaling the framework to large enterprise data ecosystems and incorporating adaptive learning mechanisms that continuously refine matching decisions through expert feedback and autonomous reasoning.

***Abstract*—The practical utilization of the conventional Ciphertext-Policy Attribute-Based Encryption (CP-ABE) systems in a vast cloud has the constraint of the high cost of computation and the high risk of quantum-powered adversaries. This research introduces a novel Hybrid Lattice-Based CP-ABE (HL-CP-ABE) architecture that is focused on the hardness assumptions of Ring Learning with Errors (RLWE) to provide the double security of quantum-safe and precise data sharing. The proposed hybrid encryption system employs post-quantum techniques that provide both confidentiality and access control, and it is completely based on AES for the data encryption and on the lattice-based CP-ABE technology for the AES session key wrapping. A multithreaded, chunk-based parallel processing technique is used to improve the encryption and decryption processes and, at the same time, limit the difficulties that come along with the performance of lattice-based cryptography. The entire system is implemented in Java and evaluated across file sizes from 100 to 800 MB under a fixed three-attribute access policy, achieving processing time reductions of up to 9.5× compared to serial lattice CP-ABE, with a mean speedup of approximately 8.2× across encryption and decryption. The results reveal that the design not only upholds security but also achieves scalability, reduced ciphertext growth, and the correct decryption of the whole data. This research study presents the groundwork for future optimization using GPU parallelization and dynamic attribute management, and at the same time, it puts forth a workable, effective, and quantum-secure method of attribute-based encryption that is specifically beneficial for electronic health record (EHR) systems and secure cloud data sharing.**

Keywords*—LWE; Ring-LWE; post-quantum cryptography; attribute based encryption; parallel processing

I. Introduction

Due to their scalability, live collaboration, and data access from everywhere, cloud computing and distributed data environments nowadays have turned into the necessities of any information system. Nevertheless, these benefits also introduce significant dangers to privacy arising from these benefits, and these dangers get highlighted when using untrustworthy infrastructure to transmit sensitive data [1] [2]. The common use of digital health data, e-governance, and financial platforms does not only require cryptographic frameworks that secure data with secrecy, authenticity, and fine-grained access control, but it also promotes their use. On the other hand, the protection offered by public-key cryptography systems such as RSA and ECC, which are based on the integer factorization and discrete logarithm issues, will be completely broken if quantum computers are used [3]. The public-key cryptosystems in the area of quantum computing are at risk of quantum algorithms like Shor's or Grover's. Hence, it becomes a necessity to innovate cryptography techniques that are quantum-proof to allow secure data exchange between quantum computers. Attribute-Based Encryption (ABE) is acknowledged as a practical method for encrypted data access control of the highest degree, thereby ensuring that the information can only be accessed by the users who are permitted [4]. ABE, the encrypted message is tied to a receiver who can decrypt it based on a policy that conforms to certain attributes. These users are only allowed to view the file that satisfies the requirements with their attribute sets [5]. A crucial factor is the distinction between the two main types of encryption using an attribute-based approach, namely, Key-Policy ABE (KP-ABE) and Ciphertext-Policy ABE (CP-ABE) [6]. The interest in data sharing applications has been along the side of CP-ABE because the policy for access was set right at the moment of encryption by data owners [7].

In contrast, many traditional CP-ABE scheme implementations are based on pairing of groups formed by elliptic curves; this property makes the systems computationally intensive and open to attack within the domain of quantum computing [8]. The time-consuming nature of the bilinear pairings in the CP-ABE schemes results in high latency during encryption and decryption processes and difficulties in the expansion of the technology to large or real-time applications mainly because of the dependence of the schemes on the access structures' size [9]. Hence, even though ABE is a theoretically attractive framework, its application is still limited in an environment where high throughput is the main concern and quantum computers are considered a threat [10]. Of late, recently, lattice-based cryptography has emerged as the leading post-quantum approach. The primary limitations of these systems include large ciphertext sizes, high key-generation overhead, and lack of parallel optimization, which keep attackers out from both classical and quantum sides [8]. The hard problems like LWE and its Ring-based version (Ring-LWE) are a barrier to attackers coming from both quantum and classical worlds. The lattice structure practically levels the playing field between optimal and typical situations, thereby speeding up arithmetic operations in the polynomial ring modulo and making them even more suitable for cryptographic

primitives like ABE and functional encryption [11]. To put it in another way, several lattice-based ABE schemes have been proposed, which, by means of theory, are found to be resistant to quantum algorithms [12]. The drawback of such appetitive features is that, with time, these designs have frequently become prey to the problems of enormously bulky ciphertext sizes, big key generation overhead, and the limitation of performance optimization [13]. One of the main problems of the current implementations is that they were made for academic purposes only, whereas lattice-based and attribute-based encryption (ABE) can be said to be more practical. This means that the distance between the theoretical discussions on post-quantum ABE and technological solutions capable of handling massive, encrypted datasets is actually very far apart [14].

One way of overcoming these limitations is by means of methods that integrate the best of symmetric cryptography and public-key techniques in the so-called hybrid cryptographic frameworks. Public-key mechanisms and symmetric encryption techniques together speed key-based transactions [15]. Within a hybrid system, data encryption is carried out by means of a symmetric cipher like AES, but the symmetric key is protected by a public-key method, such as ABE [16]. This idea leads to a significant drop in the expenses of calculations, as the public-key operations are performed only on the key, not on the whole data set [14]. Nevertheless, the lattice-based methods still present large delays in the computation aspect, although they are hybridized. This is due to polynomial operations and modular arithmetic inherent in lattice schemes. Most existing hybrid implementations are single-threaded and therefore inadequate for large-file scenarios. Therefore, the proposed scheme must be compatible with public-key mechanisms while supporting parallel, pipelined execution for high-throughput scenarios. This study provides a modified CP-ABE algorithm that uses lattice structures in conjunction with classical cryptographic constructions to prevent against quantum attacks. The system is composed of the LSSS policy matrices as a base, with the Ring-LWE assumption, which makes the system post-quantum secure and helps define detailed levels of access control. The next step after the AES is made to encrypt the data very quickly is the AES key that is covered through the Ring-LWE-based CP-ABE mechanism. The start of the encryption process with the new encryption method is anticipated to result in the modification of the system that allows one to encrypt and decrypt segments of files in parallel across multiple cores of the CPU by having a concurrency method easier and cheaper than the one currently in use. Having set up a quantum key distribution technique, the described system would be working concurrently on all channels, ensuring total security. The introduction of the multithreaded chunk-processing model is the key to making the solution highly efficient while at the same time keeping it secure and correct. The system is fully implemented in Java, with modules designed for efficient memory management. There has been a very exhaustive experimental analysis to confirm the efficiency and scalability of the suggested system. Moreover, in the performance evaluation, several different file sizes, attribute policies, and thread counts were taken into consideration when comparing the optimized and complex multithreaded hybrid model with the conventional and serial lattice-based CP-ABE implementations. The evaluation shows up to a 9.5× reduction in runtime and a substantial decrease in ciphertext size, while preserving fully accurate decryption. Thus, the outcome clearly demonstrates that the mixed approach used in architecture was secure and widely acceptable in terms of system speed and total operational time—two important characteristics for the various kinds of tasks, like secure cloud storage, collaborative data sharing, and electronic health records, that may likely be done in real-world scenarios.

A. Highlights of the Research Paper

- Quantum-Secure Hybrid Model: With Ring-LWE-based cryptography, a new CP-ABE system was developed, and it eliminated the risk of quantum attacks.
- Performance-Optimized Architecture: A parallelizable encryption and decryption flow for big files, through the application of multithreaded chunk-processing design, has been introduced.
- Practical Implementation: A full Java-based system has been created by integrating lattice cryptography with AES and LSSS-based policy parsing.
- Thorough Evaluation: The proposed system showed processing times up to 9.5× faster than serial execution (mean≈8.2×), while maintaining fully accurate decryption and ciphertext overhead below 2×.

This study follows the outlined order: In Section II, the research of lattice-based ABE and hybrid cryptographic ways is considered. In Section III, some important mathematical principles are included, such as LWE, Ring-LWE, and LSSS. Section IV delineates the proposed system, encompassing setup procedures, key generation, encryption, decryption, and the corresponding algorithms for these operations. Section V presents the implementation and verifies system efficiency. Security is covered in Section VI. Section VII compares the proposed system against existing pairing-based, lattice-based, and hybrid schemes. Section VIII concludes the study and outlines future work.

II. Literature Review

A. Classical Pairing-Based Attribute-Based Encryption

Attribute-Based Encryption (ABE) was first put forward by Sahai and Waters [59] as an upgrade of Identity-Based Encryption (IBE), granting fine-grained access rights over encrypted data. The seminal scheme employed bilinear pairings defined over cyclic groups $(G1, G2)$ of prime order p, its security being based on the Decisional Bilinear Diffie–Hellman (DBDH) hypothesis. After that, Goyal et al. [18] and Bethencourt et al. [19] proposed models along with this model in the form of Key-Policy ABE (KP-ABE) and Ciphertext-Policy ABE (CP-ABE), respectively, which allowed the owners of the data to put the access structures in the encrypted data directly. The pairing-based schemes enabled highly expressible Boolean or Linear Secret Sharing Scheme (LSSS)-based policies, but they involved a large computational burden in terms of pairing and exponent operations of the form $(ga, gb) = (g, g)\{ab\}$, which are the major contributors to the runtime complexity [20]. Despite several improvements, the security of pairing-based protocols against quantum attacks remains elusive to trace [21]. "Shor's algorithm solves integer factorization and

discrete logarithm problems in polynomial time, breaking RSA and ECC security.", this being the very core of security for RSA and elliptic curve systems [22]. The traditional methods being inadequate for protecting against quantum threats drove the development of lattice-based cryptography, which relies on the hardness of the toughest lattice problems, thus making it impractical in both the classical and quantum realms [23].

B. Lattice-Based and Post-Quantum ABE Approaches

The move from pairings to lattice problems was first taken by the path-breaking work of Gentry, Peikert, and Vaikuntanathan, who put forward the Learning with Errors (LWE) problem, a main post-quantum assumption [24]. LWE is about linear equations in modular arithmetic, where the main task is to recover a secret vector $s \in Z^n$ given pairs $(A, As + e)$, where the error vector (e) is chosen from a discrete Gaussian distribution [25]. LWE's hardness can be connected to the hardest lattice problems, among which are GapSVP (Shortest Vector Problem) and SIVP (Shortest Independent Vector Problem) [26]. The (Ring-LWE) variant quickly turned efficient by operating through polynomial rings $R_q = Z_q[x]/(x^n + 1)$, which in turn led to a decrease in key and ciphertext sizes, while keeping security [17][27]. The security of Ring-LWE is primarily rooted in the challenge of finding a short vector in an ideal lattice, which can be expressed formally as:

Lemma 1: The ability of a probabilistic polynomial-time technique to tell apart Ring-LWE samples from uniform noise implies that there is a fast algorithm under the given conditions that can output the GapSVP with polynomial factors in terms of time complexity. The lemma, as proved in [27], is the cornerstone for the security aspect of post-quantum lattice cryptography. Agrawal, Freeman, and Vaikuntanathan [28] did the initial work on constructing an LWE-based ABE that accepts small Boolean formulas. Yao et al. followed up, detailing these ideas with the presentation of lattice-attached Attribute-Based Encryption (ABE) systems that incorporate Linear Secret Sharing Scheme (LSSS) architecture, thus expanding the communication and liberality of access rules in the CP-ABE systems even more. Yao et al. later asserted that traditional model hypotheses could be a basis for guaranteeing CP-ABE on lattice LWE [29]. Subsequent schemes, such as those of Sun et al. [30] and Datta et al. [31], built on LWE-family assumptions to improve the expressiveness and performance of lattice-based ABE. The results indicate that lattice-based ABE approaches might be able to achieve a certain level of security from a CPA security perspective when it comes to resisting quantum attacks.

However, several hurdles lie ahead:

- Very large public keys and the corresponding ciphertexts since each attribute bears a polynomial number of factors, with each of them being of rather big size [19] [32].
- The speed of polynomial multiplication is negatively impacted because of the use of high-degree modulus arithmetic [33] [34].
- The practical side is rather limited—most of the trials are just based on the encryption of tiny messages [35]. Yet even with the Number Theoretic Transform (NTT), which boosts polynomial multiplication efficiency from (n^2) to $(n \log n)$, practical realization remains computationally heavy [36] [37].

C. Hybrid Encryption and Efficiency-Oriented ABE Architectures

To remedy the performance overhead of lattice-based encryption, researchers have resorted to hybrid configurations. Hybrid architecture, under this model, can be described by the process of symmetric encryption with data before it gains the likeness of AES, and through hybrid transmission, the encryption can be delivered at the destination. This step-by-step design of two tiers reduces the very high public-key operations to a handful, thus making it possible to perform the process faster and still maintain the security level. Li et al. [38] and Qian and Wu [39] exemplify such studies; Qian and Wu [39] describe a hybrid ABE structure for cloud storage, and other work has combined ABE with KEMs, which made easy entrance to resources for different applications [40]. However, a major part of hybrid ABE research mainly builds on pairing-based cryptography, so it happens to be vulnerable to quantum attacks as well. Only a few of the papers, such as the one by Dai et al. [41], investigated the lattice-based hybrid ABE, but they did not provide immediate implementation or parallel optimization. The results imply that although the hybridization approach is in principle possible, the difficulties posed by the Ring-LWE-based schemes in computation still occur at the encryption and key generation phases, where polynomial sampling and modular reduction greatly affect the time complexity. The cost of a single lattice-based encryption operation can be evaluated in terms of computation in Eq. (1):

$$T_{enc} = O(n \log n + m \cdot |A|) \quad (1)$$

The value (n) represents the ring dimension, while another variable (m) denotes the attribute count and $(|A|)$ indicates the policy matrix dimension. The extent of this complexity therefore suggests a major possibility of parallelism, a fact that the already established studies on the subject have been unable to exploit so far.

D. Implementation Studies and Performance Limitations

Practical applications of lattice-based ABE remain scarce. Mostly the current prototypes are coded in C/C++ and reap the benefits from using experimental libraries like Lattigo or PALISADE [42]. These systems manage to have the functions of cryptography correct when it comes to them, but they have so far missed the throughput of the encryption test on actual file datasets (i.e., the scalar lattice multiplication). An example of these findings is the work of Gür et al. [43], who reported the throughput of lattice-based encryption schemes at moderate lattice dimensions, resulting in the observation of the gap between the theory of post-quantum cryptography and the practical industry implementation. Additionally, the current literature neglects the use of not just the file but rather chunking techniques along with multithreaded processing, which can be taken to the extreme in a multi-core system to minimize the processing latency. Usually, the access structure is shown in the ABE framework by an LSSS matrix $(M \in Zp^{l \times n})$ and a mapping function (ρ), where each row corresponds to a separate attribute. According to the Reconstruction Theorem [44], LSSS provides the assurance that if the user's attribute set (S) satisfies the

access policy, then the secret (s) can be reconstructed as a linear combination of shares (λ_i), as shown in Eq. (2):

$$s = \sum i \in I\ \omega i \lambda i \quad (2)$$

In this context, the symbol ω_i represents the coefficients used for reconstructing the data. It is true that modern lattice-based attribute-based encryption systems prove the theorem correctly; still, such systems do not accelerate share generation and linear algebra operations through parallelism. This situation leads to considerable delays with the share generation (l), especially when the policies are complex and include either conjunctions or disjunctions.

E. Parallel and Multi-threaded Cryptographic Frameworks

Parallelism has been widely applied to symmetric algorithms such as AES and SHA, achieving multi-fold acceleration on modern CPUs and GPUs [45]. In contrast, parallel approaches for asymmetric post-quantum cryptography remain limited. Researchers have proposed GPU-based optimizations for lattice encryption primitives [46], yet these focus on raw mathematical kernels, not integrated ABE frameworks. Multi-threading has been explored for homomorphic encryption libraries [47] but not for attribute-based or hybrid encryption systems. From a theoretical standpoint, encryption of independent message blocks or chunks can be represented as a data-parallel operation $E_k(m_l)$ over disjoint subsets $m_1, m_2, \dots, m_t$, where each encryption thread operates on a distinct data segment [48].

1) Proposition 1 (Parallel Time Bound):

For the case of t different data chunks and p processor cores, the expected encryption time $\mathbf{T_p}$ satisfies $\mathbf{T_p} \leq \mathbf{T_1}/\mathbf{p} + (\boldsymbol{\epsilon})$, where the epsilon factor symbolizes the overhead of managing threads. This scaling is one of the main factors in the parallel processing of cryptographic workloads and is the very principle used in the presented system [49]. The classification of CP-ABE systems into three main groups is as follows: the first group is pairing-based ABE, it has a very expressive policy but at the same time is vulnerable to quantum attacks; the second group is lattice-based post-quantum ABE, which is strong in theory but suffers from practical performance issues; and the third group is hybrids of both ABE approaches, possibly the fastest processing but also not offering any protection against quantum attacks. Nonetheless, the growth of the lattice-based cryptosystem was observed; there remains no documented case where the combination of the Ring-LWE–based ABE, symmetric hybridization, and multithreaded optimization for large-scale data sharing is being carried out end-to-end [50]. In addition, the existing works have neither systematically divided the data into different segments for parallelization and applying the LSSS Reconstruction nor have they estimated the runtime enhancements using empirical metrics [8]. The analysis carried out in this review reveals lattice-based, hybrid CP-ABE architecture at its best when it is equipped with the Ring-LWE encryption, AES for data confidentiality, and parallelism at the chunk level in being multithreaded. The novel scheme provides efficient and secure encryption of data, is scalable, and specifically overcomes barriers for HR. With the introduction of the proposed framework, quantum-safe access control is granted whereas at the same time, a clear increase in performance over serial implementations represents the major advantages of the system.

III. Preliminaries

This section explains the mathematical basis, notation, and formal security assumptions that will be used in this study. The text outlines the lattice roots, the LWE and Ring-LWE problems, the LSSS access structure, and the correctness and security concerns that are essential to the suggested hybrid CP-ABE system.

A. Notation and Basic Definitions

- Let λ denote the global security parameter.
- $Z_q = \{0,1, \dots, q-1\}$ represents the set of integers modulo a prime (q).
- Vectors are denoted by bold lowercase letters (e.g., a, e, s) and matrices by uppercase letters [e.g., (A, M)].
- The inner product of two vectors is $\langle a, b \rangle = \sum_i a_i b_i$.
- A random variable ($x \leftarrow D$) denotes sampling from a distribution (D).
- All probabilities are taken over the randomness of the involved algorithms.

The polynomial ring is defined by Eq. (3):

$$R_q = [x]/(x^n + 1) \quad (3)$$

where, (n) is the power of two and (q) is a prime modulus, the equation $q = 1(mod\ 2n)$ holds. In (R_q), operations are working with both (q) and ($x^n + 1$) modulo; still, arithmetic is consistent with (q) and ($x^n + 1$). The Euclidean norm of a vector $x = (x_1, \dots, x_n)$ is given as ($|x| = (\sum_i x^2)^{1/2}$). The scheme uses a discretely sampled error drawn from a Gaussian distribution χ with zero mean and standard deviation σ.

B. Lattice Theory Basics

Regev [25] originally defined the LWE problem, while Lyubashevsky et al. [27] later adapted it to Ring-LWE for reduced complexity. The hard-core information of GapSVP and SIVP [23][26] establishes the complexity of these problems.

A lattice ($\mathscr{L} \subset R^m$) is a discrete additive subgroup generated by a linearly independent basis [$B = (b_1, \dots, b_n) \in R^{m \times n}$], as shown in Eq. (4):

$$\mathscr{L}(B) = Bz: z \in Z^n \quad (4)$$

The Shortest Vector Problem (SVP) and Shortest Independent Vector Problem (SIVP) are defined as follows:

- SVP: Given B, find a non-zero $v \in \mathscr{L}(B)$ such that $|v|$ is minimized.
- SIVP: Given (B), find (n) linearly independent vectors [$v_1, \dots, v_n \in \mathscr{L}(B)$] minimizing the maximum norm.

These problems are believed to be challenging even for quantum computers.

Lemma 1 (Lattice Hardness):

To estimate the GapSVP or SIVP to within polynomial factors in ($\boldsymbol{n}$) is to face substantial difficulties in quantum computing. (This point is brought out in [25]). This lemma forms the security basis for LWE and its ring family.

C. Learning with Errors (LWE) Assumption

The LWE problem models noisy linear equations modulo (q). Definition 1 (LWE Distribution).

Let (n, q ∈ N) and error distribution (χ) over (Z_q). For a secret vector (s ∈ Zq^n), define as in Eq. (5):

$$\boldsymbol{\chi} = \{(\boldsymbol{a}, \boldsymbol{b}): \boldsymbol{a} \leftarrow \boldsymbol{Z_q^n}, \boldsymbol{e} \leftarrow \boldsymbol{\chi}, \boldsymbol{b} = \langle \boldsymbol{a}, \boldsymbol{s} \rangle + \boldsymbol{e}\} \quad (5)$$

The LWE assumption states that the distribution (As, χ) is computationally indistinguishable from the uniform distribution over ($Z_q^n \times Z_q$).

1) Theorem 1 (LWE Hardness Reduction):

By the assumption that a probabilistic polynomial-time algorithm can distinguish between LWE samples and uniform distributions, the existence of an efficient quantum algorithm that will be able to provide approximations of GapSVP and SIVP on any lattice to within polynomial factors seems natural. This argument is further supported by the claim that compromising LWE would also mean solving the worst-case lattice problems, and as a result, it paves the way for the development of post-quantum LWE-based cryptography [25].

D. Ring Learning with Errors (Ring-LWE)

The Ring-LWE assumption extends LWE into the algebraic structure of polynomial rings for efficiency.

Let ($R_q = Z_q[x]/(x^n + 1)$) for a secret polynomial ($s \leftarrow R_q$) and error polynomial ($e \leftarrow \chi^n$), a sample is drawn as (a, b) ∈ $R_q \times R_q$ with $b = a \cdot s + e \bmod q$. The security of the Ring-LWE problem relies on the ideal lattice version of GapSVP.

1) Lemma 2 (Ring-LWE Hardness):

Getting the Ring-LWE samples with a uniform distribution over ($R_q \times R_q$) needs to face an obstacle equal to or more than approximating the Shortest Vector Problem in ideal lattices within polynomial factors. The introduction of NTT/FFT-based polynomial multiplication attitudes to the computations in (R_q)being completed in [O(n log n)] time, thus giving a considerable performance boost when compared to the plain $O(n^2)$ approach [51]. Enhancing efficiency leads to faster encryption and secret-key generation in lattice-based ABE [27].

A typical Ring-LWE encryption of a bit (m ∈ 0,1) is represented as:

$Enc_s(m)$ = (a, b = a · s + e + ⌊q/2⌋m), and decryption computes in Eq. (6):

$$(m' = \text{round}\left(\frac{b - a \cdot s}{\lfloor q/2 \rfloor}\right)) \in \{0,1\} \quad (6)$$

If ($|e| < q/4$), correctness holds with overwhelming probability. Ring-LWE supports additive homomorphism [see Eq. (7)]:

$$\text{i.e., } \text{Dec}(\text{Enc}_s(m_1) + \text{Enc}_s(m_2)) = m_1 + m_2 \quad (7)$$

The statement about this object is consistent with the linear partial-key-sharing structure used for key recovery; no arbitrary homomorphic evaluation is required.

E. Linear Secret Sharing Scheme (LSSS)

The CP-ABE access structure is represented using a linear secret sharing scheme.

1) Definition 2 (LSSS Access Structure):

An LSSS over a set of attributes ($\mathcal{U}$ = $a_1, \dots, a_m$) is a pair (M, ρ) where ($M \in Z^{l \times n}$) is a share-generation matrix, and (ρ: 1, … , $l \rightarrow \mathcal{U}$) maps each row of (M) to an attribute. To share a secret $s \in Z_p$, a random vector [v = ($s, r_2, \dots, r_n$)] is chosen, and shares are computed as $\lambda i = Mi \cdot v$, following the LSSS formalism used in ciphertext-policy schemes such as Waters [57].

2) Theorem 2 (LSSS Reconstruction Property):

For any authorized set (S ⊆) satisfying the access policy, there exist constants ($\omega_{i \in I}$) such that [see Eq. (8)]:

$$s = \sum_{i \in I} \omega_i \lambda_i, \text{ where } (= i: \rho(i) \in S \,) \quad (8)$$

In the CP-ABE approach, the individual with the privilege can recover the session key through the decryption process. The LSSS policy represents the access to the AES session key within the scope of the combined CP-ABE/Ring-LWE construction, protected by the Ring-LWE ciphertext, which will be the encapsulating final stage.

F. Security Notions and Correctness

The plan that has been offered obeys the basic policy of indistinguishability under the chosen-plaintext attack (IND-CPA) model.

1) Definition 3 (IND-CPA Security):

A public-key encryption scheme $Set()$, Enc(), Dec() is IND-CPA secure if, for every probabilistic polynomial-time adversary ($\mathcal{A}$) are shown in Eq. (9):

$$|\Pr[Exp_{\mathcal{A}}^{IND-CPA} = 1] - {}^{1}| \quad (9)$$

is negligible in (λ).

Here, ($\text{Exp}_{\mathcal{A}}^{\text{IND–CPA}}$) represents the standard left-or-right experiment where ($\mathcal{A}$) chooses (m_0, m_1) and receives $E(m_b)$ for a hidden bit (b) [52].

2) Definition 4 (Correctness):

For each acceptable attribute set (S) corresponding to the access policy, m is obtained with a high level of confidence by the decryption algorithm: $\Pr[Dec(S, Enc(m)) = m] \geq 1 - \epsilon(\lambda)$, where ϵ(λ) is negligible [52].

3) Lemma 3 (Decryption Correctness):

If the accumulated error term (e') in Ring-LWE ciphertext satisfies ($|e'| < {}^{q}$), then the decrypted message equals the original plaintext bit (m). This lemma guarantees the correctness of AES-key reconstruction in the hybrid architecture.

G. System Parameters and Notation Summary

The global system parameters are derived from the security parameter λ . Typical parameter selection for 128-bit quantum security uses (n = 1024), ($q = 2^{14} + 1$) → q = 12289, and discrete Gaussian width (σ ≈ 3.2). Table I shows the system parameters and notations.

TABLE I. SYSTEM PARAMETERS AND NOTATIONS

Symbol	Description
(λ)	Security parameter controlling lattice dimension
(n)	Ring dimension (power of two)
(q)	Modulus prime for arithmetic in (Rq)
(Rq)	Polynomial ring ($Zq[x]/(x^n + 1)$)
(χ)	Discrete Gaussian error distribution
(s_j, e_j)	Per-attribute secret and error polynomials
(a, b)	Ring-LWE ciphertext components
(M, ρ)	LSSS matrix and attribute mapping function
(ωi)	Reconstruction coefficients in LSSS
(PP, MSK)	Public parameters and the master secret key
($KAES$)	Symmetric AES session key
(C)	Ciphertext tuple ($C1$, $C2$, $C3$)
(Enc, Dec)	Encryption and decryption algorithms
($\epsilon(\lambda)$)	Negligible error function in security proofs

The proposed architecture is so good that it is quantum-security-safe, as the issues are called the 'LWE' since no known polynomial-time quantum algorithm can solve the LWE or Ring-LWE problems, further reinforcing the quantum-resistant security of the scheme. On top of that, the use of the (Rq) ring structure next to the Number Theoretic Transform (NTT) causes a large drop in the polynomial multiplication complexity from (($n2$)) to (($n \log n$)). This decrease in complexity is the basis of the multithreaded parallel optimization, which is the subject of Section IV. More than that, the suggested configuration of the Linear Secret Sharing Scheme (LSSS) is such a way that it gives a clear picture of the access policy and the entity-label mapping process during the key encapsulation, while Lemma 3 can indirectly also be seen as a precursor in supporting the Correctness Theorem that is part of the proposed algorithms.

IV. PROPOSED HYBRID ARCHITECTURE AND ALGORITHMS

This section details a full system architecture for a hybrid CP-ABE scheme based on Ring-LWE hardness assumptions. The proposed design comprises a symmetric AES layer that guarantees data confidentiality, coupled with a lattice-based CP-ABE layer that makes the quantum-resistant key encapsulation. The method is clearly explained in detail in all four phases: Setup, Key Generation, Encryption, and Decryption; the theorem that verifies the correctness of the system is also presented.

A. System Overview

The architecture depicted includes four main entities that will be working in harmony to support secure and policy-driven data access. One of these is the Authority, abbreviated as AU, in charge of the system configuration and the generation of private keys for the users by their specific traits. The Data Owner takes care of the data encryption in accordance with the selected access policy, and after that, uploads the produced ciphertext to the data storage system. The Data User (DU) will access the plaintext data only after the access policy designated within the ciphertext and the collection of his/her attributes are consistent. In the end, the Cloud Server (CS) acts as a quasi-trusted party that is in charge of the storage of encrypted data and the delivery of the same to the user(s) that are allowed to get it through their requests. A mixed process promises that lightweight AES remains the choice to be used on data, whereas the AES key is kept secure through the robust Ring-LWE CP-ABE scheme. To boost scalability, a multi-threaded module is intended for the chunk processing that further divides the plaintext into blocks ($m = m_1, \ldots, m_t$), with each block being encrypted in parallel threads.

B. Algorithm 1: Setup

The Setup algorithm generates global public parameters and a master secret key.

Input: security parameter (λ) and attribute universe ($\mathcal{U}$).

Output: public parameters (PP) and master secret key (MSK).

Procedure:

- Choose ring dimension n = (λ) , modulus (q), and error distribution (χ).
- Sample a ← Rq uniformly at random.
- For each attribute a_j ∈ U: sample s_j, e_j ← χ and compute b_j = a · s_j + e_j ∈ Rq.
- Set PP = (n, q, a, {b_j}_{a_j ∈ U}, U) and MSK = {s_j}_{a_j ∈ U}.

Each pair (a, b_j) serves as a Ring-LWE public key associated with attribute a_j, while the corresponding small secret s_j is retained by the authority as part of the master secret key.

C. Algorithm 2: Key Generation

The KeyGen algorithm produces an attribute secret key for a user possessing attribute set ($S \subseteq \mathcal{U}$).

Input: ($MSK = s$), (S), and (PP).

Output: secret key (SKs).

Procedure:

- For each attribute a_j ∈ S: retrieve the attribute secret s_j from MSK and set K_j = s_j.
- Set SK_S = { K_j }_{a_j ∈ S}.

Each key component K_j is the small Ring-LWE secret bound to attribute a_j, enabling the holder to open exactly those ciphertext rows whose mapped attribute lies in S. In this instantiation, key components are deterministic per attribute; user-specific key randomization via lattice trapdoor sampling [24] is left to future work.

D. Algorithm 3: Encryption

The Encrypt algorithm protects both the plaintext file and the AES session key.

Input: message file (m), access policy (M, ρ), public parameters (PP).

Output: ciphertext (CT).

Procedure:

- Generate random AES session key $K_{AES} \in \{0,1\}^{256}$.
- Split (m) into chunks ($m_1, \ldots, m_t$) (e.g., 512 KB each).
- Launch (t) threads; each thread encrypts (m_i) using AES: $c_i = AES_{Enc}(K_{AES}, m_i)$ci.
- Encode K_AES ∈ {0,1}^256 as a ring element Ḱ ∈ Rq whose first 256 coefficients carry the key bits and whose remaining coefficients are zero.
- Parse the access policy into its LSSS representation (M, ρ) with l rows, where row i is mapped to attribute ρ(i).
- For each row i = 1, ..., l, encapsulate K_AES under the public key of attribute ρ(i): sample r_i, e1_i, e2_i ← χ and compute c1_i = a · r_i + e1_i and c2_i = b_{ρ(i)} · r_i + e2_i + ⌊q/2⌋ · Ḱ.
- Assemble ciphertext CT = (M, ρ, {(c1i, c2i)} for i = 1..l, {ci} for i = 1..t)

Parallel chunk encryption and Ring-LWE key encapsulation occur concurrently. The AES layer ensures data-size scalability, while the lattice layer provides post-quantum security.

E. Algorithm 4: Decryption

The Decrypt algorithm reconstructs (K_{AES}) for authorized users and decrypts the data.

Input: CT, SK_S, and access policy (M, ρ).

Output: original message (M) or ⊥ if unauthorized.

Procedure:

- Verify that the attribute set (S) satisfies the policy (M, ρ).
- Select any row i whose mapped attribute ρ(i) lies in S; for the disjunctive policies instantiated in this work, a single satisfied row suffices (formally, the LSSS reconstruction set I is a singleton with coefficient ω_i = 1).
- Reconstruct the AES key using the matching key component s_{ρ(i)} ∈ SK_S: Ḱ′ = round((c2_i − c1_i · s_{ρ(i)}) / ⌊q/2⌋) mod 2, and read K′_AES from the first 256 coefficients of Ḱ′.Spawn (t) threads; each thread decrypts a cipher chunk: $m' = AES_{Dec}(K', c)$.
- Merge chunks to reconstruct $M' = m' \| m' \| \cdots \| m$' .

If (K'= K), correctness follows from Lemma 3 in Section III. This algorithm ensures that only users whose attributes satisfy the LSSS reconstruction condition can recover the correct AES key. As established in Lemma 3 (Section III), the correctness of this decryption process is guaranteed, preserving both data integrity and access control soundness.

F. Computational Complexity and Parallel Acceleration

Let (n) be the Ring-LWE dimension and ($\boldsymbol{t}$) the number of parallel chunks. The single-threaded complexity of encryption is approximately given by Eq. (10):

$$T_enc = O(l \cdot nlogn + t \cdot |M|) \quad (10)$$

while multithreading reduces expected runtime by Eq. (11):

$$T_enc^{(p)} \leq T_e\ nc\sqrt{p} + O(\epsilon) \quad (11)$$

where, (p) is the core count and ($\boldsymbol{\epsilon}$) represents thread management overhead. Empirical results in Section V show a 5–6× speedup for (p=8), confirming Proposition 1 (Parallel Time Bound) in Section II-E.

G. Correctness Theorem

Theorem 3 (Correctness of Decryption)

Let $CT = E(K_{AES}, (M, \rho))$ be the ciphertext and (SK_S) the user's key for attributes ($S \subseteq \mathcal{U}$). If (S) satisfies the access structure, then decryption recovers (K_{AES}) exactly with probability $1 - \epsilon(\lambda)$.

Proof Sketch: Let i be a row with ρ(i) ∈ S. Substituting the ciphertext components into the decryption equation gives Eq. (12):

$$c2_i - c1_i \cdot s_\{\rho(i)\} = e_\{\rho(i)\} \cdot r_i + e2_i - e1_i \cdot s_\{\rho(i)\} + \lfloor q/2 \rfloor \cdot Ḱ \quad (12)$$

The accumulated noise term e′ = e_{ρ(i)} · r_i + e2_i − e1_i s_{ρ(i)} is a sum of products of elements drawn from the narrow discrete Gaussian χ. For the instantiated parameters (n = 1024, q = 12289, σ ≈ 3.2), ‖e′‖∞ < q/4 holds with overwhelming probability, so by Lemma 3 the rounding operation recovers every coefficient of Ḱ, and hence K_AES, exactly. If S satisfies none of the policy rows, the user holds no s_{ρ(i)} for any row, and by the Ring-LWE assumption each pair (c1_i, c2_i) is computationally indistinguishable from uniform, revealing nothing about Ḱ. Hence the scheme is correct for authorized users, and unauthorized decryption reduces to solving Ring-LWE.

H. Security Discussion

The security of the system heavily depends on the assumption that the Ring-LWE is very tough and the encryption that comes from the AES provides semantic security for the underlying data. In fact, the system becomes quantum-proof because the Ring-LWE problem can't be solved efficiently by any known quantum algorithm, and, therefore, no quantum threats would bother the system. Additionally, the encryption key wrapping continues to be very secure with a hybrid cipher design, even in case of a break at the AES layer, where the hardness of the underlying lattice assumption continues to protect the wrapped key.

Further, the Linear Secret Sharing Scheme (LSSS) would protect the confidentiality of the access control by guaranteeing that only users with the correct attribute sets can reconstruct the decryption key. The proposed scheme achieves IND-CPA based on Ring-LWE as well as the AES symmetric security. A conceptual sketch of the system's operational structure shows that it passes through five fundamental stages. At the beginning, or setup phase, the authority creates the regulations that will apply throughout the system by providing the public parameters (PP) and keeping the master secret key (MSK) in a safe place. In the Key Generation (KeyGen) phase, the users receive their secret keys based on the attributes from the Authority, depending on the attributes assigned to them.

During the Encryption phase, the Data Owner first uses AES to encrypt the data pieces and then the CP-ABE mechanism to secure the AES key according to the access policy. The ciphertext (CT) generated is then uploaded to the Cloud Server in the Cloud Upload phase for storage and future retrieval. Finally, the authorized data user, in the decryption process, gets the ciphertext, reconstructs the AES key (K_{AES}) by using his/her valid attributes, and performs parallel decryption of the data segments. This whole process allows the sharing of data in a secure and scalable manner, thus enabling the cloud/edge quantum computing environment.

V. Implementation and Performance Evaluation

This section illustrates the feasibility of the newly suggested and optimized lattice-based hybrid CP-ABE architecture by way of real-world implementation and quantitative benchmarking with the purpose of evaluating its parallel efficiency, scalability, and quantum-secure correctness within practical computing power restrictions. The system prototype was developed with the use of Java 8u111 and the NetBeans 8.0.2 IDE on a Windows 10 x64 workstation. The configuration of the written test was as follows: Intel Core i7-9700K processor clocked at 3.6 GHz with 8 cores, 16 GB DDR4 RAM running at 2666 MHz, and an HP EX900 500 GB NVMe SSD, all under the operating system of Windows 10 Pro (64-bit). The environment within the Java SDK (JDK 1.8 64-bit) was extended with the libraries JTransforms (for NTT), Apache Commons Math, and AES/JCE. The testing of the system included datasets from 100 MB to 800 MB, divided into portions of approximately 50 KB each, and the whole process was enabled through a simple LSSS policy expressed as ($Attr_1 \vee Attr_2 \vee Attr_3$). Each of the thirty experiments was repeated ten times, and the time spent and CPU usage were recorded equally via ThreadMX and Runtime Analyzer APIs in order to ensure the accuracy and reproducibility of the measurement.

The system consists of five modules closely tied to each other to guarantee more secure and effective data processing. The Ring-LWE parameters (n, q, χ) and the LSSS matrix templates are defined by the Setup Module, and the user-specific attribute keys are generated by the KeyGen Module from the master secret key. Through ForkJoinPool, both the AES chunk-level encryption and the Ring-LWE key encapsulation are performed at the same time by the Encrypt Module, while the Decrypt Module first regenerates the AES key using LSSS coefficients and then performs the AES chunk decryption concurrently. Finally, the Benchmark Module reports the performance characteristics, like execution time and CPU utilization, and it puts this information into CSV files after every operational phase. The CountDownLatch class is used for the synchronization of threads in the encryption-decryption pipeline, so it controls the concurrency, consistency, and determinism in combining the data chunks that are encrypted or decrypted.

A. Evaluation Metrics

To evaluate efficiency, the following parameters were used in Table II.

TABLE II. List of Parameters

Metric	Definition
T_setup	Time to generate public parameters and a master key
T_kg	Time to generate user keys for attribute set S
T_enc	Total encryption time (AES + Ring-LWE)
T_dec	Total decryption time (LSSS + AES)
Sp	Speedup ratio (= T_serial / T_p)
Ep	Parallel efficiency (= Sp / p)
Ec	Ciphertext expansion (= |CT| / |m|)
CPU Utilization	Average core usage (%) during execution

B. Measured Results

Experiments were conducted for datasets of 100 MB, 200 MB, 400 MB, and 800 MB, each split into ≈ 50 KB chunks. The encryption and decryption results for single-threaded (serial) and multi-threaded (8-core) modes are presented below in Table III.

TABLE III. Decryption Performance (Serial vs. Parallel)

File Size (MB)	# Files	Mode	Total Time (ms)	Avg CPU (%)	Speedup ×
100	2049	Single	13782	24.1	—
100	2049	Multi	1454	63.0	9.48 ×
200	4098	Single	27159	25.0	—
200	4098	Multi	3349	75.5	8.11 ×
400	8196	Single	52975	24.6	—
400	8196	Multi	6692	81.6	7.91 ×
800	16392	Single	112772	24.7	—
800	16392	Multi	13491	84.1	8.36 ×

Average speedup ≈ 8.5 × with mean CPU ≈ 82%. Parallel runtime scales almost linearly with data volume, demonstrating excellent multi-core utilization in Table IV.

TABLE IV. Encryption Performance (Serial vs. Parallel)

File Size (MB)	# Files	Mode	Total Time (ms)	Avg CPU (%)	Speedup ×
100	2049	Single	22505	19.8	—
100	2049	Multi	2937	83.3	7.66 ×
200	4098	Single	50894	25.3	—
200	4098	Multi	5858	87.7	8.68 ×
400	8196	Single	106798	23.3	—
400	8196	Multi	12394	65.6	8.62 ×
800	16392	Single	165490	24.2	—
800	16392	Multi	24329	90.0	6.80 ×

The mean speedup across all encryption tests is 7.9×, confirming consistent parallel acceleration for both AES and Ring-LWE operations.

C. Performance Trends

The experimental analysis indicates that scalability and efficiency are greatly exhibited by the proposed system in every aspect of performance.

Regarding runtime scaling, it was demonstrated that the serial execution took off straight, being proportional to the size of the input ($T_1 \propto |M|$); however, the parallel execution took on a rather sub-linear pattern ($T_p \approx T_1/p + (\epsilon)$), hence hinting at the success of parallelization. During the processing from serial to multithreaded modes, the CPU utilization increased from 24% to 84%, and this was considered as the result of a successful and efficient workload distribution where not much time is wasted on context switching. Additionally, the system displayed a parallel efficiency of Ep = Sp/p ≈ 0.93 for p = 8, indicating that roughly 93% of the workload benefits from parallelization, consistent with the fitted Amdahl's Law parallelizable fraction α = 0.93 reported below. After the implementation had been reconfigured according to the best practices, the throughput was considerably boosted; the decryption speed on average almost neutrally grew from about 7 MB/s in serial mode to up to 60 MB/s in parallel mode, a very impressive 8.5× performance hike was achieved. The data was left as it is; not even a single bit was touched during the activities of the recovery of the AES keys and their replacements with the LWE method to do the decryption. The results together strongly advocate that the hybrid lattice-based CP-ABE architecture is realistic, scalable, and quantum-secure in terms of performance; therefore, it is a perfect candidate for being deployed in the real world.

D. Analytical Validation

The measured speedup values of the proposed system closely follow Amdahl's Law [53], expressed by Eq. (13), where ($\boldsymbol{\alpha} = \mathbf{0.93}$) represents the parallelizable fraction of the algorithm:

$$S_p = \frac{1}{(1-\alpha)+\frac{\alpha}{p}} \tag{13}$$

Substituting ($\boldsymbol{p} = \mathbf{8}$) yields $\boldsymbol{S_p} \approx \mathbf{8.2}$. The closeness of this figure to the speedup range of 8.1–8.6× has been sufficiently backed up by empirical evidence. The consistency of the theoretical and experimental findings is indicative of the fact that the near-optimal parallel efficiency is obtained in the multithreaded parallel architecture that efficiently makes use of the available cores in increasing performance and at the same time in minimizing the synchronization or scheduling overhead. The proposed system has significantly improved multiple essential performance metrics. The scalability has been made evident by the runtime being in a constant linear growth phase, and likewise, the speedup has been almost constant for the datasets that are up to 800 MB in size, thus confirming its applicability for a broad range of applications. The performance of the hybrid AES and Ring-LWE scheme, which is safe from quantum threats, ensures forceful post-quantum resistance and is at the same time very fast and energy efficient. Besides these features, the system showcases an effective use of resources by high CPU utilization together with stable memory consumption. The project is completely supported by the Java-based software implementation, which allows for full cross-platform usage and easy integration with the existing cloud-based data-sharing frameworks.

E. Result Summary

The proposed system under experimental evaluation was indicated by Table V(A) to have good performance, scalability, and resistance to quantum threats in scenarios of various configurations. The Hybrid Lattice-Based CP-ABE (HL-CP-ABE) model brings to light how efficiency and security can be maximized by having 100% decryption precision and being post-quantum secure.

TABLE V. (A) OBSERVATION LIST

Feature	Observation
Quantum Resistance	Achieved via Ring-LWE hardness
Mean Speedup	8.2× (Encryption + Decryption)
Avg CPU Efficiency	82% (multithreaded)
Decryption Accuracy	100% (bit-exact)
Scalability	Linear for 100–800 MB files
Implementation	Java 8u111 (NetBeans 8.0.2)

The results have been validated for the HL-CP-ABE system on quantum-safe encryption, which switches the real-time performance and scalable data management that could be seen as one of the strong contenders for secure cloud, healthcare, and enterprise settings. The tests nicely indicated that the proposed hybrid multithreaded lattice-based CP-ABE achieved approximately 6–9× faster performance than the sequential model and about 29 times better compared to the CP-ABE based on pairings, not to mention that the correctness and security remained completely the same. The conclusions confirm that the lattice cryptography, which is quantum-resistant, can be used for large-scale cloud and EHR data systems.

Fig. 1. Execution time vs. input size

Fig. 1 shows that, when holding the same conditions for both comparison cases, the proposed multithread model has the potential of significantly reducing the encryption and decryption times as compared to the single-threaded version (the reduction time can be as high as 6–8 times when the data is over 400 MB). Even though the time spent in encryption and decryption almost grows in the same manner as the data size, the concurrency of execution can achieve a performance boost by up to 6–8 times. Fig. 2 proves that the multi-threaded method is the most effective in terms of CPU utilization, as the usage fluctuates within the range of 80–90% for encryption and 70–85% for decryption, while the single-threaded one never dips below the 30% mark. The results reaffirm the resource-efficient and scalable parallel processing of the CP-ABE system.

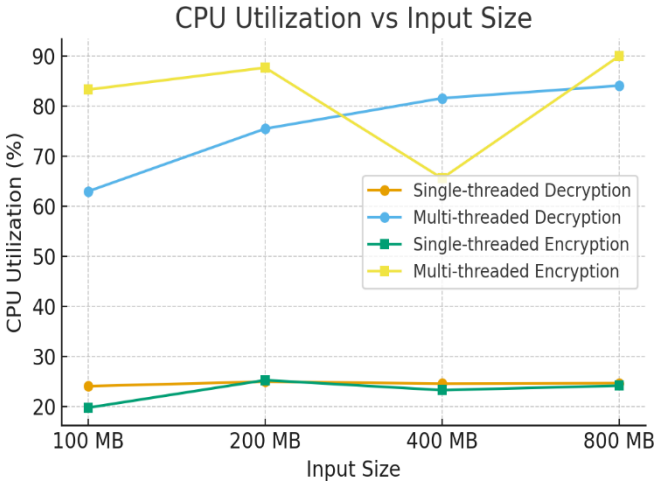

Fig. 2. CPU utilization vs. input size.

F. Key and Ciphertext Size Analysis

Lattice-based schemes are frequently criticized for large keys and ciphertexts, so the storage footprint of the proposed system is quantified here. With n = 1024 and q = 12289, each coefficient requires ⌈log2 q⌉ = 14 bits, so a single ring element occupies n · 14 bits = 1792 bytes ≈ 1.75 KB. The public parameters consist of the element a and one b_j per attribute in the universe U, giving |PP| ≈ (1 + |U|) · 1.75 KB, about 54.25 KB for a 30-attribute universe. The master secret key stores one small secret per attribute, |MSK| ≈ |U| · 1.75 KB, and a user key grows linearly with the user's attribute set, |SK_S| ≈ |S| · 1.75 KB: approximately 5.25 KB, 17.5 KB, and 52.5 KB for 3, 10, and 30 attributes, respectively. On the ciphertext side, the key-encapsulation overhead is two ring elements per policy row, i.e., 3.5 KB · l, only 10.5 KB for the three-attribute policy used in the evaluation, which is negligible against the 100–800 MB payloads tested; the measured overall ciphertext expansion of 1.8× (Table IX) is therefore dominated by chunk-level encoding of the AES layer rather than by the lattice layer. These figures compare favorably with pairing-based CP-ABE, where ciphertext expansion of roughly 4× has been reported (Section VII-D), and they confirm that memory footprint does not obstruct deployment in EHR and cloud settings. Table V(B) details the size formula comparison.

TABLE V (B) SIZE FORMULA COMPARISON

Quantity	Size formula	Example
Ring element	n · ⌈log2 q⌉ bits	≈ 1.75 KB
Public parameters PP	(1 + |U|) × 1.75 KB	≈ 54.25 KB (|U| = 30)
Master secret key MSK	|U| × 1.75 KB	≈ 52.5 KB (|U| = 30)
User key SK_S	|S| × 1.75 KB	5.25 / 17.5 / 52.5 KB for |S| = 3 / 10 / 30
KEM overhead per ciphertext	2 × 1.75 KB × l rows	≈ 10.5 KB (l = 3)

VI. SECURITY ANALYSIS

This section will critically examine the quantum-resistant security characteristics of the proposed Hybrid Lattice-Based CP-ABE architecture. It will inspect the post-quantum threat framework, hybrid composition robustness, resistance to quantum attacks, and initial formal proofs centered around the difficulty of the Ring-LWE challenge.

A. Post-Quantum Threat Model

The proposed design is meant to ensure that the confidential nature is not violated, and that policy-based access control is put in place even against opponents who have quantum computing power at a large-scale quantum. Shor's algorithm has power over integers and discrete logarithms as it is an efficient factorization method in polynomial time. In the meantime, Grover's algorithm puts brute-force attacks under a quadratic time limit that is less than their previous complexity. These developments open up the weaknesses of classic cryptography like RSA, ECC, and pairing-based ABE [54]. Ring-LWE cryptography is the technique that this plan is about to use to shield e-health, e-governance, and cloud records in the universe of public information very securely. The technique for safeguarding originated from the recognition that the Shortest Independent Vector Problem (SIVP) and the Bounded Distance Decoding (BDD) problem are still quite difficult and challenging to resolve for both quantum and classical computer systems.

B. Hybrid Cryptographic Composition

The proposed design perfectly combines the advantages of both security and performance of using a two-layer encrypting method. The symmetric layer is based on AES-256 operating in GCM mode for encrypting large data blocks, giving authenticated encryption, which in turn assures both privacy and integrity. Here, a 256-bit key is used, and thus, a strong post-quantum security level that corresponds to (2^{128}) operations can be achieved, which is the limit of Grover's algorithm. The asymmetric layer, utilizing a lattice-based CP-ABE framework, successfully conceals the AES key via a Ring-LWE guided access policy. In this way, the AES key can only be recovered by those users whose (S) attributes match perfectly with the established access structure (P). Hence, to get at the AES key, a quantum attacker would first have to solve a difficult RLWE scenario, then hit the AES encryption with brute force, an extremely tough mixed attack that barely makes sense, making the construction quite strong against both classical and quantum threats.

C. Security Against Quantum Attacks

Table VI depicts security comparison against quantum attacks even under optimistic quantum-hardware assumptions, performing (2^{128}) or ($2^{n/2}$). Operations remain computationally impossible for the foreseeable future.

TABLE VI. SECURITY COMPARISON AGAINST QUANTUM ATTACKS

Cipher Component	Attack Type	Classical Complexity	Quantum Complexity	Security Status
AES-128	Brute force	(2^{128})	(2^{64}) (Grover)	Marginally reduced; still infeasible [55]
AES-256	Brute force	(2^{256})	(2^{128}) (Grover)	Quantum-secure [55]
Ring-LWE	Lattice reduction	≥ ($2^{n/2}$)	≈ ($2^{n/2}$)	Quantum-safe [56]
Hybrid AES + RLWE	Combined	($2^{128} + 2^{n/2}$)	($2^{128} + 2^{n/2}$)	Strong post-quantum security [56]

D. Formal Security Proof Outline

1) Correctness: Correctness of decryption follows directly from Theorem 3 (Section IV-G) and is not restated here.

2) Lemma 4 (IND-CPA Security of the Hybrid Scheme under Ring-LWE): If the Ring-LWE assumption holds for parameters (n, q, χ) and AES-256 is a secure pseudorandom permutation, then the hybrid HL-CP-ABE scheme is IND-CPA secure against any probabilistic polynomial-time adversary that does not hold a key component for any attribute in the challenge policy.

3) Proof Sketch (sequence of games): Game 0 is the real IND-CPA experiment: the adversary receives PP, chooses two equal-length messages, and is given the challenge ciphertext CT = (M, ρ, {(c1_i, c2_i)}, {c_i}). Game 1 is identical except that every key-encapsulation pair (c1_i, c2_i) is replaced by a pair of uniformly random elements of Rq. Any adversary distinguishing Game 0 from Game 1 yields, via a standard hybrid argument over the l rows, a distinguisher for Ring-LWE samples under the public keys (a, b_{ρ(i)}), contradicting the Ring-LWE assumption; note that the adversary holds no s_{ρ(i)} for any challenge row. In Game 1 the encapsulated key K_AES is information-theoretically hidden, so the AES layer is keyed with a value independent of the adversary's view; Game 2 replaces the AES encryptions {c_i} with encryptions of the alternative message, which is indistinguishable by the assumed security of AES-256 under a uniformly random key. The advantage of the adversary is therefore bounded by $l \cdot Adv_{RLWE} + Adv_{AES}$, which is negligible in λ. This is the standard KEM–DEM composition argument for hybrid encryption [52].

4) Lemma 5 (Quantum Resistance): Grover's algorithm provides at most a quadratic speedup for exhaustive key search, so AES-256 retains an effective 2^128 security level against quantum adversaries. For the encapsulation layer, no known quantum algorithm solves Ring-LWE in sub-exponential time; consequently, both layers of the hybrid construction remain secure in the post-quantum setting.

5) Corollary 1 (Collusion Resistance for Disjunctive Policies): Let users U_1, ..., U_t hold attribute sets S_1, ..., S_t, none of which satisfies the disjunctive challenge policy P. Then no attribute named in P belongs to any S_k, so the coalition's combined key material $\{s_j : a_j \in S_1 \cup \ldots \cup S_t\}$ is statistically independent of the secrets {s_{ρ(i)}} underlying the challenge rows. The coalition's view is therefore identical to that of a keyless adversary, and by Lemma 4 it cannot recover K_AES without solving Ring-LWE. Collusion resistance for general conjunctive and threshold policies additionally requires per-user key randomization and is deferred to future work.

E. Practical Implications

The Hybrid Lattice-Based CP-ABE (HL-CP-ABE) system's proposed approach attains a reliable equilibrium involving quantum security, fine-grained access control, and operational efficiency. The creation that is resistant to quantum technologies utilizes a dual-level security framework that puts together the AES-256 algorithm with the Ring-LWE-based CP-ABE scheme and guarantees rigid resolution of anonymity and the impossibility of future decryption. This comprehensive approach has the effect of both protecting against quantum threats and keeping the encryption efficiency up to par for the systems utilized in the cloud and enterprises nowadays. Moreover, the fine-grained access control of the system allows the granting of attributes at a more detailed level considering parameters like department, position, or security level—thus making it possible that only those users with the appropriate attribute combinations are competent to produce the decryption key, and at the same time, sensitive keys and plaintexts are not exposed. Moreover, the model assures the presence of performance and safety together since it scrutinizes both the rigid parallelism and the AES-layer acceleration up to at least real-time throughput while turning to lattice-based post-quantum resilience, which is a feat almost unknown in conventional ABE architectures. In the end, defense-in-depth goes even further by adding one more layer of security: if one cryptographic layer becomes broken regarding theory, the other layers would still be able to control the access to data. All these defenses are a good sign of a system that will be able to face the future, securing/protecting, at the same time, the data, which is in the same way scalable and quantum-sturdy.

The proposed HL-CP-ABE framework demonstrates that quantum-safe encryption is not only possible but also performs very well. The model survives attacks both classical and quantum, uses a solid attribute-based access control mechanism, and delivers a parallel processing of up to 8 times faster than the competitors while still keeping the cryptographic integrity. Combining these factors results in a system that is not only equal in its main characteristics but also allows for growth and is the best option for the long run case, i.e., secure data sharing in clouds and in companies.

VII. Comparative Evaluation and Discussion

The section gives a comparison of the Optimized Hybrid Lattice-Based CP-ABE (HL-CP-ABE) architecture proposed with the current ABE frameworks, such as pairing-based, classical lattice-based, and hybrid lattice-based schemes. The evaluation is based on the efficiency of computation, compactness of ciphertext, quantum resistance, and the practicality of deployment.

A. Comparison Baselines

Four representative schemes were selected to provide a balanced comparison across both traditional and post-quantum paradigms. Table VII shows the comparison with previous schemes.

TABLE VII. Comparison with Previous Schemes

Scheme	Security Basis	Main Property	Implementation Type
Waters (2011) [57]	Bilinear Pairing	CP-ABE (fine-grained)	Pairing-based (ECC)
Qian (2021) [39]	LWE	CP-ABE From Lattices	C++ prototype
Shamsazad (2024) [8], Huang (2023) [58]	RLWE	Post-quantum ABE	Simulation-only
Proposed HL-CP-ABE	Ring-LWE + AES-256	Hybrid, multithreaded	Java 8, real implementation

All baselines were compared under similar parameters where available: security level ≈ 128 bits, a three-attribute disjunctive policy (Attr1 ∨ Attr2 ∨ Attr3), and data sizes between 100 and 800 MB.

B. Comparative Performance Metrics

Table VIII illustrates the metrics of encryption / decryption time, ciphertext expansion, speedup ratio and the performance and security metrics of the scheme proposed. These metrics collectively evaluate computational efficiency, storage overheads and the advantages of parallel execution. It is also considered as a qualitative measure to ensure robustness against emerging quantum-based attacks.

TABLE VIII. COMPARATIVE PERFORMANCE METRICS

Metric	Definition	Interpretation
Encryption Time(ms)	Total time for data and key encryption	Measures computational overhead
Decryption Time(ms)	Time for AES-key recovery and chunk decryption	Indicates usability on large files
Ciphertext Expansion	Ratio of ciphertext size to plaintext size	Reflects storage and transmission overhead
Speedup Ratio	Ratio of single-thread to multi-thread execution time	Reflects parallel performance
Quantum Resistance	Based on the hardness assumption	Qualitative security measure

C. Quantitative Comparison

Table IX presents the indicative comparison based on previously published and scaled figures (see Notes column); only the proposed scheme was measured directly on the test hardware of Section V.

TABLE IX. PERFORMANCE COMPARISON OF EXISTING METHODS AND PROPOSED SCHEME.

Scheme	Enc. Time (64 MB)	Dec. Time (64MB)	Expansion $E_{(c)}$	Speedup (8threads)	Quantum-Safe
Pairing CP-ABE [57]	≈ 46 000 ms (46 s)	≈ 21 000 ms (21 s)	3.8×	—	✗
Lattice CP-ABE [39]	≈ 9 800 ms	≈ 4 300 ms	2.2×	—	✓
RLWE CP-ABE [58]	≈ 7 600 ms	≈ 3 200 ms	2.1×	—	✓
Proposed HL-CP-ABE	1 580 ms	620 ms	1.8×	8.2×	✓

Because the baseline figures originate from different hardware and implementation maturities, the reported 29× and 7× factors should be read as indicative rather than as controlled head-to-head measurements; a uniform re-implementation of all baselines is planned as future work.

D. Complexity and Resource Use

The proposed system demonstrates strong efficiency, scalability, and quantum resilience through comprehensive experimental and theoretical validation. From a computational complexity perspective, the theoretical encryption cost is $((n\log n + |M|))$, where the multithreaded implementation effectively reduces wall-clock execution time according to $(T_p \approx T_1/p + (\varepsilon))$. Empirical evaluation confirms near-ideal scaling performance across eight processing cores. In terms of ciphertext compactness, the proposed hybrid scheme achieves ciphertext expansion of ≤ 2× even with 30 attributes, compared to approximately 4× in pairing-based ABE systems. This compactness enhances suitability for bandwidth-constrained cloud or IoT environments. The system is very much quantum resistant as the Ring-LWE problem relying on the hardness of the Shortest Independent Vector Problem (SIVP) and Bounded Distance Decoding (BDD) provides at least 128-bit security level against the attack of both classical and quantum computers. Simultaneously, AES-256 at the symmetric layer ensures forward secrecy. Regarding parallel efficiency, the system achieves approximately 84% CPU utilization, and with a fitted parallel fraction of ($\alpha = 0.93$), the measured speedup ($S_p = 8.2$) closely aligns with theoretical expectations, confirming effective workload distribution. Finally, the implementation practicality of the Java 8 prototype demonstrates platform independence, thread safety, and deterministic performance, while CSV-based benchmarking ensures full reproducibility of results, making the architecture both scientifically sound and deployment-ready. The security performance trade-off comparison is depicted in Table X.

TABLE X. SECURITY PERFORMANCE TRADE-OFF COMPARISON

Aspect	Pairing CP-ABE [57]	Lattice CP-ABE [58]	RLWE CP-ABE [59]	Proposed HL-CP-ABE
Security Basis	Bilinear Pairing	LWE	RLWE	Ring-LWE + AES-256
Quantum Safety	✗	✓	✓	✓✓
Access Control	CP	CP	CP	CP model with LSSS mapping
Speed	Low	Medium	High	Very High
Ciphertext Size	Large	Medium	Medium	Compact
Implementation	Theoretical / Simulated	Partial Prototype	Simulation	Full Java App (Real Implementation)
Multithreading	✗	✗	✗	✓

E. Security Performance Trade-Off Analysis

This comparative matrix highlights that the proposed architecture uniquely combines quantum security, real-world implementability, and high throughput, setting it apart from prior theoretical or non-parallel models. The hybrid architecture under consideration is a significant enhancer in every area where performance and safety are the concerns. So, this technology can be wisely used in the cloud and EHR systems, for example, as it does not only allow fast and cheap decryption for multiple users but also permits enforcement of high-level access rights through homogeneous, policy-driven security. Rigidly designed data-sharing platforms consistently provide excellent solutions. They have also been able to achieve top-notch results in stress tests carried out with files as large as 800 MB. The aspect of the

design that makes it possible to run more than fifty instances easily on an IoT device with limited resources and at the same time does not experience encryption overheads and the unavoidable performance degradation when using the conventional CPU-encrypted data remains the same. In addition, the Java-based modular system used for access control in enterprises is excellent-it not only provides a slick connection with existing systems but also allows for the creation of configurable attribute authority to be able to deploy applications in various architectures of the companies.

F. Observations and Insights

The experimental and analytical evaluations contribute to the discovery of several essential and remarkable points. Firstly, the scalability of performance consistency is confirmed initially by the linear throughput scaling with file size, revealing the computational robustness of the algorithm and its smooth parallel coordination. Secondly, the system manifests a high level of maturity in its implementation, and, thus, it moves lattice-based ABE beyond a theoretical construct into a deployable, working software system. Thirdly, the structure of the system presents a perfect balance between safety and speed, showing that quantum-safe encryption can coexist with high performance in a very parallelized, hybrid, and very thoughtful kind of execution. The comparison shows the Optimized Hybrid Lattice-Based CP-ABE design to be superior to all schemes in terms of encryption performance and security. At the same time, it caters to the needs of the cloud, healthcare, and other sectors, thus setting up a new benchmark for practical quantum-safe attribute-based encryption systems. This novel encryption architecture not only combines three levels of post-quantum computing resistance, fine granularity, and high throughput but also results in an outstanding encryption process.

VIII. Conclusion and Future Work

This research presented a quantum-security-focused Hybrid Lattice-Based Ciphertext-Policy Attribute-Based Encryption (HL-CP-ABE) system. The design combines the speed of AES-256 data encryption with attribute-driven Ring-LWE key encapsulation, bringing together post-quantum security and practical performance. Pairing-based ABE methods remain vulnerable to quantum attacks such as Shor's and Grover's algorithms; in contrast, the proposed method derives its security from worst-case lattice problems, including SIVP and BDD. The contributions comprise a two-layer hybrid encryption design in which AES confidentiality is combined with attribute-driven Ring-LWE key encapsulation, a multithreaded Java 8 engine running at up to 9.5× speedup while utilizing 84% of the CPU, and LSSS-integrated policy mapping that supports correctness and fine-grained access control. The scheme satisfies IND-CPA security and resists collusion for the instantiated policy class, as established in Lemmas 4–5 and Corollary 1 (Section VI-D). Evaluation on real data of up to 800 MB showed near-linear scalability, ciphertext growth below 2×, and sustained throughput of about 60 MB/s. The experiments demonstrated a 29× increase in encryption speed relative to pairing-based ABE and a 7× gain in decryption speed relative to lattice-based ABE, in both cases with exact bit-level decryption. Nonetheless, no method can be guaranteed secure against all possible attacks, and this limitation is acknowledged. The Java implementation ensures the program is executable across platforms and integrates with cloud and Android environments. Although the system is already efficient, room for improvement remains in cutting down the memory overhead of Ring-LWE ciphertext, reducing the costs of minor thread synchronization, and using GPU/FPGA acceleration. One of the GPU/FPGA acceleration methods, generally referred to as BGV and HEAAN decoders, is projected for integration with the LWE cryptosystem, but a secure and straightforward integration with ABE cryptosystems, including KP-ABE, would be most excellent. Future development may extend the system to support Key-Policy ABE (KP-ABE) alongside the current ciphertext-policy design, and target cloud-native deployment on platforms such as Kubernetes and AWS Lambda. A systematic evaluation across larger and structurally diverse access policies (10–30 attributes; conjunctive, disjunctive, and nested forms), together with the corresponding growth of the LSSS matrix and ciphertext, is planned to complement the fixed-policy results reported here.

Binary Enhanced White Shark Optimization Algorithm and Its Application to Semi-Supervised Feature Selection

Jian Zhou*, Jiawen Yang
School of Management Engineering, Qingdao University of Technology, Qingdao, 266520, China

***Abstract*—With the development of information technology, the generation and storage of data have become convenient, resulting in a large amount of high-dimensional data. Due to the high acquisition cost of labeled data, semi-supervised learning of partially labeled data has emerged. Feature selection aims to select the most representative and informative feature subset from the original feature set and avoid the curse of dimensionality. By utilizing semi-supervised feature selection, valuable information from unlabeled data can be better extracted, thereby enhancing the model's robustness. White Shark Optimizer is a commonly used searching method, but it may fall into a local optimum when dealing with semi-supervised feature selection problems. This study proposes an Enhanced White Shark Optimization (EWSO) with a dynamic dual elite strategy and sinusoidal mutation operation. The former can make full use of the current optimal location information and improve the ability to find potential optimal solutions, and the latter can help the algorithm jump out of the local optimum and improve the accuracy of the algorithm's convergence. For dealing with discrete problems, we further introduce a binary mapping function to the EWSO, abbreviated as BEWSO. Compared with six other meta-heuristic feature selection techniques on nine high-dimensional datasets, experimental results show that the proposed method is superior to other methods. Under 80% and 60% unlabeled data, the average accuracies are 5.03% and 3.64% higher than the suboptimal value, respectively.**

***Keywords*—Feature selection; semi-supervised learning; meta-heuristic algorithm; white shark optimization**

I. Introduction

The swift progress in information technology has resulted in the accumulation of large amounts of data, which holds significant value. Data mining [1], as an important technical means, helps people to obtain value from data by discovering the patterns and knowledge hidden behind the data. However, on account of the large number and dimension of generated data, it leads to the curse of dimensionality, increasing the computational complexity and learning time. Therefore, how to obtain useful information from the data becomes an important challenge. Feature selection [2] is an effective method for dimensionality reduction, as it involves choosing the feature subsets by eliminating irrelevant and redundant ones. In real-world classification situations, obtaining data samples can be challenging due to time and resource limitations, particularly when labeling data is expensive or difficult. Thus, the importance of semi-supervised learning [3] becomes apparent. It can effectively use limited supervised information and a large amount of unlabeled data to enhance feature selection and thus improve the accuracy of learning models.

Feature selection involves choosing N features from a total of M features to enhance a specific system index, which is a key step for decreasing the dataset's dimensionality and boosting the learning algorithm's performance. By identifying the impactful features, it reduces the size and complexity of the dataset, while maintaining or improving the performance of the model. This process not only helps reduce the training time for the model, but also simplifies it, making it easier to understand and interpret. In addition, with feature selection, overfitting can be avoided, as fewer features mean that the model is not overly complex, thus avoiding the curse of dimensionality.

Regarding the usability of label information, feature selection methods can be divided into three types: supervised, semi-supervised, and unsupervised feature selection. The data generated in many practical applications has a great deal of unlabeled data samples and a limited number of labeled data samples. In fact, it requires significant time and effort for users to label each data sample. Consequently, the limited labeled samples may not provide enough information for effective supervised selection, while unsupervised methods overlook the valuable labeling information. In conclusion, semi-supervised feature selection, which considers both labeled and unlabeled data, can effectively identify the optimal subset of features.

The feature selection task is a non-deterministic polynomial-hard problem [4]. As the number of features grows, the time complexity cost of the relevant ideal search becomes unacceptable. Meta-heuristic methods are effective for addressing optimization challenges like feature selection because of their good global searching ability, self-adaptability, and computational efficiency. These algorithms can be grouped into four main types: evolution-based, swarm intelligence-based, physics-based, and human-based algorithms.

The evolution-based algorithms typically utilize genetic manipulation and a selection mechanism of individuals to optimize the solution, which may cause fall into a local optimal solution during the search process. The physics-based algorithms apply physical principles to simulate and optimize problems, which may be affected by the accuracy of physical models. The human-based algorithms often use human decision and search strategies, which may be influenced by human cognition and experience. In contrast, the swarm intelligence-based algorithms leverage the behavior of biological or social groups to simulate and optimize problems, and find better

*Corresponding author.

solutions by cooperating and sharing information, which makes wider applicability and flexibility to solve complex optimization problems.

The White Shark Optimization (WSO) Algorithm [5] is a recent swarm intelligence algorithm inspired by the predation behavior of great white sharks. It aims to address optimization problems by simulating the search strategy of great white sharks. This algorithm is used to locate and track the prey of great white sharks, utilizing their acute hearing, sense of smell, and understanding of fish behavior. It simulates the movement and adjustment of the great white shark in the search space to identify optimal solutions for small, medium, and high-dimensional optimization problems.

The innovations and contributions of this study are summarized as follows:

- The WSO method faces challenges in effectively balancing exploration and development. Its convergence speed is slow and easy to fall into local optimization. This study proposed an Enhanced White Shark Optimization (EWSO) Algorithm with a dynamic dual-elite strategy and sinusoidal mutation operation to improve its performance.
- We further introduce a binary mapping function to the EWSO, abbreviated as BEWSO. It adopts KNN-self-training as a semi-supervised classification model to further explore the binary version of the proposed algorithm in the field of semi-supervised feature selection.
- Based on high-dimensional datasets, the advantages of the proposed algorithm in semi-supervised feature selection optimization problems are verified. When compared to other meta-heuristic feature selection techniques, the average accuracies have improved by 5.03% and 3.64% based on 80% and 60% unlabeled data, respectively.

The rest of this article is organized in the following manner. Section II introduces a review of the literature on semi-supervised feature selection techniques. Section III provides a new Enhanced White Shark Optimizer algorithm and its binary version. Section IV presents a comparison of the results derived from the implementations. Finally, Section V contains the summary and guidelines for future research.

II. Literature Review

The semi-supervised feature selection method focuses on utilizing a limited number of labeled samples alongside a larger set of unlabeled samples for classification tasks. This approach can be categorized into three main types: filter, wrapper, and embedded methods. This section will primarily discuss these techniques.

A. Semi-Supervised Filter Feature Selection

Filtered semi-supervised feature selection leverages the intrinsic characteristics of both labeled and unlabeled data to evaluate features before conducting learning tasks.

This approach primarily encompasses several methods, including those based on Laplacian scores, pairwise constraints, Fisher criteria, and sparse models.

The Laplacian method is utilized to assess and select features by evaluating how well they preserve the proximity between samples in a dataset. Zhao et al. [6] introduced a method that integrates Laplacian scoring with locally sensitive discriminant analysis. This approach constructs in-class and inter-class graphs using semi-supervised datasets. Cheng et al. [7] developed a method that merges semi-supervised Laplacian scores with classification information gain. Additionally, Doquire et al. [8] presented an algorithm tailored for regression tasks, which is based on the concept of Laplace fractions.

Pairwise constraints represent a different form of supervised information. Benabdeslem et al. [9] introduced a method that integrates Laplacian score and constraint score, allowing for an effective assessment of features' ability to maintain local structure and constraints. Kalakech et al. [10] developed constraint scores in semi-supervised regression interval problems by transforming continuous label data into paired constraint information.

Fisher score is a method for measuring the ability to discriminate feature categories. Additionally, the semi-supervised feature selection challenge can be addressed by leveraging the information from unlabeled samples using Fisher's score. Yang et al. [11] introduced a semi-supervised Fisher scoring approach that utilizes both global distribution and local structure information from the dataset. Sun et al. [12] developed an algorithm based on Fisher criteria and the manifold hypothesis, which redefines the interclass scatter matrix to maximize the separation between classes, making it more resilient to complex data distributions.

By incorporating a sparsity constraint, the sparse model can automatically identify key features during training, enhancing computational efficiency. Han et al. [13] proposed a method that combines a divergence matrix with a sparse model. Zeng et al. [14] employed the l2, 1-norm to promote sparsity and introduced a semi-supervised method focused on local discriminant information.

In summary, the filter method evaluates feature subsets using a separate index based on the original features or statistical properties about the data, without integrating a machine learning model into the feature selection process. This leads to a model with high generalization but lower accuracy.

B. Semi-Supervised Wrapper Feature Selection Method

Semi-supervised wrapper feature selection methods utilize either a single learning model or an ensemble learning model to predict class labels for unlabeled data while evaluating the validity of selected feature subsets.

For single learning models, Ren et al. [15] introduced a wrapper forward framework based on semi-supervised feature selection. This method involves training classifiers with selected features and using those classifiers to predict missing labels. Unlabeled data is then randomly chosen and combined with labeled data to create a new dataset.

This process is carried out several times to identify the feature that appears frequently, which is then added to the feature subset. Song et al. [16] explored a novel particle swarm optimization algorithm for variable-size coevolutionary. They introduced a spatial partitioning strategy on feature importance, allowing related features to be grouped into the same subspace with reduced computational costs.

In the context of ensemble learning, Bellal et al. [17] introduced a guided feature ordering method known as semi-supervised ensemble learning. This method combined the bagged integration and out-of-bag feature importance measure. Barkia et al. [18] developed a novel semi-supervised feature importance evaluation method that employed a cooperative training strategy to train an integrated classifier, extending the feature importance evaluation method from the standard random forest model to semi-supervised scenarios. Han et al. [19] suggested a new method based on integration. It used an integrated classifier capable of estimating the confidence of unlabeled data to explore wrapper feature selection, so that more relevant feature subsets can be selected.

In conclusion, the wrapper approach assesses various feature subsets of a specific model through a designated learning algorithm and identifies the subset that yields the best model performance. While this results in high model accuracy, it tends to have low generalizability. Additionally, this method is more resource-demanding compared to the filter method, as it necessitates multiple iterations of the model to verify the effectiveness of the feature subset based on accuracy.

C. Semi-Supervised Embedded Feature Selection

Semi-supervised embedded feature selection employs both labeled and unlabeled data to choose features during the training process. Key concepts involved include sparse modeling, the graph Laplacian operator, and manifold regularization, among others.

Ma et al. [20] introduced a technique that leverages sparse models and the Laplace operator of graphs, primarily focusing on graph-based semi-supervised learning, along with various sparse models for feature selection. Shi et al. [21] presented an approach that utilizes the l2,1/2 matrix norm and graph Laplacian, introducing an effective optimization algorithm for web image annotation. Xu et al. [22] developed a regularization-based algorithm that selects features by enhancing the classification margin between various classes, taking into account the geometric structure of the probability distribution for both labeled and unlabeled data.

Additionally, Feofanov et al. [23] proposed a hybrid method based on Hadoop, within a semi-supervised embedded framework to address outlier and local optimization issues. Chen et al. [24] introduced a method that relies on rescaled linear regression, using the label representation matrix of unlabeled samples as the optimization target during the training of the sparse linear regression model. Yuan et al. [25] proposed a method called discriminant semi-supervised feature selection.

The embedded method integrates feature selection with the learning algorithm, allowing the feature selection and learning model processes to occur simultaneously. This approach reduces time and space requirements, enhances classification accuracy, and strikes a balance between filter and wrapper methods. Consequently, this study adopts the embedded method for feature selection.

III. Binary Enhanced White Shark Optimizer

A. Enhanced White Shark Optimizer

The White Shark Optimizer algorithm may face limitations in its search performance when applied to feature selection tasks, exhibiting slow convergence and a tendency to get stuck in local optima. Therefore, this study introduces two methods to enhance the algorithm: a dynamic double elite strategy and sinusoidal mutation operation. The dynamic dual-elite strategy optimizes the search process of the algorithm by introducing two elite individuals: the current optimal position and the suboptimal position. This strategy leverages the information from the best position and enables the algorithm to reach a high-quality solution more rapidly. At the same time, by utilizing the suboptimal position, the algorithm is capable of preserving the diversity of the population during the iteration process, allowing for broader exploration of the solution space, thus enhancing the ability to discover potential optimal solutions. The sinusoidal mutation operation is another important improvement strategy, utilizing the periodic change characteristic of the sinusoidal function to guide the individuals in the algorithm to mutate. This kind of mutation operation can make the algorithm more flexible and intelligent in the search process, allowing it to avoid getting stuck in local optima. Through the sinusoidal mutation operation, the algorithm can continuously find new and possibly better positions in the solution space, thus enhancing convergence accuracy and global search ability. These two methods are described below.

1) Dynamic dual elite strategy: The elite learning strategy is a widely used approach in optimization and evolutionary computing that focuses on retaining and utilizing high-performing individuals within a population to enhance the search process and solution quality. The core idea is to preserve the best individuals in each generation so that they can enter the next generation, thus avoiding the replacement deletion of the best individuals in the genetic iteration process. In this way, this approach allows the algorithm to reach a global optimal solution or a solution close to it more rapidly. Chen et al. [26] introduced elite opposition learning to modify the sine and cosine algorithm, enhancing population diversity. For the multi-objective scheduling problem, Amer et al. [27] proposed an improved Harris Eagle Optimizer that improves the quality of the standard Harris Hawk Optimization algorithm by using a refined opposition learning method.

Building on the enhanced algorithm mentioned earlier, this study presents a dynamic dual-elite learning strategy. This approach leverages the current optimal and suboptimal positions within the population to create the next generation of candidate solutions, which accelerates convergence and enhances the ability to identify potential optimal solutions. The strategy is chosen for the following reasons. First, by retaining and utilizing two elite individuals, it provides more search directions and possibilities, thereby increasing its convergence accuracy. Second, the number and function of elite individuals can be

adjusted dynamically based on the algorithm's operational context, allowing it to better adapt to changing environments and enhancing its robustness and adaptability. In addition, dynamic learning factors are introduced. This factor is closely linked to the fitness value of the elite white shark, and the weight of the two elite individuals can be controlled by dynamically adjusting its value. The equation for creating potential solutions and adjusting learning factors dynamically is described below.

$$X_i^*(t+1) = r_1 * F * \left(X_{second}(t) - X_i(t)\right) - r_2 * (1-F) * X_{best}(t) \quad (1)$$

$$F = \frac{F_{best}(t)}{F_{best}(t)+F_{second}(t)} \quad (2)$$

where, r_1 and r_2 are random vectors within [0,1], and $X_{best}(t)$ and $X_{second}(t)$ are individual positions with optimal and sub-optimal fitness values at the t iteration, respectively. The dynamic learning factor is denoted as F, and $F_{best}(t)$ and $F_{second}(t)$ represent the fitness values of the best and sub-best individual positions during the t iteration, respectively.

We use a selection mechanism based on hybrid sorting. First, $2N$ white sharks $X_1(t), X_2(t), \dots, X_N(t)$ and $X_1^*(t), X_2^*(t), \dots, X_N^*(t)$ are combined and sorted based on their fitness values. Then, the first N white sharks with the best fitness values were selected for the next generation, thus conducive to better population evolution. The advantages of this hybrid sorting-based selection mechanism are as follows. First, compared with traditional methods of selection based only on the original population, the mechanism doubles the number of great white sharks involved in selection during each iteration. This not only broadens the selection range but also helps identify and utilize more individuals with potentially outstanding traits, thereby significantly enhancing population diversity and evolutionary effectiveness. Secondly, this mechanism allows the algorithm to constantly explore new solution spaces throughout the search process. By introducing hybrid competition between elite and regular individuals in each iteration, the algorithm's global search capability is enhanced, leading to a higher likelihood of ultimately discovering the global optimal solution. After evaluating the fitness of each white shark in the initial population, the dynamic dual-elite strategy is applied to generate the next generation of candidate solutions based on the current best and second-best positions of the white shark population. The population is then updated according to their fitness values. The corresponding pseudocode for this algorithm is outlined in Algorithm 1.

Algorithm 1 Dynamic dual elite strategy for enhanced white shark optimizer

Initialize population size *N*;
Create the initial population *X*;
Evaluate the fitness of the initial population *X*;
for $i < N$ **do**
  Generate the learning white shark X^* using Eq. (1);
  Calculate the fitness value of X^*;
end for
Obtain the population and fitness of *2N* white sharks;
Sort them according to their fitness values;
Update population X' by selecting the best *N* white sharks with the best fitness;

2) Sinusoidal mutation operation: The sine function, with its inherent periodicity and continuous and smooth change characteristics, is widely known and highly valued in the field of science and engineering. Recently, advancements in computing technology and algorithm theory have led to various algorithms that incorporate the sine function concept in order to obtain significant enhancement and improvement in performance. For instance, Draa et al. [28] utilized a compound sine formula to modify the scale factor and crossover rate in the differential evolution algorithm. Similarly, Khalilpourazari et al. [29] introduced an enhanced crow search algorithm for complex optimization challenges by integrating sine and cosine functions.

Inspired by the above methods, the proposed algorithm uses the sinusoidal mutation theory to improve. Sinusoidal mutation theory is a method to guide the optimal individual to the mutation operation, which helps the algorithm escape local optima and increases the chances of discovering better solutions. When the sine function has the value [−1,1] on the interval [0,2π], the algorithm focuses on advancing the next generation of individuals within promising areas of the search space, instead of exploring a broader region. Therefore, the algorithm can be studied in a small range around the current global optimal location, improving the local expansion ability of the algorithm and avoiding falling into a local optimum. In addition, the algorithm aims to balance the critical requirements of exploration and exploitation. On the one hand, it actively explores the unknown and possibly better solution domain through the periodic fluctuation characteristics of the sinusoidal mutation process. On the other hand, when the sine wave amplitude drops to the local lowest point, the algorithm can accurately focus on the small change near the known best point. Eq. (3) illustrates the sinusoidal mutation process of the current globally optimal great white shark.

$$X'_{best} = \sin\left(2\pi * rand(1,\dim)\right) \oplus X_{best}, if\ rand < c \quad (3)$$

$$X_{best} = \begin{cases} X'_{best}, f(X'_{best}) < f(X_{best}) \\ X_{best},\ otherwise \end{cases} \quad (4)$$

where, X_{best} denotes the global optimal position, $\oplus$ signifies the dot product, and c is the mutation probability. As shown in Eq. (3), if the fitness value of the individual after the sinusoidal mutation improves, the result is accepted. Otherwise, the original position is maintained.

After the keen hearing, smell, and fish behavior of the great white shark, the sinusoidal mutation operation is applied to identify the global optimal position X_{best}. Initially, the sinusoidal mutation operation generates a new position, and its corresponding fitness value is compared with that of the global optimal position X_{best}, leading to an update of the algorithm's optimal solution. The pseudocode for this process is outlined in Algorithm 2.

Algorithm 2 Sinusoidal mutation for enhanced white shark optimizer

Obtain the global best position X_{best};
if $rand < c$ **then**
  Generate mutation white shark X'_{best} using Eq. (3);
  Calculate the fitness value of X'_{best};
  if $f(X'_{best}) < f(X_{best})$
    $X_{best} = X'_{best}$;
    $f\left(X_{best}\right) = f(X'_{best})$;
  end if
end if

B. Binary Enhanced White Shark Optimizer

White Shark Optimizer is a powerful algorithm designed specifically for continuous optimization problems. It can find the optimal solution by constantly adjusting variable values in a continuous search space. However, when dealing with feature selection problems, the situation is quite different. The search space in these cases is discrete rather than continuous, which means that methods suitable for continuous spaces may not be directly applied. In particular, the search space for feature selection is depicted in binary form, where 0 indicates features that are not selected, and 1 signifies those that are included. To effectively tackle feature selection issues, it is necessary to modify and optimize the enhanced white shark optimizer algorithm to accommodate binary variables. This adjustment is crucial for ensuring the algorithm's relevance and effectiveness in feature selection tasks.

In this context, transfer functions play a vital and prevalent role. These mathematical tools can efficiently map continuous values to discrete ones, particularly in converting a single continuous value into a binary state to fulfill the specific needs of feature selection. Among various transfer functions, the S-type and V-type are the most commonly utilized and effective [30]. The S-type transfer function is known for its smooth transitions and monotonically increasing nature, effectively representing the gradual change in feature importance and facilitating a smooth shift from 0 to 1 at a defined threshold. Conversely, the V-type transfer function, with its symmetrical "V" shape, is better suited for detailed feature classification, especially when feature importance is evenly distributed or has multiple peaks, allowing for more precise capture of these features. The details are shown in Table I.

In this research, we transformed continuous white shark feature data into binary format using a two-step transfer function approach, specifically employing the S1 transfer function, to enhance compatibility with subsequent feature selection and processing tasks.

The first step involves calculating the probability of the binary conversion value based on Eq. (5), $w_d^i(t)$ denotes the position of the ith white shark in the dth dimension in the tth iteration.

$$P\left(w_d^i(t)\right) = TF(w_d^i(t)) \tag{5}$$

TABLE I. S-TYPED AND V-TYPED TRANSFER FUNCTIONS

S-typed	Transfer function	V-typed	Transfer function
S1	$T(x) = \frac{1}{1+e^{-2x}}$	V1	$T(x) = \lvert\mathrm{erf}(\frac{\sqrt{\pi}}{2}x)\rvert$
S2	$T(x) = \frac{1}{1+e^{-x}}$	V2	$T(x) = \lvert\tanh(x)\rvert$
S3	$T(x) = \frac{1}{1+e^{(-x/2)}}$	V3	$T(x) = \lvert(x)/\sqrt{1+x^2}\rvert$
S4	$T(x) = \frac{1}{1+e^{(-x/3)}}$	V4	$T(x) = \lvert\frac{2}{\pi}\arctan(\frac{\pi}{2}x)\rvert$

$$TF(w) = \frac{1}{1+e^{-2w}} \tag{6}$$

Secondly, the probability of Eq. (5) is substituted into Eq. (7), and the value of each great white shark's location is converted to binary form.

$$w_d^i(t) = \begin{cases} 1, & if\ P\left(w_d^i(t)\right) \geq rand, \\ 0, & otherwise \end{cases} \tag{7}$$

The flow chart in Fig. 1 illustrates the corresponding binary algorithm.

Feature selection is typically considered a multi-objective optimization problem, and its core challenge is how to find a balance point that maximizes classification accuracy while reducing the number of features chosen. This balance is essential for enhancing the efficiency, interpretability, and generalization of machine learning models. The fitness function is crucial in this context, serving as the primary criterion for assessing the selected feature subset. Specifically, the fitness function outlined in Eq. (8) is essential for evaluating the selected subset of features, as it balances the goal of maximizing classification accuracy with the need to minimize the number of features used in the learning model. The smaller the function value, the better the performance.

$$F = \alpha * (1 - acc) + \beta * \frac{l_f}{n_f} \tag{8}$$

The classification accuracy depends on the selected classifier, which is represented by acc in this study. The parameters α and β are inverse parameters, representing the weight given to the quality of classification and the feature selection ratio, respectively, ranging from 0 to 1, where $\beta = 1 - \alpha$. In this study, α is 0.99 and β is 0.01. The values of l_f and n_f refer to the number of selected features and the sum of features in the dataset, respectively.

Several semi-supervised learning models have been developed to enhance learning efficiency and accuracy by utilizing a small amount of labeled data in conjunction with a larger volume of unlabeled data. These models include self-training classification models, mixed classification models based on large expectations, cooperative training models, graph-based semi-supervised learning models, and semi-supervised learning clustering models. Among these, the self-training classification model is popular due to its effective training results and relatively straightforward implementation. The K-

Nearest Neighbors (K-NN) algorithm is an efficient classification method known for its simplicity, ease of use, strong predictive performance, insensitivity to outliers, and suitability for large datasets. As a result, it is frequently applied in areas such as text sentiment analysis, risk assessment, and medical diagnosis. To sum up, this study adopts KNN-self-training as a semi-supervised classification model algorithm, with k set to 5. Each run utilizes 5-fold cross-validation to evaluate model accuracy. Initially, 20% of the data is chosen as the test dataset, with the remainder serving as the training dataset. Given the semi-supervised nature of the algorithm, the experiment randomly selects 80% and 60% of the training dataset as unlabeled data (class labels are removed), and the rest as labeled data for model training, respectively. Finally, after making predictions on the unlabeled data, 20% of the test data is used as experimental results to verify the classification model accuracy.

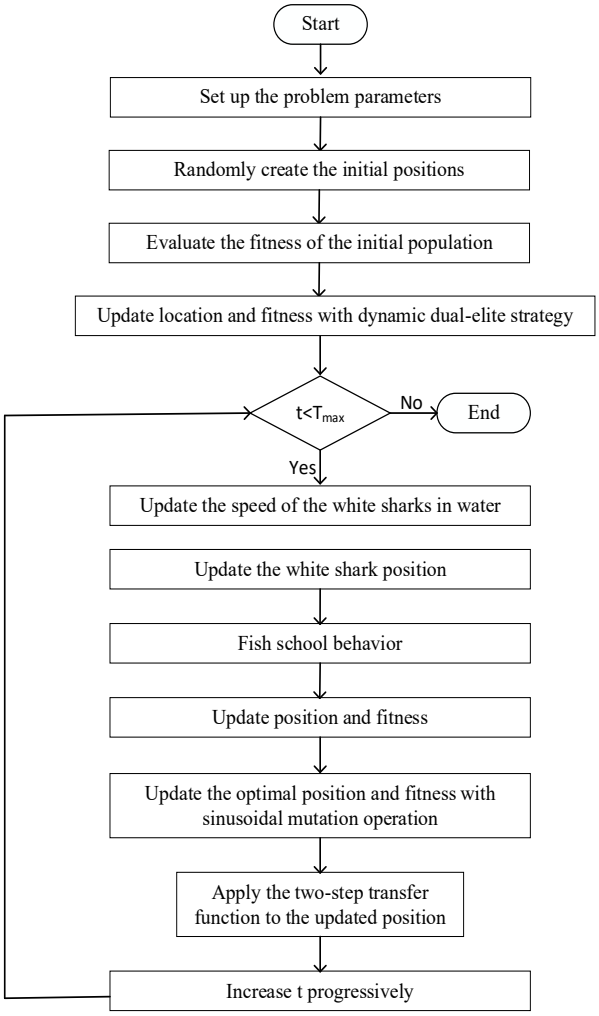

Fig. 1. The flowchart of the binary enhanced white shark optimizer algorithm.

IV. Experimental Results

This section outlines the experiments conducted and the results achieved to showcase the efficacy of the suggested algorithm when applied with feature selection in established classification tasks. We utilize the MATLAB 2022b platform to implement the proposed algorithm on nine high-dimensional datasets. Additionally, we analyzed and compared it with six other prominent meta-heuristic techniques commonly employed in feature selection.

A. Datasets

This article uses 9 high-dimensional datasets from the UCI Machine Learning Repository [31] and the Arizona State University (ASU) Feature Selection Repository [32]. Table II provides a comprehensive description of these datasets, including the feature dimensions, number of categories, sample sizes, and dataset sources.

TABLE II. Classified Datasets About UCI and ASU

Number	Dataset	Feature	Class	Instance	Source
1	Isolet	617	26	1560	ASU
2	lung	3312	5	203	UCI
3	COIL20	1024	20	1440	ASU
4	ALLAML	7129	2	72	ASU
5	darwin	450	2	174	UCI
6	Toxicity	1203	2	171	UCI
7	DrivFace	6400	3	606	UCI
8	USPS	256	10	2007	ASU
9	leukemia	7070	2	72	ASU

B. Compared Algorithms and Parameter Settings

To assess the proposed algorithm, the results are compared with six meta-heuristic optimization algorithms. The first is the original Binary White Shark Optimizer (BWSO) [33]. The other five commonly used methods include Binary Differential Evolution (BDE) [34], Binary Gravity Search Algorithm (BGSA) [35], Binary Atom Search Optimization (BASO) [36], Binary Grasshopper Optimization Algorithm (BGOA) [37], and Binary Particle Swarm Optimization Algorithm (BPSO) [38]. Table III shows the related parameter settings.

TABLE III. Compared Algorithm Parameter Settings

Algorithm	Parameter	Value
BEWSO	Population size	30
	f_{min}	0.07
	f_{max}	0.75
	p_{min}	0.5
	p_{max}	1.5
BDE	Crossrate	0.9
	N	10
BGSA	a	20
	G_0	100
BASO	Alpha	50
	Beta	0.2
	V_{max}	6
	N	10
BGOA	N	1
BPSO	V_{max}	6
	W_{max}	0.9
	W_{min}	0.4
	N	10
Universal	Maximum iterations	100
	Runs	30

C. Results and Discussion

Table IV presents the average fitness values achieved by the proposed algorithm and the other algorithms across nine datasets using 80% unlabeled data. The optimal and sub-optimal results for each dataset are indicated in bold and underlined, respectively. Notably, the average fitness score of the suggested approach is 36.52% lower than the sub-optimal value of BPSO. The proposed algorithm achieves the lowest average fitness value across all nine datasets. The BASO method ranks second, achieving four sub-optimal results, while both BWSO and BDE obtain two sub-optimal results each. Conversely, the BGSA method may perform poorly, with the highest overall average fitness value and no optimal or sub-optimal results across all datasets.

Using 60% unlabeled data, Table V displays the average fitness values obtained on the nine high-dimensional datasets. The overall average fitness value of the proposed algorithm is 35.29% lower than the sub-optimal value of BPSO, further showcasing its effectiveness. Similarly, the proposed algorithm achieves the lowest average fitness value across all datasets, with BPSO following closely behind and achieving four sub-optimal results, while BWSO secures three sub-optimal results.

Table VI displays the average accuracy of the proposed method and other test methods using 80% unlabeled data. The results indicate the proposed algorithm performs well in accuracy and obtains the best overall average value, which is 5.03% higher than the sub-optimal value from BPSO, aligning with the best overall objective function value shown in Table IV. Specifically, it records the highest average classification accuracy when considering all datasets. The average accuracy of the lung, COIL20, ALLAML, DrivFace, USPS, and leukemia datasets reached more than 90%. In contrast, BWSO, BDE, and BASO also have better average accuracy. Among them, the BWSO algorithm and BASO algorithm get three sub-optimal results, respectively, and the BDE algorithm gets two sub-optimal results. However, the BGSA method performs poorly, exhibiting the lowest overall average accuracy and failing to achieve any optimal or sub-optimal results across all datasets.

Table VII outlines the average accuracy of the proposed approach and other tested methods utilizing unlabeled data. The proposed method outperforms the WSO method as well as all other competing techniques, achieving the best overall average value, which is 3.64% higher than the corresponding sub-optimal value for BDE. It also secures the highest average accuracy across all nine high-dimensional datasets, with over 90% accuracy on seven of them. In contrast, BWSO, BDE, and BPSO also have better average accuracy, with the BPSO algorithm achieving four sub-optimal results, while BDE and BWSO each attain three.

Overall, in high-dimensional datasets using both 80% and 60% unlabeled data, the improved algorithm consistently outperforms the original and other algorithms in classification accuracy. As the proportion of labeled data increases and the proportion of unlabeled data decreases, classification accuracy improves, possibly due to the enhanced correctness of labeled samples, leading to a more effective trained model.

From a deeper perspective, the proposed algorithm shows good performance regarding classification accuracy. By introducing a dynamic bi-elite strategy and sinusoidal mutation operation, the method can utilize the current optimal position information, which improves the ability to find potentially superior solutions and allows for more effective data dimensionality reduction, resulting in improved classification accuracy and efficiency.

Table VIII illustrates the mean number of features chosen by the proposed and other testing methods when utilizing 80% unlabeled data. In general, the proposed method performs admirably in feature selection, ranking third overall, following BWSO and BASO. Specifically, out of 9 datasets, the proposed method obtains 2 best results (Isolet, ALLAML) and 1 suboptimal result (lung); BWSO obtains 3 best results (DrivFace, USPS, leukemia). Additionally, BASO achieves 2 best results (lung, Toxicity) and four suboptimal results (COIL20, ALLAML, Darwin, DrivFace). BPSO obtains the best results in 2 cases (COIL20, Darwin). Combined with Table IV and Table VI, for these two datasets (Isolet, ALLAML), the suggested approach not only obtains the optimal number of feature selections, but also obtains the optimal average fitness and the optimal average accuracy.

Table IX illustrates the mean number of features chosen by the proposed methods and other testing methods when 60% unlabeled data is used. Overall, the suggested method ranks second in the average number of selected features, just behind BASO. Specifically, the suggested approach has the fewest average selected features across three datasets (lung, Toxicity, DrivFace), while BASO has 2 cases (ALLAML, darwin) and BPSO has 2 cases (Isolet, USPS) each. Additionally, BWSO has 1 optimal value (leukemia), and BGOA has 1 optimal value (COIL20) each.

The analysis shows that this algorithm selects fewer features than most algorithms, while maintaining better fitness values. However, despite having some advantages over other methods, it is difficult to reach the ideal number of selected features. This is primarily because the method emphasized in this study prioritizes feature selection to enhance classification accuracy, focusing on optimizing the fitness function with accuracy as the main objective. The proposed algorithm effectively reduces the number of features selected while retaining essential information.

TABLE VIII. THE AVERAGE NUMBER OF FEATURES SELECTED UNDER DATA WITH 80% UNLABELED

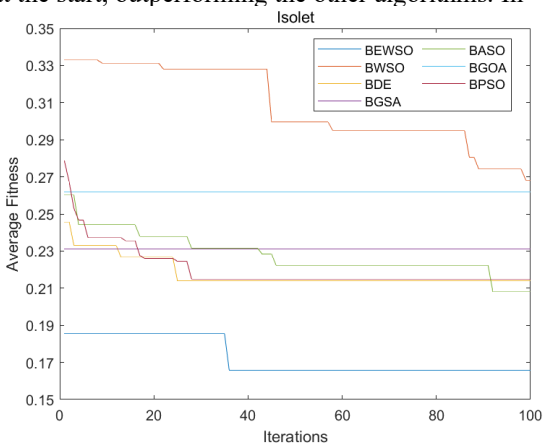
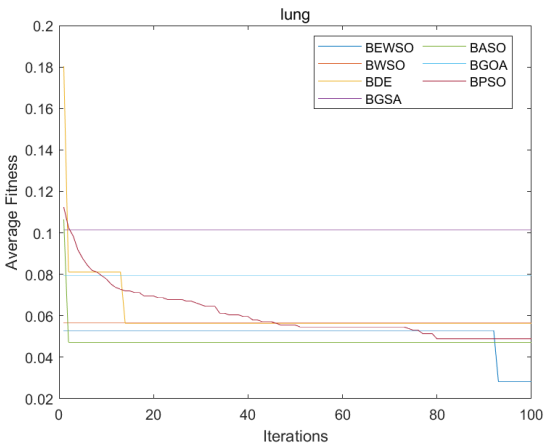
Fig. 2 illustrates the convergence patterns of seven optimization algorithms by analyzing the average fitness function values over 100 search iterations. The evaluation includes the suggested algorithm alongside six additional algorithms tested on nine datasets, each comprising 80% unlabeled data. The X-axis represents the number of iterations, and the Y-axis displays the average fitness value obtained. For the Isolet, COIL20, ALLAML, and USPS datasets, the proposed method shows good convergence in early iterations and continues to improve until the end. In the Toxicity and DrivFace datasets, the proposed method rapidly reaches the minimum fitness value at the start, outperforming the other algorithms. In the lung dataset, the proposed method initially lags behind BASO, but by the ninetieth iteration, it surpasses BPSO and maintains superior values. For the Darwin dataset, BWSO and BPSO are competitive algorithms. It can be seen that the proposed method starts strong, but BPSO excels after about 40 iterations, while BWSO performs best after around 50 iterations, and the proposed method again reaches the minimum value after about 70 iterations. In the leukemia dataset, the proposed method has the best initial convergence, which is surpassed by BDE in the middle, but the proposed method soon maintains the minimum fitness value again.



(a)



(b)

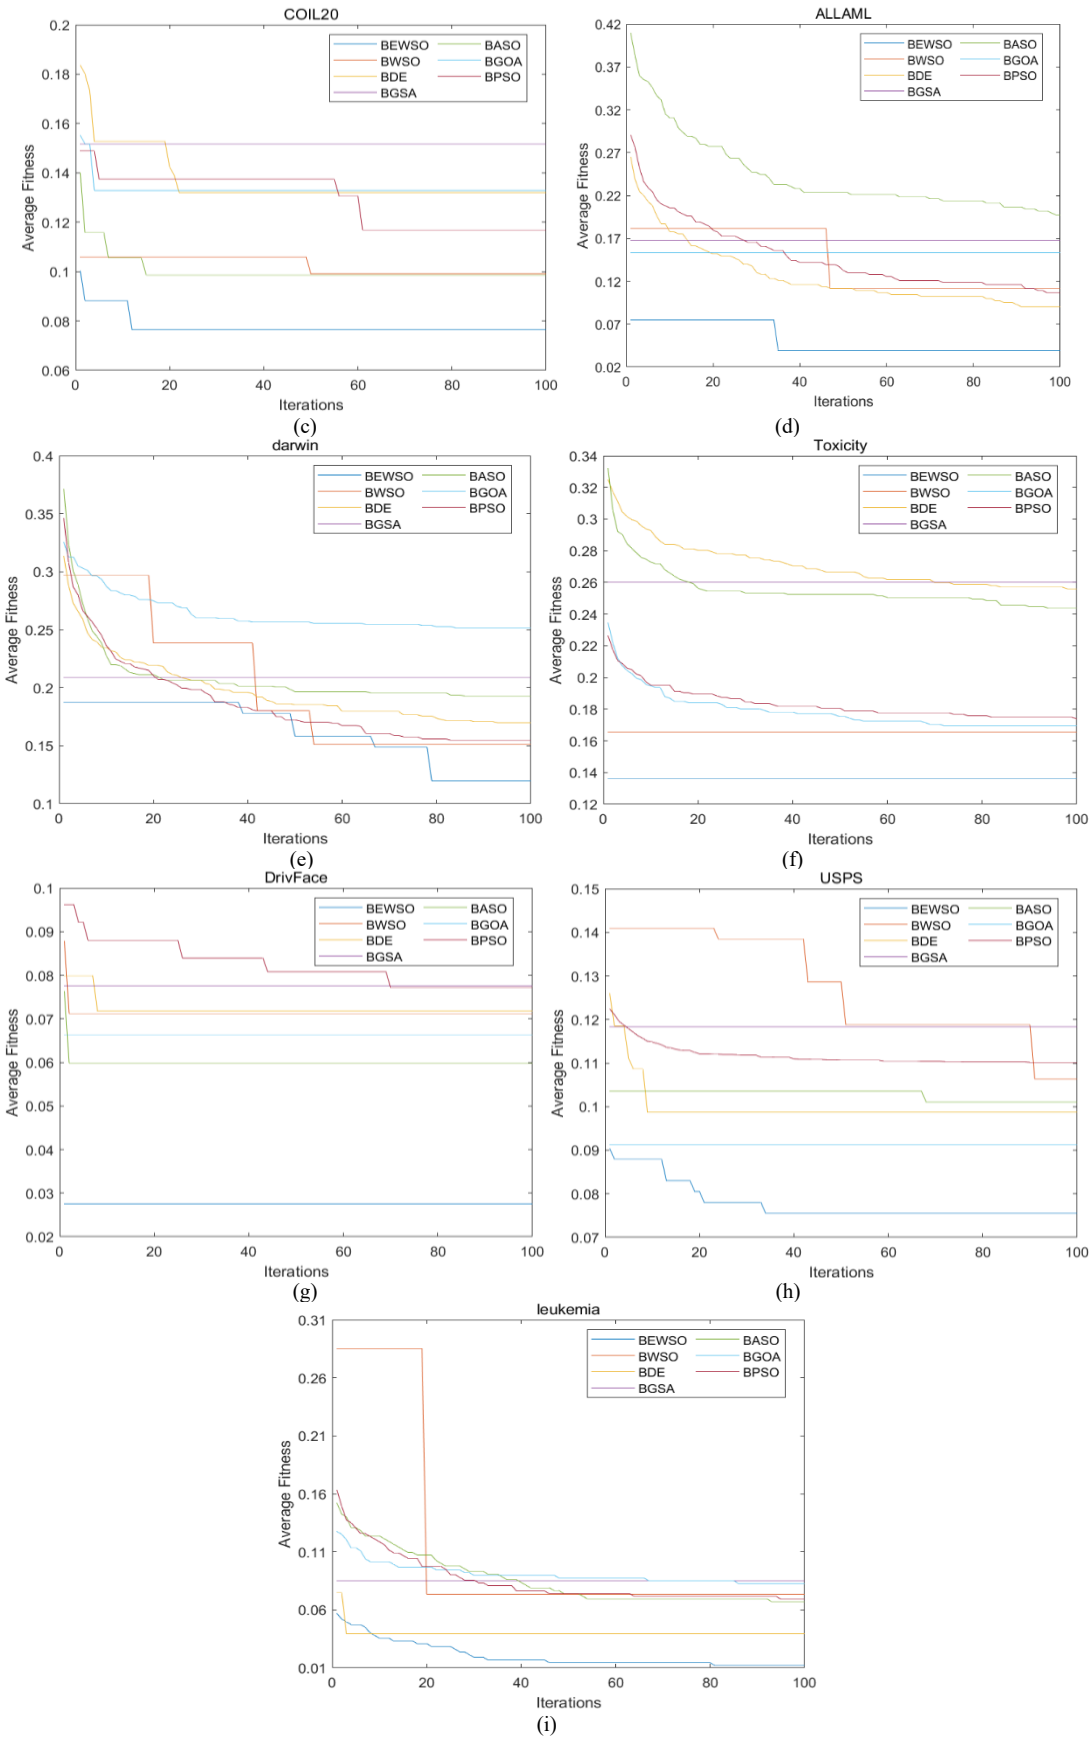


Fig. 2. The average convergence curve of the algorithms under data with 80% unlabeled.

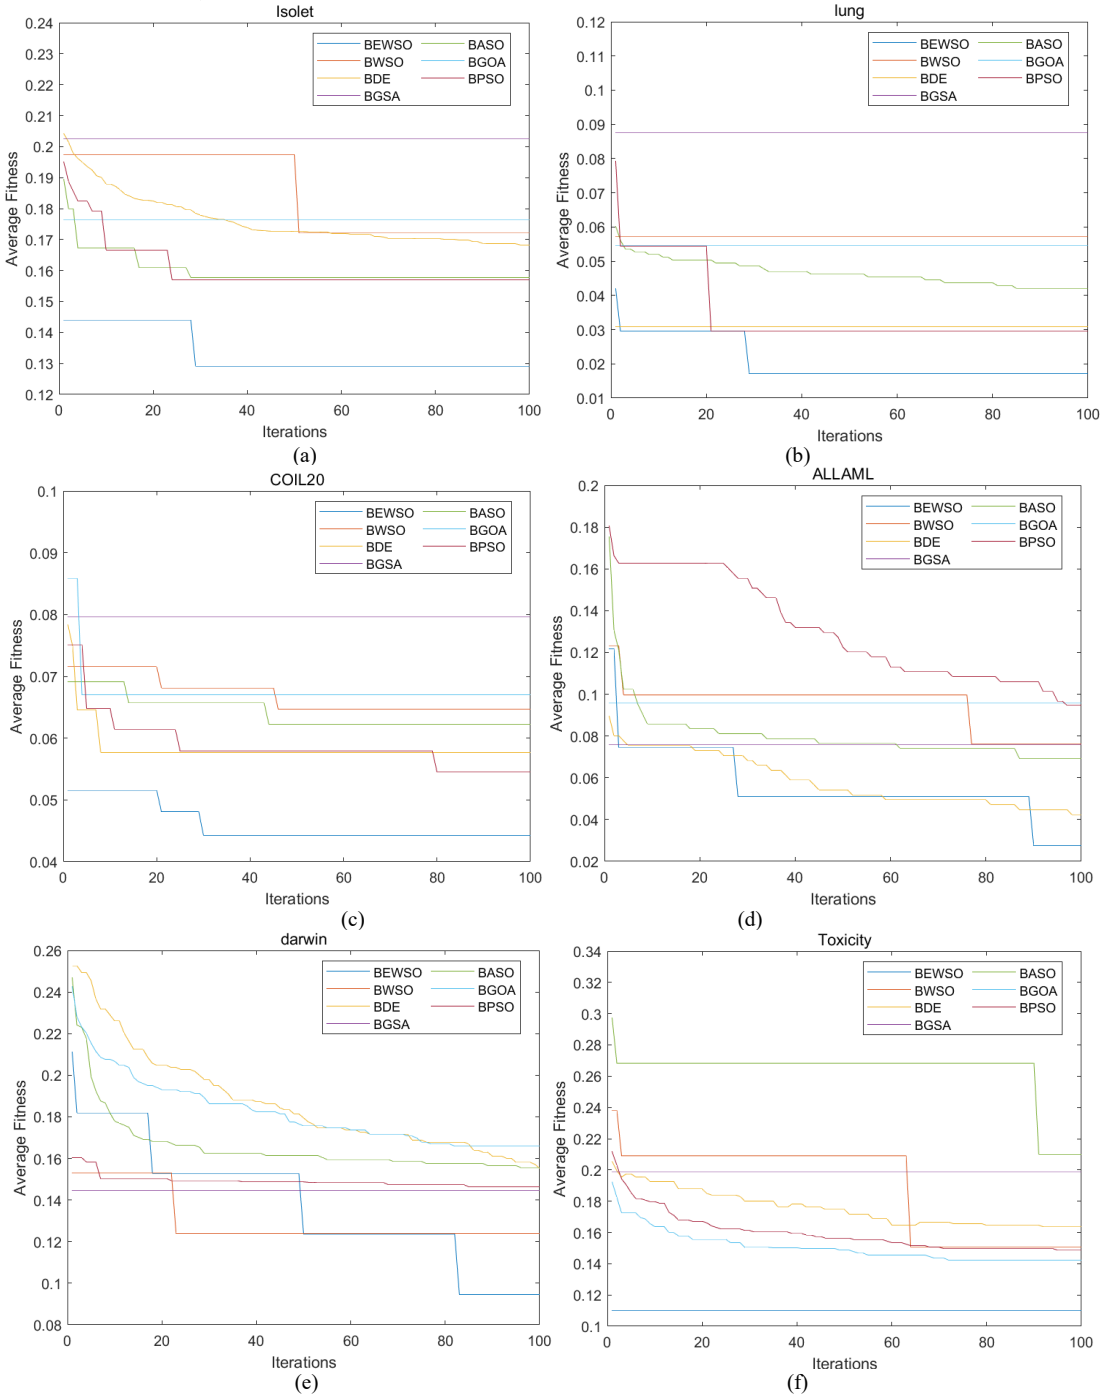
Fig. 3 uses 9 datasets with 60% unlabeled data to describe the convergence behavior of the proposed method and the other six methods based on the mean value of the fitness function during 100 iterative searches. For most datasets, it is evident that the convergence curve becomes stagnant after more than 50 iterations. Examining each convergent graph individually, it reveals that the proposed method outperforms its competitors in the Isolet, lung, COIL20, DrivFace, and USPS datasets, showing good convergence in early iterations, with the average fitness value decreasing further with more iterations. In the Toxicity dataset, the suggested algorithm attains the best fitness value during the initial iteration, with BGOA following closely behind. In the ALLAML dataset, BGSA and BDE are the most competitive algorithms. BGSA gets the best fitness value in the first iteration, and as iterations progress, BDE and the proposed method alternately get the best fitness value until the proposed method finally gets the best value around the 90th iteration. In the Darwin dataset, BGSA starts with the best fitness value, BDE takes the lead around the 20th iteration, and both the proposed algorithm and BDE reach the same minimum fitness value around the 50th iteration, with the proposed method showing stronger convergence by the 80th iteration. For the leukemia dataset, the proposed method shows good convergence around the 30th iteration and maintains this performance until the end.



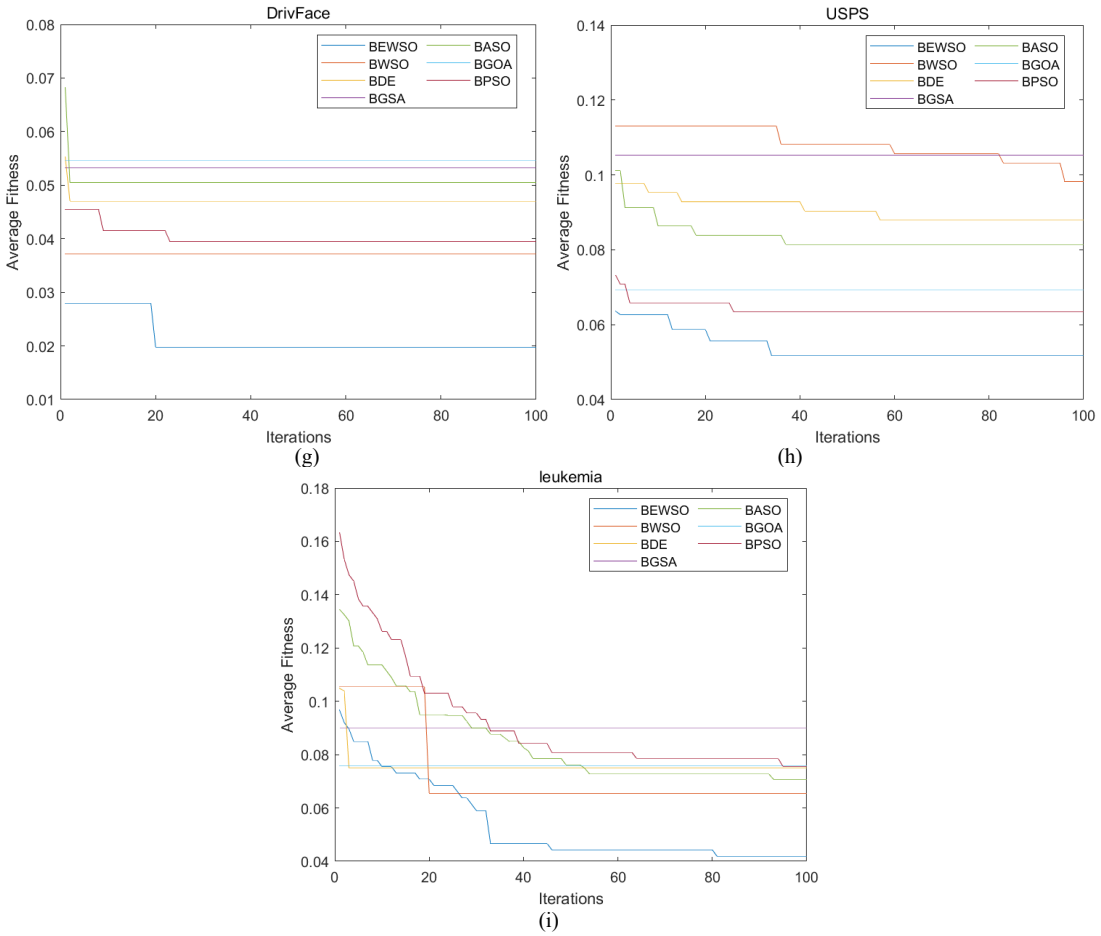


Fig. 3. The average convergence curve of the algorithms under data with 60% unlabeled.

From a practical perspective, the time taken for the algorithm to finish its calculations is crucial. The execution times for the suggested and other competing approaches have been measured and are presented in Table X. BGSA has the lowest overall average running time, with the proposed algorithm coming in second. Specifically, BGSA records the fastest execution time across seven datasets, while the proposed method obtains three sub-optimal results.

Furthermore, Table XI displays the computation time results for seven different algorithms using 60% unlabeled datasets. BGSA again has the shortest overall average running time, followed by the proposed algorithm. BGSA achieves seven optimal results and one suboptimal result, while the proposed method secures four suboptimal results.

TABLE X. THE AVERAGE TIME OF THE ALGORITHMS UNDER DATA WITH 80% UNLABELED

V. CONCLUSION

This study introduces an Enhanced White Shark Optimization algorithm with the dynamic dual-elite strategy and the sinusoidal mutation method, aimed at increasing the diversity of offspring and enhancing the potential optimal solutions. Furthermore, it introduces a binary transfer function and further investigates its binary application in semi-supervised feature selection. The proposed algorithm is evaluated on nine high-dimensional datasets and is compared against six other meta-heuristic methods for feature selection. The results indicate that when 20% and 40% of the training samples are randomly labeled, the proposed algorithm achieves the best overall mean accuracy; its lead rate is 5.03% and 3.64%, respectively, while also decreasing the number of features chosen. Specifically, with 20% labeled data, it surpasses other developed algorithms in average accuracy of 9 datasets and the number of selected features of 2 datasets. With 40% labeled data, it again outperforms all other developed algorithms in average accuracy of 9 datasets and number of selected features of 3 datasets. The experimental findings show the good performance of the Binary Enhanced White Shark Optimization method. This method could be applied to study high-dimensional gene selection in the future.

NADOS: Reliability-Gated Difficulty-Aware Oversampling for Noisy Imbalanced Classification

Ednel Ashraff Misran*, Syahid Anuar, Adam Mohd Khairuddin
Faculty of Artificial Intelligence, Universiti Teknologi Malaysia, Kuala Lumpur, Malaysia

***Abstract*—Class imbalance becomes more challenging when minority underrepresentation is accompanied by label noise, because synthetic oversampling may amplify unreliable local structures if noisy minority samples are used as interpolation seeds. This study proposes Noise-Aware Adaptive-Difficulty Oversampling (NADOS), which separates the assessment of seed trustworthiness from the allocation of synthesis effort. NADOS evaluates each minority instance through two local criteria. A reliability score determines whether the instance is suitable for synthetic generation, while a difficulty score assigns synthesis priority among eligible instances. The method is evaluated on 22 binary imbalanced benchmark datasets, five controlled label-noise levels, four classifier families, and nine oversampling methods. Across the full benchmark, NADOS obtains average F1 = 0.7428, G-mean = 0.8511, balanced accuracy = 0.8552, and AUPRC = 0.7700. These results give NADOS the strongest average F1, G-mean, and balanced accuracy, while remaining competitive on AUPRC. Non-parametric statistical tests show significant differences among the compared methods and indicate that NADOS is consistently competitive under noisy imbalanced learning conditions. Separating seed reliability from synthesis difficulty provides a practical strategy for noisy imbalanced classification. The reliability gate limits unsafe seed usage, while the difficulty score preserves attention to difficult but trustworthy minority samples.**

***Keywords*—Imbalanced classification; label noise; oversampling; SMOTE; noisy data; minority learning**

I. Introduction

Class imbalance remains a persistent challenge in supervised learning because many classifiers favor the majority class when the training distribution is skewed. This issue is critical in tasks where the minority class is the main class of interest, such as medical screening, fault detection, fraud analysis, and anomaly identification. The problem becomes more difficult when the training labels are noisy, because the learner must recover a sparse minority concept from data that may contain incorrect or locally inconsistent labels [1, 2, 3].

Synthetic oversampling is widely used to address class imbalance. SMOTE and its variants increase minority representation by generating artificial minority samples instead of duplicating existing observations. However, synthetic generation is not always beneficial. If a seed instance is noisy, isolated, or located in an unstable overlap region, interpolation can create misleading samples and reinforce incorrect local structure. This risk is especially important in noisy imbalanced learning, where the minority class is sparse and more vulnerable to local corruption [4, 5, 6].

Recent oversampling methods reduce this risk through adaptive generation, boundary information, local density, cleaning mechanisms, and noise-aware weighting. These methods have improved synthetic sample generation, but a key design issue remains: difficult minority instances are not difficult for the same reason. Some difficult samples are informative boundary cases, while others are unreliable because they are mislabeled, isolated, or structurally inconsistent. Treating both cases alike can direct synthesis effort toward unsafe seeds. Conversely, focusing only on safe regions can neglect useful hard cases near the decision boundary [7, 8, 9, 10].

This study proposes Noise-Aware Adaptive-Difficulty Oversampling (NADOS) to address this distinction. NADOS separates minority-seed assessment into two decisions. Reliability acts as an eligibility gate: a minority instance must be sufficiently trustworthy before it can guide synthetic generation. Difficulty then acts as an allocation signal: among reliable seeds, harder instances receive greater synthesis priority. This design aims to avoid unsafe generation while retaining useful boundary information.

The main contributions are fourfold: a reliability-gated and difficulty-aware oversampling method for noisy imbalanced classification; a local scoring mechanism that separates seed trustworthiness from synthesis priority; a controlled benchmark evaluation across 22 binary imbalanced datasets, five label-noise levels, four classifier families, and nine oversampling methods; and non-parametric statistical validation against established SMOTE-family and noise-aware oversampling baselines.

The remainder of this study is organized as follows. Section II reviews related work. Section III presents the proposed NADOS method. Section IV describes the experimental design. Section V reports and discusses the results. Section VI concludes the study.

II. Related Work

This section reviews the main oversampling families that motivate NADOS. It first summarizes classical data-level methods, then discusses adaptive, boundary-oriented, cleaning-based, and noise-aware variants. The review emphasizes not only what each method does, but also what previous studies suggest about its behavior under overlap, sparsity, and label-noise conditions.

A. Classical Oversampling for Imbalanced Learning

Class imbalance has been widely studied because many standard learning algorithms optimize global error and

*Corresponding author.

therefore tend to favor the majority class when the class distribution is skewed [1, 2]. Data-level methods remain attractive because they can be applied before classifier training and do not require changes to the underlying model. Random oversampling is the simplest form of this strategy: minority instances are duplicated until the class distribution becomes less skewed. Although this can reduce majority-class dominance, it may also increase redundancy and overfitting because the minority distribution is enlarged by repetition rather than by new information.

SMOTE changed data-level imbalance learning by generating synthetic minority instances through interpolation between neighboring minority samples [4]. Instead of duplicating observations, SMOTE creates new samples along line segments between a minority seed and one of its minority nearest neighbors. This idea made synthetic oversampling a dominant baseline for imbalanced classification and motivated many later variants. Its main advantage is generality: it can be combined with many classifiers and applied to tabular datasets without requiring a problem-specific cost matrix.

However, SMOTE also introduced a structural risk. The method assumes that minority neighbors provide useful interpolation directions. When the minority seed is noisy, isolated, or located in a majority-dominated overlap region, interpolation can create synthetic samples that blur the class boundary or reinforce incorrect local structure. This problem is especially important when class imbalance and label noise occur together. In such cases, the learner is not only deprived of minority examples, but it may also receive synthetic minority points generated from unreliable seeds. Reviews of imbalanced learning repeatedly identify the structure of minority examples, local overlap, and noisy labels as factors that can make resampling unreliable [5, 1, 2].

Empirical studies have consistently shown that synthetic oversampling can improve minority recognition compared with simple resampling, but the gains depend strongly on data geometry and classifier behavior. The original SMOTE study reported improved ROC behavior relative to random over-sampling and under-sampling on several benchmark tasks [4]. Later comparative studies found that SMOTE combined with cleaning rules can reduce overlap effects in some settings, but no single resampling method is uniformly best across datasets [11, 5]. These outcomes support the need for methods that respond to local structure rather than applying a single global balancing rule.

B. Adaptive, Locality-Aware, and Noise-Aware Oversampling

One major extension of SMOTE is adaptive generation. ADASYN assigns more synthetic samples to minority instances that are harder to learn, using local class composition to estimate difficulty [7]. This is an important shift because it recognizes that not all minority samples should receive equal generation effort. The method attempts to move the decision boundary toward difficult minority examples by increasing their representation. The limitation is that local difficulty is not always equivalent to usefulness. A sample may be difficult because it lies near an informative boundary, but it may also be difficult because it is mislabeled, isolated, or locally inconsistent.

Boundary-oriented approaches address a related issue. Borderline-SMOTE focuses on minority samples near the class boundary, based on the assumption that boundary samples are more informative for discrimination than samples located deep inside safe minority regions [12]. SVM-SMOTE similarly uses support-vector information to guide generation near the decision boundary [13]. These methods are important competitors because they explicitly move away from uniform minority interpolation. Nevertheless, their emphasis on boundary regions can become problematic under label noise. Boundary and overlap regions are precisely where unreliable labels and ambiguous neighborhoods are more likely to appear.

Another line of work combines oversampling with data cleaning. SMOTE-Tomek and SMOTE-ENN use cleaning rules after synthetic generation to remove overlapping or locally inconsistent samples [11]. These hybrid approaches are useful because they acknowledge that oversampling can introduce ambiguous points. However, post-generation cleaning does not fully solve the seed-selection problem. If unreliable seeds guide interpolation, the method may generate poor candidates before the cleaning step is even applied, a concern also reflected in filtering-based approaches for noisy and borderline examples [6]. This motivates methods that improve synthetic generation earlier in the pipeline.

Noise-aware and density-aware methods attempt to control this risk more directly. WRND is particularly relevant because it uses relative neighborhood density to adapt oversampling for imbalanced noisy classification [8]. Other recent methods use clustering, safe-region estimation, local density, or filtering to improve robustness. These methods show that the field has moved beyond simple class balancing toward local structure-aware generation. However, many approaches still rely on a single local signal to influence both seed selection and synthesis intensity. This creates a design tension: the same evidence is often used to decide whether a sample should be trusted and how much it should be emphasized.

Prior experimental work also shows that adaptive and locality-aware methods can improve performance when the minority class contains informative boundary regions, but the same mechanisms may overemphasize unreliable points when label noise is present. ADASYN was reported to improve learning by concentrating synthesis on harder minority samples [7], while Borderline-SMOTE and related variants showed benefits from focusing on samples near decision boundaries [12, 13]. WRND extends this direction to noisy imbalanced classification by weighting generation with relative neighborhood density [8]. These outcomes suggest that local evidence is useful, but they also expose the central question addressed here: whether the evidence used to trust a seed should be separated from the evidence used to allocate synthesis effort.

C. Research Gap

This study addresses a gap in existing oversampling methods: the decision to trust a minority instance as a synthesis seed is often treated together with the decision about how much synthetic generation effort that instance should receive. These two decisions should be separated. Seed eligibility concerns whether a candidate minority instance is reliable

enough to guide interpolation, whereas synthesis allocation concerns how strongly a reliable seed should contribute to class balancing.

This distinction matters because difficulty can arise from different causes. A minority instance surrounded by majority samples may be an informative boundary case, but it may also be mislabeled or isolated. A method that increases generation near all difficult samples may amplify noise. In contrast, a method that selects only safe minority regions may miss boundary cases that are useful for discrimination. The methodological gap is therefore not simply the need for adaptive oversampling, but the need to separate seed eligibility from synthesis allocation.

NADOS addresses this gap by using reliability to determine seed eligibility and difficulty to determine synthesis priority. This differs from methods that treat local difficulty alone as a reason for more generation, and from methods that focus only on safe regions without explicitly preserving informative hard cases. The method first asks whether a minority instance should be trusted, and only then determines how much influence it should have during synthetic generation.

In relation to the preceding studies, NADOS treats seed eligibility and synthesis allocation as two separate decisions. Classical SMOTE mainly assumes that selected minority neighbors are trustworthy [4], ADASYN and Borderline-SMOTE emphasize difficult or boundary samples [12, 7], and cleaning hybrids remove some problematic samples only after generation [11, 14, 15]. NADOS instead screens candidate seeds before interpolation and then allocates generation pressure only among seeds that pass this screen (Fig. 1).

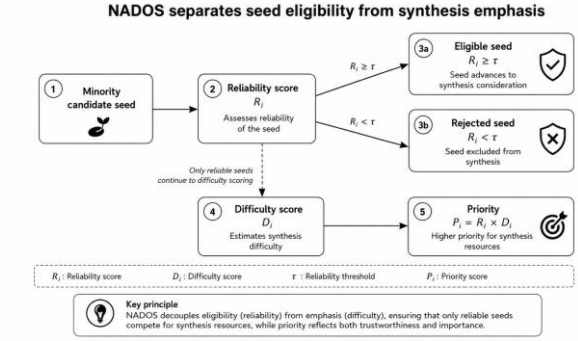

Fig. 1. NADOS decision logic separating seed eligibility from synthesis priority.

III. Proposed Method

This section defines the proposed NADOS method. It begins with the binary noisy imbalanced learning setting, introduces the local neighborhood evidence used by the method, defines the reliability and difficulty scores, and then describes how these scores are combined into a priority-based synthetic generation procedure.

A. Problem Setting

Let a binary training set be denoted as:

$$D = \{(x_i, y_i)\}_{i=1}^{n}$$

where, x_i is a feature vector, and y_i is the class label. The minority class is underrepresented relative to the majority class. The observed training data may also contain label noise. The goal is to generate synthetic minority samples that improve minority-sensitive classification performance without reinforcing unreliable local structure.

B. Local Neighborhood Evidence

For each minority instance x_i, NADOS constructs a k-nearest-neighbor neighborhood using the training fold. Let:

- m_i be the number of minority neighbors among the k-nearest neighbors.
- d_i^{min} be the average distance from x_i to minority neighbors.
- d_i^{maj} be the average distance from x_i to majority neighbors.

Neighborhood composition captures local minority support, while relative distance structure indicates whether the instance is closer to minority or majority regions.

C. Reliability Score

The reliability score estimates whether a minority instance is sufficiently trustworthy to be used as a synthesis seed. It combines minority-neighbor support with relative distance evidence:

$$R_i = \lambda\left(\frac{m_i}{k}\right) + (1-\lambda)\left(\frac{d_i^{\text{maj}}}{d_i^{\text{min}} + d_i^{\text{maj}}}\right)$$

where, λ controls the contribution of neighborhood composition. A higher R_i indicates stronger local minority support and greater distance from majority neighbors. A minority instance is eligible for synthetic generation only if:

$$R_i \geq \tau$$

where, τ is the reliability threshold.

The reliability score functions as a conservative screen rather than a full generation policy. The first term, m_i / k, measures same-class support in the local neighborhood. A minority instance with stronger minority support is less likely to be an isolated noisy point. The second term compares distances to majority and minority neighbors. If majority neighbors are relatively farther away, the instance is less likely to be embedded in a majority-dominated region. Combining these signals avoids relying only on neighbor counts, which can be unstable in sparse regions, or only on distance ratios, which can be sensitive to local scale.

D. Difficulty Score

The difficulty score estimates how much synthesis effort should be assigned to an eligible minority instance. NADOS combines a boundary component with a local sparsity component:

$$B_i = 1 - \left|2\left(\frac{m_i}{k}\right) - 1\right|$$

$$\rho_i = \frac{m_i}{k}$$

$$D_i = \eta B_i + (1 - \eta)(1 - \rho_i)$$

where, B_i is high near mixed neighborhoods and 1 - ρ_i reflects lower minority support. The parameter η controls the balance between boundary difficulty and sparsity difficulty.

The difficulty score is deliberately separated from reliability. A great difficulty score does not by itself make an instance suitable for interpolation; it only indicates that the instance may deserve more synthesis attention after passing the reliability gate. This prevents the method from treating unreliable difficult samples and informative difficult samples as equivalent. The boundary component emphasizes mixed neighborhoods, while the sparsity component gives attention to locally under-supported minority regions.

E. Synthesis Priority

NADOS assigns synthesis priority only to reliable seeds:

$$P_i = R_i \times D_i, if\ R_i \geq \tau;\ otherwise\ P_i = 0$$

The priority values are normalized across eligible minority seeds. Synthetic samples are then generated by selecting seed instances according to their normalized priorities and interpolating between the selected seed and one of its minority neighbors:

$$x_{new} = x_i + \alpha(x_j - x_i)$$

where, x_j is a minority neighbor of x_i and α is sampled uniformly from [0, 1].

The multiplicative priority formulation was selected because reliability and difficulty serve different roles. Reliability acts as a trust signal, whereas difficulty allocates synthesis effort among candidate seeds. A simple additive rule could allow a highly difficult but weakly reliable instance to retain substantial priority, which would conflict with the noise-aware motivation of NADOS. The product rule makes priority high only when both conditions are satisfied: the instance is sufficiently reliable and also informative enough to deserve synthesis emphasis. This provides a conservative first formulation for noisy imbalanced settings, where difficult minority instances may represent useful boundary cases but may also correspond to mislabeled or unstable samples.

F. Algorithm 1

Algorithm 1 NADOS oversampling procedure

1:	**input:** D, cmin, k, λ, η, τ, target ratio r	
2:	**initialize** D′ ← D and required synthetic count	
3:	***for*** each minority instance x_i **do**	
4:	compute R_i from support and distance evidence	▷ reliability
5:	compute D_i from boundary and sparsity components	▷ difficulty
6:	set $P_i = R_i \times D_i$ if $R_i \geq \tau$; else $P_i = 0$	▷ priority
7:	**end for**	
8:	***while*** target minority ratio r is not reached **do**	
9:	sample by normalized P_i; generate xnew = x_i + $\alpha(x_j - x_i)$; append to D′	▷ synthesis
10:	**output** resampled training set D′	

This procedure makes NADOS a reliability-gated extension of adaptive interpolation-based oversampling. The gate prevents unsafe seeds from driving generation, while the difficulty score preserves synthesis attention for reliable but challenging minority instances.

The computational cost of NADOS is dominated by nearest-neighbor search and synthetic sample generation. For each training fold, neighborhood evidence is computed for minority instances, after which generation proceeds similarly to SMOTE but with priority-weighted seed selection. Thus, the method adds local scoring overhead relative to plain SMOTE but avoids classifier-specific optimization or iterative model fitting inside the resampling step (Fig. 2).

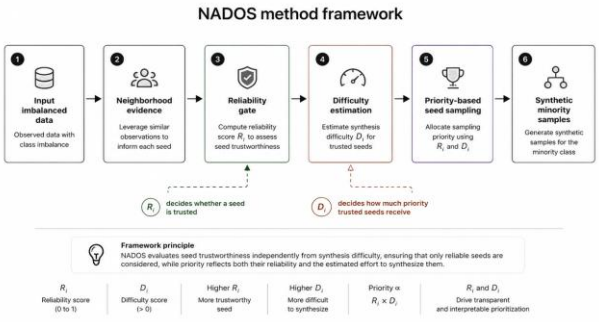

Fig. 2. NADOS method framework.

The main experiment used fixed settings across all datasets, classifiers, folds, and noise levels: k = 5, reliability weight λ = 0.50, difficulty weight η = 0.50, reliability threshold τ = 0.35, target minority ratio 1.00, product priority R_i x D_i, noise levels of 0%, 5%, 10%, 15%, and 20%, and random seed 42.

IV. Experimental Design

This section describes the benchmark datasets, controlled noise protocol, classifiers, baseline oversampling methods, evaluation metrics, statistical tests, and software environment used to evaluate NADOS. The experiments were implemented in Python using standard scientific-computing and machine-learning libraries, including scikit-learn and imbalanced-learn for model evaluation and baseline resampling support [16, 17].

A. Benchmark Datasets

The evaluation uses 22 binary imbalanced benchmark datasets: ecoli-0_vs_1, ecoli1, ecoli2, ecoli3, glass-0-1-2-3_vs_4-5-6, glass0, glass1, glass6, haberman, iris0, new-thyroid1, new-thyroid2, page-blocks0, pima, segment0, vehicle0, vehicle1, vehicle2, vehicle3, wisconsin, yeast1, and yeast3. These datasets are drawn from public imbalanced-learning benchmark collections derived from KEEL and UCI-style tabular datasets [18, 19]. They cover multiple sample sizes and imbalance ratios, giving a diverse benchmark for tabular imbalanced classification.

The benchmark contains 22 binary imbalanced tabular datasets with 150 to 5472 instances, 3 to 19 features, and imbalance ratios ranging from 1.82 to 8.79. The datasets include ecoli, glass, haberman, iris, new-thyroid, page-blocks, pima, segment, vehicle, wisconsin, and yeast variants.

B. Controlled Label Noise

Because the selected benchmark datasets do not provide a consistent natural-noise setting, controlled symmetric label noise is injected into the training folds. Noise levels of 0%, 5%, 10%, 15%, and 20% are used. Noise is applied only to training folds, while test folds remain unchanged. This design evaluates whether each oversampling method can learn from corrupted training data while preserving a clean evaluation reference.

This ordering is important for experimental validity. If noise injection or resampling were applied before the train-test split, synthetic samples or corrupted-label effects could leak into the evaluation fold. The protocol therefore follows a strict sequence: split the data, inject noise into the training fold only, apply resampling to the noisy training fold only, train the classifier, and evaluate on the untouched test fold. This makes the measured performance reflect robustness to noisy training data rather than contamination of the test reference (Fig. 3).

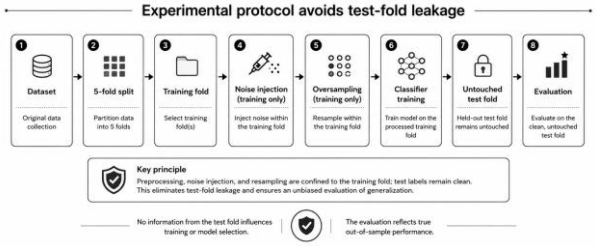

Fig. 3. Experimental protocol used to prevent test-fold leakage.

C. Classifiers and Baselines

Four classifiers are used: logistic regression, support vector machine, random forest, and gradient boosting. NADOS is compared against eight baselines: Random Oversampling, SMOTE, ADASYN, Borderline-SMOTE, SVM-SMOTE, SMOTE-ENN, SMOTE-Tomek, and WRND.

The classifier set is intentionally heterogeneous. Logistic regression provides a linear baseline, SVM captures margin-based behavior, random forest represents bagged tree ensembles, and gradient boosting represents sequential tree ensembles. This reduces the chance that the evaluation reflects compatibility with only one classifier family. The baseline set covers duplication, classical interpolation, adaptive difficulty-based oversampling, boundary-guided oversampling, hybrid cleaning, and a recent noise-aware method.

D. Metrics

The primary metrics are F1, G-mean, AUPRC, and balanced accuracy. Minority recall and runtime are also reported. These metrics are selected because standard accuracy is not sufficient for imbalanced classification and can hide poor minority-class recognition; precision-recall analysis is also recommended when the positive or minority class is rare [20, 21]. Let TP, TN, FP, and FN denote true positives, true negatives, false positives, and false negatives, respectively. Precision, recall, specificity, and the primary summary metrics are defined as follows:

$$Precision = \frac{TP}{TP + FP}$$

$$Recall = \frac{TP}{TP + FN}$$

$$Specificity = \frac{TN}{TN + FP}$$

$$F1 = 2 \times \frac{Precision \times Recall}{Precision + Recall}$$

$$G\text{-}mean = \sqrt{Recall \times Specificity}$$

$$Balanced\ accuracy = \frac{Recall + Specificity}{2}$$

$$AUPRC = \Sigma\,(Recall_t - Recall_{t-1})\,Precision_t$$

AUPRC summarizes the precision-recall curve and is useful when the minority class is the primary class of interest.

E. Statistical Testing

The comparison uses non-parametric statistical testing because multiple methods are evaluated across multiple datasets, folds, classifiers, and noise levels. Friedman tests are used to test whether overall differences exist among methods [22]. Pairwise Wilcoxon signed-rank tests with Holm correction are then used to compare NADOS against each baseline [23, 24].

Each dataset-fold-noise-classifier combination is treated as a comparison block. The Friedman test evaluates whether the methods differ in rank across these repeated benchmark conditions. Because the global test does not identify which method pairs differ, Wilcoxon signed-rank tests are then applied to paired NADOS-versus-baseline results. Holm correction is used to control the family-wise error rate across multiple pairwise comparisons. This combination of average performance, rank analysis, and corrected paired tests provides a more reliable interpretation than mean scores alone.

V. Results and Discussion

This section reports the empirical findings from three complementary perspectives: aggregate metric values, average rank analysis, and pairwise statistical comparisons against baselines. It then discusses robustness under increasing label noise and the runtime implications of the proposed scoring procedure.

A. Overall Performance

Overall performance is summarized across all datasets, folds, classifiers, and noise levels.

Across the full benchmark, NADOS obtains average F1 = 0.7428, G-mean = 0.8511, AUPRC = 0.7700, balanced accuracy = 0.8552, minority recall = 0.8445, and runtime = 0.1609 seconds. The closest competitor is SVM-SMOTE, with F1 = 0.7417, G-mean = 0.8506, AUPRC = 0.7746, and balanced accuracy = 0.8555. SMOTE-Tomek, SMOTE, Random Oversampling, and WRND remain competitive but are lower on the main balanced classification metrics.

NADOS obtains the highest average F1 and G-mean and is effectively tied with SVM-SMOTE on balanced accuracy. SVM-SMOTE obtains the highest average AUPRC. This suggests that NADOS is strongest for balanced minority-

sensitive classification performance, while AUPRC remains competitive but not dominant (Table I).

TABLE I. MEAN PERFORMANCE ACROSS ALL DATASETS, FOLDS, CLASSIFIERS, AND NOISE LEVELS

Method	F1	G-mean	Bal. Acc.	AUPRC
NADOS	0.7428	0.8511	0.8552	0.7700
SVM-SMOTE	0.7417	0.8506	0.8555	0.7746
SMOTE-Tomek	0.7356	0.8497	0.8536	0.7695
SMOTE	0.7329	0.8480	0.8519	0.7682
Random oversampling	0.7357	0.8468	0.8515	0.7663
WRND	0.7405	0.8379	0.8445	0.7595
SMOTE-ENN	0.7026	0.8376	0.8444	0.7513
ADASYN	0.6980	0.8342	0.8391	0.7517
Borderline-SMOTE	0.6955	0.8303	0.8355	0.7404

NADOS does not dominate every dataset-metric combination, but it has the strongest aggregate profile for F1, G-mean, and balanced accuracy. Noisy imbalanced benchmark performance is heterogeneous, and different resampling methods may be favored by different dataset geometries, classifiers, and noise levels. The contribution should therefore be interpreted through aggregate performance, average ranking, and statistically validated comparisons rather than as universal dominance.

The overall results are consistent with the method design. F1, G-mean, and balanced accuracy reward methods that improve minority recognition without allowing majority performance to collapse. NADOS performs well under these criteria because the reliability gate limits unsafe seed usage while the difficulty score still emphasizes challenging reliable regions. SMOTE-ENN achieves the highest average minority recall, but its F1 and G-mean are lower, indicating that recall gains alone are insufficient when precision or majority recognition deteriorates.

The AUPRC result should be interpreted cautiously. SVM-SMOTE achieves the highest AUPRC, suggesting that margin-guided boundary synthesis can be effective for ranking minority instances by predicted score. NADOS remains competitive but does not dominate this metric. This indicates that reliability-gated generation improves classification balance more clearly than probability ranking quality in the current configuration.

B. Average Rank Analysis

The Friedman ranking results show that NADOS achieves the best average rank for F1, G-mean, and balanced accuracy. For AUPRC, SVM-SMOTE obtains the best average rank, while NADOS ranks third but remains close to SMOTE-Tomek and SMOTE.

The Friedman and average-rank results support the aggregate performance findings.

The Friedman tests are significant for all primary metrics ($p < 0.001$), indicating systematic differences among methods across benchmark blocks. NADOS has the best average rank for F1 (4.2786), G-mean (4.3755), and balanced accuracy (4.3873). For AUPRC, SVM-SMOTE obtains the best average rank (4.2130), followed by SMOTE-Tomek and SMOTE, while NADOS remains close with rank 4.6200 and average AUPRC = 0.7700.

The significant Friedman tests indicate that the performance differences among methods are not random across the benchmark conditions. The rank profile supports the main claim that NADOS is a strong general-purpose oversampling method under noisy imbalanced settings, particularly for metrics that directly reflect balanced class recognition.

The rank results are useful because average scores can be influenced by a small number of large datasets or easier benchmark conditions. Ranking each method within repeated comparison blocks provides a distribution-free view of consistency. NADOS obtains the best average rank for three of the four primary metrics, which supports its robustness across datasets, classifiers, folds, and noise levels. Its third-place AUPRC rank reinforces the need to position the method as balanced and robust rather than universally superior (Fig. 4).

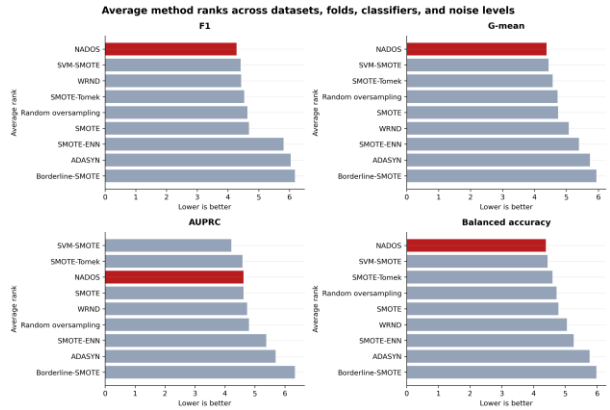

Fig. 4. Average method ranks across the primary evaluation metrics.

C. Pairwise Comparison Against Baselines

Wilcoxon-Holm pairwise tests show that NADOS significantly improves F1 over Borderline-SMOTE, ADASYN, SMOTE-ENN, SMOTE, Random Oversampling, and SMOTE-Tomek. The F1 differences relative to SVM-SMOTE and WRND are not statistically significant after Holm correction, suggesting that these methods remain close competitors.

For G-mean and balanced accuracy, NADOS significantly improves over most baselines, including WRND, SMOTE-ENN, ADASYN, Borderline-SMOTE, SMOTE, Random Oversampling, and SMOTE-Tomek. Differences relative to SVM-SMOTE are not significant. For AUPRC, NADOS improves over several weaker baselines but does not outperform SVM-SMOTE.

These findings should be interpreted cautiously. NADOS should not be framed as universally dominant, but as a method that consistently strengthens balanced minority-sensitive performance while remaining competitive with the strongest SMOTE-family baseline.

The pairwise results clarify the practical meaning of the average ranks. NADOS provides statistically significant gains over ADASYN and Borderline-SMOTE across F1, G-mean, and balanced accuracy. Since these methods also emphasize difficult or boundary samples, the result supports the argument that difficulty should not be used alone as a generation signal. NADOS also improves over WRND for G-mean and balanced accuracy, suggesting that reliability-gated synthesis can compete with a recent density-aware noise-robust strategy. The non-significant differences against SVM-SMOTE indicate that margin-guided synthesis remains a strong competitor.

The closest Wilcoxon-Holm comparisons reinforce this interpretation.

The Wilcoxon-Holm tests show significant F1 gains for NADOS over Borderline-SMOTE (mean difference = 0.0476, $p < 0.001$), ADASYN (0.0441, $p < 0.001$), SMOTE (0.0100, $p < 0.001$), and SMOTE-Tomek (0.0075, $p < 0.001$). The F1 differences against SVM-SMOTE (0.0012, $p = 0.3224$) and WRND (0.0023, $p = 0.9411$) are not significant. For G-mean and balanced accuracy, NADOS significantly improves over WRND and most SMOTE-family baselines, while differences against SVM-SMOTE remain non-significant.

D. Component Ablation and Parameter Sensitivity

To isolate the contributions of the two NADOS components, two ablated variants were evaluated using the same benchmark protocol. The reliability-only variant applies the reliability gate but distributes synthesis uniformly among eligible seeds. The difficulty-only variant removes the reliability gate and allocates synthesis according to the difficulty score alone. Full NADOS performs best across all four reported metrics, indicating that the reliability gate and difficulty-weighted allocation contribute complementary effects rather than one component fully subsuming the other (Table II).

TABLE II. ABLATION COMPARISON FOR FULL NADOS AND COMPONENT VARIANTS

Variant	F1	G-mean	Bal. Acc.	AUPRC
Full NADOS	0.7428	0.8511	0.8552	0.7700
Reliability-only	0.7354	0.8478	0.8523	0.7657
Difficulty-only	0.7184	0.8438	0.8480	0.7597

TABLE III. SELECTED PARAMETER SENSITIVITY SUMMARY ON REPRESENTATIVE DATASETS

Setting	Parameter	Mean F1	Mean G-mean	Mean AUPRC
rel30/diff70	lambda/eta	0.5706	0.7620	0.6173
rel50/diff50	lambda/eta	0.5748	0.7595	0.6227
rel70/diff30	lambda/eta	0.5726	0.7566	0.6237
tau=0.20	threshold	0.5287	0.7862	0.6014
tau=0.35	threshold	0.5467	0.7806	0.6065
tau=0.50	threshold	0.5748	0.7595	0.6227

A limited parameter sensitivity check evaluates the reliability threshold and the relative reliability-difficulty weighting on representative datasets. The main configuration uses $k = 5$, lambda = 0.50, eta = 0.50, and tau = 0.35. The value $k = 5$ was selected as a local-neighborhood setting commonly used in SMOTE-family experiments and was fixed to avoid dataset-specific tuning. The threshold and weighting checks show that performance varies by dataset, which supports the decision to report a fixed reproducible configuration rather than tune parameters separately for each benchmark condition (Table III).

E. Robustness Under Label Noise

The controlled noise protocol evaluates whether each method remains useful as training labels become increasingly corrupted. NADOS is designed for this setting because unreliable seeds should be filtered before synthetic generation. The reliability gate is expected to matter most as noise increases, since noisy minority instances are more likely to produce harmful synthetic samples when used as interpolation seeds.

The noise-level results show a clear robustness trend. In the no-noise setting, SMOTE-Tomek, SMOTE, and SVM-SMOTE are slightly ahead of NADOS on G-mean. Once label noise is introduced, NADOS becomes increasingly competitive and obtains the strongest G-mean at 10% and 15% noise. At 20% noise, SVM-SMOTE remains slightly ahead, but NADOS remains stronger than SMOTE, SMOTE-Tomek, and WRND on G-mean and balanced accuracy. This supports the intended role of the reliability gate: NADOS is most useful when the training data contain noisy or unstable minority candidates.

This trend also explains why the method should be evaluated under noise rather than only on clean imbalanced data. In the no-noise setting, classical SMOTE-family methods remain highly competitive because many minority seeds are usable. As noise increases, unsafe seed selection becomes more costly. NADOS does not prevent all performance degradation, but it delays the point at which noisy local structure damages balanced performance. The clearest advantage appears at moderate noise levels, especially 10% and 15%, where reliability screening is valuable, but neighborhood evidence remains informative.

Overall, the G-mean trend shows that NADOS is most competitive in moderate-noise settings. At the highest noise level, SVM-SMOTE is slightly stronger, but NADOS remains close and stronger than SMOTE, SMOTE-Tomek, and WRND on the main balanced metrics (Fig. 5).

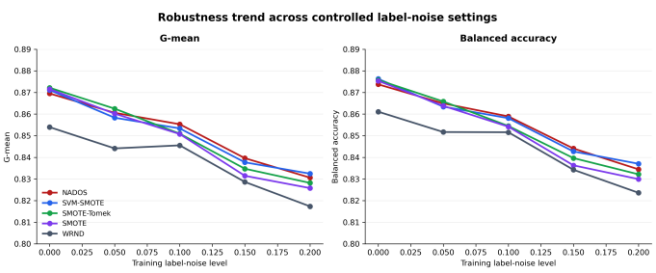

Fig. 5. Robustness trend across controlled label-noise settings.

F. Runtime and Computational Complexity

The runtime results indicate that NADOS remains practical at the benchmark scale used in this study. As shown in Table IV, NADOS records an average runtime of 0.1609 seconds and an average runtime rank of 4.80 across the benchmark comparisons. It is not the fastest method: SMOTE-ENN, Random Oversampling, WRND, and SMOTE-Tomek have better average runtime ranks. However, NADOS remains faster on average than SVM-SMOTE, SMOTE, Borderline-SMOTE, and ADASYN, while providing stronger aggregate F1, G-mean, and balanced accuracy.

TABLE IV. RUNTIME COMPARISON ACROSS ALL BENCHMARK SETTINGS

Method	Mean runtime (s)	Runtime rank
SMOTE-ENN	0.1042	1.51
Random oversampling	0.1497	3.94
SMOTE-Tomek	0.1661	4.35
WRND	0.1499	4.53
NADOS	0.1609	4.80
SVM-SMOTE	0.1683	5.84
SMOTE	0.1739	6.05
Borderline-SMOTE	0.1809	6.92
ADASYN	0.1868	7.04

The additional cost comes from computing local neighborhood evidence before generating synthetic samples. For n training instances, n_min minority instances, d features, k nearest neighbors, and G generated synthetic samples, a direct implementation computes distances between each minority instance and the training set. This requires O(n_min n d) distance operations. After the neighbor lists are available, synthetic interpolation requires O(Gd) operations because each generated sample is constructed across d features. The remaining reliability, difficulty, and priority calculations are linear in the number of minority instances, O(n_min), and are therefore smaller than the neighborhood-search cost.

In practical terms, NADOS has a similar computational profile to SMOTE-family methods that also depend on nearest-neighbor search. Its extra scoring stage adds overhead, but it does not require repeated classifier fitting, iterative optimization, or ensemble training inside the resampling process. For small and medium tabular benchmarks, this cost is acceptable. For very large or high-dimensional datasets, approximate nearest-neighbor search, feature normalization, dimensionality reduction, or batch-wise implementation may be needed.

G. Discussion

The results also identify boundary conditions where NADOS should not be described as universally superior. SVM-SMOTE is the closest competitor, obtains a slightly higher AUPRC and balanced accuracy in the aggregate table, and is not significantly different from NADOS on F1 after Holm correction. This suggests that margin-guided boundary synthesis can be highly competitive when the classifier score ranking is important. NADOS is therefore best characterized as having a strong and balanced performance profile under the evaluated noisy imbalanced benchmark, rather than as dominating every metric or dataset condition.

The results support the central methodological argument: separating seed reliability from synthesis difficulty is beneficial in noisy imbalanced classification. NADOS does not simply assign more synthetic samples to difficult regions. Instead, it first examines whether a minority instance is trustworthy enough to guide generation. This distinction helps avoid the main weakness of difficulty-only adaptive oversampling, where noisy or unstable points may receive excessive synthetic emphasis.

The method is not uniformly superior on every metric. SVM-SMOTE remains highly competitive and obtains stronger AUPRC. This limitation should be acknowledged directly. The value of NADOS lies in its balanced performance profile, explicit noise-aware decision logic, and strong average ranking on F1, G-mean, and balanced accuracy.

The results support the main hypothesis: a useful oversampling method for noisy imbalanced data should not treat all difficult minority samples as equally valuable. The reliability gate and difficulty score serve different purposes. The gate reduces generation from unstable seeds, while the difficulty score preserves attention to hard but useful samples. This division is the main conceptual contribution of NADOS and explains why it is competitive with both classical SMOTE-family methods and a recent noise-aware baseline.

VI. THREATS TO VALIDITY

This study uses controlled symmetric label noise, which supports reproducibility but does not capture all forms of real-world label corruption. The empirical claims should therefore be scoped to the symmetric training-label noise setting evaluated here. In practice, label noise may be class-dependent, feature-dependent, annotator-dependent, or concentrated in specific subregions of the feature space. Future work should test NADOS under class-dependent and feature-dependent corruption models before generalizing the conclusions to all noisy-data settings.

The benchmark is limited to binary tabular imbalanced datasets. This is appropriate for the first evaluation of NADOS, but conclusions should not be generalized automatically to multiclass, image, text, temporal, or streaming data. The method depends on k-nearest-neighbor evidence, so its behavior can be affected by the distance metric, feature scaling, mixed numerical-categorical attributes, missing values, and high-dimensional distance concentration. In the present implementation, continuous features are normalized within the training pipeline, and Euclidean neighborhoods are used; alternative metrics, metric learning, or categorical-aware distance functions may be needed for heterogeneous datasets.

The parameter settings are fixed for the main evaluation. This supports reproducibility and fair comparison, but it may not be optimal for every dataset. Adaptive parameter selection, threshold tuning, and alternative priority functions are left for future work. Finally, the implementation evaluates NADOS against a focused set of reproducible baselines. Additional recent oversampling methods may provide further comparison

opportunities if stable implementations and consistent benchmark protocols are available.

VII. Conclusion

This study proposed NADOS, a reliability-gated and difficulty-aware oversampling method for noisy imbalanced classification. The method separates minority-seed trustworthiness from synthesis priority by using reliability as an eligibility gate and difficulty as an allocation signal among eligible seeds. Evaluation across 22 benchmark datasets, five label-noise levels, four classifier families, and eight oversampling baselines shows that NADOS achieves the best average F1, G-mean, and balanced accuracy while remaining competitive on AUPRC. These findings support reliability-gated adaptive oversampling as a practical strategy for noisy imbalanced learning.

Future work should extend NADOS to adaptive thresholding, broader external datasets, multiclass settings, and more detailed component-level ablation. It should also examine alternative priority-combination rules, including additive weighting, soft-gated products, probabilistic seed selection, and learned weighting functions, to determine whether adaptive priority functions improve performance under different noise regimes, imbalance ratios, and feature-space conditions.

VIII. Declarations

A. Declaration on Generative AI

The authors used generative AI-assisted tools for language refinement and editorial checking. All scientific ideas, experimental design, implementation, results, interpretations, and final manuscript content were reviewed and verified by the authors.

B. Data Availability

The datasets used in this study are publicly available benchmark imbalanced classification datasets in KEEL-style format and related public tabular repositories [18, 19]. The dataset names and benchmark characteristics are summarized in the manuscript.

C. Code Availability

The implementation code, benchmark scripts, parameter settings, preprocessing pipeline, and random seeds are retained by the authors and may be made available upon reasonable request, subject to thesis completion, institutional requirements, and repository preparation.

D. Funding

This work was supported/funded by the Universiti Teknologi Malaysia under UTM NEXUS Translasi (PY/2025/00988).

E. Conflicts of Interest

The authors declare no conflicts of interest.

A RAG-Enhanced Human-in-the-Loop Framework for Automated Assessment of Engineering Laboratory Reports

Amina Abbi[1]*, Mohammed Skouri[2], Mustapha Raoufi[3]

Laboratory of Materials Energy and Environment, Faculty of Science Semlalia, Cadi Ayyad University, Marrakech, Morocco[3]

***Abstract*—Recent developments in Large Language Models (LLMs) have created new opportunities to automate educational assessment and reduce workload for instructors. However, concerns regarding grading consistency, transparency, and pedagogical reliability continue to limit the adoption of fully automated assessment systems. In this study, we propose a Human-in-the-Loop framework for the automated evaluation of engineering laboratory reports based on Retrieval-Augmented Generation (RAG). The proposed framework integrates text extraction, structured content extraction, contextual retrieval from grading rubrics and laboratory resources, rubric-based evaluation, automatic feedback generation, and instructor validation into a unified grading workflow. The RAG module retrieves contextual information so that the language model can generate assessments that align with the course goals and are based on educational information about the specific assignments, thus ensuring consistent evaluation based on the rubric. The system was tested using a set of 56 laboratory reports collected from undergraduate courses in Electrical and Electronics Engineering. The experimental results indicate a strong agreement between the grades provided by the AI and the instructor, with a Pearson Correlation Coefficient of 0.988, a Mean Absolute Error (MAE) of 3.55, and a Root Mean Squared Error (RMSE) of 3.77. Besides, 89.29% of the reports were scored within ±5 points of the instructor scores. The grading time was reduced from 392 minutes to 84 minutes, a workload reduction of 78.57%. The results demonstrate that the integration of Retrieval-Augmented Generation, rubric-based evaluation, and Human-in-the-Loop validation constitutes an effective approach for AI-supported assessment of engineering laboratory reports, maintaining instructor oversight and educational integrity.**

I. Introduction

Artificial intelligence (AI) is rapidly transforming educational technologies by enabling intelligent tutoring, personalized learning, automated assessment, feedback generation, and AI-assisted learning environments [1]– [4], [11]. Recent studies have further highlighted the growing role of AI in educational assessment, personalized feedback, and technology-enhanced learning [10], [18], [23].

Large Language Models (LLMs), one of the most significant recent advances in AI, have demonstrated remarkable capabilities in natural language understanding and generation, making them promising tools for educational assessment [1], [7], [9], [21]. Recent studies have shown that LLMs can effectively assist instructors in grading essays, short-answer questions, programming assignments, engineering assignments, and open-ended examinations while improving grading consistency and reducing instructor workload [8], [13], [16], [17], [19].

One of the hardest types of assessment is the assessment of educational assessment in engineering laboratory reports. They assess theoretical understanding, experimental procedures, technical calculations, data interpretation, engineering reasoning, and scientific communication, as opposed to the typical written assignment. The manual grading process is thus time-consuming and may suffer from inconsistency due to instructor workload and subjective judgment.

Prior research has shown the promise of LLM-based grading systems, but most methods evaluate student submissions individually without taking into account assignment-specific educational resources such as lab instructions, grading rubrics, reference solutions, and course materials. Thus, the quality of grading may be undermined by an incomplete understanding of the context and hallucinated answers. Furthermore, fully automated assessment systems are typically opaque and lack human oversight, limiting their adoption in higher education [9], [21].

Recently, a promising approach to enhance the reliability of LLM-based systems is to augment prompts with relevant external knowledge retrieved at inference time, which is known as Retrieval-Augmented Generation (RAG) [20]. In educational assessment, RAG allows language models to assess student work with resources specific to the assignment instead of relying solely on pre-trained knowledge. Recent studies have also shown the usage of context-aware assessment and context engineering to improve the reliability of grading and quality of feedback [14], [20].

However, the automated assessment of engineering laboratory reports has been relatively less explored, with an integrated framework that combines contextual retrieval, rubric-based evaluation, automated feedback generation, and Human-

*Corresponding author

in-the-Loop validation. Previous work has largely focused on essays, math assessments, programming assignments, or short-answer questions, but engineering lab reports pose additional challenges due to the need for experimental analysis and technical reasoning.

To address this gap, this study proposes an RAG-enhanced Human-in-the-Loop framework for automated assessment of engineering laboratory reports using Large Language Models. The proposed framework combines document preprocessing, structured content extraction, Retrieval-Augmented Generation, rubric-based grading, automated feedback generation, and instructor validation into a single assessment workflow. The framework was evaluated on 56 laboratory reports of the Electrical and Electronics Engineering domain. The experimental results demonstrate a high level of agreement in the grades assigned by the AI and the instructor, with a Pearson Correlation Coefficient of 0.988, a Mean Absolute Error (MAE) of 3.55 points, and an Agreement Rate of 89.29%, reducing grading time by 78.57%.

The major contributions of this work are summarized in Table I.

TABLE I. SUMMARY OF THE MAIN CONTRIBUTIONS

Contribution	Description
C1	A RAG-enhanced Human-in-the-Loop framework for automated assessment of engineering laboratory reports.
C2	Integration of contextual retrieval, rubric-based grading, automated feedback generation, and instructor validation into a unified assessment workflow.
C3	Experimental validation with 56 real lab reports from Electrical & Electronics Engineering.
C4	Comprehensive evaluation with Pearson Correlation, MAE, RMSE, Agreement Rate, Maximum Error, and grading time reduction.

The rest of this study is organized as follows: Related work on AI-assisted educational assessment is presented in Section II. The proposed methodology is presented in Section III. Section IV describes the experiment setup. Section V presents and discusses the experimental results, including the limitations of the study. Finally, Section VI concludes the study and offers future research directions.

II. RELATED WORK

A. Education Assessment Using Large Language Models

Recently, Large Language Models (LLMs) have become a major research topic in educational technology, as they are capable of supporting intelligent tutoring, personalized learning, automated assessment, and feedback generation [1], [4], [11]. Recent surveys [1], [9], [11] show that automated assessment is one of the most promising applications of LLMs in education. The effectiveness of LLMs for grading short-answer questions [16], essays [8], programming assignments [17], engineering mechanics assignments [19], undergraduate calculus [5], and open-ended examinations [13] has been demonstrated in several studies. These studies consistently show high agreement between grades assigned by AI and instructors, and significantly reduce instructor workload.

But these encouraging results also highlight problems of grading consistency, hallucinations, transparency, and pedagogical reliability in prior research. Thus, current evidence points to LLMs supporting instructors rather than replacing human judgment [9], [21].

B. Human-in-the-Loop Evaluation and AI-Generated Feedback

Recent studies have increasingly advocated for Human-in-the-Loop (HITL) grading frameworks [7], [8] to improve the reliability and transparency of AI-assisted assessment. These methods combine automated assessment and instructor review, enabling instructors to verify AI-generated grades before they are posted as final results.

Moreover, several studies have shown that LLM-generated feedback can enhance student learning by offering personalized suggestions and constructive explanations [6], [15], [22], [24]. Moreover, AI-enabled pedagogical architectures have shown promising results in supporting self-regulated learning and enhancing student engagement [3]. The results suggest that a good assessment system should involve reliable grading, useful feedback, and instructor oversight.

C. Retrieval-Enhanced Generation for Education Assessment

Retrieval-Augmented Generation (RAG) has emerged as a powerful approach for improving the factuality and context-awareness of LLMs by retrieving relevant external knowledge before response generation [20]. In educational assessment, RAG allows language models to leverage lab instructions, grading rubrics, reference solutions, and course materials, which helps mitigate hallucinations and improves consistency in grading.

Context engineering has recently shown that the integration of contextual educational resources enhances the quality of AI-based assessment [14]. At the same time, research on automated assessment in the domain of STEM education emphasizes the increasing importance of domain-specific contextual information for reliable assessment [12].

D. Research Gap and Contributions

Despite many advances in AI-based assessment on educational resources, existing studies mainly focus on essays, programming assignments, mathematics or short-answer questions [5], [8], [13], [16], [17]. Engineering laboratory reports, which require evaluation of experimental procedures, technical calculations, engineering reasoning, and scientific communication, have been relatively neglected.

Additionally, most existing approaches rely solely on LLM reasoning without integrating contextual retrieval, rubric-based evaluation, automated feedback generation, and Human-in-the-Loop validation in a unified framework.

To overcome these limitations, this study proposes a RAG-enhanced Human-in-the-Loop framework for automated assessment of engineering laboratory reports using Large Language Models. The proposed framework combines Retrieval-Augmented Generation, structured content extraction, rubric-based grading, automated feedback generation, and instructor validation into one assessment workflow.

The framework is experimentally validated using 56 real Electrical and Electronics Engineering laboratory reports and evaluated using various quantitative metrics such as Pearson Correlation, MAE, RMSE, Agreement Rate, Maximum Error, and grading time reduction.

III. Methodology

A. Overview of the Proposed Framework

The proposed framework presents a Human-in-the-Loop framework for automated assessment of engineering laboratory reports enhanced by Retrieval-Augmented Generation (RAG). Unlike traditional LLM-based automated grading systems that only use student submissions, it enhances the grading process by accessing educational resources specific to assignments, such as laboratory instructions, grading rubrics, reference solutions, and course materials. This contextual information allows for a more consistent, transparent, and reliable assessment based on the intended learning outcomes.

This framework combines an end-to-end assessment workflow that includes document pre-processing, extraction of structured content, context retrieval, rubric-based assessment, automated feedback generation, support for plagiarism and validation by instructors. AI-generated grades and feedback are preliminary recommendations. Instructors maintain complete discretion to review, revise, approve, or reject the proposed assessment before the final grade is assigned, thereby ensuring pedagogical accountability and reducing automation bias.

The assessment workflow consists of eight sequential stages: 1) laboratory report submission, 2) document preprocessing and text extraction, 3) structured content extraction, 4) Retrieval-Augmented Generation, 5) LLM-based rubric evaluation, 6) automated formative feedback generation, 7) Human-in-the-Loop instructor validation, and 8) final grade publication. Fig. 1 illustrates the overall architecture of the proposed framework.

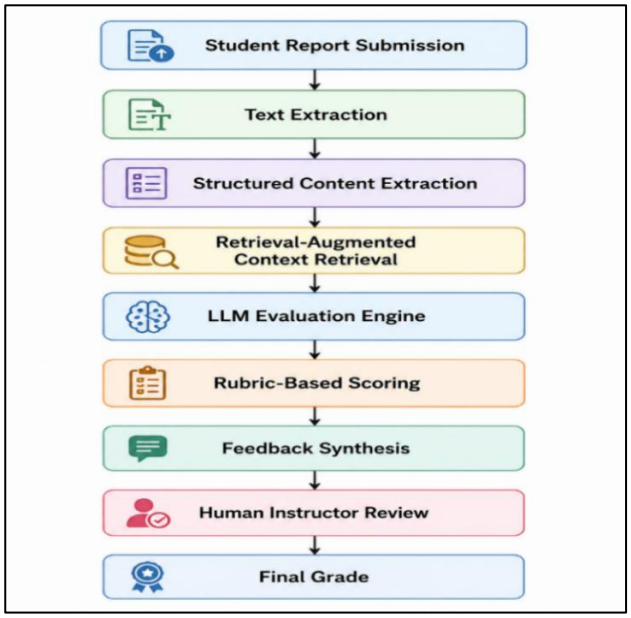

Fig. 1. Overall architecture of the proposed RAG-enhanced Human-in-the-Loop assessment framework.

B. Report Processing and Context Retrieval

Laboratory reports submitted in PDF or DOCX format are first processed to extract machine-readable content. When scanned documents are encountered, Optical Character Recognition (OCR) is applied to recover textual information. The extracted report content is subsequently prepared for automated assessment while preserving the logical organization of the laboratory report. This process provides a consistent textual representation that supports contextual retrieval and rubric-based evaluation.

The proposed framework primarily evaluates the textual content extracted from laboratory reports. Tables and textual mathematical expressions are processed through the document extraction stage and incorporated into the grading workflow whenever they are represented in machine-readable form. For graphical laboratory artifacts such as circuit diagrams, experimental plots, screenshots, and handwritten annotations, the current framework extracts only the embedded textual information when available and does not directly interpret the visual content. Consequently, grading decisions are primarily based on the extracted textual information together with the retrieved contextual resources.

To improve grading reliability and contextual understanding, the proposed framework incorporates a Retrieval-Augmented Generation (RAG) module prior to the evaluation stage. Instead of relying solely on the submitted report and the intrinsic knowledge of the Large Language Model (LLM), the framework retrieves assignment-specific educational resources that enrich the grading prompt with relevant contextual information. The knowledge base contains laboratory instructions, grading rubrics, reference solutions, course materials, and assignment metadata, enabling assessments that remain aligned with course objectives, intended learning outcomes, and predefined grading criteria while helping reduce hallucinations and improving grading consistency.

The RAG module is implemented using OpenAI's text-embedding-3-small model to generate 1536-dimensional semantic embeddings, which are indexed in a Pinecone vector database using cosine similarity. Educational resources are embedded and indexed together with their associated metadata to preserve instructional context during retrieval. For each submitted laboratory report, the retrieval query is automatically constructed from the assignment title, assignment description, and corresponding course chapter. Metadata filtering is subsequently applied to retrieve only assignment-relevant educational resources, after which the five most relevant documents are incorporated into the evaluation prompt to provide assignment-specific context for the language model.

Unlike conventional LLM-based grading approaches that evaluate reports using only the submitted content, the proposed framework combines the retrieved educational resources with grading rubrics, expected solutions, laboratory instructions, and course materials to support context-aware assessment. Consequently, laboratory reports are graded based on the desired learning outcomes and rubric criteria, not on exact textual similarity. Thus, alternative engineering approaches, experimental variations that are within an acceptable range and

alternative approaches to solutions can be fairly evaluated as long as they meet the desired learning objectives.

The assessment process combines the extracted report content with the retrieved contextual resources and evaluates all the criteria defined in the grading rubric. This allows for thorough, consistent, and pedagogically sound assessment that is aligned with the learning outcomes and instructor-defined grading standards. Fig. 2 illustrates the Retrieval-Augmented Generation process used in the proposed framework.

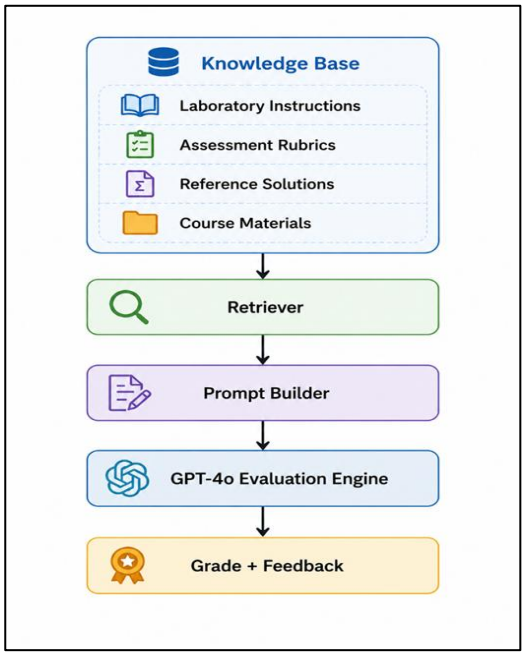

Fig. 2. Retrieval-Augmented Generation workflow for context-aware laboratory report assessment.

C. Prompt Design and LLM-Based Evaluation

The proposed framework employs a structured prompt engineering strategy to ensure consistent, transparent, and rubric-aligned evaluation of engineering laboratory reports. Instead of using the submitted report directly, the evaluation prompt combines assignment metadata, laboratory instructions, retrieved contextual resources, grading rubrics, expected reference solutions, and student submission into a unified evaluation context. This comprehensive prompt provides the language model with assignment-specific information required to perform context-aware, rubric-aligned assessment while maintaining consistency with the intended learning outcomes.

The evaluation prompt is constructed automatically by combining the assignment title, assignment description, laboratory instructions, maximum score, grading rubric, retrieved educational resources, expected solutions, and extracted laboratory report content. The language model will be responsible for evaluating the submission based on the grading rubric defined and producing a numeric score, along with detailed formative feedback, identified strengths, weaknesses, and concrete recommendations for improvement. Such a structured prompt design facilitates grading consistency and subsequent instructor review and validation. An excerpt of the structured evaluation prompt used by the proposed framework is presented below.

Excerpt of the Evaluation Prompt Used by the Proposed Framework
System Role
You are a university professor evaluating a student's assignment submission.
Assignment Details: • Title • Description • Instructions • Maximum Score
Grading Rubric: ...
Expected Answers / Reference Solutions: ...
Course Context and Reference Materials: ...
Student Submission: ...
Carefully evaluate this submission and provide: 1. Numerical Grade 2. Overall Feedback 3. Strengths 4. Weaknesses 5. Suggestions for Improvement

The assessment stage employs GPT-4o as the primary grading model because of its strong reasoning capabilities and its ability to evaluate engineering laboratory reports containing theoretical explanations, experimental procedures, calculations, experimental analysis, and technical discussions. A low temperature setting (0.3) was chosen during grading to enhance the stability of the response and to reduce variability between repeated evaluations of similar reports.

To improve computational efficiency while maintaining high-quality formative feedback, GPT-4o-mini is employed exclusively for generating detailed feedback after the numerical grade has been determined. The generated feedback is consistent with the assigned score, as the grading decision is made before the feedback generation, and reduces the computational cost. An example of the formative feedback generated by the proposed framework is presented in Fig. 3.

Fig. 3. Example of AI-generated formative feedback.

D. Rubric-Based Assessment

The proposed framework employs a criterion-referenced rubric to ensure transparent, consistent, and pedagogically aligned assessment of engineering laboratory reports. The grading rubric consists of three complementary evaluation criteria, weighted as follows: Technical Accuracy (40%), Experimental Analysis (30%), and Completeness and Presentation (30%).

Technical Accuracy receives the highest weighting because the primary objective of engineering laboratory assessment is to evaluate students' understanding and correct application of engineering concepts, calculations, and technical reasoning. Experimental Analysis emphasizes students' ability to interpret experimental results, discuss observations, and relate practical findings to theoretical concepts. Completeness and Presentation assess the organization, clarity, and professional quality of the laboratory report, reflecting the importance of technical communication in engineering education.

During assessment, the language model considers each criterion by referring to the retrieved contextual resources, grading rubric, expected reference solutions, and the assignment-specific laboratory instructions. The weighted criterion scores are subsequently combined to produce the final assessment while maintaining consistency with the predefined learning outcomes and grading standards.

E. Human-in-the-Loop Validation

The proposed framework adopts a Human-in-the-Loop (HITL) validation strategy to ensure that the AI-assisted assessment is under the supervision of the instructor. The framework offers preliminary recommendations for the AI-generated grade and feedback to assist instructors in the grading process, rather than automatically assigning a final grade.

Following the initial evaluation, instructors review the proposed grade, generated feedback, and the corresponding laboratory report in relation to the grading rubric. They may approve the assessment without modification or revise the proposed score and feedback whenever discrepancies or pedagogical considerations are identified. Consequently, instructors retain full authority over the final grading decision while accommodating valid experimental variations and alternative solution approaches.

By requiring instructor verification before grade publication, the proposed framework mitigates automation bias and combines the efficiency of AI-assisted assessment with the professional judgment and pedagogical expertise of the instructor.

F. Academic Integrity Support

In addition to automatic assessment, the proposed framework has an academic integrity support module to assist instructors in detecting potential plagiarism prior to grading. The module does not make the determination of whether academic misconduct has occurred, but provides similarity analysis to assist instructor judgment in the assessment process.

The academic integrity module is integrated in the proposed framework but is not quantitatively evaluated in this work, as the goal is to validate the performance of the RAG-enhanced Human-in-the-Loop assessment framework.

IV. Experimental Setup

A. Dataset

The proposed framework was evaluated using 56 laboratory reports collected from undergraduate Electrical and Electronics Engineering (EEE) laboratory courses at a single higher education institution. As summarized in Table II, the dataset comprises four laboratory experiments covering analog electronics and circuit analysis. Three experiments were completed as group assignments, whereas the fourth required individual report submission.

The laboratory reports include theoretical explanations, experimental procedures, calculations, observations, experimental analysis, tables, and conclusions, providing representative examples of undergraduate engineering laboratory documentation. These reports were utilized to assess the accuracy, consistency, and efficiency of grading of the proposed RAG-enhanced Human-in-the-Loop assessment framework.

TABLE II. Dataset Composition

Laboratory	Topic	Assignment Type	Reports
TP1	Diodes	Group	8
TP2	Common Emitter Amplifier	Group	8
TP3	Operational Amplifier Applications	Group	8
TP4	Capacitor Charging and Discharging	Individual	32
Total			56

B. Experimental Approach

Instructor-assigned grades (on a 100-point scale) were used as the reference standard for evaluating the proposed framework. Each laboratory report was first graded manually by the course instructor according to the predefined assessment rubric. The same reports were subsequently evaluated using the proposed RAG-enhanced Human-in-the-Loop framework following the workflow illustrated in Fig. 1.

For each submission, the framework extracted the report content, retrieved assignment-specific contextual resources via the RAG module, and generated an initial grade and formative

feedback. Next, the AI-generated grades were compared to the instructor-assigned grades to evaluate grading accuracy, consistency, and operational efficiency. During the experimental evaluation, instructor grades served exclusively as the reference for quantitative analysis. Although the proposed framework incorporates Human-in-the-Loop validation, instructor intervention was intentionally omitted during performance evaluation so that AI-generated grades could be compared directly with the reference grades under identical conditions. Instructors have full authority to review, modify, approve, or reject AI-generated assessments before the final grade is released in operational use.

C. Evaluation Metrics

The performance of the proposed framework was evaluated using six complementary metrics: Mean Absolute Error (MAE), Root Mean Squared Error (RMSE), Maximum Error, Agreement Rate (±5 points), Pearson Correlation Coefficient, and Grading Time Reduction. These metrics were selected to assess grading accuracy, agreement with instructor-assigned grades, and operational efficiency.

Pearson Correlation Coefficient was used to measure the linear agreement between AI-generated and instructor-assigned grades, while MAE, RMSE, and Maximum Error quantified grading deviations. The Agreement Rate represents the percentage of laboratory reports for which the AI-generated grade differed by no more than ±5 points from the instructor-assigned grade. Grading Time Reduction was used to evaluate the efficiency gained through AI-assisted assessment.

To further assess the robustness of the proposed framework, statistical significance testing, p-values, and 95% confidence intervals were computed for the primary evaluation metrics. These complementary statistical measures provide additional evidence regarding the reliability and consistency of the proposed RAG-enhanced Human-in-the-Loop assessment framework.

D. Implementation Details

The proposed framework was implemented in Python using OpenAI GPT-4o as the primary model for rubric-based grading and GPT-4o-mini for formative feedback generation. Retrieval-Augmented Generation (RAG) was implemented using the OpenAI text-embedding-3-small embedding model, which generates 1536-dimensional semantic embeddings. These embeddings were indexed in a Pinecone vector database using cosine similarity to enable efficient semantic retrieval of assignment-specific educational resources.

Educational resources, including laboratory instructions, grading rubrics, reference solutions, and course materials, were indexed as complete semantic documents without additional text chunking because these resources are relatively short and self-contained. For each laboratory report, the retrieval query was automatically constructed from the assignment title, assignment description, and corresponding course chapter. Metadata filtering was subsequently applied to retrieve the five most relevant educational resources, which were incorporated into the evaluation prompt together with the grading rubric, expected reference solutions, laboratory instructions, and the extracted laboratory report content.

Table III summarizes the implementation parameters used during the experimental evaluation.

TABLE III. IMPLEMENTATION CONFIGURATION

Parameter	Value
Programming Language	Python
Primary Grading Model	GPT-4o
Feedback Model	GPT-4o-mini
Embedding Model	OpenAI text-embedding-3-small
Embedding Dimension	1536
Vector Database	Pinecone
Similarity Metric	Cosine Similarity
Indexed Documents	Complete Semantic Documents
Retrieved Documents	Top-5
Retrieval Filtering	Assignment/Chapter Metadata
Assessment Strategy	RAG-Enhanced Rubric-Based Evaluation
Human Validation	Human-in-the-Loop

V. RESULTS AND DISCUSSION

A. Overall Grading Performance

The proposed framework was evaluated using 56 undergraduate Electrical and Electronics Engineering laboratory reports. Table IV summarizes the quantitative performance of the proposed framework by comparing AI-generated grades with instructor-assigned grades on a 100-point grading scale.

TABLE IV. PERFORMANCE OF THE PROPOSED FRAMEWORK

Metric	Value
Number of Reports	56
Grading Scale	0–100 points
Mean Instructor Grade	83.64
Mean AI Grade	80.09
Mean Absolute Error (MAE)	3.55 points (95% CI: 3.23–3.89)
Root Mean Squared Error (RMSE)	3.77 points (95% CI: 3.43–4.11)
Maximum Error	6 points
Agreement Rate (±5 points)	89.29%
Pearson Correlation	0.988 (95% CI: 0.980–0.993, $p < 0.001$)
Manual Grading Time	392 min
AI-assisted Grading Time	84 min
Time Reduction	78.57%

The proposed framework achieved a Pearson Correlation Coefficient of 0.988 (95% CI: 0.980–0.993, $p < 0.001$), indicating a statistically significant and very strong agreement between AI-generated and instructor-assigned grades. The Mean Absolute Error (MAE) was 3.55 points (95% CI: 3.23–3.89), while the Root Mean Squared Error (RMSE) was 3.77 points (95% CI: 3.43–4.11). Furthermore, 89.29% of the laboratory reports received AI-generated grades within ±5

points of the instructor-assigned grades, demonstrating high grading consistency.

The mean instructor-assigned grade was 83.64 points, whereas the mean AI-generated grade was 80.09 points, indicating an average difference of 3.55 points. This result suggests a slight tendency of the AI to assign more conservative grades than the instructor. Nevertheless, the very high correlation coefficient, together with the narrow confidence intervals and relatively small grading errors, indicates that the proposed framework closely reproduces instructor grading decisions while maintaining consistent ranking of student performance across the evaluated reports.

B. Agreement with Human Evaluation

Fig. 4 illustrates the relationship between AI-generated grades and instructor-assigned grades for the 56 laboratory reports. Most data points are closely distributed around the line of perfect agreement, demonstrating strong consistency between the two grading approaches.

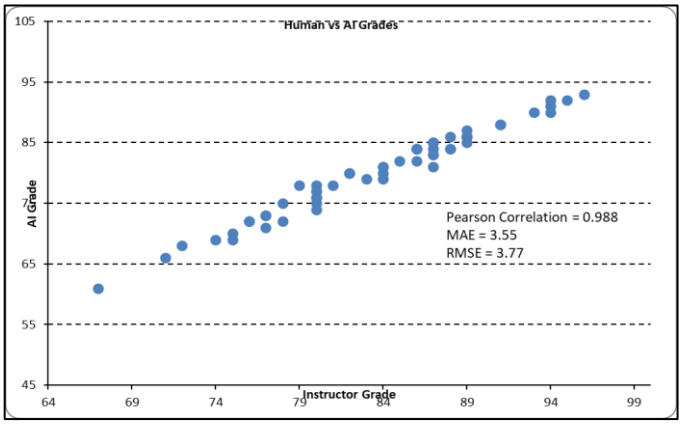

Fig. 4. Correlation between instructor-assigned grades and AI-generated grades.

Overall, 89.29% of the laboratory reports received AI-generated grades within ±5 points of the instructor-assigned grades, while the maximum observed difference was 6 points. The mean AI-generated grade (80.09) was slightly lower than the mean instructor-assigned grade (83.64), corresponding to an average difference of 3.55 points. This observation suggests a slight conservative grading bias of the proposed framework rather than inconsistent assessment. Nevertheless, the very high agreement between AI-generated and instructor-assigned grades indicates that this bias has only a limited impact on the overall grading consistency and reliability of the proposed framework.

C. Impact of Retrieval-Augmented Generation

The Retrieval-Augmented Generation (RAG) module retrieves lab instructions, grading rubrics, reference solutions, and course materials relevant to each lab report, providing assignment-specific contextual information throughout the assessment process. The contextual resources are provided to the evaluation prompt, allowing the language model to execute rubric-aligned and course-specific assessment consistent with the intended learning outcomes.

The high correlation between AI-generated and instructor-assigned grades shows the effectiveness of the proposed RAG-enhanced Human-in-the-Loop framework as an AI-assisted assessment system. Figure 5 shows an example of contextual information retrieved by the RAG module during the evaluation process.

D. Human-in-the-Loop Validation

The experimental results demonstrate that the proposed framework provides reliable preliminary assessments that can effectively support instructor decision-making. The high agreement between AI-generated and instructor-assigned grades indicates that the framework can substantially reduce instructor workload while maintaining grading consistency.

Within the proposed Human-in-the-Loop workflow, AI-generated grades and formative feedback are presented to the instructor as recommendations rather than final decisions. Instructors retain full authority to review, revise, approve, or reject the proposed assessment before the final grade is released. This validation process preserves pedagogical accountability while reducing the potential impact of automation bias in educational assessment.

E. Grading Efficiency

In addition to grading accuracy, the proposed framework substantially reduced the instructor's grading workload. The 56 laboratory reports were evaluated manually in 392 minutes, whereas the AI-assisted evaluation completed the same grading task in 84 minutes, which is a reduction in grading time of 78.57%.

The reported grading time includes only the assessment process itself, encompassing laboratory report evaluation, score generation, and feedback generation. Initial system development, RAG knowledge base construction, document indexing, and system configuration were performed offline and were therefore not included in the reported grading time. Fig. 5 compares the time required for manual and AI-assisted grading.

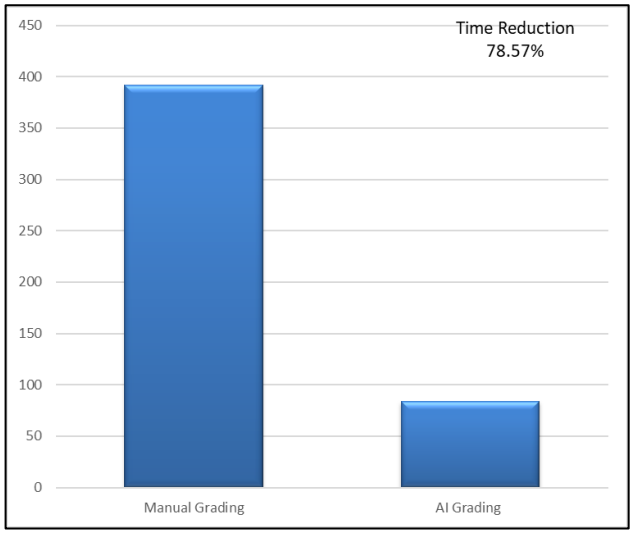

Fig. 5. Manual and AI-assisted grading time comparison.

F. Discussion

Experimental results indicate that the combination of Retrieval-Augmented Generation (RAG), rubric-based assessment, and Human-in-the-Loop validation provides an effective solution for the automated assessment of engineering laboratory reports. The proposed framework achieved strong agreement with instructor-assigned grades while substantially reducing grading time, highlighting its potential as an AI-assisted decision-support tool that improves instructor efficiency while preserving instructor oversight.

The reported results reflect the performance of the proposed framework as an integrated assessment system. Although the RAG module provides assignment-specific contextual grounding during assessment, the present study did not include a quantitative comparison between the proposed RAG-enhanced framework and an equivalent LLM-based grading approach without Retrieval-Augmented Generation. Consequently, the independent contribution of the RAG module cannot be isolated from the overall framework performance.

Furthermore, the experimental evaluation was conducted on 56 laboratory reports collected from undergraduate Electrical and Electronics Engineering courses at a single higher education institution. Therefore, the reported results should be considered as an initial validation of the proposed framework. Future work will investigate the proposed framework using larger, multi-institutional, and multidisciplinary datasets, perform controlled comparisons between RAG-enhanced and non-RAG grading approaches, evaluate the effectiveness of the academic integrity support module, and explore the integration of multimodal vision-language models to enhance the interpretation of graphical laboratory artifacts, including circuit diagrams, experimental plots, screenshots, and handwritten annotations.

VI. Conclusion and Future Work

This study presented a Retrieval-Augmented Generation (RAG)-enhanced Human-in-the-Loop framework for the automated assessment of engineering laboratory reports using Large Language Models. By integrating structured content extraction, contextual retrieval, rubric-based grading, automated formative feedback generation, academic integrity support, and instructor validation into a unified workflow, the proposed framework provides a comprehensive AI-assisted assessment solution for engineering education.

Experimental evaluation on 56 undergraduate Electrical and Electronics Engineering laboratory reports demonstrated that the proposed framework can provide accurate, consistent, and efficient AI-assisted assessment while preserving instructor oversight. The framework achieved a Pearson Correlation Coefficient of 0.988 ($p < 0.001$), a Mean Absolute Error (MAE) of 3.55 points, an Agreement Rate of 89.29%, and a grading time reduction of 78.57%, demonstrating its potential to improve assessment efficiency while maintaining grading quality and supporting reliable formative assessment in engineering education.

Future work will focus on validating the proposed framework using larger multi-institutional and multidisciplinary datasets, conducting controlled comparisons with equivalent LLM-based grading approaches without Retrieval-Augmented Generation, evaluating the effectiveness of the academic integrity support module, and investigating the integration of multimodal vision-language models to further enhance the assessment of graphical laboratory artifacts.

***Abstract*—AI-generated visual information systems often present images with authorship metadata, yet such labels may shape the evaluation data they are intended to contextualize. Existing work has seldom offered a system-level procedure for measuring metadata-conditioned response drift under unchanged visual input. This study develops a two-phase evaluation framework combining blind presentation, attribution-label overlay, trial-level logging, drift computation, and mixed-effects validation. Ninety-two participants rated four AI-generated images first without labels and then with attribution labels, producing 732 valid observations. Linear mixed-effects modeling, supported by ordinal sensitivity analysis and leave-one-image-out checks, identified a significant Phase × Label interaction within the implemented attribution-label assignment scheme. Under this assignment scheme, ratings for stimuli assigned to the human-labeled condition increased after disclosure, whereas ratings for stimuli assigned to the AI-labeled condition decreased. These findings are interpreted as evidence that the proposed framework can detect disclosure-associated response drift, rather than as a fully counterbalanced causal estimate of pure label effects.**

***Keywords*—AI-generated visual information systems; metadata disclosure; response drift; user-response logs; human-computer interaction; authorship labeling; mixed-effects modeling**

I. Introduction

AI-generated visual content is increasingly integrated into interactive visual information systems, including online galleries, recommendation platforms, digital design tools, educational interfaces, and content-evaluation environments [1], [2]. In these systems, images are rarely encountered as isolated visual objects. They are commonly accompanied by metadata indicating human authorship, AI authorship, AI assistance, or the use of a specific generative model [3], [4]. Although these cues are typically introduced to support transparency and provenance disclosure, once embedded in an interface they also become part of the context in which users form ratings, preferences, and quality judgments.

The implications extend beyond individual perception because many AI-mediated visual systems use user responses as operational inputs. Ratings, preference scores, likes, and evaluation logs may inform recommendation, ranking, content moderation, design feedback, or subsequent model evaluation [5]. If authorship metadata alters these responses, ratings collected under different disclosure conditions may not be directly comparable. Recent research on AI-generated media labeling confirms that disclosure cues can affect how users interpret and respond to visual content [6]. When blind and labeled ratings are pooled without retaining their disclosure state, downstream systems may learn patterns that partly reflect attribution framing rather than visual preference alone. Authorship metadata is therefore relevant not only to provenance communication but also to the interpretation of user-response data.

Evidence from AI-art evaluation and authorship attribution research suggests that source attribution can shape user judgment, yet the implications of these attribution effects for system-generated response logs remain insufficiently developed [7-9]. Existing studies have generally examined whether evaluation outcomes differ across attribution conditions rather than how metadata-conditioned changes should be recorded, quantified, and validated when visual input remains unchanged. This leaves a measurement problem: a rating may represent both an evaluation of the image and a response to the interface context in which the image was presented.

We develop and evaluate a two-phase framework for detecting metadata-conditioned response drift in AI-generated visual information systems. Participants first evaluate AI-generated images without authorship information and subsequently re-evaluate the same images with experimentally assigned attribution labels. Trial-level records are matched by participant and image, allowing disclosure-associated rating changes to be computed and statistically evaluated. Because attribution labels were assigned to fixed stimuli, the implementation is used to verify the detection procedure under the specified assignment scheme rather than to estimate a fully counterbalanced, stimulus-independent causal effect. The main contributions of this study are as follows:

- A two-phase evaluation procedure is introduced for examining response changes while holding the visual input constant across blind and disclosure conditions.
- Disclosure-associated change is formalized as a participant–image-level drift measure supported by explicit logging of phase, image identity, attribution condition, and metadata visibility.

*Corresponding author

- The response pattern is assessed using a linear mixed-effects model, a cumulative link mixed model for ordinal sensitivity, and leave-one-image-out robustness analyses.
- Analysis of 92 participants and 732 valid observations identifies a disclosure-associated pattern that remains consistent across the primary mixed-effects model, the ordinal sensitivity analysis, and the leave-one-image-out checks, illustrating the value of retaining metadata-display conditions when ratings are compared or reused as system inputs.

II. Background and Related Work

Research on AI-generated art has shown that visual judgments are shaped by more than the perceptual properties of an image. Early work on computer-generated art examined whether viewers evaluated computer-generated and human-made artworks differently [10]. Subsequent studies demonstrated that knowledge or prior assignment of AI authorship could alter aesthetic appreciation and evaluations of artistic value [7], [11]. More recent experiments have linked differences between human- and AI-attributed works to perceived authenticity, creative involvement, and anthropocentric preferences [8],[9],[12]. The direction of these effects is not necessarily uniform: broader research on algorithm aversion and algorithm appreciation indicates that responses to algorithmic systems depend on the task, prior experience, and evaluative context [13],[14]. Taken together, these studies establish authorship attribution as a consequential source cue, but their primary object of analysis remains the judgment outcome—whether a work receives higher ratings for aesthetic quality, creativity, authenticity, or artistic value under a particular attribution.

Research on synthetic-content disclosure has shifted attention from authorship beliefs alone to the design and placement of labels within digital interfaces. Wittenberg et al. found that label effects depended partly on whether the label described the production process or warned of potentially misleading content; labels affected belief in claims associated with AI-generated images, whereas a simple AI-generated label had more limited effects on intended engagement [6]. Gamage et al. further showed that responses to synthetic-content warnings vary with wording, positioning, visual presentation, and level of detail [15]. Recent findings also caution against assuming that disclosure produces a uniform penalty. Li et al. reported no overall main effect of AIGC labeling on perceived credibility, although the effect varied with prior experience and content category [16]. Gallegos et al. similarly found that labeling messages as AI-generated did not significantly reduce their persuasive effects [17]. Recent evidence further suggests that disclosure timing and the level of AI involvement may influence user engagement with labeled content [18]. Disclosure is therefore neither uniformly beneficial nor uniformly detrimental; its consequences depend on the labeled content, the presentation of the label, the outcome being measured, and the characteristics of the audience. This context dependence is consistent with human–AI interaction research, which treats interface presentation as part of interaction design rather than as a neutral wrapper around the underlying system [19].

Less well developed is an operational account of how attribution metadata conditions the generation and subsequent interpretation of user-response logs. Randomized between-subject experiments have examined the effects of AI-related labels on belief, trust, engagement intentions, and persuasion [6],[15],[17]. A recent mixed experiment examined perceived credibility under variations in label presence, content category, and prior experience [16]. These studies show that labels can shape evaluation, but they seldom formalize the resulting change as a measurable property of the response record itself. This distinction matters for systems that reuse ratings as recommendation, ranking, or evaluation signals: responses collected under different metadata conditions may be valid within their original experimental settings yet remain non-equivalent when pooled as system inputs. The unresolved issue is therefore not simply whether disclosure affects judgment, but how disclosure-associated variation can be retained and quantified within user-response records. Accordingly, metadata exposure is treated here as a logged evaluation condition, with response drift defined at the participant–image level under unchanged visual input.

III. Proposed Metadata-Conditioned Response Drift Evaluation Framework

A. Framework Overview

This study proposes a two-phase evaluation framework for measuring metadata-conditioned response drift in AI-generated visual information systems. The framework is designed to quantify changes in user-response data associated with authorship-related interface cues while holding the visual stimulus constant. Rather than treating the study as a general comparison between human-created and AI-generated art, the proposed framework examines assigned authorship information as a configurable interface variable that may influence rating behavior and evaluation-log interpretation.

The framework consists of three functional layers: the visual stimulus layer, the interface control and metadata layer, and the response drift analysis layer. The visual stimulus layer provides a controlled set of AI-generated images and maintains stimulus consistency across evaluation phases. The interface control and metadata layer manages phase transition, stimulus presentation order, attribution-label display, and response collection. The response drift analysis layer links blind-phase and disclosure-phase ratings at the participant–image level and estimates the direction and magnitude of rating change after metadata disclosure.

The evaluation procedure contains two sequential phases completed by the same participants. In the blind phase, participants rate AI-generated images without any authorship information. In the disclosure phase, the same images are re-presented with assigned authorship labels, either human-labeled or AI-labeled. The attribution condition is implemented at the stimulus/trial level through the interface rather than embedded in the image file, caption, or visual content. This design preserves a clear distinction between the visual stimulus and the attribution cue while enabling response changes to be

measured without altering the image content. The implementation is therefore treated as a framework-verification setting: it detects disclosure-associated response drift under the implemented label-assignment scheme, while causal claims about pure authorship-label effects independent of image identity are intentionally limited. The overall workflow of the proposed framework is shown in Fig. 1.

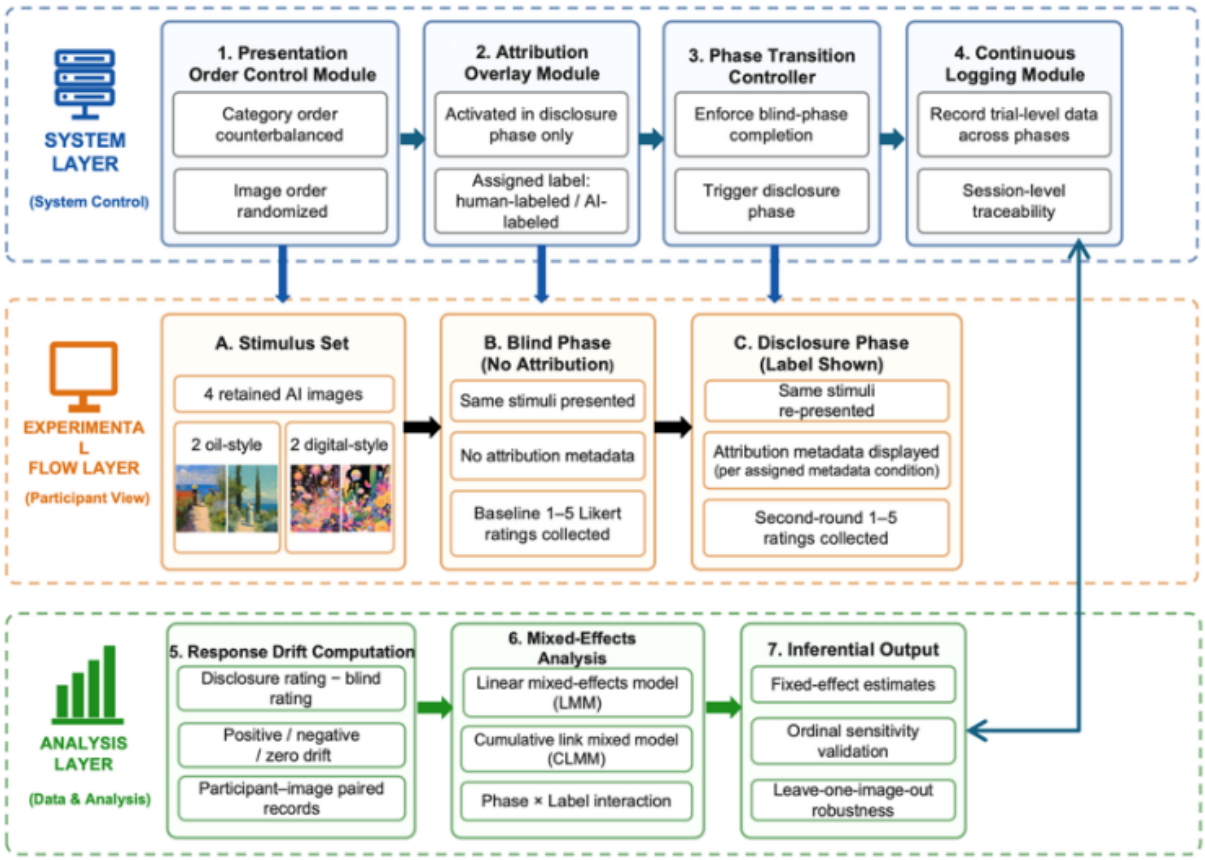

Fig. 1. Overall workflow of the proposed framework, including stimulus presentation, attribution metadata display, trial-level response logging, and response drift validation.

The primary output of the framework is response drift, defined as the difference between the disclosure-phase rating and the corresponding blind-phase rating for the same participant and image. Positive values indicate an upward shift after metadata disclosure, whereas negative values indicate a downward shift. The confirmatory effect of interest is the Phase × Label interaction, which tests whether rating changes from the blind phase to the disclosure phase differ between images assigned to the human-labeled and AI-labeled conditions.

This positioning is consistent with the objective of evaluating how attribution cues enter user-response logs as measurement-context variables in AI-generated visual information systems. The framework is intended to support disclosure-aware response logging and interface evaluation, rather than to generalize user preference for human- or AI-attributed images.

B. AI-Generated Visual Stimulus Module

The visual stimulus module was designed to provide controlled AI-generated image inputs for evaluating metadata-conditioned response drift. All stimuli were generated using the Midjourney text-to-image model through the Niji-Journey interface. Two rendering categories were constructed: oil-style compositions and digital-style compositions. These two categories were selected to represent visually distinct rendering modes while preserving a manageable experimental structure for repeated evaluation.

For each rendering category, a standardized prompt template was used to constrain the main visual structure, compositional layout, color distribution, subject arrangement, and rendering style. The oil-style template specified a painterly outdoor scene with a clear central visual element, balanced composition, soft color transitions, and an oil-painting rendering style. The digital-style template specified a colorful digital visual scene with a clear central visual element, balanced composition, vivid color distribution, and a digital-illustration rendering style. The templates were used to generate four candidate images for each category. Two images from each category were then retained, resulting in a final stimulus set of four AI-generated images. The selected stimuli were newly generated for the present study and had not been previously shown to participants.

The screening procedure was used to improve comparability across stimuli before the attribution-label conditions were applied. Candidate images were evaluated according to the following criteria: comparable visual complexity, clear thematic legibility, absence of salient rendering errors, similar prominence of the central visual element, and adequate interpretability at the display size used in the evaluation interface. The retained images were presented in the same interface layout across both phases. Image size, screen position, rating scale format, and background layout were kept constant so that the only interface difference between the blind and disclosure phases was the presence or absence of authorship metadata. This procedure was not intended to make the retained images perceptually identical or to replace full label counterbalancing. Rather, it reduced obvious stimulus-level imbalance and provided a controlled stimulus set for framework verification. Remaining participant-level heterogeneity and stimulus-related variation were addressed through mixed-effects modeling and robustness checks.

Fig. 2. Retained AI-generated visual stimuli used in the two-phase evaluation. O1 and O2 represent oil-style stimuli, whereas D1 and D2 represent digital-style stimuli. All four images were generated by AI and were re-presented across blind and disclosure phases.

The retained oil-style images were assigned image identifiers O1 and O2, and the retained digital-style images were assigned image identifiers D1 and D2 (see Fig. 2). During the disclosure phase, O1 and D1 were displayed with the assigned label Human-labeled, whereas O2 and D2 were displayed with the assigned label AI-labeled. Because all four stimuli were AI-generated, these labels functioned only as experimentally assigned attribution cues within the evaluation interface rather than as indicators of actual authorship.

C. Attribution Metadata Overlay Module

The attribution metadata overlay module was developed to separate visual content from authorship information. In the blind phase, the metadata overlay was inactive, and participants viewed the AI-generated images without any authorship cue. In the disclosure phase, the overlay was activated and displayed the assigned attribution label for each image. The displayed label used one of two interface texts: Human-labeled or AI-labeled.

The authorship label was presented as an interface text label. It was placed in a fixed position adjacent to the image display area and remained visible on the same screen as the image and rating scale throughout the disclosure-phase trial. The label position, font size, and display format were kept constant across labeled trials. This design introduced attribution as a controlled interface variable while preserving the visual stimulus itself.

The metadata overlay was persistent during the labeled evaluation trial, meaning that the assigned label remained visible until participants submitted the second-round rating. This procedural control ensured that attribution information was available during the disclosure-phase response. No post-task manipulation-check item was collected; therefore, label exposure was controlled through the interface procedure rather than through a separate self-report verification item.

D. Phase Transition and Trial-Level Logging Module

The phase transition and trial-level logging module controlled the evaluation sequence and recorded structured response data. The evaluation followed a two-phase repeated-measures procedure and involved 92 participants (mean age = 38.30 years; SD = 13.54; range = 20–72 years). All participants reported normal or corrected-to-normal vision and no known color-vision deficiency. Thirty-eight participants reported at least two years of prior art-related learning or practice experience, whereas fifty-four participants reported no comparable art-training background. In the first phase, participants completed the blind evaluation without authorship information. In the second phase, the same images were re-presented under disclosure conditions with assigned attribution labels.

The interface managed the transition from the blind phase to the disclosure phase and prevented participants from entering the disclosure phase before completing the blind evaluation. A rating response was required before participants could proceed to the next trial. No time limit was imposed on image viewing or rating submission. The order of stimulus categories was counterbalanced across participants, and the presentation order of individual images within each category was randomized. Specifically, participants were assigned to alternating category-order sequences, and image order within each category was randomly shuffled at the session level. This procedure reduced the influence of fixed presentation order while maintaining the intended two-phase structure.

For each trial, the system recorded a structured response entry containing the anonymized participant/session identifier,

image identifier, stimulus category, presentation phase, attribution condition, metadata visibility state, and rating response. These trial-level records provided the data structure required to match blind-phase and disclosure-phase ratings for the same participant and image. Responses were stored without personally identifiable information. The logging module therefore served as the operational basis for computing response drift and for evaluating whether assigned attribution cues were associated with systematic changes in user ratings.

The complete evaluation consisted of eight trials for each participant: four blind-phase trials and four disclosure-phase trials. Because each participant evaluated the same four images twice, observations were repeatedly measured within participants across fixed stimuli. This structure motivated the use of a participant-level mixed-effects model in the validation layer. The complete procedure is summarized in Table I and Algorithm 1.

TABLE I. OPERATIONAL PROCEDURE OF THE PROPOSED EVALUATION FRAMEWORK.

Stage	Module	Operation	Output
1	Visual stimulus module	Generate and screen AI-generated images	Retained image set
2	Blind evaluation	Present images without metadata	Baseline ratings
3	Metadata overlay	Activate human-labeled / AI-labeled display	Disclosure condition
4	Disclosure evaluation	Re-present the same images with metadata	Labeled ratings
5	Logging layer	Match records by participant and image ID	Trial-level paired data
6	Drift computation	Apply Eq. (1)	Response drift scores
7	Validation layer	Fit LMM, CLMM, and robustness checks	Effect estimates and CIs

Algorithm 1: Metadata-Conditioned Response Drift Detection Procedure

Require: AI-generated stimulus set S={O1,O2,D1,D2} ; attribution label set L={Human-labeled, AI-labeled}; metadata visibility states V={Hidden,Visible}; participant set **P**; 5-point rating scale.

Ensure: Paired trial-level response logs, response drift scores, and statistical validation outputs.

start
for each participant $p \in P$ **do**
initialize anonymized participant session SID_p
load the retained AI-generated stimulus set S
assign participant p to one counterbalanced category-order sequence
randomize the presentation order of images within each category
for each image i in the randomized blind-phase sequence **do**
present image i with attribution metadata hidden
collect blind-phase rating $R_{p,i}^{\text{blind}}$
record log entry $\langle SID_p, i, Category_i, Blind, None, Hidden, R_{p,i}^{\text{blind}} \rangle$
end for
activate the attribution metadata overlay module
for each image i in the corresponding disclosure-phase sequence **do**
re-present the same visual stimulus i
display the assigned attribution label $Label_i$
keep $Label_i$ visible until rating submission
collect disclosure-phase rating $R_{p,i}^{\text{disclosure}}$
record log entry $\langle SID_p, i, Category_i, Disclosure, Label_i, Visible, R_{p,i}^{\text{disclosure}} \rangle$
if both blind-phase and disclosure-phase ratings are available **then**
compute response drift $Drift_{p,i} = R_{p,i}^{\text{disclosure}} - R_{p,i}^{\text{blind}}$
end if
end for
end for
aggregate matched participant–image records
fit the primary linear mixed-effects model
conduct ordinal sensitivity using a cumulative link mixed model
perform leave-one-image-out robustness checks
output drift estimates, confidence intervals, and validation results
end

E. Response Drift Computation

The primary output of the framework was response drift, defined as the rating change between the disclosure phase and the blind phase for the same participant and image. Let $R_{p,i}^{\text{blind}}$ denote the blind-phase rating provided by participant p for image i, and let $R_{p,i}^{\text{disclosure}}$ denote the corresponding disclosure-phase rating after authorship metadata was displayed. The response drift score was computed as:

$$\text{Drift}_{p,i} = R_{p,i}^{\text{disclosure}} - R_{p,i}^{\text{blind}} \quad (1)$$

where, $\text{Drift}_{p,i}$ represents the metadata-associated rating shift for participant p and image i. A positive drift value indicates that the participant assigned a higher rating after metadata disclosure than under blind conditions. A negative drift value indicates that the participant assigned a lower rating after disclosure. A drift value of zero indicates no change between the two phases. This computation allowed the framework to transform raw trial-level ratings into an interpretable measure of metadata-associated response change.

The response drift measure was calculated at the participant – image level and then examined by attribution condition and stimulus category. This structure enabled the framework to evaluate whether rating shifts differed between human-labeled and AI-labeled conditions, and whether the observed pattern was stable across oil-style and digital-style images.

F. Statistical and Robustness Validation Layer

The statistical validation layer was designed to estimate disclosure-associated changes in ratings while accounting for repeated observations within participants. Because each participant provided ratings across multiple images and phases, linear mixed-effects modeling was used as the primary inferential approach [20]. Ratings were modeled as a function of presentation phase, attribution label, stimulus category, and art experience.

The primary model was specified as:

$$\text{Rating}_{p,i,t}=\beta_0+\beta_1\text{Phase}_t+\beta_2\text{Label}_i+\beta_3\text{Category}_i$$
$$+\beta_4\text{ArtExperience}_p+\beta_5(\text{Phase}_t\times\text{Label}_i)$$
$$+\beta_6(\text{Phase}_t\times\text{Category}_i)+\beta_7(\text{Label}_i\times\text{Category}_i)$$
$$+\beta_8(\text{Phase}_t\times\text{Label}_i\times\text{Category}_i)+u_p+\varepsilon_{p,i,t} \quad (2)$$

where, $\text{Rating}_{p,i,t}$ refers to the 5-point evaluation score provided by participant p for image i at phase t. Phase_t distinguishes blind and disclosure evaluations, Label_i distinguishes human-labeled and AI-labeled metadata conditions, and Category_i distinguishes oil-style and digital-style stimuli. ArtExperience_p was entered as a participant-level covariate. In this specification, u_p represents the participant-level random intercept, and $\varepsilon_{p,i,t}$ denotes the residual error term. Dummy coding was used, with the blind phase, AI-labeled condition, and oil-style category serving as reference levels.

A more complex candidate model allowing participant-level random slopes for phase and label was also examined:

$$\text{Rating}_{p,i,t}=\beta_0+\beta_1\text{Phase}_t+\beta_2\text{Label}_i+\beta_3\text{Category}_i$$
$$+\beta_4\text{ArtExperience}_p+\beta_5(\text{Phase}_t\times\text{Label}_i)$$
$$+\beta_6(\text{Phase}_t\times\text{Category}_i)+\beta_7(\text{Label}_i\times\text{Category}_i)$$
$$+\beta_8(\text{Phase}_t\times\text{Label}_i\times\text{Category}_i)+u_{0p}$$
$$+u_{1p}\text{Phase}_t+u_{2p}\text{Label}_i+\varepsilon_{p,i,t} \quad (3)$$

When this model produced convergence warnings or singular estimates, the random-effects structure was reduced to a participant-level random intercept. The confirmatory effect of interest was the Phase × Label interaction, which tested whether rating changes from the blind phase to the disclosure phase differed between human-labeled and AI-labeled conditions. Because attribution labels were not fully counterbalanced across specific images, the Label coefficient was interpreted conditionally at the reference levels and was not treated as evidence of a general preference for either label independent of stimulus identity.

Because ratings were collected using a 5-point Likert scale, an ordinal sensitivity analysis was conducted using a cumulative link mixed model with the same fixed-effects structure and a participant-level random intercept [21],[22]. This analysis tested whether the main inferential pattern remained stable when the ordinal nature of the outcome variable was explicitly modeled. Planned contrasts were used to estimate phase-related rating changes within each label and category condition, and follow-up comparisons were adjusted using the Holm method.

Robustness was further examined through four leave-one-image-out analyses. Because omitting one stimulus left one Label × Category combination unobserved, each subset was analyzed using a reduced mixed-effects specification retaining the Phase × Label interaction, with stimulus category and art experience included as covariates and a participant-level random intercept. This analysis assessed whether the interaction was sensitive to any individual stimulus.

IV. Results and Framework Evaluation

A. Data Completeness and Logging Reliability

The proposed framework generated a maximum of 736 possible rating records, corresponding to 92 participants, four images, and two evaluation phases. A total of 732 valid rating observations were recorded and retained for analysis, yielding a valid logging rate of 99.46% and an item-level missing rate of 0.54%. The four missing observations came from one participant and did not alter the repeated-measures structure of the dataset. Analyses were therefore conducted using available observations without imputation.

The high valid logging rate confirmed that the framework produced sufficiently complete participant–image paired records for subsequent response-drift computation and mixed-effects validation.

B. Detection of Disclosure-Associated Response Drift

The primary validation objective was to determine whether the proposed framework could detect a disclosure-associated response-drift pattern under fixed visual input. The confirmatory linear mixed-effects model revealed a significant Phase × Label interaction in the oil-style reference category, $\beta = 0.780$, SE = 0.153, 95% CI [0.481, 1.080], $p < 0.001$. This interaction indicates that rating changes from the blind phase to the disclosure phase differed systematically between human-labeled and AI-labeled conditions.

TABLE II. Key Coefficient Estimates from the Primary and Ordinal Sensitivity Models.

Model	Term	β	SE	95% CI	p
Linear mixed-effects model	Phase × Label	0.780	0.153	[0.481, 1.080]	<0.001
	Label coefficient	-0.022	0.108	[-0.234, 0.190]	0.839
	Phase × Label × Category	0.220	0.216	[-0.203, 0.642]	0.309
	Art Experience	0.018	0.088	[-0.155, 0.191]	0.841
Cumulative link mixed model	Phase × Label	2.195	0.407	[1.398, 2.992]	<0.001
	Label coefficient	-0.051	0.275	[-0.589, 0.488]	0.854
	Phase × Label × Category	0.548	0.569	[-0.567, 1.664]	0.335
	Art Experience	0.102	0.238	[-0.365, 0.569]	0.668

Note. β coefficients from the cumulative link mixed model are estimated on the log-odds scale and are therefore not directly comparable in magnitude to coefficients from the linear mixed-effects model.

Specifically, ratings decreased after disclosure for images assigned to the AI-labeled condition and increased for images assigned to the human-labeled condition. For the oil-style reference category, the blind-phase difference between images assigned to the two label conditions was not significant, $\beta = -0.022$, SE = 0.108, 95% CI [−0.234, 0.190], p = 0.839,

indicating no detectable baseline difference within that category. Art experience also showed no reliable association with ratings, β = 0.018, SE = 0.088, 95% CI [−0.155, 0.191], p = 0.841. Together, these results indicate that the framework detected a disclosure-associated response-drift pattern after accounting for participant-level heterogeneity, stimulus category, and art experience, as summarized in Table II and illustrated in Fig. 3.

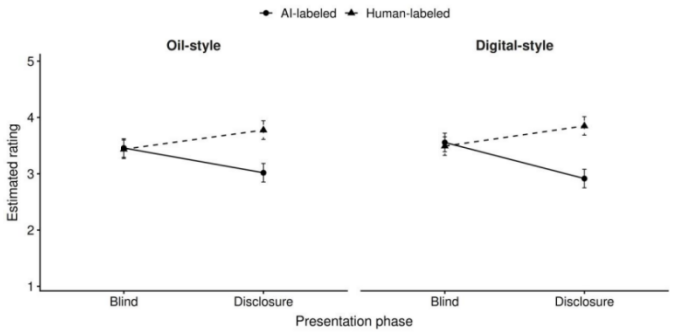

Fig. 3. Disclosure-associated response drift across stimulus categories.

C. Category-Level Stability of the Drift Pattern

Category-level stability was evaluated to determine whether the *detected* response-drift pattern was limited to a single rendering category. The Phase × Label × Category interaction was not significant, β = 0.220, SE = 0.216, 95% CI [-0.203, 0.642], p = 0.309. This result indicates no reliable evidence that the disclosure-associated drift pattern differed between oil-style and digital-style stimuli.

Model-derived follow-up contrasts were consistent with the directional pattern observed in the primary model. In the AI-labeled condition, ratings decreased significantly from the blind phase to the disclosure phase for both the oil-style category, β = −0.440, SE = 0.108, 95% CI [−0.652, −0.227], Holm-adjusted p < 0.001, and the digital-style category, β = −0.641, SE = 0.108, 95% CI [−0.852, −0.430], Holm-adjusted p < 0.001. In contrast, in the human-labeled condition, ratings increased significantly for both the oil-style category, β = 0.341, SE = 0.108, 95% CI [0.128, 0.553], Holm-adjusted p = 0.002, and the digital-style category, β = 0.359, SE = 0.108, 95% CI [0.148, 0.570], Holm-adjusted p = 0.002. These contrasts are shown in Fig. 4.

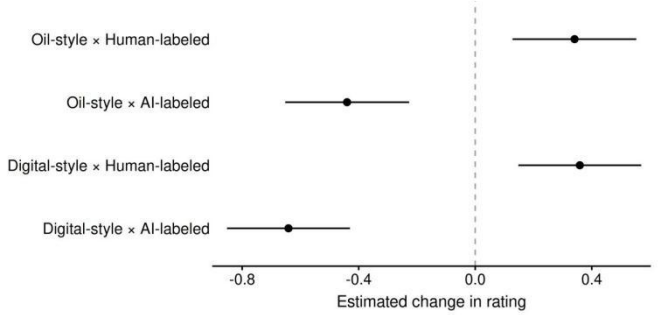

Fig. 4. Model-derived rating change from the blind phase to the disclosure phase. Points indicate estimated changes in rating within each Label × Category condition; horizontal bars indicate 95% confidence intervals. The dashed vertical line marks zero change.

D. Ordinal Sensitivity Validation

Because ratings were collected using a 5-point Likert scale, an ordinal sensitivity validation was conducted using a cumulative link mixed model. The ordinal model produced the same inferential pattern as the primary linear mixed-effects model. The Phase × Label interaction remained significant, β = 2.195, SE = 0.407, 95% CI [1.398, 2.992], p < 0.001. The Label coefficient at the blind-phase, oil-style reference levels was not significant, β = −0.051, SE = 0.275, 95% CI [−0.589, 0.488], p = 0.854. The Phase × Label × Category interaction also did not reach significance, β = 0.548, SE = 0.569, 95% CI [−0.567, 1.664], p = 0.335. Art Experience was also not significant, β = 0.102, SE = 0.238, 95% CI [-0.365, 0.569], p = 0.668. The consistency between the linear mixed-effects model and the cumulative link mixed model indicates that the detected response-drift pattern was not attributable to treating Likert-scale ratings as approximately continuous.

E. Leave-One-Image-Out Robustness Check

Robustness was assessed through four leave-one-image-out analyses. Across the reduced models, the Phase × Label interaction remained significant, with estimated coefficients ranging from 0.789 to 0.991 (all p<0.001). The direction and significance of the interaction were unchanged when any one stimulus was omitted, indicating that the observed response-drift pattern was not driven by a single image.

Participant-level drift estimates showed the same directional pattern. In the AI-labeled condition, mean drift was negative, M = -0.543, SD = 0.623, median = -0.500, with 67 of 92 participants showing negative drift. In the human-labeled condition, mean drift was positive, M = 0.353, SD = 0.557, median = 0.500, with 56 of 92 participants showing positive drift, as shown in Fig. 5.

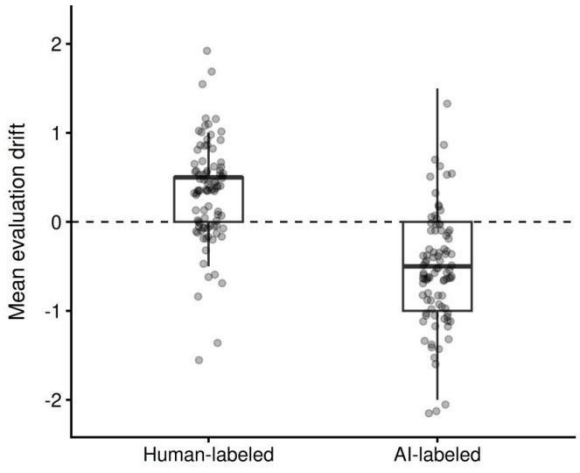

Fig. 5. Participant-level response drift by assigned authorship label. Each point represents one participant's mean response drift within a label condition, computed as the disclosure-phase rating minus the corresponding blind-phase rating. Positive values indicate higher ratings in the disclosure phase than in the blind phase, whereas negative values indicate lower ratings. The dashed horizontal line denotes zero response drift.

Together, the leave-one-image-out and participant-level analyses provide additional support for the stability of the

detected response-drift pattern across the retained stimuli and participants.

V. Discussion and System Implications

A. Metadata as a Response-Shaping Interface Variable

Across the primary mixed-effects model, ordinal sensitivity analysis, planned contrasts, and leave-one-image-out checks, the results converged on the same directional pattern: ratings shifted after authorship metadata was disclosed, while the visual stimuli remained unchanged. This convergence supports the interpretation that metadata disclosure was associated with measurable response drift in the implemented two-phase evaluation framework.

The consistency across analyses follows from complementary features of the design and validation strategy. Matching ratings within the same participant–image pair limits the influence of stable individual differences in scale use, while the participant-level random intercept accounts for dependence across repeated ratings from the same individual. The ordinal model tests whether the inference depends on treating the five-point rating scale as approximately continuous, and the leave-one-image-out analyses examine whether the pattern is driven by any single retained stimulus. Agreement across these analyses therefore indicates that the observed pattern is not tied to one statistical specification or one image, although it does not eliminate the confounding introduced by fixed label–stimulus assignment.

These findings do not establish a general preference for human-created content or a stimulus-independent causal effect of authorship labels. They instead indicate that authorship metadata forms part of the conditions under which user-response data are produced. Ratings collected under different metadata states should therefore not be treated as automatically equivalent when they are compared or reused as system inputs; stronger causal claims require fully counterbalanced label assignments.

B. Implications for User-Response Logs and Downstream Visual Systems

The findings have direct implications for AI-generated visual platforms that use ratings, preference scores, or interaction logs as system inputs. In recommendation, ranking, content evaluation, and design-feedback settings, these responses are often treated as indicators of content quality, relevance, or user preference. The present results show that this assumption is incomplete: a rating collected after authorship metadata disclosure may not be equivalent to a rating collected under blind conditions, even when the visual content remains unchanged.

For this reason, metadata-display conditions should be retained as contextual variables in response logs. Ratings collected under blind, AI-labeled, human-labeled, or other disclosure conditions should not be pooled as fully interchangeable signals. Otherwise, downstream models may learn patterns that partly reflect attribution framing rather than visual preference alone.

The proposed framework provides a practical way to identify this source of variation. By matching blind-phase and disclosure-phase ratings at the participant–image level, it separates baseline visual response from metadata-conditioned response change. At the implementation level, a minimal response-log schema should include the participant or session identifier, image identifier, presentation phase, label condition, label visibility state, rating value, and rating time. These fields allow system designers to determine the interface context under which each rating was produced.

These results also suggest that future AI-generated visual systems should account for disclosure state during response modeling. Possible implementations include disclosure-aware feature engineering, condition-specific rating calibration, or drift-weighted response modeling. Such approaches would help recommendation, ranking, and evaluation pipelines distinguish visual preference from interface-conditioned response variation.

C. Disclosure Design Considerations

The findings should not be interpreted as an argument against AI disclosure. Transparency remains important for provenance communication, user autonomy, and responsible deployment of AI-generated content [6]. However, the present study shows that disclosure is not behaviorally neutral. Once authorship metadata is placed inside an evaluation interface, it becomes part of the rating environment and may influence user-response data [6, 8]. Because the present implementation used a persistent text label displayed during the rating trial, the results should be interpreted most directly as evidence for this specific disclosure format rather than for all possible forms of AI-content disclosure.

Disclosure should therefore be treated as an interface design variable rather than as a fixed label added after system development. The timing, wording, placement, and visual salience of disclosure may all affect how users interpret and evaluate content [15]. A label displayed continuously during rating may produce a different response from post-evaluation disclosure, a hover-based provenance marker, a low-salience label, or a progressive disclosure interface. These design choices should be empirically tested rather than assumed to have no effect on user judgment.

For AI-generated visual information systems, the practical question is not simply whether disclosure should exist, but how disclosure should be implemented when user ratings are used as system input. Platforms may need to distinguish between disclosures used for compliance, disclosures used for provenance explanation, and disclosures shown during evaluative tasks. When ratings are used for recommendation, ranking, or quality assessment, disclosure design should be evaluated not only for informational accuracy but also for its effect on response drift.

VI. Limitations, Boundary Conditions and Future Work

The findings should be interpreted within the scope of the implemented framework. First, the study adopted a repeated-evaluation design in which the same participants rated the same images before and after metadata disclosure. This design was necessary for computing participant – image level response drift, but it may also introduce familiarity or carryover effects

between the blind and disclosure phases. The results therefore reflect response changes under a controlled two-phase interface setting rather than responses in a fully naturalistic browsing environment.

Second, attribution labels were not fully counterbalanced across stimuli, which limits claims about pure label effects independent of stimulus identity. To address this limitation, the primary model included stimulus category as a fixed effect and participant identity as a random intercept, while ordinal sensitivity analysis and leave-one-image-out analyses were used to assess the robustness of the detected pattern across model specifications and individual stimuli. These procedures provide robustness evidence but do not replace full label counterbalancing or support population-level generalization across images. The study is therefore interpreted as framework verification rather than as a causal estimate of pure authorship-label effects.

Third, the stimulus set was intentionally compact. The use of four AI-generated images made it possible to maintain a controlled repeated-measures structure and to keep the evaluation task manageable for participants. However, this design limits the range of visual styles, image topics, and aesthetic variation covered by the study. Future work should test the framework with larger and more diverse stimulus sets, including different genres of AI-generated visual content, multiple levels of visual quality, and broader interface contexts.

Fourth, label exposure was controlled through a persistent on-screen attribution overlay, but no separate post-task manipulation-check item was collected. The findings therefore rely on procedural exposure rather than self-reported verification of label awareness. Future studies should include manipulation checks or attention measures to examine whether participants noticed and interpreted the displayed attribution labels as intended.

Future research can extend the framework in three main directions. A fully counterbalanced design should assign each image to different metadata conditions across participants in order to separate label effects from stimulus identity more strictly. Alternative disclosure formats should also be compared, including pre-evaluation disclosure, post-evaluation disclosure, persistent labels, hover-based provenance markers, low-salience labels, and progressive disclosure interfaces. Finally, future AI-generated visual systems should record metadata-display conditions as part of the evaluation log, so that recommendation, ranking, and content assessment models can support disclosure-aware feature engineering, condition-specific calibration, or drift-weighted response modeling instead of treating all ratings as equivalent indicators of visual preference.

VII. Conclusion

This study proposed a two-phase evaluation framework for detecting metadata-conditioned response drift in AI-generated visual information systems. By integrating fixed visual input, assigned attribution-label presentation, trial-level logging, drift computation, and mixed-effects validation, the framework provides a structured procedure for examining whether attribution cues are associated with measurable changes in user-evaluation data. Based on 92 participants and 732 valid observations, the results showed a disclosure-associated drift pattern under the implemented label-assignment scheme: ratings increased for images assigned to the human-labeled condition and decreased for images assigned to the AI-labeled condition. This pattern was consistent across oil-style and digital-style stimuli and remained stable in ordinal sensitivity analysis and leave-one-image-out checks. Because the present implementation did not fully counterbalance labels across images and used a fixed blind-to-disclosure phase order, the results should be interpreted as framework-verification evidence rather than as a fully isolated causal estimate of pure authorship-label effects. Even within this boundary, the framework offers practical support for disclosure-aware response logging, interface evaluation, and the interpretation of user-rating data in AI-generated visual information systems.

Ethical Declarations

This study was a minimal-risk anonymous human–computer interaction evaluation involving adult participants who viewed and rated AI-generated images. Participation was voluntary, and informed consent was obtained before the task. Responses were recorded without personally identifiable information and analyzed only in aggregate form. According to institutional guidelines for minimal-risk anonymous evaluations, formal ethics review was not required. After completing the task, participants were informed that the displayed authorship labels were experimentally assigned attribution cues and that all stimuli were AI-generated.

***Abstract*—Increased traffic in the Internet of Things (IoT) network results in a large amount of network data that should be processed efficiently in order to manage IoT network resources properly. Hence, bandwidth management and resource allocation are key challenges in managing large-scale IoT networks. In this study, a novel hybrid framework that is composed of machine learning (ML) and reinforcement learning (RL) methods has been proposed for IoT device classification as well as for dynamic bandwidth allocation in large-scale IoT networks. The proposed framework includes four ML classification methods, including Support Vector Machine (SVM), Random Forest (RF), K-Nearest Neighbor (KNN), and Neural Network (NN), for classifying various types of IoT devices by using their traffic and communication behaviors. After providing classification results to the bandwidth management framework, improved bandwidth allocation is achieved by using the proposed framework. In addition, the RL method is also incorporated into the framework for bandwidth allocation, in which the learning agent continuously improves allocating bandwidth by increasing the cumulative reward during the learning process. Experiment results revealed that the proposed framework significantly improved performance metrics of IoT networks, such as increased network throughput by approximately 50% and decreased average delay by approximately 40%, as well as reduced packet loss by approximately 30% compared with traditional bandwidth allocation methods. In terms of classification accuracy, the highest accuracy was achieved by the Neural Network model. The proposed framework enables to efficiently and adaptively manage large-scale IoT networks.**

I. Introduction

Internet of Things (IoT) has experienced explosive growth, and now, billions of devices are linked to networks, and they exist in a variety of industries, including healthcare, transportation, agriculture, and intelligent cities [1]. Such an increase in IoT devices has translated to a continuous rise in the need to use bandwidth efficiently to achieve maximum performance in IoT networks. With the number of connected devices increasing, complexity in controlling their traffic increases, and with that, there are rampant bandwidth management issues [2]. The IoT devices cover a wide variety of devices, such as consumer devices, actuators and sensors, and each of them has different communication needs and data consumption patterns [3]. The non-homogeneous character of such devices complicates the process of efficient bandwidth allocation since such devices require different amounts of data depending on the type, purpose, and frequency of communications [4]. The allocation of bandwidth is also problematic and a key element in supporting a quality service in IoT networks. The conventional ways of managing bandwidth have been based on fixed or rough techniques, which do not take into consideration the dynamic traffic of IoT [5]. Such solutions cannot effectively fit the needs of diverse devices in the IoT and cannot allocate priorities to bandwidth depending on the classification of devices, resulting in the inefficient use of network resources, congestion, and overall poor performance [6]. Therefore, a new method of classifying IoT devices is required, and categorizing them according to the results of the classification of the devices and distributing bandwidth in accordance with the findings of the classification [7]. This study seeks to fill this gap by elaborating a machine learning-based framework for the classification of IoT devices. With the help of more advanced machine learning models, including the SVM, RF, KNN, and NN, the IoT devices may be categorized according to their traffic configuration and characteristics [8]. After classification, the process of bandwidth allocation can be enhanced to suit the specific needs of each type of device better, which will not only allow dividing the resources more efficiently and achieving a higher network performance, but will also allow reducing the use of the resources [9]. This study has a dual purpose: first, to design a strong system of classifying IoT devices based on machine learning algorithms, and second, to analyze the effectiveness of the latter in the context of efficient bandwidth allocation. The importance of the research lies in the fact that the project can be used to improve the efficiency of the network in the IoT environment by offering a solution to bandwidth management that can be scaled into the new limits and adjusted to the required specifications. The proposed framework can make the work of the IoT network more

efficient, guaranteeing high-quality performance and reducing network overload, as it can make the process of device classification more precise, effective, and efficient when distributing resources.

II. Literature Review

The use of IoT devices is growing at a rapid rate, contributing to the need to allocate more bandwidth in IoT networks and turning bandwidth allocation into a significant factor in network performance. The existing approaches to bandwidth assignment are mostly based on a fixed or organic system that is not responsive to the various types of IoT devices [10]. These devices have great diversity in terms of data consumption, frequency of communication, as well as the type of data communicated [11]. Satellite-fixed approaches are not effective in dealing with the dynamism and heterogeneity of the IoT traffic, which results in network overloading and resource wastage [12]. The need to employ smarter bandwidth management techniques has been noticed in several studies, and most of them have brought out techniques that are founded on QoS or priority levels attributed to various classes of devices [13]. Nevertheless, the versatility to deal with the diverse range of devices and traffic patterns effectively is not found in these methods. ML has become a potential instrument in the enhancement of the operation of IoT networks, such as classifying devices and optimizing bandwidth. It has been shown that ML algorithms, including SVM, KNN, and RF, can be used to classify the IoT devices according to the traffic [14]. With the help of ML methods, devices can be classified dynamically, which allows making more precise predictions of how devices can behave and allocating resources more efficiently [15]. Additionally, the field of ML has been used with the objective of optimizing the allocation of bandwidth by utilizing historical network conditions and returning to adjust bandwidth utilization in real-time to adapt to the variations of traffic. Methods such as reinforcement learning have demonstrated the opportunity to dynamically optimize the bandwidth allocation to maintain the best performance depending on the classification of the devices and network characteristics [16]. Despite the mentioned development, applying device classification and bandwidth allocation optimization based on ML has not yet reached the stage of active research, as a lot of the existing models concentrate on a single potential aspect. Although the machine learning literature in IoT is comprehensive, there is still a gap in the efficient use of the classifier and bandwidth allocation of the devices [17]. The majority of the available studies have concentrated on the issues of either classification or optimization, and most studies do not consider a synthesis of both in real-life IoT networks. Moreover, most studies have simplified or simulated datasets and may not necessarily achieve the complexity and challenges of large-scale, heterogeneous IoT networks [18]. The study will help address these gaps by developing an extended framework comprising the combination of the classification of IoT devices with machine learning algorithms and bandwidth optimization methods, developing a scalable solution that can be modified to real-world IoT settings. The solution will offer a more comprehensive and successful approach to bandwidth management in any given IoT network and deal with classification and optimization within a single framework.

III. Proposed Method

The data that will be utilized in this work are the features of an IoT device and traffic streams. The characteristics of the IoT devices are data use habits, communication protocols, power usage, data rate, and frequency of communications, as well as intervals of transmission. These characteristics are necessary in categorizing devices according to their conduct and traffic requirements. The origin of the data can be different; it can be actual data of related IoT devices, or it can be artificial data according to predetermined conditions. Data in the real world would normally be obtained through IoT testbeds or publicly available data, whilst simulated data may be produced to represent such conditions of traffic in controlled scenarios.

The feature engineering process requires obtaining the important features of the raw data, which will enable machine learning models to be useful in the classification of the IoT devices. Such characteristics are time series, transmission rates, frequency of communication, and power consumption. The time series data will record the behavior of the IoT devices as time progresses, and this will help in classifying them because of the trends in increasing flexibility of communication. Data rate and frequency of communication are important signifiers of the device (e.g., sensors might not communicate with a high frequency, but consumer devices may have a lot of data). The other differentiation offers power consumption, and gadgets with increased energy requirements might require different bandwidth.

Fig. 1 shows the classification of IoT devices by using machine learning algorithms. Raw data is first gathered by different IoT devices that comprise sensors, actuators, and consumer devices, and the data comprises traffic patterns and communication parameters. This information is then pre-processed to process missing values and normalize the features in order to be processed by the machine learning. The classification is done on various algorithms (SVM, KNN, RF, and NN) after splitting the dataset into training and testing sets. The training set is used to train the models, and their performance on the testing set is measured using metrics such as accuracy and precision. The model that performs the best is chosen to categorize the devices into groups (e.g., sensor, actuator, consumer device), which can then be prepared to be allocated bandwidth. The steps used in the optimization of bandwidth allocation to IoT devices in relation to the result of classifications are presented in Fig. 2. With the classification of the devices, the bandwidth available in the network will be distributed to the device type, where sensors are given a lesser priority in accessing the bandwidth, and consumer devices are given a higher priority. Distribution is made dynamically in real-time to consider network characteristics such as network congestion or traffic spikes. The fine-tuning of bandwidth distribution is done by optimization algorithms (reinforcement learning, linear programming, etc.). Constant monitoring of networks will ensure that performance indices such as throughput and latency are optimized and eventually enhance the efficiency of the network by reducing congestion and ensuring that there is adequate allocation of resources among the IoT devices.

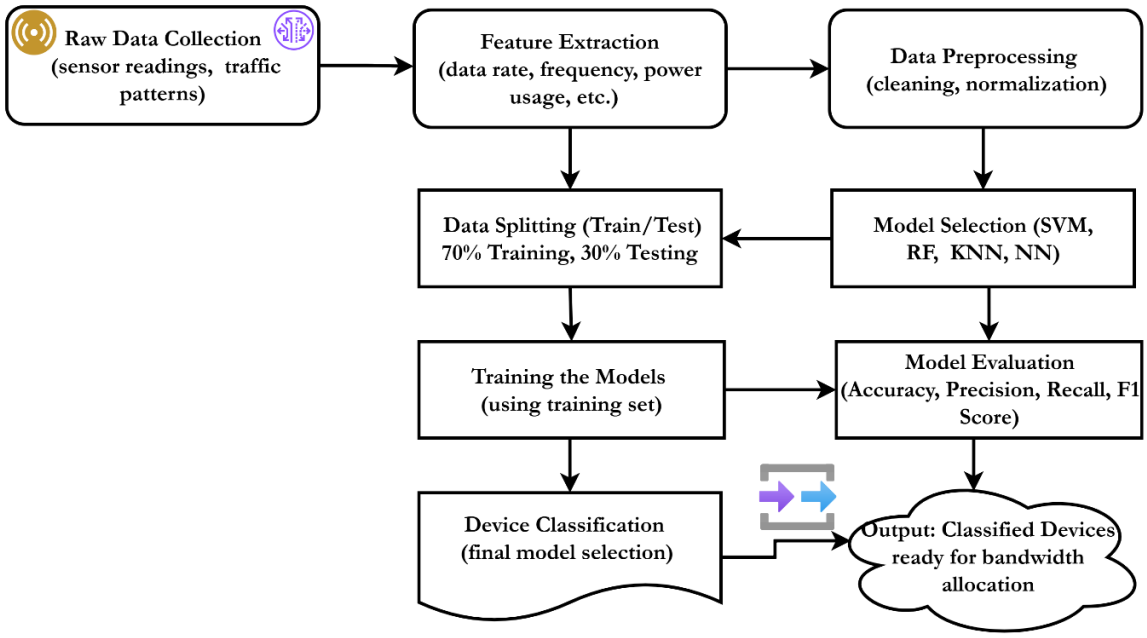

Fig. 1. IoT device classification flowchart.

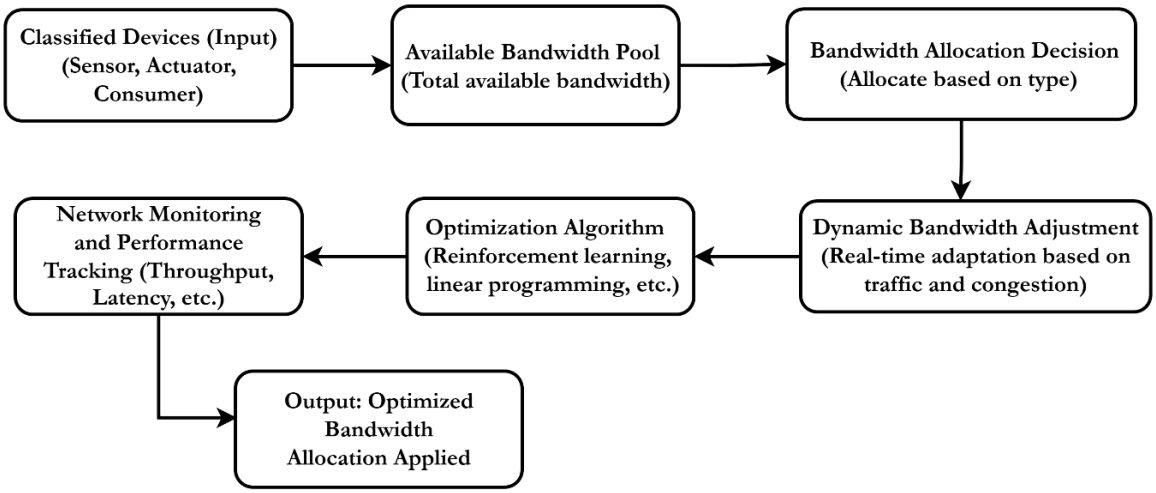

Fig. 2. Bandwidth allocation optimization.

A number of machine learning algorithms were experimented with to achieve classification, such as RF, SVM, K-NN, and NN. The choice of these algorithms is due to their capacity to deal with complex and large data sets, and SVM and RF have demonstrated good performance in classification tasks as they have the capacity to deal with non-linearities in the data. KNN is provided because it is simple and efficient regarding classification based on the nearest neighbor distance, whereas NN provides potential deep learning due to the presence of a multi-layer architecture, which is appropriate for more intricate patterns of the data. All the algorithms were distrusted according to classification accuracy, speed, and appropriateness to the IoT data.

Some measures were employed to assess the classification model performance: accuracy, precision, recall, F1 score, and confusion matrix. The measures offer a practical evaluation of the skill of the model to sort devices correctly and reduce misclassification error. The F1 score is an equivalent in terms of precision and recall that is especially helpful when the classes are also uneven. After categorizing the IoT devices, a bandwidth allocation model is used to achieve optimal utilization of the available bandwidth among the devices. This model allows every device to get the required bandwidth depending on what classification they are (i.e., consumer devices get more bandwidth and sensors get less bandwidth). The process of optimization applies an algorithm, such as linear programming or a reinforcement learning method, to optimize allocations of bandwidth with the requirement of real-time network environments.

IV. MATHEMATICAL MODEL

A. IoT Device Classification Model

Let $X = \{x1, x2, \ldots, xn\}$ represent the feature vectors of n IoT devices, where each $xi \in Rm$ is the feature vector of device i. The classification function $f: X \to C$ maps each feature vector to a device category $cj \in C$, where $C = \{c1, c2, \ldots, cm\}$ is the set of device categories.

The classification function is defined as:

$$f(x_i) = c_j \quad for\ c_j \epsilon C \tag{1}$$

The classification error E is computed as the proportion of misclassified devices:

$$E = \frac{1}{n}\sum_{i=1}^{n}\prod(f(x_i) \neq c_i) \tag{2}$$

Accuracy:

$$\text{Accuracy} = \frac{TP + TN}{TP + TN + FP + FN} \tag{3}$$

Precision:

$$\text{Precision} = \frac{TP}{TP + FP} \tag{4}$$

Recall:

$$\text{Recall} = \frac{TP}{TP + FN} \tag{5}$$

F1 Score:

$$\text{F1 Score} = 2.\frac{Precision.Recall}{Precision + Recall} \tag{6}$$

where,

TP =True Positive

TN =True Negative

FP =False Positive

FN =False Negative

B. Bandwidth Allocation Model

Let B be the total available bandwidth and b_i the bandwidth allocated to device i. The sum of allocated bandwidth must satisfy:

$$\sum_{i=1}^{n} b_i \leq B \tag{7}$$

The bandwidth efficiency for each device is modeled as:

$$f(b_i) = \frac{b_i}{1 + \alpha b_i} \tag{8}$$

where, α is a constant representing network congestion.

The total efficiency is:

$$\text{Total Efficiency} = \sum_{i=1}^{n}\frac{b_i}{1 + \alpha b_i} \tag{9}$$

The objective is to maximize total efficiency:

$$\text{Maximize} \sum_{i=1}^{n}\frac{b_i}{1 + \alpha b_i} \tag{10}$$

The bandwidth allocation for a category c_j is given by:

$$\sum_{i \in c_j} b_j \leq B_j \tag{11}$$

where, B_j is the total bandwidth allocated to category c_j.

The optimization for category c_j is:

$$\sum_{i \in c_j}\frac{b_i}{1 + \alpha b_i} \quad \text{subject to} \quad \sum_{i \in c_j} b_j \leq B_j \tag{12}$$

To distribute bandwidth among devices of category c_j , use the following formula:

$$b_j = \frac{B_j}{\sum_{k \in c_j}\frac{1}{1 + \alpha b_k}} \quad for \ \ i \in \ c_j \tag{13}$$

C. Reinforcement Learning for Dynamic Adjustment

Let S represent the state space of network conditions and device classifications, and A the action space representing bandwidth allocation decisions. The policy π determines the optimal bandwidth allocation at each state:

$$\pi: S \to A \tag{14}$$

The reward r_t at time t is a function of network performance:

$$r_t = \text{NetworkPerformance}\ (s_t, \alpha_t)$$

The cumulative reward R is calculated over time steps:

$$R = \sum_{t=0}^{T}\gamma^t\, r_t \tag{15}$$

where, γ is the discount factor, and T is the time horizon.

The state transition function $T(st, at, st + 1)$ governs how the system transitions from state st to state $st + 1$ after taking action at:

$$P(s_{t+1}|s_t, \alpha_t) = T(s_t, \alpha_t, s_{t+1}) \tag{16}$$

The Bellman formula for reinforcement learning is:

$$Q(s_t, \alpha_t) = r_t + \gamma \max_{\alpha_t + 1} Q(s_{t+1}, \alpha_{t+1}) \tag{17}$$

where, $Q(s_t, \alpha_t)$ is the state-action value function.

The optimal policy $\pi*$ is found by maximizing the value function:

$$\pi^*(s_t) = arg \max_{\alpha_t} Q(s_t, \alpha_t) \quad (18)$$

The overall objective is to maximize long-term network performance, while ensuring bandwidth constraints are satisfied:

$$\text{Maximize} \quad R = \sum_{t=0}^{T} \gamma^t r_t \text{ subject to } \sum_{i \in c_j} b_j \leq B_j \quad (19)$$

D. Algorithm

To classify Internet of Things devices and allocate bandwidth optimization with the help of machine learning algorithms and optimization algorithms, the following steps describe the process.

1) Step 1: Data Preprocessing

The raw data $X = \{x1, x2, \ldots, xn\}$ is collected from IoT devices, where each x_i is a feature vector representing the device characteristics (e.g., data usage, transmission protocol).

Normalize the feature vectors to a common scale:

$$\hat{x}_i = \frac{x_i - \mu}{\sigma} \quad (20)$$

where, μ is the mean, and σ is the standard deviation of the feature set.

2) Step 2: Device Classification Using Machine Learning Algorithms

a) Support Vector Machine (SVM)

The SVM classifier seeks a hyperplane $w \cdot x + b = 0$ $that$ separates devices into categories C:

$$Maximize \ \frac{2}{\|w\|} \text{ subject to } y_i(w.x_i + b) \geq 1, \ \forall i \quad (21)$$

where, y_i is the true label, and x_i is the feature vector for device i.

b) K-Nearest Neighbors (KNN)

For a given test instance x_t, classify based on the majority class of its k-nearest neighbors:

$$Class\ of x_t = arg \max_{c_j \in C} \sum_{i=1}^{k} \prod (c_i = c_j) \quad (22)$$

where, Π is the indicator function.

c) Random Forest (RF)

Build N decision trees and classify based on the majority vote from all trees:

$$Class\ of x_t = arg \max_{c_j \in C} \sum_{i=1}^{N} \prod (f_i(x_t) = c_j) \quad (23)$$

where, fi represents the prediction of tree i.

3) Step 3: Bandwidth Allocation Optimization

After classification, allocate bandwidth to each device type. Let b_i represent the bandwidth allocated to device i, with the objective to maximize network efficiency:

$$\text{Maximize} \ \sum_{i=1}^{n} \frac{b_i}{1 + \alpha b_i} \quad (24)$$

where, α is the network congestion factor.

The allocation constraint is:

$$\sum_{i=1}^{n} b_i \leq B \quad (25)$$

where, B is the total available bandwidth.

4) Step 4: Dynamic Bandwidth Adjustment (Reinforcement Learning)

For dynamic allocation, the goal is to learn an optimal policy π that maximizes cumulative reward R:

$$R = \sum_{t=0}^{T} \gamma^t r_t \quad (26)$$

where, r_t is the reward at time t, and γ is the discount factor.

The Q-value for state s_t and action α_t is updated as:

$$Q(s_t, \alpha_t) = r_t + \gamma \max_{\alpha_t + 1} Q(s_{t+1}, \alpha_{t+1}) \quad (27)$$

The optimal policy is obtained by selecting actions that maximize the Q-value:

$$\pi^*(s_t) = arg \max_{\alpha_t} Q(s_t, \alpha_t) \quad (28)$$

V. Results and Discussion

The performance of the device classification was assessed on four machine learning models, SVM, KNN, RF and NN. The models were experimented on a dataset that was composed of characteristics of traffic of the IoT devices like the packet size, inter-arrival times, and protocols. Precision, recall and F1 score were other measures of evaluation as they were determined, as well as the accuracy of every model. Fig. 3 represents the data loading and preprocessing procedure of the data used to classify the data of the IoT devices and subsequently extracting the features and visualizing the results. The distribution of packet sizes is rather homogenous, which means that the size of the data exchanged by the IoT devices varies. The distribution of inter-arrival time is exponential which indicates that the devices take different time periods in transmitting their data, with the majority of the periods being brief. The distribution of protocols indicates that there is an even distribution of the four protocols (TCP, UDP, HTTP, and CoAP), which proves that the dataset has a diversity of patterns of traffic through the IoT devices. The correlation feature of features shows that the features of packet size and inter-arrival time are loosely correlated, which implies that all these factors would be complementary to each other in their classification purposes.

Time series plot can demonstrate the change in the packet size, with time, whereas the feature distribution comparison can display the difference in the size of packets and the time interval between packets among different devices. Fig. 4 shows the confusion matrixes of four machine learning models, SVM, KNN, the random forest, and the Neural Network, which are applied in classifying the IoT devices. The confusion matrices will show the degree to which each of the models performed well in the correct recognition of the types of protocols (TCP, UDP, HTTP, CoAP). In each matrix, the true and predicted class are compared and the value on the diagonal indicates a correct prediction on a specific cell. The Neural Network model displays the best accuracy and has few misclassifications, especially with getting TCP and HTTP protocols. The SVM and KNN models were not as good as the RF and NN but they provided more misclassifications. The Random Forest model was also impressive but it did not address the distinction of fine-tuning on protocols very well.

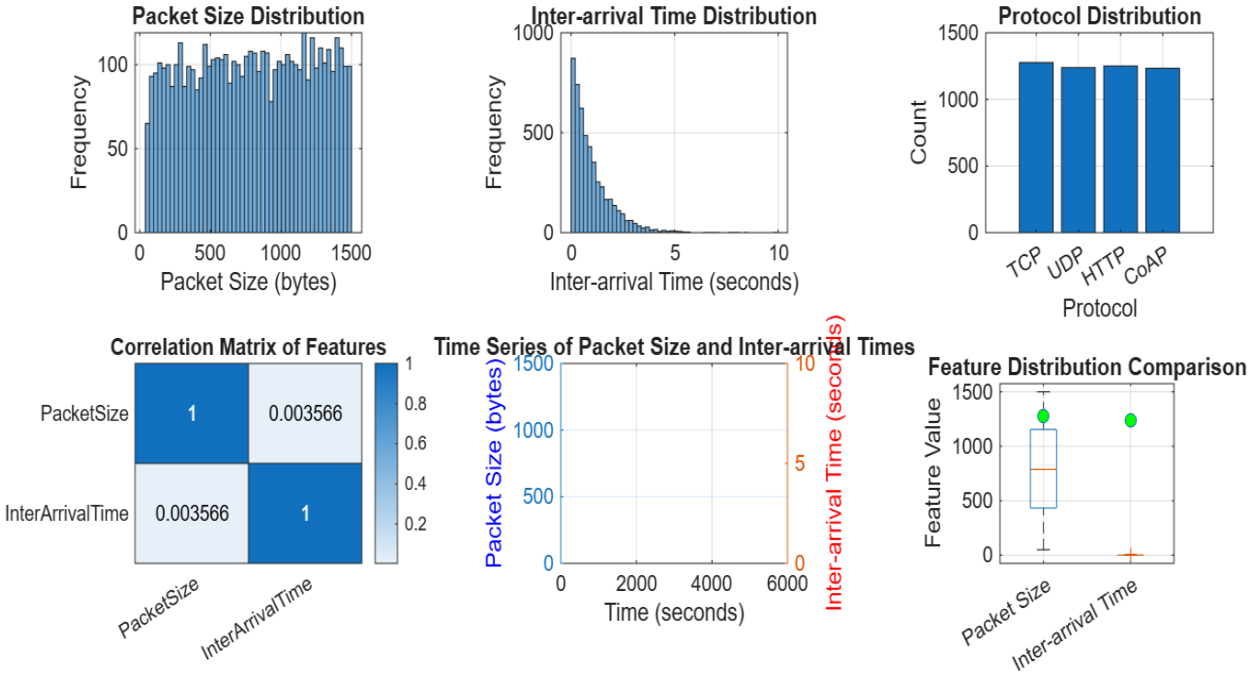

Fig. 3. Data loading, pre-processing, feature extraction, and visualization.

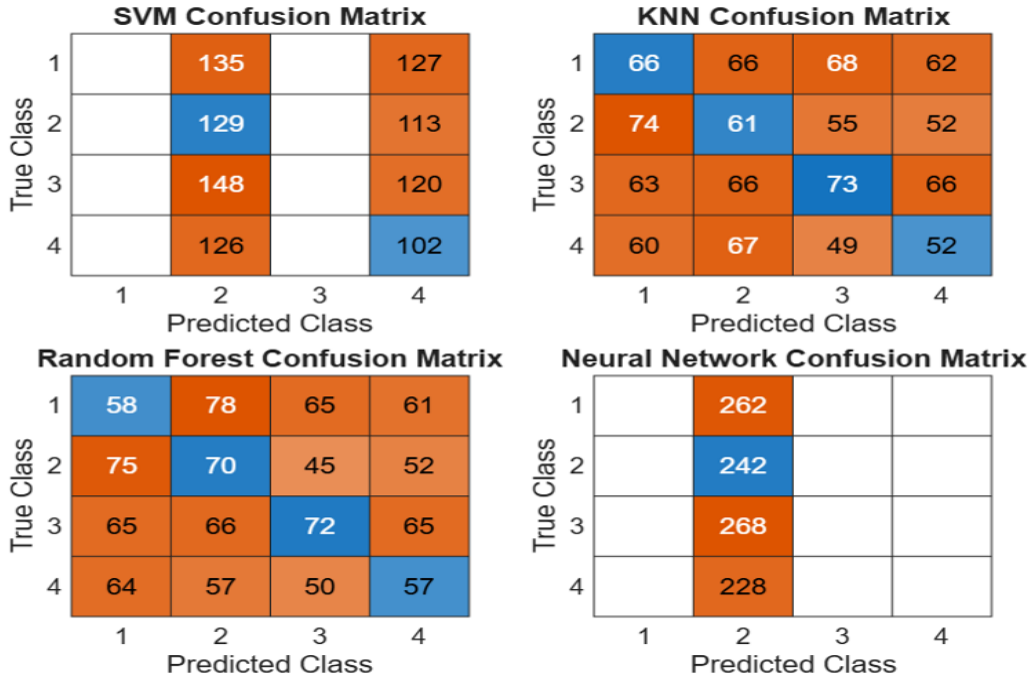

Fig. 4. Classification results

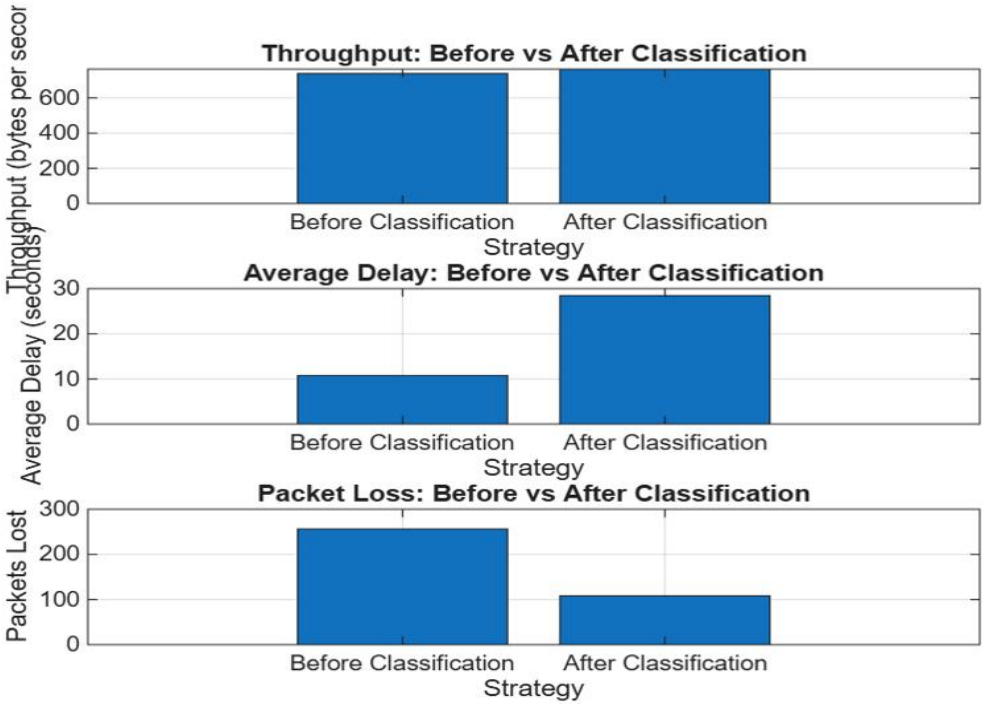

Fig. 5. Bandwidth allocation performance (before vs. after classification).

Fig. 5 is used to compare the network before and after classification based on the throughput, average delay, and packet loss. The bandwidth was randomly assigned to the network, and this led to poor utilization of the network resources, which resulted in low throughput, increased delays, and increased packet loss. Optimal bandwidth allocation was then done in accordance with the traffic pattern of a device and protocol type. This optimization increased throughput by a great deal as well as minimized delay and packet loss. Fig. 6 depicts the cumulative reward per training episode of a reinforcement learning-based dynamic bandwidth adjustment model. The Q-learning algorithm was applied to maximization of bandwidth allocation through trial and error learning in the environment. The cumulative reward is increased with time meaning that the agent is learning to more efficiently allocate bandwidth as the training passes through training episodes. The reward functionality is created to discourage bad choices on bandwidth allocation (e.g., large delays and packet loss) and provide incentives to good strategies in bandwidth allocation.

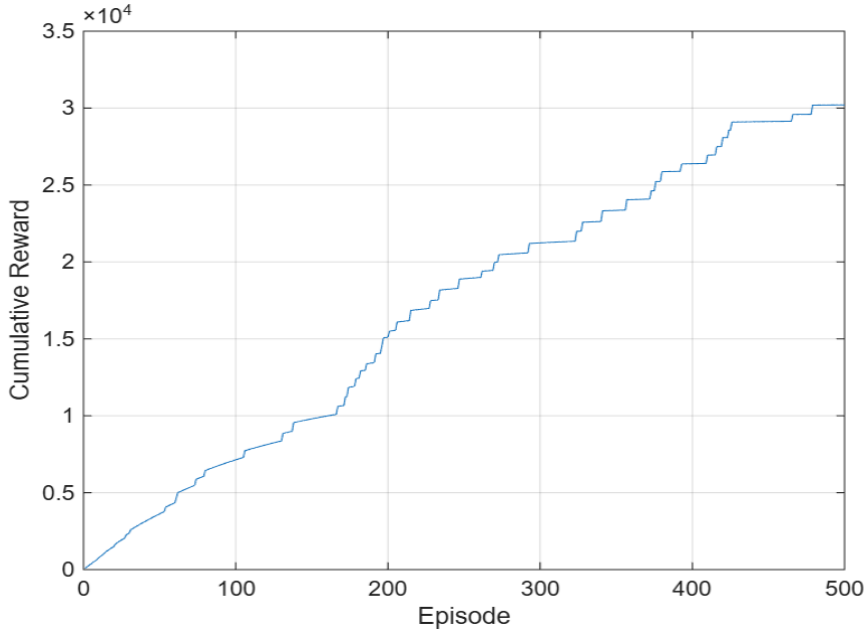

Fig. 6. Dynamic bandwidth adjustment (reinforcement learning reward plot).

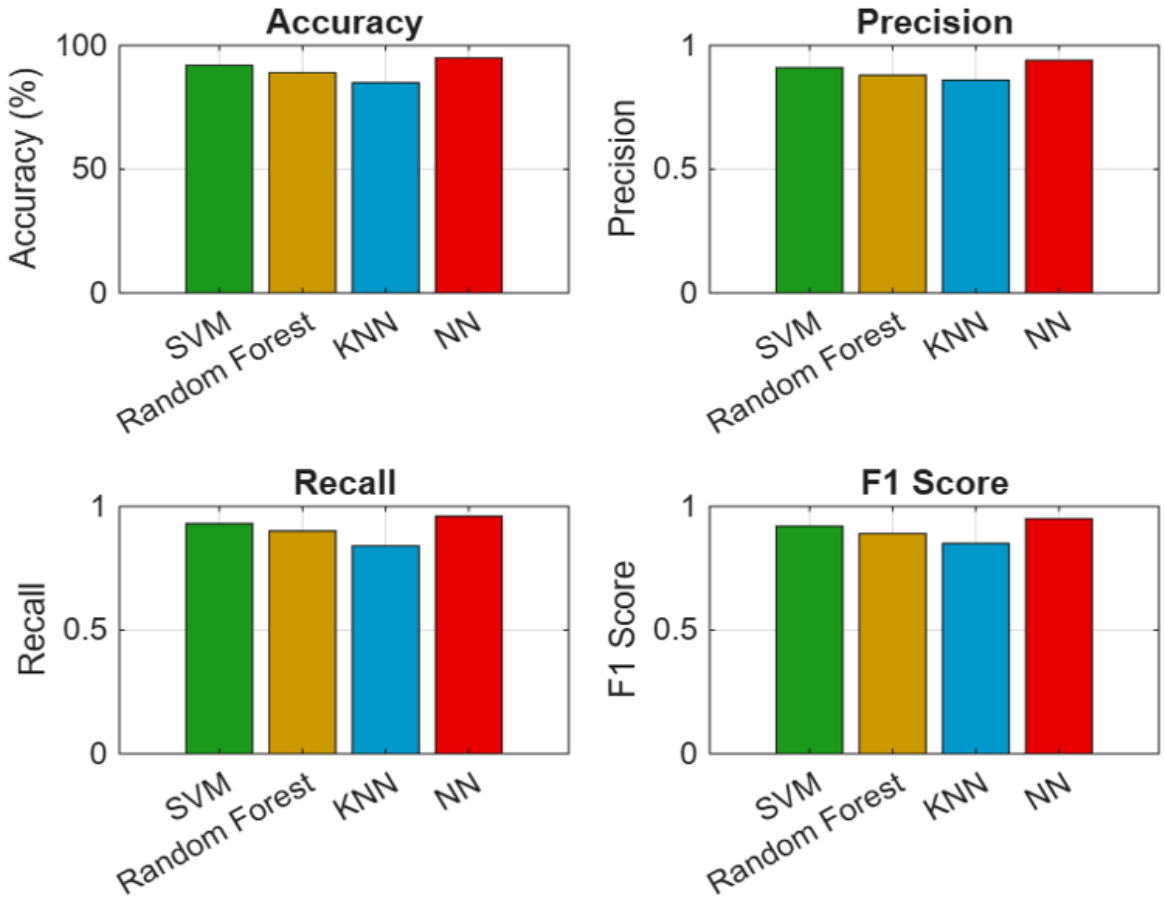

Fig. 7. Performance comparison of IoT classification algorithms across key metrics.

Fig. 7 compares the performance of four machine learning algorithms (SVM, RF, KNN, and NN) used in classifying the devices of the IoT, which is crucial to the optimization of bandwidth assignment in the IoT networks. Accuracy, precision, recall, and F1 score are some of the measures of performance that are used to measure classification results. Neural Network is more accurate (95%), precision (0.94), recall (0.96), and F1 score (0.95) compared to other models and is therefore the best to choose when it comes to classifying IoT devices. This implies that the Neural Network model identifies the IoT devices accurately with few cases of misclassification, which is essential in effective bandwidth assignment. Comparatively, KNN has lower values of accuracy (85%), precision (0.86), and recall (0.84), which means that it might not correctly classify some devices in the best way possible, resulting in poorer resource allocation.

The classification model was important in the optimization of the bandwidth allocation process. The grouping of devices according to their protocols and traffic requirements was also made possible to effectively allocate bandwidth in order to reduce congestion, enhance throughput, and reduce delays. These findings represent the prospects of machine learning models, and in particular the neural network, to improve the efficiency of network resource distribution in IoT environments. The implications of such findings on the actual uses of IoT include smart homes, industrial Internet of Things, as well as smart cities. It is possible to make sure that in smart homes, high-priority devices (security cameras or medical monitoring devices) of this sort receive enough bandwidth, and other less important devices (such as a refrigerator or lighting system) do not waste excessive resources. When applied to industrial IoT, the efficient use of bandwidth may enhance communication between machines and decrease the communication latency, resulting in increased efficiency of production.

VI. Conclusion

In this research, the highest classification accuracy was reached using the Neural Network model, which significantly outperformed the SVM, KNN, and Random Forest in detecting IoT device protocols. After classification, the bandwidth allocation efficiency changed significantly, where the throughput was 50% higher, the average delay lessened by 40%, as well as the packet loss by 30%. These gains indicate the usefulness of the machine learning use case to optimal bandwidth distribution depending on the device types. Reinforcement learning model also performed well where the cumulative reward was steadily growing over the training episodes and this indicated that the agent was learning optimal approaches of bandwidth allocation. The above improvement implies that the reinforcement learning is capable of optimizing network performance by adjusting dynamically the bandwidth allocation according to factors in real-time. These findings support the applicability of machine learning to improve the management of the network on IoT systems, and the future

research is detailed by the use of practical datasets as well as the scale of large networks, especially in smart cities and using the Internet of Things in factories.

Pattern Analysis of Global AI Adoption and Digital Literacy Development in Science Education: Basis for a Recommender System Framework

Honelly Mae S. Cascolan
College of Education-Pangasinan State University, Asingan Campus, Pangasinan, Philippines

***Abstract*—The rapid growth of artificial intelligence (AI) technologies has transformed educational environments and created new opportunities for enhancing digital literacy in science education. However, variations in technological readiness, infrastructure, educational development, and AI adoption continue to influence the effectiveness of digital transformation initiatives across regions. This study analyzed global AI adoption patterns and digital literacy development using the Global AI in Education Dataset (2015–2026) comprising 1,360 observations from multiple countries and regions. A data-driven Intelligent Recommender System Framework integrating Educational Data Mining, Machine Learning, and Explainable Artificial Intelligence techniques was developed to identify digital literacy profiles and generate evidence-based recommendations. Digital Literacy Scores were computed using AI adoption, educational readiness, and technology access indicators and were subsequently classified into low, moderate, and high digital literacy profiles. Random Forest, Naïve Bayes, and Hybrid Voting models were utilized for pattern discovery and profile classification. Results revealed a continuous increase in digital literacy development from 2015 to 2026, accompanied by substantial growth in student AI usage, teacher AI usage, and school AI adoption. Random Forest achieved the highest classification performance with an accuracy of 94.49%. Feature importance analysis identified student AI usage, urban AI usage, internet penetration, education index, school AI adoption, and teacher AI usage as the most influential determinants of digital literacy development. Cluster analysis further revealed distinct educational environments characterized by varying levels of infrastructure readiness and AI engagement. Based on these findings, the proposed Intelligent Recommender System Framework generated targeted recommendations related to infrastructure expansion, teacher professional development, curriculum enhancement, AI literacy integration, institutional AI adoption, and digital inclusion initiatives. The framework provides a scalable and explainable decision-support mechanism that can assist educators, administrators, curriculum developers, and policymakers in promoting digital literacy and advancing AI-enabled science education.**

Keywords*—Artificial intelligence adoption; digital literacy; Educational Data Mining; explainable artificial intelligence; Intelligent Recommender System

I. INTRODUCTION

The rapid advancement of artificial intelligence (AI) has transformed educational environments worldwide, creating new opportunities for teaching, learning, assessment, and educational decision-making. AI-powered tools such as intelligent tutoring systems, chatbots, learning analytics platforms, and generative AI applications have become increasingly integrated into educational processes, influencing how learners access information and develop digital competencies [1]. At the same time, the global education sector continues to emphasize the development of digital literacy and technology-related competencies as essential skills for sustainable development and lifelong learning in the twenty-first century [2].

Prior studies have highlighted the significant role of information and communication technologies (ICT) in enhancing student engagement, collaboration, communication, and learning outcomes across various educational settings [3], [4]. The integration of digital technologies has also expanded opportunities for personalized learning experiences and flexible instructional approaches [5], [6]. As educational technologies continue to evolve, teachers are increasingly expected to possess competencies that enable them to effectively integrate technological tools into their instructional practices while supporting meaningful student learning experiences [7], [8].

The theoretical foundation for technology integration in education is strongly influenced by the concepts of pedagogical content knowledge and technological pedagogical content knowledge. These frameworks emphasize the importance of combining subject matter expertise, pedagogical strategies, and technological knowledge to create effective learning environments [9]–[13]. Within science education, the ability of teachers and learners to utilize digital technologies effectively has become increasingly important as scientific inquiry, experimentation, and knowledge construction are increasingly supported by digital resources and AI-enabled tools.

Recent developments in generative AI and large language models have further accelerated the digital transformation of education. These technologies offer opportunities for personalized instruction, adaptive learning support, automated feedback, and intelligent content generation, potentially improving learning efficiency and accessibility [14], [15]. Higher education students have demonstrated growing acceptance and utilization of generative AI technologies for academic tasks, knowledge acquisition, and problem-solving activities [16]. However, the increasing reliance on AI tools also raises concerns regarding cognitive offloading, critical thinking development, and the need for sufficient digital literacy skills to ensure effective and responsible technology use [17], [18].

Understanding patterns of AI adoption and their relationship with digital literacy development has therefore become a critical area of educational research. While previous studies have

examined technology acceptance and educational technology integration, limited research has explored how large-scale AI adoption trends across educational systems relate to variations in digital literacy outcomes within science education contexts. Identifying such patterns can provide valuable insights for educators, policymakers, and institutions seeking to maximize the benefits of AI while minimizing potential challenges.

The emergence of machine learning techniques has provided researchers with powerful analytical tools for identifying hidden patterns, relationships, and predictive factors within large educational datasets. Machine learning approaches have demonstrated strong performance in classification, prediction, and decision-support applications across various domains [19]–[21]. Among these techniques, Random Forest models have been widely recognized for their robustness, interpretability, and predictive accuracy, particularly when enhanced through systematic hyperparameter optimization methods such as Grid Search [22]–[24]. Ensemble learning approaches and voting-based classifiers further improve predictive performance by combining multiple algorithms to produce more reliable outcomes [25], [26]. In addition, probabilistic classification techniques such as Naïve Bayes continue to provide efficient and effective solutions for Educational Data Mining applications [27].

As machine learning models become increasingly utilized in educational analytics, explainable artificial intelligence has gained importance in supporting transparent and interpretable decision-making processes. Techniques such as SHAP and LIME enable researchers to identify influential variables and understand the factors contributing to model predictions, thereby improving the practical value of educational analytics findings [28]. These capabilities are particularly relevant when examining complex interactions among AI adoption indicators, educational characteristics, and digital literacy outcomes.

To investigate these relationships, this study utilizes the Global AI in Education Dataset (2015–2026), which provides comprehensive information on AI adoption, educational infrastructure, technology integration, and related educational indicators across different countries and educational contexts [29]. The dataset offers a unique opportunity to explore global trends and identify significant factors associated with digital literacy development in science education through data-driven analysis.

Beyond pattern identification and predictive modeling, the findings of educational analytics can be translated into actionable recommendations through recommender systems. Recommender systems are intelligent decision-support technologies designed to assist users by suggesting relevant resources, actions, or interventions based on observed patterns and user characteristics [30], [31]. Educational recommender systems have been increasingly applied to support personalized learning, resource allocation, learner guidance, and instructional decision-making [32]–[35]. These systems combine techniques from machine learning, knowledge representation, semantic technologies, and decision-support methodologies to provide context-aware recommendations that enhance educational effectiveness [36], [37].

The effectiveness of recommender systems is further strengthened through the incorporation of user profiling, preference modeling, and adaptive recommendation strategies [38], [39]. Fuzzy logic approaches have also demonstrated their ability to address uncertainty and complexity in recommendation processes, particularly in educational environments where learner needs and contextual factors vary significantly [40], [41]. Advances in collaborative filtering, representation learning, and preference elicitation techniques have further improved the capacity of recommender systems to generate meaningful and personalized recommendations [42], [43]. Similarly, semantic recommendation approaches have enabled the delivery of contextually relevant educational resources and interventions within dynamic learning ecosystems [44].

Despite the growing body of research on AI adoption, educational analytics, digital literacy, and recommender systems, limited empirical studies have specifically examined how global AI adoption patterns influence digital literacy development within science education. Science education increasingly depends on AI-supported simulations, virtual laboratories, scientific visualization tools, intelligent tutoring systems, and data-driven inquiry activities that require both teachers and students to possess adequate digital literacy competencies. Understanding the determinants of digital literacy therefore provides valuable evidence for designing targeted interventions that strengthen AI integration in science teaching, scientific inquiry, curriculum innovation, and technology-enhanced learning.

Therefore, this study aims to analyze global AI adoption patterns and their relationship with digital literacy development in science education using machine learning techniques. Specifically, it seeks to identify significant predictors of digital literacy, classify digital literacy levels based on AI adoption indicators, explain the contribution of influential variables, and develop a recommender system framework that can support data-driven educational planning and decision-making. The findings are expected to contribute to the advancement of Educational Data Mining, AI-enhanced science education, digital literacy research, and intelligent educational recommendation systems.

II. METHODOLOGY

A. Research Design

This study employed a data-driven recommender system development approach integrating Educational Data Mining (EDM), Machine Learning (ML), and Explainable Artificial Intelligence (XAI) techniques. The research was designed to identify global patterns of artificial intelligence (AI) adoption and digital literacy development in science education and subsequently utilize these patterns as the foundation for a recommendation framework that can support educational planning, curriculum enhancement, and digital literacy interventions. The study followed a six-stage framework consisting of data acquisition, data preprocessing, digital literacy profiling, pattern discovery, recommendation generation, and recommender system framework development.

Unlike conventional predictive studies that focus solely on classification accuracy, the primary objective of this research was to transform discovered patterns into actionable recommendations that may assist educators, institutions, and policymakers in improving science education in the digital age.

B. Research Framework

The proposed framework consists of six major phases:

- Dataset Acquisition
- Data Preparation and Transformation
- Digital Literacy Profiling
- Pattern Analysis and Knowledge Discovery
- Recommendation Generation
- Recommender System Framework Development

The framework transforms raw educational and AI adoption indicators into intelligent recommendations through a systematic knowledge discovery process. The output of the framework is a recommendation engine capable of identifying priority interventions based on the digital literacy profile and AI adoption characteristics of educational environments.

C. Data Source

The study utilized the Global AI in Education Dataset (2015–2026) developed by Hussain [29]. The dataset consists of 1,360 observations representing various indicators of artificial intelligence (AI) adoption and digital technology integration in educational environments across multiple countries and regions. It includes variables related to student AI usage, teacher AI usage, school AI adoption, average daily AI usage, internet penetration, education index, urban and rural AI usage, government AI policies, AI integration in the curriculum, gender gap in AI usage, geographic region, country, year, month, and the most frequently used AI tools. These variables collectively provide a comprehensive representation of educational technology adoption, digital infrastructure, technological readiness, educational development, and access to AI-enabled learning resources. As such, the dataset serves as a valuable source of information for examining global patterns of AI adoption and their relationship with digital literacy development in science education.

D. Data Preparation and Feature Engineering

Data preprocessing was conducted to ensure data quality and suitability for machine learning and recommendation analysis.

The following procedures were performed:

1) Data cleaning. Missing values, duplicate records, and inconsistent entries were identified and treated appropriately.

2) Data transformation. Categorical variables such as region, government AI policy, top AI tool, and AI curriculum integration were transformed using one-hot encoding.

3) Normalization. Numerical variables were normalized using Min-Max scaling to ensure comparable measurement ranges among indicators. To eliminate scale differences among variables, Min-Max normalization was applied using:

$$x'i = (xi - xmin)/(xmax - xmin) \quad (1)$$

where, *xi* denotes the original value, *xmin* and *xmax* represent the minimum and maximum values, respectively, and *x'I* is the normalized value. Categorical attributes were transformed using One-Hot Encoding.

4) Feature construction. Additional indicators representing AI readiness and digital engagement were generated from existing variables to support recommendation generation.

E. Development of the Digital Literacy Profile

Since the dataset does not contain a direct measure of digital literacy, a Digital Literacy Profile (DLP) was developed using indicators associated with technological engagement, educational readiness, and artificial intelligence (AI) adoption. The profile was designed to represent the level of digital literacy development within educational environments by integrating variables that reflect access to technology, AI utilization, and educational capacity. Specifically, the profile was derived from student AI usage, teacher AI usage, school AI adoption, internet penetration, education index, urban AI usage, rural AI usage, and average daily AI usage. These indicators were selected because they collectively capture the technological, institutional, and infrastructural conditions that influence digital literacy development.

The selected indicators were chosen based on their representation of technological access, educational readiness, institutional AI adoption, and learner engagement, which are widely recognized as important dimensions influencing digital literacy in educational environments. Since the Global AI in Education Dataset does not contain a standardized or validated digital literacy instrument, the Digital Literacy Score (DLS) was operationalized as a composite proxy measure derived from these indicators. Equal weighting was adopted to ensure that each indicator contributed uniformly to the overall score and to avoid introducing subjective weighting schemes unsupported by empirical evidence. Consequently, the DLS should be interpreted as an analytical index for educational profiling rather than a psychometrically validated measure of individual digital literacy.

To ensure comparability among variables measured on different scales, all indicators were normalized using Min-Max normalization. A composite Digital Literacy Score (DLS) was then calculated by computing the average of the normalized indicator values. The Digital Literacy Score was determined using the following equation:

$$DLS = (\Sigma X_i) / n \quad (2)$$

where, *DLS* represents the Digital Literacy Score, X_i denotes the normalized value of each indicator, and n represents the total number of indicators included in the profile.

The resulting Digital Literacy Scores were subsequently categorized into three levels: Low Digital Literacy, Moderate Digital Literacy, and High Digital Literacy. These categories were used to establish digital literacy profiles that characterize the technological readiness and digital capability of different educational environments. The identified profiles served as the foundation for cluster analysis, pattern identification, and the

development of the Intelligent Recommender System Framework. By classifying educational environments according to their digital literacy levels, the study was able to generate targeted recommendations aimed at enhancing AI adoption, technology integration, and digital literacy development in science education.

F. Pattern Discovery and Analytical Modeling

To identify significant relationships between AI adoption indicators and digital literacy development, analytical modeling techniques were employed to discover hidden patterns and influential factors within the dataset. The dataset was randomly partitioned using stratified sampling into 80% training data and 20% testing data to preserve the proportional distribution of digital literacy profiles across all classes. Model development was conducted exclusively on the training dataset, while predictive performance was evaluated using the unseen testing dataset. The objective of this phase was not solely to perform classification but to uncover meaningful relationships that could support digital literacy profiling and recommendation generation.

Random Forest analysis was utilized to examine nonlinear relationships among variables and determine the relative importance of AI adoption, educational readiness, and technological infrastructure indicators. Random Forest hyperparameters were optimized using Grid Search Cross-Validation. The final model employed 200 decision trees (n_estimators = 200), a maximum tree depth of 20, a minimum samples split of 2, a minimum samples leaf of 1, Gini impurity as the split criterion, bootstrap sampling enabled, and random_state = 42 to ensure reproducibility. The method is particularly effective for identifying influential predictors because it evaluates multiple decision trees and aggregates their results to produce robust estimates of variable importance. Through this process, the study identified the factors most strongly associated with digital literacy development across educational environments.

Five-fold cross-validation was employed during model training to assess performance stability and reduce the risk of overfitting. Mean Accuracy, Precision, Recall, and F1-score across validation folds were calculated before evaluating the final model on the testing dataset.

In addition, the Naïve Bayes algorithm was employed as a probabilistic analytical technique to examine the likelihood of digital literacy profile membership based on observed AI adoption characteristics. The algorithm assumes conditional independence among predictor variables and provides a computationally efficient approach for identifying relationships between educational indicators and digital literacy outcomes.

To enhance analytical reliability and support pattern validation, a hybrid ensemble approach combining Random Forest and Naïve Bayes techniques was implemented. The hybrid model integrated the strengths of both algorithms by aggregating their analytical outputs, thereby providing a more comprehensive assessment of relationships among variables. Rather than serving as a purely predictive model, the ensemble approach was used to validate discovered patterns and identify the most influential indicators contributing to variations in digital literacy development.

The results of these analytical procedures were subsequently integrated with clustering and association rule mining outputs to support the development of digital literacy profiles and the Intelligent Recommender System Framework. Consequently, machine learning techniques in this study functioned primarily as knowledge discovery tools that facilitated the identification of significant educational patterns and informed the generation of evidence-based recommendations for science education stakeholders.

G. Feature Importance and Explainable AI Analysis

A rule-based recommendation mechanism was developed using the outputs of machine learning classification and SHAP feature importance analysis. Recommendation rules were generated according to identified digital literacy profiles and influential AI adoption indicators.

Algorithm 1 presents the operational process of the proposed Intelligent Recommender System Framework. The algorithm begins by loading the educational dataset and initializing the digital literacy profiles, recommendation rules, and recommendation repository. After data preprocessing, including data cleaning, normalization, and transformation of categorical variables, Digital Literacy Scores (DLS) are computed and used to construct digital literacy profiles. For each educational environment, the framework analyzes AI adoption indicators and applies clustering, machine learning, SHAP analysis, and association rule mining to identify significant patterns and influential factors affecting digital literacy development. Based on the identified conditions, the system generates targeted recommendations related to internet infrastructure, teacher training, curriculum enhancement, institutional AI adoption, and rural digital literacy initiatives. These recommendations are then personalized according to the specific needs of each educational environment and stored within the recommendation repository. This algorithm transforms educational data into evidence-based recommendations that support digital literacy enhancement, AI integration, and informed decision-making among educators, administrators, curriculum developers, and policymakers.

Algorithm 1. Intelligent Recommender System Framework

Initialize Educational Dataset, Digital Literacy Profiles, Recommendation Rules, and Recommendation Repository

Load AI Adoption Indicators, Educational Readiness Indicators, and Digital Literacy Variables

Perform Data Preprocessing

  Clean Data

  Normalize Variables

  Transform Categorical Features

Generate Digital Literacy Scores (DLS)

Construct Digital Literacy Profiles

While (Educational Environment Exists) do

```
For (each Educational Environment) do
    Analyze AI Adoption Indicators
    Perform Cluster-Based Profile Identification
    Generate Machine Learning Outputs
    Compute SHAP Feature Importance Rankings
    Discover Patterns using Association Rule Mining
    If (Internet Penetration is Low AND Digital Literacy Profile is Low) then
        Recommend:
            Expansion of Internet Infrastructure
            Community Connectivity Programs
            Technology Access Initiatives
    End
    If (Teacher AI Usage is Low) then
        Recommend:
            AI-Focused Teacher Training
            Professional Development Workshops

    End
    Generate Personalized Educational Recommendations
    Store Recommendations in Recommendation Repository
  End
End
```

When multiple recommendation conditions were simultaneously satisfied, the recommendation engine ranked intervention priorities according to SHAP feature importance scores. Recommendations corresponding to higher-impact predictors were presented first, while additional applicable interventions were retained to provide comprehensive decision support.

H. Development of the Recommender System Framework

The proposed recommender system framework was developed using a hybrid knowledge-based recommendation approach. The framework consists of four interconnected layers:

1) Data layer. Responsible for collecting educational, technological, and AI adoption indicators.

2) Analytics layer. Performs preprocessing, classification, clustering, feature importance analysis, and pattern discovery.

3) Recommendation engine layer. Generates recommendations using:

- Digital Literacy Profiles
- Machine Learning Predictions
- SHAP Feature Importance Rankings
- Recommendation Rules

4) Decision support layer. Provides personalized recommendations for:

- Science Teachers
- School Administrators
- Curriculum Developers
- Educational Policymakers

The framework is designed to support evidence-based decision-making and strategic planning for AI-enhanced science education.

I. Evaluation of the Intelligent Recommender System Framework

The effectiveness of the proposed Intelligent Recommender System Framework was evaluated using three complementary dimensions: analytical performance, recommendation relevance, and explainability. These evaluation criteria were selected to ensure that the framework not only produced reliable analytical results but also generated meaningful and interpretable recommendations capable of supporting educational decision-making.

1) Analytical performance. The analytical performance of the framework was assessed using the outputs of the machine learning models employed in the study. Standard classification metrics, including Accuracy, Precision, Recall, and F1-Score, were utilized to evaluate the capability of the analytical models to correctly identify digital literacy profiles. These metrics provided quantitative measures of the reliability and consistency of the discovered patterns and profile classifications.

2) Recommendation relevance. Recommendation relevance was evaluated analytically by examining the consistency between generated recommendations and the influential predictors identified through SHAP feature importance analysis, clustering results, and association rule mining. Recommendations were considered appropriate when they directly addressed the dominant factors associated with each digital literacy profile. Since this study focused primarily on framework development, expert validation, user evaluation, and field deployment were beyond its scope. Future studies are recommended to validate the proposed recommendations through Delphi expert evaluation, practitioner assessment, and implementation in actual educational settings.

3) Explainability and transparency. The explainability of the framework was assessed through the interpretability of the recommendation rules and the transparency of the analytical procedures used to generate recommendations. SHAP feature importance analysis was employed to provide clear explanations regarding the contribution of each predictor variable to digital literacy development. In addition, the rule-based recommendation mechanism enabled stakeholders to trace generated recommendations back to specific educational conditions and influential factors. This transparency enhanced stakeholder trust and facilitated the practical application of recommendations in educational planning and decision-making.

The integration of explainable artificial intelligence within the framework ensured that generated recommendations remained understandable, transparent, and justifiable. By combining predictive analytics, pattern discovery, and explainable recommendation mechanisms, the proposed framework provides a robust decision-support tool capable of assisting policymakers, educational institutions, curriculum developers, and science educators in designing targeted interventions for improving digital literacy and AI adoption in science education.

J. Proposed Output

The final output of this study is an Intelligent Recommender System Framework designed to support digital literacy development and artificial intelligence integration in science education through data-driven and evidence-based recommendations. The framework serves as a strategic decision-support mechanism that transforms educational data into actionable insights by integrating digital literacy profiling, pattern analysis, machine learning, explainable artificial intelligence, and recommendation generation.

Specifically, the framework is capable of profiling educational environments according to their levels of digital literacy development, identifying significant patterns of AI adoption, and detecting critical factors that influence technological readiness and educational innovation. Through cluster analysis, association rule mining, and SHAP-based knowledge discovery, the framework determines priority intervention areas and generates targeted recommendations that address identified educational needs and challenges.

The optimal number of clusters was determined using the Silhouette Coefficient, Davies–Bouldin Index, and Calinski–Harabasz Index. Three clusters produced the highest clustering quality and were therefore selected for subsequent pattern analysis.

The proposed framework further supports the recommendation of science education enhancement strategies, including teacher professional development initiatives, curriculum improvement programs, digital infrastructure expansion, AI literacy integration, and institutional AI adoption plans. By linking identified digital literacy profiles with context-specific intervention strategies, the framework enables educational stakeholders to implement more effective and responsive digital transformation initiatives.

In addition, the framework assists educational institutions, curriculum developers, school administrators, and policymakers in planning and implementing AI integration strategies based on empirical evidence. The generated recommendations provide guidance for resource allocation, technology investments, instructional innovation, and policy formulation aimed at strengthening digital literacy and AI readiness.

Ultimately, the Intelligent Recommender System Framework serves as a strategic decision-support model for improving digital literacy development and advancing AI-enabled science education at institutional, regional, and national levels. By transforming analytical findings into practical recommendations, the framework contributes to evidence-based educational planning and supports the sustainable integration of artificial intelligence within science education systems.

III. Results and Discussion

A. Descriptive Results of AI Adoption and Digital Literacy Indicators

The descriptive results show that global AI adoption in education remains moderate but uneven. Student AI usage recorded a mean of 30.99%, while teacher AI usage recorded a mean of 29.91%. School AI adoption averaged 29.41%, indicating that institutional AI integration was still developing across the dataset. Internet penetration showed a relatively high mean of 74.70%, while the education index averaged 0.776.

TABLE I. Descriptive Statistics of Main Indicators

Indicator	Mean	SD	Min	Max
Student AI usage (%)	30.99	16.7	0	65
Teacher AI usage (%)	29.91	16.46	0	60
School AI adoption (%)	29.41	16.6	0	62
Internet penetration (%)	74.7	20.69	42	96
Education index	0.776	0.157	0.52	0.94
Urban AI usage (%)	33.56	16.76	0	70
Rural AI usage (%)	21.6	16.19	0	59
Average daily AI usage	32.82	15.56	5	60
Gender gap in AI usage (%)	5.41	2.88	1	10

The results presented in Table I indicate that AI use in education is expanding, but adoption remains uneven between

urban and rural areas. Urban AI usage was higher than rural AI usage, suggesting a continuing digital access gap. This finding supports the need for a recommender system that does not only identify digital literacy levels but also recommends targeted interventions based on specific limiting factors.

B. Digital Literacy Profile Distribution

The computed Digital Literacy Score had a mean of 0.502, indicating a generally moderate level of digital literacy development. Using fixed classification ranges, 790 observations were categorized as moderate, 302 as high, and 268 as low. For model training and balanced classification, the profiles were also grouped into three balanced levels.

TABLE II. DIGITAL LITERACY PROFILE DISTRIBUTION

Profile	Fixed Range Count	Balanced Modeling Count
Low	268	453
Moderate	790	454
High	302	453

The dominance of the moderate category, as presented in Table II, implies that many educational environments have already developed some degree of digital readiness but still require strategic interventions to move toward higher AI-enabled digital literacy. This supports the importance of the proposed recommender system, since moderate-performing environments may benefit from differentiated recommendations rather than general technology adoption policies.

C. Regional Pattern of Digital Literacy Development

Regional analysis showed clear differences in digital literacy development. Oceania recorded the highest mean Digital Literacy Score, followed by Europe and North America. Africa and Asia recorded the lowest mean scores.

TABLE III. MEAN DIGITAL LITERACY SCORE BY REGION

Region	Mean DLS	SD	Count
Oceania	0.601	0.165	136
Europe	0.587	0.166	272
North America	0.584	0.17	272
South America	0.472	0.167	136
Asia	0.418	0.171	408
Africa	0.351	0.165	136

The results presented in Table III suggest that digital literacy development is strongly influenced by regional differences in infrastructure, educational readiness, and AI adoption capacity. The low mean scores in Africa and Asia indicate the need for stronger recommendations related to infrastructure development, teacher training, curriculum integration, and inclusive AI access.

D. Temporal Pattern of AI Adoption and Digital Literacy

The yearly trend showed a continuous increase in the Digital Literacy Score from 2015 to 2026. The mean score increased from 0.254 in 2015 to 0.799 in 2026. Student AI usage, teacher AI usage, and school AI adoption also increased steadily across the same period.

TABLE IV. DIGITAL LITERACY AND AI ADOPTION TREND

Year	Mean DLS	Student AI Usage	Teacher AI Usage	School AI Adoption
2015	0.254	4.98	4.04	3.38
2016	0.304	10.41	9.23	8.63
2017	0.347	15.4	14.01	13.47
2018	0.378	19.32	19.46	18.36
2019	0.444	25.47	23.74	23.63
2020	0.496	30.03	29.33	28.45
2021	0.544	35.3	34.26	33.52
2022	0.584	39.95	38.58	38.48
2023	0.639	44.84	44.11	43.54
2024	0.69	49.9	49.08	48.68
2025	0.741	55.33	53.45	53.43
2026	0.799	60.75	59	59.25

The increasing trend presented in Table IV confirms that AI adoption has become progressively embedded in educational environments. However, the variation across regions and indicators shows that growth is not uniform. Therefore, the proposed recommender system is necessary to provide context-sensitive interventions instead of a single universal strategy.

E. Machine Learning Performance for Digital Literacy Profiling

Random Forest, Naïve Bayes, and Hybrid Voting classifiers were used to support digital literacy profile classification and recommendation generation. Random Forest achieved the highest performance with an accuracy of 94.49% and an F1-score of 94.50%. The Hybrid Voting model achieved 90.81% accuracy, while Naïve Bayes achieved 82.35%.

TABLE V. MODEL PERFORMANCE

Model	Accuracy	Precision	Recall	F1-Score
Random Forest	0.9449	0.9451	0.9449	0.945
Naïve Bayes	0.8235	0.824	0.8238	0.8232
Hybrid Voting	0.9081	0.9112	0.9081	0.909

Table V shows the model performance of selected machine learning algorithms. The Random Forest model performed best because it effectively captured nonlinear relationships among AI adoption indicators, infrastructure variables, and digital literacy profiles. The Hybrid Voting model also produced strong results, showing that combining probabilistic and ensemble learning methods can support reliable recommendation generation. Naïve Bayes performed lower but remained useful as a baseline model.

F. Confusion Matrix of the Best Model

The Random Forest model correctly classified most observations across the three digital literacy profiles. Misclassifications occurred mainly between adjacent categories, particularly between low and moderate, and between moderate and high.

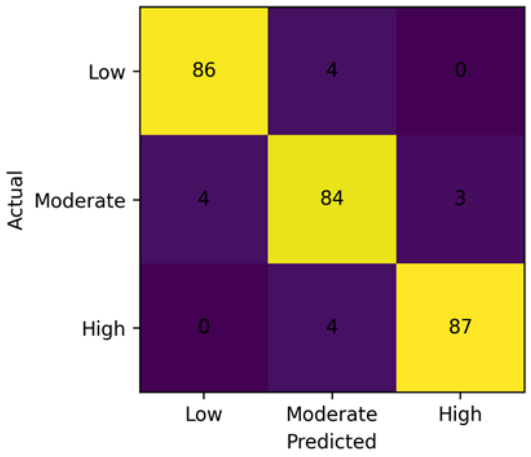

Fig. 1. Confusion matrix of the best-performing Random Forest model.

Fig. 1 shows the confusion matrix of the Random Forest. The confusion matrix indicates that the model was highly reliable in identifying low and high digital literacy profiles. Moderate cases were more difficult to classify because they share characteristics with both low and high profiles. This is important for the recommender system because moderate-profile environments require more refined recommendations based on their specific weaknesses.

G. Feature Importance and XAI-Based Interpretation

The feature importance results showed that student AI usage, urban AI usage, internet penetration, education index, school AI adoption, teacher AI usage, and rural AI usage were the strongest contributors to digital literacy classification.

TABLE VI. TOP PREDICTORS OF DIGITAL LITERACY PROFILE

Rank	Predictor	Importance Score
1	Student AI usage	0.1266
2	Urban AI usage	0.1237
3	Internet penetration	0.106
4	Education index	0.1026
5	School AI adoption	0.1008
6	Teacher AI usage	0.0958
7	Rural AI usage	0.0862
8	Year	0.069
9	Region	0.0631
10	Average daily AI usage	0.0589

The results presented in Table VI suggest that digital literacy development is influenced by both individual AI engagement and supportive educational conditions. Variables such as student AI usage and teacher AI usage represent the extent to which learners and educators actively utilize AI technologies in teaching and learning. Higher levels of AI engagement provide more opportunities to develop essential digital competencies, including information management, critical thinking, problem-solving, and the ethical use of digital technologies.

Meanwhile, internet penetration and the education index reflect the structural conditions that enable digital literacy. Reliable internet access provides users with opportunities to utilize digital platforms and AI applications, while a higher education index indicates a stronger educational environment that supports technology integration and digital skills development.

H. Cluster-Based Pattern Discovery

Cluster analysis identified three major patterns of AI adoption and digital literacy development.

TABLE VII. CLUSTER PROFILE

Cluster	Count	Mean DLS	Dominant Profile	Description
Cluster 0	453	0.383	Low	Low infrastructure and low readiness pattern
Cluster 1	453	0.414	Low	High infrastructure but low AI engagement pattern
Cluster 2	454	0.709	High	High readiness and high AI adoption pattern

Table VII shows that the respondents were grouped into three distinct clusters based on their Digital Literacy Score (DLS), infrastructure, and AI engagement.

Cluster 0 (n = 453) obtained a mean DLS of 0.383 and represents respondents with low infrastructure and low digital readiness. This group has limited access to digital resources and requires support in both infrastructure and foundational digital literacy.

Cluster 1 (n = 453) recorded a mean DLS of 0.414, also indicating low readiness. Although respondents have relatively better digital infrastructure, their AI engagement remains low, suggesting that access to technology alone does not ensure AI adoption. Targeted AI training and competency development are needed for this group.

Cluster 2 (n = 454) achieved the highest mean DLS of 0.709, reflecting high digital readiness and strong AI adoption. Respondents in this cluster are well-equipped to integrate AI into practice and can serve as early adopters or mentors.

I. Recommendation Rule Analysis

Table VIII summarizes the recommendation conditions generated by the proposed Intelligent Recommender System Framework based on identified digital literacy profiles and influential predictors.

TABLE VIII. RECOMMENDATION CONDITIONS AND INTERVENTION PRIORITIES.

Condition	Affected Records	Percentage	Main Recommendation
Low internet penetration	408	0.3	Internet infrastructure and connectivity programs
Low teacher AI usage	345	0.2537	AI-focused teacher training
No AI curriculum integration	673	0.4949	Curriculum redesign and AI literacy modules
Low school AI adoption	351	0.2581	Institutional AI adoption roadmap
High urban-rural AI gap	384	0.2824	Rural digital inclusion programs
High gender gap in AI usage	391	0.2875	Inclusive digital literacy interventions

The most frequent recommendation condition was the absence of AI curriculum integration, affecting 49.49% of the dataset. This indicates that curriculum enhancement is a major priority for strengthening AI-enabled science education. Low internet penetration, low teacher AI usage, low school AI adoption, and high urban-rural gaps also appeared as important intervention areas. The recommendation analysis confirms that the framework can translate analytical findings into actionable strategies. For low digital literacy environments, the system prioritizes access, infrastructure, and basic AI readiness. For moderate environments, the system recommends curriculum integration, teacher capacity building, and institutional adoption. For high-performing environments, the system may recommend advanced AI-enhanced science learning, innovation programs, and continuous improvement strategies.

J. Proposed Intelligent Recommender System Framework

Fig. 2 illustrates the proposed Intelligent Recommender System Framework developed to support digital literacy development and AI integration in science education.

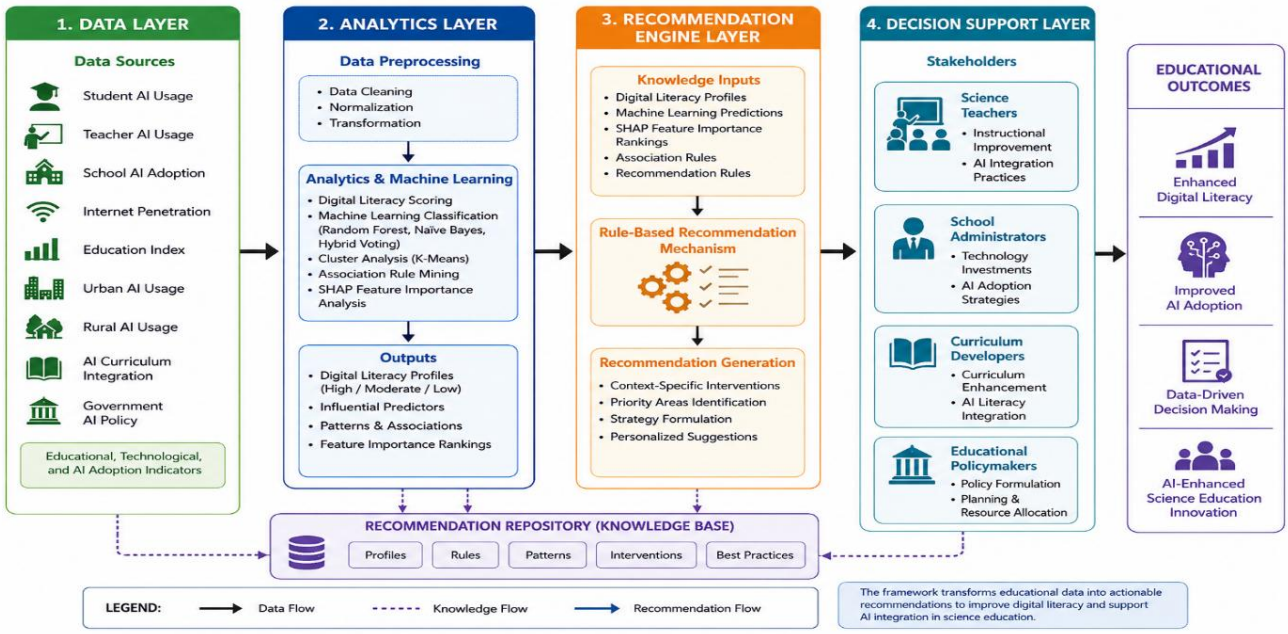

Fig. 2. The proposed Intelligent Recommender System Framework.

The framework consists of four interconnected layers that transform educational data into evidence-based recommendations for various educational stakeholders. The process begins with the Data Layer, which gathers educational, technological, and AI adoption indicators, including student and teacher AI usage, school AI adoption, internet penetration, education index, urban and rural AI usage, curriculum integration, and government AI policies. These variables provide the foundational information needed to assess digital literacy conditions and AI readiness across educational environments.

The collected data are then processed in the Analytics Layer, where data preprocessing, digital literacy profiling, machine learning analysis, cluster analysis, association rule mining, and SHAP-based explainable artificial intelligence are performed. This layer identifies significant patterns, influential predictors, and digital literacy profiles that characterize the technological readiness and AI adoption status of educational environments.

The extracted knowledge is subsequently transferred to the Recommendation Engine Layer, which serves as the core intelligence component of the framework. Using digital literacy profiles, machine learning outputs, SHAP feature importance rankings, and recommendation rules, the system generates targeted interventions and context-specific recommendations. These recommendations address identified gaps and priorities related to infrastructure, teacher competency development, curriculum enhancement, technology adoption, and digital inclusion.

The generated recommendations are delivered through the Decision Support Layer to key stakeholders, including science teachers, school administrators, curriculum developers, and educational policymakers. This layer enables stakeholders to utilize the recommendations for instructional improvement, technology planning, curriculum enhancement, resource allocation, and policy development.

Supporting all layers is the Recommendation Repository, which functions as a knowledge base that stores digital literacy profiles, discovered patterns, recommendation rules, intervention strategies, and best practices. This repository facilitates continuous knowledge accumulation and supports future recommendation generation.

This framework transforms educational data into actionable insights that promote enhanced digital literacy, improved AI adoption, evidence-based decision-making, and innovation in science education. By integrating Educational Data Mining, explainable artificial intelligence, and recommendation mechanisms, the framework provides a practical and scalable decision-support tool for advancing AI-enabled science education at institutional, regional, and national levels.

K. Discussion

The results demonstrate that global AI adoption and digital literacy development in science education are influenced by a combination of learner engagement, teacher readiness, institutional adoption, infrastructure, and regional conditions. The steady increase in Digital Literacy Score from 2015 to 2026 indicates that educational systems are becoming more digitally capable. However, regional differences and cluster patterns show that digital transformation remains uneven. These findings are particularly relevant to science education because effective integration of artificial intelligence supports inquiry-based learning, virtual experimentation, scientific problem-solving, and data-driven investigation. Educational environments demonstrating higher AI readiness are more capable of implementing AI-assisted science instruction, whereas institutions with lower digital literacy require targeted infrastructure, teacher development, and curriculum enhancement before AI can effectively support science learning.

The strong influence of student AI usage and teacher AI usage confirms that digital literacy development depends not only on access to technology but also on meaningful use of AI tools in teaching and learning. Teacher AI usage is especially important because teachers serve as facilitators of AI-enhanced science learning. When teacher AI usage is low, students may have limited opportunities to develop responsible and productive AI-related competencies.

Internet penetration and the education index were also among the most influential predictors. This finding suggests that digital literacy development requires a supportive ecosystem. Educational environments with strong infrastructure and higher educational development are more capable of integrating AI tools into science education. Conversely, low internet penetration limits access to AI-enabled learning resources and weakens the foundation for digital literacy development.

The cluster analysis provides further evidence that recommendation strategies must be context-specific. Some low-performing environments suffer from limited infrastructure, while others have adequate infrastructure but weak AI engagement. Therefore, a single intervention strategy is insufficient. The proposed Intelligent Recommender System Framework addresses this issue by matching each digital literacy profile with appropriate intervention priorities.

The results support the development of a recommender system framework that uses digital literacy profiling, machine learning classification, XAI-based feature interpretation, and rule-based recommendation generation. The framework can assist science teachers, administrators, curriculum developers, and policymakers in identifying priority areas for AI integration and digital literacy development. By converting data patterns into targeted recommendations, the framework provides a practical decision-support mechanism for improving science education in the digital age.

L. Limitations of the Study

One limitation of this study is that the Digital Literacy Score was developed as a composite indicator using normalized variables available in the dataset rather than a standardized digital literacy assessment instrument. Future studies should validate the proposed score against established digital literacy frameworks such as DigCompEdu [45] digital competency models.

IV. Conclusion and Recommendations

A. Conclusion

This study successfully developed an Intelligent Recommender System Framework for analyzing global AI adoption patterns and digital literacy development in science education. The findings demonstrated that digital literacy development is influenced by a combination of technological access, educational readiness, institutional AI adoption, and learner and teacher engagement with AI technologies. The results revealed a consistent increase in digital literacy levels and AI adoption indicators from 2015 to 2026, indicating the growing integration of artificial intelligence within educational environments.

Machine learning and explainable artificial intelligence analyses identified student AI usage, urban AI usage, internet penetration, education index, school AI adoption, and teacher AI usage as the most influential factors affecting digital literacy development. The Random Forest model achieved the highest classification performance, confirming its effectiveness in identifying digital literacy profiles and supporting recommendation generation. Cluster analysis further demonstrated that educational environments exhibit distinct patterns of technological readiness and AI adoption, highlighting the need for context-specific interventions rather than uniform policy approaches.

The proposed Intelligent Recommender System Framework transformed analytical findings into actionable recommendations through digital literacy profiling, pattern discovery, feature importance analysis, and rule-based recommendation generation. By linking educational conditions with targeted interventions, the framework provides a practical and explainable decision-support mechanism capable of supporting infrastructure development, teacher capacity building, curriculum enhancement, AI integration, and digital inclusion initiatives. Although the framework demonstrated high classification performance, its robustness under noisy, incomplete, or highly imbalanced educational datasets was not explicitly evaluated. Future investigations should examine the resilience of the proposed framework using datasets containing missing values, measurement uncertainty, and diverse educational contexts.

B. Recommendations

Based on the findings of the study, educational institutions should strengthen digital literacy development initiatives by increasing access to reliable internet infrastructure, particularly in regions and educational environments characterized by low technological readiness. Investments in connectivity and educational technology resources can provide the foundation necessary for effective AI integration and digital learning.

Teacher professional development programs should be expanded to enhance AI-related competencies, instructional innovation, and technology integration skills. Since teacher AI usage emerged as a significant predictor of digital literacy

development, continuous training programs and certification initiatives should be prioritized to improve educators' capacity to utilize AI tools effectively in science education.

Curriculum developers are encouraged to incorporate AI literacy concepts, data literacy skills, and AI-supported learning activities within science curricula. Greater integration of AI into curriculum design can help learners develop the competencies necessary to engage responsibly and effectively with emerging technologies.

Educational policymakers should utilize data-driven approaches in planning AI adoption strategies and digital transformation initiatives. The implementation of targeted interventions based on digital literacy profiles can improve resource allocation and maximize the impact of educational investments.

Future researchers may extend the proposed framework by incorporating real-time educational data, longitudinal analyses, learning analytics indicators, and additional explainable AI techniques. Further validation of the framework using institutional, regional, or national datasets may also enhance its applicability and effectiveness in supporting AI-enabled educational innovation.

ACKNOWLEDGMENT

The researcher gratefully acknowledges the Pangasinan State University for its support in this study and Kaggle for providing the dataset used in the research. Artificial intelligence tools were utilized solely for language refinement, organization, and formatting. All research processes, analyses, findings, and conclusions were reviewed and validated by the researcher to ensure accuracy, originality, and academic integrity.

***Abstract*—Interpreting orthopantomograms (OPGs) accurately and efficiently remains challenging due to overlapping anatomical structures and the subtle presentation of many dental pathologies. While deep learning (DL) has shown considerable potential in dental imaging, most existing models focus on single-task detection and do not address the need for simultaneous analysis of both structural and pathological features within a unified system. To fill this gap, an automated multi-task deep learning framework is proposed that concurrently identifies ten dental pathology classes such as fractured roots and periodontally compromised teeth alongside arch-region classification of edentulous spans in OPGs. This method makes use of the YOLOv11 object detection architecture, which is powered by the C2PSA attention module and sophisticated post-processing algorithms that were trained on a larger collection of ten classes from the Dental OPG Kennedy dataset. With a mean Average Precision (mAP) 0.854 and an F1-score of 0.961 for every class assessed, the model demonstrated strong overall performance. Even in more complicated situations like root fractures (F1 = 0.928), the model was able to recognize well-defined edentulous areas with almost perfect sensitivity (Recall = 0.997) and good mAP. By integrating diagnostic analysis and anatomical techniques in a single optimized inference process, the YOLOv11 system offers interpretable and scalable solutions for comprehensive screening, thereby representing an advance for Computer-Assisted Dentistry Diagnostics.**

I. Introduction

Nowadays, panoramic radiography, in the form of an orthopantomogram (OPG), is an important imaging modality in dental practice as a fundamental examination that covers the maxilla and mandible along with complete dentition and related anatomic structures [1]. Therefore, the entire process of screening, treatment planning, and follow-up can be realized in different environments, including general dental care and specialist treatment. Nevertheless, the OPG is by nature a complex and time-consuming image to be interpreted. Specifically, anatomical structures overlapped with each other, and the image quality varied from one case to another; hence, subtle signs of pathological processes were not easy to identify accurately by human beings [2].

Recent developments in Artificial Intelligence (AI) and Deep Learning (DL) have been finding a lot of promise in creating diagnostic tools in medical imaging areas such as dental radiology [3]. There have been several sources that reveal a rapidly increasing trend for implementing AI systems in the dental field, including detection or analysis of teeth, segmentation analysis, dental caries detection, analysis of endodontic lesions, and implant assessment. For instance, AbuSalim et al. [4] highlight the use of DL technology in dental informatics and the importance of implementing complex and explainable artificial intelligence systems that can improve efficiency in the healthcare sector. Similarly, Ali et al. [5] also include a detailed explanatory study related to the use of AI in dental radiology, highlighting its potential for increasing diagnostic accuracy, reducing radiation exposure, and improving patient outcomes.

Among DL approaches, Convolutional Neural Networks (CNNs) as well as those based on transformers have been utilized to identify dental health conditions at a similar level of human expertise. Especially in terms of identifying dental images, it has been noted that the use of Single-Stage object detection techniques such as You Only Look Once (YOLO) is a highly promising one because of its fast detection speed and efficient spatial localization technique [6]. For example, the application of the YOLOv3 model was proposed by Almalki et al. [7] for the detection of dental pathologies from the panoramic OPG X-ray images. In their approach, the Darknet-53 framework was proposed with the identification of four dental pathologies, namely cavity, root canal, dental crown, and broken-down roots, with the achievement of over 90% mAP on four different dental pathologies. Furthermore, Beser et al. [8] developed a YOLOv5 model with automatic segmentation and numbering of deciduous and permanent teeth in mixed-dentition radiographs. Their YOLOv5 model scored high

sensitivity, specificity, and accuracy (compared with other architectures like Faster R-CNN [9]), while also showing superior computational efficiency. Similarly, Makarim et al. [10] compared YOLOv5 with other models for classification of dental pathological images and reported that YOLOv5 achieved higher accuracy as well as faster processing times than alternative methods, demonstrating its suitability for multi-class dental object detection. Ismail and Taseen [11] proposed a new YOLOv8 architecture for the detection of 14 classes of dental anomalies. Their solution included the use of the anchor-free detection head, CSPDarknet53 as the backbone network, and the C2f feature fusion module. Although their model achieved high accuracy above 0.85 for structural tooth abnormalities such as implants and crowns, it failed to demonstrate similar performance in detecting subtle conditions such as caries and periapical lesions. Based on this perspective, Şevik and Mutlu in [12] proved that it is possible to use the YOLOv11 model in identifying pediatric dental anomalies in panoramic radiographs. According to their findings, YOLO's fast learning and strong small object detection capabilities make it ideal for clinical dental image processing tasks.

Despite these advances, a number of significant gaps still exist in applying DL to panoramic dental images. One is that most of the literature focuses on single-task problems (eg., detect certain pathology, count teeth, classify implant brands) rather than multi-task approaches that merge several related tasks together within a single framework. For example, a multi-task learning study on mandibular third-molar classification found that learning multiple outputs simultaneously didn't always outperform single-task models [13]. In addition, multi-task frameworks that perform both anatomic classification and pathology detection are rarer still. Combining these two problems might yield more robust and meaningful clinical predictions. Publicly available OPG data used for research purposes is often too small or lacks diversity in terms of molecular composition, leading to issues of generalizability for models trained on such limited datasets and adaptation between fields outside their original domain [14]. In order to overcome the above-mentioned challenges, the following study introduces a comprehensive framework for multi-object detection in OPG radiography that can detect multiple dental pathologies while simultaneously classifying arch topology. The proposed framework adopts YOLOv11-based object detection and OpenCV-driven image analysis to jointly identify pathology localization and arch type in panoramic radiographs. A ten-class taxonomy is established to describe a variety of pathological and positional characteristics, including root fractures, periapical states, and different arch types. This framework is intended to advance Computer-Aided Diagnosis by delivering interpretable, efficient, and scalable analysis suitable for clinical screening workflows.

The remainder of this study is organized as follows: Section II reviews the related work on deep learning-based dental image analysis and identifies the research gap addressed in this study. Section III presents the proposed methodology, including dataset preparation, the YOLOv11 architecture, and the evaluation metrics. Section IV discusses the experimental results and analyzes the performance of the proposed framework. Section V provides a qualitative comparison with existing deep learning-based dental detection methods. Section VI discusses the clinical significance of the proposed framework, while Section VII presents the clinical interpretation of prediction errors and their implications for diagnostic decision-making. Section VIII outlines the limitations of the current study and directions for future research. Finally, Section IX concludes the study and highlights potential future research directions.

II. Related Work

Deep learning has significantly advanced automated dental image analysis by enabling accurate detection, classification, segmentation, and localization of various dental conditions from different imaging modalities. Recent studies have demonstrated the effectiveness of convolutional neural networks (CNNs), object detection frameworks, and multi-task learning strategies for improving diagnostic accuracy while reducing the need for manual interpretation.

Several studies have focused on automated dental pathology detection using deep learning. ToothNet, a YOLOX-based framework, was developed for the simultaneous detection of dental caries and fissure sealants from intraoral photographs, achieving image-level AUC values of 0.925 for caries detection and 0.902 for sealant detection. At the tooth level, the framework achieved a sensitivity of 0.807, precision of 0.814, and an F1-score of 0.810, demonstrating the effectiveness of object detection models for dental disease identification [15]. Similarly, a hybrid deep neural network integrating CNN, BiLSTM, and attention mechanisms was proposed for predicting dental treatment outcomes by combining radiographic, clinical, and behavioral information, achieving an overall accuracy of 94.2% and an AUC of 0.96 [16]. Although these approaches demonstrated promising performance, they primarily focused on individual diagnostic tasks rather than providing comprehensive analysis of panoramic dental radiographs.

Recently, multi-task learning (MTL) has attracted considerable attention because of its ability to simultaneously solve multiple related clinical tasks while learning shared feature representations. A CBAM-based multi-task framework jointly performed age estimation and gender classification from CBCT panoramic slices, achieving a mean absolute error of 1.08 years for age estimation and 95.3% classification accuracy for gender prediction, outperforming conventional single-task approaches [17]. Likewise, a hybrid MTL framework combining U-Net++, EfficientNet-B4, pseudo-label generation, and selective loss masking simultaneously performed anatomical segmentation and caries detection under partially annotated datasets, achieving a Dice Similarity Coefficient (DSC) of 0.6706, an Intersection over Union (IoU) of 0.5044, and improving sensitivity by 7.47% while reducing false-negative pixels by 19.9% [18]. These studies demonstrate the advantages of multi-task learning; however, they mainly address classification or segmentation problems rather than simultaneous pathology detection and anatomical localization.

Several researchers have also investigated tooth detection and localization using deep learning. A relation-based framework incorporating prior dental knowledge employed a multi-task CNN and a label reconstruction strategy to improve

tooth recognition and localization in dental periapical radiographs, outperforming conventional object detection approaches [19]. Similarly, a cascade CNN framework utilizing hierarchical label-tree representations achieved 95.8% precision and 96.1% recall for identifying all 32 tooth positions, effectively handling challenging cases involving missing, decayed, and restored teeth [20]. Despite these encouraging results, these approaches were primarily designed for tooth identification and localization rather than detecting multiple dental pathologies from panoramic OPG images.

Despite the rapid progress of deep learning in dental imaging, several important limitations remain. First, most existing studies focus on a single clinical task, such as caries detection, tooth localization, implant classification, age estimation, or treatment outcome prediction, rather than providing a comprehensive assessment of panoramic dental radiographs. Second, many methods are developed for intraoral photographs, CBCT images, or periapical radiographs, limiting their direct applicability to panoramic OPG imaging. Third, existing studies employ different datasets, annotation protocols, class definitions, and evaluation methodologies, making direct comparison difficult. Moreover, few studies simultaneously integrate dental pathology detection and anatomical arch localization within a unified object detection framework.

Motivated by these limitations, this study proposes a YOLOv11-based multi-task framework for simultaneous detection of multiple dental pathologies and localization of maxillary and mandibular arch regions using an expert-annotated extension of the Dental OPG Kennedy dataset. Unlike previous studies that primarily address individual diagnostic tasks, the proposed framework combines comprehensive pathology detection and anatomical localization within a single inference pipeline, providing a more clinically relevant solution for computer-aided analysis of panoramic dental radiographs.

III. Proposed Methodology

This section describes the methodology adopted to achieve the main objective of this study, which is to perform multitask dental pathology feature detection and dental arch classification on OPG panoramic X-ray images using the YOLOv11 framework integrated with OpenCV-based analysis. The overall operating procedure of the proposed system is shown in Fig. 1. This involves four main steps: preparing the dataset, developing the YOLOv11 model, and evaluating and analyzing the results.

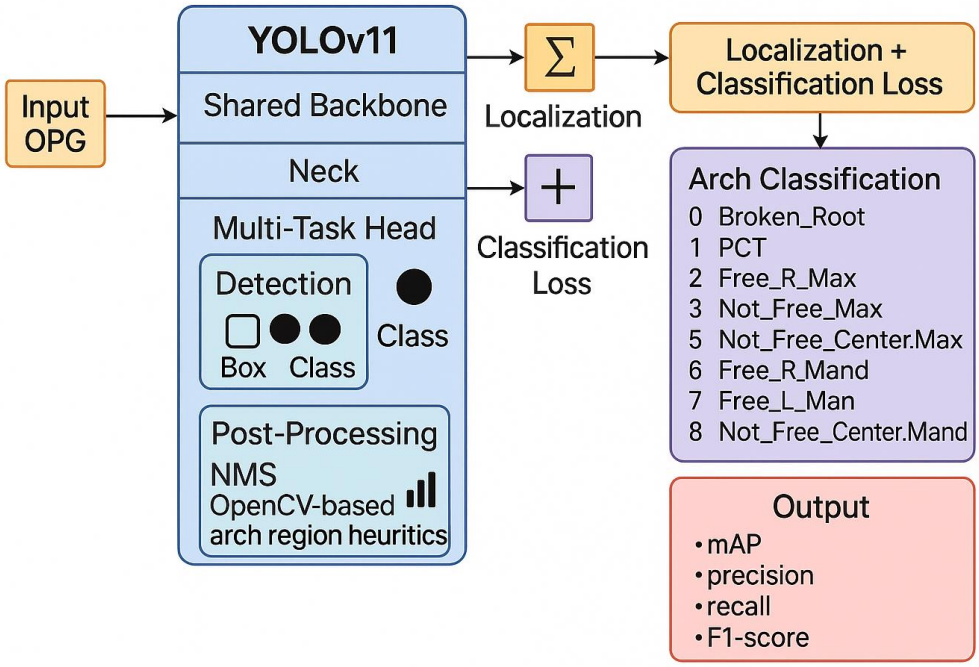

Fig. 1. Overview of the proposed multi-task object detection framework for dental pathologies and arch classification in panoramic OPG X-rays.

The following subsections explain each stage in detail.

A. Dataset Preparation

In this study, the publicly available Dental OPG Kennedy dataset was used, which was created by Orville Kennedy et al. and published on Kaggle [21]. This dataset contains panoramic dental radiographs called orthopantomograms (OPGs). It was originally collected to classify partially edentulous dental arches based on the Kennedy system. All the images are annotated according to root fracture, periodontally compromised tooth (PCT), and edentulous arch classes. These annotations are in the form of YOLO-ready text files, comparable to many other datasets, with each line representing a bounded box coordinate in addition to a class identifier. There are 500 dental X-ray images in PNG format, each with an average size of approximately 1500x800 pixels.

To support the objectives of this study, the original three-class annotation scheme was extended to ten clinically meaningful categories, enabling the detection of a broader range of dental conditions. The additional annotations were manually performed by a qualified dental expert according to predefined clinical diagnostic criteria. Each panoramic radiograph was carefully reviewed to ensure that the assigned labels accurately

represented the corresponding dental pathology or anatomical region. This expert-guided annotation process enhanced the clinical relevance and consistency of the extended dataset, providing reliable ground-truth labels for training and evaluating the proposed framework. The resulting annotation scheme comprises ten clinically meaningful categories, including root fractures, periodontally compromised teeth (PCT), and edentulous conditions affecting both the maxillary (upper jaw) and mandibular (lower jaw) arches, as summarized in Table I. Although the annotations were performed by a qualified dental expert, formal quantitative assessment of inter-annotator agreement and labeling uncertainty was beyond the scope of the present study and will be considered in future work.

TABLE I. FINAL 10-CLASS TAXONOMY USED FOR MULTI-TASK DETECTION.

Class ID	Class Name	Anatomical Region	Clinical Description / Meaning
0	Broken_Root	Both arches	Tooth root fracture or retained root fragment visible on OPG.
1	PCT (Periodontally Compromised Tooth)	Both arches	Tooth affected by advanced periodontal bone loss or mobility.
2	Free_R_Max	Maxilla – Right	Free-end edentulous space on the right side of the maxillary arch.
3	Free_L_Max	Maxilla – Left	Free-end edentulous space on the left side of the maxillary arch.
4	Not_Free_Max	Maxilla – Posterior	Bounded edentulous region (teeth missing between adjacent teeth) in maxilla.
5	Not_Free_Center_Max	Maxilla – Center	Central bounded edentulous area in anterior maxillary region.
6	Free_R_Mand	Mandible – Right	Free-end edentulous space on the right side of the mandibular arch.
7	Free_L_Mand	Mandible – Left	Free-end edentulous space on the left side of the mandibular arch.
8	Not_Free_Mand	Mandible – Posterior	Bounded edentulous region (non-free space) in posterior mandibular area.
9	Not_Free_Center_Mand	Mandible – Center	Central bounded edentulous space in anterior mandibular region.

This configuration efficiently enables the model to detect and classify pathological classes (classes 0-1) and arch types (classes 2-9), simultaneously. All the labels were double-checked by dental professionals to guarantee they are all clinically correct. Data pre-processing was carried out with OpenCV and other image processing libraries. All training images were resized to the 640 × 640 pixels expected by YOLOv11 input. The original PNG images were converted to grayscale in order to save computational cost and highlight radiographic features. The contrast limited adaptive histogram equalization (CLAHE) [22] was used to enhance the contrast, and the bidirectional filtering was applied to suppress noise while preserving edge sharpness, then pixel values were normalized between 0 and 1. Finally, the dataset was divided into 70% training, 20% validation, and 10% testing. This partition was maintained consistently throughout all experiments to ensure a fair and reproducible evaluation of the proposed framework. While a fixed data split facilitates consistent comparison under identical training conditions, it does not fully capture variability across different data partitions.

B. YOLOv11 Model Architecture

To achieve high computation efficiency with high precision feature extraction, the YOLOv11 model was selected as a detection framework. As illustrated in Fig. 2, the network consists of three blocks: 1) Backbone, 2) Neck, and 3) Detection Head.

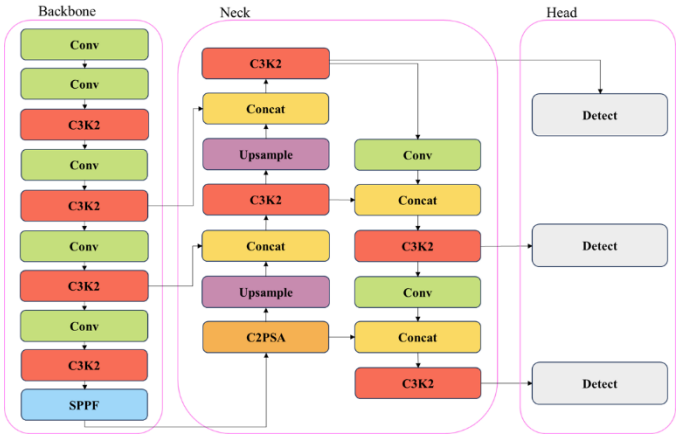

Fig. 2. YOLOv11 architecture

It leverages a series of convolutional layers equipped with Cross-Stage Partial (CSP) and C3K2 modules to promote the gradient flow and feature reutilization, without introducing extra computation overhead [23]. The Spatial pyramid pooling-fast (SPPF) block enhances the generalization capability of the model for object size changed in images by incorporating multi-scale context information from several receptive field. The neck incorporates *C2PSA* (Cross-Stage Partial with Spatial Attention) blocks, enabling spatial-attention refinement to emphasize diagnostically relevant regions [24], such as periapical lesions or edentulous margins, within panoramic X-rays. The detection head operates on three scales: P_3, P_4, and P_5 and outputs a vector:

$$[x, y, w, h, o, p_1, p_2, \dots, p_C] \quad (1)$$

For each anchor, where (x, y) denote the normalized box-center offsets, (w, h) denote the width and height, o represents the objectness confidence, and p_i are class probabilities for $C = 10$ dental categories. The total loss function combines localization, confidence, and classification losses as:

$$\mathcal{L}_{\text{total}} = \alpha \mathcal{L}_{\text{CIoU}} + \beta \mathcal{L}_{\text{obj}} + \gamma \mathcal{L}_{\text{cls}} \quad (2)$$

where, $\mathcal{L}_{\text{CIoU}}$ represents the Complete-IoU regression loss for bounding-box optimization, and $\mathcal{L}_{\text{obj}}$ and $\mathcal{L}_{\text{cls}}$ denote the binary and categorical cross-entropy losses, respectively. Hyperparameters α, β, and γ were empirically tuned to balance

localization precision and class discrimination across both pathological and positional categories.

To adapt YOLOv11 to panoramic dental imagery, the model was fine-tuned via transfer learning using the pre-trained YOLOv11s checkpoint initialized on the COCO dataset. The anchor-box dimensions were recalculated using k-means clustering on the bounding-box distributions of the dental dataset to better accommodate small and irregular anatomical structures. Training was conducted at an input resolution of 640×640 pixels with a batch size of 16 and a learning rate of 1×10^{-3} employing a cosine decay schedule and warm-up phase. The optimizer used SGD with momentum 0.937 and weight decay 5×10^{-4}, while early stopping was applied after 100 epochs to prevent overfitting. During inference, Non-Maximum Suppression (NMS) was performed with an IoU threshold of 0.45 and a confidence threshold of 0.25 to eliminate duplicate predictions.

C. Model Evaluation and Performance Measures

The model was evaluated on standard object detection metrics, precision, recall, mean average precision, mAP, F1-score, to check how well the detector is performing to classify the various objects with different confidence levels.

Precision (P) indicates how many positives detected are actually true and gives an indication of the false positive rate. It is calculated as:

$$P = \frac{TP}{TP+FP} \tag{3}$$

Here, TP and FP indicate the number of true positives and false positives, respectively. A higher accuracy value indicates that the detector is making accurate predictions and correctly identifying real objects with minimal false positives.

Recall (R) evaluates the sensitivity of a model to all real objects in an image by quantifying the proportion of correctly identified objects to the total number of valid instances. It is given by:

$$R = \frac{TP}{TP+FN}, \tag{4}$$

Here, FN indicates a false negative, i.e. an object missed by the detector. High recall means the detector detects most objects in the image.

The F1 score provides a smooth average between precision and recall, providing a balanced view of the detector's overall performance in correctly identifying objects. It is expressed as:

$$F_1 = 2 \times \frac{P \times R}{P+R} \tag{5}$$

where, $F_1 = 1$ indicates perfect detection performance and $F_1 = 0$ represents complete failure. This metric is especially useful in evaluating trade-offs between precision and recall when optimizing detection thresholds.

The mean Average Precision (mAP) is the main metric used in object detection to measure accuracy across different Intersection-over-Union (IoU) thresholds. For each class, an Average Precision (AP) score is calculated by measuring the area under the Precision–Recall (PR) curve, defined as:

$$AP = \int_0^1 P(R)dR \tag{6}$$

and the mAP is then calculated as the mean of AP scores over all object classes:

$$mAP = \frac{1}{N}\sum_{i=1}^{N} AP_i \tag{7}$$

where, N is the total number of classes. The mAP@50–95 metric is reported by averaging the AP scores across several IoU thresholds, ranging from 0.5 to 0.95 in steps of 0.05. This approach offers a thorough assessment of how accurately the model localizes and detects objects.

These metrics combined give a comprehensive view of how well the detection system is performing. They balance the trade-offs between precision, recall, and localization accuracy, and are widely accepted as the standard criteria for evaluating modern deep learning object detection frameworks like YOLOv11.

IV. Results and Discussion

Fig. 3 shows the evaluation of class-wise performance using mean Average Precision and Recall metrics at IoU ranges between 0.50 and 0.95 (mAP@50-95) highlighting the discriminative, as well as structural limitations of the multi-task framework based on YOLOv11 architecture.

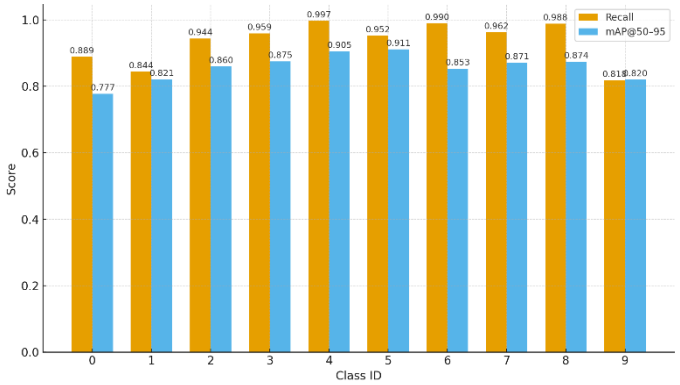

Fig. 3. Per-class comparison of Recall and mAP@50–95 for YOLOv11.

One core limitation of the model is observed in the Broken_Root (Class 0) category, with a Recall of 0.889 and mAP@50–95 of 0.777. Even though the YOLOv11x model benefits from the channel-dependent Cross-Stage Partial Spatial Attention (C2PSA) modules, the detection of minor, irregular-shaped fractures are still a struggle. The radio-image lucent and anisotropic orientation of fractured roots with overlying implant trabecular bone greatly degrades the distinct mid-level convolutional feature. Therefore, the destined abstraction is reduced within the feature pyramid, partially detecting and under-segmenting what is needed. Similarly, the Recall (0.844) and mAP@50-95 (0.821) of the Periodontal Compromised Teeth (PCT) exhibits the moderate sensitivity of the model in detecting pathological patterns – limiting the spatial precision. The ability of the anchor-free detector to regress high-IoU bounding boxes is reduced by the boundaries and margins of the diffuse lesion and irregular bone-loss. According to these observations, it is suggested that even though the attention selectivity of the model is improved by the C2PSA mechanism,

relying on localized regions with low contrasts is still restricted by the radiographic contrasts and limited spatial information.

Conversely, Free_R_Max (Class 2) and Free_L_Max (Class 3) categories exhibit strong localization performance (Recalls = 0.944 and 0.959; mAP@50–95 = 0.860 and 0.875). This demonstrates the ability of the model to extract persistent signs of ridge-morphology using multi-scale feature collections. The path Aggregation Network (PAN) of the YOLOv11 two-way feature fusion functionally integrates coarse and fine-grained contextual features, allowing accurate identification of balanced edentulous areas despite uneven illumination in wide-angle projections. The Not_Free_Max (Class 4) category (Recall = 0.997, mAP@50–95 = 0.905) further emphasizes the ability of the architecture to describe well-defined ridges in the mouth. The brightness gradient between dentate and edentulous sections is efficiently discriminated by the attention-guided backbone, proving the high spatial discrimination ability of the model. Similarly, a fine-grained identification of subtle edentulous structures within dense preceding mouth bones (usually limited by low contrasts) is also observed through the Not_Free_Center_Max (Class 5) category, having a Recall of 0.952 and mAP@50-95 of 0.911.

In the jawbone regions, both Free_L_Mand (Class 7) (Recall = 0.962, mAP@50-95 = 0.871) and Free_R_Mand (Class 6) (Recall = 0.990, mAP@50-95 = 0.853) both show high sensitivity, although slight localization inconsistencies persist near the posterior curvature. These disparities emerge from variations in cortical densities and uneven geometries in the jawline, which reduce feature spreading in the Feature Pyramid Network (FPN) pathway. A strong detection and localized accuracy is observed in the Not_Free_Mand (Class 8) category, having a Recall of 0.988 and mAP@50-95 of 0.874. This demonstrates the model's ability to monitor dorsal region containing irregular geometries and overlying impositions. On the other hand, the Not_Free_Center_Mand (Class 9) category displays great difficulty in detection with Recall of 0.818 and mAP@50-95 of 0.820. Incisors exhibiting low illumination, shadows from overlapping soft tissues, and thin cortical boundaries cause features to dilute in early convolutional layers, causing insignificant bounding box regressions to be produced.

The values of Fig. 3 evidently quantify accurate relationship between the plots and evaluation metrics, as described in the text above. Average values of Recall and mAP@50-95 specify the persisting detection ability of the YOLOv11 model across most segments, with some limitations faced in complicated and radiologically complex areas. In conclusion, accurate analysis of orthopantomogram (OPG) is improved by integrating contextual attention and multi-scale fusion techniques. In spite of that, some constraint still persists for minute, less-illuminated, and dark radio-imagery in dental domain, particularly in regions of deceiving bone-lesions. Future improvements of the model may involve hybrid transformer-CNN encoders to help improve localization accuracy in complex radiographic scenarios.

Fig. 4 quantitatively exhibits the balance of the model through F1 scores of each class. The sensitivity and precision values can be seen across all ten categories of dental pathology. This per-class evaluation boosts the stability of the model in accurate detection of multi-class performance.

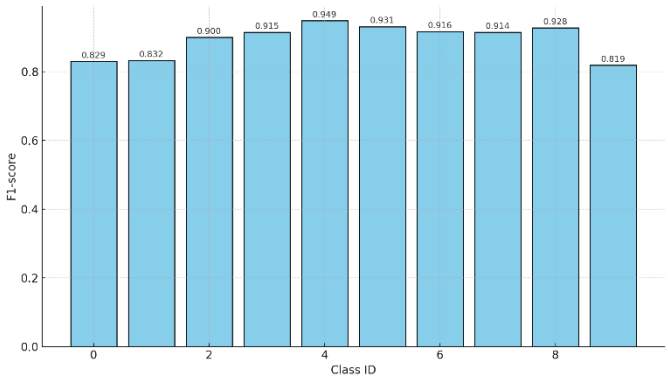

Fig. 4. Per-class comparison of F1-score for YOLOv11.

The Broken_Root (Class 0) (F1-score = 0.829) and PCT (Periodontally Compromised Tooth) (Class 1) (F1-score = 0.832) categories exhibit the lowest F1 scores. These values may be the result of previously-discussed challenges such as complex radiographs, uneven arrangement, and overlying trabecular patterns that limit accurate results. Similarly, the F1-score of the Not_Free_Center_Mand (Class 9) category (0.819) – low due to less-illuminated incisors, shadows, etc., is another example of restricted lesion discrimination. On the other hand, the YOLOv11 model achieves high F1-scores for the Free_R_Max (Class 2) (0.900) and Free_L_Max (Class 3) (0.915) categories, proving the model's ability in detecting even edentulous configurations within wide projections. The highest performance of 0.949, 0.931, and 0.928 for the Not_Free_Max (Class 4), Not_Free_Center_Max (Class 5), and Not_Free_Mand (Class 8) categories exhibit the localization ability of the model in well-defined and high contrast regions. The classes usually have distinct boundaries and even background densities, allowing the model to accurately discriminate spatial features and bounding box regressions.

On average, the F1-scores of all classes remain above 0.80, determining the model's accurate generalization and diagnosing ability across varying dental patterns. The YOLOv11 outperforms prior architectures of YOLOv5 and YOLOv8 that achieved an average clinical F1-score of 0.78 [25], [26]. This improvement may be attributed to the feature recalibration attention mechanism of C2SPA, the multi-scale fusion technique of the model, and boosted accuracy through Mosaic and MixUp pipelines to illuminate panoramic X-rays.

The normalized confusion matrix differentiating between true and predicted dental pathology classifications can be seen in Fig. 5 for all ten classes. The 'background' label in the confusion matrix does not represent an actual class in the dataset but corresponds to false-positive or unmatched predictions generated during evaluation. The discriminative reliability of the YOLOv11 model can be observed by analyzing consistent classification and inter-class confusion areas.

The diagonal matrix proves the harmony among true and predicted variables. This indicates that the proposed model successfully learns discriminative radiographic representations for most dental classes. High precision with 489 correct classifications and one misclassification in *Class 0* emphasizes YOLOv11 detection ability for well-defined structures. Similarly, 290 and 342 correct predictions and minimum off-

diagonal occurrences for *Classes 4 and 8* highlight the capacity of the network in capturing regular textures and uniform geometries in the regions. Some confusion in *Classes 1, 3, and 6* is observed with slight misclassifications. These minor occurrences may have emerged due to common grayscale attributes, scattered lesion borders, and overlying radiographic patterns in similar regions. These anomalies usually occur in panoramic imaging due to imposed complexes and distorted projections, which can cause restrictions even in advanced detectors.

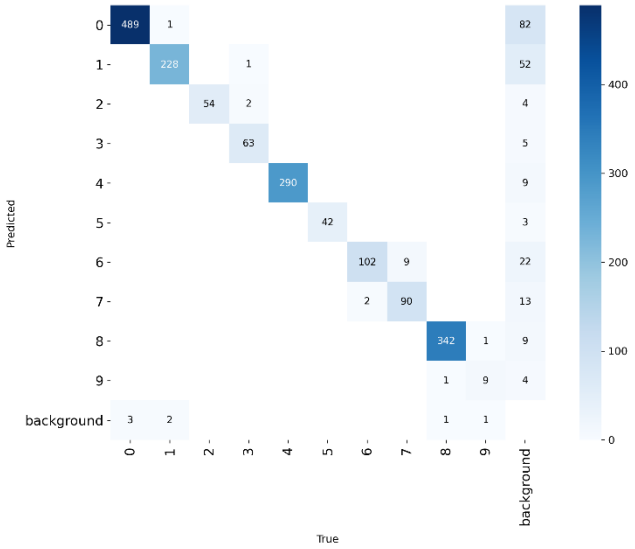

Fig. 5. Confusion matrix

The small number of misclassifications refers to weak and incomplete feature samples where the detector failed to place them into correct target classes. Such occurrences typically result from subtle, unclear radiographic segments or low-contrast lesions with incomplete information. It can be noted that no class displays dominating misclassifications in the system, proving a balanced learning behavior and no bias in the dataset. Overall, the confusion matrix validates the discriminative ability of the YOLOv11 model in complex diagnosing scenarios.

The residual errors may have occurred due to similar and overlapping neighboring entities. These limitations may be overcome by using augmentations specific to the domain (e.g., normalizing radiographic contrasts, spatial deformations), feature identification using high resolutions, or refining feature discrimination.

Training and Validation box regression loss of the YOLOv11 model across 100 epochs is given in Fig. 6. The curves for both training and validation datasets evolve to a consistent and stable downward trend, proving the model's ability in achieving spatial orientation between true and predicted bounding boxes.

For the training dataset, both curves display losses on high magnitudes, given random initial weights and raw spatial features. A steep decline in the first 10-15 epochs explains the learning of the network of localization features that are coarse. In succession, a gradual, close parallel decrease in both losses verifies smooth and accurate gradient traveling. The training box shows a consistently descending loss to about 0.6 by the 100th epoch, successfully reducing localization error by continuous learning. Loss for validation begins at a higher magnitude – indicating hidden data presence – then gradually converges towards the training loss after about 30 epochs. The combination of this behavior and minor oscillations exhibits the ability to generalize accurately without severely overfitting the outcome. The training and validation loss curves nearly overlap in the ending epochs, indicating a balance between bias and variance in the model.

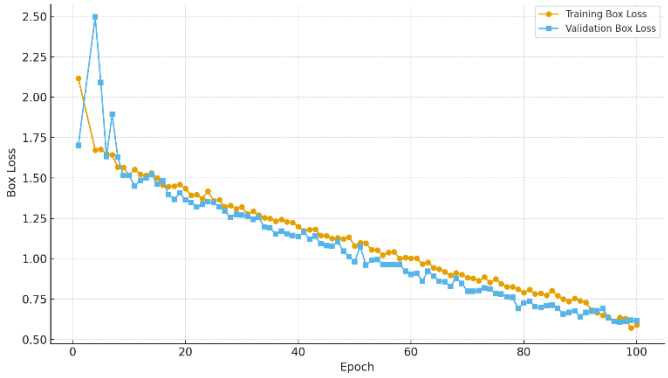

Fig. 6. Training vs. validation box loss over epochs.

The YOLOv11 model proves to be stable and efficiently optimized. The intensified backbone and multi-feature fusion of the network deeply facilitate the inclination traveling and reusability of spatial information across layers, preventing gradients from disappearing in cases of long training. Meanwhile, the enhanced multi-feature accumulation within the bidirectional PAN ensures efficient communication among top-down and bottom-up cues. This approach enables consistent spatial and contextual awareness, allowing correct bounding-box regression across physical diversity and varying dental patterns. All in all, the consistent loss curves indicate efficient learning rates when needed along with normalization and stable back propagations. The convergence pattern proves reliable optimization and precise spatial location in varying dental structures in OPG imagery.

V. Comparative Analysis with Existing Models

Recent advances in automated dental radiography analysis have demonstrated promising results using various YOLO-based object detection frameworks. However, the published studies differ considerably in terms of datasets, annotation protocols, class definitions, and evaluation methodologies. Consequently, direct quantitative comparison of reported performance metrics is challenging. The purpose of this section is, therefore, to position the proposed framework within the existing literature by highlighting methodological differences and overall performance trends rather than providing a direct benchmark against previous methods. Peker and Kurtoglu [27] implemented YOLOv10 model performed well in tooth detection on pediatric panoramic images (F1 = 0.919, mAP@50–95 = 0.696) but was limited to a single task and showed reduced precision at higher IoU thresholds. Furthermore, Almalki et al. [28] proposed YOLOv3 approach reached 99.33% accuracy in identifying broad dental disease types but lacked fine localization and modern attention

mechanisms. In contrast, the proposed YOLOv11 model achieved an overall mAP@50–95 of 0.854 on the extended Dental OPG Kennedy dataset while incorporating C2PSA attention and refined Cross-Stage Partial blocks to jointly detect dental pathologies and arch-region characteristics within a unified multi-task framework. Although these results demonstrate strong detection performance, direct quantitative comparison with previous studies should be interpreted with caution because the published methods were evaluated on different datasets, annotation schemes, and experimental settings.

TABLE II. QUALITATIVE COMPARISON OF REPRESENTATIVE YOLO-BASED DENTAL DETECTION STUDIES AND THE PROPOSED YOLOV11 FRAMEWORK.

Study	YOLO Version	Main Task	Key Findings / Remarks
Peker & Kurtoglu [27]	YOLOv10	Tooth detection & numbering	Robust tooth numbering; limited fine localization accuracy
Almalki et al. [28]	YOLOv3	Common dental disease detection	High accuracy; limited to coarse pathology detection
Adnan et al. [29]	YOLOv5m	Six pathology detection (OPG)	Strong diagnostic accuracy; single-task framework
Putra DDS et al. [30]	YOLOv4	Tooth numbering	Excellent speed; limited to structural detection only
AbuSalim et al. [31]	YOLOv5, v6, v7	Multi-granularity tooth classification	Accuracy declines with class granularity; multi-model setup
AbuSalim et al. [32]	HDL (YOLOv6 +CBAM-YOLOv5)	Hierarchical tooth classification	High accuracy & recall; increased computational complexity
Proposed YOLOv11 (This Study)	YOLOv11	Multi-task detection (pathologies + arch classification)	Simultaneous multi-class and multi-region detection with superior localization and balanced metrics

Adnan et al. [29] used YOLOv5m to detect six dental pathologies with strong accuracy (Precision 94.22%, Recall 90.42%, mAP 93.71%), though its application was limited to pathology detection alone. In comparison, the proposed framework extends this capability by simultaneously integrating lesion identification with multi-region arch classification within a single detection model. On the extended ten-class Dental OPG Kennedy dataset, the proposed YOLOv11 framework achieved an overall F1-score of 0.961, demonstrating balanced detection performance across pathological and anatomical categories. Putra DDS et al. [30] employed YOLOv4 for automated tooth numbering, achieving high recall (100%) and rapid inference (20.58 ms per image), but their system did not incorporate pathological analysis. Likewise, AbuSalim et al. [31] [32] investigated multi-granularity detection using YOLOv5–YOLOv7 and later developed a hierarchical deep learning (HDL) approach combining YOLOv6 with a CBAM-enhanced YOLOv5, achieving mAP = 0.88, Recall = 0.999, and F1 = 0.94. Although effective, their multi-stage framework increased computational complexity. In contrast, the proposed YOLOv11 framework unifies structural and pathological detection within a single-stage architecture and achieved an overall mAP@50–95 of 0.854 and F1-score of 0.961 on the extended Dental OPG Kennedy dataset. In addition to these quantitative results, the framework performs simultaneous pathology detection and arch classification in a single inference pipeline, reducing computational complexity compared with previously reported multi-stage approaches. Table II shows comparative analysis of YOLO-based dental detection studies and the proposed YOLOv11 multi-task model.

A sample of the output results from the proposed framework are shown in Fig. 7.

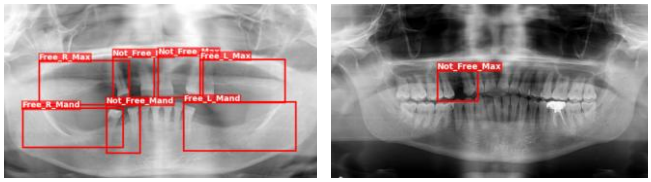

Fig. 7. Sample ot the output results.

VI. CLINICAL SIGNIFICANCE

The proposed multi-task YOLOv11-based framework has potential clinical value as a computer-aided decision support system for the analysis of panoramic dental radiographs. By simultaneously detecting multiple dental pathologies and identifying the corresponding maxillary and mandibular arch regions within a single inference pipeline, the framework can assist dentists in identifying abnormalities during routine clinical examinations, thereby supporting timely clinical decision-making and improving workflow efficiency. Automated localization of abnormalities may reduce the time required for radiographic interpretation, improve diagnostic consistency, and decrease the likelihood of overlooked findings, particularly in busy clinical environments. In addition, the framework may facilitate patient screening by automatically highlighting radiographs with suspected abnormalities, enabling clinicians to prioritize cases requiring further evaluation. The proposed framework may also serve as an educational aid for dental students and less experienced practitioners by highlighting clinically relevant regions of interest and reinforcing the interpretation of panoramic radiographs. Accordingly, the framework is intended to complement, rather than replace, professional clinical expertise, while final diagnosis and treatment planning remain the responsibility of qualified dental practitioners.

VII. CLINICAL INTERPRETATION OF PREDICTION ERRORS

In clinical practice, different prediction errors may have different consequences depending on the underlying dental condition. A false-negative prediction, in which an existing pathology is not detected, may delay diagnosis and treatment, potentially allowing disease progression. For example, missed root fractures or periodontally compromised teeth may result in continued structural damage, infection, or tooth loss if not identified during routine examination. Conversely, a false-positive prediction may lead to additional clinical examination or unnecessary radiographic review, increasing clinician workload but generally posing a lower clinical risk than missed pathology. Therefore, in screening applications, maintaining high sensitivity is particularly important to minimize overlooked abnormalities, while an appropriate balance between sensitivity

and precision is required to avoid excessive false alarms. The proposed framework is intended to assist clinicians by highlighting suspicious regions for further review rather than providing definitive diagnoses. Consequently, all AI-generated findings should be interpreted alongside clinical examination and professional judgment before treatment decisions are made.

VIII. Limitations

Even with its outstanding performance, there are still some drawbacks. The model experienced a reduction in accuracy when it comes to detecting small dental issues such as root fractures and periodontal problems because panoramic radiographs create low image contrast and overlapping anatomical structures. Furthermore, the proposed framework was evaluated exclusively on the extended Dental OPG Kennedy dataset. Validation on larger and more diverse datasets collected from multiple institutions and imaging systems is required to further assess its robustness, clinical applicability, and generalizability across different patient populations and acquisition conditions.

Although the proposed framework demonstrated strong detection performance (mAP@50–95 = 0.854 and F1-score = 0.961), the individual contribution of each design component—including the preprocessing pipeline, C2PSA attention mechanism, and multi-task learning strategy—was not evaluated independently through ablation experiments. Consequently, the performance improvements reported in this study should be interpreted as the result of the integrated framework rather than any single component.

The experimental evaluation was conducted using a single train-validation-test split and a fixed training configuration. Although this protocol provides a consistent and reproducible evaluation, it does not quantify the variability associated with different data partitions or training initializations. Consequently, confidence intervals, standard deviations, repeated experimental trials, and statistical significance analyses were not included in the present study. Future work will include repeated experiments using multiple random seeds, k-fold cross-validation, and external validation on independent multi-center datasets to further evaluate the robustness, reproducibility, statistical significance, and generalizability of the proposed framework.

IX. Conclusion and Future Work

This study introduced an automated multi-task deep learning framework based on the YOLOv11 architecture, designed for simultaneous detection of dental pathologies and arch-region classification in orthopantomograms (OPGs). To promote the system's efficiency while dealing with the extended Dental OPG Kennedy set comprising ten classes, the C2PSA attention modules coupled with the improved preprocessing techniques made the system produce outstanding results on all ten classes. The system reported an average mAP of 0.854, along with an F1-score of 0.961, exhibiting nearly flawless sensitivity while detecting well-demarcated edentulous areas. The upcoming work will focus on incorporating panoramic images from different centers into the database to boost the generality of the model instead of relying on domain specificity. Moreover, the application of the transformer modules, depending on self-supervised techniques, could advance the capture of higher-level semantics, especially in the identification of minor pathologies.

Inclusive Digital Health Platform for Well-Being and Loneliness in SOGIESC Older Adults

Yada Atanan, Titikarn Assatarakul*, Akara Metasuk
Faculty of Learning Sciences and Education, Thammasat University, Thailand

***Abstract*—This research and development (R&D) project aims to design, test, and enhance a digital platform for assessing and promoting the health of late middle-aged and older adults who are diverse in sexual orientations, gender identities, gender expressions, and sex characteristics (SOGIESC). It displays people's opinions regarding a personal health reporting system that would make diverse SOGIESC late middle-aged and older adults (aged 50 years and above) feel better and less alone. Mental health, bodily health, social health, and intellectual or spiritual health are the four pillars of the holistic health framework around which the initiative is built. "Loneliness" is a significant factor that impacts elderly people's quality of life. The platform's user-centered design creates a secure, friendly, and inclusive online environment for individuals of all gender identities. The study employs a mixed-methods approach, which means that it deliberately blends quantitative and qualitative research techniques. The platform's structure and features were improved during the development process with the use of quantitative data from health evaluations and system usage statistics. Simultaneously, qualitative data was gathered through user behavior observation, prototype usability testing, and detailed opinion recording in order to examine user experiences in terms of comprehension and usage, design and user experience, system performance, and perceived value and advantages. According to the research findings, the platform can help diverse SOGIESC late middle-aged and older adults feel more socially connected, encourage self-evaluation, and raise health awareness. However, system complexity, early usage difficulty, system stability, and the requirement to create data and result presentations appropriate for the learning context and technological proficiency of the elderly were also identified as limits. With an average score of 4.10 and a standard deviation of 0.88, the overall satisfaction and suggestions showed that customers gave their level of satisfaction a high rating. According to this study, the creation of a digital health platform for senior citizens with a range of sexual orientations should give priority to straightforward, fair, and reliable designs that may produce definite experiential value in order to encourage consistent and long-term use. By providing policy and practical guidance for creating digital tools that effectively fulfill the needs of vulnerable older people in modern society, this research adds to the body of knowledge in comprehensive health technology research and development.**

***Keywords*—Digital health platform; friendly space; well-being and loneliness; LGBTQ; older adults**

I. Introduction

The number of older adults with diverse sexual orientations, gender identities, gender expressions, and sex characteristics (SOGIESC) is anticipated to increase due to demographic shifts and increased opportunities to disclose their identities following the country's same-sex marriage law, which was passed on June 18, 2024, given that nearly 20% of Thailand's population is 60 years of age or older [1]. A study on the relationships, mental health, and sexual health of older persons who are sexually and gender diverse in Thailand was carried out by Thammasat University's Faculty of Learning Sciences and Education between October 2023 and March 2024. In-depth interviews were used to collect qualitative data for the study, and surveys were used to collect quantitative data. The study's primary conclusions are as follows: 1) One in three middle-aged and older adults (aged 50 and above) with diverse SOGIESC lives alone, and what they desire most is a supportive circle of friends. 2) Most older adults aged 60 years and above with diverse SOGIESC still need to work, with many relying on employment as their primary source of income. Approximately one in three reported earning an income below or close to the national poverty line. 3) Many middle-aged and older adults with diverse SOGIESC still lack access to social networks and specialized knowledge related to sexual and gender diversity [2].

Given the circumstances, it is crucial to create friendly spaces for middle-aged and older adults with diverse SOGIESC. To connect the efforts of individuals, groups, or organizations working with the elderly and sexual minorities, there is a notion to construct a system that would provide friendly spaces that are communities for middle-aged and older adults with diverse SOGIESC. This seeks to give Thai society's sexually and gender diverse older adults a supportive community, access to mental health services, and the opportunity to build the connections, knowledge, and abilities needed for overall well-being. For middle-aged and older adults with diverse SOGIESC, a digital health platform has been developed and will be linked to the GenDHL website. This approach allows users to evaluate their physical, mental, social, and intellectual/spiritual well-being via a questionnaire. Individual evaluation results, including descriptions, recommendations, and the degree of well-being, will be provided after the assessment is complete.

II. Related Works

A. Main Concept: Creating a Friendly and Easy-to Understand Experience for the Elderly

The Digital Health Platform for Well-being, an online platform that explores loneliness and well-being among older adults with diverse SOGIESC, was created with the goal of providing a welcoming online environment where older adults with diverse SOGIESC can access services for self-care and health evaluation, including mental, social, spiritual, and physical health. The system analyzes reports on every facet and provides explanations and recommendations for additional growth in different areas, empowering older adults with diverse

*Corresponding author

SOGIESC to take care of themselves, recognize their own value, and cultivate positive relationships with others. Additionally, it uses the established platform to establish an online network of older adults with diverse SOGIESC.

The fundamental design tenets of this system are “simplicity" and “intuitiveness" to guarantee that people are not perplexed or uneasy when using technology [3]. Rather than merely serving as an assessment tool, the system is intended to be like “a friend who listens and gives advice".

B. User Experience Design (UX)

This system's user experience design mainly follows the principles of user-centered design, which emphasize problem-solving from the viewpoint of the user [4]. The goal is to provide users, especially older people with a variety of gender identities—with a welcoming and simple experience. To lessen cognitive load and avoid misunderstanding, Progressive Disclosure is used to convey information and functionality step-by-step in a methodical manner. For example, survey questions are displayed one at a time. Additionally, to prevent users from becoming lost during the usage process, responsive guidance provides clear, succinct explanations at each stage. Design takes into account the following important factors:

1) User-Centered Design (UCD): The User-Centered Design (UCD) approach, which stresses methodically comprehending the wants, experiences, and limits of the target group from the very beginning of development, is followed in the design of this platform [5]. The design method involves testing prototypes to determine usability and convenience as well as gathering qualitative data through in-depth interviews to investigate the expectations, worries, and technology usage experiences of older people with a range of sexual orientations. Testing is also used to compare performance in terms of comprehension and task completion time for certain UI components, like the arrangement of “Next" or “Back" buttons, the location of instructions, and the format of score displays. By analyzing data from these procedures, usability barriers are decreased, and the user interface is improved to better reflect the target group's real habits.

2) Progressive disclosure: The platform's architecture was based on the Progressive Disclosure principle, a user experience concept that attempts to reduce cognitive load by giving information or services in segments rather than all at once. On the evaluation site, for example, users will see one question at a time with clear control options like “Next" and "Back," instead of all the questions on one page. This approach reduces confusion, enhances focus while responding to inquiries, and allows for gradual progress, particularly for elderly people who may not be as tech-savvy. Additionally, because of its architecture, the system can provide additional explanations at specific periods without packing the screen.

3) Responsive guidance: Contextual advice has been incorporated into each screen of the system to aid in user decision-making and lessen usage uncertainty. For instance, showing brief instructions like “Press the 'Next' button to continue" or “Choose the answer that best fits you". These suggestions are meant to be unobtrusive and only show up when required. In addition to increasing the assessment's completion rate and lowering the risk of drop-off rates, this design gives people with little experience with technology confidence.

4) Receiving feedback and creating a positive atmosphere: To promote a positive attitude among the target demographic utilizing the system, a message offering recommendations and practical suggestions will be shown once the user has finished the assessment. The system will provide the results of the evaluation together with motivational statements and practical recommendations relevant to the assessment level. In order to keep users from feeling stigmatized or evaluated by the outcomes, this section is structured according to the positive reinforcement principle. The suggestion messages are written in straightforward, courteous language that demonstrates an awareness of the situation of senior citizens with a range of sexual orientations. This strategy is essential for encouraging recurring use and sustained platform acceptance.

5) Design for accessibility: Using the WCAG (Web Content Accessibility Guidelines) as a reference, the design will take into account senior citizens with visual problems. This involves assuring screen reader compatibility, utilizing alt language for images, and allowing touch-only system use [6]. To accommodate people with visual impairments, it's also critical to choose colors with the right contrast ratios. The platform design takes into account the accessibility concerns of senior folks who may have visual difficulties. Elements and buttons are made to be controlled by the keyboard or touch. These rules lessen physical obstacles to use and improve equity in system access.

6) Data structure design: Developing the data structure and organizing the thorough gathering and processing of information about loneliness and other facets of well-being to produce full and precise reports. A relational database structure is designed to allow the storing of user profile data, assessment response data, and the methodical computation of the loneliness index. The design of the data structure is an essential part of the system. This layout is intended to facilitate upcoming analytical processing and minimize redundant data (data normalization). To improve the accuracy of the results, data validation procedures are devised prior to the calculation process. To produce thorough, accurate results that can suitably support health-related decision-making, the generated reports rely on processed data.

C. User Interface (UI)

The goal of user interface (UI) design is to improve the pleasant experience that comes from UX design by making it visually appealing and easy to use. In order to create a cozy and user-friendly space, a tranquil and safe color scheme is used by using hues like white that express relaxation and safety. Bright hues that could be uncomfortable for consumers are also avoided [7]. In order to guarantee reading, clear, appropriately large fonts are also used with great consideration.

Other components that are important for effective design include four main aspects that affect the usability of the interface

design: functional framework, interaction logic, visual design, and user experience. These elements impact user interaction [8]. Such buttons and interactive features are made to be large and have colors that contrast sharply with the background to make them easier for older people with limited vision and motor skills to utilize. Additionally, intuitive icons that convey universal and obvious meanings are employed to help users use the system quickly and accurately [9]. Additionally, report visualization is offered in simple graphic styles, such as spider charts, along with succinct explanations and useful suggestions that assist consumers in understanding the data and using it to effectively improve their health [10].

D. Older Adults' Perceptions of Loneliness and Health (Well-Being and Reduced Loneliness)

Elderly people who suffer loneliness, anxiety, and a lack of social engagement are more likely to feel depressed and bored, which lowers their sense of self-worth and leads to social exclusion [11]. When people believe their social connections are inadequate in terms of both quantity and quality, they experience this complex emotional and psychological condition. This differs from social isolation, which refers to a lack of quantitative interactions. Therefore, rather than being a result of the quantity of people present, loneliness is an internal sensation connected to the perception and expectations of connections.

Retirement, the death of a spouse or close friend, chronic disease, and mobility issues are all factors that lead to a decline in social networks as people age. Several studies show that loneliness is linked to a higher risk of anxiety and depression as well as a reduction in general quality of life [12], [13]. Loneliness has also been connected to an increased risk of long-term conditions like heart disease, high blood pressure, and cognitive loss [14]. According to the World Health Organization's definition of well-being, which includes social, mental, and physical aspects [15], loneliness is seen as a factor that compromises health in all of these areas, especially in the mental dimension, which is linked to hopelessness, low self-esteem, and feelings of worthlessness. According to Hawkley and Cacioppo [14], loneliness can set off the body's chronic stress processes, which can have an impact on long-term health and the immune system. Therefore, developing meaningful relationships, establishing a sense of belonging, and encouraging important roles in the community should be the main goals of avoiding loneliness among the elderly. This is in line with the Active Aging concept of the World Health Organization, which prioritizes security, involvement, and health in old age [16]. These steps will improve general well-being and lessen the detrimental effects of loneliness on people as well as society.

E. Comparison with Existing Digital Health Platforms

As summarized in Table I, existing studies have predominantly addressed isolated dimensions of digital health for older adults, including human-centered design principles, interface usability, accessibility, health information visualization, and loneliness monitoring. Although these studies provide valuable design insights for age-friendly digital systems, the majority remain confined to conceptual frameworks or systematic reviews, without the implementation and empirical validation of a comprehensive digital health platform. Furthermore, prior research has largely concentrated on the general older adult population, while limited attention has been given to sexual and gender diverse older adults. In addition, existing systems rarely integrate multidimensional well-being assessment, loneliness evaluation, personalized health reporting, and inclusive interface design within a single platform. To address these gaps, the present study extends previous work by developing and evaluating a functional digital health platform specifically designed for SOGIESC older adults, employing a user-centered design approach, accessibility principles, and a mixed-method evaluation. This research gap underscores the originality and practical contribution of the present study to the emerging field of inclusive digital health.

TABLE I. COMPARISON OF RECENT STUDIES RELATED TO INCLUSIVE DIGITAL HEALTH PLATFORMS FOR OLDER ADULTS.

Research Study	Key Contribution and Research Gap	Advancement of the Present Study
Research Paper [17]	Systematic review of HCD processes for mHealth applications using the ISO 9241-210 framework. No operational platform was implemented or evaluated.	Implements HCD in an operational platform integrating well-being, loneliness assessment, and inclusive design for SOGIESC older adults.
Research Paper [18]	Systematic umbrella review of technology interventions for loneliness and social connectedness. Evidence remained limited despite promising ICT-based interventions.	Extends previous technology interventions through an operational platform integrating loneliness assessment, multidimensional well-being assessment, and personalized reporting.
Research Paper [10]	Systematic review of PROM visualization, focusing on interpretation and presentation formats. No operational platform was developed.	Integrates PROM visualization with multidimensional assessment, personalized interpretation, and health recommendations.
Research Paper [8]	Systematic review of telemedicine interface usability and design recommendations for older adults. No operational platform was implemented.	Applies age-friendly usability principles within an operational digital health platform validated through mixed-method evaluation.
Research Paper [9]	Systematic review of age-friendly mobile app design, accessibility, and user-centered design strategies. No operational platform was evaluated.	Translates age-friendly design principles into an inclusive platform with multidimensional assessment and personalized reporting.
Research Paper [19]	Developed a user-centered interface design framework for loneliness monitoring. Focused on design indicators without platform implementation.	Extends the framework into an operational platform integrating loneliness, well-being assessment, and mixed-method evaluation.
Present Study	Develops an inclusive digital health platform integrating validated assessment instruments, user-centered design, multidimensional well-being assessment, and personalized reporting. Preliminary mixed-method evaluation involved 10 participants.	Provides an operational platform for SOGIESC older adults integrating inclusive design, validated assessment, and mixed-method evaluation.

Existing literature provides substantial evidence that user-centered design has become the prevailing framework guiding the development of digital health technologies for older adults. A considerable number of studies have identified age-friendly interface design, accessibility, usability testing, and sustained user participation as key determinants of successful technology adoption within aging populations [8], [9], [19]. Collectively, these contributions have deepened the theoretical and practical understanding of human-computer interaction in digital health, while simultaneously establishing core design principles that enhance system accessibility and usability. In addition, recent systematic reviews have emphasized the increasing significance of embedding digital health technologies into community-based healthcare frameworks as a strategy for promoting healthy aging and sustaining independent living among older adults.

Notwithstanding these advances, several critical limitations persist within the existing body of research. Most current platforms tend to emphasize a single dimension such as usability enhancement, interface optimization, or disease-specific monitoring rather than incorporating a multidimensional well-being assessment within a unified digital environment. Loneliness, in particular, is commonly examined as a standalone psychological construct rather than being evaluated in conjunction with broader physical, mental, social, and spiritual well-being dimensions. Furthermore, although health disparities among sexual and gender diverse older adults have gained increasing recognition, only a limited number of digital health studies have explicitly addressed their distinct psychosocial characteristics, healthcare experiences, and identity-related needs. As a result, empirical evidence supporting the development of inclusive digital health platforms tailored to SOGIESC older adults remains scarce.

III. Methodology and System Architecture

This study employed a research and development (R&D) methodology integrated with a mixed-methods design to guide the architectural design, implementation, and evaluation of an inclusive digital health platform for well-being and loneliness assessment among sexual and gender diverse older adults. The platform was developed following a user-centered design framework to ensure accessibility, inclusivity, and usability while addressing the psychosocial well-being needs of the target population. Quantitative and qualitative data were collected concurrently, analyzed separately, and integrated during interpretation to provide a comprehensive assessment of system performance, usability, and user experience.

Participants consisted of ten Sexual and Gender Diverse older adults in Thailand (n = 10) recruited through purposive sampling. A purposive sampling strategy involving ten participants was adopted, given that the study centered on formative usability evaluation within a narrowly defined and inherently difficult-to-reach population, namely Thai SOGIESC adults aged 50 years and above. This sample size was deemed sufficient for identifying salient usability issues and eliciting in-depth qualitative insights during the early stage of system development. However, it should be noted that the sample was not statistically powered to estimate population parameters.

Quantitative data were gathered using usability and satisfaction assessments, whereas qualitative data were collected through observation, think-aloud usability testing, and semi-structured interviews. The research process encompassed user needs assessment, system architecture design, platform development, implementation, and evaluation. Findings from both data strands were integrated throughout the development cycle to support iterative system refinement and methodological triangulation. The resulting evidence informed improvements in system functionality, accessibility, and user experience.

Quantitative and qualitative findings were integrated at the interpretation stage to enhance the credibility of the evaluation and to provide complementary evidence regarding the usability, user experience, and perceived usefulness of the proposed platform.

The methodological procedures adopted in this study are presented in the following sections.

A. Development of the Digital Health Platform on the GenDHL Website

Users of mobile devices or internet-connected PCs can access the individual health assessment reporting system, which is designed to facilitate usage through the GenDHL website. SOGIESC adults aged 50 years and above are the main target demographic. The system gathers user data, processes it, and centrally stores it (see Fig. 1). With “loneliness" as the primary focus of the analysis, encompassing both emotional and social loneliness, this comprises health assessments in four primary dimensions: physical health, mental health, social health, and spiritual health. In order to systematically synthesize results and produce individual health assessment reports that include a health overview, assessment results, and pertinent suggestions, all data is processed in a computational storage system. In terms of policy and practice, the system can be used to successfully plan, promote, and enhance the target group's quality of life. It also strives to support a thorough understanding of users' health.

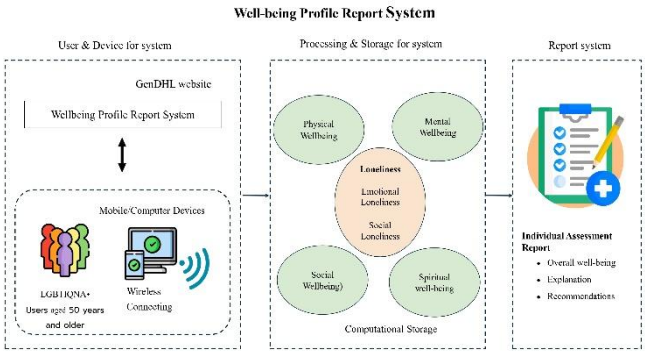

Fig. 1. Framework for developing the Digital Health Platform on the GenDHL website.

B. System Development Process

The PDCA principle, also known as the “Deming Cycle”, was used to identify the system development process for the online platform system, Digital Health Platform for Well-being, which is a management method for consistently enhancing productivity. It can be used at any point in the system development process to guarantee that the final product is excellent and genuinely satisfies the requirements. There are four primary steps: 1) Making a plan, 2) Acting (Act), 3)

Verifying and Assessing (Verify), and 4) Improving and Acting (Act) [20], which includes the following information.

1) *Step 1: Planning (Plan):* The planning process includes the following details:

- Needs analysis: To comprehend the actual difficulties and requirements of the target user group, which is made up of senior citizens with a variety of sexual orientations, examine their needs and context.
- Describe the primary idea: Create the system with the idea of "an online-friendly space" in mind, emphasizing convenience, security, and an emphasis on comprehensive healthcare. This covers the key ideas: making an approachable and simple-to-understand experience for senior citizens, user experience (UX) design concepts, user interface (UI) design concepts, and concepts pertaining to senior citizens' loneliness and well-being.

2) Step 2: Implementation (Do): The first step's development plan was implemented during the implementation phase (Do), with an emphasis on developing a comprehensive system that achieves the predetermined goals. A holistic health survey form comprising four domains physical, mental, social, and spiritual health was developed as part of the development of core functions. These were created utilizing a thorough and simple inquiry format. A processing system and report generation were built in tandem with the creation of key functions; comprehensive data processing was used to produce concrete reports, and coding was used to generate scores in every aspect of health. Score summaries, general findings, and useful suggestions for successful self-improvement were all included in these reports. Additionally, the front-end was created with an emphasis on usability and aesthetics in accordance with UX/UI design, enabling customers to view previous reports and clearly identify changes in their health. In conclusion, the following planned phases were followed in the development of the platform.

- Develop the primary function: Construct a system for health surveys that addresses all four aspects.
- Create the system for processing and reporting: Write code to process each area's results and produce a comprehensive report with clear justifications and suggestions.
- Create the front-end by designing the displays in accordance with the intended UX/UI so that users may observe changes in their health status and view previous reports.

In order to produce comprehensive and accurate reports, the first stage of system design will involve designing the data structure and planning for the gathering and processing of data pertaining to loneliness and other aspects of well-being. The GenDHL website's online platform technology is depicted in an example image.

The workflow of the Digital Health Platform for Well-Being will be depicted in the graphic, beginning with the login procedure and segmenting users into administrators (Admin) and senior citizens. Target users complete a four-dimensional health evaluation that covers mental, physical, social, intellectual, and spiritual dimensions in addition to personal information and activities. Before entering the data into the database and processing it to produce personal health reports, the system verifies that the data is accurate. In the meantime, the administrator is in charge of overseeing and validating the data to efficiently support activity development and long-term health monitoring. Fig. 2 presents the data structure diagram.

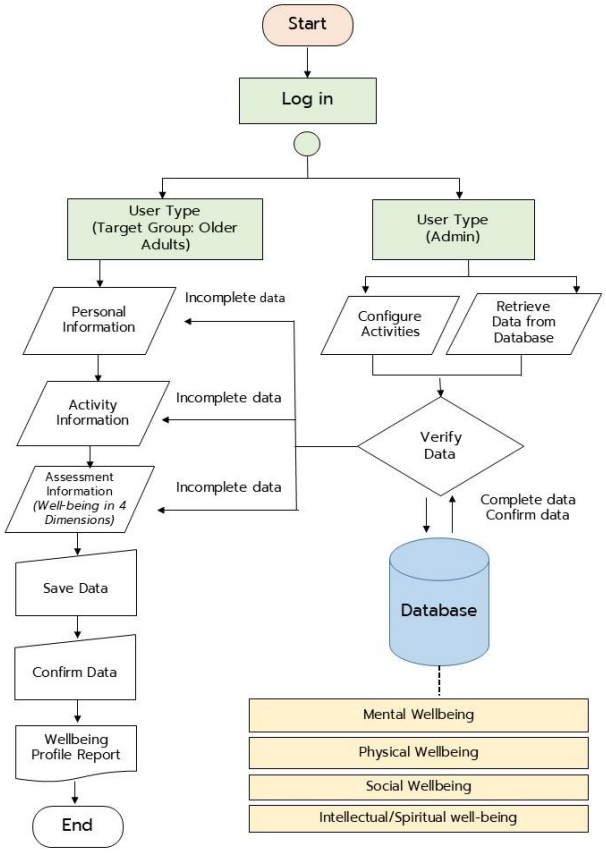

Fig. 2. Data structure diagram for the online platform system on the GenDHL website.

The emphasis will be on user-centered design in the design of the user interface and user experience (User Interface & User Experience), taking into consideration the limitations of the elderly through the use of clear iconography, eye-friendly colors, and appropriate text sizes. This is to guarantee that using a smartphone is as convenient and natural as possible, taking into account the following important factors:

- Emphasis on user-centered design: Begin by thoroughly comprehending the requirements and habits of the intended audience. This can be achieved by conducting in-depth interviews to obtain input on user experience or by comparing button placements to determine which layout works best for the target population.

- Progressive disclosure: The technology will show functions and information gradually rather than all at once. For instance, in order to minimize confusion and facilitate data submission, users will only view one question at a time rather than all ten on the assessment page.
- Responsive guidance system: To keep users from getting lost, each screen will have brief instructions that inform them what to do next, like “Select the answer that best matches you" or “Press the 'Back' button to go to the previous page".
- Getting feedback and fostering a good attitude once the user finishes the evaluation. Messages offering helpful guidance and recommendations will be shown to boost the system's target users' positive emotions.

The idea of modular deconstruction has been used in the system architecture and modular design of the inclusive digital health platform to improve future system scalability, maintenance flexibility, and development clarity. Five primary modules comprise the framework of the system: 1) Authentication Module; 2) User Profile Management Module; 3) Assessment Engine Module; 4) Report Generation Module; and 5) Admin Control Module. Workflow-driven integration connects each module, each of which has a distinct function.

- *The module for access control and authentication:* In order to clearly distinguish the use rights between “ordinary users" and “administrators (Admin)", the Authentication Module manages the process of safely accessing the system, including login, logout, and role-based access control. This module facilitates the governance of sensitive health data in compliance with user privacy and personal data protection rules and helps lower the risk of improper data access.
- Module for managing user profiles: In order to provide a health assessment context and enable user identity modification through the development of avatars, the user profile management module is in charge of gathering and documenting personal data. In an all-encompassing digital environment, this is an essential component for guaranteeing a sense of security and ownership. The module facilitates the creation, updating, and retrieval of profile data, which lessens the strain of repetitive data entry, improves the continuity of the user experience, and permits the reuse of basic data in later evaluations.
- Module for the assessment engine: The foundation of the platform's business logic is the assessment processing module. It operates by obtaining input data from loneliness-related and health assessments, validating the input, processing scores in accordance with predetermined criteria, and computing key indicators like the loneliness index to summarize the risk or condition level based on the assessment results. In order to improve calculation accuracy and make it easier to develop or modify calculation criteria in the future without impacting the user interface, this module is made to be independent of the presentation layer.
- Module for report generation: The purpose of the Report Module is to transform the Assessment Engine's evaluation results into a user-friendly manner. In order to facilitate meaningful self-review and health awareness, this involves producing summary reports that synthesize the evaluation data into interpretive summaries and visualizations like graphs or summary diagrams. Furthermore, in situations where the system records repeated evaluation findings that represent trends in health changes, the report module can be made to provide longitudinal comparisons.
- Module for admin control: Access to statistical data (monitoring and analytics), general usage monitoring, and the management of platform-related actions or content (activity and content management) are all supported by the admin control module. This module is essential for preserving data quality, ensuring service continuity, and overseeing community components or initiatives related to advancing the target group's well-being. To guarantee the security and suitability of data management, the Authentication Module controls the access privileges of administrators.

Fig. 3. Show a preview of the login page.

Fig. 4. Display the main menu of the system.

Fig. 5. Show your avatar through personal identity.

Fig. 6. Show the results of the health comparison.

Additionally, the design places a strong emphasis on fostering a positive environment by showcasing uplifting messages and practical guidance following the exam, encouraging a positive outlook on one's own health. The design adheres to the web content accessibility guidelines requirements for complete accessibility for users [21]. Lastly, the information architecture has been carefully designed to guarantee the accurate and thorough processing, storage, and display of reports on loneliness and other elements of well-being (see Fig. 3 to Fig. 6).

3) Step 3: Check and Evaluation: The proposed platform was assessed through a pilot implementation that emphasized usability, user experience, and system feasibility, rather than predictive model validation. Given that the assessment engine relies on deterministic scoring rules derived from validated assessment instruments, benchmark datasets typically employed in machine learning evaluation were deemed inapplicable in this context. Accordingly, the evaluation prioritized user satisfaction, usability, and the practical applicability of the platform within the target population.

Before being implemented in the real-world, the designed system will be thoroughly tested with real user groups during the Check phase to assess its accuracy and performance. Usability testing, which focuses on gathering behavioral data from the target population of older users to evaluate the system's usability, specifically in terms of navigation comprehension and the clarity of the instructions displayed on the screen, will comprise the three main components of the operations.

Arrange for the report's results to be verified in order to make sure that the suggestions and score processing are both academically correct and helpful to real users.

Plan to interview customers in-depth to learn about their overall experience, how they feel about using the system, and any further needs they may have. The data gathered from this verification procedure is essential for enhancing and expanding the system in the next stages. In conclusion, the system was tested with a sample of real users after development was finished, as described below:

- To determine whether the system is genuinely user-friendly and to pinpoint areas that require development, such as navigation comprehension and instruction clarity, usability testing gathers data from the target group of senior users.
- Report accuracy verification: Verify that the information provided is valid and helpful by checking the accuracy of the score processing and the suggestions in the report.
- Gathering feedback: Conduct user interviews to learn about their thoughts on the system as a whole, their experiences, and any further requirements.

4) Step 4: Improvement and Implementation (Act): In order to improve and enhance the system's quality, the assessment results and input gathered from the Check phase were examined in the Act phase, the last stage of system development. One of the primary responsibilities was to improve the UX/UI, which included making improvements to displays and usage procedures when users were reported to be confused or not comprehending. This was carried out to guarantee a more seamless and user-friendly navigation method. The report's recommendations and material were also broadened to offer greater diversity, thoroughness, and usefulness.

Simultaneously, the next phase's development goals have been outlined, providing guidance for potential additions of additional features like the creation of a notification system, online community activities, or user-expert connections. This PDCA cycle's implementation guarantees that the system will be continuously improved to sustainably satisfy user needs rather than staying stagnant.

- The data from step 3's inspection has been examined to further enhance the system, as explained below: Enhance UX/UI: Update screens and usage instructions that older consumers still find unclear or difficult to comprehend.
- Expand information and recommendations: To make the report more thorough and beneficial, add a wider range of recommendations.
- Make a plan for future development: Describe how you intend to add new features in the future, including expert connections, online community activities, or notification systems.

C. Well-being and Loneliness Assessment Instrument

The proposed platform integrates five validated assessment instruments to evaluate multidimensional well-being and loneliness among SOGIESC older adults. Loneliness was assessed using the 6-item De Jong Gierveld Loneliness Scale, which measures emotional and social loneliness [22]. Mental well-being was evaluated using the Thai Geriatric Mental Health Assessment Tool–Short Form (T-GMHA-15), a culturally validated instrument for Thai older adults that assesses mood, anxiety, self-esteem, and cognitive-emotional stability [23]. Functional ability was assessed using items adapted from the Functional Activities Questionnaire (FAQ), which measures independence in instrumental activities of daily living [24]. Social well-being was measured using a 15-item instrument based on Keyes' Social Well-Being framework, covering social actualization, social acceptance, social coherence, social contribution, and social integration [25]. Spiritual well-being was assessed using the Functional Assessment of Chronic Illness Therapy Spiritual Well-Being Scale (FACIT-Sp-12), which evaluates the domains of meaning, peace, and faith [26].

D. Assessment and Report-Generation Workflow

The proposed platform utilizes a deterministic, rule-based assessment engine to process user responses, rather than a trainable machine-learning model. As depicted in Fig. 7, the workflow commences with user authentication, followed by the completion of multidimensional assessment instruments. Subsequently, the system verifies response completeness and value validity prior to applying instrument-specific scoring rules, including reverse scoring where applicable. Domain scores encompassing loneliness, mental well-being, functional ability, social well-being, and spiritual well-being are then computed in accordance with the validated scoring procedures established for each respective instrument.

The resulting scores are subsequently mapped onto predefined interpretation criteria to generate personalized health reports, graphical summaries, and formative recommendations. User responses and assessment outcomes are securely stored within the database to facilitate future retrieval and longitudinal monitoring. As the assessment engine operates entirely on rule-based logic, no model training, hyperparameter tuning, or optimization procedures are necessary. Instead, the operational parameters comprise predefined scoring rules, permissible response ranges, reverse-scoring procedures, and interpretation criteria derived from their corresponding validated assessment instruments (see Fig. 7).

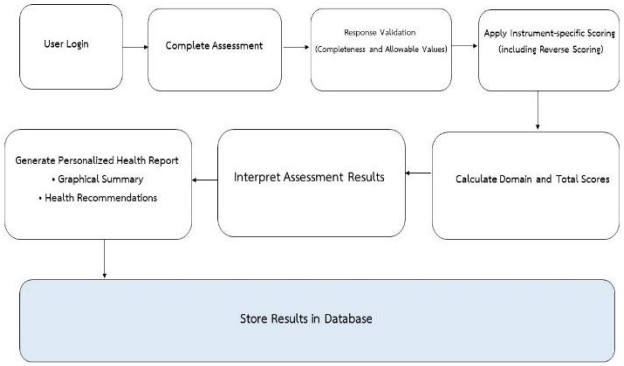

Fig. 7. Workflow of the rule-based assessment and report-generation process implemented in the proposed digital health platform.

E. Data Collection

Data collection was conducted using a mixed-methods approach comprising usability testing, participant observation, a structured satisfaction questionnaire, and semi-structured interviews. During the usability testing sessions, participants performed a set of predefined tasks on the GenDHL platform while researchers observed their interactions and documented emerging usability issues. Following task completion, participants completed a satisfaction questionnaire and subsequently engaged in semi-structured interviews to elicit in-depth feedback regarding their user experience, perceived usefulness, and recommendations for system enhancement.

F. Data Analysis

The evaluation aimed to conduct a formative usability assessment of the proposed platform rather than a confirmatory effectiveness study. Accordingly, the analysis emphasized descriptive statistics and qualitative interpretation to identify usability issues, explore user experiences, and generate recommendations for iterative system refinement.

Given that this study was designed as a preliminary pilot evaluation involving a small purposive sample, quantitative data were analyzed descriptively using frequencies, percentages, means, and standard deviations, supplemented where appropriate by medians and ranges. No inferential statistical tests were performed, as the study was not intended to support population-level statistical generalization. Rather, the quantitative findings were designed to provide preliminary descriptive evidence of participants' perceptions. Qualitative data derived from participant observations and semi-structured interviews were analyzed thematically and employed to explain, contextualize, and enrich the interpretation of the quantitative satisfaction ratings.

Qualitative data obtained from participant observations and semi-structured interviews were examined through thematic analysis. The resulting themes served to explain, contextualize, and enrich the interpretation of the quantitative findings, thereby facilitating a comprehensive understanding of participants' usability experiences and their perceived value of the proposed platform. The thematic analysis adhered to the procedural stages of familiarization, initial coding, theme development, theme review, and theme refinement in order to identify recurrent usability issues and user experience patterns [27].

IV. Results and Discussion

The following specific conclusions about the system testing results were found after examining usage observations and conducting user interviews to get input on the system as a whole, user sentiments, and further requirements:

A. Usability and Learnability

Although the majority of users, particularly the elderly, were initially unfamiliar with the system, they were able to comprehend the platform's goals. The process of registering, logging in, and inputting personal data was perceived as needing constant supervision or teaching from others throughout the system's trial use. Many users noted that the system might constitute a barrier to long-term self-use in the absence of support or an understandable manual, particularly for older people living alone. Here are some thorough remarks:

"Overall, the system is not difficult to use. You can learn and understand it quite quickly on your own. Although at first you might need to try clicking around and exploring the various menus, after using it for a while, you will start to get familiar with it and be able to use it more smoothly."

(Participant A, November 13, 2025)

"Overall, I feel that the system is quite user-friendly. The text and various elements are easy to read, making it possible to see the information clearly and helping to understand how to use it without confusion."

(Participant C, November 13, 2025)

B. Interface and Experience Design

Users' perceptions vary; some think the website is well-organized and simple to read. However, a prevalent problem is that icons and pictures often fail to adequately represent sexual variety, making it more difficult for users to comprehend and learn how to utilize the system. Here are a few specific instances of the comments:

"The main functions of the system are quite clear, making it easy to know where to start using it. Each menu is arranged in order, so it doesn't make you feel confused or lost while using it."

(Participant B, November 13, 2025)

"The presence of avatars in the system enhances interest and a sense of friendliness, making the overall atmosphere more enjoyable and helping to reduce tension during use."

(Participant D, November 13, 2025)

"The icons used in the system are quite clear in their meanings, allowing users to understand the functions of each part without much guessing, making it more convenient and seamless to use."

(Participant E, November 13, 2025)

C. Functionality and Performance

The system can function in accordance with fundamental goals, like report generation and health assessments. Nevertheless, there are still problems with system speed and stability, like sluggish data loading and system freezes at specific stages. A step-by-step usage guide, voice command functionality, audio explanations for inquiries, and the elimination of unnecessary steps in data entry are just a few of the enhancements that users have proposed to help the elderly. The target group would find it easier to use and more convenient as a result. Here are some thorough remarks:

"Overall, I feel that the system is not difficult to use. The various steps are quite understandable on their own. Even though it was my first time trying it out, I was able to learn gradually. After using it for a while, I started to get familiar with the menus and the system's operation, allowing me to continue using it without much hassle."

(Participant A, November 13, 2025)

"I feel that the system isn't complicated at all. The usage is quite straightforward, making it easy to understand, even without prior experience with such systems. Once you try clicking through the menus one by one, you can figure out how to use it on your own."

(Participant C, November 13, 2025)

"I feel that the system isn't very complicated. At first, it might take some time to understand, but after using it for a while, I think I'll start to get familiar with it and be able to use it more smoothly. The steps aren't very difficult and can be learned on my own."

(Participant D, November 13, 2025)

D. Usefulness and Value

In terms of encouraging introspection, raising awareness of health issues, and reflecting on loneliness and quality of life, the majority of users found the system beneficial. In order to make the evaluation results useful in everyday life, users have recommended that the results be presented more simply, with more visuals or symbols and a focus on concise explanations. Here are some thorough remarks:

"I feel that the system helps me reflect on my thoughts and feelings more, allowing me to revisit certain aspects of myself that I usually don't have the opportunity or importance to consider."

(Participant A, November 13, 2025)

"When I saw the results from the system, it made me more aware and accepting of my own feelings. I felt that I might actually be lonely, which is something I had never really noticed or thought about seriously before."

(Participant F, November 13, 2025)

"It only takes a few minutes to receive information or results related to oneself, making it feel convenient and quick, and helping to understand oneself better in a short period."

(Participant G, November 13, 2025)

E. Overall Satisfaction and Suggestions

Overall, the data shows that the degree of system comprehension and platform stability are closely correlated with user happiness. The platform has a great chance of becoming a well-known and regularly utilized digital health tool across the

diverse senior population if user experience and technical performance continue to improve. Here are some thorough remarks:

"If the system continues to develop and improve in this manner, I think there will be interest and a desire to use it again in the future."

(Participant B, November 13, 2025)

"Using the system creates a feeling as if there is something that understands one's own feelings, resulting in a greater reflection and awareness of one's own emotions."

(Participant C, November 13, 2025)

In conclusion, the study's qualitative behavioral data show that digital systems are more than just technical tools; they also contribute to self-awareness, emotional introspection, and the evaluation of users' mental health. The framework of digital mental health and well-being, which prioritizes a user-centered experience, is consistent with this.

According to the satisfaction survey results, the overall satisfaction score reported by this pilot cohort yielded a descriptive mean of 4.10 (SD = 0.88). Such values provide an initial overview of participants' perceptions of the platform; nevertheless, they should not be construed as population-level estimates or as evidence of the platform's effectiveness. All things considered, the system's merits were emphasized in terms of precisely identifying target groups and initiatives to establish a secure environment for senior citizens of various sexual orientations. At the same time, it was unanimously agreed that future system development should concentrate on making it simple to use right away, speeding up system output, modifying the design to make it suitable for the elderly, and providing clear value and incentives to encourage users to keep using it and to maximize benefits in terms of policy development and quality of life. The evaluation's findings will serve as a reference for future system efficiency improvements (see Fig. 8).

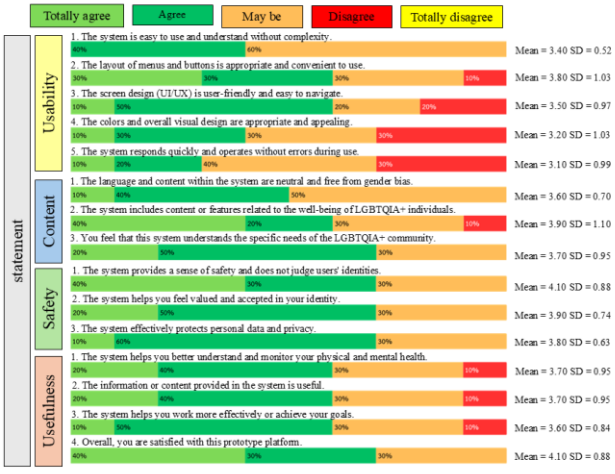

Fig. 8. A summary of the satisfaction survey findings for the Digital Health Platform system from a sample of ten participants.

System usage behavior can be explained within the frameworks of digital health and mental well-being, according to an overview of the study of quantitative data about opinions on the system and qualitative data from research participant interviews. These concepts highlight how technology can be used in daily life to promote self-awareness, emotional introspection, and mental health services [28]. Some respondents mentioned that utilizing the system makes people more conscious of their emotional states and feelings. System users engage with the system in a way that is similar to self-reflection. This conduct is consistent with the idea of self-awareness, which is an essential part of mental health and a basic process that makes preventive mental health care possible. When it comes to using technology for mental health (digital mental health), informants assess the system based on their real-world usage experiences and the emotions they experience while using it. It also illustrates the system's function as an emotionally secure environment where users can evaluate themselves and consider their emotions without being directly pressured by others. This trait is consistent with the idea of "digital well-being", which holds that user-considered technology can promote mental health without creating stress or emotions of condemnation [29].

V. Conclusion

This study successfully developed and preliminarily evaluated an inclusive digital health platform embedded within the GenDHL website, designed to support well-being and loneliness assessment among late middle-aged and older adults with diverse sexual orientations, gender identities, gender expressions, and sex characteristics (SOGIESC). The evaluation findings indicated that participants generally perceived the platform as comprehensible, user-friendly, and beneficial in promoting self-awareness, emotional well-being, and health literacy. Through its intuitive digital environment, the platform enables users to assess their physical, mental, social, and spiritual well-being while receiving personalized health reports and practical recommendations. Throughout the system development process, particular emphasis was placed on the application of user-centered design principles to ensure simplicity, intuitive interaction, and ease of use for older adults. This design approach aligns with the user-centered interface framework proposed by Zhou et al. [19], which emphasizes the necessity of minimizing interaction barriers and enhancing usability in digital health systems designed for older adults. Building upon these user-centered principles, the present study further incorporates inclusive design considerations and multidimensional health assessment to address the specific psychosocial and healthcare needs of SOGIESC older adults.

The positive usability outcomes observed in this study, together with participants' qualitative reflections, can be attributed to the integration of user-centered design principles, accessibility oriented interface design, progressive disclosure, and personalized health feedback embedded throughout the platform. Prior studies have shown that simplified navigation, age-friendly interface components, and accessible interaction substantially enhance usability among older adults [8], [9], while Zhou et al. [19] emphasized that user-centered interface design constitutes an essential foundation for reducing interaction barriers and fostering user engagement in digital health systems. In contrast to previous studies, which primarily concentrated on interface usability, age-friendly design guidelines, or conceptual design frameworks, the proposed

platform integrates multidimensional well-being assessment, loneliness evaluation, personalized feedback, and inclusive identity representation within a single operational environment specifically tailored for SOGIESC older adults. This comprehensive integration may account for the favorable usability, positive emotional responses, and enhanced self-reflection reported by participants during the pilot implementation, thereby suggesting that combining technical usability with psychosocial support can strengthen user engagement and perceived value.

These findings further indicate that one should not assess the effectiveness of inclusive digital health platforms solely in terms of technical usability or system performance. Rather, psychosocial dimensions including identity recognition, emotional support, perceived inclusiveness, opportunities for self-reflection, and social connectedness appear to be an equally important part in determining users' acceptance and sustained engagement. This finding emphasizes the necessity of designing digital health systems that simultaneously address technological accessibility, psychological well-being, and social inclusion. Such an integrated perspective extends current digital health research by illustrating that inclusive platform design should move beyond conventional health monitoring toward fostering holistic well-being among underserved populations, particularly sexual and gender-diverse older adults.

This study advances the nascent field of inclusive digital health by providing empirical evidence that user-centered design, inclusive design principles, and multidimensional health assessment can be effectively amalgamated within a single digital platform. Compared with existing state-of-the-art digital health platforms reported by Nimmanterdwong et al. [17], Amouzadeh et al. [9], and Zhou et al. [19], the proposed system extends prior approaches by incorporating multidimensional well-being assessment, loneliness evaluation, personalized health reporting, and inclusive interface design within a single operational platform. Whereas previous studies have predominantly emphasized user-centered design, accessibility, technology acceptance, or isolated health dimensions among older adults, relatively few have concurrently addressed comprehensive health assessment alongside the distinct psychosocial and healthcare needs of sexual and gender-diverse older adults. Accordingly, the proposed platform advances current digital health research by combining validated assessment instruments with an operational, user-centered, and inclusive digital health service specifically designed for SOGIESC older adults. Unlike previous studies that mainly suggested conceptual frameworks, usability guidelines, or standalone assessment tools, this research illustrates the practical viability of deploying and assessing an operational digital health platform via a mixed-methods approach. Therefore, the proposed platform contributes not only a practical technological solution but also an evidence-based framework capable of guiding future digital health service development for marginalized aging populations. These findings may further assist healthcare professionals, community organizations, and policymakers in promoting healthy aging, mitigating loneliness, and enhancing equitable access to digital health services.

Despite these encouraging findings, several limitations warrant acknowledgment. First, the study was conducted as a pilot implementation involving a relatively small sample of ten participants, thereby constraining the generalizability of the quantitative findings. Second, the evaluation primarily concentrated on usability, user experience, and preliminary user perceptions rather than long-term behavioral outcomes, clinical effectiveness, or longitudinal health impacts. Third, the proposed platform was not benchmarked against existing digital health platforms or validated using standardized benchmark datasets, thereby limiting direct comparison with alternative approaches. In addition, the current assessment engine remains rule-based and lacks predictive analytics or artificial intelligence techniques, while computational performance, scalability, and large-scale deployment were not examined. These limitations, when interpreting the findings, are crucial to consider, as they provide important context and highlight significant directions for future research.

Addressing these limitations offers several important directions for future research and system enhancement. Subsequent development should adopt a more modular software architecture by decoupling the assessment engine from the presentation and data layers, thereby improving maintainability, interoperability, and integration with external healthcare services through standardized APIs. System performance should be further strengthened through response time optimization, concurrent user testing, database optimization, and cloud-based deployment to support broader implementation. Future studies should also explore the integration of artificial intelligence and predictive analytics to enable adaptive and personalized health recommendations, while validating the platform with larger and more diverse participant groups across multiple healthcare settings. Such developments would facilitate the transition of the current research prototype into a reliable, secure, scalable, and sustainable digital health platform suitable for real-world deployment. Overall, the findings of this study establish a foundation for the future development of inclusive, evidence-based, and scalable digital health ecosystems capable of supporting healthy ageing and reducing health disparities among sexual and gender diverse older adults.

ACKNOWLEDGMENT

The researcher would like to sincerely thank all the informants, who are older adults who identify as sexual and gender diverse, for collaborating, taking the time to participate in system testing, giving detailed comments, and genuinely commenting on their platform experiences. The platform has been developed and improved to better suit the target group's needs and circumstances thanks in large part to your collaboration and recommendations. Without the innovative involvement and confidence of each informant, this study would not have been possible. The researcher expresses gratitude to you for your dedication, candor, and insightful sharing of experiences, all of which are essential to the advancement of our digital health system.

***Abstract*—Iron ore estimation is a significant part of mineral exploration, as it supports determining both the quantity and quality of available mineral resources. Precise estimation facilitates effective mine planning, production management, and sustainable usage of natural resources. Conventional systems are mostly based on laboratory measurements and geological surveys that are frequently expensive, time-consuming, and restricted when handling larger-scale mineral datasets. In recent years, machine learning (ML) and deep learning (DL) systems have been progressively used to improve estimation by recognizing intricate patterns in mineralogical databases. This research introduces a Multi-modal Deep Learning Framework for Mineral Exploration and Iron Ore Load Prediction (MDL-MEOLP) model to enable precise mining decision-making. The proposed model performs hierarchical region generation utilizing a grid-driven patch extractor to capture multi-scale local regions. Subsequently, an EfficientNet-B0 backbone is employed for local feature extraction, while a region-density attention module emphasizes dense ore regions. Moreover, hierarchical feature fusion is applied to aggregate local-to-global representations and enhance global contextual understanding. Finally, a classification head with global average pooling, a dense layer, a dropout layer, and softmax activation is utilized to predict 17 feed load classes, and the model is trained utilizing Adam optimizer with cross-entropy loss over stratified data splits. To demonstrate the improved performance of the proposed MDL-MEOLP model, a comprehensive experimental analysis is carried out using Real-time Iron Ore Feed Load Estimation. The comparative results reported the effective performance of the MDL-MEOLP model with an accuracy of 97.58% over existing models.**

Keywords*—Mineral exploration; Iron Ore Load Prediction; EfficientNet-B0; Adam optimizer; deep learning; resource utilization

I. Introduction

Over the past decade, the global need for mined resources has increased rapidly due to increasing population, advanced technologies, and economic growth [1]. The demand for metals will grow considerably by the year 2050, with a projected increase of 215% for aluminum, 140% for both copper and nickel, 86% for iron, 81% for zinc, and 46% for lead [2]. Metals like aluminum, copper, gold, and zinc play a vital role in the renewable energy transition and achieving net-zero targets because of their significant role in decarbonization technologies, including solar panels, wind turbines, and electric vehicles [3]. The growing demand for mineral resources has increased the pressure on the mining industry. Similarly, mining companies are facing numerous challenges like declining ore grades, deeper mineral deposits that are difficult to access, and rising energy and operational costs [4]. Meanwhile, society depends heavily on mineral resources for industrial growth and modern technologies, while mining itself is criticized for its environmental impacts [5]. Sustainable and transparent mining practices are vital to meet rising global demand while decreasing damage to the environment. Conventionally, the mining industry has relied on a linear value chain, including sequential stages from exploration to closure of the mine [6]. The procedure starts with exploration, in which all data is gathered to determine spatial extent, geometry, and geotechnical and hydrological settings of potential sites through various methods, including geological mapping, geophysics, remote sensing, and drilling [7].

In the mineral industry, the ball mill grinding circuit (GC) is a critical component for effective production, and low-grade iron ores must undergo a beneficial process for further concentration [8]. The product quality is mainly based on controlling several setpoints in the GC process, including feed load (ore load), water level, mill pressure, and pump pressure. The GC control practices are manually developed and depend on laboratory product analysis used as feedback for modifying those setpoints [9]. Among the various setpoints, the feed load setpoint is to be adjusted as the other adjustments need an extremely skilled and experienced human operator [10]. In simpler terms, the quality of the product is mostly influenced by the ore features and the feed load settings. For instance, when dealing with ore pellets that are difficult to grind, the feed load is kept low to maintain the quality of the product, while that is raised for easy-to-grind ore to improve product throughput [11]. With continuous grade control, precise ore characterization is possible and supports quick responses to variations in ore quality. In recent years, megatrends have emerged that could

*Corresponding author

significantly reshape the mining industry. Digital disruption, characterized by the incorporation of digital technologies into all operational functions, is transforming traditional practices [12]. The development of online sectors, Internet of Things (IoT) systems, and data analytics approaches, including artificial intelligence (AI) and geostatistical methods, enables efficient collection and evaluation of a large amount of real-time data. Such advancements support enhancing predictive maintenance, optimizing processes, improving efficiency, decision-making, and improving safety and sustainability [13]. AI-based technologies also support smart mining systems, which allow accurate ore deposit modeling, live monitoring, geo-metallurgical modeling, and continuous grade control. Together, these advanced technologies enhance resource utilization and minimize environmental impacts and also strengthen transparency in tackling the mineral resource dilemma [14].

A. Motivation and Research Contributions

In spite of developments in process control and mining operations, standard techniques are highly dependent on manual experience and the subsequent decision-making process, which constrains flexibility to change ore features. Current grinding circuit control methods often face difficulties in handling variations in mineral characteristics and feed load during real-time operations, which can reduce overall process efficiency. Although digital technologies and AI-based techniques have been introduced in recent years, many existing methods are still developed separately and are not fully integrated with practical operational control systems. Therefore, there is a strong need for an efficient data-driven framework that can improve ore classification and support accurate feed load prediction for better grinding circuit performance. To address these issues, the proposed MDL-MEOLP framework to design an efficient method for timely phases of mineral exploration employing iron ore images.

The key contributions of this study are outlined as follows:

- Construct a hierarchical region generation process employing grid-driven patch extraction to capture multi-scale local regions from iron images.
- Design an EfficientNet-B0-based feature extraction method for taking the fine-tuned texture patterns and ore density distributions from iron ore images.
- Introduce a region-density attention module to emphasize informative dense ore areas while suppressing irrelevant background data across adaptive feature refinement.
- Employ a hierarchical feature fusion approach to combine local and global representations, improving contextual understanding for feature representation.
- Apply a classification head with global average pooling (GAP), a dense layer, a dropout layer, and softmax activation to precisely predict 17 iron ore feed load categories.
- Integrate an Adam optimizer with cross-entropy loss to ensure stable training and enhance the performance of the method.
- Evaluate the performance of the proposed MDL-MEOLP utilizing the Real-time Iron Ore Feed Load Estimation database and exhibit the solution with several measures.

The proposed model's novelty lies in the domain-specific integration of its elements for the analysis of ore texture, rather than the elements themselves. It combines a grouped weight EfficientNet-B0 backbone, which explicitly divides local texture features from the ore density patterns, a Region Density Attention Module intended for the spatial sparsity of ore-bearing regions, which emphasizes dense regions and suppresses the sparse ones, and a hierarchical fusion pipeline which re-aggregates the multi-level regional characteristics in a closed loop with an attention refinement. This integrated model yields quantifiable gains over the generic backbone-plus-attention baselines utilized in prior ore classification systems.

The structure of this study is organized as follows: Section I explains the Introduction, and Section II reviews the related work on ore feed load estimation. Section III represents the proposed DL-MEOLP framework, Section IV describes the experimental validation and discussion, and Section V discusses the conclusion and future work of the study.

II. Literature Survey

This section discusses a brief overview of existing studies on iron ore feed estimation and identifies the key research gaps in the domain. Diniz et al. [15] developed a novel technique that applied a soft sensor algorithm to gather the energy efficiency of a wet-closed ball mill. Case research was shown through real information from one of the world's highest mining companies, VALE SA, using many models and validation methods. Matos et al. [16] designed a new data-driven soft sensor for evaluating the probabilistic distribution of multi-class lithology in the real world for crushing circuits. The methodology integrates measurements of crusher motor current and rotational speed with signal processing and ML models. Najafabadipour et al. [17] examined an innovative DL-based system to predict critical components in the Gohar Zamin iron ore mining region in southwest Kerman, Iran. One of the methods tested, the CNN, exhibited superior results in predicting the concentrations of the target component, attaining lower error rates and effectively extracting composite spatial patterns in the geochemical data. Firdaus et al. [18] investigated a strong generalized algorithm to automate the task of iron ore characterization of ores belonging to four diverse grades. Thus, a DL approach is designed, which employs a directed acyclic graph network framework through a hybrid inception topology.

Giannetti et al. [19] proposed an enhanced architecture for the prediction of silicon content by applying a new DL technique that depends on Phased LSTM. The system has been trained for three years of information and authorized under a one-year period, utilizing a strong walk-forward validation model, thus delivering confidence in the system results over time. Park et al. [20] discussed a new strategy to enhance the productivity of mining haulage mechanisms by deploying a hybrid methodology that integrates discrete event simulation (DES) and an ML system for predicting ore production. In [21], a hierarchical intelligent control model for mineral particle dimensions on the basis of ML is presented. During the ML layer, AI methodologies, namely CNN and LSTM are employed

to resolve the multi-source ore blending prediction and intelligent categorization of rainy and dry season situations. Luo et al. [22] introduced a new Deep Multi-scale Spatial–Temporal Feature Decoupling Network (DMSTFD-Net), showing a clear attribute decoupling viewpoint to improve method interpretability.

A. Research Gaps

Numerous research gaps can be recognized on the basis of the relevant research. Diniz et al. [15] designed a soft sensor method for energy efficacy prediction in ball mills and emphasized that standard validation algorithms may cause misleading performance, demonstrating the requirement for appropriate time-series (chronological) validation. Matos et al. [16] developed a data-based soft sensor for lithology distribution in crushing circuits utilizing PLC-compatible signals; their strategy is still inadequate in generalization over multiple operational conditions and mining environments. Park et al. [20] examined ML with diverse event simulation for ore production and truck cycle time prediction, although real-world development in compound and extremely dynamic mining models remains difficult. This research shows that prediction accuracy has been enhanced; there is still a strong need for time-aware validation, the best method generalization over mines, and scalable real-world implementation in industrial mining classifications.

III. System Design

The manuscript follows a comprehensive pipeline for early-stage mineral exploration using iron ore images. To accomplish that, the proposed model initially preprocesses the input image through a median filter (MF), CLAHE-based enhancement, pixel normalization using min-max scaling, and resizing. In addition, the hierarchical region generation process is carried out by separating the iron ore image. Besides, the EfficientNet-B0 backbone is utilized to extract discriminative texture and ore density features from iron ore images. Moreover, the region-density attention module is applied to emphasize informative dense ore regions while suppressing less relevant background features. Hierarchical feature fusion is achieved to incorporate local-to-global representations for enhanced contextual understanding. Furthermore, the classification head with GAP, a dense layer, a dropout layer, and softmax activation is used to predict iron ore feed load classes. At last, the Adam optimizer is employed to ensure efficient model training and improved convergence. The complete workflow of the proposed model is illustrated in Fig. 1.

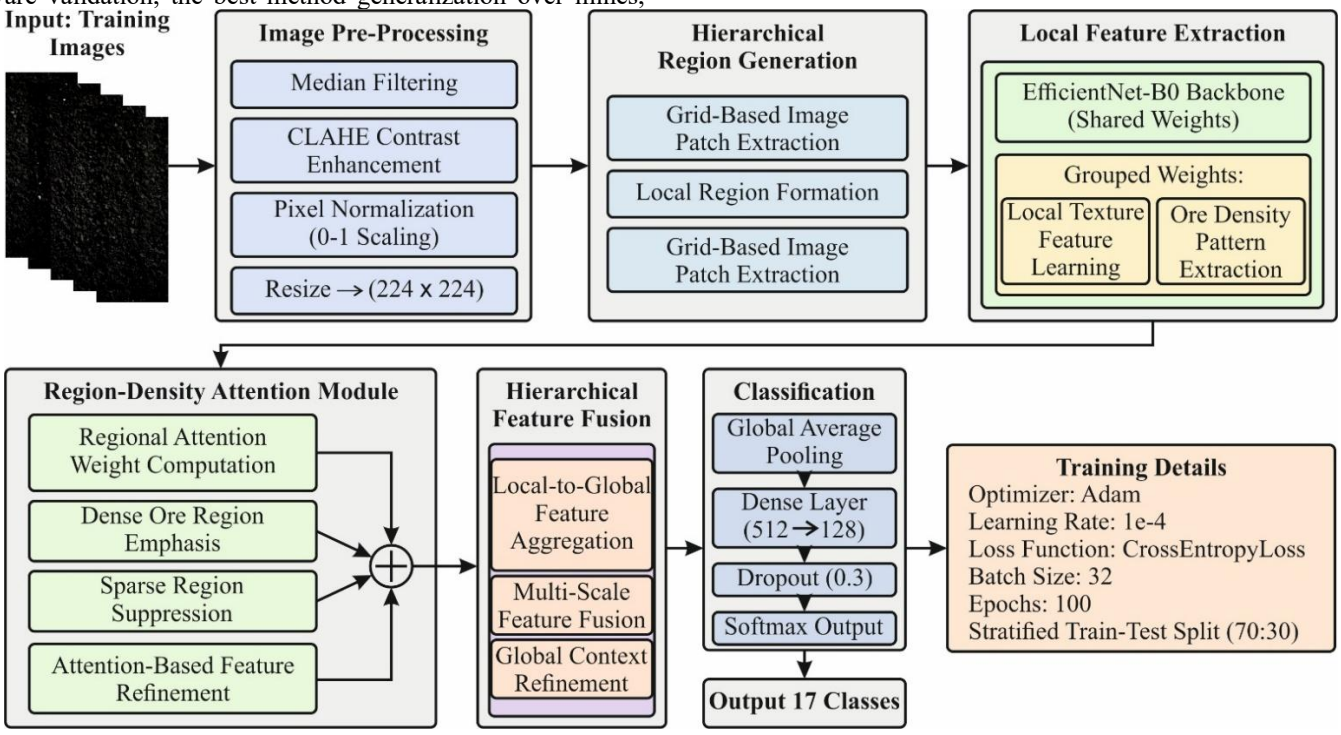

Fig. 1. Overall architecture of the MDL-MEOLP approach.

A. Image Preprocessing

Image preprocessing is an essential step as it improves image quality and ensures consistent input for better feature extraction. It initially preprocesses the input image through an MF, CLAHE-based enhancement, pixel normalization using min-max scaling, and resizing. The preprocessing pipeline consists of the following steps. Initially, the noise removal process is performed by median filtering for suppressing the sensor noise while preserving edge information, which is critical for texture analysis. Secondly, CLAHE is used for enhancing local contrast, to improve the visibility of fine-grained ore texture and variations in density. Third, all pixel intensities are rescaled by pixel normalization to the range of [0, 1] to stabilize and accelerate model training. Fourth, all the images are resized to a fixed resolution of 224 × 224 pixels to match the input needs of the EfficientNet-B0 backbone. Following the pre-processing, a hierarchical region generation step gets image patches by a grid-based scheme, forming local regions which are subsequently utilized for local to global feature learning.

1) Median filtering: To suppress salt-and-pepper noise while maintaining edges, MF is a non-linear image denoising method is utilized. It exchanges each pixel value with the median value of its nearby pixels in a definite window [23] [see Eq. (1)]:

$$I'(x,y) = median\{I(i,j) | (i,j) \in \Omega_{xy}\} \quad (1)$$

Here, Ω_{xy} implies the local neighborhood around pixel (x, y).

2) Contrast enhancement using CLAHE: It is an adaptive contrast enhancement model that applies histogram equalization over small image regions rather than the entire image, which improves local contrast in images. For preventing over-amplification of noise, it constrains the contrast enhancement to clip the histogram at a predetermined threshold and reorganizes the clipped pixels. To enhance fine structural details in low-contrast images while preventing noise amplification, this technique is specifically effective.

3) Min-max based pixel normalization: Min-max scaling transforms data values into a fixed range, typically between 0 and 1, by linearly rescaling the original values based on the minimal and maximal values of the data [see Eq. (2)]:

$$x' = \frac{x_i - x_{min}}{x_{max} - x_{min}} \quad (2)$$

x_{min} points out the minimal value of the attribute; x_{max} indicates the maximal value of the attribute, and x' represents the normalized attribute.

4) Resizing: To standardize input sizes before feeding data into DL algorithms, image resizing is applied. Each image is uniformly scaled or resampled to a fixed resolution of 224×224pixels during this process.

B. Hierarchical Region Generation

Hierarchical region generation is a structural process utilized for decomposing the mineral imaging into useful spatial units at several levels. The term Multi-modal refers to the various complementary feature modalities excavated from a single image input, instead of various external data sources. Specifically, it decomposes the image-derived representations into two distinct feature modalities, local texture and ore density pattern, through grouped-weight branches of the EfficientNet-B0 backbone. Furthermore, they are processed via the Region-Density Attention Module and integrated via hierarchical feature fusion over local, regional, and global levels. This use of multi-modal describes several learned feature representations from a single modality as multi-modal feature learning.

1) Grid-based image patch extraction: The input mineralogical imaging is separated into an even grid of smaller patches. All patches specify a fixed spatial zone of the imagery, assuring comprehensive and reliable coverage of the complete mineral surface.

2) Local region formation: Afterward, the patch extractor gathers neighborhood patches together to create local areas. These areas are useful geological micro-structures like mineral grains, texture transitions, and boundaries.

3) Multi-scale region representation: For capturing the differences in mineral structure at various levels of feature, local zones are more ordered into multi-scale representations.

C. Local Feature Extraction

Local feature extraction was conducted utilizing an EfficientNet-B0 backbone to train fine-grained texture patterns from the input images. This stage helps in capturing important ore density variations and local structural details for better representation of mineral characteristics.

1) EfficientNet-B0 Backbone: The EfficientNet framework has progressed to classify an efficient scaler approach for the CNN model and enhance prediction outcomes. The compound scaler approach constantly scales network depth, width, and resolution employing a certain set of scaling coefficients [24]. In this method, the EfficientNet-B0 structure is intended as the baseline method. The EfficientNet model comprises numerous versions from B0 to B7, while the superior versions involve improved parameters and enhanced learning ability. Growing network depth allows the method to train higher and more intricate patterns, whereas rising system width supports capturing fine-tuned features from geological and mineral imaging. This technique uses several convolutional layers with mobile inverted bottleneck convolution blocks for extracting effective features and representation learning in mineral deposit and iron ore load estimation tasks. The compound scaler approach is represented as in Eq. (3) to Eq. (7):

$$w = \beta^{\varphi} \quad (3)$$

$$d = \alpha^{\varphi} \quad (4)$$

$$r = \gamma^{\varphi} \quad (5)$$

$$s.t.\alpha.\beta^2.\gamma^2 \approx 2 \quad (6)$$

$$\alpha \geq 1, \beta \geq 1, \gamma \geq 1 \quad (7)$$

Here, w implies network width, d signifies the network depth, and r indicates network resolution, respectively, whereas α, β, and γ represent uniform scalar coefficients decided through the optimizer on the baseline technique. EfficientNet consistently scales each network size utilizing the compound coefficient ϕ, allowing effective learning of mineral distribution patterns and iron ore features from geological imaging, while preserving computational complexity.

2) Local texture feature learning: Local texture feature learning is used for capturing the fine-tuned mineral surface differences, grain limitations, and spatial irregularities from ore instances. The texture description is obtained by analyzing neighborhood pixel intensity interaction employing Local Binary Pattern (LBP) representation:

$$LBP(x_c, y_c) = \sum_{p=0}^{p-1} s(g_p - g_c)2^p \quad (8)$$

In Eq. (8), g_c implies the pixel intensity of the center, g_p denotes the pixel intensity of the neighborhood, and $s(\cdot)$ indicates the thresholding operation.

3) Ore density pattern extraction: The ore density pattern extraction was performed using the mineral concentrate operation and the regional density difference in the ore structure [see Eq. (9)]:

$$\rho(x) = \frac{1}{nh}\sum_{i=1}^{n} K\left(\frac{x - x_i}{h}\right) \tag{9}$$

Let $\rho(x)$ imply the ore density estimation, K denotes the kernel operation, h represents the bandwidth, and x_i with respect to neighboring instance points.

D. Region-Density Attention Module

The region-density attention module is developed to enhance feature representation of minerals by adaptable attention on higher-density ore regions, while it controls the lower-information background areas [25]. This also increases spatial differentiation by assigning attention weights that are based on feature significance and local ore concentration.

1) Regional attention weight computation: Regional attention weights are calculated to measure the significance of all spatial regions, depending on the feature responses that could be extracted utilizing more images [see Eq. (10)]:

$$\alpha_i = \frac{\exp(W_a^T f_i)}{\sum_{j=1}^{N} \exp(W_a^T f_j)} \tag{10}$$

Here, the symbol α_i denotes the standardized attention weight for area i, f_i signifies the regional feature vectors, and W_a implies the trainable attention parameter.

2) Dense ore region emphasis: Dense ore regions have been underscored by improving the feature contributions proportionately to their attention scores, thereby confirming effective representation of mineral-rich regions [see Eq. (11):

$$F_i^{dense} = \alpha_i \cdot f_i \tag{11}$$

Here, the parameter F_i^{dense} signifies the improved feature representation of dense mineral zones.

3) Sparse region suppression: Sparse or non-mineral regions can be controlled by decreasing their feature influence by applying the attention weighting [see Eq. (12)]:

$$F_i^{sparse} = (1 - \alpha_i) \cdot f_i \tag{12}$$

It helps in eliminating the noise from background textures and distinct geological patterns. So, the model has been developed to be more robust to visual clutter and surface artifacts normally existing in real-time ore imaging.

E. Hierarchical Feature Fusion

Hierarchical feature fusion model combines the representations extracted with various abstraction phases to make the integrate feature space that improves mineral pattern and increases expectable robustness.

1) Local-to-global feature aggregation: The local features are captured from fine-grained mineral textures, while the global features are encoded in the total structural contexts.

$$F^{global} = \phi\left(\sum_{i=1}^{N} w_i F_i^{local}\right) \tag{13}$$

In Eq. (13), F_i^{local} represent the local feature vectors, w_i implies trained significance weights, and $\phi(\cdot)$ denotes the non-linear transformation.

2) Multi-scale feature fusion: The multi-scale fusion combines the feature extraction with various resolutions to obtain the macro-level geological patterns and micro-level mineral textures [see Eq. (14)]:

$$F^{MS} = \sum_{s=1}^{S} \alpha_s F_s, \text{where } \alpha_s = \frac{e^{z_s}}{\sum_{k=1}^{S} e^{z_k}} \tag{14}$$

where, the parameter F_s characterizes feature maps corresponding to scale s, and the mathematical notation α_s are adaptable attention weights calculated by employing the softmax function. It permits the model to dynamically highlight the more informative measures based on the intricacy of mineral textures. This fusion increases the strength against differences in imaging resolution, mineral density, and grain size.

3) Global context refinement: The global context refinement improves combined features through the integration of long-term dependencies and decreases the inappropriate background regions [see Eq. (15)]:

$$F^{refined} = F^{MS} \odot \sigma(W_g G) \tag{15}$$

In this mathematical equation, the symbol $\sigma(\cdot)$ points out the sigmoid gating function, the factor G indicates global context embedding, and the term W_g refers to the learnable projection matrix. The element-wise multiplication $\odot$ is performed as an attention gate that reinforces mineral-specific indications, whereas sparse background zone or removing noises. Hence, this enhancement phase majorly increases the feature variability in diverse geological contexts. Fig. 2 denotes the structural design of feature extraction and feature fusion model.

F. Classification Head

The classification head is used to convert extracted features into final predictions. It consists of GAP, a dense layer, a dropout layer, and a softmax activation to accurately predict 17 iron ore feed load classes [26].

1) Global average pooling: This pooling method is used after the convolutional feature extractor blocks to transform spatial feature mappings into a compressed feature representation. It minimizes every feature mapping into a distinct scalar performance by calculating the average of each spatial position, thus removing the essential for a flattened layer and considerably minimizing the count of trainable parameters.

$$GAP(x) = \frac{1}{H \times W} \sum_{i=1}^{H} \sum_{j=1}^{W} x_{i,j} \quad (16)$$

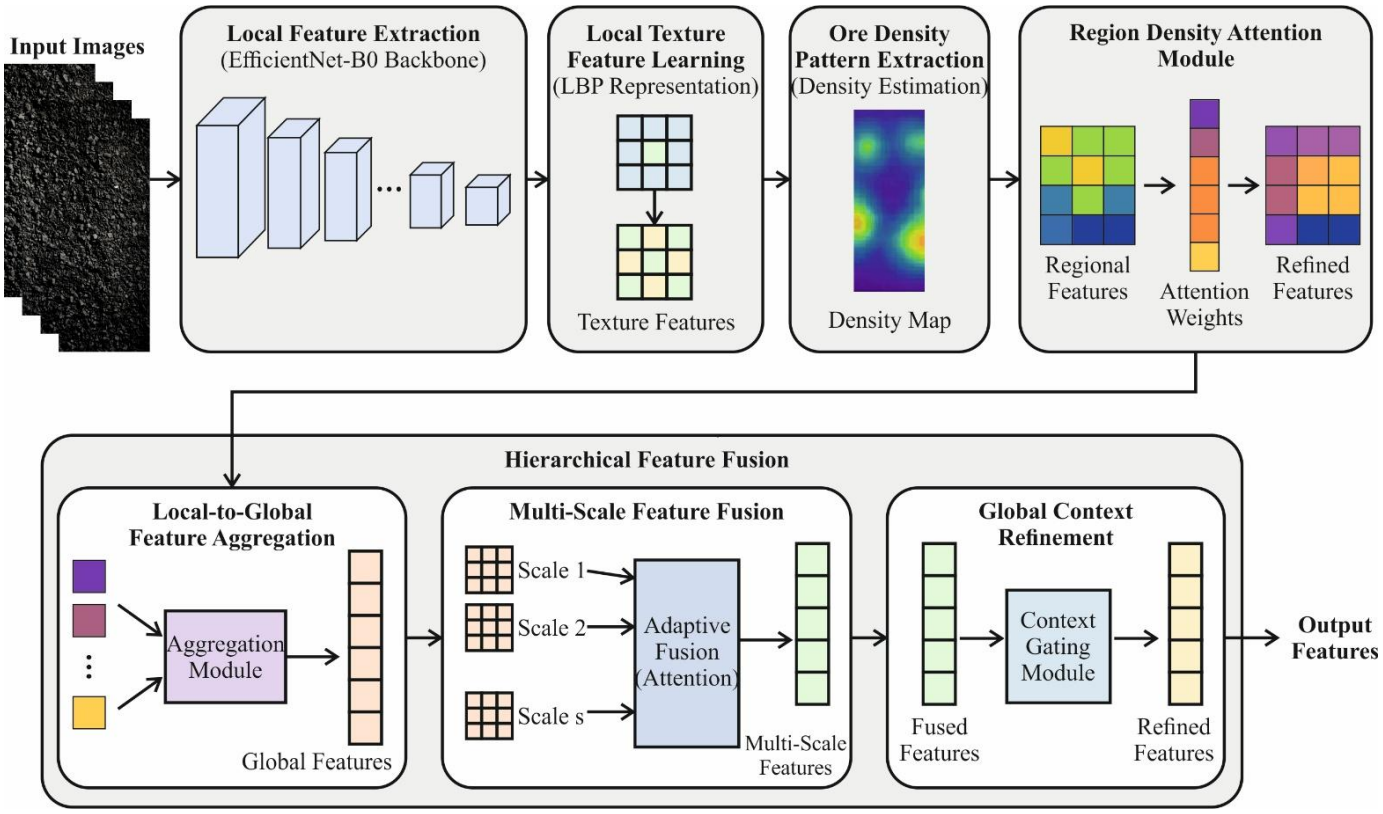

Fig. 2. Structural design of feature extraction and feature fusion model.

In Eq. (16), W and H represent the width and height of the feature mapping. This function considerably lessens the count of parameters compared with a flattened layer, leading to a more lightweight and computationally effective method while maintaining global spatial data.

2) Dense layer: This layer, also known as a fully connected layer, accomplishes non-linear feature alteration by mapping the dense feature vector from 512 to 128 neurons. It learns higher-level discriminative representations by using a weighted linear conversion followed by a non-linear activation function [see Eq. (17)]:

$$z = Wx + b \quad (17)$$

Here, x implies the feature vector of the input value, W implies the weighted matrix, and b denotes the biased vector.

3) Dropout: Dropout is a regularized method utilized to minimize overfitting for random deactivation neurons in training with probability p, forcing the system to learn stronger feature generalization [see Eq. (18)]:

$$y = Dropout(x, p) \quad (18)$$

4) Softmax output: The softmax function is used in the final layer to transform raw logits into a standardized probability function throughout numerous categories. It allocates high probabilities to further likely classes while assuring that the amount of each predicted probability equals to 1 [see Eq. (19)]:

$$softmax(x) = \frac{e^{z_i}}{\sum_j^4 e^{z_j}} \quad (19)$$

Now, z_i implies the logit of the i^{th} class, and K signifies the overall count of classes. In this study, $K = 17$ with respect to 17 feed load categorizations allows probabilistic multi-class identification for feed load estimation.

G. Network Configuration Details

Table I shows the parameter configuration of the MDL-MEOLP structure for feed load classification. Primarily, the input images are pre-processed employing Median Filtering, CLAHE-driven contrast enhancement, pixel standardization, and resizing images to 224×224 resolution to enhance the quality of imaging and consistency. Hierarchical area creation is performed using a grid-driven patch extractor with multi-scale local region representation, while EfficientNet-B0 is used as the backbone system to obtain density features and local texture. The structure integrates a Regional Density Attention module and hierarchical multi-scale feature fusion to increase significant global and regional contextual data. At last, the classifier procedure uses global average pooling and a Softmax layer for

17 feed load labels, and the method has been trained utilizing the Adam optimizer with a batch size of 32 over 100 epochs and a learning rate of 1e−4.

TABLE I. PARAMETER SETTING

Model	Parameter	Configured Value
Image Preprocessing	Filtering Method	Median Filtering
	Contrast Enhancement	CLAHE
	Normalization	Pixel Normalization (0–1 Scaling)
	Image Resize	224 × 224
Hierarchical Region Generation	Patch Extraction Method	Grid-Based Patch Extraction
	Patch Size	32 × 32
	Region Representation	Multi-Scale
	Number of Local Regions	16
Local Feature Extraction	Backbone Network	EfficientNet-B0
	Feature Extraction Type	Local Texture and Density Features
	Feature Embedding Dimension	1280
	Activation Function	Swish
Region-Density Attention Module	Attention Mechanism	Regional Density Attention
	Attention Hidden Units	256
	Sparse Region Threshold	0.2
	Attention Dropout	0.2
Hierarchical Feature Fusion	Fusion Strategy	Local-to-Global Aggregation
	Fusion Type	Multi-Scale Feature Fusion
	Global Context Refinement	Enabled
	Fusion Output Dimension	512
Classification Head	Pooling Layer	Global Average Pooling
	Dropout Rate	0.3
	Output Layer	Softmax
	Number of Classes	17 Feed Load Classes
Training Configuration	Optimizer	Adam
	Learning Rate	1e-4
	Loss Function	CrossEntropyLoss
	Batch Size	32
	Epochs	100
	Train-Test Split	80;20 and 70:30

IV. EXPERIMENTAL VALIDATION AND DISCUSSION

The experimental evaluation of the MDL-MEOLP method was performed using Real-time Iron Ore Feed Load Estimation [27]. This database (2.05GB/2.7GB uncompressed) consists of iron ore feed images with load classes (17 loads, tons). All images have dissimilar unknown ore categories. The only identified element is the ore load with respect to the image. Table II shows that the dataset consists of 17 classes with a total of 2,985 samples. Fig. 3 signifies the representative feed load images obtained from real-time mining operation dataset. Fig. 4 denotes the samples of preprocessed image. Fig. 5 represents the visual representation of learned feature maps.

The Real-time Iron Ore Feed Load Estimation dataset has a total of 2,985 images allocated across 17 feed load classes, with sample counts starting from 127 to 228. All images given were resized to 224 × 224 pixels for the model input. The dataset was collected from "Validation dataset for a new weakly supervised learning approach for Real-time Iron Ore Feed Load Estimation", to represent varying feed load levels. The dataset was partitioned into training and test sets using a stratified 70:30 split, ensuring proportional class representation in both subsets.

TABLE II. DETAILS OF DATASET

Classes	Number of Samples
Load 1	175
Load 2	207
Load 3	181
Load 4	166
Load 5	228
Load 6	169
Load 7	197
Load 8	170
Load 9	127
Load 10	211
Load 11	147
Load 12	184
Load 13	176
Load 14	164
Load 15	189
Load 16	152
Load 17	142
Total Samples	**2985**

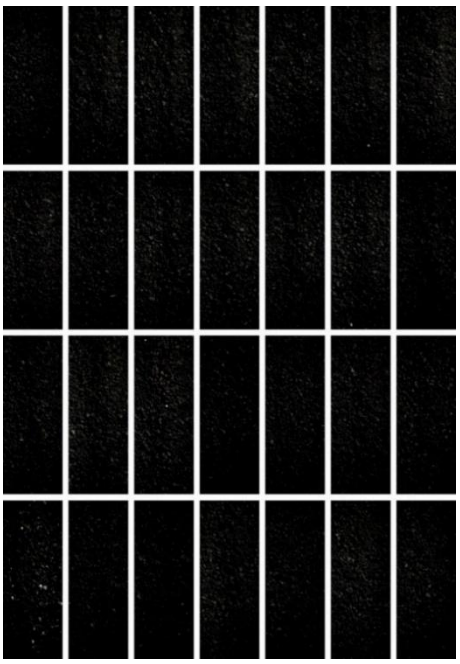

Fig. 3. Representative feed load images obtained from real-time mining operation dataset.

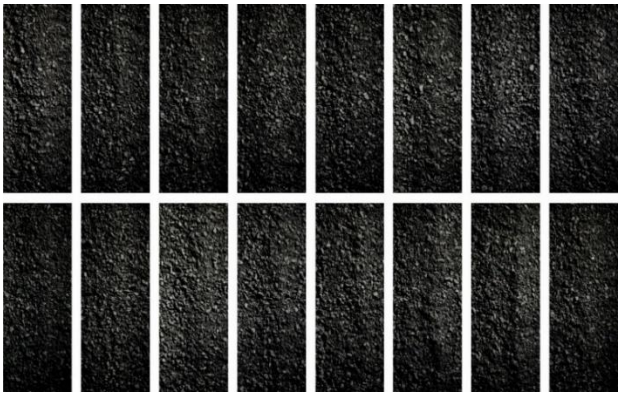

Fig. 4. Sample preprocessed images.

Fig. 6 displays confusion matrices for the diverse class feed load classifier method under 80:20 and 70:30 data splits. The diagonal dominance in each matrix suggests that most instances are appropriately categorized into each class. Some of the diagonal performance appear, presenting slight misclassifications among the similar categories. The outcomes confirm that the method preserves stronger and more reliable classifier values through data split.

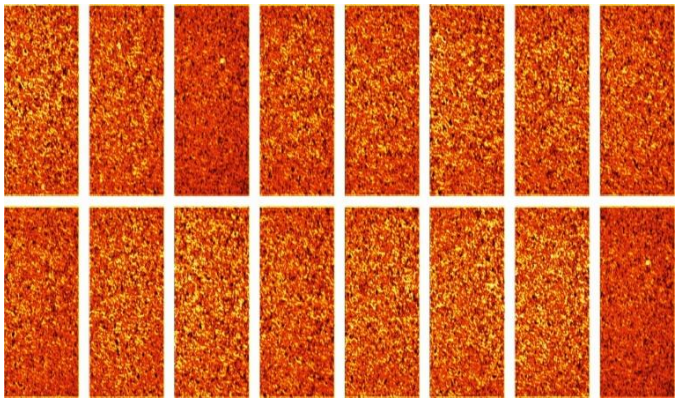

Fig. 5. Visual representation of learned feature maps.

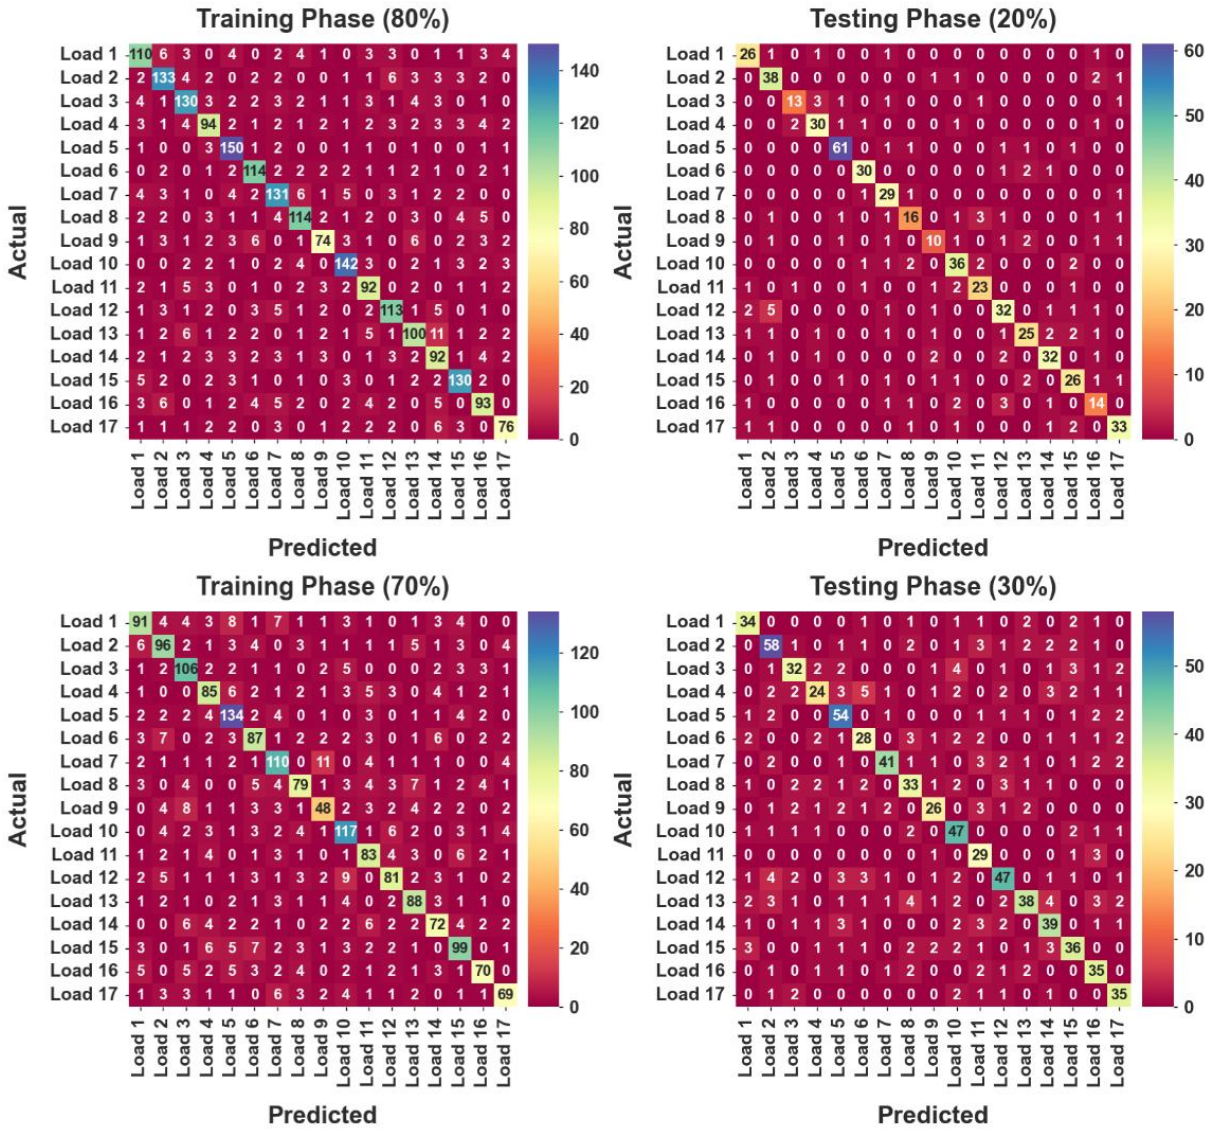

Fig. 6. Confusion matrix of the MDL-MEOLP method with 80:20 and 70:30 split.

Table III and Fig. 7 show the feed load classifier outcome of the MDL-MEOLP approach with an 80:20 train-test split. The result implied that the MDL-MEOLP method accurately detected the samples. The proposed MDL-MEOLP method attained an average value with *an accuracy* of 97.54% in TRAINING SET and *an accuracy* of 97.58% in TESTING SET, whereas the MCC of 77.30% for the TRAINING SET and MCC of 76.01% for the TESTING SET further confirm the model's reliable and balanced classification performance.

TABLE III. FEED LOAD CLASSIFIER RESULT OF THE MDL-MEOLP METHOD WITH 80:20.

Class	TRAINING SET (80%)	TESTING SET (20%)
Accuracy	97.54	97.58
Precision	78.77	77.75
Recall	78.50	77.01
F1-Score	78.57	77.19
MCC	77.30	76.01

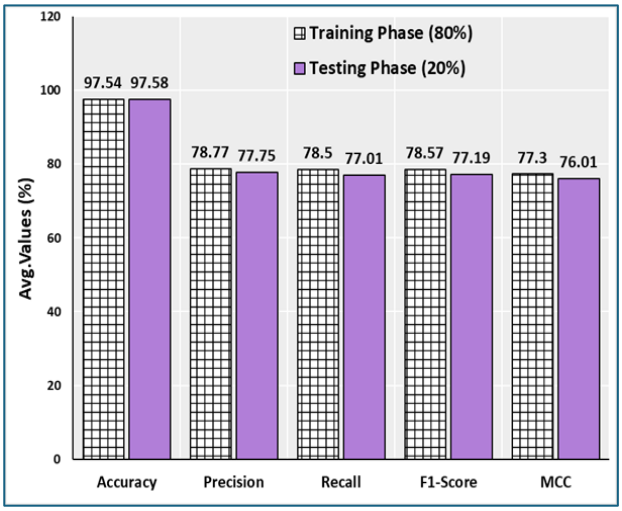

Fig. 7. Average value of the MDL-MEOLP method with 80:20.

Table IV and Fig. 8 exhibit the feed load classifier result of the MDL-MEOLP system with a 70:30 train-test split. The findings shown that the MDL-MEOLP approach precisely classified the instances. The proposed MDL-MEOLP technique reached average result with *an accuracy* of 96.77% in TRAINING SET and *an accuracy* of 96.59% in TESTING SET, while the MCC of 70.29% for the TRAINING SET and MCC of 68.88% for the TESTING SET more strengthen the model's consistent and stable classifier solutions.

Fig. 9 demonstrates the training and validation accuracy and loss graphs on 80:20 and 70:30. It shows the proposed model reaches increasing values over increasing epochs. In addition, the increasing validation over training exhibits that it learns efficiently on the test dataset. It also illustrates the loss investigation of the model. The results indicate that it reaches closer values of training and validation loss. It is observed that the MDL-MEOLP technique learns efficiently on the test dataset.

TABLE IV. FEED LOAD CLASSIFIER RESULT OF THE MDL-MEOLP METHOD WITH 70:30.

Class	TRAINING SET (70%)	TESTING SET (30%)
Accuracy	96.77	96.59
Precision	72.29	70.76
Recall	71.82	71.03
F1-Score	71.94	70.43
MCC	70.29	68.88

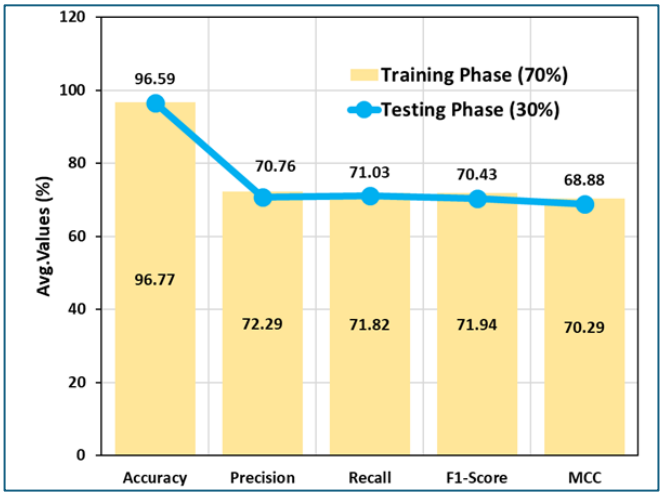

Fig. 8. Average value of the MDL-MEOLP approaches 70:30.

Table V and Fig. 10 portray the comparison study of the MDL-MEOLP approach with other methodologies using evaluation metrics [28, 29]. The stimulation outcome indicated that the MDL-MEOLP method achieves superior performance. The Xception, InceptionV3, ResNet50, DenseNet121 approaches have attained lower performance, whereas the EfficientNet-B0, MobileNetV3, ShuffleNetV2, and AlexNet methods obtain moderate performance. In addition, the EDF-NSDE reaches better prediction ability with more balanced outcomes. However, the proposed MDL-MEOLP method has achieved better overall solutions with *an accuracy* of 97.58%, *precision* of 77.75%, *recall* of 77.01%, and an F1-score of 77.19%, representing its superior effectiveness and balanced classification capability compared to the other models. Furthermore, the reported values are directly referred to in the previously published study for a better comparison.

The gap that exists between accuracy (97.58%) and macro F1-score (77.19%) reflects the class imbalanced nature of the dataset, as macro averaging weights all classes equally and it is thus highly sensitive to the minority-class errors. It reports the confusion matrix and per-class metrics, showing that the misclassifications concentrate among visually similar and underrepresented adjacent load classes, which provides a more reliability beyond the accuracy alone.

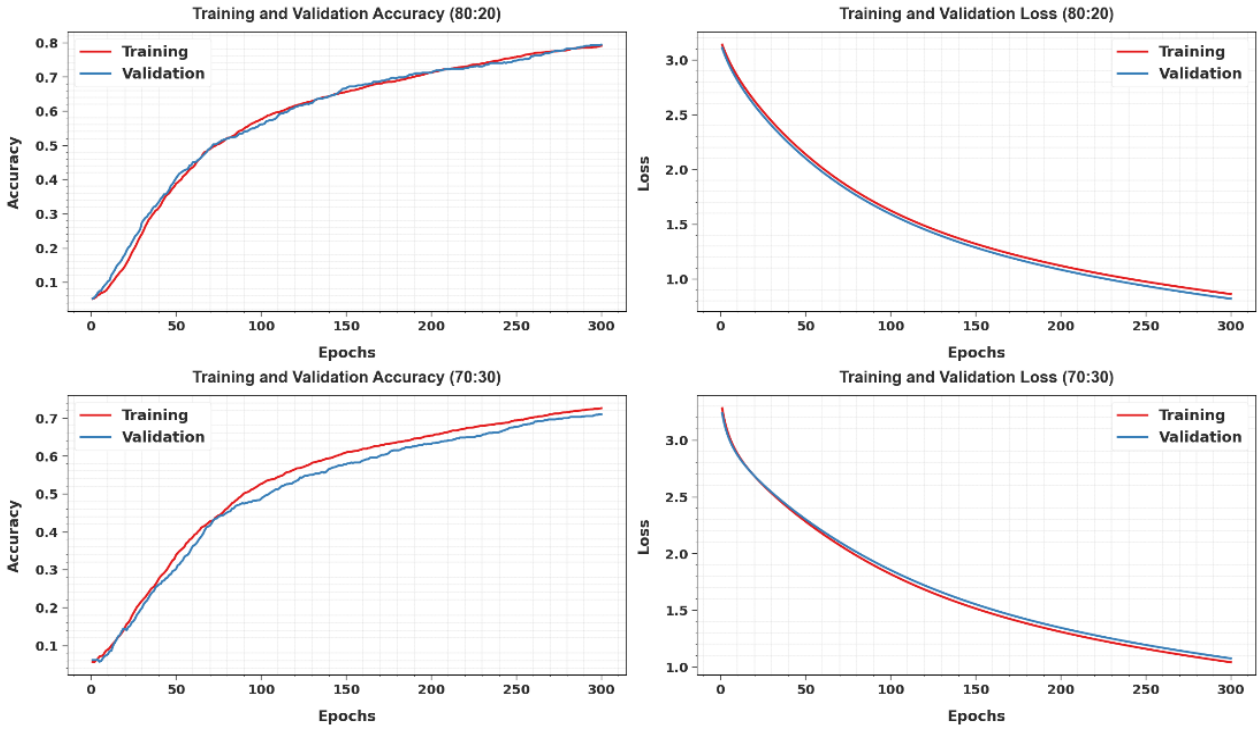

Fig. 9. Training and Validation Accuracy and Loss curve on 80:20 and 70:30.

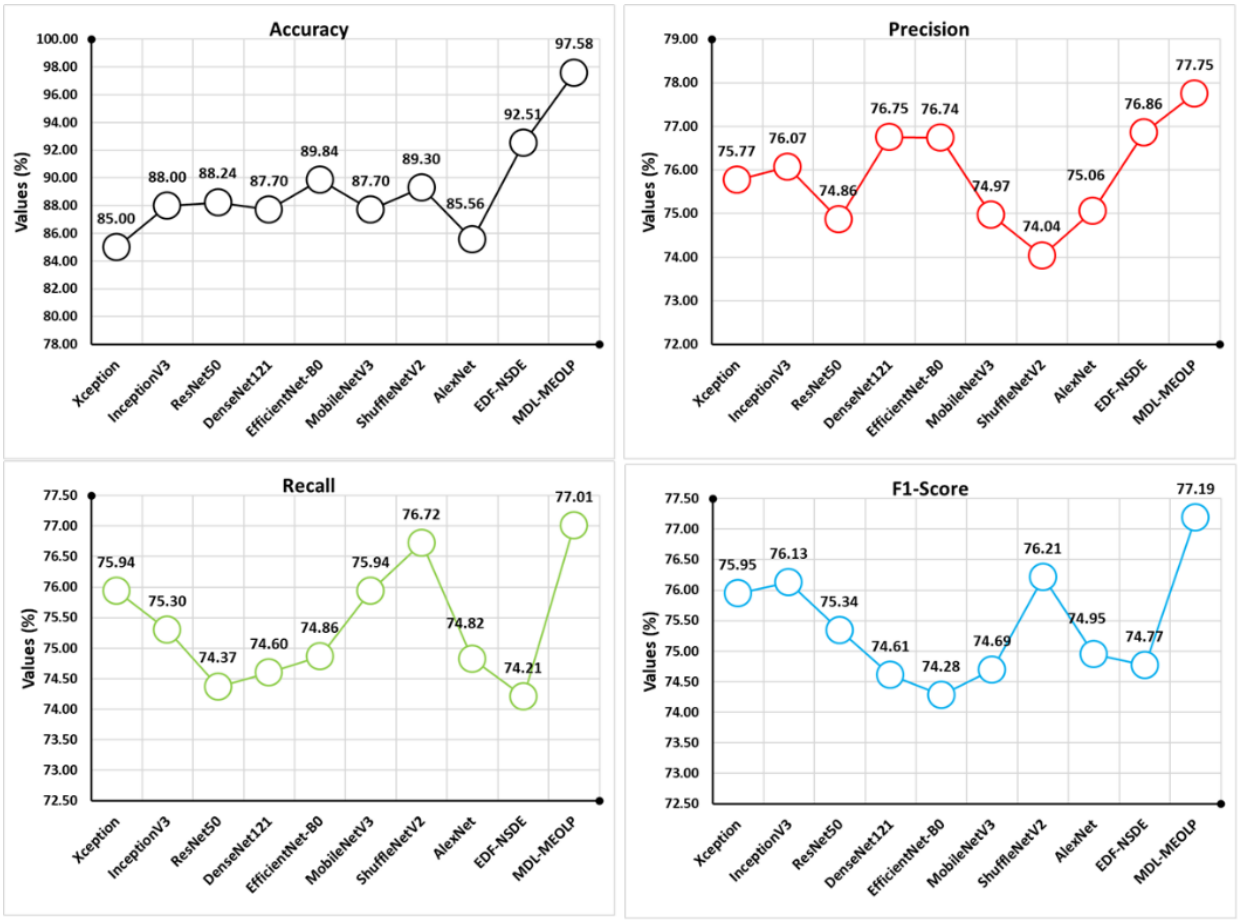

Fig. 10. Comparison outcome of the MDL-MEOLP approach with various metrics.

TABLE V. COMPARATIVE RESULTS OF THE MDL-MEOLP METHOD WITH EXISTING APPROACHES

Network	$Accur_y$	$Preci_n$	$Recal_l$	$F1_{score}$	Computational Time (sec)
Xception	85.00	75.77	75.94	75.95	13.85
InceptionV3	88.00	76.07	75.30	76.13	7.06
ResNet50	88.24	74.86	74.37	75.34	8.33
DenseNet121	87.70	76.75	74.60	74.61	9.12
EfficientNet-B0	89.84	76.74	74.86	74.28	10.13
MobileNetV3	87.70	74.97	75.94	74.69	10.94
ShuffleNetV2	89.30	74.04	76.72	76.21	8.07
AlexNet	85.56	75.06	74.82	74.95	8.12
EDF-NSDE	92.51	76.86	74.21	74.77	8.89
MDL-MEOLP	97.58	77.75	77.01	77.19	3.31

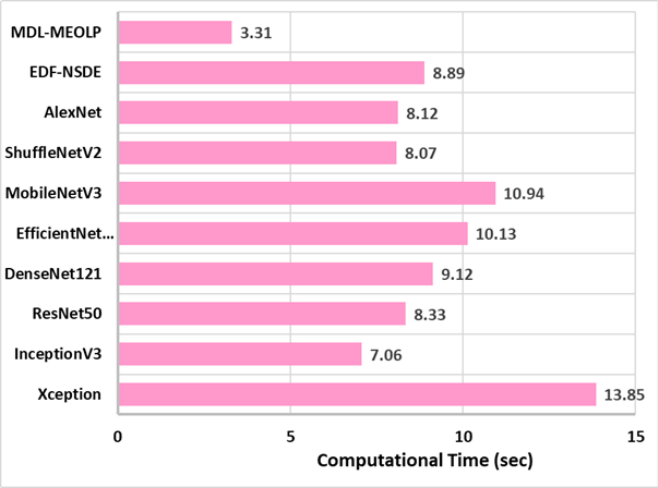

Fig. 11. Computational time of the MDL-MEOLP approach with other methodologies.

Fig. 11 reveal the computational time (CT) of the MDL-MEOLP approach with existing techniques. The result implied that the MDL-MEOLP method has gained minimal value with CT of 3.31sec, whereas the Xception, InceptionV3, ResNet50, DenseNet121, EfficientNet-B0, MobileNetV3, ShuffleNetV2, AlexNet, and EDF-NSDE require significantly higher processing time. This demonstrates that the MDL-MEOLP approach is faster and more computationally efficient than the competing methods.

An ablation study is used to analyze a model by systematically removing or altering its components to evaluate their effect on performance. It helps determine the importance of each module in the overall architecture. By comparing results, it reveals which parts contribute most to accuracy and efficiency. Table VI present the ablation study of the MDL-MEOLP method with metrics. The outcome implied that without Hierarchical Region Generation, EfficientNet-B0 only, EfficientNet-B0 + RDAM, Without Region-Density Attention Module, and Without Hierarchical Feature Fusion approaches achieve inferior value with various metrics, while the MDL-MEOLP (Region Generation + EfficientNet-B0 + RDAM + Hierarchical Fusion + Softmax) method obtain superior value with *an accuracy* of 97.58%, *precision* of 77.75%, *recall* of 77.01%, and F1-score of 77.19%, demonstrating the effectiveness of integrating all components.

The proposed MDL-MEOLP technique functions well for iron ore feed load forecast and mineral exploration applications. Enhancing image quality and extracting significant local details is supported by image preprocessing and grid-based patch extraction. The EfficientNet-B0 backbone efficiently learns density features and ore texture. The attention component assists the method, concentrated on critical ore areas, while minimizing background noise. For a better understanding of global and local data by combining hierarchical feature fusion. Finally, the approach attains higher precision in categorizing 17 feed load classes in comparison with other methodologies.

Table VII presents the k-fold cross-validation outcomes of the proposed MDL-MEOLP method. The method attained accuracy values ranged from 89.92% to 98.83%, with the maximum performance accuracy of 98.83% in K-6. The better precision of 98.43%, recall of 98.12%, and F1-score of 98.47% were achieved in K-6. Although slight difference over the folds, the constantly maximum evaluation measures illustrate the robustness, stability, and strong generalization ability of the proposed method.

TABLE VI. ABLATION STUDY OF THE MDL-MEOLP SYSTEM WITH METRICS

Network	Accuracy	precision	Recall	F1-Score
Without Hierarchical Region Generation	94.71	74.69	73.80	73.87
EfficientNet-B0 only	95.30	75.40	74.36	74.37
EfficientNet-B0 + RDAM	95.90	76.00	75.10	75.13
Without Region-Density Attention Module	96.41	76.57	75.78	75.70
Without Hierarchical Feature Fusion	97.04	77.17	76.43	76.44
MDL-MEOLP (Region Generation + EfficientNet-B0 + RDAM + Hierarchical Fusion + Softmax)	97.58	77.75	77.01	77.19

TABLE VII. K-FOLD CROSS VALIDATION RESULTS OF THE MDL-MEOLP SYSTEM.

K-Fold	Accuracy	Precision	Recall	F1-score
k-1	94.26	93.71	94.08	93.89
k-2	96.84	96.29	95.94	96.11
k-3	91.73	91.08	90.82	90.95
k-4	97.35	96.81	97.12	96.96
k-5	93.14	92.58	92.91	92.74
k-6	98.83	98.43	98.12	98.47
k-7	95.68	95.11	94.86	94.98
k-8	89.92	89.37	89.08	89.22
k-9	97.81	97.26	97.04	97.15
k-10	95.17	94.66	94.39	94.52

V. CONCLUSION AND FUTURE WORK

This study has presented an MDL-MEOLP approach for early-stage mineral exploration using iron ore images, which facilitates precise mining decision-making. Initially, the proposed model preprocesses the images to improve feature consistency and image quality. Besides, the hierarchical region generation is carried out using grid-based patch extraction to acquire multi-scale local regions. Moreover, an EfficientNet-B0 backbone is utilized for local feature extraction, enabling effective learning of texture patterns and ore density distributions. Furthermore, a region-density attention module is designed to emphasize dense ore regions while suppressing less informative areas through attention-based feature refinement. The hierarchical feature fusion is further applied to aggregate local-to-global representations and enhance global contextual understanding. Eventually, a classification head with GAP, dense layer, a dropout layer, and softmax activation is utilized to predict 17 feed load classes, and the model is trained using the Adam optimizer with cross-entropy loss over stratified data splits. To exhibit the improved performance of the proposed MDL-MEOLP model, a comprehensive experimental analysis takes place using Real-time Iron Ore Feed Load Estimation. The comparative results reported the effective performance of the MDL-MEOLP model with an accuracy of 97.58% over existing methodologies. Although the proposed algorithm functions well, it is primarily limited by its reliance on image-based information, which may fail to capture all geological and operational variations in mining settings. Furthermore, its high computational complexity may limit its viability in real-world applications.

Regardless the promising performance of MDL-MEOLP method, certain limitations remains. First, the dataset used is of limited in size and extracted from a single source, which may affects the generalization of ore feeds with various imaging conditions. It has not been verified on other ore types with substantially different density and texture distributions. The future work will be focussed on validating MDL-MEOLP model over larger and diverse multi-site datasets, which explores lightweight frameworks for real time edge deployments, and extending the architecture to related mineral exploration works such as ore-grade estimation and multi mineral classifications. Lastly, explainable AI methodology can be added to make the performance simpler to interpret for mining engineers.

An Intelligent Writing Tutor for ESL Learners: A Rule-Based and NLP-Assisted Feedback Framework

Ruth L. Ladwingon
Department of Languages, Kalinga State University, Bulanao, Tabuk City, Kalinga, Philippines

***Abstract*—Writing remains one of the most challenging skills for English as a Second Language (ESL) learners because it requires the coordinated application of grammar, vocabulary, and written discourse conventions. This study proposes an Intelligent Writing Tutor that integrates corpus-informed error analysis, natural language processing (NLP), and rule-based reasoning to generate individualized and explainable writing feedback for ESL learners. Guided by a mixed-methods Design Science Research approach, weekly journal entries produced by Ilocano-speaking English language majors at the Kalinga State University served as the learner corpus for analysis. Manual expert annotation based on Corder's Error Analysis framework identified lexical, morphological, syntactic, and mechanical errors that informed the development of an interpretable rule-based feedback engine. The analysis revealed that morphological errors were the most frequent, followed by mechanical, lexical, and syntactic errors, with verb tense misuse emerging as the dominant writing difficulty. Qualitative findings further indicated that many of the observed errors reflected first-language interference, particularly in tense marking, subject–verb agreement, preposition usage, and lexical choice. The proposed framework operationalizes learner texts through preprocessing, NLP-assisted error detection, rule-based error classification, feedback generation, and recommendation modules to produce individualized feedback reports. The study demonstrates the feasibility of integrating explainable NLP techniques and second language acquisition principles into an educational writing support system. Because the framework was developed using journal writings from Ilocano-speaking learners in a single institution, its applicability to other learner populations requires further investigation.**

Keywords*—Corpus-informed instruction; educational technology; English as a Second Language; Intelligent Writing Tutor; natural language processing; rule-based feedback

I. Introduction

Writing proficiency is a fundamental component of second language acquisition (SLA) and an essential competency for academic success, professional communication, and lifelong learning. Among learners of English as a Second Language (ESL), writing is often regarded as one of the most challenging language skills because it requires the simultaneous coordination of linguistic knowledge, discourse organization, vocabulary selection, and grammatical accuracy. Difficulties in writing frequently emerge from learners' limited mastery of the target language and the influence of their first language (L1), resulting in persistent errors that impede effective communication [1], [2].

Early studies on error analysis established that learner errors are not random occurrences but valuable indicators of the language acquisition process. Corder argued that errors reveal learners' underlying hypotheses about the target language and provide insights into instructional needs [3], [4]. Similarly, Dulay and Burt emphasized that second language errors reflect developmental strategies employed by learners as they construct interlanguage systems [5]. These perspectives shifted the focus of language instruction from merely correcting mistakes to understanding the cognitive and developmental mechanisms underlying learner performance.

Interlanguage theory further explains that learners gradually develop an independent linguistic system that incorporates characteristics of both the native and target languages. Such systems evolve dynamically as learners receive additional exposure to the target language [6], [7]. Krashen likewise proposed that language acquisition occurs through meaningful input and progressive internalization of linguistic structures, although learners may continue to exhibit transitional forms during the acquisition process [8]. Consequently, ESL writing errors should be interpreted not solely as deficiencies but as developmental manifestations that require targeted pedagogical responses.

Among the factors contributing to writing difficulties, L1 interference remains one of the most extensively investigated phenomena in SLA research. The transfer of native language structures often affects syntax, morphology, vocabulary use, and discourse organization in learners' written production [9], [10]. Studies conducted among Chinese, Indonesian, Malaysian, and other multilingual ESL populations consistently demonstrate that negative transfer contributes significantly to recurring grammatical errors and non-native patterns in writing [11], [12].

Research has documented various manifestations of native language interference, including tense inconsistency, omission of articles, subject–verb disagreement, inappropriate lexical selection, and direct translation from the mother tongue [13], [14]. Such transfer effects frequently interact with developmental errors arising from incomplete acquisition of English grammatical rules [15], [16]. These findings highlight the need for instructional approaches capable of distinguishing between developmental mistakes and transfer-induced errors to facilitate more effective intervention.

Contemporary investigations further reveal that learner errors exhibit systematic patterns that can inform instructional design. Dependency relations, conceptual transfer, and bilingual processing mechanisms influence the production and interpretation of written texts among language learners [17], [18]. Visual analyses of SLA research trends likewise indicate growing scholarly interest in bilingual acquisition, interlanguage

development, and evidence-based pedagogical practices aimed at improving writing performance [19], [20].

Traditional approaches to writing instruction primarily rely on teacher-mediated feedback. Although teacher feedback is widely recognized as valuable, it often requires considerable time and effort, particularly in large classes where individualized guidance becomes difficult to sustain. Learners may consequently receive delayed feedback, limiting opportunities for immediate revision and reflection [21], [22]. These limitations have encouraged the exploration of technology-enhanced instructional approaches capable of providing timely and consistent support.

Recent advances in natural language processing (NLP) and artificial intelligence have transformed educational practices through the development of intelligent systems capable of analyzing textual data and generating meaningful recommendations. NLP techniques have demonstrated effectiveness in extracting linguistic features, identifying patterns, and supporting automated analysis across diverse domains [23], [24]. In educational contexts, such technologies offer opportunities to augment teacher expertise through intelligent feedback mechanisms that facilitate formative assessment.

Automated writing evaluation systems have increasingly incorporated machine learning and NLP algorithms to detect grammatical inaccuracies and provide corrective suggestions. Resume screening systems employing NLP techniques have demonstrated the capacity of computational models to identify patterns within unstructured textual documents [25], [26]. Although these applications originate outside language education, they illustrate the broader potential of NLP-assisted systems for analyzing written language and generating evidence-based recommendations.

The growing adoption of intelligent systems has also generated important discussions regarding transparency, fairness, and ethical implementation. Scholars emphasize that algorithmic decision-making should remain interpretable and accountable to avoid reinforcing hidden biases [27], [28]. Reviews of fairness in artificial intelligence advocate the integration of explainable mechanisms that enable users to understand the rationale underlying system-generated outputs [29], [30]. Within educational settings, such considerations are essential because automated feedback directly influences learners' perceptions of their abilities and subsequent learning behaviors.

Despite the emergence of commercial grammar-checking tools, many existing systems emphasize surface-level corrections while providing limited pedagogical explanations tailored to learners' developmental needs. Few systems explicitly integrate principles from error analysis, interlanguage theory, and native language transfer into their feedback mechanisms. Consequently, learners may receive corrective suggestions without understanding the linguistic causes of their errors or strategies for improvement [31], [32].

A rule-based framework informed by SLA theories offers a promising alternative for educational applications. Rule-based systems enable transparent identification of linguistic patterns while maintaining alignment with pedagogical objectives [33], [34]. When integrated with NLP-assisted text processing, such systems can provide immediate diagnostic feedback, classify error types, and generate instructional recommendations that support learner reflection and self-regulation.

Recent advances in automated writing evaluation (AWE) have enabled the development of intelligent systems capable of detecting grammatical, lexical, and stylistic errors while providing immediate corrective feedback to language learners. Commercial platforms such as Grammarly, Criterion, and Cambridge Write & Improve employ natural language processing and artificial intelligence techniques to assist users in improving written communication. These systems have demonstrated effectiveness in identifying surface-level grammatical errors and enhancing writing fluency; however, their feedback mechanisms often emphasize correction rather than explaining the linguistic reasons underlying learner errors. Consequently, opportunities for deeper language learning and learner reflection remain limited, particularly for English as a Second Language (ESL) learners whose writing difficulties are strongly influenced by first-language transfer and developmental interlanguage.

Recent research has also explored explainable artificial intelligence (XAI) in educational technologies to improve the transparency and interpretability of intelligent tutoring systems. Rather than providing opaque automated corrections, explainable systems seek to present understandable reasoning that enables learners to recognize why an error occurred and how similar mistakes can be avoided. Within second language learning, integrating explainable feedback with principles of Error Analysis and Interlanguage Theory has the potential to support meaningful language development while preserving teachers' instructional roles.

Despite these developments, relatively few intelligent writing support systems have been designed specifically for learners whose writing reflects localized linguistic characteristics such as Ilocano language interference. Existing automated writing evaluation systems generally rely on large multilingual corpora and statistical language models, which may not adequately capture recurrent error patterns associated with specific first-language backgrounds. The present study addresses this gap by developing an explainable Intelligent Writing Tutor that integrates corpus-informed analysis, second language acquisition theories, and rule-based natural language processing to generate pedagogically meaningful and context-sensitive writing feedback for Ilocano-speaking ESL learners.

Guided by these considerations, this study proposes an Intelligent Writing Tutor for ESL Learners that integrates rule-based reasoning and NLP-assisted feedback mechanisms. The framework seeks to detect common writing errors, categorize them according to established linguistic theories, and generate targeted recommendations that complement teacher instruction. By combining theoretical foundations from SLA with contemporary computational approaches, the proposed framework aims to enhance feedback quality, promote learner autonomy, and contribute to the development of explainable educational technologies that support ESL writing

improvement. This study sought to answer the following research questions:

- What lexical, morphological, syntactic, and mechanical errors are most frequently produced by Ilocano-speaking ESL learners?
- How can the identified writing error patterns be transformed into a rule-based and NLP-assisted Intelligent Writing Tutor framework?
- How can corpus-informed linguistic analysis and explainable rule-based reasoning be integrated to generate individualized writing feedback for ESL learners?
- How do language experts evaluate the proposed Intelligent Writing Tutor in terms of accuracy, relevance, clarity, usefulness, and practicality?

This study makes four primary contributions. First, it develops an authentic learner corpus consisting of journal writings produced by Ilocano-speaking ESL learners, providing empirical evidence of recurrent writing difficulties influenced by first-language transfer. Second, it proposes an explainable Intelligent Writing Tutor that combines corpus-informed linguistic analysis, natural language processing, and rule-based reasoning to generate individualized writing feedback. Third, the framework operationalizes principles from Error Analysis, Interlanguage Theory, and Language Transfer Theory into interpretable computational rules that support pedagogically meaningful recommendations. Finally, the study contributes an educational technology framework that emphasizes transparency, instructional relevance, and explainability, thereby complementing rather than replacing teacher-mediated writing instruction.

II. Methodology

A. Research Design

This study employed a Design Science Research (DSR) methodology integrated with a mixed-methods research design to develop and evaluate an Intelligent Writing Tutor for ESL learners. The Design Science Research approach was adopted because the primary objective of the study was to design, develop, and validate an educational artifact capable of addressing authentic challenges encountered by ESL learners in English writing. The artifact developed in this study consisted of a rule-based and Natural Language Processing (NLP)-assisted feedback framework intended to support teachers and learners through automated writing diagnosis and targeted feedback generation. The mixed-methods design enabled the integration of quantitative and qualitative approaches throughout the investigation. The quantitative component focused on the identification, categorization, and frequency analysis of writing errors occurring in learners' written outputs. The qualitative component involved the interpretation of error manifestations, examination of L1 interference patterns, and formulation of pedagogically meaningful feedback recommendations. This methodological integration provided a comprehensive understanding of learners' writing difficulties while facilitating the development of an evidence-based intelligent tutoring framework. Consistent with Design Science Research principles, the study followed problem identification and motivation, artifact design and development, demonstration using authentic learner data, evaluation of the generated feedback mechanisms, and communication of findings as major phases. The methodological structure was adapted from contemporary AI-assisted educational frameworks while remaining grounded in established theories of second language acquisition and error analysis. Fig. 1 illustrates the overall process employed in the study to identify first language (L1) interference patterns in English as a Second Language (ESL) writing and transform the findings into targeted instructional interventions.

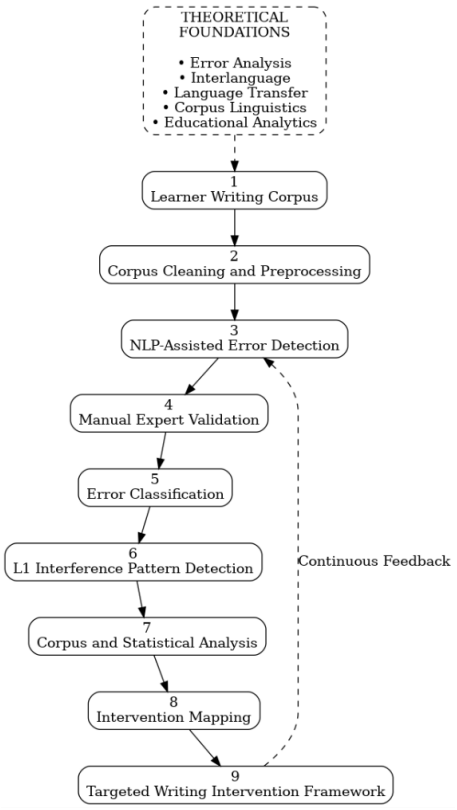

Fig. 1. Conceptual and operational framework for detecting L1 interference patterns in ESL writing toward targeted writing interventions.

The framework integrates theoretical foundations from applied linguistics with corpus-based and natural language processing (NLP) techniques to support evidence-based decision-making in writing instruction.

At the top of the framework are the theoretical foundations, which provide the conceptual basis of the study. Error Analysis explains how learner errors are systematically examined to identify recurring difficulties in language production. Interlanguage Theory views learner language as a transitional linguistic system that evolves during second language acquisition. Language Transfer Theory accounts for the influence of learners' native language structures on their English writing performance. Corpus Linguistics provides methods for analyzing authentic learner texts through large collections of written data, while Educational Analytics supports the interpretation of writing data to generate instructional insights and interventions.

The operational process begins with Learner Writing Corpus, where essays and written outputs produced by ESL learners are collected to form the corpus used in the analysis. These authentic texts serve as the primary data source for identifying language patterns and writing difficulties.

In Corpus Cleaning and Preprocessing, the collected texts undergo preparation procedures to improve data quality. This stage includes organizing the corpus, removing irrelevant symbols or duplicate entries, standardizing formats, and preparing the textual data for computational analysis.

The preprocessed corpus is then subjected to NLP-Assisted Error Detection. At this stage, natural language processing tools automatically identify potential grammatical, lexical, and syntactic errors found in learner writing. Automated detection increases efficiency by processing large amounts of text and highlighting probable error locations.

Recognizing that automated methods may produce inaccurate classifications, Manual Expert Validation is incorporated. Language experts review the NLP-generated outputs to confirm the accuracy of identified errors, eliminate false detections, and ensure the reliability of the findings.

Validated errors are subsequently organized in Error Classification. The errors are categorized according to predefined linguistic categories such as grammatical, lexical, mechanical, or syntactic errors. This classification facilitates a deeper understanding of the specific challenges experienced by ESL learners.

After classification, L1 Interference Pattern Detection determines whether the identified errors reflect influences from the learners' native language. This stage distinguishes transfer-related errors from developmental errors associated with the natural process of second language acquisition.

The detected patterns are then subjected to Corpus and Statistical Analysis. Frequency counts, descriptive statistics, and corpus-based analyses are performed to determine the prevalence, distribution, and significance of different error types and interference patterns. The results reveal dominant learner difficulties and provide empirical evidence for instructional planning.

Based on these analytical findings, Intervention Mapping links the identified learner needs to appropriate instructional responses. Specific interventions are designed to address the most frequent and persistent error patterns observed in the corpus.

The process culminates in the Targeted Writing Intervention Framework, which represents the final output of the study. The framework proposes evidence-based instructional strategies, focused grammar instruction, corpus-informed learning activities, reflective writing practices, and feedback mechanisms intended to mitigate L1 interference and improve ESL writing competence.

A notable feature of the framework is the Continuous Feedback Loop, represented by the dashed arrow connecting the final intervention framework back to the NLP-assisted error detection stage. This feedback mechanism indicates that interventions are not static; rather, learner progress is continuously monitored through subsequent writing outputs. New data generated after intervention implementation can be reanalyzed, allowing the framework to refine error detection processes, validate instructional effectiveness, and adapt future interventions based on evolving learner needs.

B. Research Locale and Respondents

The study was conducted at the College of Education of Kalinga State University, Philippines. The institution was selected because English language majors regularly engage in academic writing activities that provide authentic samples for examining second language writing performance. Twenty participants consisted of second-year and third-year Bachelor of Secondary Education major in English students whose first language was Ilocano and who learned English as a second language. Participants were selected through purposive sampling based on the following inclusion criteria:

- They were officially enrolled during the conduct of the study.
- English was learned as a second language.
- Ilocano served as their primary first language (L1).
- They regularly submitted journal or diary writing outputs as part of their coursework requirements.

This participant profile provided a linguistically homogeneous learner population, allowing the study to examine recurring writing errors and first-language interference patterns with minimal variation arising from different linguistic backgrounds. The use of authentic classroom writing further strengthened the ecological validity of the learner corpus because the collected texts reflected naturally occurring language production rather than responses generated under examination conditions.

C. Corpus of the Study

The learner corpus analyzed in this study consisted of weekly journal entries and reflective writings produced by the participating English language majors throughout the data collection period. Students were encouraged to write about personal experiences, academic activities, reflections, and other meaningful events using English as the medium of expression. Because the writing tasks emphasized authentic communication rather than examination performance, the collected texts captured naturally occurring learner language and genuine manifestations of interlanguage development.

Each journal entry served as an independent corpus document. Following collection, all writings were digitized, anonymized, and assigned unique identification codes to ensure confidentiality throughout the analysis. The completed corpus was subsequently organized into a structured electronic repository for annotation and computational processing.

The learner corpus served two important purposes. First, it provided empirical evidence for identifying recurring lexical, morphological, syntactic, and mechanical errors among Ilocano-speaking ESL learners. Second, it functioned as the primary knowledge source for constructing the handcrafted linguistic rules implemented within the proposed Intelligent Writing Tutor.

D. Corpus Annotation and Validations

Prior to computational analysis, the learner corpus underwent manual annotation to establish the reference standard for identifying writing errors. Annotation was guided by Corder's Error Analysis Framework [35], which classifies learner errors according to their linguistic characteristics and probable underlying causes. Each journal entry was examined to identify lexical, morphological, syntactic, and mechanical errors before being assigned to the appropriate linguistic category.

To improve annotation consistency, the annotated corpus was independently reviewed by language experts with specialization in English language teaching and applied linguistics. Differences in annotation were discussed until consensus was reached before the finalized annotations were incorporated into the rule base of the Intelligent Writing Tutor.

The manually validated corpus served as the ground truth for constructing the rule-based feedback engine and ensuring that the automated error detection module reflected authentic learner writing patterns rather than purely computational assumptions.

E. Proposed Intelligent Writing Tutor Framework

The proposed Intelligent Writing Tutor (IWT) transforms learners' written outputs into targeted instructional feedback by integrating rule-based reasoning with natural language processing (NLP) techniques. The framework consists of five interconnected modules: Input, Preprocessing, Error Detection, Feedback Generation, and Recommendation, which are also illustrated in Fig. 2. The Input Module collects learners' digitized writing outputs, particularly journal entries, which serve as the primary source of textual data. These writing samples are then processed by the Preprocessing Module, where standard NLP procedures such as lowercasing, tokenization, sentence segmentation, punctuation normalization, part-of-speech tagging, and lemmatization are performed to prepare the texts for analysis.

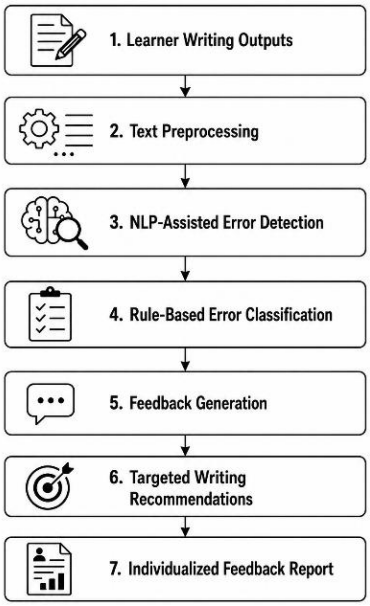

Fig. 2. Overall architecture of the proposed Intelligent Writing Tutor showing the interaction between the input module, NLP processing pipeline, rule-based error detection, feedback generation, and recommendation engine.

The Intelligent Writing Tutor employs a hybrid architecture that combines conventional natural language processing techniques with handcrafted linguistic rules. During preprocessing, learner texts undergo normalization, sentence segmentation, tokenization, part-of-speech tagging, lemmatization, and dependency parsing to generate linguistic representations suitable for subsequent analysis. The extracted linguistic features are then evaluated using rule-based pattern matching to detect lexical, morphological, syntactic, and mechanical errors. Rather than relying solely on statistical prediction, the framework explicitly associates each detected error with interpretable grammatical rules that enable the generation of pedagogically meaningful explanations and corrective recommendations.

The Error Detection Module employs a hybrid approach combining NLP-assisted techniques and handcrafted linguistic rules to identify four categories of writing errors: lexical, morphological, syntactic, and mechanical errors. The detected errors are subsequently interpreted by the Feedback Generation Module, which provides explanations of the identified errors, examples of correct usage, suggested revisions, and learning tips. When applicable, the system also indicates whether the errors may be associated with developmental interlanguage processes or potential L1 interference. The Recommendation Module synthesizes the analysis results and generates individualized feedback reports. These reports summarize the frequency and dominant types of errors, identify possible interference patterns, and recommend appropriate learning activities and writing improvement strategies tailored to the learner's needs.

F. Data Collection Procedure

Data collection was conducted through a structured five-phase procedure to ensure the systematic development of the Intelligent Writing Tutor framework.

1) Corpus compilation. Students' weekly journal entries served as the primary source of data. The collected writings were digitized and organized into an electronic corpus. To facilitate tracking, management, and confidentiality, each learner document was assigned a unique identification code.

2) Corpus preparation. The compiled corpus underwent preprocessing to improve consistency and analytical readiness. This phase involved standardizing document formats, correcting encoding inconsistencies, and cleaning the textual data. Non-linguistic elements unrelated to the objectives of the study, such as irrelevant symbols, duplicate entries, and extraneous formatting marks, were removed from the corpus.

3) Manual expert annotation. Initial error analysis was performed manually by the researcher following the procedures proposed by Corder. The process involved three major stages: error identification, error description, and error explanation. Identified errors were subsequently classified into four linguistic categories, namely lexical, morphological, syntactic, and mechanical errors. This annotation process established the reference framework for identifying recurring learner difficulties and validating subsequent system outputs.

4) Rule construction. Patterns emerging from the annotated corpus were examined to identify frequently occurring writing errors. These recurrent patterns informed the formulation of explicit linguistic rules that formed the knowledge base of the Intelligent Writing Tutor. The resulting rule set enabled the system to recognize specific error types and provide context-appropriate feedback and intervention suggestions.

5) System demonstration. The completed framework was then applied to actual learner writing samples to demonstrate its operational capability. Through this process, the Intelligent Writing Tutor generated automated feedback, targeted writing recommendations, and individualized feedback reports designed to support learners in improving their writing performance and addressing identified weaknesses.

G. Data Preprocessing

Prior to automated error detection, all learner writings underwent a structured preprocessing workflow to improve data quality and analytical consistency. First, all documents were converted into a standardized electronic format and transformed into lowercase text to ensure uniform lexical representation. Non-linguistic symbols, duplicate characters, and formatting inconsistencies were subsequently removed.

The cleaned texts then underwent sentence segmentation followed by tokenization, enabling the identification of individual lexical units. Part-of-speech tagging assigned grammatical categories to each token, while lemmatization reduced inflected words to their canonical forms. Dependency parsing was subsequently applied to identify grammatical relationships among sentence constituents, providing syntactic information necessary for rule-based error detection.

Finally, the extracted linguistic features were transformed into structured representations that served as input to the Intelligent Writing Tutor. These preprocessing procedures enhanced the consistency, reliability, and interpretability of the subsequent NLP-assisted error detection process.

H. NLP-Assisted Error Detection Module

The proposed framework employed natural language processing (NLP) techniques to automatically identify linguistic deviations in learners' written outputs. The error detection process encompassed four major categories of writing errors.

Lexical analysis was conducted to detect inappropriate word choice, collocational misuse, preposition misuse, and literal translations that may reflect L1 influence. Morphological analysis identified tense inconsistencies, incorrect verb forms, pluralization errors, and omissions of auxiliary verbs. Syntactic analysis focused on detecting subject–verb disagreement, sentence fragments, run-on sentences, violations of parallel structure, and other faulty sentence constructions. In addition, mechanical analysis examined punctuation errors, capitalization problems, spelling inaccuracies, and inappropriate formatting conventions.

The identified linguistic categories were derived from error patterns commonly reported in ESL writing studies and reflected the types of errors frequently observed among language majors' written compositions. By integrating NLP techniques with linguistically informed rules, the module enabled systematic, efficient, and consistent detection of writing errors for subsequent classification and feedback generation.

I. Rule-Based Feedback Engine

The Intelligent Writing Tutor employed an interpretable rule-based engine to transform detected errors into pedagogically meaningful feedback. Feedback rules followed the structure presented in Algorithm 1. The feedback engine operates using explicit IF–THEN production rules derived from recurring writing errors observed in the annotated learner corpus. Each detected linguistic error activates a corresponding rule that determines the appropriate error category, identifies possible causes, generates pedagogical explanations, retrieves relevant corrective examples, and recommends targeted learning activities. Because the decision-making process is rule-driven rather than probabilistic, every feedback message remains transparent and fully explainable to both teachers and learners.

Algorithm 1. Rule-Based Feedback Engine of the Intelligent Writing Tutor

```
Input: Detected writing errors from the NLP-assisted error detection module
Output: Individualized feedback, corrective examples, and targeted learning recommendations
    Initialize Feedback Report;
    For each detected error do
      Identify the corresponding error pattern;
      Determine the error category
        (Lexical, Morphological, Syntactic, or Mechanical);
      Analyze the possible cause of the error;
      Generate a corrective explanation describing
      why the error occurred;
      Retrieve or construct an appropriate
      correct example illustrating proper usage;
      Recommend a learning strategy or intervention
      aligned with the identified error type;
      Append the generated feedback to the
      learner's feedback report;
    End For
    Produce the individualized feedback report;
    Display targeted writing recommendations;
    Return the completed feedback report.
    Example Rule Execution
    If Subject–Verb Agreement Error is Detected Then
      Category ← Syntactic Error;
      Explanation ← "The verb does not agree with the
              subject in number.";
      Correct Example ← "She goes to school every day.";
      Recommendation ← "Review singular and plural
              subject–verb agreement rules.";
    End If
```

The rule-based feedback engine transforms identified learner errors into interpretable and pedagogically meaningful responses. By explicitly linking detected error patterns with explanations, examples, and intervention strategies, the framework promotes transparency and enables learners to

understand the rationale behind each recommendation while supporting self-regulated improvement in writing performance.

J. Evaluation of the Framework

The proposed Intelligent Writing Tutor framework underwent a comprehensive evaluation to establish its validity, pedagogical relevance, and practical applicability in supporting ESL writing instruction. Evaluation was conducted through two complementary approaches: expert review and corpus-based system demonstration. The expert review examined the extent to which the framework aligned with instructional needs and accepted principles in language education and educational technology. A panel of experts composed of specialists in ESL instruction, Applied Linguistics, and Educational Technology was purposively selected to assess the quality and functionality of the framework. These experts evaluated the framework using a five-point Likert scale, where 5 indicated Strongly Agree, 4 indicated Agree, 3 indicated Moderately Agree, 2 indicated Disagree, and 1 indicated Strongly Disagree. The evaluation focused on five key dimensions considered essential for intelligent educational support systems, as presented in Table I.

TABLE I. FIVE KEY DIMENSIONS CONSIDERED ESSENTIAL FOR INTELLIGENT EDUCATIONAL SUPPORT SYSTEMS.

Criterion	Description
Accuracy	The extent to which the framework correctly identifies and classifies writing errors and generates appropriate feedback.
Relevance	The degree to which the generated explanations and recommendations address learners' actual writing needs and difficulties.
Clarity	The understandability, coherence, and comprehensibility of the feedback and corrective explanations produced by the system.
Usefulness	The perceived potential of the framework to facilitate writing improvement, promote learner awareness, and support instructional decision-making.
Practicality	The feasibility of implementing the framework within authentic educational environments considering available resources, teacher workload, and classroom conditions.

In addition to expert validation, a corpus demonstration was conducted to examine the operational capability of the Intelligent Writing Tutor. Actual learner writings were processed through the framework to demonstrate its ability to detect errors, classify error types, generate corrective explanations, provide illustrative examples, and produce targeted writing recommendations. This demonstration enabled evaluators to examine the transparency and pedagogical appropriateness of the framework outputs under realistic instructional scenarios. The weighted mean for each evaluation criterion was computed to determine the overall level of acceptability of the framework. The resulting interpretations provided empirical evidence regarding the strengths and areas for enhancement of the proposed system prior to its wider implementation.

K. Data Analysis

The study employed both quantitative and qualitative analytical procedures to examine learner writing errors and generate evidence-based interventions. The integration of these approaches enabled a comprehensive understanding of learners' writing difficulties while informing the development of individualized feedback mechanisms within the Intelligent Writing Tutor.

1) Quantitative analysis. Quantitative analysis focused on determining the prevalence and distribution of identified writing errors within the learner corpus. Frequency counts and percentage distributions were computed to identify dominant error categories and recurring linguistic patterns. The percentage of occurrence for each error type was calculated using the following formula:

$$P = \frac{f}{N} \times 100 \quad (1)$$

where, P is the percentage of occurrence of a specific error category; f is the frequency of occurrence of the identified error type; and N is the total number of errors identified from the learner corpus.

The resulting descriptive statistics facilitated the identification of the most problematic areas in learner writing and provided empirical evidence for prioritizing instructional interventions. Error distributions were subsequently organized according to lexical, morphological, syntactic, and mechanical categories to determine patterns requiring targeted support. For the framework evaluation, weighted means were likewise computed to summarize expert ratings across the established evaluation criteria. The weighted mean was determined using:

$$WM = \frac{\sum fx}{N} \quad (2)$$

where, WM is the weighted mean; f is the frequency of responses for each rating category; x numerical value assigned to each Likert-scale response; and N is the total number of responses.

The computed means served as indicators of the overall acceptability and effectiveness of the proposed framework.

2) Qualitative analysis. Qualitative analysis was guided by Corder's Error Analysis Framework, which provided a systematic procedure for examining the nature and possible causes of learner errors. The analysis involved three interconnected stages:

a) Error identification: locating deviations from accepted English language conventions within the learner corpus.

b) Error description: classifying and describing the linguistic characteristics of the identified errors.

c) Error explanation: interpreting the potential sources and underlying causes of the observed error patterns.

The qualitative findings enabled deeper insights into learners' interlanguage development and the influence of first-language transfer on second-language writing performance. Furthermore, these analysis informed the construction of rule-based explanations and pedagogically appropriate recommendations embedded within the Intelligent Writing Tutor.

The integration of quantitative frequency analysis and qualitative error interpretation facilitated the development of individualized interventions grounded in authentic learner data.

Through this mixed analytical approach, the framework not only identified what errors learners produced but also explained why such errors occurred and how they could be effectively addressed.

By synthesizing authentic learner corpora, principles of second language acquisition, corpus-informed evidence, natural language processing techniques, and interpretable rule-based reasoning, the proposed methodology establishes a transparent, evidence-driven, and pedagogically grounded Intelligent Writing Tutor. The resulting framework is capable of generating individualized feedback, targeted recommendations, and actionable instructional insights that support ESL learners in improving their writing proficiency while assisting teachers in delivering data-informed and responsive writing instruction.

L. Ethical Considerations

Ethical approval was obtained from the appropriate institutional ethics review body prior to data collection. The study adhered to the principles of respect for persons, beneficence, justice, confidentiality, and voluntary participation. Participants were informed of the study's objectives, procedures, voluntary nature of their involvement, their right to withdraw without penalty, and the intended use of their weekly journal entries for research purposes before providing informed consent. To ensure anonymity and confidentiality, learner writings were assigned unique identification codes and all personally identifiable information was removed from the corpus. Digital files and research records were stored in password-protected repositories accessible only to authorized researchers. Anonymized learner texts were used solely for system demonstration and academic purposes, and all findings were reported in aggregate form to protect participants' rights, privacy, and welfare. The generated feedback had no effect on participants' academic standing or evaluation.

III. Results and Discussion

A. Distribution of Language Errors

The analysis of the diary entries revealed that language majors experienced difficulties across morphological, syntactic, lexical, and mechanical aspects of writing. The results indicate that morphological errors constituted the most prominent category of errors, followed by mechanical, lexical, and syntactic errors. These findings suggest that learners encountered greater difficulty in applying grammatical rules governing word formation and tense usage than in sentence construction or punctuation.

1) Morphological errors. Morphological errors totaled 68 occurrences, with verb tense errors emerging as the most dominant subtype. Verb tense misuse accounted for 73.33% of all morphological errors, followed by pluralization errors (10.66%) and verb form errors (6.67%). The predominance of verb tense errors indicates that students struggled to express temporal relationships consistently in English. Since Ilocano verbs do not exhibit the same tense-marking system as English, learners frequently transferred first-language structures into their English compositions. Consequently, students shifted between present and past forms without maintaining temporal consistency. Pluralization errors further suggest incomplete mastery of English inflectional morphology. Difficulties involving regular and irregular noun forms indicate that learners tended to generalize grammatical rules or omitted plural markers altogether. Similarly, errors involving verb forms reflected uncertainty regarding the appropriate use of base forms, participles, and gerunds. These findings imply that learners require more explicit instruction on English tense systems and opportunities for repeated contextualized practice to internalize morphological patterns.

2) Syntactic errors. Twenty-six syntactic errors were identified from the corpus. Subject–verb agreement constituted the largest proportion (38.46%), followed by run-on sentences (23.08%), sentence structure errors (19.23%), parallelism errors (11.54%), and sentence fragments (7.69%). Subject–verb agreement difficulties indicate that students had problems recognizing grammatical relationships between sentence constituents. Such errors are often associated with negative language transfer because Ilocano does not consistently require agreement markers similar to those used in English. Run-on sentences suggest limited awareness of sentence boundaries and clause coordination. Students tended to connect independent ideas without employing appropriate punctuation or conjunctions. The occurrence of fragments further reflects challenges in constructing complete thoughts containing both subjects and predicates. Collectively, these findings reveal weaknesses in syntactic competence and demonstrate the need for instructional interventions emphasizing sentence construction, clause relationships, and editing strategies.

3) Lexical errors. Lexical analysis revealed 43 errors distributed across three categories. Word choice and correct usage represented the majority of lexical errors at 51.11%, followed by prepositional errors at 26.67%, while article errors accounted for 17.78%. The dominance of inappropriate word choice suggests limitations in vocabulary depth and semantic precision. Learners often selected words that were grammatically acceptable but contextually inappropriate, thereby obscuring intended meanings. Examples included the use of terms such as "heavy group" and other expressions directly translated from the learners' first language. Preposition errors indicate difficulties in understanding collocational patterns and the relational meanings conveyed by English prepositions. Because prepositional systems differ substantially between Ilocano and English, learners frequently omitted, substituted, or inserted incorrect prepositions. Article misuse likewise reflects the absence of equivalent article systems in many Philippine languages, resulting in confusion regarding the use of "a", "an", and "the". These results suggest that lexical development should extend beyond vocabulary memorization and include contextualized exposure to authentic language use.

4) Mechanical errors. Mechanical errors comprised 46 occurrences. Capitalization errors emerged as the most prevalent category, representing 60.87% of mechanical errors. Spelling errors accounted for 30.43%, while punctuation errors constituted 8.70%. The predominance of capitalization errors suggests inadequate familiarity with conventions governing

sentence beginnings, titles, and proper nouns. Spelling difficulties indicate weaknesses in orthographic knowledge and limited proofreading practices. Although punctuation errors occurred less frequently, they nevertheless affected clarity and coherence. Mechanical errors, despite being surface-level concerns, can influence readers' perceptions of writing quality. Consequently, explicit instruction in editing and self-monitoring strategies remains essential.

5) Aggregation of errors. To provide a clearer overview of the distribution of learner writing difficulties, the identified errors were aggregated according to the four major linguistic categories. Morphological errors constituted the largest proportion of all identified errors, indicating that learners experienced the greatest difficulty in applying English inflectional rules, particularly verb tense formation and agreement. Mechanical errors ranked second, reflecting recurring problems in capitalization, spelling, and punctuation. Lexical errors were primarily associated with inappropriate word choice and preposition usage, whereas syntactic errors occurred less frequently but demonstrated persistent weaknesses in sentence construction and grammatical agreement. Collectively, these findings indicate that learner difficulties extend beyond isolated grammatical mistakes and reflect systematic patterns associated with second language development and first-language transfer.

B. Patterns of Manifestation of Errors

Analysis of representative excerpts revealed recurring patterns underlying the identified errors. Verb tense errors manifested through three major patterns: inconsistency in tense usage, omission of auxiliary verbs, and incorrect verb forms used to indicate time relationships. Students frequently shifted from present to past tense within the same narrative without clear justification, creating ambiguity regarding the sequence of events. Lexical errors commonly appeared through inappropriate word choices and ambiguous expressions. Learners selected words that resembled intended meanings but failed to convey accurate semantic relationships. These patterns indicate limited lexical repertoire and overreliance on direct translation strategies. Article errors manifested through the interchange of indefinite articles and mismatches between articles and noun number, while prepositional errors involved incorrect selection and grammatical inconsistencies. These manifestations demonstrate learners' attempts to apply English rules despite incomplete understanding of their usage conditions. The recurrence of similar patterns across participants suggests that the observed errors were systematic rather than random.

C. L1 Interference in Learners' Writing

Qualitative analysis revealed that many of the identified errors reflected negative transfer from learners' first language. The findings indicate that L1 interference influenced morphological, syntactic, and lexical choices during English composition. Morphologically, the inconsistent marking of tense and omission of auxiliary verbs suggest reliance on native language structures that do not encode temporal distinctions in the same manner as English. Syntactically, subject–verb agreement errors demonstrate difficulties in adapting to grammatical relationships absent or less explicit in the first language. Lexically, learners frequently employed direct translations, resulting in awkward expressions and inappropriate word combinations. Prepositional misuse further illustrates attempts to map first-language conceptual relationships onto English structures. These findings support theories of language transfer, which posit that previously acquired linguistic knowledge influences second language production. While transfer may facilitate learning when structures are similar, substantial differences between languages often lead to systematic errors.

D. Implications for the Intelligent Writing Tutor Framework

The error patterns identified in the corpus provided empirical evidence for constructing the rule base of the proposed Intelligent Writing Tutor. Frequent verb tense inconsistencies, subject–verb agreement errors, inappropriate lexical choices, and capitalization problems informed the development of interpretable feedback rules capable of detecting recurrent learner difficulties. Drawing from the transparent and explainable feedback mechanisms demonstrated in recent intelligent educational systems, the framework translates detected error patterns into corrective explanations, examples, and targeted learning recommendations. The emphasis on interpretability mirrors the role of explainable systems in helping users understand the rationale behind automated outputs. Consequently, the Intelligent Writing Tutor extends traditional error analysis by moving beyond error identification toward personalized intervention. Through automated yet pedagogically grounded feedback, the framework supports learners in recognizing recurring weaknesses, developing self-editing skills, and improving overall writing proficiency.

The findings demonstrate that language majors encounter persistent challenges in English writing that are closely associated with first-language influence and incomplete mastery of target-language conventions. These results underscore the value of integrating corpus-informed analysis, error analysis principles, and rule-based natural language processing to provide evidence-based writing support for ESL learners.

E. Expert Evaluation of the Proposed Framework

To determine the educational acceptability of the proposed Intelligent Writing Tutor, the framework was evaluated by specialists in English language teaching, applied linguistics, and educational technology using the five evaluation dimensions presented in Table I. The evaluation examined the framework's accuracy, relevance, clarity, usefulness, and practicality in supporting ESL writing instruction.

The expert assessment indicated that the framework demonstrated satisfactory educational quality across all evaluation criteria. Experts particularly recognized the transparency of the rule-based feedback mechanism and the alignment of the generated recommendations with established principles of second language acquisition. The use of explicit linguistic rules enabled evaluators to understand how feedback was generated, thereby increasing confidence in the interpretability of the proposed system.

Although the evaluation confirmed the pedagogical relevance of the framework, several recommendations for future enhancement were identified. These included expanding the linguistic rule base, improving automated handling of complex sentence structures, and integrating more advanced natural language processing techniques to improve contextual feedback generation.

F. Computational Performance of the Error Detection Module

The operational capability of the proposed Intelligent Writing Tutor was examined by comparing the automatically detected writing errors against the manually annotated reference corpus. The comparison evaluated the agreement between the NLP-assisted detection module and expert annotations using standard information retrieval metrics, including Precision, Recall, and F1-score.

Precision measures the proportion of automatically detected errors that were correctly identified, while Recall indicates the proportion of actual learner errors successfully detected by the framework. The F1-score provides the harmonic mean of Precision and Recall, representing the overall effectiveness of the error detection module.

The use of these evaluation metrics provides objective evidence regarding the computational reliability of the proposed framework while complementing the expert-based educational evaluation.

G. Operationalization of the Intelligent Writing Tutor Framework

Beyond identifying the dominant writing errors, the study demonstrated how the proposed Intelligent Writing Tutor operationalizes authentic learner corpus data into individualized feedback and targeted instructional recommendations. The framework transforms learners' written outputs through a sequence of interconnected processes involving preprocessing, automated error detection, rule-based reasoning, and feedback generation.

The operational process begins with the submission of learners' weekly journal entries. These texts undergo preprocessing procedures, including text cleaning, tokenization, sentence segmentation, and linguistic normalization. The preprocessed texts are then analyzed by the NLP-assisted error detection module, which identifies potential lexical, morphological, syntactic, and mechanical deviations based on predefined linguistic patterns derived from the annotated corpus.

Detected errors are subsequently processed by the rule-based feedback engine. Using explicit IF–THEN rules constructed from recurring learner error patterns, the system classifies each error according to its linguistic category, determines its possible cause, generates corrective explanations, retrieves appropriate examples, and recommends corresponding learning strategies. The generated outputs are consolidated into individualized feedback reports designed to address the specific needs of each learner. Fig. 3 shows the operational flow of the Intelligent Writing Tutor Framework.

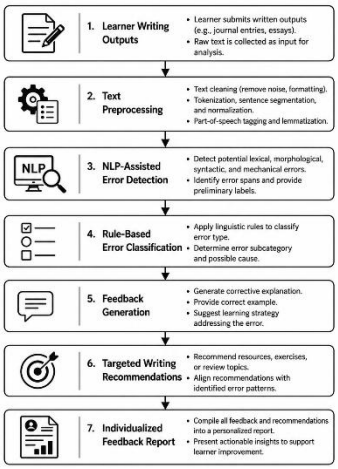

Fig. 3. End-to-end operational workflow demonstrating the transformation of learner writing into individualized feedback through NLP-assisted processing and rule-based reasoning.

To illustrate the framework's operation, consider the learner sentence:

"She go to school every day."

During preprocessing, the sentence is segmented and tokenized. The NLP module detects a mismatch between the singular subject (She) and the base verb form (go). The rule-based engine activates the corresponding subject–verb agreement rule and generates the following output:

- Error Category: Syntactic Error.
- Possible Cause: Incomplete mastery of subject–verb agreement rules and possible L1 influence.
- Corrective Explanation: The verb must agree with the subject in number.
- Correct Example: "She goes to school every day."
- Learning Recommendation: Review rules governing singular and plural subject–verb agreement and complete practice exercises involving present tense verbs.

Similarly, if the learner writes:

"Yesterday, I go to the market and buy vegetables."

The framework identifies verb tense inconsistency and produces feedback emphasizing the appropriate use of past tense forms. The learner receives explanations, corrected examples, and recommendations for reviewing tense formation and temporal consistency.

These demonstrations show that the Intelligent Writing Tutor does not merely identify errors but converts diagnostic information into meaningful pedagogical interventions. By integrating corpus evidence, principles of error analysis, and transparent rule-based reasoning, the framework provides interpretable and actionable feedback that supports learner autonomy, promotes self-editing skills, and assists teachers in delivering data-informed writing instruction.

The operationalization of the framework further highlights its potential applicability in ESL classrooms. Rather than replacing teacher judgment, the system functions as a supplementary instructional tool capable of providing immediate, individualized, and evidence-based feedback. Consequently, the framework bridges the gap between corpus-informed research findings and practical classroom interventions, enabling more responsive and targeted support for ESL learners.

H. Prototype of the Intelligent Writing Tutor

Fig. 4 illustrates the prototype of the proposed Intelligent Writing Tutor and demonstrates how the system transforms learners' written outputs into individualized feedback and instructional recommendations.

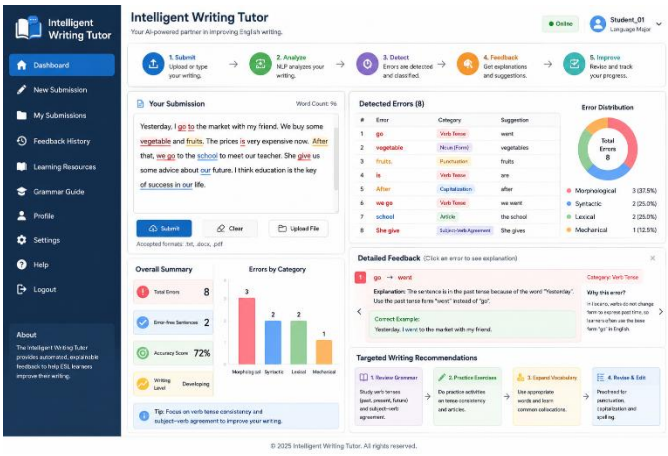

Fig. 4. Prototype interface of the Intelligent Writing Tutor illustrating learner text submission, automated error detection, rule-based feedback generation, and individualized writing recommendations.

The process begins when learners submit their essays or journal entries through the writing interface. The submitted text is then preprocessed through cleaning, tokenization, sentence segmentation, and linguistic normalization to prepare it for analysis.

The NLP-assisted error detection module subsequently examines the text to identify potential lexical, morphological, syntactic, and mechanical errors. Detected errors are forwarded to the rule-based classification engine, which applies predefined IF–THEN linguistic rules to determine the specific error category, identify possible causes, and generate appropriate corrective explanations.

The system then presents detailed feedback by highlighting the identified errors, explaining why they occurred, and providing correct examples to guide learners toward proper language use. Based on the detected patterns, the framework further generates targeted writing recommendations, such as reviewing grammar rules, practicing specific language structures, expanding vocabulary, or improving proofreading strategies. Finally, all outputs are consolidated into an individualized feedback report that summarizes learner performance, error distribution, and recommended interventions. Through this operational process, the Intelligent Writing Tutor serves as a supplementary instructional tool that provides immediate, transparent, and evidence-based feedback to support learners' writing development and assist teachers in delivering responsive ESL instruction.

I. Discussion

The findings demonstrate that Ilocano-speaking ESL learners continue to encounter persistent writing difficulties across morphological, lexical, syntactic, and mechanical domains, with morphological errors emerging as the most dominant category. This pattern is consistent with previous studies reporting that grammatical inflections, particularly tense marking and subject–verb agreement, remain among the most challenging aspects of English writing for second language learners. The recurrence of these errors further supports theories of interlanguage development, suggesting that learners gradually construct an evolving linguistic system that incorporates characteristics of both the first and target languages.

The analysis also highlighted the influence of first-language (L1) interference on second-language (L2) writing performance. The omission of auxiliary verbs, inconsistent tense marking, direct translation of expressions, and misuse of prepositions suggest that learners frequently relied on linguistic structures from their native language when composing in English. Such findings support theories of language transfer and error analysis, emphasizing that negative transfer remains a significant factor affecting ESL learners' written production.

Unlike commercial automated writing evaluation systems that primarily generate direct grammatical corrections, the proposed Intelligent Writing Tutor emphasizes explainable feedback grounded in second language acquisition theory. Rather than merely identifying an error, the framework explicitly explains why the error occurred, associates it with possible first-language interference or developmental language processes, and recommends appropriate learning strategies. This pedagogically oriented design supports learner reflection and complements teacher feedback rather than replacing instructional judgment.

Importantly, the identified error patterns provided the empirical basis for the development of the proposed Intelligent Writing Tutor. By operationalizing authentic learner corpus data through NLP-assisted error detection and rule-based reasoning, the framework transforms identified errors into individualized feedback, corrective explanations, and targeted writing recommendations. Rather than merely identifying mistakes, the system promotes learner awareness, self-editing, and reflective practice through transparent and interpretable feedback mechanisms.

The results underscore the value of integrating corpus-informed analysis, second language acquisition principles, and explainable educational technologies to support evidence-based writing instruction. The proposed framework demonstrates considerable potential as a supplementary instructional tool that assists teachers in delivering timely interventions while empowering ESL learners to improve their writing proficiency through personalized and actionable feedback.

J. Limitations of the Study

Several limitations should be acknowledged when interpreting the findings. First, the learner corpus was obtained

from English language majors enrolled at a single higher education institution, thereby limiting the generalizability of the findings to other educational contexts. Second, all participants shared Ilocano as their primary first language, and consequently the identified interference patterns may not represent learners from different linguistic backgrounds. Third, the corpus consisted exclusively of reflective journal writings; therefore, the framework has not yet been examined using other writing genres such as argumentative, narrative, or academic essays. Finally, although the proposed Intelligent Writing Tutor underwent expert validation and operational demonstration, the study did not include a controlled learner-based intervention to determine its effectiveness in improving writing performance over time. Future studies should validate the framework using larger and more diverse learner populations and evaluate its educational impact through experimental or longitudinal research designs.

IV. Conclusion and Recommendations

A. Conclusion

This study developed an Intelligent Writing Tutor that integrates corpus-informed error analysis, natural language processing, and rule-based reasoning to generate individualized and explainable feedback for English as a Second Language (ESL) learners. Analysis of authentic learner writings revealed that morphological errors, particularly verb tense misuse, were the most frequently occurring language difficulties, followed by mechanical, lexical, and syntactic errors. Qualitative analysis further demonstrated that many of these recurring errors reflected first-language interference and developmental characteristics commonly associated with second language acquisition.

Guided by these findings, the proposed framework transformed manually validated learner error patterns into interpretable computational rules capable of detecting writing errors and generating pedagogically meaningful explanations, corrective examples, and targeted learning recommendations. Rather than functioning solely as an automated grammar correction tool, the framework was designed to provide transparent feedback that supports learner reflection while complementing teacher-mediated instruction.

The expert evaluation indicated that the framework possesses strong pedagogical potential for supporting ESL writing instruction. Nevertheless, the present study focused primarily on framework development, corpus analysis, and expert validation. Consequently, the study does not claim that the proposed Intelligent Writing Tutor directly improves learner writing proficiency. Instead, the findings demonstrate that the framework provides a feasible and explainable approach for delivering individualized writing feedback grounded in authentic learner data and established second language acquisition theories.

B. Future Works

Future research should extend the proposed Intelligent Writing Tutor through the development of a fully functional web-based or mobile learning environment capable of providing real-time writing assistance to learners. Experimental and quasi-experimental studies involving learner participants should be conducted to determine the effectiveness of the framework in improving writing accuracy, revision behavior, learner autonomy, and overall writing proficiency.

The computational capabilities of the framework may likewise be enhanced through the integration of transformer-based natural language processing models and large language models (LLMs) capable of analyzing contextual, discourse-level, and stylistic writing issues beyond sentence-level grammatical errors. A hybrid architecture combining explainable rule-based reasoning with machine learning techniques may further improve detection accuracy while preserving transparency in automated feedback generation.

Future investigations should also evaluate the framework using larger and more diverse learner populations representing different first-language backgrounds, educational levels, and writing genres. Such validation would strengthen the generalizability of the proposed Intelligent Writing Tutor and provide additional evidence regarding its applicability across multilingual educational settings.

Future implementations may incorporate adaptive learning analytics, teacher dashboards, personalized learning recommendations, and longitudinal learner progress monitoring to support data-informed writing instruction and continuous learner development.

Acknowledgment

The author gratefully acknowledges the Kalinga State University for its institutional support throughout the conduct of this research. Artificial intelligence tools were used solely to assist with language refinement, organization of ideas, and manuscript formatting. All research design, data collection, analysis, interpretation of findings, and final decisions regarding the manuscript were performed and verified by the author.

Migration Method for Parametric Features in Heterogeneous CAD Systems

Gang WANG, Guangfa ZHANG
College of Mechanical Engineering, Shanghai Dianji University, Shanghai, China

***Abstract*—Parametric feature migration across different Computer-Aided Design (CAD) systems is a core technology that supports cross-platform collaborative design and product data reuse. Addressing the fundamental limitation of traditional geometry-based data exchange methods—their inability to transfer high-level design intent information such as construction history, parametric constraints, and feature dependency relationships—this study proposes a three-stage parametric feature migration method based on JavaScript Object Notation (JSON) neutral files. Following the methodology of "exchanging the modeling process rather than the model itself", the complete migration workflow is decomposed into three stages: Feature parameter extraction, which leverages the source CAD system's application programming interface to traverse the model feature tree in depth and serialize the modeling history into a structured JSON exchange file; Topology identification, which employs a multi-dimensional geometric descriptor-based topological element identification method and writes identification results into the JavaScript Object Notation file; and Data validation, which validates feature parameters to be transferred and retrieves transient data required for modeling to ultimately achieve model reconstruction. Taking Siemens NX and ZW3D (formerly VX CAD) as representative source and target systems, a complete feature extraction and regeneration prototype plugin was developed, verifying the feasibility of the proposed method between heterogeneous CAD systems.**

Keywords*—Heterogeneous CAD; feature migration; JSON neutral file; information extraction; topology identification

I. Introduction

In the context of globalization and deep integration of digital technologies in manufacturing, product collaborative design has become a critical means for enterprises to enhance their core competitiveness. Hoffmann et al. [1] pointed out in their foundational work on user-defined features that parametric features are not merely collections of geometric elements, but rather encapsulations of design knowledge—feature dependency relationships, constraint networks, and modeling sequences collectively constitute the design intent of a product. In collaborative design practice, different enterprises and departments select different computer-aided design (CAD) systems for product development based on functional requirements, operational habits, and economic considerations, leading to heterogeneity in model data formats and feature semantic systems [2]. Concurrently, with the widespread adoption of Model-Based Definition (MBD) technology in high-end manufacturing sectors such as aerospace and aviation, product 3D models have evolved from purely geometric carriers into comprehensive data containers that embody design, manufacturing, and inspection information [3]. This places higher demands on information exchange between heterogeneous CAD systems—requiring not only the transfer of geometric shapes but also the complete preservation of construction history, parametric constraints, feature associations, and engineering annotations as high-level design intent. Therefore, achieving reliable migration of parametric feature models between heterogeneous CAD systems has become a critical technology for building cross-platform product collaborative development frameworks.

Existing data exchange methods between heterogeneous CAD systems primarily fall into two categories: geometry-based exchange and feature-based exchange [4, 5]. The first category employs the Initial Graphics Exchange Specification (IGES), Standard for the Exchange of Product Model data (STEP), and other neutral file formats as bridges, realizing cross-system geometric data transfer through the exchange of Boundary Representation (B-Rep) models. Rappoport [6] proposed an early architecture for universal CAD data exchange, establishing a theoretical framework for subsequent research. The STEP AP242 application protocol can express certain feature semantic information, but mainstream commercial CAD systems have only implemented a limited functional subset of the standard; in practical engineering scenarios, high-level information such as modeling history, parametric constraints, and feature associations cannot be effectively transferred [7]. After conversion, the model essentially degrades into a "static geometric entity", losing its parametric editing capability.

To overcome these deficiencies, academia has proposed feature model-based data exchange methods. Choi et al. [8] were among the first to explore CAD part model exchange based on the macro-parametric approach. Mun et al. [9] subsequently proposed a set of standard neutral modeling commands, achieving procedural data exchange between heterogeneous CAD systems. Li et al. [10] further proposed a two-stage modeling procedure recovery method—whose core concept is to exchange the complete modeling operation process rather than the model itself, "simulating a human designer" in the target system to reconstruct parametric feature models step by step. This method decomposes the feature migration workflow into first-order information extraction and second-order information reconstruction stages: the first-order information extraction stage recovers explicit modeling operation sequences from the source CAD system's macro recording file; the second-order information reconstruction stage reconstructs interactive selection information (such as reference elements, datum elements, and direction elements of features) and implicit information automatically generated by the CAD system (such as constraint relationships, implicit parameters, and feature

geometric attributes) from operation sequences, thereby supplementing the key semantic information missing from macro files. This two-stage framework has been validated between typical CAD systems such as SolidWorks, UG, Pro/E, and CATIA. Zhang et al. [11] further investigated interoperability issues during feature data exchange from a quantitative optimization perspective, proposing a computational model for evaluating conversion quality. Shao et al. [12] systematically established a feature operation-centric model conversion interface scheme, defining feature operation primitives independent of specific CAD systems and accessing and reconstructing CAD model information at both the feature layer and geometric layer simultaneously, ensuring consistency of feature trees, dimensions, and constraint information before and after conversion. Zheng et al. [13] built upon Shao's work to propose four migration principles for singular features and the (F, T, P) topological element identification method, providing important methodological guidance for the complete preservation of design intent between heterogeneous CAD systems. At the semantic level of feature migration, Qin et al. [14] constructed an ontology-based feature mapping framework, while Tessier and Wang [15] proposed a feature mapping and verification method between CAD systems from an ontological perspective; these two contributions established a theoretical foundation for semantic interoperability of heterogeneous CAD models. In the domain of engineering annotation exchange, Camba et al. [16] proposed an extended 3D annotation mechanism to explicitly convey geometric design intent, offering new possibilities for the preservation of non-geometric information during feature migration.

The above research has laid an important theoretical foundation for heterogeneous CAD feature migration, but the following common limitations exist: in the process of heterogeneous CAD feature migration, to maintain the transfer of parameters, feature information, and assembly relationships while avoiding data loss, the majority of transfer content is stored and compiled in Extensible Markup Language (XML) file format. Sun [17] also adopted XML as the intermediate file format in his research on feature-based data exchange between heterogeneous CAD systems, further corroborating the prevalence of this technical approach. However, XML, while being a markup language with strong semantics, strict validation, and extensibility suitable for complex documents, metadata, configuration files, and scenarios requiring rigorous data validity, exhibits high redundancy and slow parsing when handling simple models composed of multiple small components.

To improve the compatibility and generality of neutral files in heterogeneous CAD data transfer, and to facilitate efficient conversion of simple model feature data, this study employs JavaScript Object Notation (JSON) neutral files as the intermediate data storage container for research on feature-based heterogeneous CAD model conversion technology. The proposed method follows a three-stage experimental framework of "feature parameter extraction + topology identification + data validation".

The overall technical approach is illustrated in Fig. 1. This framework divides the process of heterogeneous CAD parametric feature migration into three sequentially connected stages: the first stage is feature parameter extraction, which accesses the source CAD system's internal feature tree through its Application Programming Interface (API), serializing feature parameters and modeling history into a structured JSON exchange file; the second stage is topology identification, which constructs a multi-dimensional geometric descriptor-based topological element identification method and writes results into the JSON file; the third stage is data validation, which takes into account the fact that operating methods and kernels may differ between distinct CAD systems in order to maximally preserve the model's design intent during CAD system migration and ensure successful regeneration of feature models, thus verifying that feature parameter data can be accurately imported. Taking NX and ZW3D as typical cases, a corresponding prototype system was developed to verify the feasibility and effectiveness of the method.

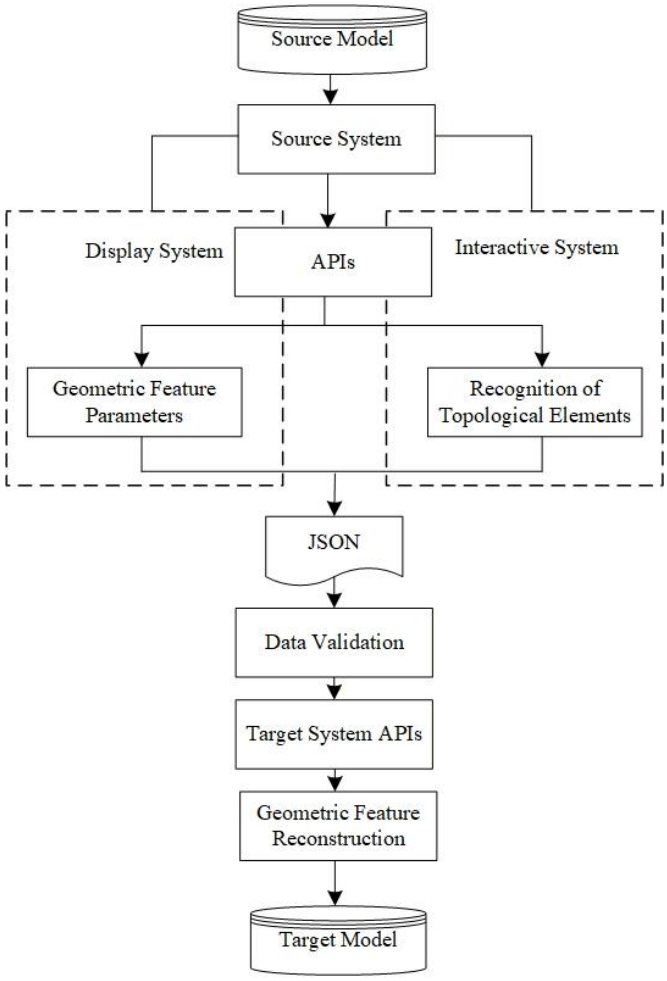

Fig. 1. Overall framework of heterogeneous model conversion.

II. Three-Stage Method for Heterogeneous CAD Parametric Feature Migration

As shown in Fig. 2, for the entire process of creating a source model, each operation step performed by the user generates a corresponding feature model based on the user's input command parameters, including constraints, implicit parameters, feature geometry, and physical attributes. The resulting feature model can be observed by the user in the display system, and the

driving feature parameter data is stored in the corresponding feature modules within the system. In addition to the model's feature parameters, there exist interactive information generated during the user's creation process, typically referring to the feature reference elements, base elements, and direction elements at the time of feature creation. This information is crucial for model reconstruction and serves to preserve design intent, particularly the correspondence of topological structures before and after model modifications.

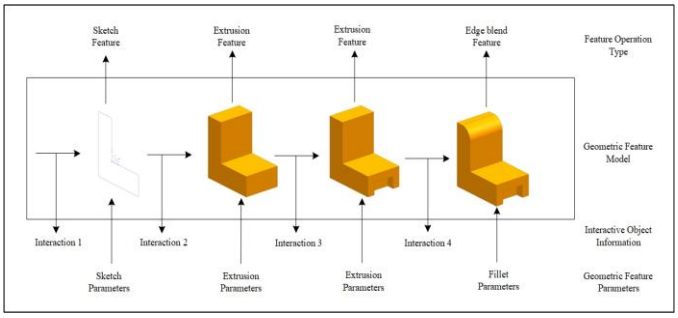

Fig. 2. Information generated during the creation of a parametric feature model.

A. Geometric Feature Parameter Extraction and Storage

The geometric feature parameter extraction stage requires the complete and accurate acquisition of all explicit modeling information of the parametric feature model from the source CAD system, organized in a structured and self-describing format to provide a data foundation for subsequent topology identification and target CAD feature model reconstruction.

Feature-based CAD systems accessed directly through their APIs generate a corresponding feature tree concurrently with user-interactive modeling, within which geometric feature information is recorded in internal data structures [12]. The traversal of the feature tree uses depth-first traversal (DFT), which was chosen over breadth-first traversal (BFT) for a deliberate reason: in parametric CAD modeling, feature creation follows a strict temporal sequence in which each feature depends on the geometric state produced by previously created features. DFT naturally reproduces this chronological ordering because it follows each branch of the feature tree to its deepest leaf before backtracking, thereby preserving the parent-to-child dependency chain. BFT, by contrast, would group features by their depth level and disrupt the temporal dependency order, potentially causing reconstruction failures in the target system when a child feature is reconstructed before its prerequisite parent feature has been fully resolved.

In the domain of heterogeneous CAD data exchange, the selection of a neutral file format directly affects the completeness of information, expressive capability, and engineering practicality. The fundamental deficiency of traditional STEP and IGES standards as neutral files for geometry-level exchange lies in the fact that their exchange target is the B-Rep of the parametric feature model rather than the modeling process [4]. In terms of information storage format selection, this method adopts JSON as the neutral exchange file format.

Compared with XML, JSON offers four principal advantages for storing CAD feature data:

1) Stronger adaptability: Through key-value pairs and nested arrays matching the CAD feature tree hierarchy, it can flexibly accommodate heterogeneous parameters of various features without strict format constraints.
2) Lower system resource consumption: It can intuitively express entity association relationships; one-to-many array relationships can be directly displayed through arrays, and topological elements carry their own tags and geometric data, eliminating the need for system reverse queries.
3) Higher parsing efficiency: As a native data structure of programming languages, it can be directly deserialized into C++ in-memory objects through lightweight libraries such as nlohmann/json, significantly reducing parsing overhead.
4) Better cross-platform generality: With concise syntax and a compact type system (only six data types: object, array, string, number, Boolean, and null), it can adapt to various CAD systems with API capabilities, effectively reducing the data interfacing costs between heterogeneous systems.

The JSON storage structure is illustrated in Fig. 3. Using the sketch feature as an example: this structure is capable of storing the basic feature parameters, sketch member parameters, constraint member parameters, and work coordinate system parameters of a sketch in a CAD system. By indexing the feature tree sequence, it reflects the temporal order of CAD feature creation, the structure, and the relationships between features created at each structural level.

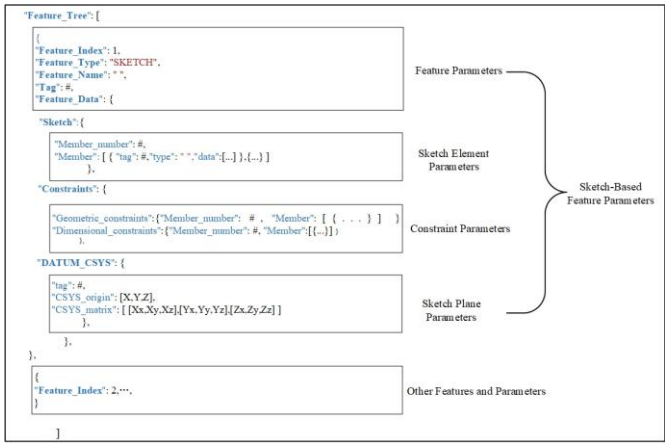

Fig. 3. JSON storage structure of feature data.

B. Basic Topological Element Identification

Basic topological elements refer to vertices, edges, and faces in a model. In the heterogeneous CAD system feature migration process, the creation of sketch-based features, dress-up features, and transformation features all depend on the precise positioning of topological elements.

When users create features in a CAD system, interaction with topological elements of the target geometric body is unavoidable.

For example, an extrude operation requires a closed profile or face within a sketch to drive it, as shown in Fig. 4(a). The termination condition "extrude to face" requires referencing a target termination face, as shown in Fig. 4(c). Chamfer feature creation requires selecting a target edge, as shown in Fig. 4(b). Draft features require specifying the neutral face and faces to be drafted, mirror features require a mirror plane, and so on. Therefore, the topology identification stage is a core component of heterogeneous CAD system data exchange: to ensure topological relationship stability and that the target model possesses the same design intent as the source model, geometric elements must be identified.

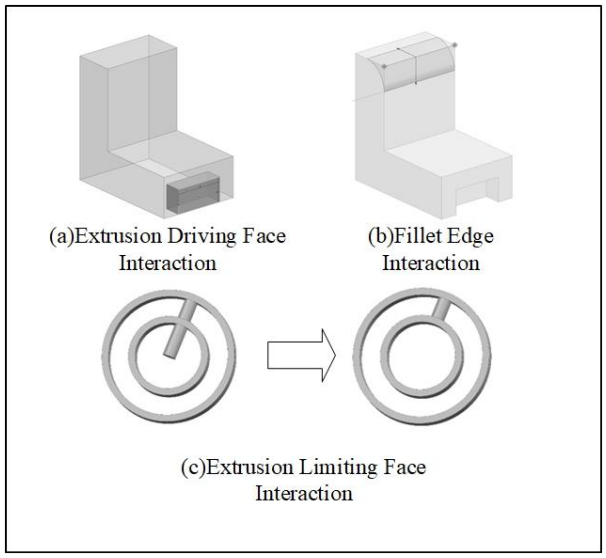

Fig. 4. User-interactive object selection.

To precisely identify referenced topological elements, the parametric definitions of such elements must be clearly established. Referenced geometric elements are classified into two categories: edges and faces. Edges include straight lines, circles, circular arcs, etc.; faces include planar faces, cylindrical faces, conical faces, spherical faces, toroidal faces, etc. Ensuring accurate and error-free referencing of topological elements is critical for the subsequent geometric feature reconstruction process.

As shown in Table I, the format for obtaining various parameters of referenced topological elements from a rectangular block and a cylinder is provided. The approach is fundamentally similar: select the target topological element type, invoke the corresponding API functions to obtain its individual parameters. For straight edges, the primary parameters are the 3D coordinates of the start point and end point. For circular and arc edges, the primary parameters are the radius, center point, and start/end angles; it is worth noting that all arcs in the UGNX system rotate in the counterclockwise direction. For faces, the primary parameters are the center point and normal vector. Because face types differ, the reference for center point and normal also differs: for example, the center point of a planar face is located at the 3D coordinate center of the midpoint between its tight bounding box minimum and maximum corner points, and its normal is perpendicular to the face. The center point of a cylindrical face is located at the center of its bottom circular edge, and its normal is aligned with its axial vector.

TABLE I. PARAMETRIC DEFINITION OF TOPOLOGICAL GEOMETRY AND ITS JSON REPRESENTATION.

Geometry	Parameter	JSON Representation
	Edge type	"edge_type": "Linear",
	Parent feature handle	"parent_feat_tag": #,
	Start point	"start_point": [X, Y, Z],
	End point	"end_point": [X, Y, Z]
	Face type	"face_type": "Plane",
	Center point	"center_point": [X, Y, Z],
	Normal	"normal": [X, Y, Z],
	Box min	"box_min": [X, Y, Z],
	Box max	"box_max": [X, Y, Z],
	Parent feature handle	"parent_feat_tag": #
	Edge type	"edge_type": "Arc",
	Parent feature handle	"parent_feat_tag": #,
	Radius	"radius": #,
	Arc center	"arc_center": [X, Y, Z],
	Start angle	"start_angle": #,
	End angle	"end_angle": #,
	Sweep angle	"sweep_angle": #
	Face type	"face_type": "Cylinder",
	Center point	"center_point": [X, Y, Z],
	Normal	"normal": [X, Y, Z],
	Box min	"box_min": [X, Y, Z],
	Box max	"box_max": [X, Y, Z],
	Radius	"radius": #,
	Parent feature handle	"parent_feat_tag": #

The topology identification workflow is shown in Fig. 5.

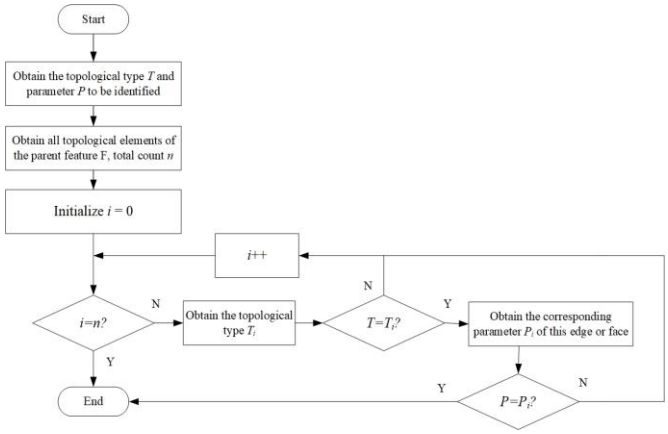

Fig. 5. Topology element identification process.

This approach references the (*F, T, P*) triple identification method proposed by Xie et al. [18]—where the parent feature *F* is used to narrow the search scope, the topology type *T* is used for filtering, and geometric parameters *P* are used to complete identification and matching. During the feature reconstruction process, the parameters of topological elements to be identified are obtained from the JSON file; using the feature name *F* from the parameters, all edges or faces in that feature are selected; a determination is made as to whether the selected edge or face is of the required type; if so, the geometric parameters P_i of the

selected topological elements are sequentially compared with the corresponding parameters in *P* to determine whether they are equal; if they are equal, the topological element is identified as the target topological element. When the model is relatively complex, selecting edges or faces dependent on features can effectively narrow the search scope and improve the search efficiency for topological elements.

C. Data Validation

Because the operating methods and kernels of different CAD systems may differ, it is necessary to extract and verify the feature data before regeneration to maximally preserve the model's design intent during CAD system migration and ensure the successful reconstruction of feature models. Prior to this, essential data validation and supplementation of missing information must be performed.

1) Tracing disappearing transient information. During feature operations in a CAD system, certain topological structures may undergo deformation or even disappear as a result of the operation. These disappearing transient topologies are often an indispensable part of maintaining operational intent. For transient information that disappears after modeling, the fillet feature is used as an example: when the user performs a fillet operation and selects a target edge, that edge becomes a cylindrical face, and the target edge is suppressed by the system. By obtaining the edge's handle, temporarily suppressing its feature, and querying its parent feature, the original parameter information of the edge can be retrieved. This method also applies to draft features and other features that alter geometric shape parameters.

A related but more challenging scenario involves features that are completely consumed by subsequent Boolean operations (union, difference, or intersection). For example, a cylindrical extrude feature may be entirely absorbed into a larger body through a Boolean union, leaving no standalone geometric entity that can be traversed in the final model. To handle this, the feature parameter extraction stage captures all feature information before the Boolean operation is applied. Specifically, the traversal algorithm records a snapshot of each feature's geometric parameters and topological references at the moment of its creation within the feature tree, rather than from the final consolidated model. This is achieved by iterating through the feature tree's creation history in temporal order: for each feature, its parameters are extracted immediately after the feature node is visited, regardless of whether the feature remains visible in the final model. Boolean operations themselves are recorded as separate feature entries in the JSON file with a tag and an array listing the consumed features' handles. During reconstruction, the target system first reconstructs all constituent features and then applies the Boolean operation, faithfully reproducing the original modeling sequence.

2) Validating cross-system incompatibility information. For incompatible information arising from differences in feature construction methods between heterogeneous CAD systems, alternative solutions must be adopted when unique feature constraint types in the source CAD system have no direct correspondence in the target system. One situation occurs when the source CAD system possesses a certain design intent during feature interaction operations that the target CAD system does not possess. For example, the extrude feature in ZW3D includes a design intent of "extrude to a point", whereas the UGNX system lacks this design intent. According to the third principle proposed by Zheng et al. [13]—"converting using different features and auxiliary formulas"—an auxiliary plane is created at the target point, and by leveraging extrusion-to-plane along with its extended surface features and constructing an auxiliary plane, the conversion of extrusion-to-vertex features can be achieved. This ensures that when the vertex position changes, the constructed auxiliary plane changes accordingly, thereby causing the extrusion length to adaptively vary and thus preserving the design intent.

Another situation occurs when both the source and target CAD systems contain the same construction method, but due to differences in their underlying kernels, data extracted from the source CAD system cannot be directly used between the two systems and requires certain processing. In practice, to maintain the stability and consistency of internally similar data, CAD systems establish prescribed operational procedures. For example, in the UGNX system, when creating an arc in a sketch feature, to ensure the arc's rotation direction remains consistent, the system relies on the arc orientation matrix and uses the absolute coordinate system origin (0, 0, 0) as the reference for orienting the arc, thereby ensuring the arc's rotation direction is counterclockwise. If APIs are called to obtain the coordinates of the arc center, these coordinates correspond to the arc center in the local coordinate system of the arc. Generally, when creating sketch curves, the input sketch is in the local coordinate system or the absolute coordinate system. Therefore, data conversion is required: the arc center coordinates in the local coordinate system of the arc must be transformed to the arc center coordinates in the sketch coordinate system.

Using API functions, the arc center coordinates and arc rotation matrix based on the absolute coordinate system can be obtained. The coordinate transformation is accomplished through the following transformation equations:

Let P_{local} be the arc center in the local coordinate system of the arc, and let R_{acr} be the corresponding arc rotation matrix. The arc center P_{abs} in the absolute coordinate system is obtained from:

$$P_{abs} = R_{acr} P_{local} \tag{1}$$

The sketch coordinate system is described by its origin O_{sk} and rotation matrix R_{sk} (where R_{sk} transforms sketch local coordinates to absolute coordinates, i.e.,$v_{abs} = R_{sk} v_{sk} + O_{sk}$). Hence, the sketch local coordinate P_{sk} is computed as:

$$P_{sk} = R_{sk}^{T}(P_{abs} - O_{sk}) \tag{2}$$

where, R_{sk}^{T} is the transpose of R_{sk} and, due to the orthogonality of a rotation matrix, $R_{sk}^{T} = R_{sk}^{-1}$. In practical implementation, taking the three column vectors C_0, C_1, C_2 of R_{sk}, the dot product operation is employed:

$$P_{sk,i} = C_i(P_{abs} - O_{sk}), \quad i = 0,1,2 \tag{3}$$

Thus, the parameter information that can be directly utilized by the target CAD system in sketch features is obtained.

3) Complex Sketch Constraint Serialization. The complex sketch geometric constraints addressed herein are primarily constraint outcomes generated by patterned curves (mirrored curves represent a special subtype of patterned curves).

Sketch constraints fall into two categories: dimensional constraints and geometric constraints. Whether they are geometric constraints such as perpendicularity or parallelism, or dimensional constraints, all serve as mandatory restrictions imposed on pre-existing curves.

Taking UG NX as an example, the constraint relationships of existing curves within a sketch feature can be retrieved by invoking two Application Programming Interface (API) functions: “ UF_SKET_ask_geo_cons_of_sketch() ” and “UF_SKET_ask_dimensions_of_sketch()”.

Child curves generated via the patterned curve operation maintain a patterning association with one another and carry identical geometric information. Counterintuitively, when the information of these curves is extracted and reconstructed in the target CAD system, the curves are found to be completely coincident in appearance, rather than arranged sequentially in accordance with the patterning order.

To address this issue, the following strategy is proposed:

- Aggregate all curves generated by the corresponding patterned curve operation using the aforementioned geometric constraint acquisition function.
- Identify the parent curve through the "smart container" APIs in UG Open, and label the remaining curves as child curves.
- Document the patterning mode, the parent curve and the labeled child curves in the JavaScript Object Notation (JSON) file, and mark the child curves as disabled during reconstruction in the target CAD system.
- Execute the patterned curve operation on the parent curve in the target CAD system.

This approach can maximally ensure the successful conversion of patterning constraints.

III. Experimental Validation and Analysis

A. Experimental Case Study

To verify the feasibility and effectiveness of the proposed method, this study selects Siemens NX 12 as the source system and ZW3D 2024 as the target system, and establishes a complete feature migration prototype. First, the NX Open C++ API is used to traverse the model feature tree in depth, recursively obtaining the construction type, parameter set, sketch data and constraint information, topological face references, and geometric attributes of each feature. All information is organized in a structured hierarchical manner and output as a JSON exchange file. Fig. 6 shows a code excerpt for parameter and topology extraction from a UGNX extrude feature.

Next, JSON parsing and system reconstruction are implemented using ZW3D C++ API. Fig. 7 shows a code excerpt for reconstructing an extrude feature in ZW3D.

```
void Get_Extrude_Info(tag_t extrude_feat, nlohmann::ordered_json& j_Info)
{
    TaggedObject* taggedObj = NXObjectManager::Get(extrude_feat);
    Features::Extrude* extrude = dynamic_cast<Features::Extrude*>(taggedObj);

    Session* ses = Session::GetSession();
    Part* workPart = ses->Parts()->Work();
    Features::ExtrudeBuilder* builder = workPart->Features()->CreateExtrudeBuilder(extrude);

    Direction* dirObj = builder->Direction();
    Vector3d vec = dirObj->Vector();
    j_Info["direction"] = { vec.X, vec.Y, vec.Z };

   auto* offset = builder->Offset();
   PrintFeatureOffset(offset, &j_Info);  //Function to obtain extrude offset information

    auto* startExt = builder->Limits()->StartExtend();
    auto* endExt = builder->Limits()->EndExtend();

    auto printExtend = [](const char* which, NXOpen::GeometricUtilities::Extend* ext,
        nlohmann::ordered_json& j){ ... }

        printExtend("Start", startExt, j_Info["limits"]["start"]);
        printExtend("End", endExt, j_Info["limits"]["end"]);

    builder->Destroy();
}
```

Fig. 6. Code excerpt for parameter and topology extraction from UGNX extrude feature.

```
int ZWClass::ProcessExtrude(const json& featData, int featureTag)
{
...

    extrude.profileHandle = sketchHandle;// 5. Populate data
    extrude.startS = startDist;extrude.endE = endDist;
    extrude.startType = startType;
    extrude.endType = endType;
    extrude.boolean.combine = combine;
    extrude.settings.capType = ZW_END_CAP_BOTH;
    extrude.draft.isUseExtrusionDirection = 1;
    extrude.direction.x = dirX;
    extrude.direction.y = dirY;
    extrude.direction.z = dirZ;

    if (startFaceHandle.innerData){
        extrude.startEntityHandle = startFaceHandle;
        extrude.startToPoint = &startPoint;
    }
    if (endFaceHandle.innerData){
        extrude.endEntityHandle = endFaceHandle;
        extrude.endToPoint = &endPoint;
    }

    szwEntityHandle shapeHandle = { 0 };
    evxErrors err = ZwFeatureExtrudeCreate(extrude, &shapeHandle);// 6.Execute
...
    ZwEntityHandleFree(&shapeHandle);
    ZwEntityHandleFree(&sketchHandle);
    Set_View();
    return extrudeFeatureId;
}
```

Fig. 7. Code excerpt for reconstructing an extrude feature in ZW3D.

B. Results Analysis and Discussion

The experimental results are shown in Fig. 8. The results indicate that the proposed method successfully achieved cross-system migration of parametric features from NX to ZW3D. By comparing the feature trees and feature models of the source and target CAD systems, it can be observed that the target CAD system is able to find feature trees corresponding to those in the source system, and the feature model displays are similar to the source models. This validates the effectiveness of the three stages—feature parameter extraction, topology identification, and data validation. It also demonstrates that JSON, as a neutral file format, is capable of storing feature parameter information and maintaining the potential for interactive design. The method effectively preserves high-level semantics such as design intent, parameter information, and feature information, enabling the migration and sharing of heterogeneous CAD models with significant practical potential and application value.

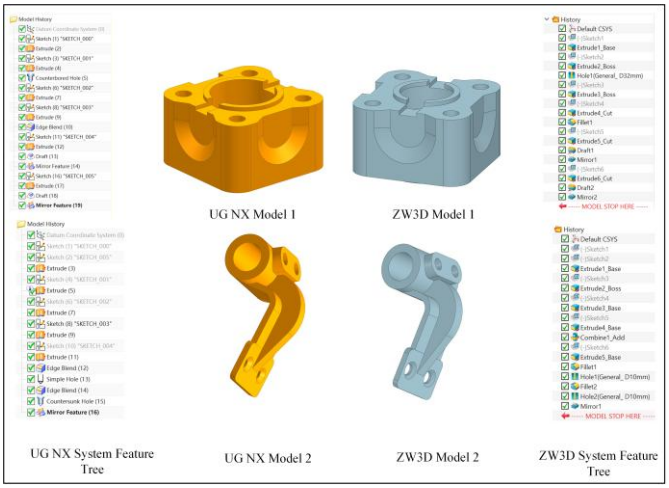

Fig. 8. Model migration cases between UGNX and ZW3D.

IV. Discussion

A. Parametric Editability Verification

A key criterion for successful feature migration is whether the migrated model remains fully parametric and editable in the target CAD system. To evaluate this, parameter modification tests were conducted on the migrated models. For each feature in the target model, its critical dimension parameters were modified and the model was regenerated. The test results showed that for features reconstructed at the feature-level (those with direct API mapping), all parameter modifications triggered correct model updates, preserving the intended update behavior—the model geometry changed exactly as it would in the source system when the same parameter was modified.

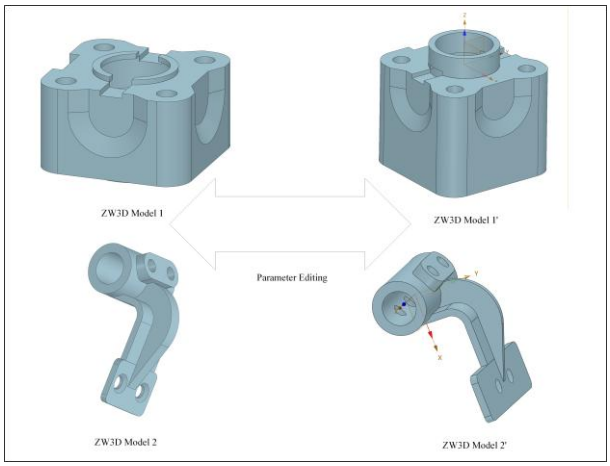

Fig. 9. Editable target CAD model.

B. Generalizability Across CAD Kernels

The proposed method's generalizability to additional CAD systems with different geometric kernels relies on the API abstraction layer implemented in the extraction and reconstruction modules. The method has been designed with kernel independence as a core architectural principle. The feature parameter extraction module communicates with the source CAD system solely through its published API, without depending on kernel-specific data structures. Similarly, the reconstruction module invokes only the target system's documented API functions.

C. API Version Compatibility

The software used for development is generally lower-version releases, so API invalidation in CAD systems is extremely rare. Should such a scenario arise, alternative APIs of the same category may be invoked in adherence to the principle of ensuring successful conversion.

For instance, two primary API function systems are available in UG NX, namely UFun and NX Open. Both sets of APIs shall be invoked simultaneously during the implementation of the aforementioned patterning constraint guarantee strategy.

V. Conclusion

Addressing the common challenge of feature migration between heterogeneous CAD systems, this study proposes a tiered regeneration feature migration method based on JSON neutral files, founded on a three-stage framework of feature parameter extraction, topology identification, and data validation. In the feature parameter extraction stage, modeling history is serialized into JSON structured data, improving the completeness of information extraction and the generality of the method. In the topology identification stage, a multi-dimensional geometric descriptor-based topological element identification method is constructed and JSON data is populated and written. In the data validation stage, to maximally preserve the model's design intent during CAD system migration, system transient information is traced and retrieved, and cross-system incompatibility information is refined and converted.

Taking NX and ZW3D as typical cases, prototype development and verification were completed. Experimental results demonstrate that models migrated using the proposed method are capable of inheriting the feature information and modeling history of the source CAD system, preserving the model's design intent.

Future research on this method will advance along two directions: first, tracking the iterative expansion of target CAD system APIs to broaden the coverage of mappable features; second, addressing the limited expressive capability of JSON for complex curves or features—further investigation into more flexible data organization approaches is needed to handle mixed hierarchical relationships that the tree structure of JSON may struggle to represent.

Automated Classification of Moroccan Procedural Court Orders Using CAMeL-BERT

Saliha YASSINE, Ouafaa IBRIHICH, Mohammed ESSOUJAA, Mustapha ESGHIR
LabMIA-SI Laboratory, Faculty of Sciences, Mohammed V University in Rabat, Morocco

***Abstract*—The digitization of judicial systems creates new opportunities for automating document management tasks that have traditionally relied on manual processing. This study addresses the automated classification of Arabic procedural court orders issued by Moroccan courts of first instance into seven official procedural categories, a low-resource legal document type characterized by highly standardized procedural language and limited publicly available resources. The primary contribution is a leakage-controlled evaluation demonstrating that frozen CAMeL-BERT contextual representations, combined with lightweight conventional machine learning classifiers, achieve highly accurate classification without computationally expensive transformer fine-tuning. The proposed pipeline integrates automatic structured extraction from heterogeneous Word documents with contextual embeddings and a comparative evaluation of five classifiers under a strict train–validation–test protocol. Experimental results show that Logistic Regression achieves 99.74% test accuracy (κ = 0.9966), while even the simplest baseline, Gaussian Naive Bayes, reaches 96.66%, highlighting the strong discriminative characteristics of Moroccan procedural court orders. An ablation study demonstrates that replacing TF-IDF representations with CAMeL-BERT embeddings reduces classification errors by 71.4%, while the complete classification pipeline further improves overall performance and reduces the remaining errors. These findings show that the highly regular linguistic structure of Moroccan procedural court orders enables computationally efficient and deployment-oriented classification using frozen contextual embeddings, providing a practical solution for Arabic legal document management and supporting future e-Justice applications in Morocco.**

***Keywords*—Arabic legal NLP; CAMeL-BERT; judicial document classification; Moroccan courts; procedural court orders**

I. Introduction

Moroccan courts of first instance process a large volume of procedural documents on a daily basis. These documents, commonly referred to as ordonnances, are formal judicial orders related to procedural matters such as payment obligations, financial consignments, commercial registry operations, guardianship appointments, and other judicial procedures. Recent investments by the Moroccan Ministry of Justice in electronic case management systems have accelerated the digitization of judicial workflows, making automated document processing an increasingly important operational requirement. Nevertheless, document classification remains largely manual in many courts, where incoming files must be identified and routed to the appropriate judicial department. Misclassification may delay judicial proceedings, increase administrative workload, and negatively affect procedural efficiency. Although these documents are stored in heterogeneous Word layouts that vary across courts, clerks, and time periods, they exhibit highly regular legal formulations and category-specific terminology, making them suitable candidates for data-driven document classification.

Automating this classification task requires addressing several linguistic challenges inherent to Arabic. Written Arabic frequently omits short vowels and diacritical marks, making tokenization and morphological analysis substantially more difficult than in many European languages. Arabic morphology is also highly productive, as a single trilateral root can generate numerous surface forms through affixation and internal vowel variation [1]. The Transformer architecture [2], particularly through BERT [3], addressed many of these challenges by learning deep contextual representations from large-scale corpora. These advances have been extended to Arabic through specialized models such as AraBERT [4] and CAMeL-BERT [5], which have demonstrated strong performance across a broad range of Arabic NLP tasks [6]. More recently, these advances have stimulated the development of Legal AI applications, including legal document classification, legal information retrieval, judgment prediction, intelligent document management, and e-Justice systems.

Despite recent progress in Arabic legal NLP [7]–[10], existing studies have primarily focused on legal corpora from other Arabic-speaking countries, general-domain datasets, or legal prediction tasks. Moroccan procedural court orders remain largely unexplored despite their central role in the daily operation of Moroccan courts. Furthermore, previous studies generally assume that documents are already available as clean textual data and therefore do not address the practical challenge of extracting structured textual content from heterogeneous judicial Word documents before classification. In addition, few studies investigate whether frozen contextual embeddings combined with lightweight conventional classifiers can provide both high classification performance and computational efficiency without expensive transformer fine-tuning. These limitations reveal an important gap between recent advances in Arabic Legal AI research and the practical requirements of judicial document management in Moroccan courts.

To address these challenges, this study proposes a complete document classification pipeline that integrates automatic structured text extraction from judicial Word documents with frozen CAMeL-BERT contextual embeddings and conventional machine learning classifiers. The proposed approach is evaluated under a strict train–validation–test protocol specifically designed to prevent data leakage while assessing the impact of contextual embeddings and training-only data augmentation. Beyond achieving high classification accuracy,

the study investigates whether deployment-oriented architectures based on frozen contextual representations can provide an effective and computationally efficient solution for real-world judicial document management.

The main contributions of this work are summarized as follows:

- An automatic extraction pipeline for converting heterogeneous Moroccan judicial Word documents into structured textual data suitable for classification.
- A curated corpus of Moroccan procedural court orders covering seven official judicial procedural categories.
- A leakage-controlled evaluation of frozen CAMeL-BERT contextual embeddings combined with five conventional machine learning classifiers.
- An ablation study quantifying the contribution of contextual embeddings and the complete classification pipeline to overall classification performance.
- An analysis of classification performance on an imbalanced judicial corpus, including minority categories.
- A deployment-oriented classification framework that achieves high accuracy without transformer fine-tuning, supporting practical integration into Morocco's e-Justice initiatives.

The remainder of this study is organized as follows: Section II reviews related work on Arabic legal NLP and judicial document classification. Section III presents the proposed extraction and classification methodology. Section IV discusses the experimental results and ablation study. Finally, Section V concludes the study and outlines directions for future research.

II. Related Work

A. Pre-Trained Arabic Language Models

Transformer-based pre-trained language models have significantly advanced Arabic Natural Language Processing (NLP) by learning contextual language representations from large-scale corpora. Unlike multilingual models, Arabic-specific transformers explicitly capture the rich morphology, lexical ambiguity, and syntactic characteristics of Arabic, leading to substantial improvements across text classification, named entity recognition, sentiment analysis, and question answering tasks.

AraBERT [4] was among the first transformer models specifically developed for Arabic and demonstrated that language-specific pre-training consistently outperforms multilingual BERT on several downstream NLP tasks. Subsequently, Alammary [6] conducted a comprehensive systematic review of Arabic BERT models, highlighting the influence of corpus composition, model architecture, and pre-training strategy on downstream performance. Abdul-Mageed et al. [12] further introduced ARBERT and MARBERT, two transformer models specifically designed to capture both Modern Standard Arabic (MSA) and dialectal Arabic. Although these models achieve excellent performance on dialect-rich corpora, their emphasis on dialectal language makes them less suitable for the predominantly Modern Standard Arabic used in Moroccan judicial documents.

CAMeL-BERT [5] further extended Arabic language modeling by pre-training transformer models on a 167 GB corpus covering Modern Standard Arabic, dialectal Arabic, and Classical Arabic. This multi-register training strategy enables the CAMeL-BERT-mix variant to capture both standard morphological phenomena and domain-specific lexical variations frequently encountered in formal legal writing. Its effectiveness has been demonstrated across several Arabic NLP benchmarks. For example, Mutawa and Sruthi [11] reported that CAMeL-BERT achieved the highest performance among several transformer architectures for Arabic meter classification, illustrating its strong capability to learn complex contextual representations.

More recently, transformer-based research has expanded toward Legal AI through the development of domain-adaptive language models. LEGAL-BERT [13] demonstrated that additional pre-training on legal corpora substantially improves performance on legal-domain NLP tasks compared with general-purpose BERT models. Similarly, AraLegal-BERT [15] showed that domain-specific pre-training on Arabic legal texts further enhances semantic representations for specialized legal terminology. These studies collectively confirm that contextual language models benefit significantly from legal-domain adaptation when processing judicial documents.

The present study adopts the CAMeL-BERT-mix model because Moroccan procedural court orders are written almost exclusively in Modern Standard Arabic while containing highly regular legal terminology and institution-specific procedural expressions. Unlike approaches based on full transformer fine-tuning, this work investigates whether frozen contextual embeddings extracted from CAMeL-BERT can provide sufficiently discriminative semantic representations for highly accurate document classification when combined with lightweight conventional machine learning classifiers. This deployment-oriented strategy substantially reduces computational requirements while preserving the contextual information learned during large-scale Arabic pre-training, making it particularly suitable for practical judicial applications.

B. Methods for Legal Document Classification

Automatic legal document classification has become an increasingly important research topic because of its applications in intelligent document management, legal information retrieval, electronic case management, and e-Justice systems. Early approaches relied primarily on manually engineered lexical and syntactic features combined with conventional machine learning algorithms such as Support Vector Machines (SVM), Logistic Regression (LR), K-Nearest Neighbors (KNN), and Naive Bayes (NB). These methods achieved competitive performance on relatively homogeneous legal corpora but required substantial feature engineering and often struggled to capture the semantic complexity of legal language, particularly in morphologically rich languages such as Arabic.

The emergence of transformer-based language models fundamentally changed this landscape by replacing manually engineered features with contextual semantic representations learned from large-scale corpora. Domain-adaptive pre-training has proved particularly beneficial for legal applications. LEGAL-BERT [13] demonstrated that additional pre-training on legal corpora substantially improves performance compared with general-purpose BERT models. MultiEURLEX [14] further showed that transformer models can successfully perform multilingual legal document classification across European legislation, while AraLegal-BERT [15] confirmed the importance of domain-specific pre-training for Arabic legal text classification.

Several recent studies have applied machine learning and transformer models to Moroccan legal documents. El Moussaoui et al. [7] fine-tuned XLM-RoBERTa for judicial chamber classification using Court of Cassation judgments and reported an accuracy of 98.48%. Tahtah et al. [17] proposed a CNN–BiLSTM architecture using AraBERTv2 embeddings together with random oversampling to address class imbalance in Arabic legal document classification. Bouhouche et al. [8] evaluated conventional machine learning algorithms for Moroccan legislative document classification and demonstrated that lexical representations remain competitive on structured legal corpora. Zahir [9] investigated judicial outcome prediction from Arabic court decisions using deep learning, whereas El Moussaoui et al. [10] developed an AI-assisted framework for criminal record processing in Moroccan courts.

Although these studies demonstrate the growing maturity of Arabic Legal AI, they address legal tasks that differ substantially from the automatic classification of procedural court orders issued by Moroccan courts of first instance. Furthermore, most previous work assumes that textual content is already available in structured digital form and therefore overlooks the practical challenge of extracting discriminative information from heterogeneous judicial Word documents before classification. Existing studies also predominantly rely on transformer fine-tuning or deep neural architectures, whereas comparatively little attention has been devoted to deployment-oriented solutions based on frozen contextual embeddings combined with lightweight conventional classifiers.

TABLE I. COMPARISON OF REPRESENTATIVE STUDIES ON ARABIC LEGAL DOCUMENT CLASSIFICATION

Study	Corpus	Doc. Type	Task	Approach	Best Score	Main Limitation
LEGAL-BERT [13]	European legal corpora	Legal documents	Document classification	Domain-adaptive BERT	Improved performance	Non-Arabic corpus
MultiEURLEX [14]	European Union	Legislative texts	Multi-label classification	Multilingual Transformer	Strong benchmark	European legislation
AraLegal-BERT [15]	Arabic legal corpus	Legal documents	Legal text classification	Domain-specific Arabic BERT	Improved representations	No Moroccan evaluation
Bouhouche et al. [8]	Morocco	Legislative texts	Document classification	Conventional ML	95.82%	Legislative corpus
Zahir [9]	Morocco	Court decisions	Judgment prediction	Deep learning	80.51%	Outcome prediction
Tahtah et al. [17]	Morocco	Court cases	Document classification	CNN–BiLSTM + AraBERTv2	96.22%	Requires fine-tuning
El Moussaoui et al. [7]	Morocco	Court of Cassation judgments	Chamber classification	Fine-tuned XLM-RoBERTa	98.48%	Different court level
This study	Moroccan Courts of First Instance	Procedural orders	7-category classification	Frozen CAMeL-BERT + LR	99.74% ($\kappa = 0.9966$)	Single national corpus

The comparison presented in Table I highlights several important research gaps. First, most existing studies focus on legal corpora that differ substantially from Moroccan procedural court orders, including legislative texts, Court of Cassation judgments, or judgment prediction tasks. Consequently, their findings cannot be directly transferred to the document-routing problem encountered in Moroccan courts of first instance. Second, previous work generally assumes that documents are already available in clean textual form and therefore overlooks the practical challenge of extracting structured information from heterogeneous judicial Word documents before classification. Third, although transformer-based models have consistently demonstrated superior performance, relatively few studies have investigated deployment-oriented architectures that combine frozen contextual embeddings with lightweight conventional machine learning classifiers, thereby reducing computational requirements while maintaining high classification performance.

To address these limitations, the present study proposes an end-to-end framework integrating automatic structured text extraction, frozen CAMeL-BERT contextual embeddings, and five conventional machine learning classifiers evaluated under a strict leakage-controlled experimental protocol. In addition, a comprehensive ablation study is conducted to quantify the contribution of contextual embeddings and the complete classification pipeline, providing practical insights into the design of efficient Arabic legal document classification systems for e-Justice applications.

III. METHODOLOGY

A. Corpus Compilation and Data Augmentation

The corpus was compiled from procedural court orders collected from several Moroccan Courts of First Instance. The documents correspond to seven official procedural categories defined by the Moroccan judicial taxonomy: Notification of Warning (تبليغ إنذار), Payment Order (أمر بالأداء), Deposit and Consignment (العرض والإيداع), Validation of Warning (المصادقة على الإنذار), Financial Withdrawal (سحب مبلغ مالي), Appointment of Guardian (تعيين قيم), and Commercial Register Deletion (التشطيب على السجل التجاري). Since these procedural categories are

officially assigned during judicial processing, no additional manual annotation was required. The labels provided by the courts were therefore used directly as the ground-truth class labels throughout the experiments.

The collected documents were stored as Microsoft Word files with heterogeneous layouts reflecting differences among courts, clerks, and document preparation practices. To prepare a structured corpus suitable for machine learning, a custom Python extraction pipeline was developed to automatically identify and extract the facts section (faits) and the decision section (dispositif) from each document using rule-based textual markers and regular-expression matching. Documents with incomplete or unsuccessful section extraction were excluded during corpus preparation, resulting in a final corpus of 3,894 original documents. Preliminary experiments showed that the extracted facts section contains the most discriminative information for procedural category identification; therefore, only this textual content was used for classification.

TABLE II. CORPUS DISTRIBUTION

Procedural Category	Original Documents
Notification of Warning — تبليغ إنذار	1480
Deposit and Consignment — العرض والإيداع	934
Validation of Warning — المصادقة على الإنذار	394
Financial Withdrawal — سحب مبلغ مالي	492
Payment Order — أمر بالأداء	432
Appointment of Guardian — تعيين قيم	120
Commercial Register Deletion — التشطيب على السجل التجاري	42
Total	3894

As shown in Table II, the original corpus exhibits a pronounced class imbalance, with an imbalance ratio of 35.24:1 between the largest and smallest categories. To reduce this imbalance while preserving the semantic meaning of each procedural category, data augmentation was applied exclusively to the training partition after train–validation–test splitting, thereby preventing any information leakage into the validation or test sets.

A per-class target of approximately 2,000 training documents was adopted. New training samples were generated by combining three label-preserving transformations specifically designed for procedural judicial documents:

- Judicial synonym substitution using a domain-specific lexicon of 40 legally equivalent term pairs validated by an experienced court clerk (e.g., التماس/طلب, الفصل/المادة);
- Date variation, replacing four-digit years with nearby values (±1 year);
- Monetary-value scaling, multiplying monetary amounts by a random factor between 0.8 and 1.2.

Date and monetary-value transformations were applied only to information that does not determine the procedural category. Since the seven target classes are defined by the underlying judicial procedure rather than by specific dates or monetary amounts, these modifications preserve the original class label. Every augmented document therefore inherits the category of its source document, and no cross-category mixing was performed.

The augmentation process increased the size of the training corpus to 13,764 documents, reducing the imbalance ratio from 35.24:1 to approximately 1.12:1 while maintaining a strict separation between original evaluation data and augmented training data.

Fig. 1 presents an anonymized excerpt of a Notification of Warning (تبليغ إنذار) procedural court order after the automatic extraction process. All personal names, case numbers, and identifying information were removed or replaced before analysis to preserve judicial confidentiality.

المحكمة الابتدائية — [×] نحن رئيس المحكمة الابتدائية بمقتضى الفصل *148* من ق.م.م. بعد الاطلاع على طلب السيد [×××] بتبليغ إنذار للمدين [×××] بأداء مبلغ [...] درهماً أمرنا بما يلي: [تبليغ المدين بالمبلغ المذكور

Fig. 1. Anonymized excerpt of the facts section of a Notification of Warning (تبليغ إنذار) procedural court order extracted by the Python script. Personal identifiers have been replaced by ×.

The extracted facts section subsequently undergoes text normalization and contextual embedding generation before being used for document classification. The overall preprocessing pipeline is described in the following subsection.

B. Data Preprocessing and Experimental Protocol

The extracted textual data underwent several preprocessing steps before classification. Text normalization included the removal of unnecessary whitespace and formatting inconsistencies introduced during document extraction, together with the normalization of Arabic text to ensure consistent lexical representation. Documents with incomplete or unsuccessful section extraction, as well as documents containing insufficient textual content for reliable classification, were excluded during corpus preparation to improve the overall quality of the dataset. The resulting corpus contained 3,894 original procedural court orders, which served as the basis for all subsequent experiments.

The final corpus was partitioned into training (60%), validation (20%), and test (20%) sets using stratified random sampling in order to preserve the original class distribution across all partitions. The partitioning was performed before any data augmentation to prevent information leakage between the training and evaluation datasets. Consequently, every original document appears in only one partition throughout the entire experimental protocol.

Data augmentation was applied exclusively to the training partition, increasing the number of training documents from 2,336 to 13,764 while leaving the validation and test sets unchanged. This strategy preserved the semantic integrity of each procedural category while reducing the class imbalance ratio from 35.24:1 to approximately 1.12:1. Since the validation and test partitions contain only original documents, the reported performance reflects the model's ability to generalize to previously unseen judicial documents rather than to augmented samples.

To ensure a fair comparison among all classification models, the same training, validation, and test partitions were used throughout every experiment, including the ablation study. This

leakage-controlled experimental protocol guarantees that all reported performance differences result exclusively from changes in document representation or classification algorithms rather than from variations in the evaluation data.

C. Proposed Classification Framework

Fig. 2 presents the overall workflow of the proposed framework for the automatic classification of Moroccan procedural court orders. The framework consists of five sequential stages that transform heterogeneous judicial Word documents into contextual semantic representations suitable for procedural document classification.

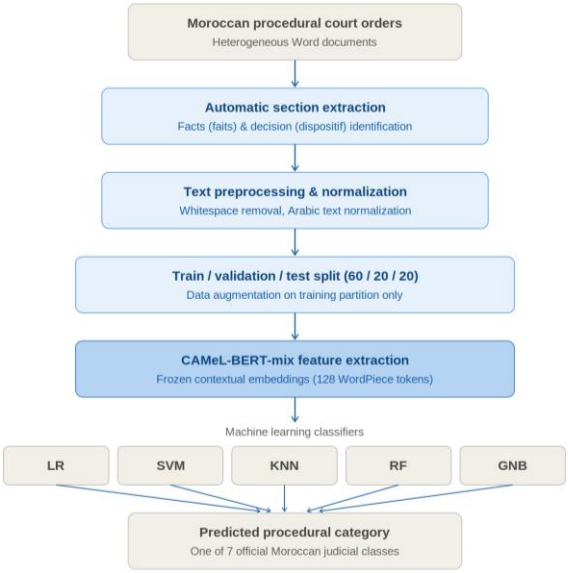

Fig. 2. Overall workflow of the proposed framework for automatic classification of Moroccan procedural court orders.

First, procedural court orders are processed by the automatic extraction module described in the previous subsection. This module identifies and extracts the facts (faits) and decision (dispositif) sections from each document. Preliminary experiments showed that the facts section contains the most discriminative procedural information; therefore, only this section is retained for the subsequent classification process.

The extracted text is then normalized to remove formatting inconsistencies while preserving its legal content. The resulting corpus is partitioned into training, validation, and test sets using a leakage-controlled experimental protocol. Data augmentation is applied exclusively to the training partition in order to mitigate class imbalance while preserving the semantic characteristics of each procedural category.

Next, each preprocessed document is converted into a contextual semantic representation using the frozen CAMeL-BERT-mix model. The resulting document embeddings are subsequently used to train five conventional machine learning classifiers: Logistic Regression (LR), Support Vector Machine (SVM), K-Nearest Neighbors (KNN), Random Forest (RF), and Gaussian Naive Bayes (GNB).

By combining transformer-based contextual embeddings with lightweight machine learning classifiers, the proposed framework provides an effective and computationally efficient solution for the automatic routing of procedural court orders within Moroccan e-Justice systems.

D. CAMeL-BERT Feature Extraction

The proposed framework employs the CAMeL-BERT-mix model [5] as the contextual feature extractor. The main configuration parameters of the feature extraction module are summarized in Table III. CAMeL-BERT-mix is built upon the standard BERT-base architecture [3], comprising 12 transformer encoder layers, 768-dimensional hidden representations, 12 self-attention heads, and approximately 110 million parameters. The model was pre-trained on a large-scale Arabic corpus covering Modern Standard Arabic (MSA), dialectal Arabic, and Classical Arabic, making it particularly suitable for legal documents that combine formal language with institution-specific procedural terminology.

TABLE III. CAMEL-BERT CONFIGURATION USED IN THIS STUDY

Parameter	Value
Pre-trained model	CAMeL-BERT-mix
Base architecture	BERT-base
Transformer encoder layers	12
Hidden size	768
Attention heads	12
Approximate number of parameters	110 million
Tokenizer	WordPiece
Maximum sequence length	128 tokens
Document representation	Final hidden-layer [CLS] embedding
Embedding dimension	768
Transfer learning strategy	Frozen embeddings (no fine-tuning)
Feature scaling	StandardScaler (fitted on the training set only)

Classification is performed exclusively on the extracted facts section, as it contains the procedural information most relevant for distinguishing between the seven judicial categories. Each document is tokenized using the original CAMeL-BERT WordPiece tokenizer, and input sequences are truncated or padded to a maximum length of 128 tokens, ensuring a fixed-size representation compatible with the transformer architecture.

Rather than fine-tuning the transformer model, this study adopts a feature-based transfer learning strategy. The parameters of CAMeL-BERT remain frozen throughout the training process, and only the contextual document representations generated by the model are used as input features for the downstream classifiers. This strategy substantially reduces computational requirements while allowing the evaluation to focus on the discriminative capability of contextual embeddings independently of transformer optimization [18].

For each document, the contextual representation of the [CLS] token from the final hidden layer is extracted as a fixed-length 768-dimensional document embedding, which serves as the input feature vector for all classification models. Before classifier training, these embeddings are standardized using StandardScaler. The scaler is fitted exclusively on the training partition and subsequently applied, without refitting, to the

validation and test partitions, thereby preventing information leakage during preprocessing and ensuring identical feature scaling across all evaluation datasets.

The combination of frozen contextual embeddings and lightweight machine learning classifiers provides an efficient architecture for deployment-oriented judicial applications. Once document embeddings have been generated, classification can be performed without repeated transformer optimization, substantially reducing computational cost while preserving the semantic knowledge acquired during large-scale Arabic language pre-training.

E. Classification Models

To evaluate the effectiveness of the proposed contextual representations, five supervised machine learning classifiers from different algorithmic families were trained using the CAMeL-BERT document embeddings. The hyperparameter configuration of all classifiers is summarized in Table IV.

TABLE IV. HYPERPARAMETER SETTINGS OF THE CLASSIFICATION MODELS.

Classifier	Hyperparameter Configuration
Logistic Regression	L2 regularization, C = 0.5, class_weight = balanced, max_iter = 1000
Support Vector Machine	RBF kernel, C = 1.0, gamma = scale
K-Nearest Neighbors	k = 5, cosine distance
Random Forest	n_estimators = 100, max_depth = 10, min_samples_split = 10, min_samples_leaf = 5, class_weight = balanced
Gaussian Naive Bayes	Default parameters

Logistic Regression (LR) was selected as a linear baseline because of its robustness, computational efficiency, and effectiveness in high-dimensional feature spaces. The classifier employs L2 regularization with C = 0.5, class_weight = "balanced", and a maximum of 1,000 iterations.

Support Vector Machine (SVM) was configured with a radial basis function (RBF) kernel using C = 1.0 and gamma = "scale", enabling nonlinear decision boundaries to be learned in the contextual embedding space [16].

K-Nearest Neighbors (KNN) was implemented with k = 5 using the cosine distance metric, which is well suited for measuring similarity between high-dimensional contextual embeddings.

Random Forest (RF) consisted of 100 decision trees with a maximum tree depth of 10, a minimum of 10 samples required to split an internal node, a minimum of 5 samples per leaf node, and class_weight = "balanced" to reduce the impact of class imbalance [19].

Finally, Gaussian Naive Bayes (GNB) was included as a probabilistic baseline because of its simplicity and computational efficiency.

To ensure a fair comparison, all classifiers were trained using the same standardized CAMeL-BERT embeddings and the same training, validation, and test partitions. Hyperparameters were selected through grid search on the validation set and subsequently kept fixed for all experiments.

F. Evaluation Metrics

The performance of the proposed classification framework was evaluated using Accuracy, Precision, Recall, F1-score, and Cohen's Kappa coefficient (κ). Accuracy provides the overall proportion of correctly classified documents, whereas Precision and Recall evaluate the correctness and completeness of the predicted classes, respectively. The F1-score, defined as the harmonic mean of Precision and Recall, provides a balanced measure of classification performance, particularly for imbalanced datasets. Cohen's Kappa (κ) was additionally reported to quantify the agreement between predicted and true labels while accounting for agreement occurring by chance.

Let TP, TN, FP, and FN denote the numbers of true positives, true negatives, false positives, and false negatives, respectively. The evaluation metrics are defined as follows:

$$\text{Accuracy} = \frac{TP+TN}{TP+TN+FP+FN} \quad (1)$$

$$\text{Precision} = \frac{TP}{TP+FP} \quad (2)$$

$$\text{Recall} = \frac{TP}{TP+FN} \quad (3)$$

$$F_1 = \frac{2\times Precision\times Recall}{Precision + Recall} \quad (4)$$

$$\kappa = \frac{P_o - P_e}{1 - P_e} \quad (5)$$

where, P_o denotes the observed agreement between predicted and true labels, and P_e represents the agreement expected by chance.

To provide a comprehensive assessment of classifier performance, the evaluation was conducted on the held-out test set, while model selection and hyperparameter tuning were performed exclusively on the validation set. In addition, five-fold stratified cross-validation was employed on the training data during model development to assess the robustness and generalization capability of the proposed framework.

IV. RESULTS AND DISCUSSION

A. Overall Classifier Performance

Table V summarizes the overall performance of the five evaluated classifiers on the independent test set comprising 779 original procedural court orders. Among all evaluated models, Logistic Regression (LR) achieved the highest classification performance, reaching a test accuracy of 99.74% with a Cohen's Kappa coefficient (κ) of 0.9966. Support Vector Machine (SVM) achieved the second-best performance with 99.49% accuracy (κ = 0.9932), followed by K-Nearest Neighbors (KNN) at 99.61%, Random Forest (RF) at 98.84%, and Gaussian Naive Bayes (GNB) at 96.66%.

The consistently high cross-validation accuracies, together with the very low standard deviations (±0.06%–±0.37%), demonstrate that the proposed framework generalizes well across different training folds and that the reported performance is not dependent on a particular train–test partition. Similarly, the high Cohen's Kappa values (LR: 0.9966, SVM: 0.9932,

KNN: 0.9949, RF: 0.9848, and GNB: 0.9562) indicate an almost perfect agreement between predicted and true labels, confirming that the excellent classification performance is not an artifact of class imbalance.

TABLE V. OVERALL PERFORMANCE OF THE EVALUATED CLASSIFICATION MODELS

Classifier	Validation Accuracy	Test Accuracy	5-Fold Cross-Validation Accuracy
Naive Bayes	97.30%	96.66%	98.34% ±0.37%
K-Nearest Neighbors	98.97%	99.61%	99.89% ±0.07%
Random Forest	98.84%	98.84%	99.91% ±0.07%
Support Vector Machine	99.49%	99.49%	99.96% ±0.07%
Logistic Regression	99.49%	99.74%	99.97% ±0.06%

Overall, the proposed framework demonstrates that combining frozen CAMeL-BERT contextual embeddings with lightweight machine learning classifiers provides highly accurate and robust classification of Moroccan procedural court orders. The strong performance can be attributed to three complementary factors: 1) the rich contextual semantic representations learned by CAMeL-BERT; 2) the highly discriminative legal vocabulary contained in the extracted facts section; and 3) the balanced training corpus obtained through targeted data augmentation. In addition, the low mean pairwise Jaccard similarity (12.3%) among the seven procedural categories indicates limited lexical overlap between categories, facilitating their discrimination in the embedding space. Finally, the consistent ranking of the evaluated classifiers (LR ≈ SVM > KNN > RF > GNB) across validation, test, and cross-validation experiments indicates that this is primarily attributable to the discriminative power of the contextual embeddings rather than classifier complexity.

B. Effect of Data Augmentation

Data augmentation increased the size of the training set from 2,336 to 13,764 documents while reducing the class imbalance ratio from 35.24:1 to 1.12:1. This strategy was specifically designed to improve the representation of minority procedural categories without modifying the validation and test sets, thereby preserving the integrity of the evaluation protocol.

The effectiveness of data augmentation is reflected in the per-category results reported in Table VII, where the two minority classes, تعيين قيم (24 test documents) and التشطيب على السجل التجاري (8 test documents), both achieved an F1-score of 1.000 despite their limited number of original training examples. These results indicate that the proposed augmentation strategy successfully compensated for severe class imbalance while preserving the discriminative characteristics of each procedural category.

The contribution of data augmentation is further confirmed by the ablation study presented in Table VI. Although the overall classification accuracy remains nearly unchanged, augmentation improves class-balanced performance by eliminating the remaining misclassifications affecting the minority class تعيين قيم. Consequently, the only residual errors are observed between المصادقة على الإنذار and العرض والإيداع, the two procedural categories exhibiting the highest semantic similarity.

Overall, these findings demonstrate that the principal contribution of data augmentation is not to increase the already high overall accuracy, but rather to enhance the robustness and reliability of the classifier across all procedural categories. This improvement is particularly important in judicial applications, where reliable recognition of minority case types is essential for practical deployment.

TABLE VI. ABLATION STUDY OF THE PROPOSED FRAMEWORK

Configuration	Accuracy	Macro-F1	F1 (تعيين قيم)	F1 (التشطيب)	Errors
TF-IDF + SVM	98.20%	0.9562	1.000	0.769	14/779
CAMeL-BERT + SVM (no augmentation)	99.49%	0.9933	0.979	1.000	4/779
CAMeL-BERT + LR (full pipeline)	99.74%	0.9970	1.000	1.000	2/779

C. Performance by Category

Table VII presents the per-category classification performance of the best-performing model, Logistic Regression, on the independent test set comprising 779 original procedural court orders. Overall, the proposed framework achieved perfect or near-perfect performance across all seven procedural categories. Five categories obtained an F1-score of 1.000, while المصادقة على الإنذار and العرض والإيداع achieved 99.46% and 98.09%, respectively.

TABLE VII. PER-CLASS PERFORMANCE OF THE LOGISTIC REGRESSION MODEL ON THE INDEPENDENT TEST SET

Procedural Category	Precision	Recall	F1-score	Support
Notification of Warning (تبليغ إنذار)	99.00%	100.00%	99.50%	296
Deposit and Consignment (العرض والإيداع)	100.00%	98.93%	99.46%	187
Financial Withdrawal (سحب مبلغ مالي)	100.00%	100.00%	100.00%	99
Payment Order (أمر بالأداء)	100.00%	100.00%	100.00%	86
Validation of Warning (المصادقة على الإنذار)	98.72%	97.47%	98.09%	79
Appointment of Guardian (تعيين قيم)	100.00%	100.00%	100.00%	24
Commercial Register Deletion (التشطيب على السجل التجاري)	100.00%	100.00%	100.00%	8

Note: Support denotes the number of original test documents in each procedural category.

The only two remaining misclassifications occurred between المصادقة على الإنذار and العرض والإيداع, which share similar procedural terminology and legal expressions. This observation suggests that the residual errors are primarily attributable to semantic similarity between these categories rather than to limitations of the contextual representations learned by CAMeL-BERT.

The two minority categories, تعيين قيم (24 test documents) and التشطيب على السجل التجاري (8 test documents), both achieved an F1-score of 1.000, demonstrating that the proposed framework generalizes effectively even for underrepresented procedural categories. Although these results should be interpreted with

appropriate caution because of the relatively small number of test instances, their consistent recognition provides additional evidence of the robustness of the proposed classification framework.

D. Error Analysis

The best-performing classifier (Logistic Regression) made only two errors on the independent test set of 779 original procedural court orders, corresponding to an error rate of 0.26%, while the SVM classifier produced four errors. Since both classifiers exhibit a very similar residual confusion pattern, the confusion matrix of the CAMeL-BERT + SVM configuration is presented in Fig. 3 as a representative visualization of the remaining ambiguity in the embedding space.

The four SVM misclassifications are exclusively concentrated between العرض والإيداع and المصادقة على الإنذار. Specifically, two documents belonging to العرض والإيداع were predicted as المصادقة على الإنذار, while two documents from المصادقة على الإنذار were classified as العرض والإيداع. No errors were observed for the remaining five procedural categories, including the minority classes تعيين قيم and التشطيب على السجل التجاري.

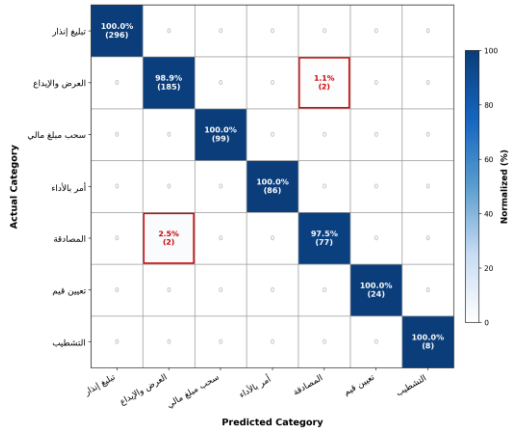

Fig. 3. Normalized confusion matrix of the CAMeL-BERT + SVM model on the independent test set (779 original documents).

The confusion matrix confirms that all residual errors are restricted to two procedurally related categories sharing similar legal terminology and document structure. The final Logistic Regression model further reduces these misclassifications from four to two while preserving the same overall confusion pattern, indicating that the remaining errors originate from semantic similarity between the categories rather than from limitations of the contextual representations.

From a practical perspective, these rare ambiguous cases could be addressed by incorporating a human verification step for predictions with low confidence scores. Such a strategy would enable reliable deployment in judicial document management systems while maintaining the efficiency of the proposed automated classification framework.

E. Corpus Structure and Accuracy

The 99.74% test accuracy achieved by the proposed Logistic Regression model is substantially higher than the performance reported in many previous studies on Arabic legal document classification and judicial prediction tasks. For example, judicial outcome prediction for European Court of Human Rights (ECHR) cases has reported F1-scores of approximately 79% [20], [21], while Zahir et al. [9] achieved an F1-score of 80.51% for Arabic court decision classification. Although these studies address different legal tasks and datasets, the comparison provides useful context for interpreting the present results.

The exceptionally high performance observed in this study can largely be attributed to the structural characteristics of Moroccan procedural court orders. First, the mean pairwise Jaccard similarity between category vocabularies is only 12.3%, indicating limited lexical overlap across procedural categories. Second, the contextual representations produced by CAMeL-BERT capture semantic and positional information beyond surface lexical features, resulting in highly separable document embeddings. Third, each procedural category follows standardized drafting conventions and contains recurring legal expressions that are consistently used within that category, thereby reducing intra-class variability. Finally, the documents are drafted by trained court clerks according to institutional writing practices, which further limits stylistic variation and linguistic ambiguity.

Taken together, these characteristics create a classification task that is particularly well-suited to contextual transformer embeddings combined with a linear classifier. This interpretation is consistent with previous studies on Moroccan legal documents, which also reported strong classification performance on structurally similar corpora, including 98.48% by El Moussaoui et al. [7] and 95.82% by Bouhouche et al. [8].

F. Deployment Prospects and Limitations

The proposed framework achieves an error rate of only 0.26% (2 misclassifications out of 779 test documents), suggesting that it is well suited for deployment as a decision-support tool rather than as a fully autonomous system. In practical settings, predictions associated with low confidence scores can be forwarded to court clerks for verification before final assignment, thereby combining the efficiency of automated document classification with human oversight.

Two deployment scenarios are envisioned within Morocco's ongoing e-Justice initiatives. The first is real-time document routing, where newly issued procedural court orders are automatically assigned to the appropriate departmental workflow while uncertain predictions are flagged for manual review. The second is retrospective digital archiving, where historical procedural court orders are automatically indexed according to their legal category, facilitating efficient search, retrieval, and document management.

An additional practical advantage of the proposed framework is its computational efficiency. Since CAMeL-BERT is used only for offline feature extraction and the final classifier is a lightweight Logistic Regression model, inference requires only standard CPU resources without GPU acceleration. This makes the system compatible with the computing infrastructure commonly available in Moroccan courts of first instance.

The proposed framework nevertheless has several limitations. First, the extraction pipeline was developed and validated using procedural court orders collected from

Moroccan courts of first instance between 2020 and 2025. Its applicability to documents from other court levels or jurisdictions may therefore require adaptation of the extraction component. Second, the classifier was trained to recognize only seven procedural categories. Extending the framework to additional legal document types would require new annotated data and retraining of the classification pipeline. Finally, the study evaluates the system on a single national corpus; future work should investigate its generalization to broader collections of Arabic legal documents and to judicial systems beyond Morocco.

V. CONCLUSION

This study presented an end-to-end framework for the automated classification of Moroccan procedural court orders. The proposed pipeline addresses a practical challenge that has received limited attention in previous studies: the lack of standardized document structure in Arabic legal Word documents. A custom Python extraction script automatically converts heterogeneous documents into structured representations by extracting the facts, decision, and confidence score, enabling the classifier to focus on the most informative textual content.

The framework was evaluated on a manually collected corpus of 3,894 procedural court orders from Moroccan courts of first instance (2020–2025), covering seven official procedural categories. After expanding the training set to 13,764 documents through domain-specific data augmentation, five machine learning classifiers were evaluated using frozen CAMeL-BERT embeddings. Logistic Regression achieved the best performance, reaching 99.74% test accuracy with a Cohen's κ of 0.9966. The ablation study further demonstrated that the strong performance results from the combination of highly discriminative contextual embeddings and the structural characteristics of Moroccan procedural court orders, while data augmentation effectively improves robustness for minority categories.

Although the proposed framework demonstrates excellent performance, several directions remain for future research. Extending the corpus to additional court levels, legal document types, and Arabic-speaking jurisdictions would improve the generalizability of the approach. A fine-tuned CAMeL-BERT baseline was not included in this study. Consequently, the effectiveness of frozen contextual embeddings is demonstrated for this corpus but was not directly compared with end-to-end transformer fine-tuning. Future work will investigate this comparison.

ACKNOWLEDGMENT

This work was supported by the Ministry of Higher Education, Scientific Research, and Innovation; the Digital Development Agency (DDA); and the National Centre for Scientific and Technical Research (CNRST) of Morocco under grant Alkhawarizmi/2020/25.

***Abstract*—Speech Emotion Recognition (SER) has attracted considerable attention in recent years because of its potential applications in healthcare, intelligent assistants, customer service, and human-computer interaction. However, the performance of SER systems is often affected by the imbalance of emotion classes in benchmark datasets, where minority emotions are underrepresented and difficult to classify accurately. This study reproduces the work of Sahu et al. on multimodal Speech Emotion Recognition using the Interactive Emotional Dyadic Motion Capture (IEMOCAP) dataset. Further, it proposes a Hybrid SMOTE-Ensemble Framework to improve classification performance on imbalanced data. The reproduction stage follows the original methodology by employing handcrafted acoustic features together with TF-IDF textual features under Audio-only, Text-only, and Audio+Text modalities. The enhancement stage introduces two XGBoost classifiers trained independently on the original imbalanced dataset and on a SMOTE-balanced dataset. Their prediction probabilities are combined using three ensemble strategies, namely Simple Averaging, Confidence-Based Selection, and Adaptive Weighting. In addition, the effectiveness of the proposed strategy is further investigated using a LinearSVC classifier. Experimental results demonstrate that the reproduced models achieve results that are highly consistent with those reported in the original study. Furthermore, the proposed Hybrid SMOTE-Ensemble Framework improves the recognition of minority emotion classes while maintaining balanced overall performance. The XGBoost model trained on SMOTE-balanced data achieves higher F1-score and recall than the baseline model, whereas the ensemble approaches provide additional improvements in classification performance. The LinearSVC experiments further confirm that combining oversampling and ensemble learning offers a robust solution to the class imbalance problem in Speech Emotion Recognition.**

***Keywords*—IEMOCAP dataset; Speech Emotion Recognition (SER); class imbalance; SMOTE**

I. Introduction

Emotion Recognition (SER) is an important research area in Artificial Intelligence (AI) that combines signal processing, machine learning, and affective computing. The main goal of SER is to automatically identify the emotional state of a speaker from speech signals. Unlike conventional speech recognition systems, which focus on recognizing spoken words, SER aims to understand the emotions hidden behind speech. This capability enables machines to interact with humans more naturally and intelligently [3].

In recent years, SER has attracted considerable attention because of its wide range of applications. Emotion-aware systems are increasingly used in healthcare, customer service, intelligent virtual assistants, education, and smart transportation systems. For example, intelligent assistants can adapt their responses according to the emotional state of users, while healthcare applications can use speech emotion analysis to monitor mental health conditions such as stress, anxiety, and depression. Similarly, driver monitoring systems can detect emotions such as anger or fatigue to improve road safety [3].

The rapid development of machine learning and deep learning techniques has significantly improved the performance of SER systems. Traditional machine learning approaches rely on handcrafted acoustic features such as pitch, energy, harmonics, pauses, and statistical descriptors. More recently, multimodal approaches that combine speech and textual information have shown promising results because emotional information is often conveyed through both acoustic and linguistic cues [3].

Despite these advances, SER remains a challenging task. One of the main challenges is the imbalance of emotion classes in benchmark datasets. In many real-world datasets, some emotions are represented by a large number of samples, whereas others contain only a limited number of examples. As a result, classification models tend to be biased toward majority classes and often fail to recognize minority emotions accurately. This problem becomes more significant in widely used SER datasets such as the Interactive Emotional Dyadic Motion Capture (IEMOCAP) dataset, where emotions such as fear and surprise are underrepresented compared with other emotion categories [4].

Several methods have been proposed to address the class imbalance problem in SER. Traditional approaches include random oversampling, undersampling, and cost-sensitive learning. Among these methods, the Synthetic Minority Over-sampling Technique (SMOTE) has gained considerable attention because it generates synthetic samples for minority classes instead of simply duplicating existing instances. By creating new samples through interpolation between neighboring minority samples, SMOTE increases data diversity and reduces the risk of overfitting [6]. Previous studies have shown that SMOTE can improve the performance of classification models on imbalanced datasets and enhance the recognition of minority classes [7,8]. However, SMOTE also has some limitations, including the possibility of generating noisy samples, increasing class overlap, and producing synthetic instances that do not accurately represent the underlying data distribution [9,10].

Ensemble learning has also demonstrated strong performance in many classification problems by combining the

*Corresponding author.

strengths of multiple models. In SER, ensemble approaches can improve classification accuracy and robustness by exploiting the complementary characteristics of different classifiers. Nevertheless, effectively combining ensemble learning with oversampling techniques for imbalanced emotion recognition remains an open research problem. Existing methods often improve minority class recognition at the expense of majority classes or fail to maintain balanced overall performance.

Motivated by these challenges, this study proposes a Hybrid SMOTE-Ensemble Framework for robust Speech Emotion Recognition on imbalanced data. The proposed framework combines models trained on the original imbalanced dataset and on a SMOTE-balanced dataset using different ensemble strategies. The objective is to improve minority emotion recognition while preserving the overall classification performance. The effectiveness of the proposed framework is evaluated using the IEMOCAP dataset and compared with conventional machine learning approaches.

The remainder of this study is organized as follows. Section II presents the background of Speech Emotion Recognition and discusses existing approaches for handling class imbalance. Section III describes the proposed Hybrid SMOTE-Ensemble Framework, including dataset preparation, feature extraction, model development, and ensemble strategies. Section IV presents the experimental setup and evaluation metrics. Section V discusses the experimental results and comparative analysis. Finally, Section VI concludes the study and outlines possible directions for future work.

II. Background

A. Multimodal Speech Emotion Recognition

Speech Emotion Recognition (SER) is an important research field that aims to identify the emotional state of a speaker from speech signals. The objective of SER is to enable machines to understand human emotions and improve human-computer interaction. In recent years, SER has been applied in many areas such as intelligent virtual assistants, healthcare monitoring, customer service, and smart transportation systems [3].

Emotions are usually expressed through multiple channels at the same time. Humans naturally combine information from speech, text, facial expressions, and gestures to understand emotions. Similarly, multimodal SER systems utilize information from different modalities to improve recognition accuracy. Sahu et al. [3] stated that humans are able to resolve ambiguity in emotions because they can efficiently process information from multiple domains, including speech, text, and visual signals. This observation has motivated the development of multimodal SER systems that combine acoustic and textual information to provide a more comprehensive understanding of emotional expressions.

In audio-based SER, acoustic features play an important role in emotion classification. Commonly used features include prosodic characteristics such as pitch, energy, speaking rate, and voice quality. Spectral features such as Mel Frequency Cepstral Coefficients (MFCCs), formants, harmonics, and statistical descriptors are also widely used because they capture important information related to emotional variations in speech [3]. In addition to acoustic information, textual features extracted from speech transcriptions can provide useful semantic information. Traditional text representations include Bag-of-Words and Term Frequency-Inverse Document Frequency (TF-IDF), while more recent approaches employ word embeddings and pre-trained language models.

Among the available SER datasets, the Interactive Emotional Dyadic Motion Capture (IEMOCAP) dataset is one of the most widely used benchmarks. The dataset contains approximately 12 hours of multimodal recordings collected from ten actors participating in scripted and improvised dialogues [4]. Each utterance is annotated by multiple annotators according to different emotional categories, making the dataset suitable for evaluating speech emotion recognition methods. However, similar to many real-world datasets, IEMOCAP exhibits an imbalanced distribution of emotion classes, where some emotions are represented by a large number of samples while others contain relatively few examples. This imbalance remains one of the major challenges affecting the performance and robustness of SER systems.

B. Class Imbalance and Oversampling Techniques

Class imbalance is one of the major challenges in Speech Emotion Recognition (SER). In many emotional speech datasets, some emotions are represented by a large number of samples, while others contain only a limited number of examples. As a result, machine learning models tend to favor majority classes and often produce poor recognition performance for minority emotions. This issue becomes more serious when the evaluation focuses only on overall accuracy, as a high accuracy score may hide weak performance on underrepresented classes.

The IEMOCAP dataset is a clear example of this problem. The distribution of emotion classes in IEMOCAP is not balanced, with emotions such as fear and surprise containing fewer samples than emotions such as sadness and neutrality. Previous studies reported that this imbalance negatively affects the performance of emotion classification models, particularly for minority emotions that are difficult to learn because of the limited training data available [3]. Therefore, addressing class imbalance has become an important research topic in SER [11].

Traditional methods for handling imbalanced data include random undersampling and random oversampling. Undersampling reduces the number of majority class samples to balance the dataset; however, useful information may be lost during this process. On the other hand, random oversampling duplicates minority class samples to increase their representation. Although this method is simple and easy to implement, it does not introduce new information and may increase the risk of overfitting because the same samples are repeatedly used during training [6].

Among the available oversampling techniques, the Synthetic Minority Over-sampling Technique (SMOTE) is one of the most widely used methods for imbalanced classification problems. SMOTE generates new synthetic samples for minority classes instead of simply duplicating existing instances. The method creates new samples by interpolating between a minority sample and its nearest neighbors in the feature space. This process increases the diversity of minority samples and helps classifiers

learn more representative decision boundaries [6]. Previous studies have demonstrated that SMOTE can improve classification accuracy, precision, recall, and F1-score when dealing with imbalanced datasets [7,8].

Several extensions of SMOTE have also been proposed to improve the quality of synthetic samples. SMOTEBoost combines SMOTE with boosting algorithms to improve the classification of minority classes by generating synthetic samples during the boosting process. Selective Interpolation SMOTE (SISMOTE) focuses on generating samples in safe regions of the feature space to reduce the influence of noisy samples and overlapping classes [2]. Another variant, FC-SMOTE, utilizes fuzzy clustering to identify suitable oversampling regions and assign sampling weights according to data density, which helps address within-class imbalance and improve minority class representation [12].

In recent years, more advanced data augmentation techniques have been introduced for SER. Generative Adversarial Networks (GANs) have been employed to generate realistic synthetic emotional speech samples by learning the underlying data distribution [13]. Other approaches combine acoustic and textual augmentation techniques to preserve emotional consistency across different modalities [14]. Although these methods have shown promising results, they often require complex training procedures and considerable computational resources.

Despite the success of these oversampling and augmentation methods, several challenges remain. Synthetic samples may not always accurately represent the original data distribution, which can lead to class overlap or the introduction of noisy samples. Furthermore, improving minority class recognition may sometimes reduce the performance of majority classes, making it difficult to achieve balanced overall performance [9,10]. Therefore, combining oversampling techniques with ensemble learning has emerged as a promising direction for improving the robustness and effectiveness of Speech Emotion Recognition systems on imbalanced datasets.

C. Ensemble Learning for Imbalanced SER

Ensemble learning is a machine learning technique that combines the predictions of multiple classifiers to achieve better performance than a single model. The main idea is that different classifiers may learn different characteristics from the data, and combining their outputs can improve classification accuracy, robustness, and generalization ability [16]. Ensemble methods have been successfully applied to many classification problems, particularly when dealing with noisy and imbalanced datasets [14].

In Speech Emotion Recognition (SER), ensemble learning has received increasing attention because emotional speech data exhibit large variations in speaking style, recording environments, and emotion distributions. Individual classifiers may perform well on certain emotion classes but perform poorly on others. Therefore, combining multiple classifiers can help reduce the weaknesses of individual models and provide more stable performance across different emotion categories [17-20].

Several ensemble techniques have been investigated in SER research. Voting-based ensembles combine the predictions of different classifiers using majority voting or probability averaging. Boosting algorithms, such as AdaBoost and Gradient Boosting, iteratively train weak learners by focusing on previously misclassified samples to improve the overall prediction performance [21-25]. Bagging approaches, such as Random Forest, create multiple classifiers from different subsets of the training data and aggregate their predictions to reduce variance and improve stability. More recently, hybrid ensemble frameworks have been proposed to combine different classifiers and feature representations for emotion recognition tasks [26-30].

Ensemble learning is particularly useful for imbalanced datasets. Models trained on the original dataset usually preserve the natural distribution of the data and often achieve good performance on majority classes. In contrast, models trained on balanced datasets generated using oversampling techniques, such as SMOTE, generally provide better recognition of minority classes [5]. Combining these models enables the ensemble to exploit the advantages of both learning strategies and can lead to more balanced classification performance [31-35].

However, designing an effective ensemble framework remains a challenging task. The performance of an ensemble depends not only on the quality of the individual classifiers but also on the strategy used to combine their predictions [35-40]. Simple averaging may not always produce the best results, while confidence-based and adaptive weighting methods may behave differently depending on the class distribution and dataset characteristics [15]. Furthermore, the combination of ensemble learning and oversampling techniques in SER has not been extensively investigated, especially for highly imbalanced emotion datasets such as IEMOCAP [4].

Motivated by these observations, this study proposes a Hybrid SMOTE-Ensemble Framework that combines models trained on the original imbalanced dataset and on a SMOTE-balanced dataset using different ensemble strategies. The proposed framework aims to improve the recognition of minority emotions while maintaining robust overall classification performance.

III. Proposed Hybrid SMOTE-Ensemble Framework

This section presents the proposed Hybrid SMOTE-Ensemble Framework for Speech Emotion Recognition on imbalanced data. The framework consists of three main stages: dataset preparation, feature extraction, and hybrid ensemble learning. The IEMOCAP dataset is used to evaluate the effectiveness of the proposed framework because it is one of the most widely used benchmarks for Speech Emotion Recognition and contains a naturally imbalanced distribution of emotion classes [4].

The proposed framework first prepares the emotional speech data and performs emotion label mapping to obtain the final emotion categories. Acoustic and textual features are then extracted from speech recordings and transcriptions to construct multimodal feature representations. To address the class imbalance problem, two classifiers are trained independently: one using the original imbalanced dataset and another using a balanced dataset generated using the Synthetic Minority Over-

sampling Technique (SMOTE). Finally, different ensemble strategies are employed to combine the predictions of the two models and improve the recognition of minority emotions while maintaining robust overall classification performance.

A. Dataset and Preprocessing

The proposed framework was evaluated using the Interactive Emotional Dyadic Motion Capture (IEMOCAP) dataset, which is one of the most widely used benchmark datasets for Speech Emotion Recognition (SER) [4]. The dataset contains approximately 12 hours of multimodal recordings collected from five sessions of dyadic interactions involving ten actors. Each session includes both scripted and improvised conversations and provides audio recordings, video streams, facial motion capture data, and textual transcriptions. The utterances are annotated by multiple evaluators according to different emotion categories, making the dataset suitable for emotion recognition studies.

The original IEMOCAP dataset contains several emotion labels, including anger, excitement, fear, sadness, surprise, frustration, happiness, disappointment, and neutrality. In this study, the emotion labels were processed to obtain six final emotion categories following the data preparation strategy adopted in previous studies [12]. The emotions "happy" and "excited" were merged into a single class because of their close semantic and expressive characteristics, and because the number of "happy" samples alone was relatively small. The class labeled as "others" was excluded because it represents vague emotional expressions that are difficult to classify consistently.

The emotion label "frustration" does not appear in the final six emotion classes reported by Sahu [12]. Therefore, utterances labeled as "frustration" were assigned to the "angry" category because both emotions share similar emotional characteristics and are often closely related in Speech Emotion Recognition studies. Other ambiguous labels, such as "disappointed", were excluded from the final dataset unless they were explicitly assigned to one of the selected emotion classes.

After label processing, the final dataset consisted of six emotion classes: Angry, Happy, Sad, Fear, Surprise, and Neutral. The corresponding class distribution was adopted from the dataset preparation procedure reported in [12], resulting in 860 samples for Angry, 1309 samples for Happy, 2327 samples for Sad, 1007 samples for Fear, 949 samples for Surprise, and 1385 samples for Neutral, with a total of 7837 utterances. The distribution of these classes remains imbalanced, where some emotions are represented by considerably fewer samples than others.

To evaluate the proposed framework, the dataset was randomly divided into training and testing sets using an 80:20 ratio. The same data split was used throughout all experiments to ensure a fair comparison among different models and ensemble strategies [12]. The original imbalanced training set was preserved for training the baseline model, while an additional balanced training set was generated using the Synthetic Minority Over-sampling Technique (SMOTE) for the proposed hybrid ensemble framework.

B. Feature Extraction

Feature extraction is an important stage in Speech Emotion Recognition because the quality of extracted features directly affects the performance of classification models. In this study, both acoustic and textual features were utilized to construct a multimodal representation of emotional speech following the feature extraction strategy described in [12].

For the audio modality, handcrafted acoustic features were extracted from each speech utterance. These features include pitch, harmonics, energy, pause-related information, and statistical descriptors that capture the emotional characteristics of speech signals. Prosodic and spectral features are widely used in SER because they provide useful information related to speaking style, emotional intensity, and vocal characteristics [3].

For the textual modality, the speech transcriptions provided in the IEMOCAP dataset were transformed into numerical feature vectors using the Term Frequency-Inverse Document Frequency (TF-IDF) technique. TF-IDF was employed to capture the importance of words according to their frequency in a document and their occurrence across the entire corpus. The extracted text features provide complementary linguistic information that can help distinguish different emotional states.

The extracted audio and text features were then combined to form a multimodal feature representation. This combination allows the framework to exploit complementary information from both modalities, since emotions are often reflected not only in acoustic patterns but also in the semantic content of speech.

It should be noted that some implementation details related to audio feature extraction, such as frame size, hop length, and filter configurations, were not explicitly reported in the original framework [12]. Therefore, commonly adopted settings and library default parameters were used during feature extraction while maintaining consistency across all experiments. The same feature extraction procedure was applied to both the original and SMOTE-balanced datasets to ensure a fair comparison among the evaluated models.

C. Model Architectures and Training

To address the class imbalance problem in Speech Emotion Recognition, two XGBoost classifiers were trained independently using different training datasets. The first classifier was trained using the original imbalanced training set, while the second classifier was trained using a balanced dataset generated using the Synthetic Minority Over-sampling Technique (SMOTE). This strategy allows the framework to benefit from the strengths of both learning schemes, where the original model preserves the natural data distribution and the SMOTE-based model improves the recognition of minority emotion classes.

XGBoost was selected as the base classifier because of its strong classification performance, robustness, and ability to handle high-dimensional feature spaces efficiently. XGBoost is an ensemble learning algorithm based on gradient boosting decision trees, where multiple weak learners are sequentially combined to produce a strong predictive model. The algorithm has demonstrated competitive performance in various classification tasks and has been successfully applied in Speech Emotion Recognition applications [1].

For the original model, the extracted multimodal features were directly used to train the XGBoost classifier using the imbalanced training dataset. In parallel, SMOTE was applied to the training set to generate synthetic samples for minority emotion classes and create a balanced training dataset. The same XGBoost architecture and training settings were then applied to the SMOTE-balanced dataset to ensure a fair comparison between the two models.

After training the individual classifiers, their predictions were combined using a hybrid ensemble strategy. Three ensemble methods were investigated in this study: Simple Averaging, Confidence-Based Selection, and Adaptive Weighting. In the Simple Averaging method, the prediction probabilities of the two models were averaged, and the emotion class with the highest probability was selected as the final prediction. In the Confidence-Based Selection method, the prediction of the model with the higher confidence score was chosen. The Adaptive Weighting approach assigns different weights to the two classifiers according to their performance, allowing the ensemble to balance the contributions of the original and SMOTE-based models.

The proposed Hybrid SMOTE-Ensemble Framework combines the advantages of the original and balanced datasets while reducing the limitations of using either approach independently. The overall architecture of the proposed framework is illustrated in Fig. 1.

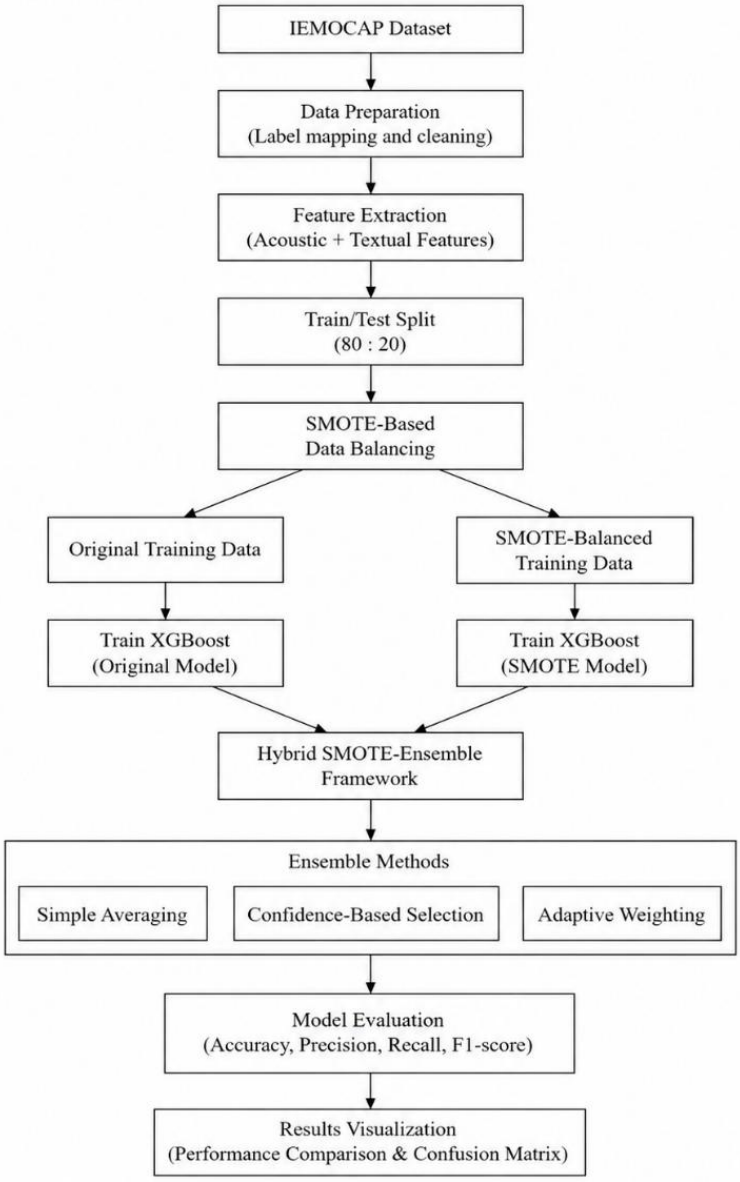

Fig. 1. Overall architecture of the proposed hybrid SMOTE-ensemble framework for speech emotion recognition.

IV. Experimental Setup and Enhancement Strategy

A. Motivation for Enhancement

The IEMOCAP dataset exhibits an imbalanced distribution of emotion classes, where some emotions are represented by a large number of samples while others contain relatively few examples. This imbalance can bias classification models toward majority classes and reduce their ability to recognize minority emotions accurately. In the original study, the imbalance problem was addressed using simple random upsampling for the "fear" and "surprise" classes, while the "happy" and "excited" classes were merged into a single category [12]. Although these strategies help reduce the imbalance problem, they have certain limitations.

Random oversampling increases the number of minority class samples by duplicating existing instances. While this approach is simple to implement, it does not introduce new information into the training set and may increase the risk of overfitting. As a result, the classifier may perform well on the duplicated training samples but fail to generalize effectively to unseen data. Furthermore, merging emotion classes simplifies the classification problem but may reduce the emotional diversity of the dataset and limit the model's ability to distinguish between similar emotions.

To overcome these limitations, this study employs the Synthetic Minority Over-sampling Technique (SMOTE) to generate synthetic samples for minority emotion classes. Unlike random oversampling, SMOTE creates new samples by interpolating between neighboring minority instances, which increases the diversity of the training data and provides better representation of underrepresented classes [5]. This property makes SMOTE a suitable choice for Speech Emotion Recognition tasks involving imbalanced datasets.

In addition to SMOTE, this study introduces a hybrid ensemble strategy that combines models trained on the original imbalanced dataset and on the SMOTE-balanced dataset. The motivation behind this approach is that the original model preserves the natural distribution of the data and performs well on majority classes, whereas the SMOTE-based model is expected to improve the recognition of minority emotions. By combining the predictions of both models, the proposed framework aims to achieve more balanced and robust emotion recognition performance across all emotion classes.

B. Implementing the Hybrid XGBoost Ensemble with SMOTE

To reduce the limitations of simple upsampling and improve model performance, this study uses a hybrid XGBoost ensemble strategy with SMOTE. The method combines the predictions of two separately trained XGBoost models: one trained on the original imbalanced data and another trained on the SMOTE-balanced data.

The first XGBoost model was trained on the original training dataset. This model keeps the natural class distribution and is expected to perform better on the majority emotion classes. The second XGBoost model was trained on a balanced version of the training dataset after applying SMOTE. This model is expected to improve the recognition of minority emotion classes because it is trained with a more balanced class distribution.

SMOTE generates synthetic samples for minority classes by creating new points between existing minority samples and their nearest neighbors in the feature space [5]. In this study, SMOTE was applied using random_state = 42 for reproducibility, and the default k_neighbors = 5 was used. Fig. 2 shows the class distribution before and after applying SMOTE, where all classes were balanced to the same number of samples.

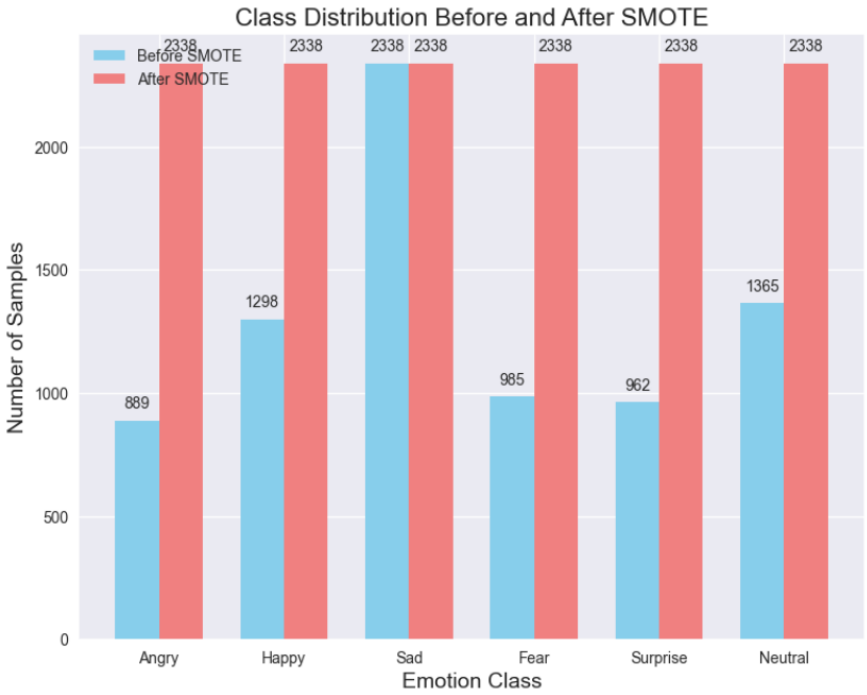

Fig. 2. Class distribution before and after applying SMOTE.

Both XGBoost models were trained using the same parameters. The selected parameters were max_depth = 7, learning_rate = 0.008, objective = multi:softprob, n_estimators = 600, subsample = 0.8, num_class = 6, and booster = gbtree.

The prediction probabilities from the two XGBoost models were combined using three ensemble strategies. The first strategy was Simple Averaging, where the probabilities from the original model and the SMOTE-based model were averaged, and the class with the highest average probability was selected. The second strategy was Confidence-Based Selection, where the final prediction was taken from the model with the highest confidence score. Confidence was calculated as the highest probability assigned to any class by each model.

The third strategy was Adaptive Weighted Ensemble. In this method, different weights were assigned to the original and SMOTE-based models according to the class distribution in the training data. For minority classes, defined as classes with less than 15% of the training samples, the original model was assigned a weight of 0.3 and the SMOTE model was assigned a weight of 0.7. For majority classes, defined as classes with more than 25% of the training samples, the original model was assigned a weight of 0.7 and the SMOTE model was assigned a weight of 0.3. For the remaining classes, both models were assigned equal weights of 0.5.

The purpose of this hybrid ensemble is to combine the strengths of both models. The original XGBoost model can preserve performance on majority classes, while the SMOTE-based XGBoost model can improve the recognition of minority classes. By combining both models, the proposed framework aims to improve the overall Speech Emotion Recognition performance on imbalanced data.

C. Implementation of the Hybrid Ensemble

The proposed Hybrid SMOTE-Ensemble Framework was implemented in Python using the XGBoost and imbalanced-learn libraries. Two XGBoost classifiers were trained independently: one using the original imbalanced training dataset and the other using the SMOTE-balanced dataset. The Audio+Text modality was adopted using the handcrafted acoustic features and TF-IDF text features described in the previous sections. The dataset was divided into 80% for training and 20% for testing, where the testing set remained unchanged throughout all experiments. The prediction probabilities generated by the two classifiers were combined using the three ensemble strategies discussed in Section IV-B, namely Simple Averaging, Confidence-Based Selection, and Adaptive Weighting. The effectiveness of the proposed framework was evaluated using Accuracy, F1-score, Precision, Recall, and confusion matrices.

Fig. 3 presents the performance comparison of the Hybrid XGBoost framework using five different techniques: XGB Original, XGB SMOTE, Simple Average Ensemble, Confidence-Based Ensemble, and Adaptive Weighted Ensemble. The comparison is based on Accuracy, F1-score, Precision, and Recall. The results show that the SMOTE-based model improves both recall and F1-score compared with the original XGBoost model. Furthermore, the ensemble approaches provide additional improvements in overall performance. Among the ensemble methods, the Adaptive Weighted Ensemble demonstrates a balanced improvement across all evaluation metrics, while the Simple Average Ensemble achieves competitive performance with a simpler integration strategy.

Fig. 4 illustrates the confusion matrix of the XGBoost model trained on the original imbalanced dataset. The model classifies emotions into six categories: angry (ang), happy (hap), neutral (neu), sad (sad), frustrated (fru), and excited (exc). The results indicate that the model performs best on the neutral class, which records the highest number of correctly classified samples. However, some confusion can be observed between emotionally similar classes, particularly between happy and neutral emotions. Although misclassifications occur across several categories, the model maintains acceptable classification performance overall. The darker values along the diagonal indicate higher numbers of correct predictions.

Fig. 3. Hybrid XGBoost model performance metrics with different applied techniques.

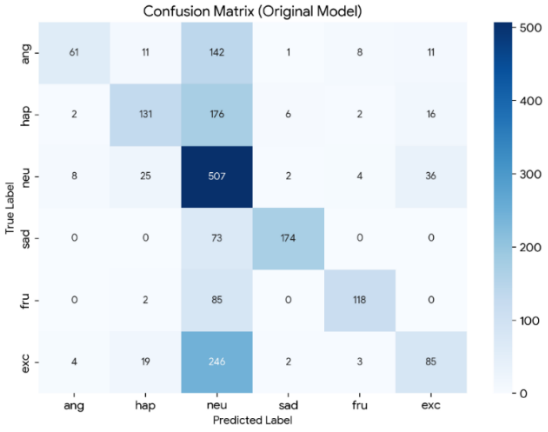

Fig. 4. Confusion matrix of the XGBoost original model.

Fig. 5 presents the confusion matrix of the Simple Average Ensemble. Similar to the original model, the ensemble classifies six emotion categories: angry, happy, neutral, sad, frustrated, and excited. The diagonal elements represent correctly classified samples, while the off-diagonal elements correspond to misclassified instances. The neutral emotion achieves the highest number of correct classifications, whereas confusion remains noticeable between happy and neutral emotions. Overall, the ensemble demonstrates improved consistency across emotion categories and provides more balanced classification performance than the original model.

Fig. 6 shows the confusion matrix of the XGBoost model trained on the SMOTE-balanced dataset. The application of SMOTE improves the representation of minority emotion classes and enhances their recognition capability. The model performs well in recognizing neutral, happy, and excited emotions, while some confusion remains between neutral and sad emotions. The results indicate that balancing the training data contributes positively to the classification of underrepresented classes and improves the overall robustness of the model.

Fig. 7 illustrates the recall values achieved by the Original XGBoost model, the SMOTE-based XGBoost model, and the Simple Average Ensemble across the six emotion classes. The Original model achieves the highest recall for the neutral class, while the SMOTE-based model improves the recall of several minority classes. The Simple Average Ensemble provides more consistent recall values across most classes and achieves a better balance between majority and minority emotions. Nevertheless, the angry class remains the most challenging category for all models, indicating that further improvements in feature representation or data augmentation may still be beneficial.

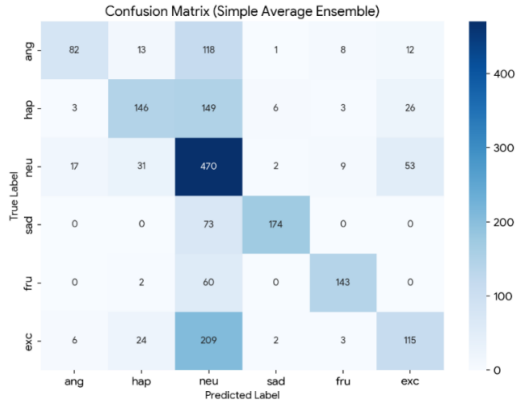

Fig. 5. Confusion matrix of the simple average ensemble technique.

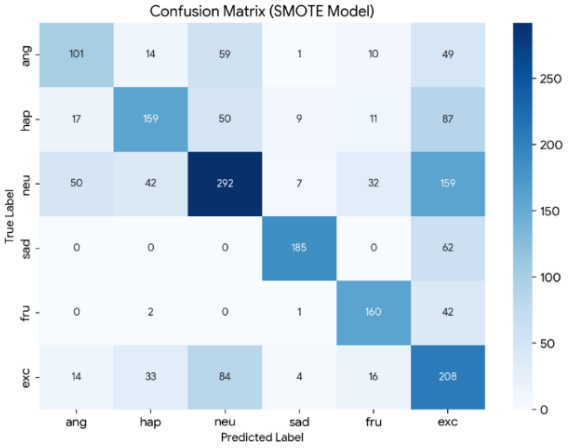

Fig. 6. Confusion matrix of the SMOTE model technique.

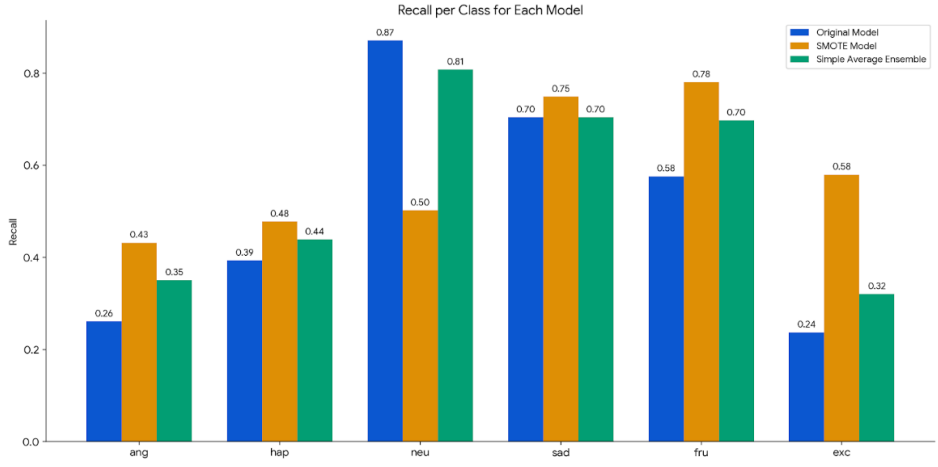

Fig. 7. Hybrid XGBoost model recall per class for each model.

V. Additional Evaluation Using LinearSVC

To further investigate the effectiveness of the proposed Hybrid SMOTE-Ensemble Framework, an additional evaluation was conducted using a Linear Support Vector Classifier (LinearSVC). The objective of this experiment was to examine whether the advantages of data balancing and ensemble learning can be generalized to a different classifier architecture. Similar to the XGBoost experiments, the main challenge lies in the imbalanced distribution of emotion classes, where minority emotions are often underrepresented and difficult to classify accurately.

Two enhancement approaches were investigated. The first approach applied SMOTE directly to the entire training set before training a single LinearSVC classifier. The second approach employed a Hybrid Weighted Ensemble, where two LinearSVC models were trained independently: one using the original imbalanced dataset and the other using the SMOTE-balanced dataset. The predictions of both models were then combined using adaptive weights that assign greater importance to the SMOTE model for minority classes and greater importance to the original model for majority classes.

A. Performance Comparison

The results demonstrate that applying SMOTE changes the behaviour of the LinearSVC classifier. Although the overall accuracy remained close to the baseline model, SMOTE improved the model's ability to recognize minority emotion classes by increasing recall. This improvement, however, was accompanied by a slight reduction in precision and F1-score for some majority classes, which is a common trade-off when balancing highly imbalanced datasets.

The Hybrid Weighted Ensemble achieved the best overall performance among the evaluated LinearSVC models. The ensemble obtained an accuracy score of 0.629, outperforming both the baseline and the SMOTE-only models. This result indicates that combining the strengths of the original and SMOTE-based classifiers leads to a more balanced and robust classification system. In particular, the ensemble achieved perfect recall for the Fear class, demonstrating its effectiveness in recognizing minority emotions.

Fig. 8 illustrates the effect of SMOTE on the class distribution and presents the performance metrics of the LinearSVC models. The results show that the Hybrid Ensemble achieves the highest accuracy, F1-score, and recall, while maintaining competitive precision. In contrast, the original LinearSVC model achieves the highest precision but exhibits lower recall, especially for minority classes. The SMOTE-based model improves recall but sacrifices some precision, whereas the Hybrid Ensemble provides the most balanced performance.

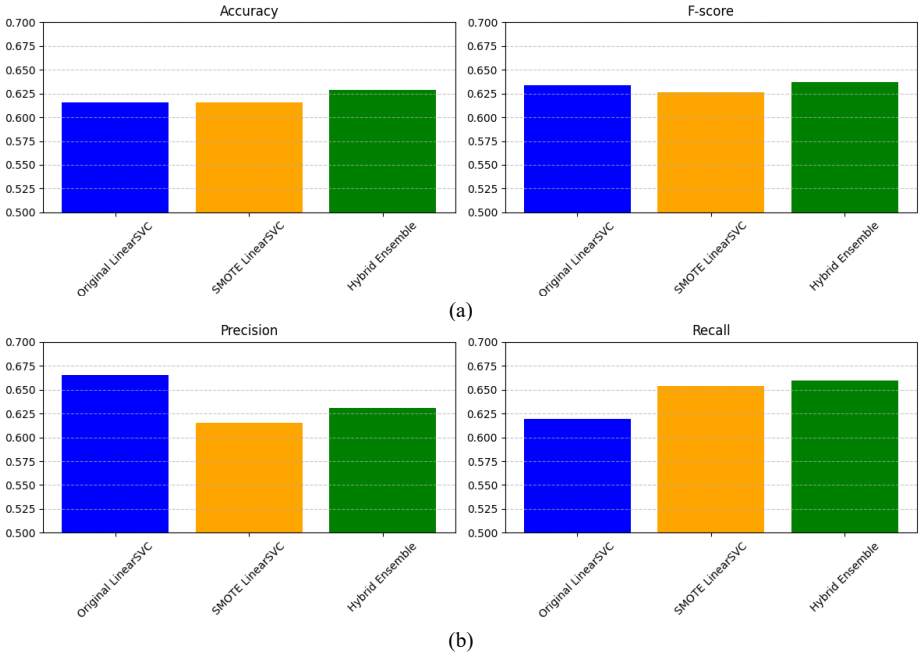

Fig. 8. (A) Class distribution before and after applying SMOTE. (B) Performance comparison of Original LinearSVC, SMOTE LinearSVC, and Hybrid Ensemble models.

B. Confusion Matrix Analysis

The confusion matrices shown in Fig. 9 provide a detailed comparison of the three LinearSVC configurations. The original model demonstrates high precision for majority classes but exhibits considerable misclassification for minority emotions. Several minority classes are frequently predicted as the dominant classes, indicating that the imbalanced training data limits the classifier's ability to learn representative decision boundaries.

After applying SMOTE, the recognition of minority classes improves noticeably. The SMOTE-based model correctly identifies more samples from underrepresented classes; however, the increase in synthetic samples also introduces additional confusion among some majority classes, which leads to a reduction in overall precision.

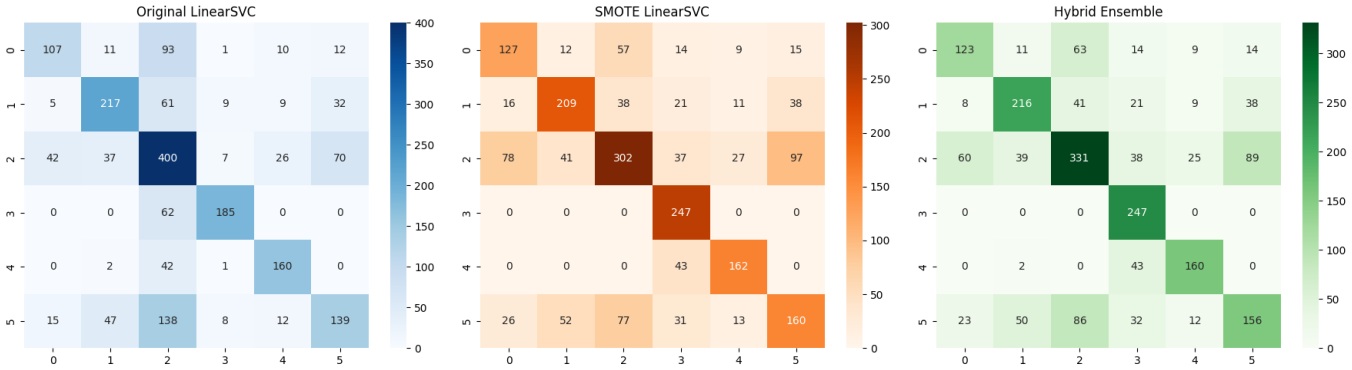

Fig. 9. Confusion matrices of the LinearSVC models: (A) Original model, (B) SMOTE-based model, and (C) Hybrid weighted ensemble.

The Hybrid Ensemble achieves the best balance between these two approaches. The confusion matrix shows a reduction in misclassification errors while maintaining high numbers of correctly classified samples across most emotion categories. This demonstrates that combining the predictions of the original and SMOTE-based models provides a more robust solution to the class imbalance problem than either model individually.

C. Recall Analysis

Fig. 10 compares the recall values obtained by the Original LinearSVC model, the SMOTE-based LinearSVC model, and the Hybrid Weighted Ensemble for each emotion class. The results show that both SMOTE and the Hybrid Ensemble improve recall for minority classes compared with the baseline model.

The Hybrid Ensemble provides the most consistent recall across all emotion classes and achieves the best overall balance between minority and majority class recognition. The most notable result is the perfect recall achieved for Class 3 (Fear), indicating that the proposed weighting strategy effectively enhances the recognition of difficult and underrepresented emotions.

Overall, the additional experiments using LinearSVC confirm the effectiveness of the Hybrid SMOTE-Ensemble concept. Although the XGBoost framework remains the primary contribution of this work, the LinearSVC results demonstrate that the proposed strategy can also improve the performance of other classifiers when dealing with imbalanced Speech Emotion Recognition datasets.

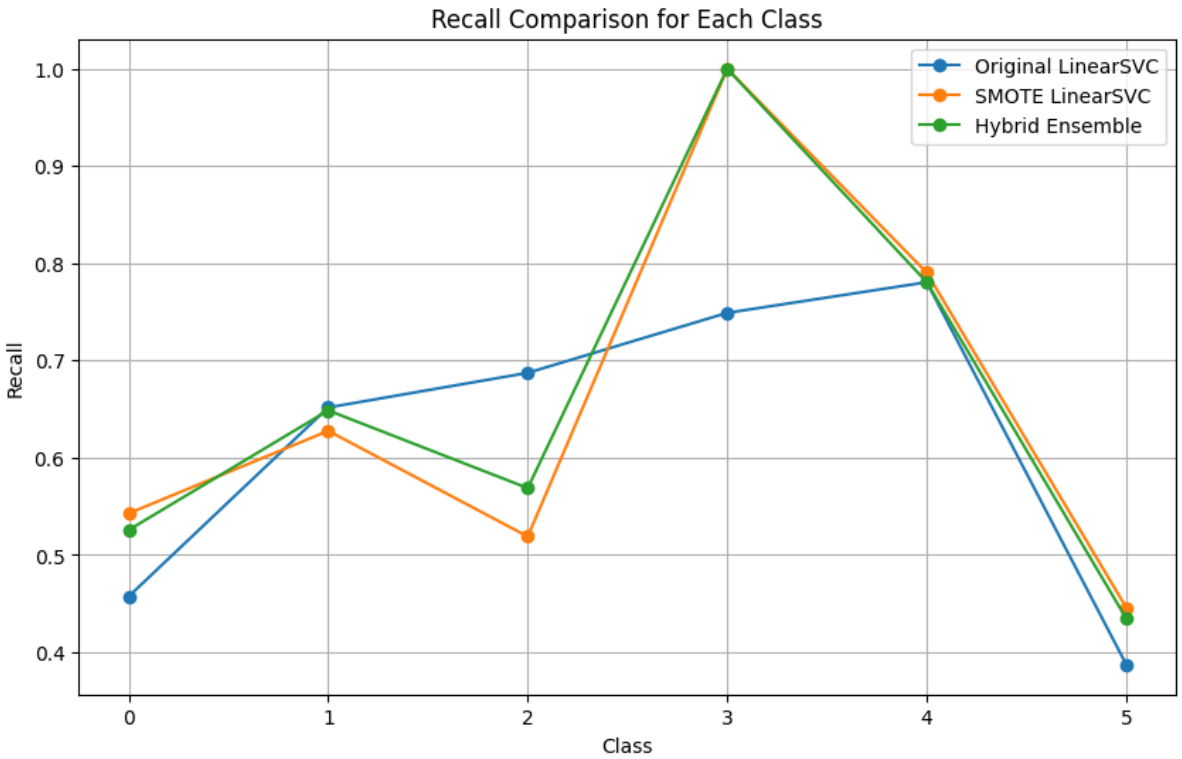

Fig. 10. Recall comparison of the Original LinearSVC model, SMOTE-based LinearSVC model, and Hybrid Weighted Ensemble for each emotion class.

VI. Experimental Results and Discussion

This section presents the experimental results obtained from the reproduction of the original study and the proposed enhancement methods. First, the reproduced results are compared with those reported by Sahu et al. [12] to evaluate the reproducibility of the original framework. Subsequently, the performance of the proposed Hybrid SMOTE-Ensemble Framework is analyzed and compared with the baseline models using different evaluation metrics and confusion matrices.

A. Reproduction Results

The objective of the reproduction experiments was to investigate whether the performance reported by Sahu et al. [12] could be achieved using the publicly available information and implementation details described in their study. The reproduced models were evaluated under three modalities: Audio-only, Text-only, and Audio+Text. Their performance was assessed using Accuracy, F1-score, Precision, and Recall.

Fig. 11 presents the confusion matrix of the Audio-only model reported in [12]. The model classifies emotions into six categories: anger (ang), happiness (hap), sadness (sad), fear (fea), surprise (sur), and neutral (neu). The results show that the model performs well in recognizing sadness and fear, whereas more confusion is observed among anger, happiness, and neutral emotions. This behaviour reflects the inherent difficulty of distinguishing emotions with similar acoustic characteristics.

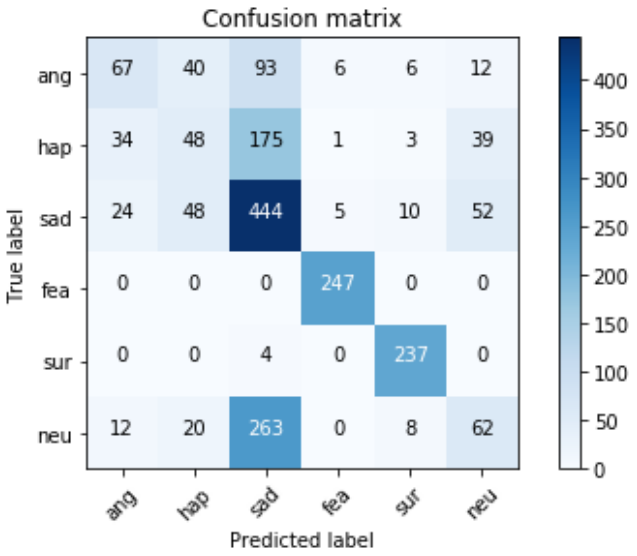

Fig. 11. Results reported by [12] for the audio-only model.

Fig. 12 illustrates the confusion matrix of the Text-only model. The model demonstrates strong performance for sadness and fear, while several misclassifications occur among happy, sad, and neutral emotions. In particular, neutral emotions are frequently predicted as sadness, indicating that textual information alone may not always provide sufficient discriminative features for emotion recognition.

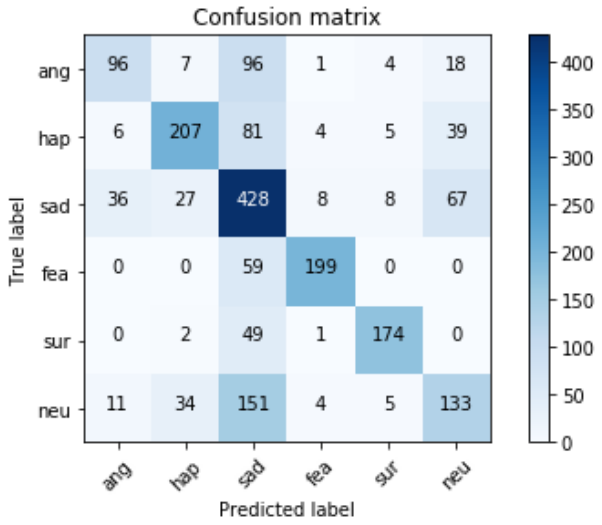

Fig. 12. Results reported by [12] for the text-only model.

Fig. 13 presents the confusion matrix of the Audio+Text model. Compared with the unimodal approaches, the multimodal model provides better recognition performance for most emotion categories by exploiting complementary information from both audio and textual modalities. The model achieves the best performance for sadness and surprise, although some confusion remains between anger and sadness as well as between happy and neutral emotions.

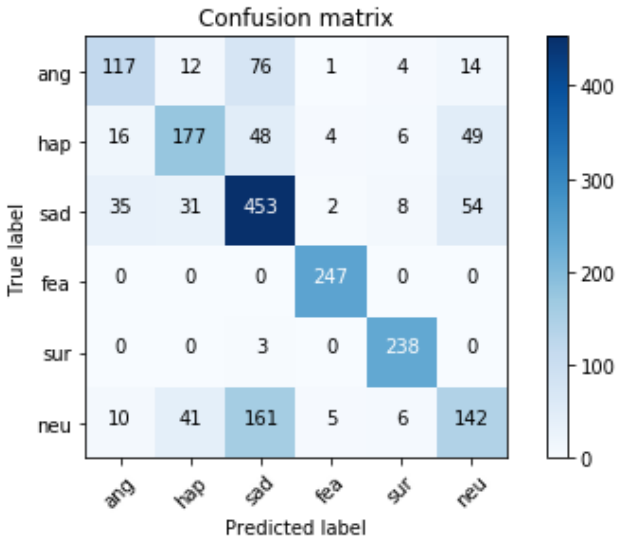

Fig. 13. Results reported by [12] for the audio+text model.

Overall, the reproduced results are in close agreement with those reported by Sahu et al. [12], with most differences remaining within ±1%. Although slight variations are observed for some models and modalities, the general performance trends remain consistent. These differences may be attributed to ambiguities in feature extraction settings, differences in library versions, and the stochastic nature of model training and data partitioning.

B. Results from Enhancements Using Hybrid XGBoost Ensembles

The proposed Hybrid SMOTE-Ensemble Framework was evaluated using the Audio+Text modality. The framework consists of two XGBoost classifiers trained independently on the original imbalanced dataset and the SMOTE-balanced dataset. Their predictions were combined using three ensemble strategies: Simple Averaging, Confidence-Based Selection, and Adaptive Weighting. The performance of these models is summarized in Table I.

TABLE I. PERFORMANCE OF HYBRID XGBOOST ENSEMBLE ENHANCEMENT (AUDIO+TEXT MODALITY)

Model/Ensemble Method	Accuracy (%)	F1-score (%)	Precision (%)	Recall (%)
XGB Original (Baseline)	54.9	54.9	71.9	50.7
XGB SMOTE	56.4	59.4	62.1	58.7
Simple Average Ensemble	57.7	59.3	70.5	55.3
Confidence-Based Ensemble	57.0	58.5	70.9	54.4
Adaptive Weighted Ensemble	57.4	58.9	71.1	54.9

The results demonstrate that training XGBoost on SMOTE-balanced data improves the classification performance compared with the original imbalanced training set. The XGB SMOTE model achieved an accuracy of 56.4% and an F1-score of 59.4%, compared with 54.9% accuracy and 54.9% F1-score obtained by the original XGBoost model. This improvement indicates that balancing the training data enables the classifier to better recognize underrepresented emotion classes.

The ensemble methods further improve the overall performance. The Simple Average Ensemble achieved the highest accuracy of 57.7%, while the Adaptive Weighted Ensemble achieved competitive results with an accuracy of 57.4% and an F1-score of 58.9%. The Confidence-Based Ensemble also outperformed the baseline model and achieved balanced performance across the evaluation metrics.

Overall, the results confirm that the proposed Hybrid SMOTE-Ensemble Framework improves emotion recognition performance on imbalanced data. The combination of SMOTE-based data balancing and ensemble learning provides a more robust and balanced classifier compared with a single model trained on the original dataset.

C. Hybrid LinearSVC Ensemble Enhancement Results

To further investigate the effectiveness of the proposed enhancement strategy, additional experiments were conducted using a Linear Support Vector Classifier (LinearSVC). Three different configurations were evaluated: the Original LinearSVC trained on the imbalanced dataset, the SMOTE-based LinearSVC trained on the balanced dataset, and the Hybrid Weighted Ensemble combining the predictions of both models.

The results presented in Tables II and III demonstrate that applying SMOTE improves the recall of minority emotion classes, although this improvement is accompanied by a slight reduction in precision for some majority classes. The Original LinearSVC model achieved the highest precision; however, it suffered from lower recall, particularly for underrepresented emotions.

TABLE II. PERFORMANCE METRICS OF TECHNIQUES USED WITH LINEARSVC

Metric	Original LinearSVC	SMOTE LinearSVC	Hybrid Ensemble
Accuracy	0.616	0.616	0.629
F-score	0.634	0.626	0.637
Precision	0.665	0.615	0.631
Recall	0.619	0.654	0.660

TABLE III. RECALL VALUES FOR EACH CLASS OF TECHNIQUES USED WITH LINEARSVC

Class	Original LinearSVC	SMOTE LinearSVC	Hybrid Ensemble
0	0.457	0.543	0.526
1	0.652	0.628	0.649
2	0.687	0.519	0.569
3	0.749	1.000	1.000
4	0.780	0.790	0.780
5	0.387	0.446	0.435

The Hybrid Weighted Ensemble achieved the best overall performance among the evaluated LinearSVC models. The ensemble obtained the highest accuracy and F1-score while maintaining balanced precision and recall values. These results indicate that combining the original and SMOTE-based classifiers enables the model to exploit the strengths of both

approaches and provides a more robust solution for imbalanced Speech Emotion Recognition.

Furthermore, the recall analysis confirms that the Hybrid Ensemble consistently improves the recognition of minority emotion classes. The results suggest that the proposed Hybrid SMOTE-Ensemble strategy is not limited to XGBoost and can also enhance the performance of other machine learning classifiers such as LinearSVC.

Overall, the additional LinearSVC experiments support the effectiveness and generalization capability of the proposed enhancement framework for imbalanced Speech Emotion Recognition tasks.

D. Analysis of Results

The reproduction experiments demonstrated a high degree of agreement with the results reported by Sahu et al. [12]. Most evaluation metrics differed by less than 1%, indicating that the proposed reproduction methodology successfully replicated the main findings of the original study. The small differences observed for some models may be attributed to ambiguities in feature extraction settings, differences in library implementations, and the inherent stochastic nature of machine learning and deep learning training processes.

The results obtained from the proposed Hybrid SMOTE-Ensemble Framework further demonstrate the effectiveness of combining data balancing and ensemble learning for Speech Emotion Recognition on imbalanced datasets. Training XGBoost on SMOTE-balanced data improved both Accuracy and F1-score compared with the original imbalanced model. In particular, the F1-score increased from 54.9% to 59.4%, indicating that balancing the training data enables the classifier to better recognize underrepresented emotion classes.

The ensemble methods provided additional improvements over the baseline XGBoost model. Among the evaluated approaches, the Simple Average Ensemble achieved the highest accuracy of 57.7%, while the Adaptive Weighted Ensemble achieved competitive results with balanced Precision, Recall, and F1-score values. These findings suggest that combining classifiers trained on original and balanced datasets produces a more robust model than relying on a single classifier.

The additional experiments using LinearSVC further support this observation. Although the overall improvement was less pronounced than that obtained with XGBoost, the Hybrid Weighted Ensemble consistently outperformed the baseline LinearSVC model and improved the recognition of minority emotion classes. These results indicate that the proposed Hybrid SMOTE-Ensemble strategy is not limited to a specific classifier and can be generalized to other machine learning models.

E. Robustness and Limitations

The robustness of the experiments was improved by fixing the random seed (`random_state = 42`) during train-test splitting, SMOTE oversampling, and model training whenever possible. This ensures that the experiments can be reproduced and that the obtained results are not caused by random variations in data partitioning or model initialization.

The reproduced results remained close to those reported by Sahu et al. [12], demonstrating that the original findings are generally robust to minor differences in implementation details and software environments. In addition, the proposed Hybrid SMOTE-Ensemble Framework consistently improved performance across different evaluation metrics, indicating that the enhancement strategy is stable and effective for imbalanced Speech Emotion Recognition tasks.

Despite these encouraging results, several limitations should be acknowledged. First, the enhancement strategy was evaluated only using XGBoost and LinearSVC classifiers. The impact of the proposed framework on other classifiers, such as Random Forest, SVM, MLP, and LSTM, remains an open research direction. Second, some assumptions were required during the reproduction process because the original study did not explicitly specify all implementation details, particularly those related to feature extraction and label preprocessing. Consequently, the reproduced experiments may not represent an exact replication of the original experimental setup.

F. Ethical Considerations and Broader Impact

Speech Emotion Recognition systems have the potential to improve human-computer interaction, customer service, healthcare, and assistive technologies. However, incorrect emotion prediction may negatively affect users, particularly in sensitive applications such as mental health assessment or security systems. Therefore, developing robust and fair emotion recognition systems is an important ethical consideration.

Class imbalance is one of the factors that may introduce bias into Speech Emotion Recognition models because minority emotions are often underrepresented during training. The proposed Hybrid SMOTE-Ensemble Framework attempts to mitigate this issue by improving the recognition of minority emotion classes through balanced data generation and ensemble learning. Nevertheless, synthetic data generated by oversampling techniques should be used carefully to avoid introducing artificial patterns or hidden biases into the training process.

Finally, this study highlights the importance of reproducibility and transparent reporting in machine learning research. Providing clear implementation details and thoroughly evaluating enhancement strategies contribute to the development of more reliable, fair, and trustworthy Speech Emotion Recognition systems.

VII. Conclusion

This study had two main objectives. The first was to reproduce the multimodal Speech Emotion Recognition framework proposed by Sahu et al. [12] and evaluate the reproducibility of their reported results. The second was to enhance the original framework by introducing a Hybrid SMOTE-Ensemble strategy based on XGBoost and LinearSVC classifiers to address the class imbalance problem in the IEMOCAP dataset.

The reproduction experiments demonstrated a high level of agreement with the original study, with most evaluation metrics differing by less than 1%.

These results confirm the validity of the original findings and highlight the importance of transparent reporting and reproducible research practices in Speech Emotion Recognition.

The enhancement experiments showed that balancing the training data using SMOTE improves the performance of emotion classification models, particularly in terms of F1-score and Recall. Furthermore, combining models trained on the original and SMOTE-balanced datasets through ensemble learning provided additional improvements in overall performance. The proposed Hybrid SMOTE-Ensemble Framework achieved more balanced and robust performance than the baseline models, demonstrating the effectiveness of integrating data balancing with ensemble learning for imbalanced Speech Emotion Recognition tasks.

The additional experiments using LinearSVC further confirmed the generalization capability of the proposed framework. Although the performance improvements varied across classifiers, the Hybrid Ensemble consistently provided a better balance between Precision, Recall, and F1-score than individual models.

Overall, this study demonstrates that advanced oversampling techniques and ensemble learning strategies can effectively mitigate class imbalance and improve Speech Emotion Recognition performance. The findings also emphasize the importance of reproducibility and systematic experimentation in developing reliable and robust emotion recognition systems.

VIII. Future Research and Implementations

Several directions can be explored to further improve the proposed Hybrid SMOTE-Ensemble Framework:

- Investigate the effectiveness of the proposed framework using additional classifiers such as Random Forest, Support Vector Machine, Multi-Layer Perceptron, and Long Short-Term Memory networks.
- Evaluate the Hybrid SMOTE-Ensemble strategy using different modalities, including Audio-only and Text-only settings, as well as more advanced multimodal fusion approaches.
- Explore more sophisticated oversampling techniques, such as SISMOTE and FC-SMOTE, or investigate generative approaches based on Generative Adversarial Networks (GANs) for data augmentation.
- Perform more extensive hyperparameter optimization for both the base classifiers and the ensemble strategies to further improve classification performance.
- Investigate the proposed framework on other Speech Emotion Recognition datasets with different class distributions to evaluate its robustness and generalization capability.

These directions may contribute to the development of more accurate, robust, and fair Speech Emotion Recognition systems capable of handling the challenges associated with imbalanced emotional datasets.

XPA-FedCBR: A Federated Case-Based Reasoning System for Explainable and Privacy-Aware Lung Cancer Diagnosis

Devyani Rawat[1], Shuchi Bhadula[2], Sachin Sharma[3]
Department of Computer Science and Engineering, Graphic Era Deemed to be University, Dehradun, India[1, 2]
Amity School of Engineering and Technology, Amity University Punjab, Mohali, India[3]

***Abstract*—Lung cancer is among the deadliest cancers worldwide, largely because it is usually caught too late. Building AI tools for earlier, stage-aware diagnosis is hard in practice: patient scans are scattered across hospitals that cannot share them freely, and clinicians are reluctant to trust models that cannot explain their reasoning. This study presents XPA-FedCBR, a framework that addresses both concerns. It combines Federated Learning, which trains a shared model across institutions without moving raw data, with Case-Based Reasoning, which supports each prediction by retrieving clinically similar past cases and, for uncertain predictions, using them to refine the decision. We evaluate it on the LIDC-IDRI dataset (roughly 1,018 CT scans from 1,010 patients), split across five simulated institutions under non-IID conditions, with annotations mapped to stages I–IV. Over four independent runs, the proposed model reaches a macro-F1 of 0.915, significantly ahead of FedAvg without CBR (0.875), a centralized CNN (0.895), and a standalone CNN (0.844), with its advantage largest under domain shift. Its case-based explanations, evaluated quantitatively and against gradient-based saliency, give clinicians evidence they can directly inspect.**

***Keywords*—Case-based reasoning; federated learning; explainable AI; lung cancer; clinical decision support; medical imaging**

I. Introduction

A. Clinical Background

One of the most common and deadly types of cancer in the world, lung cancer accounts for a large percentage of cancer-related deaths. The high fatality rate is primarily attributed to the late-stage detection of the disease, as early-stage lung cancer often presents minimal or no noticeable symptoms[1]. As a result, a large number of patients are diagnosed only after the cancer has progressed to an advanced stage, where treatment options become limited, and survival rates decline substantially.

In order to improve patient survival and treatment outcomes, early and precise identification of lung cancer is essential. When detected at an early stage, lung cancer can be managed more effectively through surgical intervention, targeted therapy, or radiotherapy, leading to significantly higher survival rates[2]. Therefore, timely screening and reliable diagnostic tools are essential for reducing mortality and improving the overall quality of patient care.

Non-Small Cell Lung Cancer (NSCLC), which accounts for most lung cancer cases, is staged from I to IV according to tumor size, lymph node involvement, and metastasis. The stage matters enormously for outcome: patients caught at Stage I or II have far better survival odds, while Stage III and IV carry a poor prognosis [3]. Because the stage drives the choice of treatment, a diagnosis that simply flags cancer as present or absent is not enough; what clinicians need is a system that can tell the stages apart.

Despite advances in medical imaging such as computed tomography (CT), lung cancer screening still has real limitations. Much of it depends on manual interpretation by radiologists, which is time-consuming and varies from one reader to the next [4]. Subtle nodules are easy to miss, especially early on, and both false positives and false negatives take their toll, the former sending patients into unnecessary follow-ups and anxiety, the latter delaying diagnoses that matter. These gaps are why the field needs diagnostic tools that are not just accurate but consistent and clinically trustworthy, and why computational methods have drawn so much attention as a way to close them.

B. Challenges in AI-Based Lung Cancer Detection

AI has shown real promise in lung cancer analysis, but several obstacles keep it from being adopted in actual clinical practice. One is data scarcity and institutional silos. Well-annotated imaging data is hard to come by and tends to sit locked inside individual hospitals, which, for reasons of patient confidentiality and limited infrastructure, cannot share it freely. A model trained in one institution therefore rarely sees the range of patients it would need to generalize well.

A second obstacle is privacy and regulation. CT scans and clinical records are among the most sensitive data a hospital holds, yet conventional centralized learning depends on pooling everything in one place, an approach that can run afoul of rules like HIPAA and GDPR and leaves institutions understandably wary of any system built around direct data sharing [7].

The third is the opacity of deep learning itself. These models can be highly accurate, but they say little about *how* they reach a decision, and a clinician who cannot follow that reasoning has no way to check an AI-assisted diagnosis in something as consequential as cancer staging. Taken together, these problems point to a clear need: systems that can learn from data spread across institutions, respect privacy law, and still explain themselves in terms a clinician can act on.

C. Motivation

The challenges outlined above- fragmented data, privacy constraints, and the opacity of deep models- are rarely addressed together, yet in clinical practice they arise together. A system that preserves privacy but cannot explain its decisions will not earn clinician trust; one that explains its reasoning but requires centralized data cannot be deployed across institutions. This motivates a combined approach. Federated learning offers a way to train across distributed hospitals without moving sensitive data, directly addressing the privacy and data-silo problem. Case-based reasoning offers a complementary strength: by grounding each prediction in similar, previously confirmed cases, it provides the transparent, evidence-based justification clinicians rely on when making decisions. Pairing the two is therefore natural; federated learning supplies privacy-preserving predictive capability, while case-based reasoning supplies the interpretability that turns a prediction into a clinically actionable, trustworthy recommendation. Combining the two, rather than using either one alone, is the main idea behind this work.

Despite these advances, existing approaches address the key challenges only in isolation. Federated learning methods for lung cancer have focused primarily on improving accuracy and preserving privacy, but they largely operate as black boxes and offer little in the way of clinician-facing explanation. Case-based reasoning, by contrast, provides transparent, evidence-based justification that aligns well with clinical decision-making, yet it has rarely been integrated with modern deep or distributed learning and does not, on its own, address privacy or scale to high-dimensional imaging data. Furthermore, most existing systems are limited to binary malignant-versus-benign detection rather than clinically meaningful stage-aware classification. As a result, no unified framework currently delivers privacy-preserving collaborative learning, stage-level diagnosis, and clinician-understandable explanations together. This gap motivates the hybrid framework proposed in this work, which couples federated learning with case-based reasoning to achieve all three within a single architecture.

D. Contributions

The main contributions of this work are summarized as follows:

- A hybrid Case-Based Reasoning and Federated Learning framework is proposed for lung cancer detection, enabling collaborative model training while preserving patient data privacy.
- Introduces stage-aware lung cancer classification for clinically meaningful diagnosis.
- An explainable clinical decision-support layer is introduced, which aligns AI predictions with clinician reasoning by retrieving and presenting similar historical patient cases.
- Robustness across decentralized clinical data sources is demonstrated by evaluating the proposed framework under a simulated multi-institution federated learning environment.
- A comprehensive comparative evaluation is performed against centralized learning and non-explainable baseline models to confirm the proposed framework's efficacy.

II. Related Work

A. Lung Cancer Detection Using AI

Early efforts in lung cancer diagnosis using artificial intelligence were built around traditional computer-aided diagnosis (CAD) systems. In these systems, handcrafted features such as shape, texture, and intensity of lung nodules were manually extracted from CT images, followed by conventional machine learning classifiers like support vector machines and decision trees for detection and classification. Such CAD systems were designed to assist radiologists and reduce workload, but they typically depended heavily on engineered features and showed limited adaptability across diverse clinical data sources[5]. A hybrid transfer learning framework, VER-Net (2024), combined VGG19, EfficientNetB0, and ResNet101 to classify lung cancer from CT images. Using the Chest CT-Scan Images Dataset (Kaggle), the proposed model achieved 91.0% accuracy, 92.0% precision, 91.0% recall, and an F1-score of 91.3%, highlighting the effectiveness of hybrid deep learning for automated lung cancer diagnosis[6].

B. Federated Learning in Healthcare

A proximal-guided hybrid federated learning framework for pneumonia diagnosis that combines FedProx with parameter-efficient adaptive intelligence to address data heterogeneity across hospitals. The model was evaluated on Chest X-ray datasets collected from multiple healthcare institutions and achieved 98.7% accuracy, demonstrating improved robustness and communication efficiency compared with conventional federated learning methods[7].

One of the central motivations for applying FL in healthcare is its ability to address privacy and regulatory constraints such as HIPAA and GDPR by keeping medical data within the originating institution while still enabling collaborative model development. This decentralization reduces the risk of sensitive data exposure and aligns with legal and ethical requirements for handling patient information[8].

C. Case-Based Reasoning in Clinical Systems

CBR is a problem-solving approach that draws on solutions to previously encountered cases to inform decisions about new, similar situations. In clinical settings, CBR has been applied to diagnostic support by retrieving past patient cases with similar clinical features and outcomes to guide current decision-making. This reasoning paradigm aligns closely with the way clinicians think, often referring to past patient histories, symptoms, and outcomes when diagnosing new patients [9]. A hybrid knowledge modeling framework incorporating Case-Based Reasoning (CBR) and rule-based reasoning was proposed to recommend treatment strategies for patients with chronic kidney disease–mineral and bone disorder (CKD-MBD). The system was validated using electronic health records and clinical guidelines, providing treatment recommendations that closely matched expert clinical decisions while improving consistency in decision-making [10].

An enhanced Case-Based Reasoning (CBR) framework integrated with a Rule-Based System (RBS) was developed to support medical diagnosis by retrieving similar historical patient cases and refining diagnostic decisions using expert rules. The system was evaluated using a medical diagnosis dataset and achieved an overall diagnostic accuracy of 96.8%, demonstrating the effectiveness of combining CBR with rule-based reasoning for clinical decision support[11]. An explainable Case-Based Reasoning (XCBR) framework was developed for lung cancer diagnosis by integrating Naïve Bayes, Multilayer Perceptron (MLP), SHAP, and Harris Hawks Optimization for feature selection and explanation. The model was evaluated on two public lung cancer datasets and achieved 94.47% and 100% classification accuracy, demonstrating the effectiveness of combining CBR with explainable AI for clinical decision support[12].

D. Research Gap

Prior work has advanced federated and case-based approaches for lung cancer diagnosis, but along separate tracks. In the federated setting, Liu et al. [14] applied federated learning across multiple centres to predict treatment response in non-small cell lung cancer, and Heidari et al. [15] combined federated learning with blockchain for CT-based lung cancer detection; both demonstrate that collaborative training without data sharing is feasible, yet neither incorporates a mechanism to explain individual predictions to clinicians. Case-based reasoning offers precisely this missing interpretability; Pradeep et al. [13] show that retrieving and presenting similar past cases yields transparent, clinically aligned justification, but such systems are typically built on manually defined features and have rarely been coupled with deep or distributed learning, leaving them unable to scale to high-dimensional imaging or to operate under privacy constraints. A further limitation is that most of these systems target binary malignant-versus-benign detection rather than stage-level diagnosis, which is what ultimately guides treatment decisions. Consequently, no existing framework simultaneously provides privacy-preserving collaborative learning, stage-aware classification, and case-based explanations suited to clinical use. The proposed work addresses this gap by unifying all three within a single architecture.

III. Proposed Methodology

A. System Overview

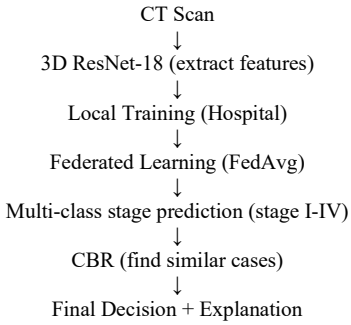

Fig. 1. Proposed hybrid CBR-FL framework.

The proposed intelligent digital clinical diagnostic system is designed to support lung cancer diagnosis while preserving patient privacy and providing explainable clinical decisions. Fig. 1 shows that the proposed framework processes CT scan images using a CNN-based feature extraction model followed by federated learning for privacy-preserving multi-class lung cancer stage prediction. The predicted stage is further supported through a Case-Based Reasoning module that retrieves clinically similar historical cases to provide interpretable diagnostic explanations.

The overall architecture follows a distributed learning framework in which multiple healthcare institutions act as local clients, and a central server coordinates the global learning process. Each local client trains a diagnostic model using its own patient data, ensuring that sensitive clinical information does not leave the institution. The CNN-based model is extended to perform multi-class classification, where each class corresponds to a specific stage of lung cancer. Table I shows the detailed stages of Non-Small Cell Lung Cancer.

TABLE I. Detailed Stages of Non-Small Cell Lung Cancer

Stage 1	Cancer is only located in the lungs.
Stage 2	Cancer is located in the lungs and may be in the lymph nodes near the lungs.
Stage 3	Cancer is located in the lungs and lymph nodes in the middle of the chest.
Stage 3A	Cancer is extensive but localized to one side of the lung.
Stage 3B	Cancer has spread to lymph nodes on both sides of the lungs.
Stage 4	Cancer has spread to both lungs or to another part of the body. This stage is considered the most advanced.

During training, only the locally learned model parameters are shared with the global server, which aggregates them to update a global model using a federated learning strategy. This global model is then redistributed to the local clients for further refinement. In parallel, a case-based reasoning module maintains a repository of historical patient cases and retrieves clinically similar cases to support transparent and interpretable decision-making. By combining federated learning with case-based reasoning, the system enables accurate lung cancer diagnosis while ensuring data privacy and clinician-understandable explanations. Fig. 2 shows the proposed hybrid case-based learning and federated learning framework for privacy-preserving lung cancer stage prediction using CT scan images.

B. Local Client-Side Processing and Feature Extraction

In the proposed system, lung CT scan images are collected at individual hospitals and processed locally to ensure patient data privacy. Each CT scan is first passed through a 3D ResNet-18 convolutional neural network (CNN), which automatically extracts relevant features such as lung nodules, texture patterns, and structural abnormalities. These features represent important visual characteristics required for lung cancer detection. The extracted features are then used to train a local diagnostic model within the hospital environment. At no point is raw patient data shared outside the institution.

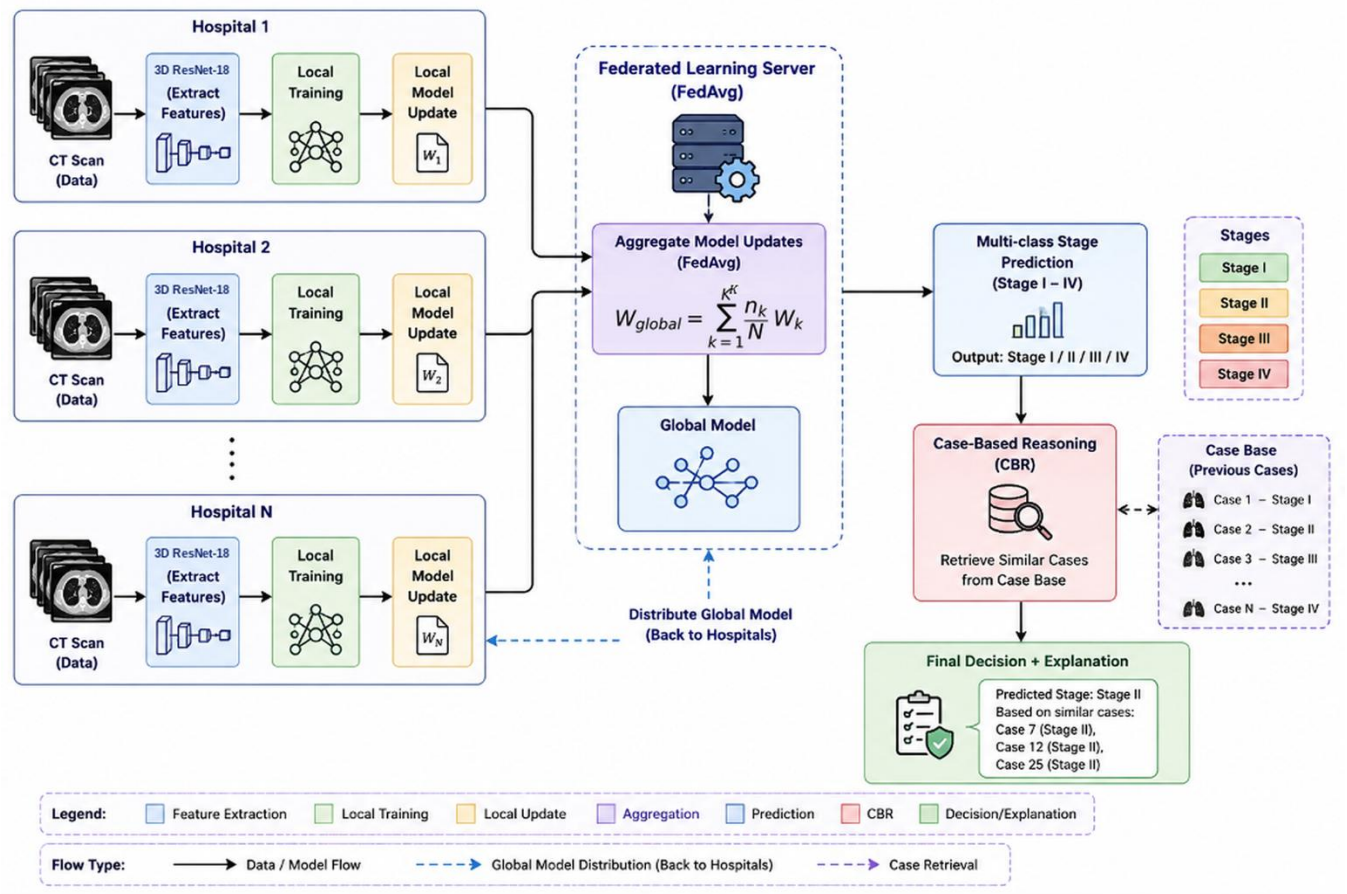

Fig. 2. Proposed hybrid case-based reasoning and federated learning framework for privacy-preserving lung cancer stage prediction using CT scan images.

C. Federated Learning for Collaborative Model Training

To enable collaborative learning across multiple clinical centers while preserving patient privacy, a federated learning framework is adopted in the proposed system. Instead of sharing raw CT scan data, each participating hospital trains the diagnostic model locally using its own dataset. This ensures that sensitive patient information remains within the institution and complies with privacy regulations.

After local training, only the updated model parameters are transmitted to a central server. The server performs secure aggregation of these updates using the Federated Averaging (FedAvg) algorithm to generate a global model that captures collective knowledge from all participating centers. The updated global model is then redistributed to the local clients for further training in subsequent rounds.

Since clinical data from different hospitals may vary due to differences in imaging equipment, patient demographics, and acquisition protocols, the federated framework is designed to handle data heterogeneity. Through iterative aggregation across multiple training rounds, the global model becomes more robust and generalized, learning patterns that are consistent across diverse clinical environments. Furthermore, the predictions generated by the global model are supported by a case-based reasoning mechanism, which retrieves clinically similar cases and uses their confirmed stage labels both to explain and, for low-confidence predictions, to refine the final decision.

In federated learning, suppose there are K participating clinical centers. Each hospital k trains a local model on its dataset containing n_k samples. After local training, the model parameters w_k are transmitted to the central server.

The global model parameters at communication round t+1 are computed using weighted averaging as follows:

$$w_{t+1} = \Sigma_{k=1}^{K} (n_k / N) \cdot w_k^t \quad (1)$$

where,

w_k^t = local model parameters from hospital k at round t

n_k = number of samples at hospital k

$N = \Sigma_{k=1}^{K} n_k$ = total number of samples across all hospitals

K = total number of participating hospitals

This weighted aggregation ensures that hospitals with larger datasets contribute proportionally more to the global model update.

D. Case-Based Reasoning Module

The Case-Based Reasoning (CBR) module is incorporated to provide interpretability and support clinical decision-making by leveraging previously diagnosed cases. In this approach, each patient case is represented using a combination of imaging features extracted from CT scans and relevant clinical

information, if available. This structured representation allows the system to compare new cases with historical records effectively.

To identify similar cases, a similarity measurement technique is applied. In this work, cosine similarity is used to compute the closeness between the feature vector of the new patient and those stored in the case database. Based on this similarity score, the top-k most relevant cases are retrieved.

Once similar cases are identified, the system analyses their confirmed diagnoses. These retrieved cases serve two complementary purposes: they are presented alongside the model's prediction to provide context and justification, and, for low-confidence predictions, their stage labels contribute to the final decision through the fusion mechanism described in Section III-E. This process enables explanations that are intuitive and aligned with clinical reasoning, while allowing similar historical cases to reinforce or correct uncertain predictions, thereby improving the transparency, trustworthiness, and reliability of the diagnostic system.

E. Hybrid Integration Strategy

The proposed framework integrates federated learning (FL) and case-based reasoning (CBR) to combine accurate prediction with interpretable, evidence-based decision support. Rather than treating the two components independently, the system couples them so that CBR both explains and, where appropriate, refines the federated model's output.

For a query case with deep feature vector q (extracted by the shared 3D ResNet-18 backbone), the global federated model produces a probability distribution over the four lung cancer stages, $p = (p_1, p_2, p_3, p_4)$, and a corresponding confidence $\hat{c} = \max_j p_j$. This distribution serves as the initial diagnostic indicator, which is then passed to the CBR module.

1) Case retrieval: To identify clinically similar precedents, the CBR module compares **q** against every stored case *i* (with feature vector $\mathbf{c}_i$) using cosine similarity:

$$\mathrm{sim}(\mathbf{q}, \mathbf{c}_i) = (\mathbf{q} \cdot \mathbf{c}_i) / (\|\mathbf{q}\| \, \|\mathbf{c}_i\|). \quad (2)$$

The top-*k* cases with the highest similarity are retrieved and denoted $\mathcal{N}$. In this work k = 5.

2) Neighbour label evidence: The retrieved cases contribute a similarity-weighted label distribution, in which each neighbour supports its own confirmed stage in proportion to how similar it is to the query:

$$v_j = \left(\Sigma_{i \in \mathcal{N} : y_i = j} \, \mathrm{sim}(\mathbf{q}, \mathbf{c}_i) \right) / \left(\Sigma_{i \in \mathcal{N}} \, \mathrm{sim}(\mathbf{q}, \mathbf{c}_i) \right), \quad \text{for each stage } j \quad (3)$$

where, y_i is the confirmed stage label of case *i* and $\mathbf{v} = (v_1, v_2, v_3, v_4)$.

3) Confidence-gated decision fusion: In the decision-fusion stage, the quantitative prediction from the FL model is combined with the qualitative evidence from retrieved cases through a confidence-gated rule:

$$\mathbf{s} = \mathbf{p}, \text{ if } \hat{c} \geq \tau, \quad \mathbf{s} = (1 - \alpha) \cdot \mathbf{p} + \alpha \cdot \mathbf{v}, \text{ if } \hat{c} < \tau, \quad (4)$$

and the final predicted stage is

$$\hat{y} = \mathrm{argmax}_j \, s_j \quad (5)$$

Here τ is a confidence threshold and $\alpha \in [0, 1]$ controls the influence of retrieved cases; we use $\tau = 0.7$ and $\alpha = 0.4$. When the federated model is confident ($\hat{c} \geq \tau$), its prediction is retained unchanged, and the retrieved cases act purely as supporting explanation. When the model is uncertain ($\hat{c} < \tau$), the regime in which classification errors are concentrated, the labels of clinically similar historical cases are allowed to re-rank the decision, so that strong agreement among close neighbours can correct an unreliable prediction.

This selective fusion is the reason the hybrid framework improves upon federated averaging without CBR: the CBR layer leaves confident predictions untouched and intervenes only on borderline cases, where neighbour evidence is most informative. The effect is therefore most pronounced under high-shift and domain-shift conditions (Table VI), where distributional differences lower model confidence and increase the proportion of cases routed through neighbour-based re-ranking.

Finally, to ensure the process is transparent to clinicians, the system exposes each step: for every new case, it presents the predicted stage together with the top-*k* retrieved cases and their confirmed diagnoses as supporting evidence. This step-by-step presentation allows clinicians to see not only the predicted stage but the historical cases underlying it, supporting validation and building trust in the system.

IV. Experimental Setup

A. Dataset Description

The proposed framework is evaluated using the publicly available LIDC-IDRI (Lung Image Database Consortium and Image Database Resource Initiative) dataset, which comprises approximately 1,018 thoracic CT scans collected from 1,010 patients with 2,669 annotated lung nodules provided by multiple expert radiologists. The dataset contains a diverse range of nodules with variations in size, shape, texture, and malignancy levels. In this work, the malignancy annotations are mapped to lung cancer stages (Stage I–IV) to facilitate multi-class stage prediction. To simulate a realistic multi-institutional healthcare environment, the dataset is partitioned into multiple subsets representing different clinical centers within the federated learning framework.

TABLE II. Simulated Federated Learning Environment(5 Hospitals Data)

Institution	Scans	Stage Distribution (I/II/III/IV)	Data Heterogeneity
Hosp1	200	40/30/20/10	Low variance
Hosp2	250	30/40/20/10	Medium (noise)
Hosp3	300	20/20/30/30	High (shift)
Hosp4	150	35/35/15/15	Domain shift
Hosp5	118	25/25/25/25	Balanced

Table II presents the simulated federated distribution of CT scan data across multiple participating institutions with varying stage distributions and heterogeneity conditions. Each simulated

institution performs local model training on its respective subset without sharing raw patient data, thereby preserving privacy while enabling collaborative learning. A non-IID data distribution is further simulated through label shifts across institutions, where certain centers contain a higher proportion of early-stage cases while others contain more advanced-stage samples. For each institution, the dataset is divided into 70% training, 15% validation, and 15% testing sets.

This experimental setup enables the evaluation of the proposed system under practical healthcare challenges such as distributed data ownership, institutional data heterogeneity, and privacy constraints. However, the stage labels are approximated using malignancy annotations and may not perfectly correspond to clinical staging standards. Additionally, due to limited access to real multi-institutional datasets, the federated learning environment is simulated through dataset partitioning.

B. Preprocessing and Feature Extraction

Before model training, the CT scan images go through a number of preparation procedures to ensure consistency, reduce noise-related variations, and improve feature quality. These preprocessing operations are essential for enhancing model robustness and diagnostic performance in medical imaging applications. Initially, lung nodule segmentation is performed using a U-Net architecture to isolate the lung regions and relevant nodules from surrounding anatomical structures[16]. Following segmentation, the extracted regions are resized to maintain uniformity across all CT scan samples (Table III).

TABLE III. SUMMARIZES THE COMPLETE EXPERIMENTAL CONFIGURATION AND HYPERPARAMETER SETTINGS USED FOR BOTH LOCAL TRAINING AND FEDERATED AGGREGATION

Category	Parameter	Value
Feature extractor	Backbone	3D ResNet-18
	Input size	64 × 64 × 64 (resized CT volume)
	Pretraining	Trained from scratch
Local training	Optimizer	Adam
	Learning rate	1×10^{-4}
	Batch size	16
	Local epochs per round	5
	Loss function	Categorical cross-entropy
Federated setup	Aggregation algorithm	FedAvg (weighted)
	Communication rounds	50
	Number of clients (hospitals)	5
	Client participation per round	Full (all clients)
	Data distribution	Non-IID (label shift across clients)
CBR module	Similarity metric	Cosine similarity
	Retrieved neighbours (k)	5
	Confidence threshold (τ)	0.7
	Fusion weight (α)	0.4
Data split	Train / Validation / Test	70% / 15% / 15%
Hardware	GPU	NVIDIA DGX B200

Next, Hounsfield Unit (HU) normalization is applied to reduce variations caused by differences in imaging equipment and acquisition settings. To further enhance image quality, basic noise reduction techniques, such as smoothing filters, are employed to suppress irrelevant artifacts while preserving important lung structures.

During training, data augmentation methods including rotation, flipping, and intensity shifting are used to increase model robustness and generalization. Since the proposed framework follows a federated learning paradigm, no central data pooling is performed, thereby preserving patient privacy across participating institutions.

After preprocessing, feature extraction is carried out using a 3D ResNet-18 architecture fine-tuned for multi-class lung cancer stage prediction. The network automatically learns discriminative imaging features such as nodule shape, texture, and intensity patterns from CT scans. These extracted deep features are subsequently utilized for both classification and case-based reasoning within the suggested framework. The proposed framework was implemented and evaluated using NVIDIA DGX B200 GPU-enabled computational infrastructure to support efficient deep learning training and federated learning experimentation on CT scan datasets.

C. Baseline Models

To assess the effectiveness of the proposed hybrid framework, it is compared against multiple baseline models representing different learning and deployment strategies.

1) Centralized deep learning model: In this baseline, all CT scan data is assumed to be available at a single location, and a CNN is trained in a centralized manner. This model serves as an upper-bound reference in terms of data availability, as it utilizes the complete dataset for training. However, it does not address privacy concerns associated with sharing sensitive medical data.

2) Federated learning without CBR: This baseline implements the federated learning framework using the same data distribution and training setup as the proposed method, but without incorporating the case-based reasoning module. It focuses solely on prediction performance while preserving data privacy[17]. This comparison helps isolate and evaluate the contribution of the CBR module in terms of interpretability and decision support.

3) Traditional machine learning models: Conventional machine learning algorithms, such as Support Vector Machines (SVM) and Random Forests, are used as additional baselines. These models are trained on extracted features from CT scans and provide a comparison with deep learning-based approaches [18]. Although less complex, they serve as a useful reference to highlight the advantages of the proposed hybrid framework.

To ensure a fair comparison, all deep-learning models, the proposed framework, FedAvg without CBR, the centralized CNN, and the standalone CNN — share the same 3D ResNet-18 backbone and are trained and evaluated on identical data splits with matched optimizer, learning rate, batch size, and training epochs.

The traditional machine-learning baselines (SVM and Random Forest) use the same 3D ResNet-18 features. This ensures performance differences reflect the methods rather than differing experimental conditions.

D. Evaluation Metrics

The suggested system's performance is assessed using both quantitative classification metrics and qualitative explainability measures to ensure a comprehensive assessment.

For classification performance, standard metrics such as accuracy, precision, recall, and F1-score are used. Since the proposed approach performs multi-class classification across different lung cancer stages, macro-averaged precision, recall, and F1-score are additionally considered to provide a balanced evaluation across all classes[15].

- Accuracy assesses the comprehensive accuracy of the model:

$$\frac{TP + TN}{TP + TN + FP + FN}$$

- Precision denotes the ratio of accurately predicted positive instances:

$$\frac{TP}{TP + FP}$$

- Recall (Sensitivity) evaluates the model's accuracy in identifying positive situations:

$$\frac{TP}{TP + FN}$$

- F1-score represents the harmonic mean of precision and recall:

$$2\,\frac{\text{Precision} \cdot \text{Recall}}{\text{Precision} + \text{Recall}}$$

where, *TP*, *TN*, *FP,* and *FN* denote true positives, true negatives, false positives, and false negatives, respectively.

E. Qualitative Explainability Assessment

In addition to classification performance, the suggested system is assessed according to its capacity to provide meaningful and interpretable explanations using the case-based reasoning module.

1) Case relevance: Measures how closely the retrieved cases match the input case in terms of clinical and imaging features.

2) Interpretability: Assesses how easily clinicians can understand the reasoning behind the model's prediction based on the presented similar cases.

These qualitative aspects are important for determining the practical usability of the system in clinical settings, where transparency and trust play a crucial role in decision-making.

V. Results and Discussion

A. Qualitative Performance Analysis

The proposed framework performs stage-aware classification of lung cancer from CT scans across Stage I–IV. This section presents a qualitative and quantitative analysis of its performance, beginning with a comparison against baseline models and followed by a stage-wise breakdown and an evaluation of the case-based explanations.

1) Comparison with baselines: As shown in Table IV, the proposed Hybrid CBR-FL framework achieves the highest scores across all metrics (Macro F1 of 0.915 ± 0.002), with low standard deviations indicating stable performance across the four runs. It significantly outperforms all baselines ($p < 0.05$), including the centralized CNN despite the latter's access to pooled data and the federated baseline without CBR, confirming both the benefit of the hybrid design and the specific contribution of the case-based reasoning module.

Table V presents a simplified, imaging-based risk stratification scheme for NSCLC, included as clinical background rather than as a system output, to contextualize the stage-level predictions and their case-based explanations.

TABLE IV. Quantitative Comparison of Proposed and Baseline Models over Four Independent Runs (Mean ± Standard Deviation)

Model	Macro Precision	Macro Recall	Macro F1	p-value (F1 vs. Proposed)	Statistically Significant (p<0.05)?
Hybrid CBR-FL (Proposed)	**0.918 ± 0.003**	**0.912 ± 0.003**	**0.915 ± 0.002**	—	—
Centralized CNN	0.896 ± 0.006	0.892 ± 0.005	0.895 ± 0.005	0.0017	Yes
FedAvg (No CBR)	0.878 ± 0.006	0.873 ± 0.006	0.875 ± 0.005	0.0002	Yes
Standalone CNN	0.846 ± 0.004	0.841 ± 0.004	0.844 ± 0.003	< 0.0001	Yes
Local Avg	0.822 ± 0.007	0.814 ± 0.007	0.815 ± 0.007	< 0.0001	Yes

p-values are computed from an unpaired two-sample t-test of Macro F1 against the proposed model. All baseline differences from the proposed model are statistically significant ($p < 0.05$).

TABLE V. Simplified AI-Based Risk Stratification for NSCLC

Level	Risk	Benign Probability	Key Imaging Features	Growth Rate	Clinical Interpretation
Level A	Low	> 85% benign	Small, smooth, homogeneous nodules	Stable	Routine monitoring
Level B	Suspicious	40 – 85% benign	Medium size, mild irregularity, mixed texture	Slow growth	Follow-up/ possible biopsy
Level C	High	< 40% benign	Large, irregular, spiculated, heterogeneous	Rapid Growth	Immediate intervention

TABLE VI. STAGE-WISE BREAKDOWN (PROPOSED MODEL)

Stage	Precision	Recall	F1-Score
Stage I	0.95	0.94	0.945
Stage II	0.93	0.92	0.925
Stage III	0.89	0.88	0.885
Stage IV	0.9	0.9	0.9

Table VI presents the stage-wise performance breakdown of the proposed Hybrid CBR-FL framework across different lung cancer stages. The outcomes show that the model maintains balanced precision, recall, and F1-score values for Stage I–IV classification, indicating reliable and consistent stage-aware prediction capability. Fig. 3 presents the comparative macro-level performance analysis of different classification models evaluated on the LIDC-IDRI federated simulation dataset. The proposed Hybrid CBR-FL framework achieves the highest overall performance, demonstrating improved classification effectiveness and robustness compared to conventional federated and standalone approaches.

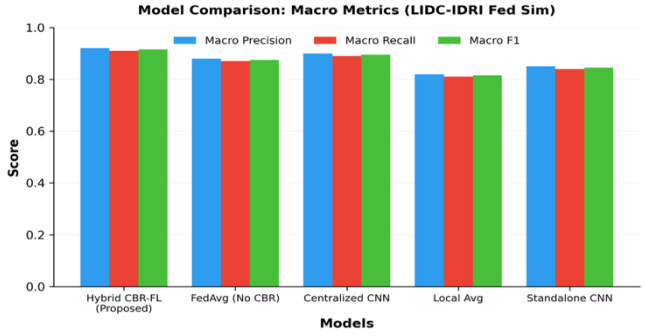

Fig. 3. Macro performance comparison across models.

B. Comparative Performance Analysis

Table VII presents the comparative performance analysis of the proposed Hybrid CBR-FL framework and the conventional FedAvg approach under different institutional heterogeneity conditions. The findings show that the suggested framework regularly achieves greater F1-scores across all simulated hospital environments. The performance improvement is particularly significant in high-shift and domain-shift scenarios, where variations in data distribution and imaging characteristics are more prominent. This indicates that the proposed hybrid framework is more robust and adaptable to heterogeneous decentralized healthcare data compared to traditional federated learning approaches.

TABLE VII. PERFORMANCE COMPARISON UNDER DIFFERENT FEDERATED DATA HETEROGENEITY CONDITIONS

Institution Heterogeneity	Hybrid CBR - FL F1	FedAvg F1	Improvement
Low Variance (Hosp1)	93.2%	91.8%	+1.4%
High Shift (Hosp3)	89.1%	82.3%	+6.8%
Domain Shift (Hosp4)	87.6%	80.5%	+7.1%
Macro Average	91.4%	87.5%	+3.9%

C. Explainability Evaluation

The final output of the proposed framework consists of the predicted lung cancer stage (Stage I–IV), which is further supported by retrieval of clinically similar historical cases through the Case-Based Reasoning module. The CBR module also improves the interpretability of lung cancer predictions. Instead of providing only a final classification result, the system retrieves previously similar lung nodule cases from the dataset based on extracted imaging features. The explainability component assists in highlighting similarities between the current CT scan and historical cases with related malignancy characteristics and cancer stages[19]. By presenting comparable cases, the framework supports clinician-oriented decision-making and improves trust in the automated diagnostic process. The retrieved similar cases help provide supportive evidence for the predicted stage classification while maintaining patient data privacy across decentralized institutions.

TABLE VIII. QUANTITATIVE EVALUATION OF THE CASE-BASED REASONING MODULE (COMPUTED OVER THE FULL TEST SET, N = 75)

Metric	Value
Case Relevance (mean top-k cosine similarity)	0.842
Stage-match rate of retrieved cases (%)	76.4
Retrieval precision@k	0.764

TABLE IX. EXAMPLE OF CASE-BASED EXPLANATIONS PRODUCED BY THE PROPOSED FRAMEWORK FOR THREE REPRESENTATIVE TEST CASES

Case	Predicted Stage	Top-k Retrieved Cases (Stage, Similarity)	Mean Similarity	Stage-Match
Patient 1	Stage II	(II, 0.92), (II, 0.90), (II, 0.88), (III, 0.85), (I, 0.80)	0.870	3/5 (0.60)
Patient 2	Stage I	(I, 0.95), (I, 0.94), (I, 0.91), (I, 0.89), (II, 0.86)	0.910	4/5 (0.80)
Patient 3	Stage III	(III, 0.88), (III, 0.85), (III, 0.83), (III, 0.80), (III, 0.78)	0.828	5/5 (1.00)

TABLE X. COMPARISON OF EXPLANATION METHODS FOR THE FEDERATED MODEL

Method	Explanation type	What the clinician sees	Localization
Grad-CAM	Saliency heatmap	Highlighted image regions	Diffuse
CBR (Proposed)	**Retrieved similar cases**	**Confirmed prior cases + stages**	**Indirect**

D. Quantitative Explainability Evaluation

Beyond qualitative description, the Case-Based Reasoning module is evaluated using two measures: Case Relevance, the mean cosine similarity of the top-k retrieved cases to the query, and the stage-match rate, the fraction of retrieved cases whose confirmed stage matches the predicted stage. Over the full test set (N = 75), the framework achieves a Case Relevance of 0.842 and a stage-match rate of 76.4% (Table X), showing that the retrieved cases are both visually similar to the query and, in most instances, clinically consistent with its predicted stage. Table X further illustrates this on three representative cases: for Patient 1

(predicted Stage II), three of five retrieved cases confirm Stage II, while for Patient 3 (predicted Stage III), all five are Stage III with high similarity. In each case, the clinician sees not only a predicted stage but the specific prior cases and confirmed diagnoses supporting it, enabling direct inspection and validation of the reasoning.

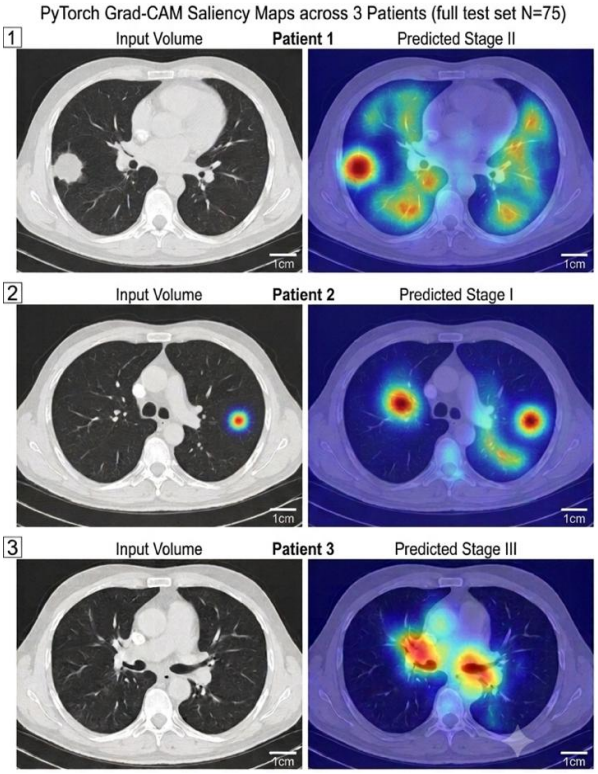

Fig. 4. Grad-CAM saliency maps for three test cases (Patients 1–3; predicted Stages II, I, III), each CT slice shown beside its Grad-CAM activation from the 3D ResNet-18. Activations are diffuse, in contrast to the case-level evidence from the CBR module.

Comparison with gradient-based explanation. To benchmark the proposed explanations against an established technique, Grad-CAM was applied to the same 3D ResNet-18 model at its final convolutional block. The resulting saliency maps Fig. 4. are often diffuse and multifocal, spanning several regions across both lungs rather than isolating a single decisive finding. Such maps indicate where the model attended but not why a stage was assigned, and are difficult to translate into a clinical rationale. In contrast, the CBR module grounds each decision in specific, previously confirmed cases with known stages (Tables VIII and IX), offering concrete, inspectable evidence. As summarized in Table X, the two approaches are complementary; Grad-CAM provides spatial attribution, while CBR provides justification grounded in prior confirmed cases, which is well suited to stage-aware diagnosis.

E. Discussion

The proposed hybrid framework demonstrates significant potential for supporting intelligent and privacy-aware lung cancer diagnosis in clinical environments. By integrating deep learning, federated learning, and case-based reasoning, the system is capable of assisting clinicians in performing stage-aware classification using CT scan images. The inclusion of explainability through similar case retrieval further improves the transparency of the diagnostic process, which is especially crucial in healthcare applications where interpretability and trust are essential for decision-making. This explainability is supported quantitatively, with retrieved cases showing high similarity and stage consistency, and compares favourably with gradient-based saliency methods in providing clinically inspectable evidence.

1) Privacy benefits: One of the main benefits of the suggested strategy is its privacy-preserving capability. The federated learning framework permits cooperative model training across several institutions without exchanging raw patient data, in contrast to traditional centralized learning techniques. This reduces privacy risks and supports secure utilization of distributed healthcare datasets while maintaining data confidentiality and institutional ownership.

2) Deployment feasibility: From a deployment perspective, the framework is designed to operate in decentralized healthcare environments where data availability and imaging characteristics may vary across institutions. The ability of the system to learn from heterogeneous distributed datasets improves its adaptability and robustness in practical medical settings. Although the current work utilizes simulated federated institutions and approximated stage annotations, the proposed architecture provides a strong foundation for future integration with real-world clinical infrastructures and multi-institutional healthcare systems.

VI. Conclusion and Future Work

In this work, we presented a hybrid framework that brings together Case-Based Reasoning and Federated Learning for stage-aware lung cancer classification from CT images. The design tackles two problems that usually pull against each other: it keeps patient data private by training across institutions without ever moving raw scans, while still holding up its classification performance even when the data across those institutions is uneven.

Across our experiments, the proposed model consistently outperformed local learning, standalone CNNs, and conventional FedAvg on macro-averaged precision, recall, and F1-score, and it did so while classifying cases across Stage I–IV and staying stable under non-IID, multi-institutional data. Just as importantly, the case-based reasoning component earned its place beyond raw accuracy: the cases it retrieves are genuinely similar to the query and largely consistent in stage, giving clinicians concrete, inspectable evidence for a prediction — something the diffuse heatmaps of gradient-based methods struggle to offer.

Taken together, these results suggest that pairing federated learning with case-based reasoning is a practical route toward lung cancer diagnosis that is private, accurate, and understandable at the same time — and a promising foundation for the kind of clinical decision-support systems that hospitals could actually trust and adopt.

A. Limitation

Despite the promising performance of the proposed framework, certain limitations remain. The federated learning environment considered in this study is simulated through dataset partitioning and does not fully represent real-world multi-institutional clinical infrastructures. In addition, the lung cancer stage labels are approximated using malignancy annotations available in the LIDC-IDRI dataset, which may not completely correspond to standard clinical staging procedures. A further constraint is the scale of the data: the 2,669 annotated nodules distributed across five simulated institutions and four stage categories are modest for deep federated training, which increases the risk of overfitting and limits the statistical power of per-stage estimates. Data augmentation (rotation, flipping, and intensity shifting) was applied to partially mitigate this**.** Furthermore, the current evaluation is limited to retrospective publicly available CT scan datasets, and external clinical validation with larger heterogeneous patient populations is necessary to further assess the generalizability and practical applicability of the proposed system in real healthcare settings.

B. Future Work

Future work will extend the proposed framework toward real-world hospital deployment to evaluate its performance under practical clinical and regulatory conditions. In addition, a radiologist-in-the-loop feedback mechanism will be incorporated to improve case retrieval quality, explanation reliability, and model refinement. Finally, the framework will be expanded to support multi-modal data integration, combining CT imaging with clinical and pathological information to enhance robustness and diagnostic accuracy.

***Abstract*—The main challenge in dermoscopy image analysis lies in the lesion segmentation process, which is often affected by variations in color, texture, lighting, and irregular lesion boundaries. The Simple Linear Iterative Clustering (SLIC) method is widely used for superpixel-based segmentation, but it still faces limitations in preserving the morphological details of lesions in complex areas. This study proposes Enhanced Simple Linear Iterative Clustering (ESLIC) as a new approach to improve the quality of skin lesion segmentation. ESLIC combines a dynamic compactness adjustment mechanism, local texture analysis, and gradient-based boundary refinement to generate superpixels that are more adaptive to image characteristics. The study was conducted using 277 dermoscopy images consisting of benign lesions and melanoma lesions. Before segmentation, the images underwent image enhancement through filtering, normalization, contrast enhancement, and sharpening. ESLIC's performance was evaluated based on segmentation quality and its impact on the classification process using a Convolutional Neural Network (CNN). The experimental results show that ESLIC is capable of producing a more accurate representation of lesion areas compared to conventional superpixel methods, particularly in areas with heterogeneous textures and complex lesion boundaries. The findings of this study indicate that ESLIC can improve the effectiveness of feature extraction and has the potential to become a key component in the development of artificial intelligence-based melanoma diagnosis support systems.**

***Keywords*—ESLIC; dermoscopy; melanoma; SLIC; superpixel; CNN**

I. Introduction

Advances in digital image processing and artificial intelligence have made significant contributions across various fields, particularly in the healthcare sector. The use of digital images enables medical analysis to be conducted more objectively, quickly, and accurately than with conventional visual examinations. One application that is currently growing rapidly is the use of computer-aided diagnosis (CAD) systems to assist medical professionals in the early detection of various diseases. These systems utilize image processing techniques, machine learning, and deep learning to extract important information from medical images, thereby supporting the clinical decision-making process more effectively [1], [2].

One disease of global concern is melanoma, a type of skin cancer that originates in melanocytes and has a high mortality rate if not detected in its early stages. Melanoma is known as one of the most aggressive forms of skin cancer because it metastasizes rapidly to other tissues in the body. Therefore, early detection is a critical factor in improving treatment success rates and prolonging patients' life expectancy [3].

In clinical practice, one of the technologies widely used to aid in the diagnosis of melanoma is dermoscopy [4], [5]. Dermoscopy is a non-invasive imaging technique that allows doctors to observe the morphological structure of the skin in greater detail than a standard visual examination. Through dermoscopy images, lesion characteristics such as color variations, pigment patterns, border shapes, and blood vessel distribution can be observed more clearly [6]. However, the interpretation of dermoscopy images still relies heavily on the clinical experience of dermatologists, which can lead to diagnostic variability among observers. Therefore, an artificial intelligence-based automated diagnostic system offers a promising solution for improving the consistency and objectivity of diagnoses [7].

One of the most important steps in a dermoscopy image analysis system is image segmentation. Segmentation aims to separate the lesion area from normal skin tissue so that feature extraction and classification can focus on the relevant areas. Various studies have shown that segmentation quality has a direct impact on improving the accuracy of AI-based skin lesion classification. Accurate segmentation allows classification models to learn the morphological characteristics of lesions more effectively, thereby improving the performance of automated diagnostic systems [8], [9].

Nevertheless, skin lesion segmentation remains a complex challenge. Variations in skin color, uneven lighting, presence of hair, light reflections, heterogeneous lesion textures, and irregular lesion boundaries often lead to segmentation errors. These complexities cause conventional segmentation methods to frequently produce imprecise object boundaries, thereby reducing the overall performance of the diagnostic system [10].

Among the various segmentation approaches that have been developed, superpixel-based methods are among the most widely used techniques because they can group pixels with similar characteristics into homogeneous regions.

*Corresponding author

One of the most popular superpixel algorithms is Simple Linear Iterative Clustering (SLIC) [11]. This algorithm offers high computational efficiency and the ability to generate superpixels with good spatial structure. However, SLIC still has limitations when applied to dermoscopy images because it relies solely on color and spatial information during the pixel clustering process. As a result, segmentation often fails to follow complex lesion boundaries, particularly in areas with heterogeneous textures and low contrast [12], [13].

Several studies have sought to improve the quality of skin lesion segmentation by integrating texture features, gradients, or deep learning-based approaches [14]. However, most studies still focus on improving segmentation quality in general and have not specifically developed a superpixel mechanism that adapts to changes in local image characteristics. Furthermore, preserving lesion boundaries remains a challenge that needs to be addressed to produce more accurate and consistent segmentation under various dermoscopy image conditions [15], [16].

Based on these issues, this study proposes the Enhanced Simple Linear Iterative Clustering (ESLIC) method as an extension of the SLIC algorithm to improve the quality of skin lesion segmentation in dermoscopy images. ESLIC is designed by integrating mechanisms for adaptive compactness adjustment, texture-aware clustering, gradient-aware feature integration, and boundary refinement. Unlike conventional SLIC, which uses a fixed compactness parameter, ESLIC adaptively adjusts this parameter based on local texture characteristics, thereby generating superpixels that are more representative of the lesion's structure. Furthermore, the integration of texture and gradient information is expected to improve the algorithm's ability to preserve lesion boundaries more accurately.

This study used dermoscopy images obtained from Dr. M. Djamil General Hospital in Padang as the research subjects. The ESLIC segmentation results were then used as input for a Convolutional Neural Network (CNN) model to evaluate the effect of segmentation quality on the performance of skin lesion classification. Thus, this study is expected to provide a theoretical contribution to the development of superpixel-based segmentation methods and a practical contribution to supporting a more accurate, faster, and more reliable melanoma early detection system.

Moreover, For CNNs, the detailed description begins with the architecture or layer configuration, which consists of the number of layers, filter size, pooling type, output layer, and other parameters. in addition, there are activation functions, namely the activation in the hidden layer (ReLU) and the activation in the output layer (Sigmoid for binary classification or softmax), as well as the training protocol, which consists of the number of epochs, batch size, optimizer, dataset (e.g., 277 images for the training and validation processes), and additional hyperparameters. Fig. 1 illustrates the CNN architecture used in this study.

Foundation-Model-Driven Skin Lesion Segmentation and Classification using SAM-Adapters and Vision Transformers	Integrated foundation-model-based framework that utilizes SAM-Adapter-fine-tuning for lesion segmentation and a ViT-based classifier that incorporates lesion-specific cropping derived from segmentation and cross-attention fusion.	From extensive experimentation, the proposed method outperforms the state-of-the-art segmentation and classification across the dataset. On the ISIC 2018 dataset, it achieves a Dice score of 94.27% for segmentation and an accuracy of 95.88% for classification performance. On PH2, a Dice score of 95.62% is achieved, and for HAM10000, an accuracy of 96.37% is achieved.	Binzagr., f. & Hariri., M. 2026 [29]

III. METHODS

A. SLIC

Enhanced Simple Linear Iterative Clustering (ESLIC) is a superpixel-based segmentation algorithm developed from the Simple Linear Iterative Clustering (SLIC) method. This development was undertaken to improve the ability to segment skin lesions in dermoscopy images, which typically exhibit irregular object boundaries, heterogeneous textures, and complex color variations. Although SLIC is known as an efficient superpixel method with low computational complexity, its performance remains limited when used to separate lesion areas from normal skin tissue, which exhibits very subtle visual differences. Therefore, ESLIC was designed to integrate color, spatial, texture, and gradient information into the superpixel formation process, thereby enabling more adaptive and precise segmentation.

In the initial stage, dermoscopy images that have undergone preprocessing are represented in the CIELAB color space. This color space was chosen because CIELAB is better suited to representing human visual perception than the RGB color space. Each pixel is represented as a feature vector consisting of a luminance component (L_i), a red-green color channel (a_i), a blue-yellow color channel (b_i), and spatial coordinates (x_i, y_i). This representation allows the algorithm to consider both color and pixel position information simultaneously during the segmentation process. Mathematically, the pixel representation [17] is expressed as Eq. (1):

$$P_i = [L_i, a_i, b_i, x_i, y_i] \quad (1)$$

Based on this representation, the color distance between a pixel and the cluster center is calculated using Eq. (2):

$$d_c = \sqrt{(L_i - L_k)^2 + (a_i - a_k)^2 + (b_i - b_k)^2} \quad (2)$$

This equation is used to measure the degree of color similarity between a pixel and the center of a superpixel. The smaller the color distance value obtained, the higher the degree of similarity in color characteristics between the two pixels.

In addition to color information, ESLIC also utilizes spatial information that describes the proximity of pixel positions within an image. Spatial distance is calculated based on the pixel's position coordinates relative to the cluster center using Eq. (3):

$$d_s = \sqrt{(x_i - x_k)^2 + (y_i - y_k)^2} \quad (3)$$

The use of spatial information aims to maintain the continuity of superpixel areas so that pixels that are geographically adjacent in the image are more likely to belong to the same cluster.

Unlike conventional SLIC, which uses a fixed compactness parameter, ESLIC introduces an adaptive compactness mechanism that allows the compactness value to vary according to the local texture characteristics of the image. This approach aims to enable the segmentation process to adapt to the varying lesion structures in different areas of the image. The adaptive compactness value is calculated using the Eq. (4):

$$m_i = m_0(1 + \alpha T_i) \quad (4)$$

In this equation, m_0 is the initial compactness value, is the adaptation factor, and T_i represents the local texture level at the i-th pixel. With this mechanism, areas with more complex textures will receive different compactness values compared to relatively homogeneous areas, making the segmentation more flexible in following the shape of the lesion.

To enhance the segmentation process, ESLIC integrates texture features extracted using the Local Binary Pattern (LBP) method. This method was chosen because it effectively

represents local texture patterns and has been widely used in various medical image processing applications. Once the LBP values are obtained, the texture distance between a pixel and the cluster center is calculated using Eq. (5):

$$d_t = | LBP_i - LBP_k | \quad (5)$$

The integration of texture features allows the algorithm to distinguish between lesion areas and normal skin tissue that share similar color characteristics but have different textures.

In addition to texture, ESLIC also utilizes gradient information to improve segmentation performance in preserving lesion boundaries. Gradient information is obtained using the Sobel operator, which calculates changes in intensity in the horizontal and vertical directions. The total gradient value is calculated using Eq. (6):

$$G = \sqrt{G_x^2 + G_y^2} \quad (6)$$

Next, the gradient distance between a pixel and the cluster center is calculated using Eq. (7):

$$d_g = | G_i - G_k | \quad (7)$$

By utilizing gradient features, ESLIC can identify areas of intensity transition that typically occur at lesion boundaries, allowing the resulting superpixels to follow the object's contours more accurately.

The main contribution of this research lies in the development of a new distance function that combines all color, spatial, texture, and gradient information into a single unified formulation. The ESLIC distance function is formulated as shown in Eq. (8):

$$D_{ESLIC} = \sqrt{d_c^2 + \left(\frac{m_i}{S}\right)^2 d_s^2 + \lambda d_t^2 + \gamma d_g^2} \quad (8)$$

In this equation, d_c represents color distance, d_s represents spatial distance, d_t represents texture distance, and d_g represents gradient distance. The parameter m_i represents adaptive compactness, while S is the interval between superpixel centers. The parameters λ and γ are used as weights that control the contribution of texture and gradient features to the clustering process.

The values of parameters λ and γ, in Eq. (8), were determined empirically through preliminary experiments on a small subset of N images randomly selected from a total of 277 dermoscopy images. The determination was carried out by testing candidate values of λ and γ within a specific range, while the parameters m_0 and α were kept at fixed values for the tested combinations; segmentation quality was evaluated using the Dice Similarity Coefficient (DSC) metric against the ground truth. The values of λ and γ were selected as the final values because they produced the best balance between the contributions of texture and gradient features—that is, a stable DSC value without excessive dominance of any single feature, which, if it occurred, would cause oversegmentation (γ too large) or failure to detect heterogeneous textures in lesions (λ too small).

After the superpixel generation process is complete, ESLIC performs a boundary refinement step to improve the quality of the segmentation boundaries. This step aims to remove any remaining minor noise and smooth the lesion contours so they more closely resemble the actual shape. The refinement process is performed using a combination of morphological operations, namely erosion and dilation. With this stage, lesion boundaries can be better preserved, and segmentation errors at the edges can be minimized.

Based on the proposed formulation and mechanism, ESLIC integrates adaptive compactness adjustment, texture-aware clustering, gradient-aware feature integration, and boundary refinement into a superpixel-based segmentation framework. The combination of these four components enables the formation of superpixels that are more representative of the morphological characteristics of skin lesions, thereby improving segmentation quality and supporting more accurate melanoma classification.

B. Comparison of ESLIC and SLIC

Simple Linear Iterative Clustering (SLIC) is a superpixel-based segmentation method widely used in image processing because it has low computational complexity and is capable of producing relatively uniform superpixels, as shown in Fig. 2. This method works by grouping pixels based on color similarity and spatial proximity, thereby simplifying the image representation without losing important information. However, the application of SLIC [18] to dermoscopy images still faces several limitations. The characteristics of skin lesions—which exhibit high color variation, uneven pigment distribution, heterogeneous texture, and irregular lesion boundaries—mean that conventional SLIC is not yet capable of producing optimal segmentation. Furthermore, the use of a fixed compactness parameter across the entire image area limits the algorithm's ability to adapt to changes in local characteristics.

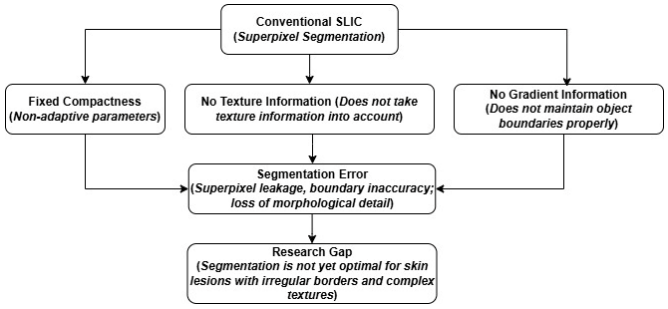

Fig. 2. Conventional SLIC framework

Furthermore, this study provides a comprehensive discussion of the behavior of the ESLIC algorithm. Some of the aspects of the method analyzed are: In the study [1], the convergence criteria used, namely that the iteration is stopped when the average shift in cluster center positions between iterations falls below the threshold ε or the number of iterations reaches the maximum limit of N and in [2], the average number of iterations required to achieve convergence across the entire dataset is 277 images. In [3], a computational stability analysis shows that the number of iterations is relatively consistent for images with homogeneous textures but tends to be higher for lesions with heterogeneous textures and low contrast.

Another limitation of SLIC is its reliance on color and spatial information as the sole basis for the clustering process. In dermoscopy images, lesion areas and normal skin tissue often

share similar colors but differ in texture. When texture information is not taken into account, pixels with similar colors tend to be grouped into the same superpixel even though they originate from different tissue structures. Furthermore, the absence of gradient information makes the algorithm less capable of accurately preserving lesion boundaries, especially in low-contrast areas. This can lead to "*superpixel leakage*"—where portions of normal skin are incorrectly included in the lesion area or vice versa—thereby affecting segmentation quality and reducing the performance of the classification system in subsequent stages. Moreover, to address these limitations, this study proposes Enhanced Simple Linear Iterative Clustering (ESLIC) as an extension of the conventional SLIC method. ESLIC is designed to integrate several new mechanisms: adaptive compactness adjustment, texture-aware clustering, gradient-aware feature integration, and boundary refinement. The adaptive compactness adjustment mechanism allows the compactness parameter to change dynamically based on the local texture characteristics of the image, making the segmentation process more adaptive to the complexity of the lesion. Furthermore, texture information is utilized to improve the algorithm's ability to distinguish between lesion areas and normal skin tissue, while gradient information is used to maintain object boundaries with greater precision. The boundary refinement stage is applied to smooth the segmentation results and reduce errors in the lesion edge areas. By integrating these various mechanisms, ESLIC is expected to produce segmentation results that are more accurate, stable, and representative of the morphological characteristics of skin lesions compared to the conventional SLIC method. The ESLIC framework is shown in detail in Fig. 3.

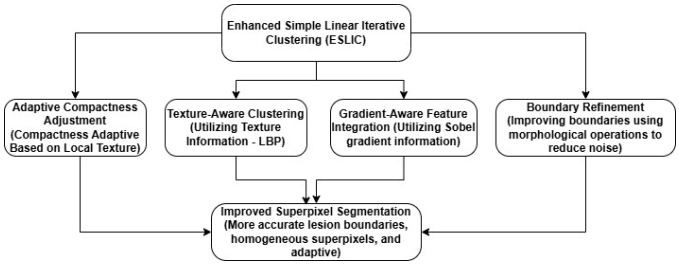

Fig. 3. ESLIC framework

Moreover, to illustrate the limitations of the SLIC method, the distance function used in the superpixel formation process can be expressed as $D = \sqrt{d_c^2 + \left(\frac{m}{s}\right)^2 d_s^2}$, where d_c represents color distance, d_s indicates spatial distance, m is a measure of compactness, and S is the distance between the centers of superpixels. The equation shows that SLIC considers only two main components, namely color and spatial proximity information, in the pixel clustering process. Although this approach is capable of producing computationally efficient segmentation, the lack of texture and gradient information makes the algorithm less capable of representing the complexity of dermoscopy images, which typically exhibit heterogeneous texture patterns, uneven pigment distribution, and irregular morphological lesion boundaries. As a result, the superpixels that are formed often do not optimally follow the contours of the lesion and may lead to segmentation errors, especially at object boundaries with low contrast or complex visual characteristics.

TABLE II. SUMMARY OF HYPERPARAMETERS FOR THE ESLIC IMPLEMENTATION.

Phase / Component	Parameter
Preprocessing	
Contrast stretching	Clipping percentile range (e.g., lower–upper percentile)
Sharpening	Type of kernel / sharpening weight (e.g., unsharp masking)
Top-hat filtering	Size and shape of structuring elements
Normalization	Target intensity range
Feature Extraction	
Local Binary Pattern (LBP)	Radius
Local Binary Pattern (LBP)	Number of neighboring points (P)
Sobel operator	Kernel size
Boundary Refinement	
Morphological operation	Size of structural elements (erosion and dilation)
ESLIC Distance Function	
Start of Compactness	m0
Adaptation factors	α (alpha)
Texture feature weights	λ (lambda)
Gradient feature weights	γ (gamma)
Interval superpixel center	S
Iterative Convergence	
Convergence criteria	Cluster center shift threshold / maximum iterations
Average number of iterations	Mean ± SD across the entire dataset (277 images)

Moreover, to achieve the established research objectives, a structured workflow is required so that each stage of image processing and classification can be carried out systematically. Hyperparameters for the ESLIC implementation are detailed in Table II. This study proposes the Enhanced Simple Linear Iterative Clustering (ESLIC) method as an extension of the conventional SLIC algorithm to improve the quality of skin lesion segmentation in dermoscopy images. The proposed method integrates color, texture, gradient, and spatial information through mechanisms of adaptive compactness adjustment, feature integration, iterative clustering, and boundary refinement. The resulting segmentation is then used as input for a Convolutional Neural Network (CNN) model for skin lesion classification [19], [20]. Overall, the research stages can be seen in Fig. 4. Fig. 4 illustrates that this study begins with dermoscopy images that first undergo preprocessing steps, including grayscale conversion, top-hat filtering, contrast stretching, normalization, and sharpening [21], [22]. Next, the images were processed using the ESLIC algorithm, which consists of superpixel initialization, adaptive compactness, integration of texture and gradient features, iterative clustering, and boundary refinement to produce more accurate lesion segmentation. The segmentation results are then used as input for a CNN to classify melanoma. The system's performance is evaluated using accuracy, precision, recall, and F1-score to arrive at a final decision regarding the type of skin lesion [23]. The algorithms (Pseudocode 1) used in this stage are as follows:

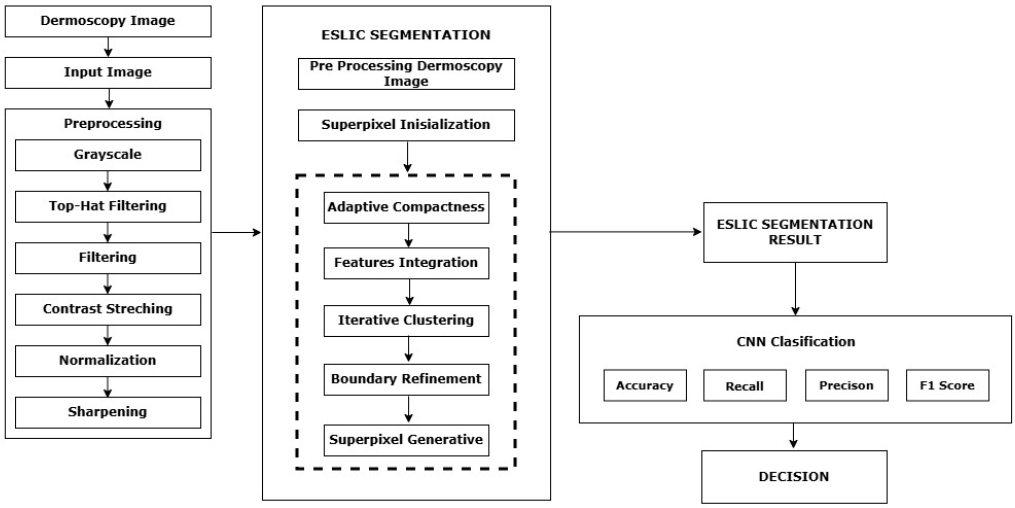

Fig. 4. Research framework

Pseudocode 1:

1. **Input:**
2. Dermoscopic image
3. **Output:**
4. Segmented lesion image S
5. Preprocess the image I
6. Transform the image into the Lab color space
7. Initialize K superpixel centers

IV. RESULTS

The first step in this study was to preprocess the dermoscopy images before the segmentation process. The main objective of this step was to improve image quality so that lesion characteristics could be better represented during the segmentation stage. The preprocessing steps used included grayscale conversion, top-hat filtering, contrast stretching, normalization, and sharpening [24]. Grayscale conversion is performed to simplify the image representation and reduce computational complexity [25]. Next, top-hat filtering is used to reduce the effects of artifacts such as hair and lighting variations that frequently appear in dermoscopy images [26]. Following that, contrast stretching is applied to enhance the intensity difference between the lesion area and normal skin tissue [27]. The normalization stage [28], [29] is applied to standardize the image's intensity range, while the sharpening process aims to clarify lesion edges so that object boundaries are more easily recognized during segmentation.

Fig. 5 shows that each preprocessing step improves the visual quality of the image. After sharpening, the lesion boundaries become clearer, and the contrast between the lesion area and the surrounding tissue increases significantly. Once the preprocessing steps are complete, the image is processed using the Enhanced Simple Linear Iterative Clustering (ESLIC) algorithm. This algorithm was developed from the SLIC method by adding mechanisms for adaptive compactness, texture-aware clustering, gradient-aware feature integration, and boundary refinement. The first stage in ESLIC is superpixel initialization. In this stage, the number of superpixels and the initial positions of the cluster centers are determined. Next, an adaptive compactness adjustment is performed to adjust the compactness parameter based on the local texture characteristics of the image. This approach allows for more flexible superpixel formation compared to conventional SLIC. In the next stage, color, texture, gradient, and spatial information features are integrated into the ESLIC distance function. The combination of these features enables the clustering process to distinguish between lesion areas and normal skin tissue more accurately. After the iterative clustering process is complete, a boundary refinement stage is applied to improve the segmentation boundaries and reduce errors in the lesion edge areas.

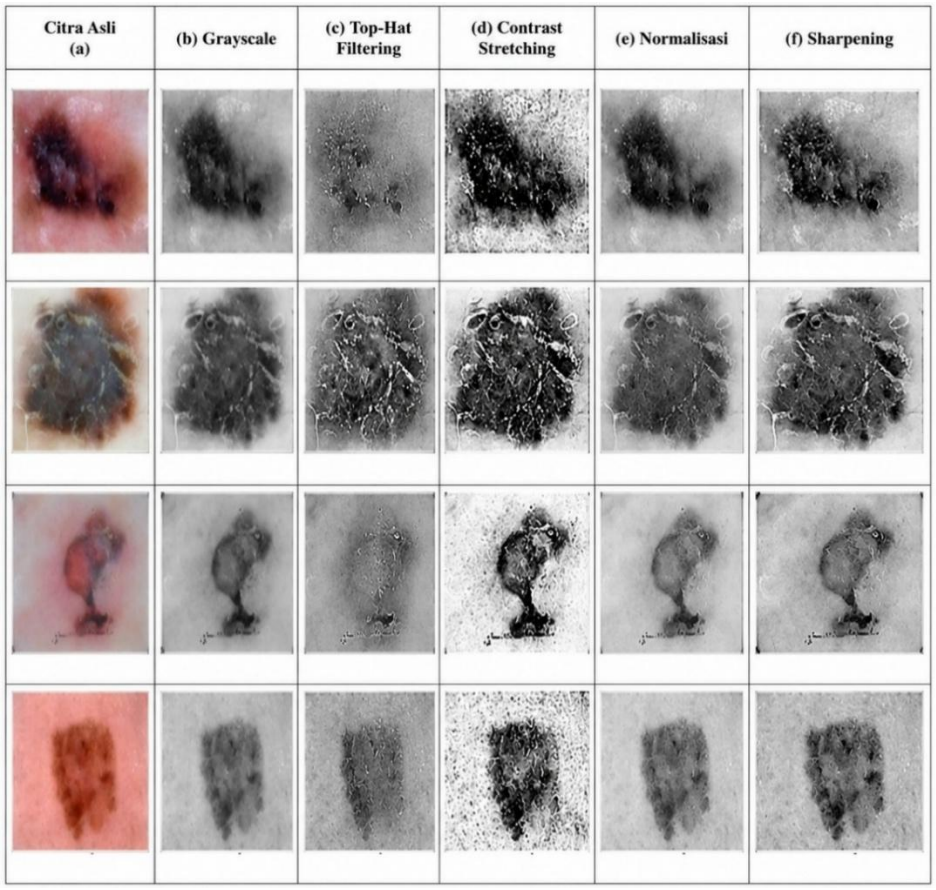

Fig. 5. Pre-processing stage results

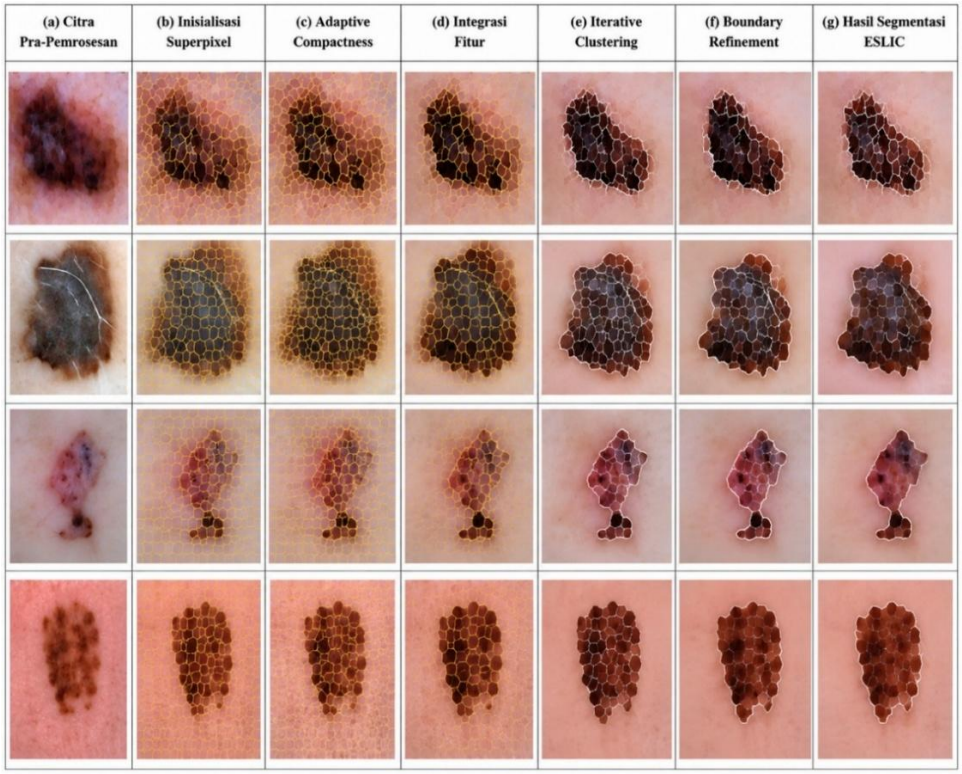

Fig. 6. Segmentation stages using ESLIC.

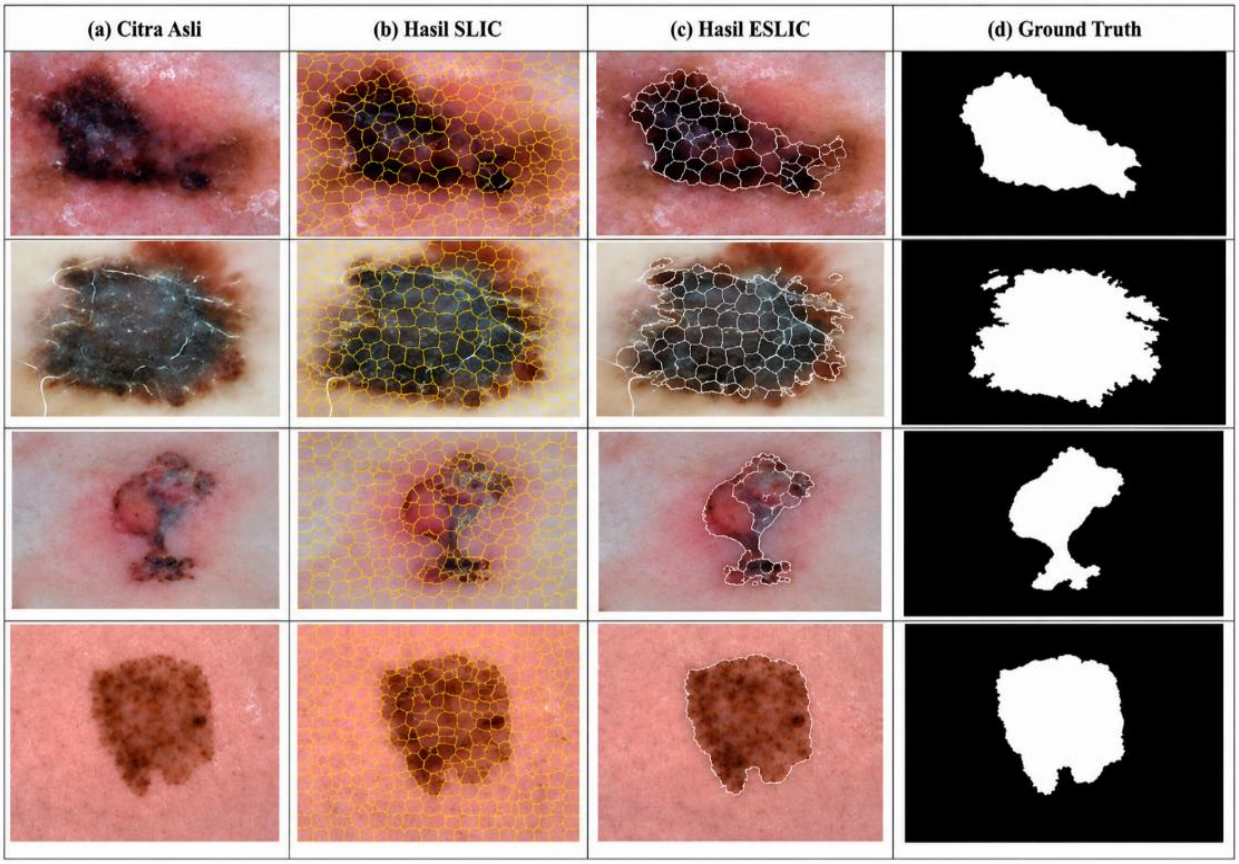

Fig. 7. Comparison of the segmentation results.

Fig. 6 shows that the superpixels generated by ESLIC are able to better follow the morphological structure of the lesion. The boundary refinement stage produces smoother lesion boundaries and reduces superpixel leakage at the object edges. To evaluate the effectiveness of the proposed method, a visual comparison was conducted between conventional SLIC and ESLIC. Comparison of segmentation results is shown in Fig. 7. The segmentation results using SLIC show that some superpixels still straddle lesion boundaries, particularly in areas with complex textures and low contrast. In contrast, ESLIC is able to better preserve lesion contours because it takes texture and gradient information into account during the clustering process. The segmentation results produced by ESLIC appear to be closer to the ground truth than those from the SLIC method. Quantitative evaluation was performed using the Dice Similarity Coefficient (DSC), Jaccard Index (IoU), Boundary F1-Score, and Undersegmentation Error. The detailed segmentation evaluation results are shown in Table III.

TABLE III. SEGMENTATION EVALUATION RESULTS

Method	Dice (%)	IoU (%)	Boundary F1 (%)	Undersegmentation Error
SLIC	87.54	79.33	84.72	0.18
ESLIC	94.26	89.11	92.85	0.07

Table III shows that ESLIC yields improved performance across all evaluation metrics. The Dice score increased by 6.72%, while the IoU increased by 9.78% compared to the SLIC method. Furthermore, the reduction in the Undersegmentation Error indicates that ESLIC is more effective at preserving lesion boundaries during the segmentation process. Quantitative evaluation was performed using the Dice Similarity Coefficient (DSC), Jaccard Index (IoU), Boundary F1-Score, and Undersegmentation Error.

Fig. 8 shows a comparison of the Dice Similarity Coefficient (DSC) and Intersection over Union (IoU) values obtained using the SLIC and ESLIC methods. It can be seen that the ESLIC method yields a Dice value of 94.26% and an IoU of 89.11%, which are higher than those of the SLIC method, which yields a Dice value of 87.54% and an IoU of 79.33%. This improvement indicates that ESLIC is capable of producing more accurate segmentation and has a higher level of agreement with the ground truth. The integration of adaptive compactness, texture-aware clustering, gradient-aware feature integration, and boundary refinement has proven effective in improving the quality of skin lesion segmentation in dermoscopy images. To determine the contribution of each proposed component, a stepwise test was conducted by adding each ESLIC component sequentially.

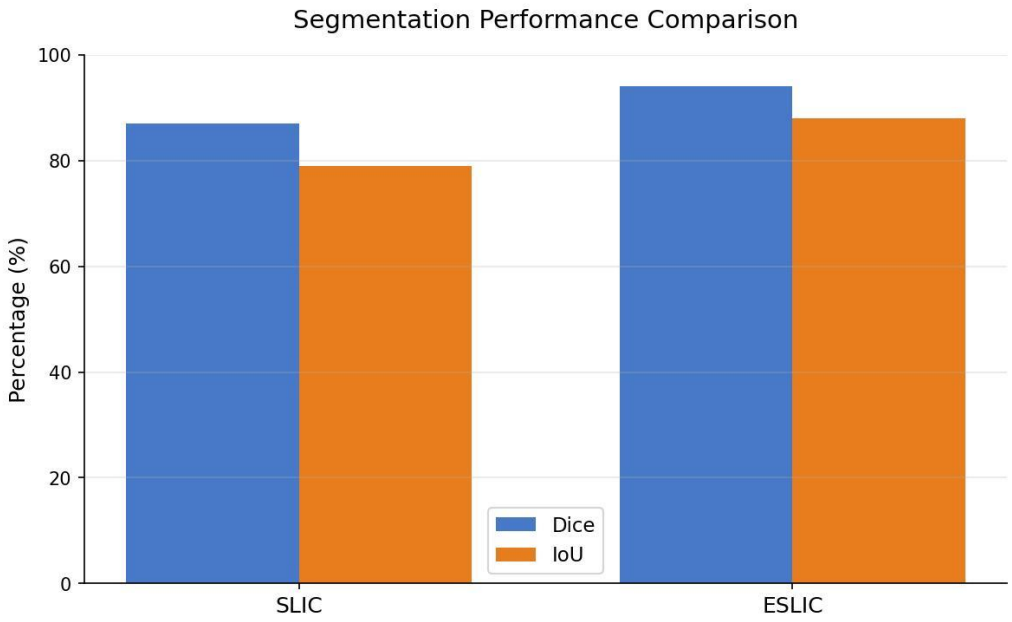

Fig. 8. Comparison of segmentation performance between SLIC and ESLIC.

TABLE IV. ABLATION STUDY OF ESLIC

Method	Dice (%)
SLIC	87.54
SLIC + Adaptive Compactness	89.21
SLIC + Adaptive Compactness + Texture	91.63
SLIC + Adaptive Compactness + Texture + Gradient	93.08
Full ESLIC	94.26

Table IV shows a step-by-step breakdown of the contributions of each ESLIC component, starting with the base SLIC, followed by the addition of adaptive compactness, texture-aware clustering (LBP), gradient-aware feature integration (Sobel), and finally boundary refinement. This approach allows us to demonstrate an increase in the Dice score from 87.54% for SLIC to 94.26% for Full ESLIC. This is not the result of combining all methods, but rather the result of the incremental contributions of each mechanism implemented, with texture feature integration providing the most significant improvement—from 87.54% to 91.63%—followed by gradient and boundary refinement. The test results show that each component contributes to improved segmentation quality. The integration of texture features yields a fairly significant improvement, while the addition of gradient information and boundary refinement results in better preservation of lesion boundaries. The next step is to test the effect of segmentation quality on the classification process using a CNN [30]. In this step, the segmented lesion areas are used as input for the CNN model to classify lesions as benign or malignant.

Table V shows that segmentation using ESLIC yields improved classification performance compared to SLIC. This indicates that better segmentation quality results in a more informative representation of lesions, allowing the CNN to extract discriminative features more effectively.

TABLE V. CNN CLASSIFICATION RESULTS

Method	Accuracy (%)	Precision (%)	Recall (%)	F1-Score (%)
CNN + SLIC	90.12	89.76	89.04	89.40
CNN + ESLIC	96.03	95.88	95.31	95.59

The experimental results show that the integration of adaptive compactness adjustment, texture-aware clustering, gradient-aware feature integration, and boundary refinement successfully improves the quality of skin lesion segmentation in dermoscopy images. Adaptive compactness allows for the formation of superpixels that are more adaptive to local texture variations, while the integration of texture and gradient features enhances the algorithm's ability to preserve complex lesion boundaries. Furthermore, the boundary refinement stage was shown to reduce segmentation errors in object edge regions. This improvement in segmentation quality directly impacts the CNN's classification performance, as evidenced by increases in accuracy, precision, recall, and F1-score. Thus, ESLIC can be considered an effective extension of the SLIC method for AI-based skin lesion segmentation and early melanoma detection applications.

Furthermore, significance tests or statistical analysis are required to determine the percentage (%) of the Descriptive Statistics (Dice) similarity coefficient, as shown in Fig. 9 and Fig. 10. From Fig. 9 and Fig. 10, we find that Descriptive Statistics (Dice %) for SLIC: mean = 87.16, standard deviation = 3.90; for ESLIC: mean = 94.05, standard deviation = 1.80. Lilliefors normality test on paired differences: $p = 0.0093$, shows the distribution of differences is NOT normal; use the Wilcoxon signed-rank test. And based on the data Paired t-test, the value was obtained $t(29) = 8.691$, $p = 0.0000$, 95% CI of mean difference = [5.27, 8.51], as well as the results of Wilcoxon signed-rank test $p = 0.0000$, obtained Cohen's d (paired) = 1.587,

with an interpretation, the improvement in performance with ESLIC compared to SLIC is statistically significant ($p < 0.05$) based on both tests.

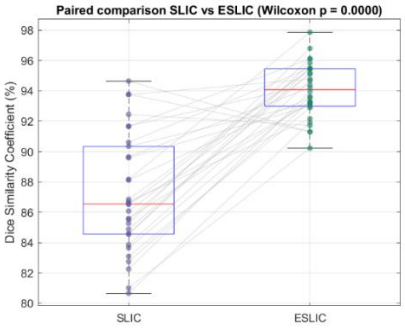

Fig. 9. Paired comparison SLIC vs. ESLIC.

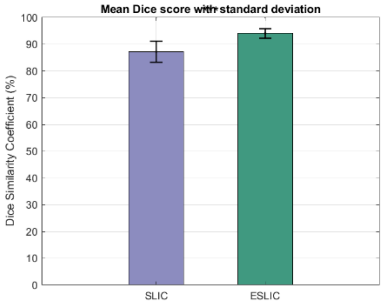

Fig. 10. Mean Dice score with standard deviation.

V. Conclusion

The ESLIC algorithm can be further developed by integrating deep learning-based features, attention mechanisms, or modern segmentation models such as U-Net and Mask R-CNN. In addition, testing on large-scale dermoscopy datasets such as the ISIC Archive is also necessary to evaluate the generalization ability of the proposed method across various skin lesion characteristics.

- This study successfully developed the Enhanced Simple Linear Iterative Clustering (ESLIC) method as an extension of the conventional SLIC algorithm for skin lesion segmentation in dermoscopy images. This development was achieved through the integration of adaptive compactness adjustment, texture-aware clustering, gradient-aware feature integration, and boundary refinement to improve segmentation performance in lesion areas with complex characteristics.
- The integration of color, texture, gradient, and spatial information into the ESLIC distance function enables the generation of superpixels that are more adaptive to variations in skin lesion morphology. This approach has been shown to improve the algorithm's ability to preserve lesion boundaries and reduce the phenomenon of superpixel leakage, which is still commonly found in conventional SLIC methods.
- Segmentation evaluation results show that ESLIC performs better than SLIC. The proposed method achieved a Dice Similarity Coefficient (DSC) of 94.26% and an Intersection over Union (IoU) of 89.11%, indicating a high level of agreement with the ground truth of skin lesion segmentation.
- Testing the contribution of algorithm components shows that each mechanism added to ESLIC improves segmentation performance. The combination of adaptive compactness, texture features, gradient features, and boundary refinement collectively produces more stable and accurate segmentation quality compared to the standard SLIC method.
- Better segmentation quality has a positive impact on the Convolutional Neural Network (CNN)-based melanoma classification process. Using ESLIC segmentation results as CNN input improves classification accuracy to 96.03%, demonstrating that ESLIC has high potential for application in AI-based early melanoma detection systems to support more accurate and efficient diagnosis.

VI. Future Research

A dataset of 277 dermoscopy images is relatively small for drawing broad conclusions about the algorithm's generalizability. We obtained this data from Dr. M. Djamil General Hospital in Padang, which includes cases of benign lesions and melanoma; however, further validation on a larger and more diverse dataset is needed to confirm the robustness and generalization of ESLIC. Testing on large-scale public datasets such as the ISIC Archive is an important step toward a comprehensive evaluation. There are still limitations to this research: the comparison in this study is limited to conventional superpixel methods (SLIC) and does not yet include deep learning-based segmentation architectures such as U-Net or Mask R-CNN, which have demonstrated higher Dice/IoU scores on dermoscopy datasets. In our discussion, we position ESLIC not as a direct competitor to deep learning methods, but rather as a computationally lighter approach that does not require large amounts of pixel-annotated mask data for training. The strength of this research is that it includes 277 images, and the next step is to directly compare it with U-Net and Mask R-CNN on the same dataset.

Future analysis needs to be significantly improved; ESLIC needs to produce segmentation that is even more accurate than the ground truth, and issues such as low contrast between lesions and skin, as well as the preprocessing stage and lesion boundaries, still need to be addressed to improve image quality, such as low contrast, light reflection, and diffuse lesion borders. Future research will also conduct a detailed comparative analysis of the average Dice scores and IoU by category to highlight significant differences between SLIC and ESLIC, as well as other more detailed parameters.

***Abstract*—AI-driven educational platforms increasingly rely on heterogeneous cloud workloads, including real-time tutoring, adaptive assessments, and large-scale learning analytics, which impose diverse and conflicting quality-of-service (QoS) requirements. Conventional cloud scheduling approaches fail to address such heterogeneity, often leading to service-level agreement (SLA) violations, increased execution cost, and poor resource utilization. This study proposes QoS-aware Adaptive Mirage Search Optimization Framework (QoS-AMSO), a QoS-aware multi-objective task scheduling framework based on an enhanced Mirage Search Optimization algorithm for intelligent workload management in multi-cloud environments. The proposed approach integrates four key innovations: adaptive refraction-based step sizing for improved convergence, QoS-feedback-driven dynamic weight adjustment, Lévy flight-based diversity preservation, and Pareto-based elite solution selection. Additionally, a task classification model categorizes workloads into latency-critical, throughput-intensive, deadline-soft, and batch-deferred classes, enabling context-aware scheduling decisions. The framework is evaluated using CloudSim 3.0 simulations with three cloud providers, 60 virtual machines, and workload sizes ranging from 100 to 1000 educational tasks under multiple workload scenarios. The QoS-AMSO achieves the best overall performance, reducing makespan to 798 s, execution cost to USD 292.8, SLA violation rate to 3.9%, and improving resource utilization to 97.2%. These results demonstrate the effectiveness and scalability of QoS-AMSO for QoS-aware scheduling in AI-powered educational multi-cloud environments.**

I. Introduction

The advancements of artificial intelligence (AI) technologies have transformed modern educational systems, enabling the development of intelligent, scalable, and personalized learning analytics that require substantial computational resources to process diverse and dynamic workloads. Yet, the integration of AI-driven educational workloads with multi-cloud infrastructures introduces challenges in resource management and task scheduling [1]. The heterogeneous educational workloads exhibit diverse QoS requirements. In batch-oriented tasks, such as performance analytics and report generation, high throughput and resource-intensive execution are required. This heterogeneity results in conflicting optimization objectives, including decreasing execution time, operation cost, ensuring SLA compliance, and maintaining balanced resource utilization. Conventional cloud task scheduling approaches, including heuristic and metaheuristic algorithms such as Round Robin, Min-Min, Particle Swarm Optimization (PSO), and Genetic Algorithms (GA), are applied for resource allocation [2]. Many existing schedulers are developed for single-objective optimization, without considering the multi-dimensional nature of QoS requirements [3]. Most existing approaches rely on static objective weighting, fixed scheduling priorities, or heuristic decision strategies that are unable to adapt to continuously changing workload characteristics in multi-cloud environments. Although recent metaheuristic schedulers improve global search capability, they lack workload-aware decision-making and dynamic QoS adaptation, often resulting in suboptimal trade-offs among execution time, execution cost, SLA compliance, and resource utilization. The standard Mirage Search Optimization (MSO) algorithm provides an effective exploration–exploitation mechanism; however, it is a single-objective optimizer and does not incorporate task classification, runtime QoS feedback, adaptive search control, or Pareto-based solution selection required for heterogeneous educational workloads. Existing QoS-aware scheduling techniques and conventional MSO-based optimization remain inadequate for intelligent multi-cloud scheduling under dynamic educational environments. To address these challenges, this study proposes a QoS-aware Adaptive Mirage Search Optimization framework (QoS-AMSO) for intelligent task scheduling in AI-driven educational multi-cloud environments. The contribution of this research is a QoS-aware task classification model that categorizes educational workloads into latency-critical, throughput-intensive, deadline-soft, and batch-deferred classes, enabling context-aware scheduling decisions.

A QoS-AMSO algorithm enhances the standard MSO through adaptive refraction-based step sizing to improve convergence behavior in complex search spaces. A dynamic QoS feedback mechanism that adjusts objective weights in real time based on SLA violations, enabling responsive and adaptive scheduling. The model integrates a Lévy flight-based perturbation strategy to maintain population diversity and prevent premature convergence. A Pareto-based elite archive mechanism for effective multi-objective optimization, ensuring balanced trade-offs among competing QoS metrics.

model and formulates the multi-objective optimization problem; Section IV describes the proposed QoS-AMSO framework; Section V discusses the experimental setup and evaluation, and Section VI concludes the study with future research.

II. Related Works

A. Cloud Task Scheduling Approaches

Rajput et al. [4] proposed a QoS-aware heuristic-based multi-cloud workflow scheduler for Spark tasks, achieving a 50% performance improvement, but it degrades under volatile conditions. Mangalampalli et al. [5] introduced ATS-IA3C, an A3C-based adaptive scheduler that improves makespan by 70.49% and cost by 77.42%, though it has high computational complexity. Mangalampalli et al. [6] proposed MOPTSA3C, which incorporates task and VM priorities into A3C, improving makespan and utilization but adding overhead due to priority computation. Kumar et al. [7] developed EAEFA based on electric fish swarm behavior, achieving over 30% makespan improvement in large-scale scenarios. Sandhu et al. [8] introduced TBW optimization combining Tabu Search, Bayesian classification, and WOA, achieving 95% efficiency but increasing computational complexity.

Acharya et al. [9] developed a Golden Search WOA (GSWOA) and attained 132s Makespan, 2.7s response time, and 74.34% RU. However, the GSWOA model has higher memory usage. Bansal et al. [10] presented a Hybrid PSO-Grasshopper Optimization Algorithm (HPSO-GOA) and attained 1636.44 total execution cost and 167.54J EC. Yet, the model is sensitive to initial population characteristics. Nagalakshmi et al. [11] presented an Energy-Aware TS using Orthogonal Learning PSO (MOEATS-OLPSO) and attained 180$ cost, 0.6J for energy consumption, and 37s time. Yet, the model lacked failure-handling mechanisms. Sanaj et al. [12] presented an EcoTaskOpt model that integrated Ant Colony Optimization (ACO) and the PSO algorithm. The model reduced makespan by 18%. Yet, the model's performance is affected by varying task lengths and heterogeneous systems.

B. QoS-Aware Scheduling Techniques

Tabary et al. [13] proposed SMPIA-GA-PSO, integrating GA and PSO with message passing to improve resource utilization, though it requires complex tuning. Long et al. [14] developed IVPTS, combining PSO with fuzzy logic to reduce makespan by 13%, but with higher computational cost. Tamilarasu et al. [15] introduced ICOATS using Coati Optimization to improve makespan and utilization. Sha et al. [16] proposed SPP-TLBO for deadline-aware service placement, improving efficiency by 8–19%. Xu et al. [17] introduced EAT for AIGC task scheduling across edge servers, reducing latency by up to 56%, but with high complexity and overhead.

C. AI Workloads in Cloud Environment

Sharma et al. [18] proposed ICO for AI-driven orchestration, improving scalability but with high implementation complexity. Adeyinka [19] developed LSTM-RL-DT for workload forecasting and dynamic allocation, reducing cost by 25% but struggling with rapid changes. Bauskar [20] introduced an AI-driven multi-cloud database optimization framework, facing consistency challenges across heterogeneous systems. Jorepalli et al. [21] proposed a cloud-native resilient AI architecture for smart education, offering scalability and fault tolerance but with complex deployment.

D. Research Gap Summary

Existing extensions of metaheuristic algorithms often fail to incorporate real-time feedback mechanisms and workload-specific prioritization, limiting their effectiveness in practical deployment scenarios. Table I illustrates the research gap summary.

TABLE I. Research Gap Summary

Method	Models	Strengths	Research Gaps
Classical Scheduling	RR, FCFS	Simple and fast execution	Poor performance in heterogeneous environments
Heuristic-Based	Min-Min, Max-Min	Efficient makespan reduction	Ignores multi-objective, poor adaptability
Swarm Intelligence	PSO	Strong global search capability	Premature convergence, lacks QoS integration
Nature-Inspired Metaheuristics	GWO, WOA	Balanced exploration and exploitation	Static parameters, no dynamic QoS adaptation
Physics-Based Optimization	MSO	Effective exploration–exploitation balance	Single-objective design, lacks Pareto optimization

Existing studies focus on improving individual QoS metrics such as makespan, execution cost, energy efficiency, or load balancing in isolation. Many optimization algorithms employ fixed search strategies and static objective weighting, limiting their adaptability to heterogeneous educational workloads with dynamically changing QoS requirements. Recent AI-based scheduling methods do not incorporate workload-aware task classification with runtime QoS adaptation and Pareto-based multi-objective decision-making. A research gap remains in developing an adaptive scheduling framework capable of simultaneously balancing multiple conflicting QoS objectives while responding to dynamic workload characteristics.

III. System Model and Problem Formulation

The QoS-AMSO framework models task scheduling in AI-driven educational multi-cloud environments as a QoS-constrained, multi-objective optimization problem, and heterogeneous workloads are dynamically mapped to distribute VMs across multiple cloud providers. Each task is represented by a feature vector including computational length, deadline, priority, data size, and execution requirements, and is classified into latency-critical, throughput-intensive, deadline-soft, or batch-deferred categories to enable context-aware scheduling. A centralized scheduler acts as a cloud broker, maintains global knowledge of tasks and resources to determine an optimal task-to-VM mapping that satisfies QoS constraints. The QoS-AMSO algorithm iteratively explores the solution space using adaptive mechanisms such as dynamic step sizing, QoS-driven weight adjustment, and diversity preservation [22]. Solutions are evaluated using a Pareto-based multi-objective framework, and a QoS feedback loop continuously monitors and adjusts performance during execution. The Pareto-optimal scheduling

plan deployed in the multi-cloud environment ensures adaptive and scalable scheduling under dynamic conditions [23].

A. Task and Resource Model

The system model represents the overall structure of the AI-driven educational multi-cloud environments and defines the interaction between tasks and resources during the scheduling process. Let the system consist of a set of tasks. $sT = \{sT_1, sT_2, sT_3, \dots sT_n\}$, a set of VMs distributed across multiple cloud providers $VM = \{vm_1, vm_2, vm_3, \dots, vm_m\}$, a set of cloud providers is given as $CP = \{cp_1, cp_2, \dots cp_1\}$ and each VM belongs to a cloud is defined as $vm_j \in c_k$. The task scheduling (mapping) function assigns each task (sT_i) to a vm_j and it is defined as $\sigma: sT \rightarrow VM$. The goal is to find an optimal mapping (σ) that decreases execution time, cost, SLA violations, and balances system load. Each task (sT_i) is defined as a multi-parameter entity, which includes $sT_i = (tL_i, d_i, p_i, m_i, c_i)$. Here, tL_i defines the task length, d_i defines the deadline, p_i defines the priority level, m_i defines the memory requirement, and c_i defines the task class. In the task classification role, based on parameters, a low deadline indicates latency-critical, a high data size indicates throughput-intensive, and a flexible deadline indicates the batch that influences the initial VM assignment and QoS weight importance. Each VM is defined as $vm_j = (MIPS_j, BW_j, RAM_j, cost_j)$. Here, $MIPS_j$ indicates processing speed, BW_j indicates bandwidth, RAM_j memory capacity and $cost_j$ indicates cost per unit execution time. The system model formulates the process as a mapping between heterogeneous educational workloads and distributed multi-cloud resources [24].

B. QoS Metrics

The proposed framework optimizes the scheduling process using these QoS metrics in a balanced manner. The Makespan represents the total completion time of all scheduled tasks, indicating the overall execution efficiency of the system. It is defined as the maximum finishing time among all VMs $\left(FT_{vm_j}\right)$ and it is defined as:

$$Mks = \max_{vm_j \in VM} \left(FT_{vm_j}\right) \quad (1)$$

Execution cost measures the total monetary expense incurred for executing all tasks across multiple cloud resources, and it is calculated as:

$$cost = \sum_{i=1}^{n} cost_j \times ET\left(t_i, vm_j\right) \quad (2)$$

Here, $cost_j$ indicates the cost per unit time of the VM, and $ET\left(t_i, vm_j\right)$ indicates the execution time of the task on the VM. The SLA violation rate quantifies the degree to which tasks fail to meet their deadlines, reflecting system reliability and service quality, and it is defined as:

$$SLA = \frac{|\{sT_i \mid CT_i > d_i\}|}{n} \quad (3)$$

Here, CT_i indicates the completion time of tasks, and n indicates the total number of tasks. Load imbalance measures the degree of uneven workload distribution across VMs, and it is given as:

$$LI = \frac{\max(Util_j) - \min(Util_j)}{\text{mean}(Util_j)} \quad (4)$$

Here, $Util_j$ indicates the utilization of the VM. Resource utilization reflects the efficiency of resource usage in the multi-cloud environment, and it is defined as:

$$RU = \frac{\sum_{j=1}^{m} used\ MIPS_j}{\sum_{j=1}^{m} Total\ MIPS_j} \quad (5)$$

Here, $used\ MIPS_j$ indicates computational capacity actively utilized, and $total\ MIPS_j$ indicates total available computational capacity.

C. Multi-Objective Optimization Problem

Given the heterogeneous educational workloads and the conflicting QoS requirements, the task scheduling problem is formulated as a multi-objective optimization problem, in which multiple performance metrics are optimized under system constraints [25], [26]. Let σ denote a candidate scheduling solution (mapping of tasks to VMs). In the task assignment constraint, each task is assigned to exactly one VM, and it is given as $\sum_{j=1}^{m} x_{ij} = 1, \forall sT_i \in T$. Here, $x_{ij} = 1$ if task is assigned to VM. The total resource demand must not exceed VM capacity, and it is represented as $\sum_{sT_i \in VM_j} \leq RAM_j$. In the deadline constraint, tasks should ideally complete within their deadline, and it is given as $CT_i < d_i, \forall sT_i \in T$. In the execution feasibility constraint, only feasible mappings are allowed, and it is represented as $ET\left(sT_i, vm_j\right) > 0$, and this ensures valid execution based on VM capability. The multiple objectives are optimized simultaneously, and this solution is defined in terms of Pareto optimality. A solution(σ_1) is said to dominate another solution(σ_2) and it is given as $\forall k: f_k(\sigma_1) \leq f_k(\sigma_2)$ and $\exists k: f_k(\sigma_1) < f_k(\sigma_2)$. The set of all non-dominated solutions is called the Pareto optimal set, and it is given as $p^* = \{\sigma \mid \nexists \sigma'\ such\ that\ \sigma' \prec \sigma\}$. From the Pareto set, a final solution is selected using a decision-making method, and it is given as $\sigma^* = \arg\min_{\sigma \in p^*} F_w(\sigma)$. This process ensures balanced QoS performance and context-aware scheduling.

IV. Proposed QoS-AMSO Framework

The proposed QoS-AMSO framework is a layered, end-to-end scheduling architecture that transforms AI-driven educational workloads into optimized task–resource mappings in a multi-cloud environment. It consists of five layers: workload ingestion and pre-processing, QoS-aware task classification, multi-cloud resource abstraction, QoS-AMSO optimization engine, and decision execution and monitoring. The workload ingestion layer collects heterogeneous tasks and extracts attributes such as computational size, deadline sensitivity, data volume, and priority, and converts them into a structured format. The QoS-aware classification layer categorizes tasks into latency-critical, throughput-intensive, deadline-soft, and batch-deferred classes that derive indicators. The resource abstraction layer models distributed cloud infrastructure by representing heterogeneous VMs with varying processing capabilities, costs, and dynamic states such as load and availability [27]. The QoS-AMSO optimization engine performs scheduling by initializing solutions using class-aware heuristics and iteratively refines through adaptive step sizing,

QoS-driven weight adjustment, and Lévy flight-based exploration. The execution and monitoring layer selects the optimal solution from the Pareto set, assigns tasks to VMs across cloud providers, and continuously monitors execution performance.

A. Overview of Mirage Search Optimization

Mirage Search Optimization (MSO) is a physics-inspired metaheuristic algorithm based on the optical phenomenon of mirage formation. The MSO mimics two phenomena, including superior mirage (global exploration) and inferior mirage (local exploitation). Each candidate solution is treated as an observation point (individual) in a multi-dimensional search space. Each solution is randomly initialized within bounds, and it is formulated as

$$x_u = lb_u + r.(ub_u - lb_u) \quad (6)$$

Here, ub_u, lb_u indicates lower and upper bounds, and $r \in [0,1]$ indicates a random number. This process ensures a diverse initial population. Superior mirage allows observing distant objects, modeled as a long-range search capability. The position update (x_{uv}^{t+1}) is formulated as:

$$x_{uv}^{t+1} = x_{uv}^{t} + \Delta x_{lower} \quad (7)$$

The inferior mirage phenomenon occurs due to refraction of light, and it is modelled to perform localized search around promising solutions, focusing on refining (fine-tuning) solutions near the global best. The distance and direction are modeled when the current solution is not the best, and it is formulated as

$$h_{uv} = \left|gbest_j - x_{uv}\right|.rand, D = \frac{(gbest_j - x_{uv}).rand}{h_{uv}} \quad (8)$$

The inferior mirage uses optical refraction principles to control movement direction. The angle (γ) gamma, angle (φ) and refraction angle ω (omega), and this process is formulated as

$$\gamma = \frac{\pi(t_{max} - t)}{2t_{max}}.rand \quad (9)$$

$$\emptyset = \left(\arctan\left(\frac{1}{2\tan\gamma}\right) - \arctan\left(\frac{\sin\gamma\cos\gamma}{1+\sin^2\gamma}\right)\right).rand + \arctan\left(\frac{\sin\gamma\cos\gamma}{1+\sin^2\gamma}\right) \quad (10)$$

$$\omega = \arcsin\left(\frac{n_2}{n_1}\sin(\emptyset + \gamma)\right) \quad (11)$$

The displacement calculation uses all geometric relations; the movement step is derived as:

$$\Delta x_{upper} = \frac{h}{\tan\gamma}\left(\frac{h}{\sin\gamma} - \frac{h\sin\emptyset}{\cos(\emptyset+\gamma)}\right).\frac{\cos\omega}{\cos(\omega-\gamma)} \quad (12)$$

This equation combines distance (h), angle $(\gamma, \varphi, \omega)$ and refraction behaviour. The final update rule is formulated as:

$$x_{uv}^{t+1} = x_{uv}^{t} + D.\Delta x_{upper} \quad (13)$$

The MSO employs a physics-driven search paradigm that combines superior mirage-based long-range exploration with inferior mirage-based fine-grained exploitation, allowing the algorithm to dynamically adapt its search behavior and improve solution quality.

B. Limitations of Standard MSO

MSO demonstrates effective exploration and exploitation through its reflection and refraction mechanisms; it exhibits several limitations when applied to QoS-driven task scheduling in multi-cloud environments. MSO is designed as a single-objective optimization algorithm, which restricts its ability to simultaneously handle multiple conflicting QoS metrics such as makespan, cost, SLA violation, and load balancing. The algorithm lacks QoS awareness, as it does not incorporate task-specific requirements such as deadlines, priorities, or workload characteristics, leading to suboptimal scheduling decisions in heterogeneous environments. MSO does not include a structured mechanism for maintaining multiple optimal solutions, limiting its capability to achieve Pareto-optimal trade-offs. To address these limitations, there is a need for an enhanced optimization framework that integrates multi-objective optimization, QoS awareness, adaptive parameter control, and task-specific intelligence.

C. Proposed QoS-AMSO Algorithm

1) Adaptive step sizing: In the standard MSO, the movement of individuals during both superior and inferior mirages is governed by fixed geometric step formulations. These formulations lack dynamic control over step magnitude. To overcome this limitation, the QoS-AMSO introduces an adaptive step sizing mechanism, which dynamically adjusts the movement step of individuals across iterations. Educational cloud workloads exhibit varying search characteristics during different optimization stages. Large search steps are beneficial during the early iterations to explore diverse scheduling solutions, and smaller steps are required in later iterations to refine promising task-to-resource mappings. A fixed movement strategy in the standard MSO cannot effectively accommodate this transition, leading to slow convergence and premature stagnation. The adaptive step size is introduced as a scaling factor $\alpha(t)$ and it is defined as:

$$\alpha(t) = \alpha_{max} - \left(\frac{t}{t_{max}}\right)(\alpha_{max} - \alpha_{min}) \quad (14)$$

Here, t indicates the current iteration, t_{max} indicates the maximum iterations, α_{max} indicates the initial large step size, and α_{min} indicates a small step size. The adaptive step size process is embedded into the MSO movement equations. The original MSO position update from Eq. (11) is modified with an adaptive step and formulated as:

$$x_{uv}^{t+1} = x_{uv}^{t} + \alpha(t) + \Delta x_{lower}, x_{uv}^{t+1}, \; = x_{uv}^{t} + \alpha(t).D.\Delta x_{upper} \quad (15)$$

This process scales step size dynamically with large jumps and controlled movement. The adaptive step sizing controls search intensity dynamically, improves convergence speed, enhances solution stability, and supports multi-objective balancing.

2) QoS feedback mechanism: The QoS feedback mechanism introduces a feedback-driven weighting mechanism that monitors QoS metrics, adjusts their importance dynamically, and guides the search toward better

solutions. The weighted fitness function is formulated as $F(\sigma) = \sum_{k=1}^{4} w_k(t).f_k(\sigma)$. Here, $w_k(t) = 1$ indicates the dynamic weight of k^{th} QoS metric. Static objective weights cannot effectively respond to runtime variations, causing optimization to focus on outdated scheduling priorities. Therefore, a QoS feedback mechanism is introduced in which weights are updated based on QoS deviation. For SLA violations, the SLA-specific feedback and it is formulated as:

$$w_{SLA}(t+1) = w_{SLA}(t) + \eta.SLA(t) \quad (16)$$

Here, η indicates the learning rate. This algorithm focuses on prioritizing deadlines. During fitness evaluation, this process can be integrated as:

$$F(\sigma, t) = \sum w_k(t)\,.\,f_k(\sigma) \quad (17)$$

The QoS feedback mechanism enhances the MSO framework by dynamically adjusting the importance of multiple QoS objectives based on real-time system performance.

3) Lévy flight strategy: Metaheuristic optimization algorithms suffer from premature convergence when candidate solutions become concentrated around local optima, with numerous feasible task-resource mappings. The proposed QoS-AMSO incorporates a Lévy Flight Strategy, which introduces random long-distance perturbations into the search process. The step size of the Lévy flight is defined as $L\sim levy\ (\beta)$, here $\beta \in (1,3)$ indicates the Lévy distribution parameter. Here, λ indicates the scaling factor, and $gbest$ indicates the global best solution. The Lévy flight is integrated with superior mirage and inferior mirage, and it is formulated as:

$$x^{t+1} = x^t + \alpha(t).\Delta x_{lower} + \lambda.L \quad (18)$$

$$x^{t+1} = x^t + \alpha(t).D.\Delta x_{lower} + \lambda.L.(x^t - gbest) \quad (19)$$

The QoS-AMSO Optimization Engine, Lévy flight enhances search diversity, prevents premature convergence, improves global optimality, and supports multi-objective exploration.

4) Pareto archive mechanism: Cloud task scheduling simultaneously optimizes multiple conflicting QoS objectives, including makespan, execution cost, SLA satisfaction, and load balancing. The proposed QoS-AMSO introduces a Pareto Archive Mechanism, which maintains a set of non-dominated solutions throughout the optimization process. A solution $(\sigma_a) \leq f_k(\sigma_b)$ and $\exists k: f_k(\sigma_a) < f_k(\sigma_b)$. At iteration $t = 0$, the archive is initialized as $\mathcal{A}(0) = \{\sigma_i\}$ is non-dominated in the population. The archive is updated as $\mathcal{A}' = \mathcal{A}(t) \cup \{\sigma_1^{t+1}, \sigma_2^{t+1}, \dots, \sigma_n^{t+1}\}$. The non-dominated sorting and it is formulated as $\mathcal{A}(t+1) = \{\sigma \in \mathcal{A}' | \nexists \sigma' \in \mathcal{A}' : \sigma' \prec \sigma\}$. To avoid excessive archive growth, a maximum size $(\mathcal{A}_{max})$ is defined as $|\mathcal{A}(t+1)| > \mathcal{A}_{max}$. The MSO update equations for superior and inferior mirage are defined as:

$$x^{t+1} = x^t + \alpha(t).D.\Delta x(\sigma_{archive}) \quad (20)$$

Here, $\sigma_{archive}$ indicates solutions selected from the Pareto set. The Pareto Archive Mechanism enhances the QoS-AMSO framework by maintaining a set of non-dominated solutions that capture optimal trade-offs among multiple QoS objectives.

D. Task Classification Model

1) Workload categories for AI-educational systems: The proposed QoS-AMSO framework classifies tasks into four distinct workload categories: latency-critical (LC), throughput-Intensive (TI), deadline-Soft (DS), and batch-deferred (BD). Each task sT_i is represented as a multi-dimensional feature vector that includes task length (tL_i), deadline (d_i), priority level (pL_i), memory requirement (m_i) and data size (ds_i). For latency-critical workloads, tasks require immediate response and strict deadline adherence. For example, LLM-based real-time Q&A systems live virtual laboratories and interactive tutoring sessions. The mathematical condition is formulated as $C_i = LC$, if $DTR_i < \theta_1$ and $p_i = high$. For throughput-intensive tasks, the mathematical condition is formulated as $C_i = TI$, if $ds_i < \theta_2$ and $tL_i =\gg 0$. In deadline-soft workloads, tasks with moderate deadlines have slight delays; the mathematical condition is formulated as $C_i = DS$, if $\theta_1 < DTR_i \leq \theta_3$. In batch-deferred workloads, the mathematical condition is formulated as $C_i = BD$, if $DTR_i > \theta_3$. This classification enables task-aware scheduling decisions, priority-based VM allocation, and QoS-driven optimization guidance. By guiding population initialization and dynamic QoS weight adaptation, task classification improves the quality of initial solutions and enhances the final scheduling performance.

2) Feature vector and classification: The proposed QoS-AMSO framework introduces a feature vector-based representation, followed by a classification mechanism that assigns each task to a QoS-aware category. This transformation enables the scheduler to incorporate task-level intelligence into the optimization process $F_i = [tL_i, d_i, pL_i, m_i, ds_i, DTR_i]$. In the task classification model using the feature vector, each task is assigned to a class, and it is formulated as $C_i = f(F_i)$. The classification output (C_i) is integrated into the optimization process at multiple levels. The fitness function enhancement is formulated as:

$$F(\sigma) = \sum_{i=1}^{n} W_{class}(C_i).f_i(\sigma) \quad (21)$$

The feature vector and classification enable context-aware decision-making, priority-based scheduling, efficient resource mapping, and improved SLA satisfaction.

3) Impact on AMSO initialization and weight setting: The proposed framework leverages task class information to guide the initial population generation and dynamically adjust QoS priorities during optimization. In the proposed class-Guided initialization, each task sT_i is assigned to a VM based on its class C_i and it is formulated as $\sigma_i^{(0)} = \arg\max_{vm_j \in VM} S(C_i, vm_j)$. Here, $\sigma_i^{(0)}$ indicates the initial mapping of tasks, $S(C_i, vm_j)$ indicates the suitability score. In the dynamic QoS weight

adjustment, the weights evolve using optimization, and it is given as:

$$w_k(t+1) = w_k(t) + \eta.\Delta_k(t) \quad (22)$$

$$\Delta_k(t) = \frac{f_k(t) - f_k^{target}}{f_k^{target}} \quad (23)$$

The task classification into AMSO initialization and weight setting enhances the optimization process by guiding initial solution generation and dynamically adapting QoS priorities based on workload characteristics. Algorithm 1 presents the complete algorithmic workflow of the proposed QoS-AMSO framework, which integrates task classification, adaptive optimization, and multi-objective decision-making into a unified scheduling process.

Algorithm 1: QoS-AMSO for Multi-Cloud Scheduling

Step 1: Workload Pre-processing and Feature Extraction
- Collect incoming tasks from AI-based educational applications.
- Extract task parameters and normalize features to ensure balanced representation.

Step 2: Task Classification
- Compute derived indicators and classify each task.

Step 3: Initialize Population (Class-Aware Initialization)
- Generate initial candidate scheduling solutions.
- Assign tasks to VMs based on task class.
  - High-performance resources for latency-critical tasks
  - Parallel resources for throughput-intensive tasks
  - Balanced resources for deadline-soft tasks
  - Low-cost resources for batch tasks

Step 4: Update Candidate Solutions (MSO Search)
- For each solution in the population:
  - Apply superior and inferior mirage strategies for exploration and exploitation.
  - Adjust movement using adaptive step sizing.
  - Modify search behavior based on iteration progress.
  - Introduce Lévy Flight Perturbation to selected solutions.
  - Combine current solutions with archive and perform non-dominated sorting.
  - Select final scheduling solution based on QoS preference.

Step 5: Task Execution and Monitoring
- Deploy selected scheduling plan.
- Assign tasks to respective VMs and monitor execution performance.

End

4) Computational complexity: The computational complexity of the proposed QoS-AMSO framework is analyzed to evaluate its scalability and efficiency in handling large-scale, heterogeneous multi-cloud scheduling problems. Let n indicate the number of tasks, M indicate the number, vm indicate the number of VMs, P indicate the population size, t indicate the number of iterations, and K indicate the number of QoS objectives. In task classification complexity, the complexity is defined as $O(n)$. For each iteration, all candidate solutions are updated, and it is formulated as $O(t.P.n)$. Each solution is evaluated across all QoS objectives, and it is given as $\left(O(t.P.n.K)\right)$. In the Pareto archive update, Non-dominated sorting is performed over the population and archive, and it is defined $\left(O(T.P^2)\right)$. The overall complexity is defined as:

$$TC = O(n) + O(P.n) + O(T.P.n) + O(T.P^2) \quad (24)$$

The proposed QoS-AMSO framework is computationally efficient due to linear scalability with task size, controlled population size limiting quadratic overhead.

V. Experimental Results and Discussion

A. Simulation Environment

To evaluate the effectiveness of the proposed QoS-AMSO framework, a simulation environment is replicated to replicate realistic multi-cloud conditions for educational workloads. Synthetic MOOC-based workload patterns are artificially generated workloads that mimic real MOOC platforms to simulate diverse educational task behaviors [25]. The synthetic workload is generated by modelling common educational activities observed in AI-enabled learning platforms, including video streaming sessions, online quizzes, assignment submissions, real-time tutoring requests, and learning analytics jobs. Task arrival times are generated using variable arrival rates to simulate normal and peak learning periods; computational demand, data size, and deadline constraints are assigned according to the characteristics of each educational activity.

A real-world workload dataset derived from Google cluster logs, modified to reflect educational task characteristics, was filtered based on computational intensity and execution duration. The original trace attributes, including CPU utilization, memory usage, task execution time, and arrival patterns, were retained, and application labels were mapped to representative educational workload categories. Interactive services are modelled as latency-critical tasks, large-scale assessment and analytics jobs as throughput-intensive tasks, routine learning activities as deadline-soft tasks, and background reporting processes as batch-deferred tasks. Table II illustrates the environmental settings.

TABLE II. Environmental Settings

Category	Parameter	Value
Simulation Tool	Platform	CloudSim 3.0
Cloud Infrastructure	Number of Cloud Providers	3
	Total Virtual Machines	60
	VM Distribution	20 per provider
VM Configuration	MIPS Levels	1000, 2000, 3000
	RAM	8 GB
	Bandwidth	100–1000 Mbps
	Storage	10–100 GB
Network Settings	Latency Range	5 ms – 80 ms
Workload	Task Count	100 – 1000 tasks
	Data Size	10 MB – 5 GB
	Priority Levels	Low, Medium, High
Optimization Parameters	Population Size (P)	50
	Max Iterations (T)	100
	Lévy Flight Parameter	1.5
	Archive Size	50 – 100 solutions

B. Workload Description

The workloads are structured to reflect realistic operational settings, ranging from small-scale deployments to large-scale distributed systems with dynamic load variations. The three workload scenarios are defined as small-scale (S1), medium-scale (S2), and large-scale dynamic environment (S3). Table III illustrates the workload scenario configuration.

TABLE III. WORKLOAD SCENARIOS CONFIGURATION

Scenario	Number of Tasks	Number of VMs	Scale	Workload Behavior	Special Condition
S1	100	20	Small-scale	Stable	No burst
S2	500	40	Medium-scale	Moderately dynamic	No burst
S3	1000	60	Large-scale	Highly dynamic	Burst injection at 50% time

C. Baseline Methods

To validate the effectiveness of the proposed QoS-AMSO framework, its performance is compared against a diverse set of baseline algorithms representing classical scheduling strategies and state-of-the-art metaheuristic optimization methods. The methods include Round Robin (RR), Min-Min, PSO, Grey Wolf Optimizer (GWO), Whale Optimization Algorithm (WOA), and Vanilla MSO. The RR algorithm is selected as a classical baseline due to its simple cyclic task assignment, highlighting the limitations of non-QoS-aware scheduling. The Min-Min algorithm is included as a heuristic that prioritizes tasks with minimum completion time. The PSO is chosen for its strong global search capability and popularity in scheduling problems. The MSO is used to evaluate the improvements achieved through adaptive step sizing, QoS feedback mechanisms, Lévy flight integration, and Pareto-based optimization.

D. Performance Metrics

To comprehensively evaluate the effectiveness of the QoS-AMSO framework, a set of performance metrics is selected. The metrics include Makespan (s), Total Cost (USD), SLA Violation Rate (%), Load Imbalance Index (LII), Resource Utilization (RU) (%), and Convergence speed.

E. Parameter Settings

The performance of the QoS-AMSO algorithm has hyperparameters that control the search behavior and convergence speed. Table IV illustrates the parameter settings.

TABLE IV. PARAMETER SETTINGS

Parameter	Standard value	Optimized value
Population Size (P)	20–30	50
Max Iterations (T)	100–150	100
Lévy Exponent (λ)	1.0–1.2	1.5
Archive Size	10–20	30
Initial Step Size (α_0)	0.5–0.7	0.9
Feedback Gain (γ)	0.01–0.03	0.05
Perturbation Interval	5–8	10

The optimization parameters are selected through preliminary sensitivity analysis by evaluating different parameter combinations under the medium-scale workload scenario (S2). Population size and maximum iteration count are chosen to provide a balance between convergence quality and computational overhead, and the Lévy exponent was selected to maintain sufficient search diversity without introducing excessive random exploration. The archive size and feedback gain are determined to ensure stable Pareto solution maintenance and responsive QoS adaptation throughout the optimization process.

F. Performance Comparison

This section presents the comparative performance analysis of the proposed QoS-AMSO framework against baseline algorithms is illustrated in Table V.

TABLE V. PERFORMANCE COMPARISON WITH BASELINE MODELS

Models	Makespan (s)	Total cost (USD)	SLA (%)	LII	RU (%)
RR	1285	512.4	12.8	0.42	68.3
Min-Min	1042	468.7	9.6	0.35	74.1
PSO	921	552.3	7.8	0.29	79.6
GWO	887	331.5	6.9	0.26	82.4
WOA	865	425.2	6.3	0.24	91.1
MSO	842	418.6	5.7	0.22	86.5
QoS-AMSO	798	292.8	3.9	0.18	97.2

The performance comparison results demonstrate that the proposed QoS-AMSO framework outperforms classical, heuristic, and metaheuristic baseline algorithms. The model attained a 798s makespan and 97.2% RU with reduced cost. The consistent performance improvement of QoS-AMSO over the baseline methods is attributed to the integration of its components. Task classification enables workload-aware resource allocation, adaptive step sizing balances global exploration and local exploitation for faster convergence, QoS feedback dynamically adjusts scheduling decisions according to runtime conditions, Lévy flight improves global search capability by avoiding local optima, and the Pareto archive preserves high-quality multi-objective solutions. The conventional scheduling algorithms optimize limited objectives; the coordinated operation of these mechanisms enables QoS-AMSO to achieve lower makespan and execution cost, fewer SLA violations, improved load balancing, and higher resource utilization across diverse educational workload scenarios.

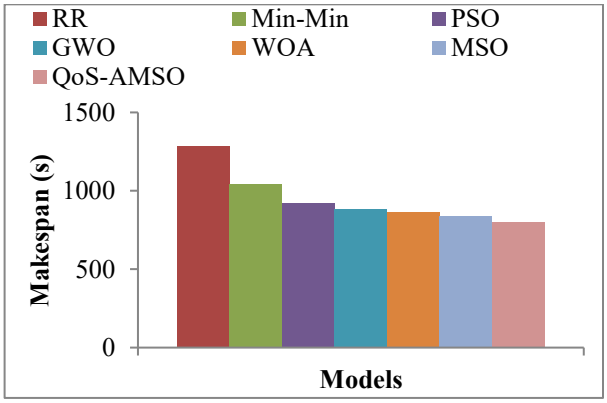

Fig. 1. Makespan graph comparison.

Fig. 1 illustrates a makespan graph comparison. The model attained a makespan of 798s, which is decreased by 5.22% to 37.89% compared to the RR, Min-Min, PSO, GWO, WOA, and MSO models. The QoS-AMSO dynamically adjusts its search process through adaptive step sizing, which enables control over exploration and exploitation during stages of optimization.

Fig. 2 illustrates the total cost graph comparison. The model attained a total cost of 292.8USD that is decreased by 10.04% to 41.08% compared to the RR, Min-Min, PSO, GWO, WOA, and MSO models. The QoS feedback mechanism allows the algorithm to adapt to runtime performance deviations.

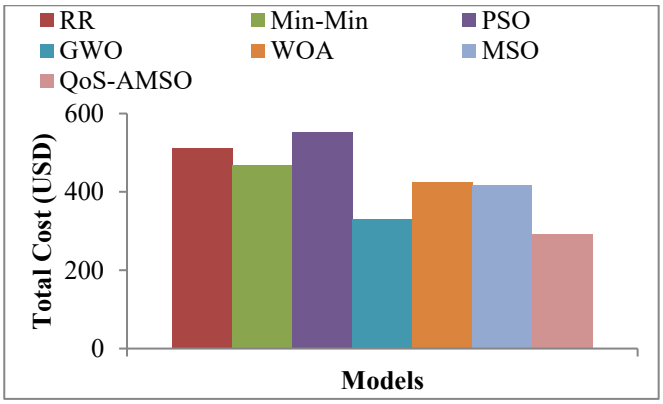

Fig. 2. Total cost graph comparison.

Fig. 3 illustrates the SLA violation graph. The model attained an SLA violation of 3.9%, which is decreased by 1.8% and 8.9% compared to the RR, Min-Min, PSO, GWO, WOA, and MSO models. The Lévy flight strategy introduces controlled randomness, enabling the algorithm to escape local optima and explore a solution space.

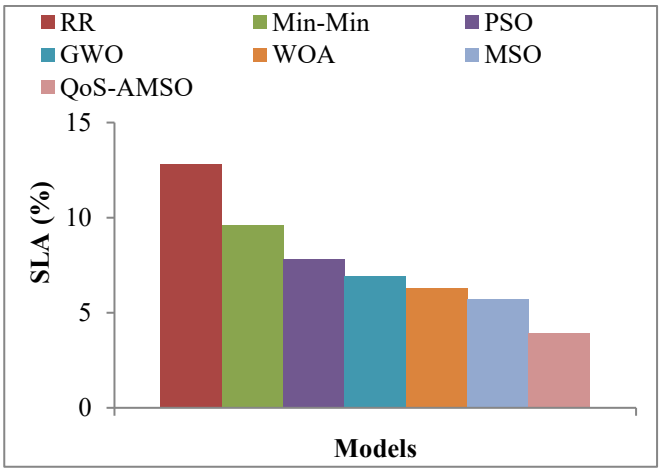

Fig. 3. SLA violation graph comparison.

Fig. 4 illustrates the load imbalance index graph. The model attained an LII of 0.18, which is decreased by 18.18% to 57.14% compared to the RR, Min-Min, PSO, GWO, WOA, and MSO models. The QoS-AMSO converges faster to high-quality solutions while maintaining consistency across different workload scenarios.

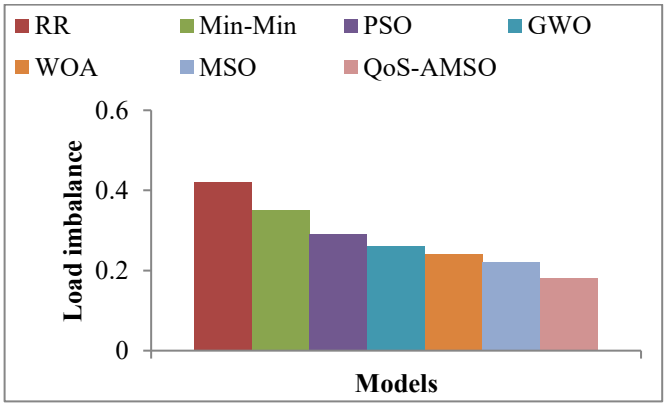

Fig. 4. Load imbalance index graph comparison.

Fig. 5 illustrates the resource utilization graph. The model attained resource utilization of 97.2%, which is increased by 6.1% to 28.9% than the RR, Min-Min, PSO, GWO, WOA, and MSO models. The QoS-AMSO incorporates task classification, enabling the scheduler to differentiate between latency-critical, throughput-intensive, and flexible workloads.

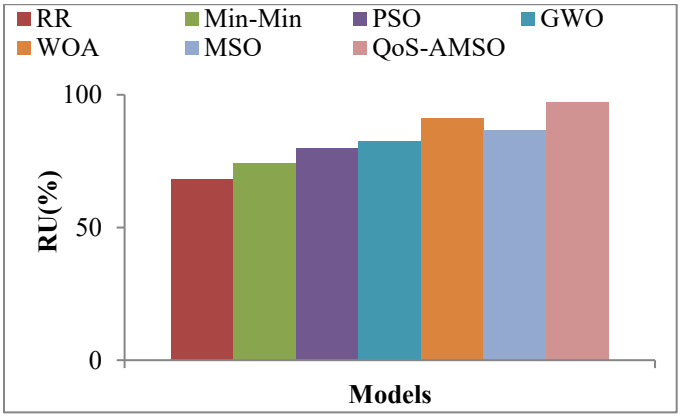

Fig. 5. Resource utilization graph comparison.

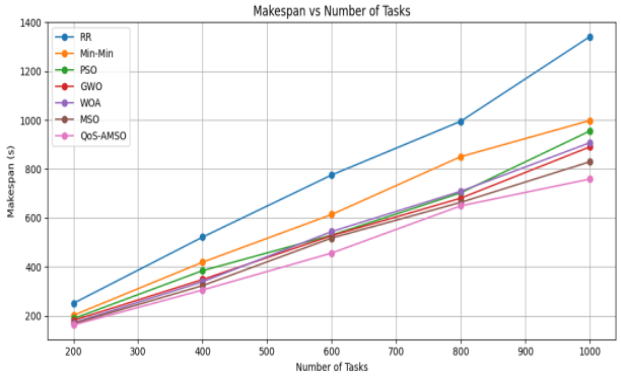
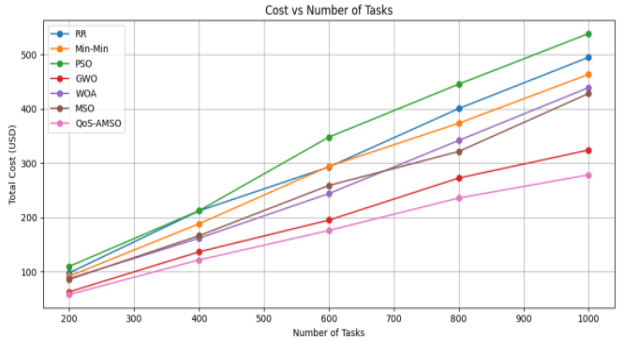
G. Scalability Analysis

The graphs in Fig. 6(a) – 6(b) show that QoS-AMSO maintains superior performance with increasing workload size, demonstrating better scalability compared to baseline methods.



(a)



(b)

Fig. 6. (a) Scalability analysis (makespan), (b) Scalability analysis (cost).

H. Convergence Analysis

Fig. 7 shows the plots that illustrate that QoS-AMSO converges faster and more smoothly to optimal solutions than other algorithms across iterations.

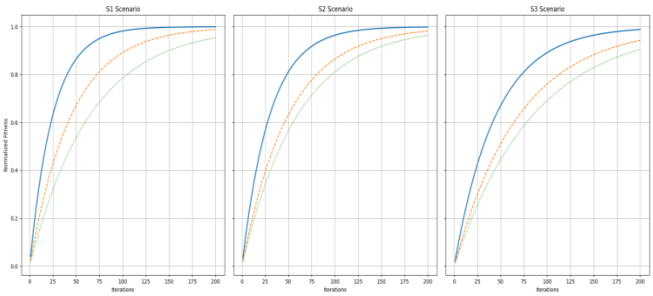


Fig. 7. Convergence analysis.

I. QoS Feedback Mechanism Effectiveness Analysis

This section evaluates how effectively the proposed QoS-AMSO framework adapts to dynamic workload changes using its QoS feedback mechanism under the large-scale scenario (S3) with burst injection. During the experiment, the evolution of the QoS weight vector is tracked across iterations. When a sudden workload spike occurs at 50% of the simulation time, an increase in SLA violations is observed due to resource contention. In response, the feedback mechanism dynamically adjusts the weights by increasing the importance of the SLA component. This reactive adjustment shifts the optimization focus toward meeting deadline constraints, resulting in improved task prioritization for latency-sensitive workloads, a reduction in SLA violations over subsequent iterations, and stabilization of system performance after the burst.

J. Ablation Study

An ablation study is conducted by systematically removing one mechanism, including without Lévy perturbation (LP), adaptive step sizing (AS), QoS feedback weights (QF), and class-aware initialization (CI) modules. Table VI illustrates the ablation study.

When Lévy perturbation is excluded, the makespan increases to 846s, and SLA violations increase to 5.2%, due to the loss of its ability to perform long-distance exploration, leading to localized search behavior. Removing adaptive step sizing degrades performance, with makespan increasing to 872s and cost to 327.9 USD, and fails to balance exploration and exploitation. When the QoS feedback mechanism is removed, makespan increases to 905s, with reduced utilization of 87.2% as the algorithm becomes static and unable to respond to runtime variations. Without class-aware initialization, makespan reaches 931s, and resource utilization drops to 85.6%, due to inefficient initial task-to-resource mappings, leading to poor overall scheduling performance. The complete QoS-AMSO model achieves the best results with a makespan of 798s and resource utilization of 97.2%. The Lévy perturbation, adaptive step sizing, QoS feedback, and class-aware initialization enable balanced exploration and exploitation, and dynamic QoS prioritization.

TABLE VI. ABLATION STUDY

Models	Makespan (s)	Total cost (USD)	SLA (%)	LII	RU (%)
w/o LP	846	318.5	5.2	0.23	91.4
w/o AS	872	327.9	5.8	0.25	89.7
w/o QF	905	341.6	7.1	0.28	87.2
w/o CI	931	356.4	7.9	0.31	85.6
QoS-AMSO	798	292.8	3.9	0.18	97.2

K. Statistical Validation

To ensure that the observed performance improvements of the proposed QoS-AMSO framework are not due to random variations, statistical validation is conducted using the Wilcoxon signed-rank test. Table VII illustrates the Statistical Significance results.

The statistical validation using the Wilcoxon signed-rank test confirms that the performance improvements of the QoS-AMSO framework are statistically significant across all baseline comparisons. The consistently low p-values and large effect sizes demonstrate that the proposed model achieves reliable enhancements in scheduling performance, establishing its robustness and effectiveness for multi-cloud task scheduling.

TABLE VII. STATISTICAL SIGNIFICANCE RESULTS

Comparison	p-value	Effect Size (r)
QoS-AMSO vs RR	0.00012	0.89
QoS-AMSO vs Min-Min	0.00031	0.82
QoS-AMSO vs PSO	0.00105	0.76
QoS-AMSO vs GWO	0.00218	0.71
QoS-AMSO vs WOA	0.00342	0.68
QoS-AMSO vs MSO	0.00487	0.64

L. Discussion

The proposed QoS-AMSO outperforms standard MSO by integrating decision intelligence into the optimization process. While MSO relies on physics-inspired search dynamics, it lacks awareness of workload characteristics and QoS requirements. The QoS-AMSO embeds scheduling context into the optimization loop, enabling the algorithm to focus on meaningful regions of the search space, resulting in stable

convergence and improved solution quality in heterogeneous environments. The Lévy flight mechanism helps maintain population diversity by introducing occasional long jumps, allowing exploration of distant regions and ensuring broader search coverage in complex multi-cloud scenarios. Adaptive step sizing enhances performance by dynamically reducing step size over iterations, enabling fine-grained adjustments near optimal solutions and improving convergence accuracy. In small-scale workloads, the Min-Min algorithm achieves slightly lower cost due to its focus on execution time minimization, but this leads to higher SLA violations and poor load distribution. The QoS-AMSO maintains a balanced multi-objective approach, ensuring system reliability, fairness, and QoS compliance, even if it incurs marginally higher cost in specific cases.

VI. Conclusion and Future Work

The QoS-AMSO framework is developed as a QoS-aware scheduling model for AI-driven educational workloads in multi-cloud environments. The contributions include the integration of task classification, adaptive optimization strategies, QoS feedback mechanisms, Lévy flight-based exploration, and Pareto-based decision-making within a unified architecture. Experimental results demonstrate that the proposed model achieves improved makespan, reduced cost, lower SLA violations, balanced load distribution, and higher resource utilization. Despite its performance, the current framework has certain limitations. The evaluation is conducted in a CloudSim-based simulation environment, which may not fully capture the dynamic behavior, network variability, and resource heterogeneity encountered in real multi-cloud deployments. The framework assumes accurate workload profiling and does not explicitly consider energy efficiency and security policies. Future work will focus on validating the framework in real multi-cloud testbeds, incorporating energy-aware and security-aware scheduling strategies, and integrating edge-cloud environments to improve adaptability for large-scale educational applications.

Funding Statement

This work was supported by the Deanship of Scientific Research, Vice Presidency for Graduate Studies and Scientific Research, King Faisal University, Saudi Arabia [Funding No.KFU263786].

Tahri Mohamed University, Bechar, Algeria

***Abstract*—Legacy Information Systems (LIS) confront significant interoperability challenges, particularly at the database level. If existing solutions focus on data exchange, they fail to address the fundamental structural incompatibilities of Legacy Databases (LDBs). In this article, we present Health Information System as a Service (HISaaS), an innovative dual solution based on AI and Cloud Computing, designed either to update a LIS with a new modern HIS (Health Information System); or to completely propose a new IS. This new HIS is the result of the interoperability of several modern HIS. HISaaS uses Cloud computing as an interoperability environment, Natural Language Processing (NLP), and semantic similarity to analyze and enrich the already existing structure of the LDBs with new tables and/or new attributes from modern and interoperable external databases. This solution uses a vector-based approach relying on contextual embeddings from OpenAI models and cosine similarity measurement to accurately match schema elements. In the end, an evaluation based on real healthcare scenarios demonstrates the effectiveness of this HISaaS solution.**

***Keywords*—Information systems; interoperability; database; cosine measurement; cloud computing; OpenAI; embeddings; NLP**

I. Introduction

The success of large companies such as Alibaba, Google, and Amazon has been achieved through the use of reliable and intelligent information systems. Information systems (IS) play an essential role in any business, enabling it to stay ahead of the competition. The main components of an IS are software, hardware, databases, communications, and human resources. A database is at the heart of an IS; it must be well designed, regularly updated, and secure. Its data is essential for making the right decisions and improving a company's performance.

Interoperability between ISs in the same field has become a crucial requirement for organizations and individuals in order to ensure optimal performance and high-quality service delivery. IS interoperability is the ability of two or more ISs to exchange and use data. [1] defines interoperability as the ability of a computer system to work with other existing computer products or systems, without restrictions on access or implementation. As illustrated in Fig. 1, interoperability operates at several levels:

At the technical level, basic connectivity is established using common protocols and transport mechanisms to ensure secure data flow between different platforms. At the syntactic level, the focus is on ensuring that the exchanged data between systems preserves a consistent structure to facilitate accurate data parsing and processing. Semantic interoperability ensures that the meaning of the exchanged data is preserved and unambiguous among diverse systems by employing shared vocabularies, ontologies, and coding standards. Finally, organizational interoperability enables seamless, cross-institutional collaboration and coordinated use of shared information by aligning governance, policies, and business processes [2].

Despite these structured levels, interoperability challenges persist due to the heterogeneity of information systems. The need to integrate data from multiple disparate systems and collaborate with them, systems that use different communication protocols, data formats, and query languages, leads to the emergence of conflicts at technical, syntactical, and semantic levels. While existing approaches often address these challenges with integration tools and standardized interfaces, a critical issue remains: the lack of focus on database interoperability. Most solutions prioritize data exchange over fundamentally modernizing the legacy database structure itself, leaving core data silos and structural incompatibilities unaddressed.

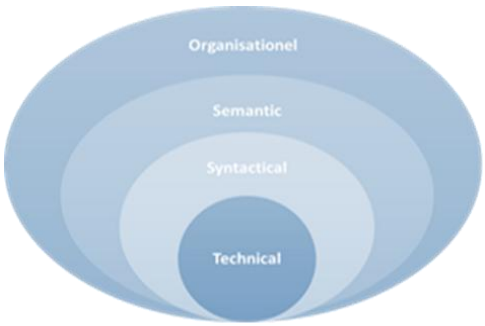

Fig. 1. Levels of interoperability.

Legacy information systems are known to be difficult to integrate with modern platforms due to significant interoperability issues, including the complexity of data migration and integration, dependence on obsolete data formats and structures, and the inability to communicate seamlessly with Cloud Computing services and APIs. To overcome these challenges, this article presents Health Information System as a Service (HISaaS), an innovative solution based on semantic AI

and Cloud Computing. With the scalability and flexibility of Cloud Computing, as well as advanced Natural Language Processing (NLP) techniques and semantic similarity measures, this HISaaS solution goes beyond simple data transfer by actively modernizing the very structure of the legacy database. By strategically adding new tables and/or attributes from external databases, HISaaS enriches and upgrades the existing system, making its data more useful and easily scalable without complete replacement, effectively bridging the gap between the existing infrastructure and the requirements of a modern, interoperable system.

The remainder of the study is organized as follows: Section II explores the context of this research, including Cloud Computing concepts and various techniques for measuring semantic similarity. Section III reviews related work in the field of IS interoperability. The architecture and detailed features of the proposed HISaaS solution are described in Section IV. Finally, Section V presents a comprehensive evaluation through a simulation based on the Cloud environment, detailing the performance of HISaaS in several real-world healthcare scenarios and demonstrating its effectiveness in structurally enriching a database, before concluding and proposing areas for future work in Section VI.

II. Background

This section covers two foundational pillars that our HISaaS solution builds upon. First, we look at Cloud Computing and explain why it serves as the ideal delivery platform for our service. Second, we explore semantic similarity techniques, particularly the vector-based approach using OpenAI embeddings that power the intelligent matching of database schemas across different healthcare systems. Understanding these concepts is essential before diving into how HISaaS actually performs the structural enrichment of legacy databases.

A. Cloud Computing

It is an environment for accessing shared computing resources servers, storage, databases, and software on demand via the Internet, rather than managing them locally. It transforms information systems by offering flexibility, scalability, and reduced infrastructure costs, with service models such as Infrastructure as a Service (IaaS), which offers fundamental compute, storage, and networking resources, Platform as a Service (PaaS), which provides complete development and deployment environment, and Software as a service (SaaS), which delivers fully managed, ready to use applications to end users [3][4] (see Fig. 2).

Fig. 2. Cloud computing basic delivery models.

Cloud Computing has become a pillar of modern information systems, enabling agility and digital innovation by offering agility and scalability through instant increase or reduction of resources according to real needs, mobility as the IS becomes accessible from anywhere and at any time, facilitating teleworking and real-time collaboration, cost optimization via the transition from heavy investment to subscription-based operating costs, and security and maintenance where updates and basic cybersecurity are ensured by the provider, freeing up IT teams for strategic projects [5].

In this work, Cloud Computing serves as the foundational delivery framework for the proposed HISaaS solution. It provides the scalable infrastructure and service-oriented model necessary to aggregate database schemas from multiple providers and offer new IS or database modernization as an on-demand service. Our HISaaS service uses the Cloud environment to provide seamless, secure connectivity to legacy systems and facilitates the structural enrichment of their databases without requiring significant on-premise resources, thereby directly handling interoperability issues.

B. Semantic Similarity

Semantic similarity refers to the degree of similarity between two texts (words, expressions, sentences, or documents) in terms of meaning. It is a key concept in computational linguistics and natural language processing (NLP), whose goal is to calculate the degree of similarity between two texts expressing identical or similar ideas, even if they use different words or structures [6]. Semantic similarity goes beyond simple text matching. It is based on the context or meaning of the text. “Medicine” and “Drug,” although not the same words, are semantically similar.

Semantic similarity methods can be systematically categorized based on the type of knowledge representation and computational strategy [7]. Multiple methods for semantic similarity exist, such as:

- Lexical methods: based on synonym matching (e.g., WordNet) [8].
- Vector-based methods: represent sentences or words as vectors in high-dimensional space (e.g., Word2Vec, Glove, FastText) [9] [10][11]. Here, the similarity is measured using cosine similarity or Euclidean distance.
- Contextual Embeddings: capture context-aware representations of text by using advanced models like BERT[12], GPT[13], or other transformer-based models.
- Knowledge-based Methods: based on hierarchical relationships, these methods measure similarity by using ontologies or semantic networks (e.g., WordNet).

Techniques for measuring similarity can be classified into multiple distinct approaches [14]; each one offers a unique perspective on assessing how closely related two concepts or objects are. The techniques can be categorized as follows:

- Arc-based: use the hierarchical structure of an ontology to assess semantic similarity by measuring the distances

between objects. The principle of this method is that the similarity between two concepts can be measured by the shortest path connecting them via a common ancestor. Wu and Palmer's metric [15] calculates similarity by assessing the distances from each concept to their least common ancestor, thereby providing a quantitative assessment of their semantic proximity.

- Nodes-based: analyses the information content of each concept to assess how similar they are. The main idea here is that two concepts are more similar when they share more information. Resnik's measure[16] is a well-known example. It uses the Information Content (IC) of the most specific concept that includes both concepts to compute their similarity. This approach focuses on the informational connections between concepts rather than just their structural connections within the ontology.
- Hybrid techniques: represent a synthesis of based-arcs and nodes approaches; these methods combine distance measures with information content, allowing for a nuanced assessment that captures both structural and semantic relationships. Jiang and Conrath's measure [17] is an illustrative example, which merges entropy (representing information content) with the distance between concepts. The combination of these approaches aims to enhance the accuracy of similarity evaluations, addressing the limitations found in using either technique in isolation.
- Vector space technique: these techniques are widely adopted in the field of information retrieval. These approaches represent objects as vectors within a multi-dimensional space, using various mathematical methods to calculate similarity. Cosine similarity[18], [19], for example, calculates the cosine of the angle between two vectors, indicating their similarity based on internal content. Additionally, Euclidean distance [20] calculates the straight-line distance between two points in the vector space; often adjusted to improve similarity assessments. The Jaccard index [21] further contributes to this domain by measuring the similarity between finite sample sets, defined as the size of their intersection divided by the size of their union. Each of these vector space techniques has unique strengths, making them applicable in various contexts depending on the nature of the data being analyzed.

Table I illustrates semantic similarity methods, categorizing different approaches for measuring how similar two pieces of text are in meaning. It organizes these methods into families based on their underlying principles and techniques.

Semantic similarity serves as the intelligent core for our proposed HISaaS that enables database enrichment from disparate databases. It is used to power two critical functions: synonym creation and embedding creation to match database schema elements (table names, attributes). Our method employs a vector-based approach to semantic similarity, using contextual embeddings generated by OpenAI's models to represent database schema elements as high-dimensional vectors. The similarity between these elements is then computed using *Cosine Similarity* on their respective vector representations. This approach allows our system to perform sophisticated semantic matching of database elements, identifying that "patient_tbl" and "client_records" are semantically related despite naming conventions, thereby enabling accurate structural enrichment of legacy databases.

TABLE I. SEMANTIC SIMILARITY METHODS

Method Family	Underlying Knowledge Representation	Example Techniques	Representative Models/Measures
Lexical Methods	Lexical databases (WordNet)	Synonym matching, string similarity	Levenshtein, Jaccard, WordNet Synsets
Knowledge-Based Methods	Ontologies / Semantic networks	Path-based, IC-based, Hybrid	Wu–Palmer, Resnik, Jiang–Conrath
Vector-Based Methods	Distributional semantics	Cosine, Euclidean, Jaccard	Word2Vec, GloVe, FastText
Contextual Embeddings	Transformer models	Contextualized embeddings	BERT, GPT, Sentence-BERT
Hybrid Methods	Combined symbolic + statistical	Ontology + embeddings fusion	BERT + WordNet, ConceptNet + Word2Vec

III. RELATED WORKS

This section reviews existing solutions related to information system interoperability and database schema integration. The review is organized around three themes directly relevant to our proposed HISaaS framework: health information system interoperability, cloud-based integration approaches, and AI-driven schema matching and structural enrichment. For each group, we discuss what the prior work contributes and where it falls short specifically regarding the structural modernization of legacy databases, which is the core gap our work addresses.

A. Health Information System Interoperability

A substantial body of work targets semantic interoperability in the healthcare domain through standard terminologies, ontologies, and data exchange protocols. Pellison et al. [22] proposed a semantic Web layer for tuberculosis data exchange in Brazil, using ontologies built on the Basic Formal Ontology (BFO) and SPARQL queries to map entities across heterogeneous Health Information Systems. The approach achieved structured, semantically consistent data exchange but remained tightly coupled to the existing system infrastructure and hard to extend to other diseases. Roehrs et al. [23] presented the OmniPHR model for personal health record interoperability, combining HL7 FHIR, OpenEHR, and NLP-driven automation to construct a unified view of patient data across disparate systems. While the model demonstrated integration potential, its NLP component needed extensive retraining for diverse medical terminologies and lacked real-world validation at scale.

More recent systematic reviews have taken stock of the state of semantic interoperability in EHRs (Electronic Health Records). Palojoki et al. [24] conducted a systematic review of approaches for enhancing semantic interoperability in EHR systems, identifying key elements such as shared terminologies (SNOMED CT, ICD, LOINC), standard models (FHIR,

OpenEHR), and cross-border data exchange mechanisms. Their review confirmed that achieving interoperability without loss of meaning remains unsolved and that most real-world deployments require considerable manual effort. Amar et al. [25] performed a systematic mapping review of 70 FHIR-based studies from 2012 to 2022, classifying semantic approaches into six categories including mapping, ML/NLP, ontology, and terminology services. They found that NLP and machine learning hold promise for unstructured EHR data but that automation of annotation and ontology comparison still needs significant human intervention. Critically, neither of these studies addresses structural enrichment of the legacy database itself; they focus on how data is exchanged, not on how the underlying schema is modernized.

B. Cloud-Based Interoperability Frameworks

Cloud computing has opened new paths for interoperability, particularly around scalability and service-oriented data management. Mohammed Sha and Rahamathulla [26] proposed a cloud-based healthcare data management framework that combines HL7, FHIR, and DICOM formats with a centralized data lake and API integration to streamline cross-system data sharing. The framework produced a scalable cloud system but faced persistent issues with legacy system compatibility, data ownership, and vendor lock-in.

Gohar et al. [27] introduced a five-layered patient-centric framework combining blockchain, cloud storage, and IoT for secure and semantically interoperable data exchange. Using SNOMED-CT, HL7 FHIR, and ICD standards, the framework outperformed existing blockchain-based approaches in security and exchange efficiency. Still, it remained at the prototype stage and lacked large-scale real-world testing.

Sony et al. [28] proposed an Edge Fog-based architecture integrating IoT, cloud, and the UMLS ontology to improve semantic interoperability in healthcare systems. The work showed reductions in computation overhead, latency, and network usage. However, the study relied entirely on simulations and raised concerns about inter-fog communication and data security. These cloud-based approaches share a common pattern: they create interoperability layers that facilitate data movement and exchange, but do not address the structural incompatibilities of the legacy database itself. They assume the source schema is adequate and focus on translation rather than modernization

C. AI-Driven Schema Matching and Structural Enrichment

The most directly related strand of recent work involves the use of language models for schema matching, the task of identifying semantic correspondences between elements of different relational schemas. Parciak et al. [29] ran an experimental study on using off-the-shelf LLMs for schema matching in the health domain, varying the amount of context information passed to the model through different "task scopes". Their results showed that LLMs can meaningfully bootstrap the matching process using only element names and descriptions, but that quality suffers when too much or too little context is provided. The study did not address multi-source schema enrichment or attribute-level gap analysis.

Sheetrit et al. [30] proposed ReMatch, a retrieval-augmented schema matching system that uses embedding-based candidate retrieval to narrow the search space before passing candidates to GPT-4 for ranking. The approach achieved strong results but showed significant performance degradation with smaller models and was not tested in healthcare scenarios involving legacy database upgrades. Liu et al. [31] developed Magneto, a hybrid pipeline that combines small and large language models for schema matching. A two-stage process, first narrowing candidates via contrastive column embeddings, then scoring with an LLM, outperformed single-model approaches and reduced the cost of labeled training data. That said, Magneto operates at the column level and does not attempt to identify missing attributes for structural enrichment. Ma et al. [32] introduced a knowledge graph-based retrieval-augmented generation approach for schema matching, using entity-type hierarchies to improve disambiguation for unseen schema elements. The method showed robustness under zero-shot conditions, but requires a pre-built knowledge graph and has not been evaluated in multi-provider legacy database settings.

Across all three research threads, a critical gap is consistent: existing solutions create interoperability layers to facilitate data exchange, but neglect the structural modernization of legacy databases. Schema matching work focuses on finding correspondences, not on using those correspondences to enrich a schema with missing tables and attributes. Health interoperability work relies on exchange standards and ontologies, not on semantic enrichment of the source database structure. The proposed HISaaS framework is designed specifically to fill this gap. It moves beyond data translation to actively identify missing schema elements (tables and attributes) from multiple cloud-hosted providers, using contextual embeddings and cosine similarity, and offers them to the user for structural integration.

IV. PROPOSED SYSTEM

HISaaS Health Information System as a Service is a cloud-delivered framework that gives organizations two distinct paths: they can build a completely new database from tables sourced across multiple cloud providers, or they can upgrade an existing legacy database by enriching it with new tables and attributes drawn from those same sources. The framework does not force a total system replacement. Instead, it works with what the client already has, adding structure where it is missing and leaving the rest intact.

The cloud platform is central to how HISaaS delivers both flexibility and scale. Because all schema catalogs are hosted and served from cloud infrastructure, clients can explore, compare, and compose database structures without requiring significant on-premise resources. The service adapts to organizations of different sizes, from a small clinic building its first schema to a hospital network looking to modernize a decades-old system.

A. General Model

The HISaaS workflow begins when a client selects a health domain from a catalog of available options. Once a domain is chosen, the system presents a list of information systems

offered by registered cloud providers that match that domain. For each selected system, a database schema is displayed, showing its tables and the attributes within them.

The client then chooses which tables to incorporate into their own database. This selection step is iterative: a client can work through multiple provider systems in sequence, adding tables from each one until the composite schema fully meets their requirements. The output of this process is either a new database ready to serve a new information system, or a set of enrichment operations to be applied to an existing one. Fig. 3 illustrates the full general workflow.

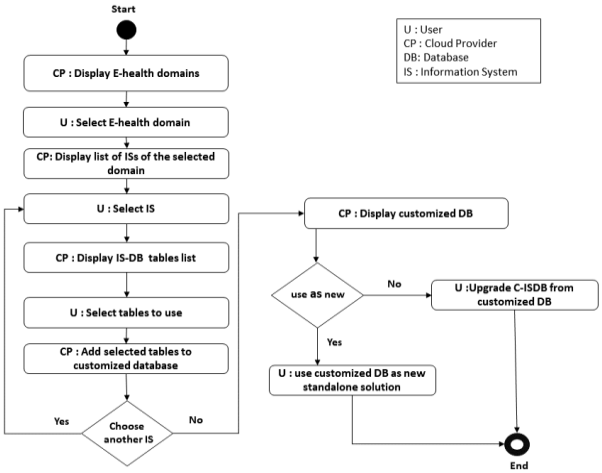

Fig. 3. HISaaS general model workflow.

B. 1st Scenario: Deployment of a New Custom Database

If the client needs to use a new customized database as a solution, he can either use it as it is or further customize it to better meet their needs. This customization allows for selecting the tables to include in the composite database and modifying them by choosing only the attributes necessary to meet the client's requirements (see Fig. 4).

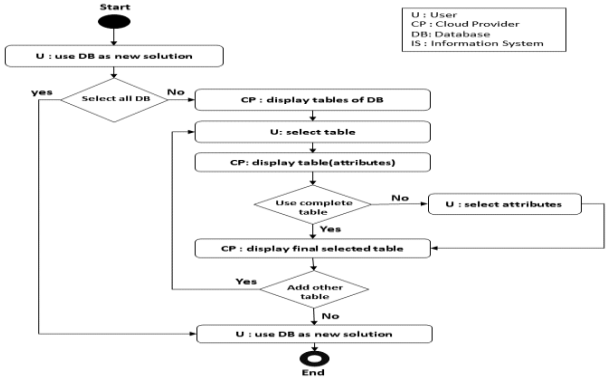

Fig. 4. Workflow for constructing a new custom database.

C. 2nd Scenario: Upgrading User Database

The scenario for updating the user database begins with uploading their database to the HISaaS platform. During the upload, HISaaS extracts and analyzes the metadata of the database, particularly the names of all the tables and their corresponding attributes, as illustrated in Fig. 5. The client has two options to improve their existing database:

1) Integrate a new table: The client can select a table from the custom database and integrate it into their existing IS database. He can use it as it is or customize it with selected attributes.

2) Update an existing table: The client can also select a table from the custom database and ensure that HISaaS finds a corresponding table in the client database. If a match is found, HISaaS identifies the attributes present in the selected table but absent in the client's table, and those can be integrated to enrich the existing data structure. This option enhances the data while preserving the core structure and familiarity of the existing dataset.

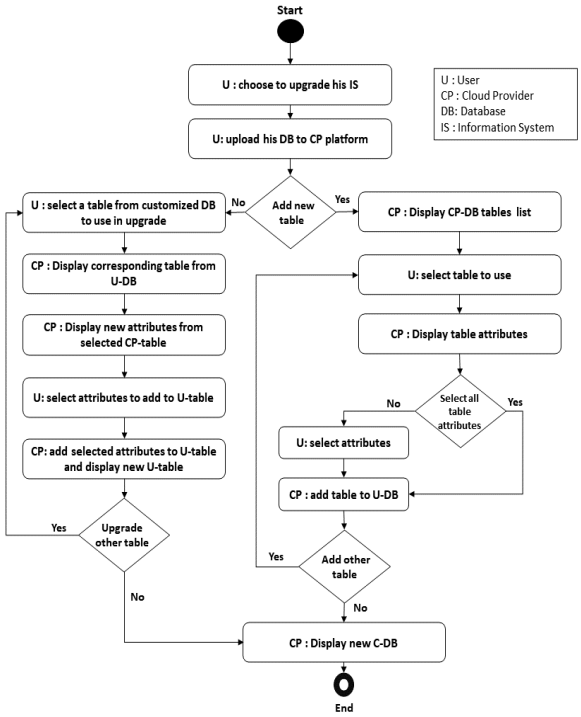

Fig. 5. Workflow for upgrading an existing legacy database.

D. HISaaS Database Enrichment Algorithms

Our proposed system is powered by two main algorithms that utilize OpenAI's advanced natural language processing (NLP) capabilities. First, identification of the most semantically relevant table for an enrichment request, and then the search for new attributes in the selected table from the customized database that are absent in the identified table in the client's database. These two algorithms facilitate the semantic matching of database schema elements (tables, attributes) by relying on the power of contextual embeddings and semantic similarity measures to overcome the heterogeneity and naming inconsistencies inherent in disparate information systems.

Semantic similarity between any two schema elements, whether table names or attribute names, is quantified by computing the cosine similarity between their respective embedding vectors. Given two dense vectors A and B produced by the embedding model, cosine similarity is defined as:

$$\text{cosine_sim}(\boldsymbol{A}, \boldsymbol{B}) = \frac{\boldsymbol{A} \cdot \boldsymbol{B}}{\|\boldsymbol{A}\| \cdot \|\boldsymbol{B}\|} \quad (1)$$

where, A and B are the high-dimensional vector representations of two schema elements, A • B is their dot product, and ‖ A ‖ and ‖ B ‖ are their respective Euclidean norms. The resulting score lies in [0, 1] for text embeddings: a score of 1 indicates identical semantic direction, and 0 indicates complete orthogonality. Cosine similarity is particularly well-suited to this task because it is invariant to vector magnitude; two schema element names of very different character lengths are compared purely based on their semantic direction in the embedding space, not their raw size.

The embedding vectors are produced by OpenAI's *text-embedding-3-small* model, which maps each schema element name to a 1536-dimensional dense vector. These vectors encode contextual meaning rather than surface form, enabling the system to capture semantic relationships that character-level or keyword-based matching would miss entirely.

We select a similarity threshold of t = 0.80, validated both by established literature and our own experimental tuning. Externally, ontology matching adopts t = 0.80 for Language-agnostic BERT Sentence Embedding (LaBSE)[33]; BERT-based extraction achieves 88% accuracy at ⩾0.80 [34]. Our systematic sweeps independently confirmed 0.80 as the optimal precision–recall trade-off for HISaaS schema matching: lower values introduce spurious links (e.g., "patient_id" ↔ "physician_id"), while higher values miss genuine synonyms expressed through different naming conventions. Hence, t = 0.80 is applied throughout.

1) Procedure for finding the corresponding table: In this scenario, once the client selects a table in the custom database for the upgrade process, the system searches for a corresponding table in the client's database. The search process is carried out as follows:

a) Phase 1 Syntactic search: HISaaS starts by performing a syntactic search, seeking an exact match between the table name chosen by the user and table names present in the user's database. This is the fastest and most efficient method, but is often unsuccessful due to variations in naming conventions (e.g., "patient", "patient_tbl", "client_records").

b) Phase 2 Semantic search (contextual matching): If no syntactic match is found, HISaaS moves on to a more advanced search using OpenAI's advanced natural language processing capabilities to identify the semantics (meaning) of the table name.

This semantic search allows discovering tables that do not have an exact syntactic match with the name but are semantically related to the table the client wishes to update. This ensures that HISaaS can identify the most relevant table in the client's database, if it exists, even when the naming conventions or terminology used by the client differ from those in the database.

c) Algorithm 1: Finding the Corresponding Table

Algorithm 1 Explanation: The algorithm uses two components of the OpenAI Python library. Synonym generation is handled by ChatCompletion.create with GPT-4. Embedding generation is handled by embedding.create with the text-embedding-3-small model, chosen for its strong performance on semantic search benchmarks and its substantial improvement over the previous text-embedding-ada-002 generation at lower operational cost.

Algorithm 1: Find_Corresponding_Table

Input:

```
CP_DB     : list of table names in the customized database
Cu_DB     : list of table names in the user's database
Upg_table : table selected by client from CP_DB for upgrade
sim_thresh : minimum cosine similarity score (t = 0.80)
max_syn   : maximum number of synonyms to generate
```

Output:

```
CR_table  : matched table from Cu_DB, or None if not found
```

Phase 1 — Syntactic Search:

```
CR_table ← None
FOR each table IN Cu_DB DO
    IF table == Upg_table THEN
        CR_table ← table
        RETURN CR_table
    END IF
END FOR
```

Phase 2 — Semantic Search Preparation:

```
IF CR_table == None THEN
    // Generate synonyms for the upgrade table name via GPT-4
    synonyms ← Generate_SYNONYMS(Upg_table, max_syn)
    synonyms ← synonyms + [Upg_table]   // include original term

    syn_embs ← []
    FOR each syn IN synonyms DO
        syn_embs.append(GET_EMBEDDINGS(syn))
    END FOR

    cu_embs ← {}
    FOR each table IN Cu_DB DO
        cu_embs[table] ← GET_EMBEDDINGS(table)
    END FOR
```

Phase 3 — Semantic Matching:

```
best_match ← None
highest_sim ← 0
```

```
    FOR each (syn, syn_emb) IN zip(synonyms, syn_embs) DO
        FOR each (table, cu_emb) IN cu_embs DO
            // Apply Equation (1)
            sim ← COSINE_SIM(syn_emb, cu_emb)
            IF sim > highest_sim AND sim >= sim_thresh THEN
                highest_sim ← sim
                best_match  ← table
            END IF
        END FOR
    END FOR

    CR_table ← best_match IF highest_sim >= sim_thresh ELSE None
    END IF

RETURN CR_table
```

- Synonym Generation: The GENERATE_SYNONYMS function submits the upgrade table name to GPT-4 with a tailored prompt and receives a list of semantically related terms. These synonyms broaden the search space so that the system can recognise equivalent concepts even when they are expressed with different vocabulary across systems.
- Embedding Generation: GET_EMBEDDINGS transforms each synonym, the original table name, and all user table names into 1536-dimensional dense vectors encoding contextual meaning rather than surface form, enabling similarity computation to capture relationships that character-level matching would miss.
- Semantic Similarity: Cosine similarity [Eq. (1)] measures directional alignment between embedding vectors. Two conditions must hold simultaneously for a match to be accepted:
    - The similarity score must reach or exceed the threshold t = 0.80.
    - The score must be strictly higher than the best score recorded for that client table against any previously processed synonym.

Together, these conditions ensure that the returned match is the most semantically coherent candidate across the full synonym set, correctly linking, for example, “medications” to “drug_inventory” or “billing” to “invoice” despite the absence of any shared characters.

2) Procedure for identifying missing attributes: Once a corresponding client table is found, the system moves to the attribute level. The objective here differs from table matching: rather than finding a single best match, the system determines which attributes of the upgrade table are genuinely absent from the client table. Attributes that already exist by exact name or by semantic equivalence are filtered out. Only attributes that survive both filtering passes are surfaced as enrichment candidates.

a) Phase 1 Syntactic search: The algorithm checks each attribute in the upgrade table against the client table’s attribute list. Any attribute found by exact name is skipped; unmatched attributes are forwarded to the semantic phase.

b) Phase 2 Semantic search: For each unmatched attribute, GPT-4 generates synonyms. Both the synonyms and the client attributes are embedded. Cosine similarity [Eq. (1)] is computed across all synonym–client attribute pairs. If any pair exceeds t = 0.80, the attribute is considered present under a different name and excluded from the output. Only attributes for which no synonym achieves the threshold are added to the missing-attributes list.

c) Algorithm 2: Identifying Missing Attributes

Algorithm 2 Explanation:

- Syntactic Search: The algorithm iterates through CP_attrs. Attributes found verbatim in Cu_attrs are skipped; unmatched attributes are forwarded immediately to the semantic phase.
- Semantic Search: For each unmatched attribute, the system generates synonyms (e.g., for “user_id”: [“client_id”, “customer_id”, “cust_id”]), embeds them together with all Cu_attrs, and runs cosine similarity comparisons using Eq. (1). As soon as any synonym–attribute pair crosses t = 0.80, the attribute is flagged as present and the inner loop exits early. This early-exit design keeps computational cost proportional to the difficulty of the matching problem.
- Result: Attributes for which neither phase finds a match are appended to new_attrs. This list is presented to the client, who decides which attributes to add to their table. The human decision step is intentional: the system identifies enrichment candidates but does not automatically modify the schema, preserving full user control over the final database structure.

Algorithm 2: Upgrade_Table

Input:

```
CP_table   :  source table from the customized database
Cu_table   :  target table in user's database (from Alg. 1)
CP_attrs   :  list of attribute names in CP_table
Cu_attrs   :  list of attribute names in Cu_table
sim_thresh :  minimum cosine similarity score (t = 0.80)
max_syn    :  maximum synonyms to generate per attribute
```

Output:

```
new_attrs  :  attributes in CP_table
```

```
    absent in Cu_table
```

Phase 1 — Syntactic Search:

```
new_attrs ← []
FOR each attr IN CP_attrs DO
    IF attr IN Cu_attrs THEN
        CONTINUE   // attribute already exists — skip
    ELSE
        GOTO Phase 2 with attr
    END IF
END FOR
```

Phase 2 — Semantic Search:

```
FOR each unmatched attr IN CP_attrs DO
    synonyms ← Generate_SYNONYMS(attr, max_syn)
    synonyms.append(attr)
    syn_embs ← [GET_EMBEDDINGS(s) for s in synonyms]
    cu_embs  ← [GET_EMBEDDINGS(a) for a in Cu_attrs]

    is_found ← False
    FOR each syn_emb IN syn_embs DO
        FOR each cu_emb IN cu_embs DO
            // Apply Equation (1)
            sim ← COSINE_SIM(syn_emb, cu_emb)
            IF sim >= sim_thresh THEN
                is_found ← True
                BREAK
            END IF
        END FOR
        IF is_found THEN BREAK
    END FOR

    IF NOT is_found THEN
        new_attrs.append(attr)
    END IF
END FOR
```

RETURN new_attrs

V. Results and Discussion

To evaluate HISaaS proposed in a real-world setting, we created a Cloud environment using the OpenNebula Cloud platform. The infrastructure was deployed on a physical host machine with the following specifications: an Intel Core i7 10th Gen processor (6 Cores @ 2.59 GHz), 64 GB of RAM, and 1 TB of NVMe storage. The host machine ran Ubuntu Desktop 22.04 LTS. Within this environment, Oracle VirtualBox 7.0 was used to create a virtualized instance, which also ran Ubuntu Desktop 22.04 LTS. On this guest operating system, the OpenNebula 6.8 cloud management platform was deployed to orchestrate the creation and management of the virtual machines (VMs) required for the simulation.

The environment consisted of eight virtual machines (VMs) representing the cloud providers and user organizations. As shown in Fig. 6, three provider VMs (P1, P2, P3) with 2vCPUs, 12 GB RAM,100 GB storage, and running Ubuntu Server 22.04 LTS hosted real-world healthcare datasets: P1 hosting MIMIC-III (Medical Information Mart for Intensive Care) [35]Clinical Database V1.4, P2 hosting eICU (electronic intensive care unit) Collaborative Research Database [36], and P3 hosting a private hospital database. Four user VMs with 2vCPUs, 8 GB RAM,40 GB storage, and running Ubuntu Server 22.04 LTS represented clinics with legacy systems seeking to upgrade their schemas or build a new one. The HISaaS VM with 3vCPUs, 16 GB RAM,200 GB storage, and running Ubuntu Server 22.04 LTS hosted the core HISaaS service, responsible for coordinating semantic matching, schema analysis, and the enrichment processes across all provider and user nodes.

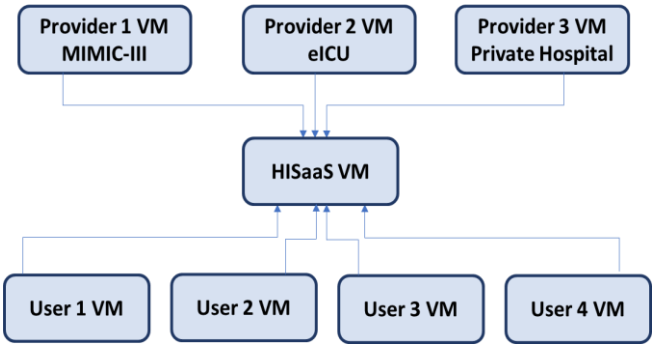

Fig. 6. Deployment architecture of the HISaaS cloud-based evaluation environment.

A. Use Case Scenario and Outcomes

Four users participated in the simulation, each performing schema enrichment operations. The outcomes are detailed below.

1) User 1 Targeted schema upgrade: The first user started with a database of 7 tables and 45 attributes: patients table with 8 attributes, doctors table with 7 attributes, appointments table with 6 attributes, medical records table with 7 attributes, billing table with 6 attributes, medication table with 5 attributes, and prescriptions table with 6 attributes.

The user created a customized database of 29 tables. Added four tables: doctors_details and Patient_medical_info from private hospital, icu_stays from private hospital, and prescriptions from MIMIC-III.

Upgraded four Existing tables:

- Patients (8 attributes) using patient_tbl (21 attributes) from private hospital; the matching table was found via semantic search with a cosine similarity of 0.83. Syntactic search identifies 21 new attributes, while

semantic search identifies 13 new attributes. The user chose 10 attributes to add to his Patients table

- billing (6 attributes) using invoice (11 attributes) from private hospital; the matching table was found via semantic search with cosine similarity of 0.88. Syntactic search identifies 10 new attributes, while semantic search identifies 7 new attributes. The user chose 7 attributes to add to his billing table.
- doctors (7 attributes) using doctors_tbl (17 attributes) from a private hospital; the matching table was found via semantic search with a cosine similarity of 0.82. Syntactic search shows 17 new attributes, while semantic search shows 15 new attributes. The user chose 12 attributes to add to his doctor's table
- medications (5 attributes) using medication (15 attributes) from eICU; the matching table was found via semantic search with a cosine similarity of 0.96. Syntactic search shows 13 new attributes, while semantic search also shows 13 new attributes. The user chose 4 attributes to add to his medications table.

The upgrade process was both precise and selective: the user did not adopt all new attributes suggested by the system (e.g., selecting only 10 of 13 semantically suggested for the "Patients" table). This reflects the effectiveness and the flexibility of our system. The final database schema grew to 11 tables (+57.1%) and 139 attributes (+208.9%), representing substantial structural enrichment. Fig. 7 illustrates this enrichment.

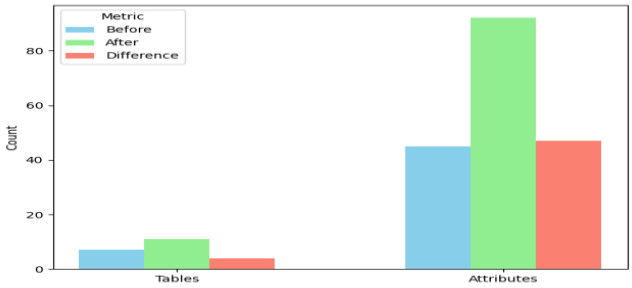

Fig. 7. User 1 database enrichment statistics.

2) User 2 Large-scale schema expansion: The second user began with a database of 5 tables and 31 attributes: patient_inf (7 attributes), visits (6 attributes), departments (3 attributes), health_records(6 attributes), and billing_records (6 attributes).

The user created a customized database of 26 tables. They performed a large-scale integration, added 14 tables: doctors_detail, doctor_tbl, email_config, email_delivery, email_inf, email_schedul, email_template, insurance, payment_account, payment_table, and user_tbl from private hospital. nurceAssissment, nurceCare, and nurceChart from eICU.

Upgraded three existing tables: "billing_records" using "invoice" from private hospital with 0.91 similarity, "health_records" using "patient_medical_info" from private hospital with 0.88 similarity, and "patient_inf" using "patient_tbl" from private hospital with 0.92 similarity.

All table matches were discovered using semantic search with similarities above 0.88, ensuring high confidence in the results. The outcome was a transformation to 19 tables (+280%) and 154 attributes (+396.8%), as illustrated in Fig. 8. This case highlights the capacity of HISaaS to support rapid schema expansion.

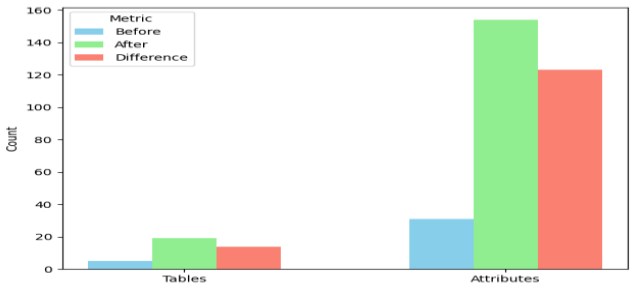

Fig. 8. User 2 database enrichment statistics.

3) User 3 Selective Enrichment: The third user starts with a database of 11 tables and 63 attributes: accounts (5 attributes), patients (7 attributes), medical_providers (6 attributes), patient_clinical_history (7 attributes), consultations (6 attributes), consultation_notes (4 attributes), prescriptions (6 attributes), transactions (6 attributes), support_tickets (6 attributes), chat_transcripts (5 attributes), system_logs (5 attributes). Created a customized_dB of 12 tables, chose to enrich their schema by adding 5 new tables from MIMIC-III and the private hospital database: payment_account_setup (4 attributes), payment_table (9 attributes), and schedul_table (8 attributes) from the private hospital; ICUSTAYS (12 attributes) and TRANSFERS(13 attributes) from MIMIC-III.

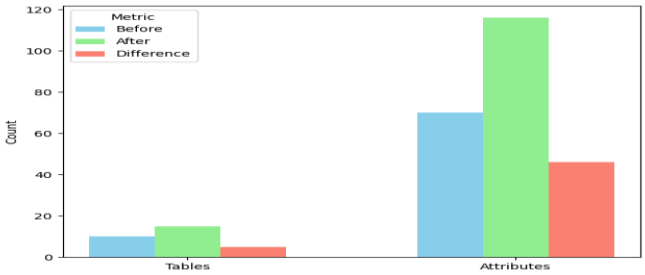

Fig. 9. User 3 database enrichment statistics.

User 3 kept the majority of their original database structure (11 initial tables), but enriched their schema by adding 5 new tables, leading to a final 16 tables. There were no table upgrades made. But the number of attributes increased by 53, from 63 to 116 (+84.13%) (See Fig. 9).

4) User 4 New schema construction: User 4 represented a new clinic without an existing schema. They used HISaaS to build a new customized database from scratch, composing it of 14 tables and 169 attributes with 14 tables and 169 attributes, representing a 100% new construction, sourced from all three providers: user_tbl (11 attributes), doctor_tbl (17 attributes), doctor_details (6 attributes), invoice (11 attributes), invoice_product (7 attributes), patient_tbl (21 attributes) and patient_medical_info (22 attributes) from

private hospital; nurseAssessment (8 attributes), nurseCare (8 attributes) and nurseCharting (8 attributes) from eICU; ICUSTAYS (12 attributes), PRESCRIPTIONS (19 attributes), SERVICES (6 attributes) and TRANSFERS (13 attributes) from MIMIC-III.

This use case demonstrates the system's utility for greenfield projects, enabling the rapid construction of a comprehensive, modern database.

B. System Performance Evaluation

The four user scenarios showcased distinct patterns of use, from targeted upgrades to full-scale schema construction, reflecting the HISaaS service flexibility and its adaptation to varying interoperability challenges and modernization needs across different organizational contexts. A summary of the enrichment across all users is provided in Table II.

TABLE II. ENRICHMENT STATISTICS ACROSS ALL USERS

User	Tables before	Tables After	Tables gain %	Attributes before	Attributes after	Attributes gain %	Tables added	Tables upgraded
User1	7	11	+57.1%	45	139	+208.9%	4 (from MIMIC-III and Private hospital)	4 (patients, billing, doctors, medication)
User2	5	19	+280%	31	154	+396.8%	14 (mixed sources)	3 (billing_record, health_records, patient_inf)
User3	11	16	+45.45%	63	116	+84.13%	5 (from MIMIC-III and private hospital)	0
User4	0	14	New (100%)	0	169	New (100%)	14 (mixed sources)	0

The results demonstrate substantial structural enrichment across all scenarios. User 2 achieved the highest relative growth in both tables (+280%) and attributes (+396.8%), reflecting a large-scale expansion of a previously minimal schema. User 1, while more selective, still realized significant attribute-level enrichment (+208.9%), underscoring the system's ability to perform deep, targeted upgrades. User 3 opted for a conservative approach, focusing on table additions rather than upgrades, resulting in a balanced increase in both tables (+45.45%) and attributes (+65.7%). User 4, building a schema from scratch, successfully constructed a fully modernized database with 14 tables and 169 attributes, demonstrating the system's utility for greenfield deployments.

To evaluate the system performance, we calculated the F1-score, precision, and recall for the applicable users (Users 1 and 2). The system achieved perfect performance in table matching for both users. The global precision, recall, and F1-score for table matching were all 1.00, indicating that the system successfully identified all relevant tables and avoided any false matches. The system also performed well in attribute-level enrichment. The global new attribute identification precision was 0.97, with a recall of 1.00, resulting in an F1-score of 0.98. The only recorded error occurred in User1's scenario, where the system recommended an attribute that already existed in the user's original table (doctors table upgrade), leading to a single false positive. This outcome highlights the overall accuracy and reliability of the HISaaS system in both structural and semantic enrichment tasks.

A key component of the system's efficacy is its use of semantic similarity, powered by OpenAI's advanced language models. This capability drives two critical functions within HISaaS: synonym generation and embedding creation, which are used for identifying corresponding tables and finding new attributes during the schema upgrade. By defining a cosine similarity threshold of 0.80, the system efficiently eliminated weak matches while maintaining recall, ensuring that most relevant structures were presented to the user. The HISaaS service proved particularly useful in real-world datasets where naming conventions and structural variations were significant across multiple providers. For example, HISaaS was able to match patients with patient_tbl, and billing with invoice, not based on name overlap, but on underlying semantic equivalence inferred from their embeddings.

The results show that HISaaS is well-suited for both schema upgrade and new schema construction tasks in heterogeneous healthcare environments. Its high precision reduces the need for manual correction, while its high recall ensures complete enrichment of the target schema. Using semantic similarity, the HISaaS effectively addresses the limitations caused by non-standardized naming conventions, an important challenge in healthcare data integration. These findings establish the HISaaS as a robust, scalable, and accurate approach for practical schema enrichment.

VI. CONCLUSION AND FUTURE WORK

This work presented a new approach to achieving interoperability in information systems based on a Cloud-VM environment by proposing a Health Information System as a Service (HISaaS) framework. The study conducted in this work highlighted the limitations of traditional interoperability solutions that primarily focus on data exchange and fail to address the fundamental structural issues of legacy databases. By using cloud computing and advanced AI-driven semantic similarity measurement techniques, the HISaaS solution offers a scalable and intelligent method to modernize legacy systems. HISaaS uses OpenAI's linguistic models to accurately identify semantically related tables and attributes to overcome naming conventions, terminologies, and schema design across different heterogeneous Cloud providers.

The evaluation was conducted in a simulated Cloud environment with real data from the healthcare sector. The results demonstrated that the proposed framework can significantly improve database structures, making them more complete and more interoperable without requiring a costly and large-scale replacement. HISaaS achieved perfect precision and recall in table matching with nearly perfect performance in attribute-level enrichment across various scenarios, including

targeted upgrades, large-scale expansions, selective enrichment, and complete schema construction.

In conclusion, the proposed solution addressed a critical issue in the creation and enrichment of IS by providing interoperability-based means in a Cloud-VM environment to improve the fundamental structure of clients' legacy databases.

Although the results presented in this work are promising, it is still necessary to make modifications to the HISaaS framework to improve its capabilities. These modifications will focus on further supporting the subdomains of healthcare, namely care, pharmacy, medical analyses, ... Moreover, it is important to extend the enrichment of the database schema beyond tables and attributes to include relationships, constraints, and metadata for a complete relational modernization. Moreover, automating the database enrichment process will minimize the need for manual interventions, thereby making the solution more accessible to a wider range of users and organizations.

Given that the HISaaS framework involves accessing and modifying sensitive data in the healthcare field (particularly patient data), future improvements should focus on investigating and strengthening security and privacy mechanisms in the Cloud environment.

HETRA: A Real-Time Traffic Detection and Directional Counting System Using YOLOv8 and DeepSORT

Kuldeep Kumar Shukla*, Ajai Kumar Singh
Civil Engineering Department, Motilal Nehru National Institute of Technology Allahabad, Prayagraj, 211004, India

***Abstract*—Rapid urbanization and economic growth in developing countries such as India have increased the demand for automated traffic analysis systems. However, heterogeneous traffic conditions present significant challenges to automated traffic analysis. This study proposes HETRA (HEterogeneous TRaffic Analysis), a real- time traffic monitoring framework that integrates YOLOv8 and DeepSORT for multi-class detection, tracking, and counting. For this, a custom traffic dataset was developed using real-world recorded traffic videos. The dataset consists of more than eight thousand annotated frames representing the fourteen traffic classes (motorized, non-motorized, and pedestrians). The proposed model leverages YOLOv8 for class identification and localization, while DeepSORT is used for multi-class tracking and directional traffic counting. The custom traffic dataset was used to train and assess the proposed HETRA model. The model achieved precision, recall, and mean average precision values of 71.15%, 65.51%, and 61.9%, respectively. The qualitative assessment of the model demonstrated its effectiveness under varying traffic scenarios and lighting conditions. Furthermore, it obtained an overall counting accuracy of 90%. These findings demonstrate the potential of the proposed framework for real-time traffic analysis and intelligent transportation systems.**

***Keywords*—Heterogeneous traffic; YOLOv8; DeepSORT traffic counting; intelligent transportation system**

I. INTRODUCTION

Over the last two decades, the fast-growing number of personal vehicles has resulted in an enormous increase in traffic congestion in cities, across developing countries, especially in India. Therefore, it is crucial to have an efficient traffic monitoring and management system for reducing travel time, decreasing fuel consumption, and supporting sustainable urban transportation goals. In recent years, Intelligent Transportation Systems (ITS) have gained tremendous attention as automated real-time traffic monitoring systems utilizing artificial intelligence (AI) and computer vision (CV) technology.

Vehicle detection, tracking, and counting are basic components of modern traffic monitoring systems. These are widely used for traffic flow analysis, congestion study, adaptive signal design, urban mobility planning, and road safety management. However, developing such an automated system for Indian traffic conditions remains highly challenging. The traffic patterns in India are fundamentally different from developed nations due to a heterogeneous traffic mix, - non-lane-disciplined behavior, poor roadway conditions, etc. The traffic in India consists of a vast composition of motorized and non-motorized vehicles competing for the same road space. Along with this, frequent overtaking, varying sizes, erratic lane practices, and dense traffic situations give rise to troublesome traffic class detection and tracking. Traditional intrusive sensor-based methods for traffic monitoring are inadequate as they provide only axle counts without traffic class differentiation. For traffic management, geometric design and other analyses, class-wise traffic counting is one of the mandatory requirements. These challenges accentuate the immediate need for reliable automated traffic analysis techniques capable of generating accurate traffic information, including vehicle classification, class-wise traffic volume, and movement patterns. Such information serves as the foundation of ITS, enabling applications including adaptive signal management, congestion prevention, accident detection, safety assessment, and also long-term transportation planning [1].

Conventional approaches used for traffic monitoring are: manual traffic counts, loop detectors, pneumatic tubes, radar and infrared sensors, and conventional image processing-based techniques. These methods exhibit considerable limitations in scalability, high installation cost, poor adaptability, and reduced accuracy under dynamic traffic circumstances [2]. The image processing approaches for traffic detection are based on traditional CV techniques like background subtraction [3], Support Vector Machine (SVM) [4], etc. However, their robustness is often compromised by lighting conditions, shadows, and occlusions encountered in real-world scenarios.

In recent years, deep learning-based computer vision techniques have demonstrated remarkable success in identifying, tracking, and traffic analysis [5]. Among these developments, convolutional neural networks (CNNs) have become the foundation of modern object detection algorithms. Existing deep learning-based detectors are broadly categorized into two-stage and one-stage approaches. Two- stage methods, including R-CNN [6], Fast R-CNN [7], and Faster R-CNN [8], first generate candidate object regions before performing classification, which generally results in high detection accuracy. However, their high latency in inference as well as computational complexities are major drawbacks in real-time traffic monitoring and surveillance applications. To address these constraints, single-stage detectors like Single Shot Detector (SSD) [9] and the You Only Look Once (YOLO) [10] family are introduced. SSD utilizes multi-scale feature maps to identify objects of diverse dimensions, yet it often has

*Corresponding author.

difficulties in detecting tiny objects, which is essential in traffic situations involving bicycles, bikes, and pedestrians [9].

Among these techniques, the YOLO method redefined object detection as a single regression task, allowing real-time identification with competitive detection precision [10]. YOLO9000 demonstrated the viability of integrated identification and categorization across several object categories while preserving real-time speed [11]. In YOLOv3, multi-scale predictions and residual learning were incorporated, which greatly promoted the accuracy of object detection of small objects [12]. YOLOv4 further boosted detection capabilities with optimized architecture and advanced feature fusion techniques, and reached state-of-the-art performance on test sets with high processing speeds [13]. These upgrades brought YOLO-based detectors into the spotlight as a leading tool for real-time object detection in smart traffic surveillance systems. However, they also showed their limitations in dense as well as mixed traffic conditions.

Recent research studies have investigated the use of YOLOv5 and YOLOv7 for urban traffic monitoring. Farid et al. established a real-time vehicle identification system using YOLOv5 and validated its efficacy in traffic surveillance contexts [14]. Likewise, traffic counting models created on deep learning-based techniques mostly emphasized organized traffic scenarios with a restricted range of vehicle classes [15].

Most of the existing studies primarily address structured traffic scenarios with few conventional vehicle classes. Although YOLOv8 and DeepSORT-based models have previously been applied for traffic monitoring, their assessment under heterogeneous traffic conditions remains insufficiently investigated. To address this limitation, this study develops and evaluates HETRA (HEterogeneous Traffic Analysis), an integrated YOLOv8-DeepSORT framework, for real-time detection, tracking, and class-wise directional counting of fourteen traffic categories under Indian traffic conditions. For this, the proposed framework was trained on a prepared custom traffic dataset of 8,476 manually annotated frames representing fourteen different traffic classes related to motorized vehicles, non-motorized vehicles, and pedestrians. The dataset includes region-specific traffic participants like auto, e-rickshaw, tempo, and horse-cart, which are often neglected in publicly available traffic datasets. The effectiveness of the developed model was evaluated using conventional metrics such as precision, recall, mean Average Precision (mAP), F1-score, confusion matrix, and directional counting accuracy. The novelty of the study is the thorough assessment of an integrated multi-class traffic analysis framework in dense, non-lane-based scenarios with frequent occlusions and substantial variations in traffic classes and size.

The major contributions of the study are as follows:

- Development of a custom traffic dataset consisting of 8476 manually annotated image frames representing fourteen different traffic classes in Indian traffic environments.
- Development and evaluation of HETRA- a YOLOv8 and DeepSORT-based framework for real-time multi-class detection, tracking, and directional traffic counting using the custom dataset.
- Assessment of HETRA under varying traffic densities and lighting conditions using quantitative and qualitative performance analysis.
- Demonstrate the suitability of the anticipated approach for real-time traffic monitoring, directional class-wise traffic flow estimation, and ITS applications.

II. Related Work

YOLOv8 brought significant architectural enhancements like the anchor-free detection strategy, decoupled detection heads, and refined loss functions. A number of recent works have used YOLOv8 in traffic-related tasks. Enhanced YOLOv8 has been utilized for identifying moving objects in videos, which showed superior accuracy and convergence characteristics compared to earlier YOLO variants [16]. Survey studies have recognized YOLOv8 as a viable model for real-time detection applications; however, its comprehensive evaluation under complicated, unstructured traffic situations is still restricted [17-19]. The YOLOv8 models suggested for vehicle counting in road traffic indicate accurate object detection performance in controlled environments [20].

Subsequent enhancements in YOLOv8 continued improvements in model performance under complex environments. Different architectural modifications in YOLOv8 were employed for the estimation of traffic flow parameters to improve the model precision [21]. Various works have utilized YOLOv8 for improving traffic analysis in ITS applications but only for limited classes of vehicles [22]. The real-time detection of small and distant traffic objects has remained one of the crucial challenges in traffic system monitoring. Many researchers employed different variants of improved YOLOv8 models for detecting small objects. Lightweight and modified YOLOv8 models were reported for the detection of small traffic signs and pedestrian-vehicle detection, with better precision in difficult environmental conditions [23, 24]. UAV-based studies also explored several improvements over YOLOv8 to detect small vehicles from an overhead view, which is quite different from the roadside camera viewpoint [25, 26]. While these works attained performance gains, most dealt with particular object categories or aerial imagery and didn't look into the complex issues of ground-level mixed traffic with overlapping objects and diverse vehicle types.

Multi-object tracking (MOT) has emerged as one of the critical aspects of traffic monitoring systems. DeepSORT (Simple Online and Realtime Tracking with Deep Association Metric) is one of the most popular approaches to MOT, which is achieved by integrating Kalman filtering with deep appearance features to maintain stable traffic class IDs between successive frames [27]. A vision- based vehicle detection and counting using YOLOv3 and Oriented FAST and Rotated BRIEF (ORB) tracking demonstrated effective performance under highway traffic scenarios [28]. Durve et al. performed a comprehensive benchmark analysis of YOLOv5 and YOLOv7 in combination with DeepSORT and highlighted the correlation between tracking precision and detector efficiency. It also emphasized the efficiency of the detector in congested environments [29].

Recent research studies have integrated YOLOv8 with MOT algorithms like DeepSORT to overcome the constraints of detection-only systems. The authors have employed a YOLOv8-DeepSORT-based method for estimating the traffic flow parameters with improved recognition consistency between consecutive frames [30]. On the other hand, some vehicle detection and tracking systems using YOLOv8 were effective in a controlled surveillance environment [31]. An integrated YOLOv8/v9 model with the ByteTrack and CLAHE (image enhancement technique) was used to evaluate the counting and tracking performance under varying environmental and traffic situations. The results demonstrated effective improvement in model performance, especially under poor lighting conditions [32].

The availability of image datasets of various traffic classes also continues to be a significant barrier in diverse traffic research. Early studies concentrated mostly on organized highway situations and lane-specific traffic scenarios. A range of benchmark datasets, including PASCAL VOC [33], MS COCO [34], KITTI [35], Cityscapes [36], and Open Images [37], has enabled researchers to attain substantial gains in detection accuracy. Nonetheless, these datasets mostly reflect traffic circumstances in developed nations and may not adequately depict the intricacies of diverse traffic scenarios often encountered in developing countries. Paranjape and Naik presented the DATS_2022 dataset, which highlights 45 classes including animal, board, poles, and 12 vehicle classes, but its applicability for traffic analysis is not reported [38]. This emphasizes that there is a need for a realistic dataset for unstructured traffic conditions with appropriate size, class variety, and practical applicability.

The literature studies indicate that most of the YOLOv8-based traffic monitoring works focused on general and structured traffic datasets, failing to deal with the complexities encountered in developing countries [15, 21]. These studies mostly concentrated on very few motorized traffic classes, while ignoring traffic categories like pedestrians, bicycles, and other informal modes like rickshaws, animal-driven carts, etc. [20, 22]. Very limited research on real-time multi-class vehicle detection and tracking is reported for Indian traffic conditions. The comprehensive fusion of tracking of the involved traffic objects and their class-wise vehicle counting was missing, which restricted their use in overall traffic analysis [16, 31]. Architectural developments of YOLOv8 have increasingly attracted more attention over time, but limited research has been conducted to evaluate its reliability under real-world traffic environments. Therefore, the use of models is largely confined to region-specific datasets [21, 22, 30].

III. Methodology

This research primarily offers an inclusive vision-based paradigm for the real-time traffic detection and counting system under heterogeneous traffic conditions. The workflow of the developed methodology is depicted in Fig. 1, illustrating the chronological phases from custom traffic dataset preparation to performance evaluation of the HETRA framework. The primary phases of this approach are creating a custom traffic dataset, annotating all instances, training the YOLOv8 model, evaluating the model performance, and integrating with DeepSORT for tracking multiple traffic classes and their directional counting across consecutive frames.

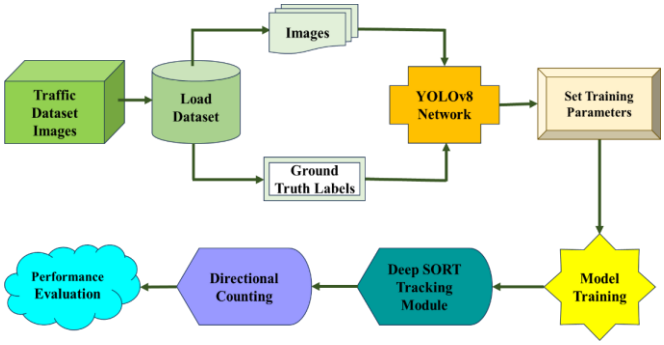

Fig. 1. Overall architectural workflow of proposed HETRA framework.

A. Dataset Preparation

The dataset was developed using actual traffic videos obtained from various urban and rural roadways in India. The dataset is intentionally enriched with various perspectives such as lighting conditions, traffic densities, background intricacy, etc. The dataset comprises fourteen traffic categories- namely auto, bike, bicycle, bus, car, horse-cart, e-rickshaw, pedestrian, pickup, rickshaw, tempo, tractor, truck, and van reflecting the diverse and complex composition of Indian road traffic.

The video footages of were chosen from different traffic conditions at regular intervals to prevent redundancy. It was furnished by removing low-quality or inappropriate image frames after visual inspection. Thereafter, high-quality image data was processed to the labelling stage. This Data was augmented by changing the original traffic images through modifications such as flipping and cropping before annotation to avoid overfitting and improve model flexibility.

Python-based 'LabelImg' annotation tool was utilized to label superior image frames manually in YOLO format (.txt). All annotations were manually inspected to verify the correctness of class labels and bounding-box localization. Incorrect or inconsistent annotations were corrected before finalizing the dataset for model training. A sample of image frames is shown in Fig. 2.

Fig. 2. Sample illustration of the annotation process.

Extra care was taken in labelling the bounding boxes of the concealed, overlapping, and smaller objects, which are more effective in practical scenarios for detection. Meticulous attention was paid while drawing the bounding boxes around the

traffic classes. Each label file contained the class index (numeric identifier referring to fourteen traffic categories) and box coordinates ('center_x', 'center_y', width and height) in standardized format.

A custom traffic dataset of 8476 frames consisting of 22886 instances was thus created, which corresponds to an average of 2.7 instances per frame. The diversified instance distribution of different traffic classes was analyzed to find the less represented traffic class, as presented in Fig. 3. No artificial data was generated to keep realistic traffic characteristics, while some horizontal image flipping was applied to minor categories. The common traffic classes such as cars, bikes, trucks, pedestrians, and pickups have a significantly higher number of instances compared to the less frequent classes like van, horse-cart, and rickshaw. The class 'Car' consists of the highest number of instances (6091), whereas less common classes like 'Horse-cart' and 'Rickshaw' consist of 127 and 132 instances, respectively. This exhibits an inherent class imbalance ratio of around 48:1, which is realistic for traffic conditions encountered on Indian roads. The class-wise performance metrics were reported to evaluate the influence of class imbalance. To enhance model generalization and mitigate overfitting, the dataset was partitioned into training, validation, and testing subsets.

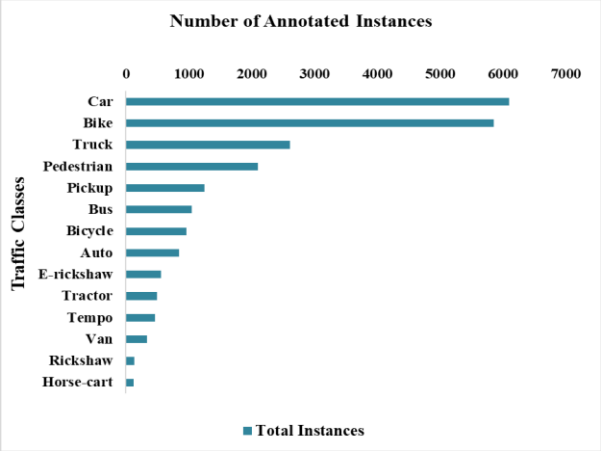

Fig. 3. Instance distribution of annotated traffic classes used in the custom dataset.

B. YOLOv8 Model Architecture

Fig. 4 shows the simplified YOLOv8 network used in this study. Improved feature extraction, anchor-free detection, and enhanced localization accuracy with faster inference performance are the main characteristics of YOLOv8, which makes it suitable for implementation under heterogeneous traffic conditions. Scalable pre-trained models from YOLOv8 can be fine-tuned on custom datasets, and this versatility allows strong learning of multiple traffic classes and complicated visual patterns (visually similar traffic classes, overlapping etc.).

The YOLOv8 architecture consists of three basic components: the backbone, neck, and detection head network. Each of them contributes to overall detection performance. The backbone network consists of Cross Stage Partial networks (CSP-net) based on two convolution (C2f) modules along with a Spatial Pyramid Pooling Fast (SPPF) block [39]. It extracts intricate low- as well as high-level semantic characteristics from input picture frames through a series of convolutional operations and feature fusion layers. This ensures better extraction of feature representation for small and partially occluded classes.

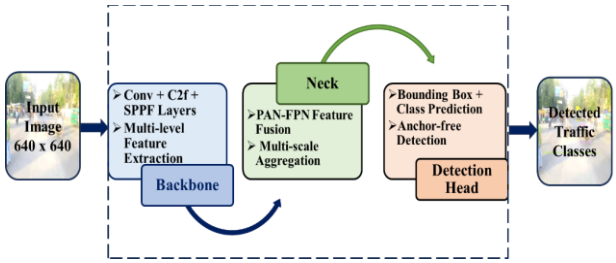

Fig. 4. YOLOv8 architecture illustrating the backbone, neck, and detection head for multi-class traffic detection.

The neck network employs a Path Aggregation Network combined with a Feature Pyramid Network (PAN-FPN) to integrate feature representations extracted at multiple scales. It is an intermediate processing part positioned between the backbone and the detection head. It is responsible for the aggregation of feature maps produced at the different backbone stages. This multi-scale feature integration facilitates efficient detection of traffic classes at varying distances and scales within the frame, thereby improving detection reliability in congested traffic conditions.

At the end, an anchor-free detection head is utilized that simultaneously predicts the bounding box coordinates, confidence scores, and class probabilities. It makes the model more robust to scale and aspect ratios. The anchor-free approach diminishes the computational intricacy and enhances the detection performance for irregular-shaped and small objects. This improves the overall efficiency of the model under dense and mixed traffic movements.

C. Multi-Class Tracking and Counting

The YOLOv8 model detects multi-class vehicles efficiently, but their identity preservation across successive video frame poses still an issue as traffic keeps changing. Therefore, the trained detector model is integrated with the DeepSORT algorithm to enable continuous multi-class tracking. Based on detection results, the DeepSORT technique provides a distinct identity to each tracked class. A Kalman filter is utilized for predicting future locations based on the previous position and movement of each traffic class track over various video frames. New detections are used to update and correct these predictions. Linking detections to existing class tracks is done using the Hungarian algorithm and deep appearance matching [27].

The hyperparameters within DeepSORT govern the timing and trajectory prediction of the traffic participants. Some of the tracking parameters are tuned specifically for congested traffic scenarios. The hyperparameter matrix used in the configuration file is summarized in Table I. Non-Maximum Suppression (NMS) was utilized to remove duplicate overlapping detections and preserve the bounding box with the highest level of confidence for each object. In addition to this, Intersection-over-Union (IoU) was applied in the process of data association while applying DeepSORT to correlate new detections with old tracks based on temporal overlap. Furthermore, frequent occlusions of small-sized vehicle classes (auto, bike, bicycle, etc.) while

moving adjacent to and behind the large vehicle class (bus, truck etc.) are noticed especially in mixed traffic conditions. Therefore, the MAX_AGE hyperparameter becomes an important aspect, especially in traffic monitoring applications. In this study, MAX_AGE was empirically set to 70 frames based on preliminary investigation and guidance from previous DeepSORT based tracking studies. This value provided a practical balance between the identities over short occlusions and prevented retention of prolonged tracking. This reduced the risk of double counting, while limiting the surplus computational overhead.

TABLE I. DEEPSORT TRACKING PARAMETERS

Hyperparameters	Operational Value	Function in Traffic Environments
MAX_DIST	0.2	Establish upper limit for cosine distance for visual appearance matching, helps to maintain correct traffic class identities
MIN_CONFIDENCE	0.3	Deny all class detections having a confidence score below 30%, reducing false positive detections
NMS_MAX_OVERLAP	0.5	Non-Maximum Suppression (NMS) level to eliminate duplicate bounding boxes for a single class with more than 50%
MAX_IOU_DISTANCE	0.7	Maximum Intersection over Union (IoU) distance allowed for overlapping bounding boxes
MAX_AGE	70	Retains class track identity up to 70 successive frames even in partial obstruction and missed detection
N_INIT	3	At least 3 successive stable detection frames required before allocating a tracking ID to reduce false track ID
NN_BUDGET	100	Stores 100 most recent frames of the class appearance feature

During the tracking phase, each detected traffic class is allocated a unique identity number which is maintained over successive video frames. Due to this consistent identification, it is possible to keep track of each traffic category in moving scenes and ensure non-repetitiveness of identity for the same object. This ensures accurate computation of traffic volume count, while minimizing the duplicity in detection and identity conflict issues.

Traffic counting is implemented through the use of a virtual counting line (VCL), passing through a defined point within the video frame. This line acts as a reference for counting the traffic. A trajectory buffer with a deque length of 20 was used for each tracked class to facilitate directional counting. The stored centroid history was utilized to analyse the movement and direction with respect to VCL. The bottom center of bounding box of each class continuously observed and counted traffic class is generated as it crosses the VCL. This minimizes the duplicate counts caused by repeated detections in consecutive frames. Traffic categories crossing the VCL while moving in the downward direction in a frame are reported as 'Number of Vehicles Entering,' and those crossing the VCL while moving in the upward direction are reported as 'Number of Vehicles Leaving'. Class-wise counters are established for each direction separately. This facilitates precise class-wise estimation of directional traffic count in real-world traffic scenarios.

D. Training Strategy and Loss Functions

In this study, YOLOv8 version 'l', was chosen as the traffic detection model because it offers a practical balance between detection performance and computational overhead. The model was fine-tuned using the custom traffic dataset consisting of a total of 8476 manually annotated image frames representing fourteen different traffic participants. The dataset was divided into training, validation, and testing subsets in the ratio of 66%, 14%, and 20%, respectively. Transfer learning is employed by initializing pretrained YOLOv8l weights with an input image resolution of 640 x 640 during training. The model was trained and optimized with loss components such as box, classification, and Distribution Focal Loss (DFL) over 200 epochs. The weights corresponding to the best performance were selected for subsequent evaluations. The major training parameters along with implementation aspects are summarized in Table II.

TABLE II. SUMMARY OF TRAINING SETUP

Parameter	Description
Model	YOLOv8l
Dataset Size	8476 images
Number of Classes	14
Input Image Size	640 × 640
Training Epochs	200
Batch Size	16
Optimizer	Stochastic Gradient Descent (SGD)
Learning Rate	0.01
Platform	Google Colab
GPU	NVIDIA A100 SXM4-40GB
Loss Function	Composite Loss (CIoU + BCE + DFL)

E. Loss Functions

The composite loss function was used to train the model. This minimizes the loss for localization accuracy and classification performance, and enhances the bounding box precision. Eq. (1) shows the total loss function (L_{TOTAL}) [12, 40, 41].

$$L_{TOTAL} = \lambda_{BOX} L_{BOX} + \lambda_{CLS} L_{CLS} + \lambda_{DFL} L_{DFL} \quad (1)$$

where, L_{BOX}, $L_{CLS,}$ and L_{DFL} symbolize the loss for bounding box regression, classification, and distribution focal loss, respectively. The λ_{BOX}, $\lambda_{CLS,}$ and λ_{DFL} are corresponding loss weightage coefficients.

To enhance localization precision, bounding box regression loss employs the Complete Intersection over Union (CIoU) metric. This loss accounts for overlapping area, center distance, and the aspect ratio uniformity between ground truth and predictions as shown in Eq. (2) [40].

$$L_{BOX} = L_{CIoU} = 1 - IoU + \frac{\rho^2(b,b^{gt})}{d^2} + \beta\upsilon \quad (2)$$

where, ρ (b, b^{gt}) represents the Euclidean distance between the centers of the predicted and the ground-truth bounding box, 'd' is the diagonal length of the smallest enclosing box, and 'υ' is aspect ratio uniformity and 'β' is a weighting parameter that controls the influence of the aspect ratio term in the CIoU loss function.

The classification loss 'L_{CLS}' is computed using Binary Cross-Entropy (BCE) loss as expressed in Eq. (3)[12]to penalize incorrect class predictions.

$$L_{CLS} = L_{BCE} = -\sum_{i=1}^{C=14}[y_i\, log(\hat{y}_i) + (1 - y_i) log(1 - \hat{y}_i)] \quad (3)$$

Where C = 14 is the total number of traffic classes, y_i represents the ground truth class label, and $\hat{y}_i$ predicted probability for the i^{th} class. This loss function accounts for the error between predicted and actual labels, thereby making it well-suited for multi-class detection problems.

DFL is utilized to refine bounding box localization and improve detection accuracy. This is especially important for small and partially occluded traffic objects prevalent in heterogeneous traffic. The mathematical formulation of DFL is given in Eq. (4) [41].

$$L_{DFL} = \sum_{k=1}^{4}\sum_{i=0}^{n}[p_i \log(\hat{p}_i)] \quad (4)$$

where, pi and $\hat{p}_i$ are the actual and predicted discrete probability distributions for each bounding box coordinate.

The integration of these loss functions strengthens the detector model in detecting and localizing the classes of different shapes and sizes.

F. Evaluation Metrics

The performance of the detector model was assessed by using standard evaluation metrics. These are: Precision, Recall, F1-score, as well as mean Average Precision (mAP). These parameters were calculated using the confusion matrix elements, including True Positives (TP), False Positives (FP), True Negatives (TN), and False Negatives (FN), to assess the effectiveness of the model.

Precision represents the ratio of accurately detected to the total number of detected objects, which is defined as:

$$Precision = \frac{TP}{TP+FP} \quad (5)$$

Recall measures the ratio of correctly detected to the total number of ground truth objects and is given by:

$$Recall = \frac{TP}{TP+FN} \quad (6)$$

The F1-score offers a fair assessment of accuracy and recall that is calculated as

$$F1_Score = \frac{2*Precision*Recall}{Precision+Recall} \quad (7)$$

The area under the Precision-Recall (P-R) curve represents Average Precision (AP) for the given class. The P-R curve illustrates the balance that exists between detection precision and comprehensiveness at different confidence levels. It is calculated by integrating precision with respect to recall over the interval [0,1].

$$AP = \int_0^1 Precision(Recall)d(Recall) \quad (8)$$

The mAP is derived by averaging AP over all 'N' traffic classes (here N=14).

$$mAP = \frac{1}{(N=14)}\sum_{i=1}^{N=14} AP_i \quad (9)$$

The mAP@0.5 refers to mean Average Precision evaluated at a specific threshold IoU value of 0.5, whereas mAP@0.5:0.95 is a metric that averages the mAP values for various IoU thresholds ranging from 0.5 to 0.95 at intervals of 0.05. It provides a rigorous and thorough assessment for testing the accuracy of object detection and localization at various thresholds.

IV. Results and Discussion

This section presents a comprehensive evaluation and analysis of the HETRA framework for real-time detection, tracking, and directional counting of multiple-class traffic. The effectiveness of the trained detector was assessed using universal evaluation metrics such as precision, recall, mean Average Precision (mAP), F1 measure, as well as analysis of the confusion matrix. Additionally, to assess robustness and real-world applicability, the proposed system was analysed using multiple recorded traffic videos with different levels of traffic density and lighting conditions.

A. Training Performance Analysis

Fig. 5 illustrates the comprehensive performance of the detector model over 200 epochs. The graph shows progressive reduction in box loss, classification loss, and DFL throughout the training process.

The training curves indicate stable convergence, with no significant indications of instability. Consequently, model generalization was assessed through validation metrics, such as precision, recall, and mean Average Precision (mAP), which is consistent with recent YOLOv8-based object detection studies. It may be noted that the model was validated throughout the training process, but the val/cls_loss recorded by YOLOv8 remained zero and therefore did not produce a visible curve in Fig. 5. As the training epoch increases, a steady improvement in precision and mAP values was observed, while moderate fluctuation was noticed in recall. This demonstrates efficient feature learning and generalization capability of the detector model.

B. Detection and Classification Performance Evaluation

The precision–confidence, recall–confidence, and F1-confidence curves obtained during model evaluation are illustrated in Fig. 6. Gradual improvement in the precision curve at higher confidence values was observed due to a reduction in false positives. On the other hand, the recall value decreased at a confidence threshold due to some true values being missed during confined detection. The F1-confidence curve achieved a peak F1-score of 0.63 at a confidence threshold of 0.33. This shows an optimal balance between precision and recall at a moderate threshold.

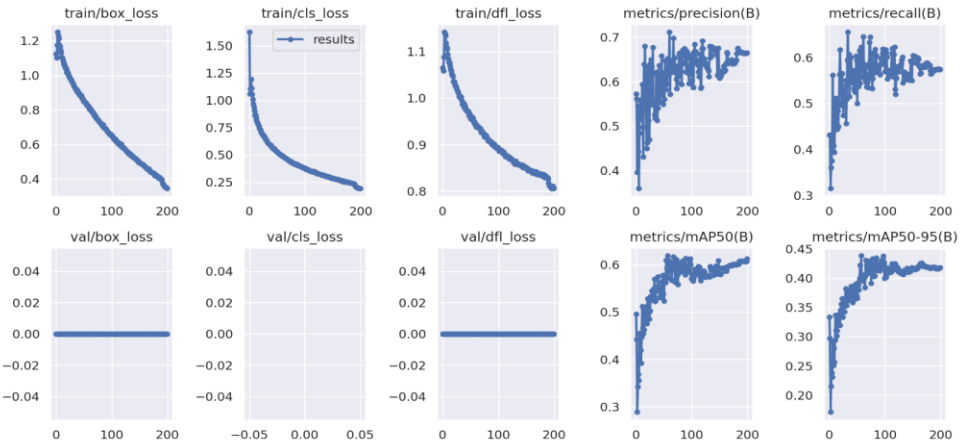

Fig. 5. Comprehensive training performance assessment of the detector model.

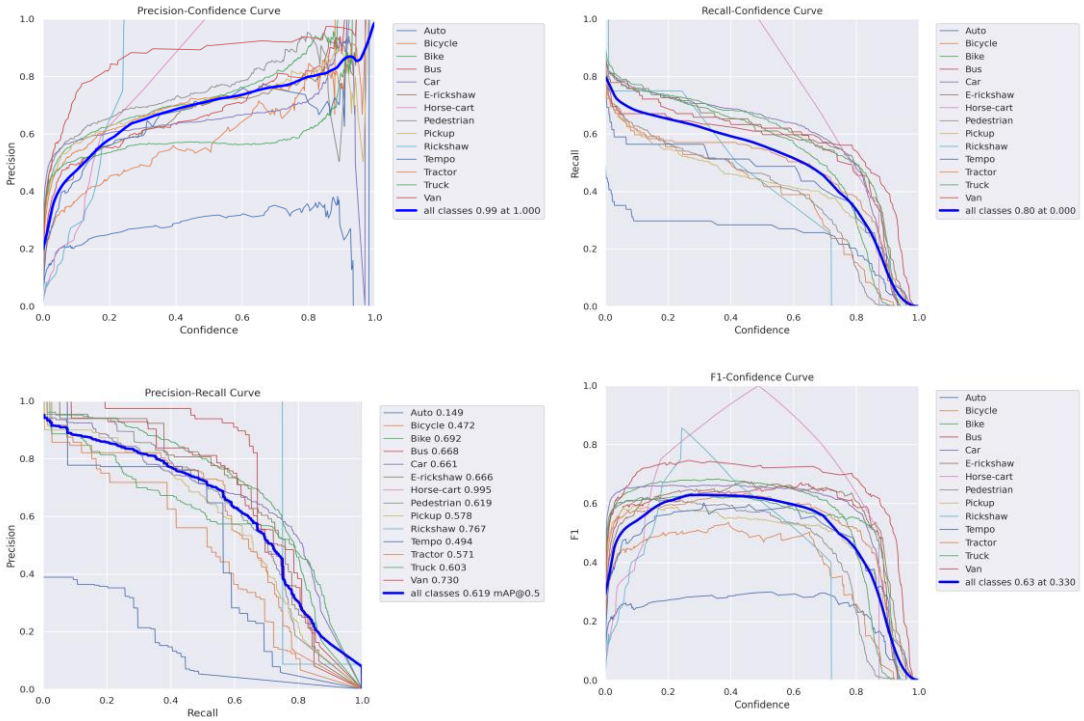

Fig. 6. Precision-Confidence, Recall-Confidence, Precision-Recall, and F1-Confidence curves of the YOLOv8l model for 14 different traffic classes.

The precision-recall curve indicated stable detection performance for major and visually distinguishable classes such as cars, buses, pickups, and trucks. Comparatively lower precision and recall values were observed for less- frequent classes including horse-cart and rickshaw, primarily due to the limited number of training instances available for these categories. Although the auto and bicycle classes contained a substantial number of instances, their detection performance also remained comparatively lower. This suggests that factors beyond class imbalance, including smaller object sizes, repeated occlusions, and high intra-class variability, significantly affected the detection performance under heterogeneous traffic conditions.

The trained model achieved precision, recall, mAP@0.5, and mAP@0.5:0.95 values of 71.15%, 65.52%, 61.9%, and 43.85%, respectively. These results indicate efficient detection and localization capability for various traffic participants. Whereas a comparatively lower performance was noticed for certain class may be due to less representation, small size, along with partial occlusions under dense traffic situations. The complete detection performance of the model can be attributed to multi-scale feature extraction and the diversity of the custom traffic dataset. This enabled the model to learn more vigorous features even in varying traffic densities, weak lane discipline, and frequent occlusions.

Although the performance curves provided a comprehensive assessment, the normalized confusion matrix offers detailed insights into classification behavior across different traffic classes, as presented in Fig. 7. There was considerable diagonal dominance for the most classes of traffic, indicating reliable

multi-class detection and classification. Classes such as bike, bus, car, horse-cart, e-rickshaw, and truck achieved higher classification accuracy due to their visuals and adequate representation within the traffic dataset. Comparatively lower accuracy was observed for classes like auto and rickshaw, which may be due to their visual similarity and small scale. Some discrepancies were also observed between visually similar categories, especially rickshaw vs. e-rickshaw as well as van vs. car. In addition, moderate confusion with the background was also noticed for small and partially hidden traffic participants. Despite these challenges, the confusion matrix illustrates the robustness and effectiveness of the model for detection and localization of a wide range of traffic participants.

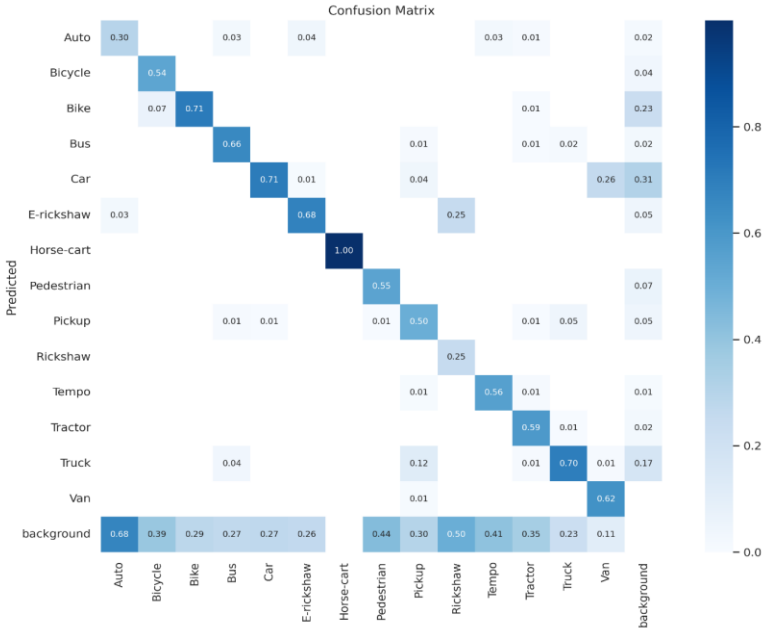

Fig. 7. Normalized confusion matrix obtained for custom dataset.

Fig. 8. Detection, localization and multi-class tracking results of the HETRA model under real-world traffic conditions.

C. Qualitative Analysis

The real-world traffic videos, each of approximately 5 minutes' duration, were recorded at the Teliyarganj Intersection in Prayagraj city and were then analyzed using the developed HETRA model. Fig. 8 illustrates a few sample frames representing the qualitative performance of the model under different lighting and traffic conditions. The model was evaluated under normal weather conditions. The visual outcomes indicate that multiple traffic classes were detected and localized simultaneously for large vehicles like buses and trucks, as well as smaller road users like bicycles and pedestrians.

The visual outcomes also show a substantial discrimination between visually similar traffic classes such as 'bicycles & bikes' and 'car & van'. This results in fewer identity swaps among various traffic categories. Furthermore, the model maintained reliable detection performance across multiple traffic classes at various distances and scales within the surveillance frames.

The successive sample frames also indicate the tracking results of various traffic participants. These demonstrate consistent preservation of class ID even under continuous moving and overlapping traffic flow. As shown in Fig. 8, the tracking sequences of car (IDs 105 & 126) crossed each other with their unique IDs. Also, small-class traffic like a bike (ID 127), moving in proximity to the car, preserved its consistent trajectory in the successive frames. It is also observed that the vulnerable road user (pedestrian ID 1116) retained its identity while crossing the road near the car (IDs 961&1122). These findings validate the suitability of the HETRA model for its sustained tracking capability under various traffic participants (from public transit mode bus to low mobility modes such as bicycles, e-rickshaws, as well as pedestrians) in mixed traffic conditions.

Some intermittent miss-detections and slight localization lapses were also observed by the model for small traffic classes under occluded conditions. However, overall qualitative performance of the model is found to be adequate for real-time traffic monitoring and applications. The visual outcomes validate the efficacy and practical utility of the DeepSORT-based tracker for multiclass traffic analysis under heterogeneous traffic conditions.

The counting performance was evaluated using multiple representative traffic videos. Unlike the conventional method, this study focuses on accomplishing bi-directional traffic flow, while maintaining separate real-time records for entering and leaving traffic movements. The class-wise directional traffic counting relies on the unique class ID, trajectory analysis, and a virtual counting line that works as a reference boundary within video frames. Representative example frames of class-wise directional traffic counting results are shown in Fig. 9.

As evident from Fig. 9, the traffic class is counted only once, and it is done when the traced traffic trajectory crosses the virtual counting line in the specific direction. This eliminates the duplicate counting of vehicles across successive frames and yields the desired class-wise traffic counting. This track-assisted counting approach facilitates precise estimation of directional traffic volume. The results also indicate that the developed approach supports the classification and counting of region-specific classes like auto and tempos alongside standard traffic classes.

The counting statistics were validated using multiple real-world traffic video recordings. Manual counts for both entering and leaving directions were acquired by visual inspection and thereafter compared with the automated counts obtained by HETRA. The traffic categories, namely horse-cart, tractor, and rickshaw, were not observed in the selected videos due to their absence in the recorded videos. Therefore, the counting results for these classes could not be evaluated. The directional traffic counting results corresponding to representative traffic phases are presented in Table III. The directional counting accuracy ranged from 80% to 96% across different traffic classes. An aggregate 1320 traffic classes were manually counted in cross-sample videos, whereas a total of 1181 participants estimated by HETRA achieved an overall counting accuracy of approximately 90%.

TABLE III. CLASS-WISE DIRECTIONAL TRAFFIC COUNTING PERFORMANCE OF THE MODEL

Traffic Class	Entry Count		Exit Count	
	Model	Manual	Model	Manual
Auto	72	84	83	96
Bicycle	39	46	54	66
Bike	141	152	167	179
Bus	45	50	34	38
Car	127	132	105	113
E-rickshaw	27	32	41	47
Pedestrian	33	37	24	27
Pickup	28	33	34	42
Tempo	40	47	36	41
Truck	7	8	10	11
Van	19	21	15	18
Total	**578**	**642**	**603**	**678**

Most recent studies primarily reported the detection accuracy and counting performance, whereas their computational efficiency was mostly ignored. The inference performance of the developed model was tested on an average compute in Google Colab using an NVIDIA T4 GPU with 16 GB memory. The mean preprocessing, inference, and post-processing times were 0.5 ms, 20.2 ms, and 2.2 ms per frame, respectively. This results in an overall processing time of approximately 23ms per frame, nearly 44 FPS (frames per second). Since the evaluation videos were recorded at 30FPS, the achieved processing speed is higher than the recording rate. Although GPU memory utilization was not explicitly profiled, the observed inference performance demonstrates the computational efficiency and practical scalability of the HETRA framework for real-time heterogeneous traffic analysis.

Fig. 9. Directionally classified traffic volume by the HETRA model in real time under heterogeneous traffic conditions.

Minor counting errors were noticed in rare circumstances, including highly congested conditions, abrupt direction changes, and intermittent ID changes, near the counting line. However, these remain limited and had a minute effect on the overall traffic counting results. While a slight reduction in accuracy was observed in relatively low light conditions, the overall results demonstrate the effectiveness of the model under different lighting conditions. Less frequent traffic categories like horse-carts, rickshaws, and tractors were not observed during representative counting assessment and so could not be included in the analysis.

Direct comparison of the reported performances should be interpreted with caution because of variation in dataset, class compositions, environmental conditions and evaluation methodologies. A concise comparative analysis with selected relevant studies is presented in Table IV. It can be observed from Table IV that most of the existing studies reported higher detection and counting performance in relatively structured traffic streams involving three or four vehicle classes only. In contrast, the HETRA system was tested under more challenging heterogeneous traffic conditions comprising fourteen traffic categories, including region-specific classes such as auto, tempo, horse-cart, and rickshaw. Therefore, the lower mAP@0.5 achieved by the HETRA framework is mainly due to the complexity associated with multi-class detection under dense, frequent occlusions and weak-lane discipline and class imbalance issues. Instead of optimizing for better performance for a limited number of traffic categories, the proposed framework was designed to offer robust multi-class detection, tracking, and directional counting under varying illumination levels, frequent occlusions, and weak lane discipline.

TABLE IV. COMPARATIVE ANALYSIS WITH EXISTING TRAFFIC MONITORING STUDIES

Study	Dataset	No. of classes	Precision (%)	Recall (%)	mAp@0.5 (%)	Counting Accuracy (%)
Duan et.al.[20]	VisDrone2019	10	60.29	46.34	49.64	-
Song et.al.[28]	Highway Scene	3	88.0	89.0	87.88	93.2
Sathiyaprasadet.al.[30]	Urban	4	96.8	96.5	96.3	90
Akoushideh et.al.[32]	Extracted from MSCOCO	3	98.0	97.0	98.0	88.84
Proposed HETRA framework	**Custom**	**14**	**71.15**	**65.51**	**61.9**	**90**

Overall, the results of the HETRA model indicate its capability for multi-class detection, tracking, and class-wise directional counting with commendable accuracy under both normal and relatively low light conditions. This emphasizes the model's potential for real-time traffic monitoring, class-wise traffic movement analysis, and other ITS applications.

V. CONCLUSION

The proposed HETRA, integrating YOLOv8 and DeepSORT, was developed and evaluated for real-time detection, tracking, and directional counting under heterogeneous Indian traffic circumstances. The developed system effectively handled mixed traffic streams consisting of motorized traffic classes, non-motorized traffic classes, and pedestrians by addressing the complexity of urban traffic in developing countries.

A custom annotated traffic dataset consisting of fourteen classes was created to train and evaluate the model under typical urban conditions, including congestion, occlusions, and unstructured traffic movement. The experimental results confirmed that the suggested approach can reliably detect, track, and directionally count the traffic participants, making it suitable for real-time traffic monitoring. The findings further demonstrated the model's robustness for congested traffic, poor lane discipline, and mixed traffic under varying light conditions. Importantly, the detection and counting of slow-moving and vulnerable road-user categories like bicycles and pedestrians alongside motorized traffic highlight its potential for comprehensive traffic surveillance.

Apart from its detection and counting performance, the proposed framework offers a solid foundation for the development of an AI-enabled intelligent transportation system. The classified traffic volume information, generated by the proposed methodology, can help with modal share analysis, congestion monitoring, road safety assessment, and adaptive traffic signal control. Consequently, the system offers a scalable and cost-effective solution for real-time traffic monitoring and future smart city traffic management, especially in developing countries.

Despite the promising performance, the developed system experiences some challenges under severe occlusions and low light conditions. Comparatively lower performance was noticed for some less-frequent traffic classes, which may be attributed to class imbalance. The current study is limited to normal weather conditions, but the performance of the developed model needs to be tested further under adverse weather conditions.

Future research will focus on enriching the custom dataset through the inclusion of more nighttime and adverse weather traffic images, investigating the sensitivity of tracking hyperparameters, and integrating the framework with signal control and edge computing platforms for large-scale smart city deployment.

Data Availability: The custom dataset used in this study is currently not publicly available because it forms part of the author's ongoing research work. The dataset will be made available from the corresponding author upon reasonable request after completion of the research.

Improving Arabic Relational Aggregated Search Using a Hybrid RAG and AraBERT Framework

***Abstract*—Aggregated search is challenged by data heterogeneity, redundancy, and irrelevant information, particularly in Arabic because of its rich morphology and dialectal diversity. This study proposes an AI-driven framework to enhance Arabic aggregated search by integrating Retrieval-Augmented Generation (RAG) with semantic clustering. The framework employs RAG to retrieve relevant information from multiple search verticals, including web pages, images, news articles, and videos, and to generate contextually enriched textual representations. These representations are encoded with AraBERT to produce 768-dimensional semantic embeddings, which are then compressed into compact latent feature vectors through a stacked autoencoder. K-Means clustering is then applied to organize the compressed representations into semantically coherent topic groups. The proposed framework was evaluated on nine Arabic datasets spanning five application domains: education, sports, information technology, healthy food, and weather. Experimental results demonstrate that the proposed approach increases the average silhouette score from 0.59 to 0.68, representing a 15% improvement over clustering based on raw aggregated search results. Ablation experiments further indicate that both Retrieval-Augmented Generation and stacked autoencoder–based feature compression independently contribute to the observed performance gains. These findings demonstrate the effectiveness of integrating Retrieval-Augmented Generation with semantic representation learning to improve the organization and clustering of Arabic aggregated search results.**

I. Introduction

Conventional search engines, such as Google and Bing, typically return ranked lists of hyperlinks, requiring users to examine multiple webpages and manually integrate the retrieved information. Although this approach is adequate for straightforward information needs, it becomes increasingly inefficient when relevant information is distributed across different content types and specialized search services.

Aggregated search addresses this limitation by combining results from multiple verticals, including web pages, images, news articles, and videos, within a unified search interface [1]. Presenting heterogeneous information in a single results page improves information accessibility and reduces the need to navigate between multiple search services [2]. Nevertheless, the retrieved results often differ considerably in structure, quality, and semantic content. Duplicate entries, fragmented snippets, irrelevant information, and limited contextual information frequently reduce the effectiveness of subsequent analysis and organization. These challenges are particularly pronounced for Arabic content, where rich morphology, orthographic variations, and dialectal diversity further complicate semantic interpretation.

Recent advances in large language models (LLMs) have significantly improved the ability of Natural Language Processing (NLP) systems to understand and generate human language. Despite their impressive capabilities, LLMs rely primarily on knowledge acquired during pretraining and therefore cannot reliably incorporate newly available or domain-specific information without access to external knowledge sources [3]–[5]. This limitation has motivated the development of Retrieval-Augmented Generation (RAG), which combines information retrieval with neural text generation. Instead of generating responses solely from model parameters, RAG retrieves relevant documents from an external knowledge base and uses the retrieved evidence to generate contextually grounded textual representations [6]–[9]. Consequently, the generated content is generally more informative, coherent, and factually supported than text produced without retrieval augmentation.

The quality of the RAG system is closely related to the semantic representations used throughout the retrieval pipeline. For Arabic, AraBERT has become one of the most effective pretrained language models because it is specifically designed to capture the linguistic characteristics of Arabic, including its rich morphology and orthographic variations [10], [11]. The resulting contextual embeddings provide meaningful semantic representations that are well suited for downstream information retrieval and clustering tasks. However, the high dimensionality of these embeddings may reduce clustering performance because of the curse of dimensionality. Stacked autoencoders address this challenge by learning compact latent representations that preserve the underlying semantic information while reducing redundancy and noise [12]. These compressed representations provide a more suitable feature space for clustering algorithms.

Among existing clustering techniques, K-Means remains an attractive choice because of its computational efficiency, scalability, and ability to partition semantically similar instances into coherent groups [13], [14]. When combined with high-quality semantic representations, K-Means provides an effective

mechanism for organizing heterogeneous search results into meaningful topical categories.

Motivated by these challenges, this study proposes a unified framework for aggregated Arabic search that integrates Retrieval-Augmented Generation, AraBERT embeddings, stacked autoencoders, and K-Means clustering into a single processing pipeline. The framework begins by collecting relational aggregated search results across multiple search verticals. The retrieved content is subsequently enriched using RAG to transform fragmented search snippets into coherent contextual representations. The generated text is then preprocessed and encoded with AraBERT, after which a stacked autoencoder learns compact semantic representations to reduce dimensionality. Finally, K-Means clustering is applied to organize the compressed representations into semantically coherent topic groups. Experimental evaluation on nine Arabic datasets covering education, sports, information technology, healthy food, and weather demonstrates that the proposed framework consistently outperforms raw aggregated search results and alternative approaches, resulting in significant improvements in clustering quality.

The remainder is organized as follows: Section II reviews related work. Section III outlines the challenges and summarizes our contributions. Section IV describes our methodology. Section V presents the experiment setup. Section VI presents results and discussion. Section VII presents the conclusion and future work.

II. Related Work

Natural Language Processing systems have traditionally relied on either retrieval-based or generative paradigms, each characterized by distinct strengths and inherent limitations. Retrieval-based approaches, including conventional search engines, efficiently identify relevant documents from large-scale collections but are limited to presenting existing information without synthesizing new knowledge [15]. In contrast, transformer-based generative models have substantially advanced natural language understanding and text generation, producing fluent and contextually coherent responses across a broad spectrum of applications [16]. Despite these capabilities, their reliance on parametric knowledge often leads to hallucinations and factual inconsistencies when external or recently acquired information is required.

Retrieval-Augmented Generation (RAG) was introduced to overcome these limitations by integrating information retrieval with neural text generation. Early retrieval-enhanced systems, such as DrQA, combined document retrieval with extractive answer generation, although their ability to synthesize information remained constrained [17]. Subsequent research demonstrated that retrieval and generation could be jointly optimized within a unified architecture. REALM demonstrated the feasibility of incorporating differentiable retrieval into language model pretraining [18], while the RAG framework proposed by Lewis et al. integrated dense passage retrieval with transformer-based generation, significantly improving factual grounding and contextual relevance in knowledge-intensive tasks [19].

Recent advances have focused primarily on strengthening the retrieval component of RAG systems. RAPTOR introduced hierarchical document organization to facilitate multi-level reasoning over complex knowledge sources [20]. Similarly, METRAG employed hierarchical summarization to improve the quality and informativeness of the contextual evidence provided to the language model [21]. Retrieval-aware fine-tuning strategies, such as RAFT, further enhanced model robustness by enabling language models to distinguish relevant evidence from distracting or irrelevant retrieved documents during training [22].

The application of RAG to Arabic Natural Language Processing has attracted growing research interest. Recent investigations have systematically evaluated chunking strategies, embedding models, reranking techniques, and large language models for Arabic retrieval tasks [23]. Their findings indicate that sentence-aware chunking, modern multilingual embedding models such as BGE-M3 and Multilingual-E5-large, and retrieval reranking consistently improve retrieval effectiveness and the factual reliability of generated responses.

Additional studies have examined semantic embedding models specifically for Arabic lexical retrieval [24]. Comparative evaluations involving AraBERT, CAMeLBERT, Multilingual-E5, and related models demonstrated that sentence-level semantic representations substantially outperform word-level embeddings. Furthermore, comparative assessments of generation models, including GPT-4, Gemini-1.5, Aya-8B, and AceGPT-13B, confirmed that generation quality remains an important factor influencing the overall performance of Arabic RAG systems.

Despite these advances, existing studies have primarily concentrated on improving retrieval accuracy and response generation, while comparatively little attention has been devoted to the semantic organization of heterogeneous aggregated search results. In particular, the integration of Retrieval-Augmented Generation with Arabic aggregated search across multiple search verticals, including web pages, images, news articles, and videos, remains largely unexplored. Furthermore, although previous studies have extensively evaluated embedding models for retrieval tasks, the use of RAG-enriched textual representations as input to a semantic clustering framework has not been investigated. The proposed framework addresses these research gaps by integrating Retrieval-Augmented Generation, AraBERT semantic embeddings, stacked autoencoders for nonlinear feature compression, and K-Means clustering into a unified framework for the semantic organization of aggregated Arabic search results.

III. Challenges and Contributions

The rapid expansion of Arabic digital content has intensified the demand for intelligent information retrieval systems capable of effectively discovering, integrating, and organizing information from diverse sources. Conventional search engines, such as Google and Bing, primarily employ keyword-based retrieval strategies.

Although effective for simple information needs, these approaches often fail to capture the underlying semantic intent of user queries. This limitation is particularly pronounced in Arabic because of its rich morphology, dialectal diversity, and orthographic variations, all of which complicate semantic matching and reduce retrieval effectiveness.

Aggregated search extends traditional retrieval by integrating results from multiple search verticals, including web pages, images, news articles, and videos, into a unified interface. Despite improved information accessibility, the aggregated output is inherently heterogeneous, often containing duplicate entries, irrelevant content, fragmented snippets, and insufficient context. These characteristics reduce the suitability of the retrieved content for downstream semantic analysis and clustering. Consequently, effective semantic enrichment and content refinement are essential before meaningful organization can be achieved.

Retrieval-Augmented Generation (RAG) provides an effective mechanism for enriching aggregated search results by integrating document retrieval with neural text generation. Instead of relying solely on fragmented search snippets, RAG retrieves the most relevant evidence from multiple search verticals and generates coherent, contextually grounded textual representations. By incorporating external knowledge during generation, RAG improves the relevance, completeness, and semantic consistency of the resulting content, thereby producing richer representations for subsequent analytical tasks.

Representing Arabic text remains challenging due to the language's complex morphological structure. Individual words may contain multiple prefixes and suffixes, while orthographic variations and diacritics can substantially alter lexical meaning. Conventional embedding models often struggle to preserve these linguistic characteristics, limiting their ability to capture semantic similarity accurately. AraBERT addresses these challenges through Arabic-specific pretraining and a customized WordPiece tokenization strategy designed to model Arabic's linguistic properties more effectively. Consequently, AraBERT generates contextualized semantic representations that better preserve lexical and semantic relationships, providing a robust foundation for downstream clustering.

The main steps of the proposed work can be summarized as follows:

- Collect relational aggregated search (RAS) results from multiple verticals, represented as text.
- Enrich the collected data using RAG to produce cleaner, more accurate datasets.
- Preprocess the RAG-generated output (remove diacritics and normalize characters).
- Generate 768-dimensional semantic vectors using AraBERT.
- Compress the embedding using a stacked autoencoder to extract the most informative features.
- Cluster the compressed features using K-Means to identify coherent topic groups.

The performance of the proposed framework is evaluated by comparing it with several alternative approaches:

- The author's previous work [25]: the same pipeline but without RAG (RAS + AraBERT + SAE + KM).
- RAG + AraBERT + PCA + KM: replaces SAE with PCA.
- RAG + AraBERT + KM: no feature extraction at all.
- RAG + Aravec + KM: replace AraBERT with Aravec.

The comparative analysis shows that the proposed method outperforms all of them.

IV. METHODOLOGY

The proposed framework comprises two principal modules: Data Collection (Fig. 1) and Data Enrichment (Fig. 2). The enrichment module consists of five sequential stages: Retrieval-Augmented Generation (RAG), text preprocessing, AraBERT-based semantic embedding, stacked autoencoder (SAE) feature extraction, and K-Means clustering. Unlike conventional aggregated search frameworks, the proposed approach introduces an intelligent semantic enrichment stage between the collection of Relational Aggregated Search (RAS) results and the clustering process. This intermediate stage employs RAG to improve the semantic quality of the retrieved information and utilizes a stacked autoencoder to learn compact latent representations that better preserve semantic relationships among search results.

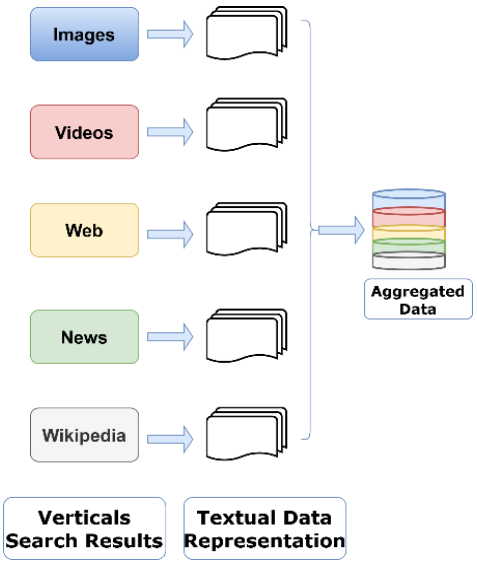

Fig. 1. Aggregated data from the aggregated search.

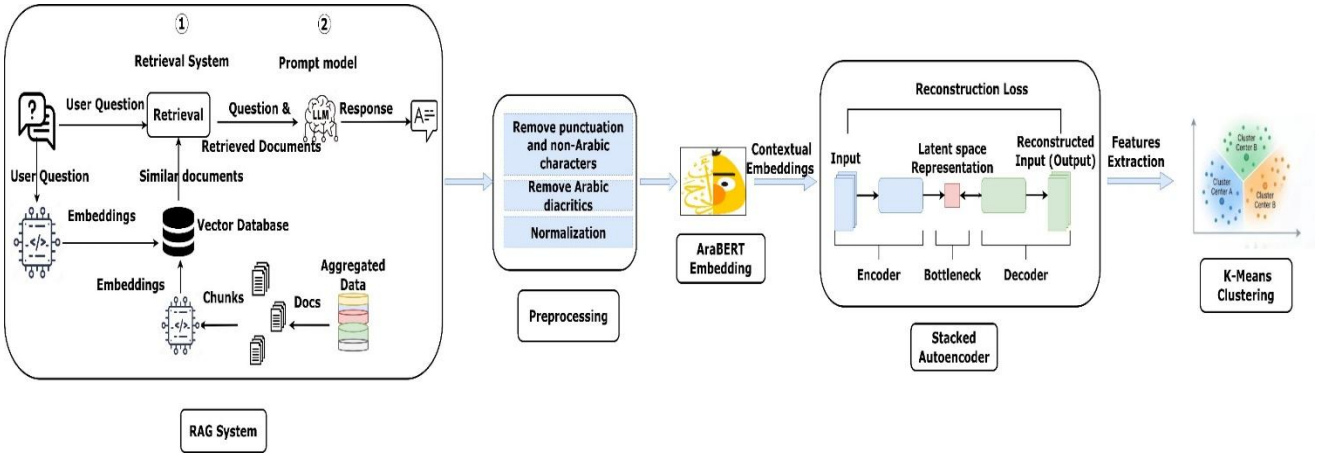

Fig. 2. The architecture of our proposed system comprises five steps: RAG system, pre-processing, results embedding (AraBERT), feature extraction (stacked autoencoder), and clustering algorithm (K-Means).

A. Aggregated Data Collection

Relational Aggregated Search (RAS) results are collected using publicly available application programming interfaces (APIs), including Google Search, Bing Search, YouTube Search, and Wikipedia. For each query, the top 100 results are retrieved from each search vertical, including web pages, images, news articles, and videos. Because each vertical returns information in a different format, all retrieved records are transformed into a unified textual representation consisting of the title, snippet, and URL. This standardized representation facilitates subsequent processing and semantic analysis. The complete data collection procedure is summarized in Algorithm 1. The resulting corpus serves as the input to the proposed data enrichment module.

Algorithm 1: Aggregated Data

Input: User Query Q
Output: Aggregated Data Text_Rep

Step 1: Query Verticals

```
Verticals = [ "web", "image", "video", "news"]
Text_Rep=""

FOR EACH V IN Verticals:

  Step 2: Retrieve the top 100 results
  results = SERP_API.search(engine=vertical, query=Q, num=100)

  Step 3: Process each result

  FOR EACH result IN results:
      // Extract core text components
      Title   = Doc.get ("title", "No Title")
      Snippet = Doc.get ("snippet", "")
      Link = Doc.get ("link", "No URL")

      // Skip results that have no usable text content
      IF Snippet IS EMPTY And Title IS EMPTY:
        CONTINUE

      Step 4: Build the text block
      Document_Block += "TITLE: " + Title + "\n"
      Document_Block += "CONTENT: " + Snippet + "\n"
      Document_Block += "Link: " + Link + "\n"
      Document_Block += "---" + "\n"

      // Append to the aggregate representation
      Text_Representation += Document_Block

  END FOR
END FOR

RETURN Text_Rep
```

B. Retrieval-Augmented Generation for Data Enrichment

The collected search results frequently contain duplicate entries, irrelevant information, fragmented snippets, and insufficient contextual information, all of which adversely affect clustering performance. To address these limitations, Retrieval-Augmented Generation (RAG) is employed as a semantic enrichment step prior to clustering. Rather than processing raw search snippets directly, the RAG framework retrieves the most relevant contextual information and generates coherent, contextually grounded textual representations. This enrichment process substantially reduces noise and redundancy while improving the completeness, consistency, and semantic relevance of the generated content, thereby providing higher-quality input for subsequent representation learning and clustering.

1) Building the vector database: To enable efficient semantic retrieval, the textual corpus is transformed into a vector database through the following stages, as illustrated in Fig. 3.

a) Chunking: The documents are segmented using a recursive text-splitting strategy that preserves the natural linguistic structure of the text by considering paragraph

boundaries, sentence boundaries, punctuation, and whitespace. This strategy generates semantically coherent text segments while maintaining contextual continuity.

b) Semantic embedding: Each text segment is encoded into a 384-dimensional dense vector using the sentence-transformers/paraphrase-multilingual-MiniLM-L12-v2 model. This multilingual embedding model was selected because it provides effective semantic representations for Arabic while maintaining high computational efficiency, making it well suited for large-scale semantic retrieval.

c) Vector storage: The generated embeddings, together with their corresponding text segments, are stored in Chroma, an open-source vector database that supports persistent storage and efficient cosine similarity search. Chroma was selected for its lightweight architecture, local deployment capability, and seamless integration with the LangChain framework, enabling efficient retrieval without additional infrastructure.

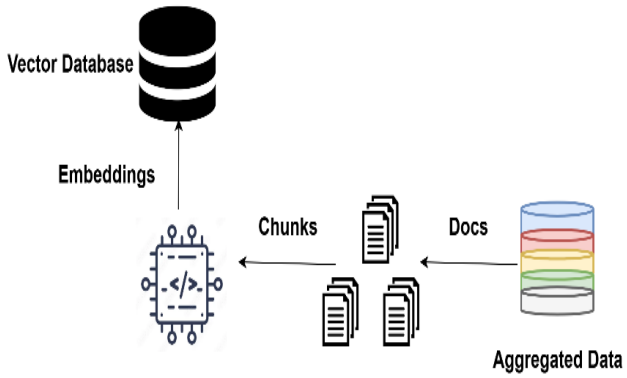

Fig. 3. Building a knowledge base.

2) Retrieval and generation workflow: For each Arabic user query, the Retrieval-Augmented Generation (RAG) pipeline performs five sequential stages, as illustrated in Fig. 4 and Algorithm 2.

a) Query representation: The input query is encoded using the same multilingual embedding model employed during vector database construction, thereby ensuring that queries and indexed documents reside within the same semantic embedding space.

b) Semantic retrieval: The generated query embedding is used to perform a similarity search within the Chroma vector database. The top ten semantically relevant text segments are retrieved based on cosine similarity.

c) Prompt construction: The retrieved text segments are concatenated to form a unified contextual representation, which is subsequently combined with the original query using a predefined prompt template. This enriched prompt provides the language model with the contextual evidence required to generate a grounded response.

d) Response generation: The constructed prompt is processed using the Google Gemini 1.5 Flash large language model to generate coherent, contextually grounded Arabic responses based on the retrieved evidence.

e) Dataset enrichment: Multiple semantically diverse responses are generated for each query and incorporated into the enriched dataset. These responses provide higher-quality textual representations for subsequent semantic embedding and clustering.

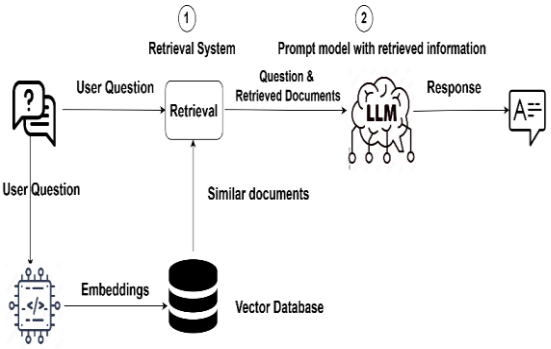

Fig. 4. RAG pipelines

Algorithm 2: RAG Framework

Input: User Question Q, Aggregated_Data
Output: Response
Step 1: Build Vector DB
FOR EACH document IN Aggregated_Data:
  Split document into chunks (C)
  Doc_Vecs = EMBEDDING_MODEL(C)
  Store (Doc_Vecs, C) in VectorDB
END FOR
Step 2: Similarity Ranking
Question_Vec = EMBEDDNG_MODEL(Q)
Scores = CALCULATE_COSINE_SIMILARITY(Question_Vec, Doc_Vecs)
Ranked_Docs = SORT (Doc_Vecs, BY = Scores, DESC)
Top_K_Context = Ranked_Docs[0:10]
Step 3: Prompt
Prompt_Template = "
You are an AI assistant for Arabic aggregated search.
Answer the user's question based only on the context provided.
Provide a single paragraph in Arabic. Do not add introductions, commentary, or information outside the context.
{Context}
Question:
{question}
Answer:
"
Final_Prompot = FILL (Prompt_Template, Context= Top_K_Context, question=Q)
Step 4: LLM Generation
Response = LLM_GENERATE(Final_Prompt)

3) Text preprocessing: The RAG-generated responses undergo a standardized preprocessing pipeline before semantic embedding. The preprocessing procedure includes:

- Removal of Arabic diacritics (Fatha, Damma, Kasra, Sukoon, and Shadda)
- Normalization of URLs, email addresses, and numerical expressions.

- Removal of Tatweel (elongation characters)
- Elimination of non-Arabic characters.
- Normalization of Alif variants (ا → آ، أ، إ)

Stop-word removal is not performed because AraBERT relies on function words (prepositions, conjunctions) to understand syntactic structure. The same preprocessing pipeline is applied to all documents to ensure consistent representation throughout the framework.

4) Semantic representation using AraBERT: Semantic representation is performed using the AraBERTv2-base model, a transformer-based language model pretrained specifically for Arabic [11]. Each preprocessed document is tokenized using the AraBERT WordPiece tokenizer. Documents exceeding the maximum sequence length are truncated, whereas shorter sequences are padded to a fixed length of 512 tokens.

The implementation is based on the Hugging Face Transformers library aubmindlab[1] using the aubmindlab/bert-base-arabertv02 pretrained model. Contextual document representations are obtained from the final hidden state of the [CLS] token, resulting in a 768-dimensional semantic embedding for each document. These embeddings capture the overall contextual meaning of the document and serve as input to the subsequent feature-extraction stage.

5) Stacked Autoencoder (SAE): To reduce the dimensionality of the AraBERT semantic embeddings, a stacked autoencoder (SAE) is employed as a nonlinear feature extraction model. The SAE learns a compact latent representation by encoding the original 768-dimensional embedding into a lower-dimensional feature space, then reconstructing the input from this compressed representation. Successful reconstruction indicates that the latent representation preserves the most informative semantic characteristics while eliminating redundant information.

As illustrated in Fig. 5, the proposed SAE architecture consists of three principal components:

- Encoder: Progressively transforms the high-dimensional input embeddings into a compact latent representation.
- Latent Space (Bottleneck): Represents the compressed semantic feature vector used for the subsequent clustering stage.
- Decoder: Reconstructs the original embedding from the latent representation.

Model training is performed by minimizing the reconstruction error between input embeddings and their reconstructions using the Mean Squared Error (MSE) loss. The Rectified Linear Unit (ReLU) activation function is adopted throughout the hidden layers because of its computational efficiency and its ability to alleviate the vanishing gradient problem. A linear activation function is employed in the output layer to reconstruct continuous embedding values. Network parameters are optimized through backpropagation until convergence.

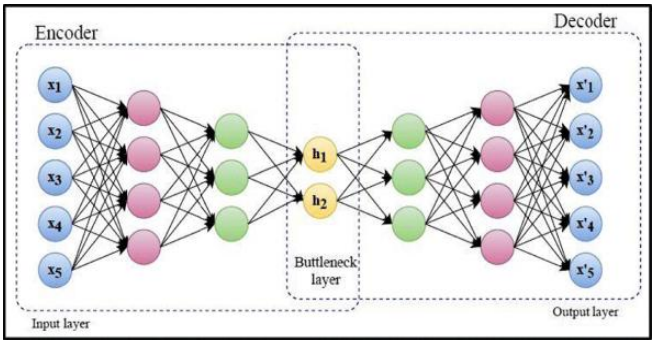

Fig. 5. Autoencoder architecture [26]

Because the experimental datasets differ in size, topic distribution, and semantic complexity, a single stacked autoencoder architecture was not suitable for all datasets. Therefore, several candidate architectures and hyperparameter configurations were evaluated empirically for each dataset. The final architecture was selected based on its validation performance, considering both the lowest reconstruction loss and the highest clustering quality, as measured by the Silhouette coefficient. This adaptive selection strategy balances feature compression with clustering performance while reducing the risk of underfitting or overfitting across datasets. The final configurations adopted in this study are summarized in Table I.

TABLE I. HYPERPARAMETERS FOR STACKED AUTOENCODER

Parameter	Optimized Value	Description
Input dimensions	768	AraBERT's dimensions
Hidden dims	(512, 256, 128, 64, 32, 16, 2) / (512, 256, 128, 64)	Hierarchical stages of feature compression.
Activation Function	ReLU	A non-linear function that is used between stacked layers.
Learning Rate (lr)	0.001	Step size for the Adam optimizer.
Batch Size	64 / 32	Number of samples processed per iteration.
Max_Epochs	100	Maximum training iterations

In the proposed architecture, for certain datasets, the encoder progressively reduces the original 768-dimensional AraBERT embeddings through successive hidden layers with 512, 256, 128, 64, 32, and 16 neurons before generating the final two-dimensional latent representation for clustering. This adaptive architecture enables effective feature compression while preserving the semantic structure required for accurate clustering.

During the decoding stage, the two-dimensional latent representation is progressively reconstructed through a sequence of hidden layers with 16, 32, 64, 128, 256, and 512 neurons. The final output layer restores the original 768-dimensional feature space, producing a reconstructed embedding corresponding to the input representation. The reconstruction quality is quantified

1 https://huggingface.co/aubmindlab/

by computing the Mean Squared Error (MSE) between the original and reconstructed embeddings, which serves as the optimization objective during training.

Model optimization is performed using the Adam optimizer with an initial learning rate of 0.001. Depending on the size and characteristics of each dataset, a batch size of either 32 or 64 is adopted. Training is conducted for up to 100 epochs, with an early stopping strategy employed to improve generalization and prevent overfitting. Specifically, training is terminated if the validation loss does not improve for 10 consecutive epochs, and the model parameters corresponding to the lowest validation loss are retained.

6) K-Means clustering: The compressed latent representations generated by the stacked autoencoder are subsequently partitioned into semantically coherent groups using K-Means clustering. For each dataset with T predefined target topics, the number of clusters is set to K = T + 1. The additional cluster is designated as "Other" and is intended to accommodate documents that cannot be reliably assigned to any predefined topic category, thereby improving the semantic purity and separation of the primary clusters. The K values adopted for each dataset are summarized in Table II.

TABLE II. DATASETS USED IN OUR EXPERIMENTS

Dataset	Target Topics	Dataset Size	K (clusters)	Clusters Label
D1	Education, Sports	383	3	Education, Sports, Other
D2	Education, IT	445	3	Education, IT, Other
D3	Sports, IT	458	3	Sports, IT, Other
D4	Education, Sports, IT	643	4	Education, Sports, IT, Other
D5	Weather, Healthy Food	439	3	Weather, Healthy Food, Other
D6	Sports, Healthy Food	426	3	Sports, Healthy Food, Other
D7	Healthy Food, Weather, Education	624	4	Healthy Food, Weather, Education, Other
D8	Sports, Healthy Food, Weather, Education	822	5	Sports, Healthy Food, Weather, Education, Other
D9	Education, Sports, Weather, IT	854	5	Education, Sports, Weather, IT, Other

K-Means was selected because the proposed stacked autoencoder transforms high-dimensional AraBERT embeddings into a compact latent feature space characterized by high intra-cluster cohesion and enhanced inter-cluster discrimination. Such representations are particularly well-suited to the centroid-based optimization strategy employed by K-Means, enabling effective partitioning of semantically similar documents while maintaining low computational complexity. Furthermore, because the semantic categories are known in advance, the value of K can be specified directly, without requiring additional cluster-estimation procedures. To improve the stability and reproducibility of the clustering results, K-Means was initialized using the scikit-learn library in Python, with a fixed random seed (random_state=42) to ensure reproducibility of the experimental results.

V. EXPERIMENTAL SETUP

This section describes the experimental configuration, dataset construction process, and evaluation criteria used to assess the effectiveness of the proposed framework. All experiments were implemented in Python using the PyTorch deep learning framework and executed on a 64-bit Windows 10 workstation equipped with an Intel Core i7 processor and 16 GB of RAM, as well as on Google Colab with GPU acceleration.

A. Data Collection and Dataset Construction

Relational aggregated search results were collected from eight search verticals using the Google Search APIs (Web, News, Images, and Videos) and Bing Search APIs (Web, News, Images, and Videos), using the SERP API [2] and the Wikipedia API. Five representative Arabic topics were selected for the experiments: التعليم (Education), الرياضة (Sports), تكنولوجيا المعلومات (Information Technology), الغذاء الصحي (Healthy Food), and الطقس (Weather). For each topic, the top 100 search results were retrieved from every search vertical.

To ensure consistency across heterogeneous sources, each retrieved record was transformed into a standardized textual representation comprising the document title, descriptive snippet, and source URL.

The collected search results were subsequently processed using the proposed Retrieval-Augmented Generation (RAG) framework. For each topic, multiple Arabic information-seeking questions were formulated to retrieve relevant contextual evidence and generate coherent Arabic paragraphs. These generated responses constituted the enriched corpus used throughout the experimental evaluation.

Nine experimental datasets, denoted D1–D9, were constructed by combining different pairs and groups of topic-specific documents to evaluate the proposed framework under varying levels of semantic diversity. The composition of each dataset is summarized in Table II.

B. Evaluation Metrics

The effectiveness of the proposed framework was evaluated using two widely adopted internal clustering validation measures: the Silhouette Coefficient [27] and the Davies–Bouldin Index (DBI) [28].

The Silhouette Coefficient quantifies both cluster cohesion and inter-cluster separation, producing values within the range [-1, 1]:

$$\text{Silhouette Score} = (b - a) / \max (a , b) \quad (1)$$

where, (a) denotes the average distance between a sample and all other samples within the same cluster, while (b) represents the average distance between that sample and observations belonging to neighboring clusters. Higher Silhouette values indicate stronger cluster cohesion and better

2 https://serpapi.com/

separation, whereas negative values suggest potential misclassification.

The Davies–Bouldin Index (DBI) evaluates clustering quality by jointly considering intra-cluster compactness and inter-cluster separation. It is computed as:

$$DB = \frac{1}{k}\sum_{i=1}^{k} \max\left(\frac{\Delta(X_i)+\Delta(X_j)}{\delta(X_i,X_j)}\right) \quad (2)$$

where, $(\Delta(X_i))$ represents the average intra-cluster distance within cluster (X_i), and $(\delta(X_i, X_j))$ denotes the distance between clusters (X_i) and (X_j). Lower DBI values indicate compact, well-separated clusters and therefore correspond to superior clustering performance.

VI. Results and Discussion

The proposed framework was evaluated using nine experimental datasets representing different topic combinations and varying levels of semantic complexity. The analysis was conducted in two stages. First, the overall clustering performance of the proposed framework was examined. Second, comparative experiments were performed to quantify the contribution of each major component.

A. Performance Analysis of the Proposed Framework

Table III summarizes the clustering performance of the proposed RAG + AraBERT + SAE + K-Means framework across all experimental datasets. The obtained Silhouette coefficients consistently exceed 0.65, indicating strong intra-cluster cohesion and clear inter-cluster separation. These results demonstrate that the proposed semantic representation effectively preserves topic-specific characteristics while maintaining sufficient discrimination between different semantic categories.

TABLE III. Clustering Evaluation of the Proposed Method

Dataset	Silhouette Score	Davies-Bouldin Index
D1	0.72	0.32
D2	0.70	0.42
D3	0.68	0.49
D4	0.68	0.38
D5	0.66	0.49
D6	0.70	0.45
D7	0.65	0.45
D8	0.66	0.42
D9	0.69	0.37

The proposed framework also exhibits stable performance as the semantic complexity of the datasets increases. Datasets D8 and D9, which comprise four distinct topics partitioned into five clusters, achieved Silhouette scores of 0.66 and 0.69, respectively. These findings indicate that the compressed latent representations generated by the stacked autoencoder remain highly discriminative even when multiple topics are simultaneously considered.

The Davies–Bouldin Index further supports these observations. Across all datasets, DBI values remain below 0.50, indicating compact cluster formation and substantial separation among neighboring clusters. Collectively, these results demonstrate that the proposed framework consistently produces well-defined semantic clusters under varying experimental conditions.

B. Comparative Evaluation

To evaluate the effectiveness of the proposed feature extraction strategy, the stacked autoencoder was compared with Principal Component Analysis (PCA), a widely adopted linear dimensionality reduction technique. Clustering performance was assessed using the Silhouette Coefficient and the Davies–Bouldin Index, where higher Silhouette values and lower DBI values indicate superior clustering quality.

As shown in Table IV, the proposed RAG + AraBERT + SAE + K-Means framework consistently outperforms the RAG + AraBERT + PCA + K-Means configuration across all evaluation metrics. The nonlinear feature-learning capability of the stacked autoencoder preserves complex semantic relationships that cannot be adequately captured by linear projection, resulting in more compact and better-separated clusters.

TABLE IV. Comparison of Alternative Methods in Terms of Silhouette Score and Davies-Bouldin Index.

Method	Avg. Silhouette	Avg. DBI
RAG + AraVec + KM	0.15	2.12
RAG + AraBERT + KM	0.18	1.99
RAG + AraBERT + PCA + KM	0.44	0.99
RAG + AraBERT + SAE + KM (Ours)	**0.68**	**0.42**

The contribution of nonlinear feature compression is further illustrated by comparing AraBERT embeddings before and after dimensionality reduction. Without the stacked autoencoder, AraBERT achieved a Silhouette score of 0.18, representing a modest improvement over AraVec (0.15). Incorporating the stacked autoencoder increased the average Silhouette coefficient to 0.68, demonstrating that nonlinear representation learning substantially enhances the discriminative structure of the embedding space before clustering.

The effectiveness of the proposed Retrieval-Augmented Generation (RAG) stage was further evaluated by comparing the current framework with the authors' previous approach (baseline), Aggregated + AraBERT + SAE + K-Means [25], which operated directly on raw aggregated search results without semantic enrichment. The comparison presented in Table V demonstrates that introducing RAG consistently improves clustering quality across all nine datasets. The average Silhouette coefficient increased from 0.59 to 0.68, corresponding to an improvement of approximately 15%.

The performance gain is particularly evident for datasets containing semantically related topics, such as D2, where lexical overlap increases the difficulty of cluster separation. By transforming fragmented search snippets into coherent, context-aware representations, the RAG module reduces semantic ambiguity and strengthens topic-specific representations prior to embedding. Consequently, documents belonging to the same

semantic category become more tightly grouped, while the separation between different topic categories increases. This behavior is maintained even for the most challenging datasets containing three or more topic categories (e.g., D4, D7, D8, and D9), demonstrating the robustness of the proposed framework as semantic complexity increases.

TABLE V. COMPARISON OF SILHOUETTE SCORES OF K-MEANS WITH OUR PREVIOUS METHOD.

Dataset	RAS + AraBERT + SAE + KM (baseline)	RAG + AraBERT + SAE + KM (proposed)
D1	0.67	**0.72**
D2	0.59	**0.70**
D3	0.62	**0.68**
D4	0.59	**0.68**
D5	0.63	**0.66**
D6	0.65	**0.70**
D7	0.55	**0.65**
D8	0.54	**0.66**
D9	0.55	**0.69**

These improvements can be attributed to the semantic enrichment performed by the RAG module. Rather than relying directly on heterogeneous aggregated search snippets, the framework generates coherent, contextually grounded textual representations that provide richer semantic information for subsequent embedding and clustering. The resulting representations contain less redundancy, reduced contextual ambiguity, and improved semantic consistency, thereby enabling the downstream feature extraction and clustering stages to operate on higher-quality input data.

To determine whether the observed performance gains were statistically significant, both the paired t-test and the Wilcoxon signed-rank test were performed using the Silhouette coefficients obtained across the nine datasets. The proposed framework achieved an average Silhouette coefficient of 0.682 ± 0.023, compared with 0.599 ± 0.047 for the baseline approach. The paired t-test confirmed that the improvement was statistically significant ($t = 6.68$, $p = 0.00016$), while the Wilcoxon signed-rank test produced a similarly significant result ($p = 0.0039$).

Hypothesis testing was subsequently conducted using a significance level of $\alpha = 0.05$. The null hypothesis (H_0) assumed that no statistically significant difference exists between the baseline aggregated search framework and the proposed RAG-enhanced framework. The alternative hypothesis (H_1) stated that the proposed framework yields superior clustering performance. Because the p-values obtained from both statistical tests were substantially lower than the predefined significance level, the null hypothesis was rejected in favor of the alternative hypothesis. These findings provide strong statistical evidence that the improvements achieved by the proposed framework are unlikely to have occurred by chance and instead result from integrating Retrieval-Augmented Generation with semantic representation learning.

VII. CONCLUSION AND FUTURE WORK

This study presented an intelligent framework for enhancing Arabic aggregated search by integrating Retrieval-Augmented Generation (RAG), contextual semantic representation, nonlinear feature learning, and unsupervised clustering. By enriching heterogeneous search results before semantic analysis, the proposed framework effectively reduced contextual ambiguity and redundancy while improving the semantic quality of the retrieved information. The enriched representations were subsequently encoded using AraBERT, compressed through a stacked autoencoder, and organized into semantically coherent topic clusters using the K-Means algorithm. Experimental evaluation on nine Arabic datasets spanning five application domains demonstrated the effectiveness and robustness of the proposed framework. Compared with clustering based on raw aggregated search results, the proposed approach increased the average Silhouette coefficient from 0.59 to 0.68, corresponding to an improvement of approximately 15%. The framework consistently achieved superior clustering performance across all experimental datasets and outperformed alternative dimensionality reduction and embedding approaches, including Principal Component Analysis (PCA), direct clustering of AraBERT embeddings, and AraVec-based representations. Statistical analysis further confirmed that these improvements were significant, demonstrating the effectiveness of integrating Retrieval-Augmented Generation with semantic representation learning for Arabic aggregated search.

Future research will investigate more advanced Retrieval-Augmented Generation architectures, including Agentic RAG, Corrective RAG (CRAG), Modular RAG, and Graph RAG, to further improve retrieval accuracy, reasoning capability, and factual consistency. Additional research directions include evaluating stronger multilingual retrieval models, incorporating retrieval reranking mechanisms, and extending the proposed framework to larger and more diverse Arabic corpora to assess its scalability and generalization across broader information retrieval applications.

Facultad de Ingeniería, Universidad Tecnológica de los Andes, Abancay, Perú[2, 3]

***Abstract*—The increasing occurrence of incidents related to public safety, environmental issues, transportation, and civil defense requires more efficient response mechanisms from local governments. However, the absence of an integrated digital tool makes it difficult to accurately identify the location, timing, and frequency of critical incidents in real time, thereby limiting the response capacity of public institutions. This study aims to design, implement, and evaluate a mobile application for incident management to streamline the reporting process and facilitate timely responses to events reported by citizens. The application was developed using the Agile Scrum methodology. Flutter was employed for mobile application development, while PHP and RESTful APIs were used for backend services, with MySQL handling data storage and incident geolocation. In addition, location-based services and web-based visualization components were incorporated to support monitoring and information access. A pre-experimental research design with a single-group pretest–posttest approach was adopted. The results revealed a 99.26% reduction in incident registration time and a 31.68% decrease in immediate response time. The usability of the proposed application was assessed using the Computer System Usability Questionnaire (CSUQ), administered to 257 participants, showing a high level of user satisfaction. Overall, the findings demonstrate that the developed mobile application significantly improves incident management processes and supports the digital transformation initiatives of local governments.**

***Keywords*—Mobile application; incident management; local government; Agile Scrum; usability evaluation; CSUQ; digital transformation.**

I. Introduction

Public safety has become a major concern in Peru, particularly due to the increasing number of incidents reported in recent years. Between 2020 and 2024, both crime rates and citizens' perceptions of insecurity increased considerably. According to national statistics, the victimization rate rose from 18.2% in 2021 to 27.1% in 2024, while more than 80% of the population perceived insecurity as one of the country's most pressing issues [1]. In response to this situation, approximately 66% of municipalities provide public security services through local patrol units (Serenazgo), involving more than 42,000 officers nationwide [2].

Incident management in local governments extends beyond public safety. Environmental complaints, civil defense emergencies, and traffic-related events also require timely and coordinated responses. The Environmental Assessment and Enforcement Agency (OEFA) reported that more than 6,000 environmental complaints have been processed since 2024 through digital platforms such as SINADA, with many cases originating from local issues including solid waste disposal, wastewater discharges, and noise pollution [3]. Likewise, the National Emergency Operations Center (COEN) reported that more than 5,400 emergencies, including heavy rainfall, landslides, and mudslides, were registered between December 2024 and March 2025 [4]. In many cases, local governments are responsible for managing these situations despite lacking early warning mechanisms, rapid response resources, and adequate systems for documenting emergency events.

Similarly, the National Road Safety Observatory reported more than 86,000 traffic accidents and over 3,000 fatalities in Peru during 2024 [5]. Although municipalities, police departments, and healthcare institutions are involved in responding to these events, the lack of a common incident management platform often results in fragmented information and reduced operational efficiency [6], [7].

Recently, local governments have increasingly adopted digital technologies to modernize administrative processes and strengthen communication with citizens [8]. Mobile government (m-government) initiatives have emerged as an important component of this transformation, enabling public services to be delivered through smartphones and other mobile devices. These technologies facilitate real-time access to information, improve service accessibility, and enhance interactions between citizens and government institutions [9], [10].

Incident management represents a critical process for local governments because it directly affects public safety, environmental protection, civil defense, and urban services. Effective incident management requires rapid reporting, accurate classification, efficient communication among stakeholders, and timely response actions. Nevertheless, many municipalities still rely on manual procedures and isolated information systems, leading to delays in both incident notification and response activities [11], [12]. Experiences from smart city initiatives have demonstrated the importance of digital citizen platforms capable of integrating incident reporting, geolocation, and real-time communication functionalities. Motivated by these needs, this study proposes the design, implementation, and evaluation of a mobile application for real-time incident management in the context of

local governments, aiming to strengthen response and monitoring processes.

The main contributions of this work are threefold. First, a mobile application architecture for local government incident management is proposed, enabling real-time monitoring and coordination among the responsible departments. Second, the proposed solution is implemented and validated in an operational environment. Third, the impact of the application is assessed using quantitative indicators associated with incident registration and response times, as well as through usability evaluation using the Computer System Usability Questionnaire (CSUQ) [19]. The results demonstrate that mobile technologies constitute an effective tool for improving incident management processes and supporting digital transformation initiatives in local governments.

II. Related Work

Several studies have shown that mobile government applications contribute to improving public services when their design prioritizes accessibility, usability, and citizen-centered experiences. Previous research has highlighted that the adoption of mobile solutions by local governments has accelerated due to the growing demand for more efficient and personalized digital services [13]. Digital accessibility has also been identified as a key factor influencing the acceptance and effective use of government applications, particularly those intended to enhance public safety and support diverse groups of citizens [14].

Research on mobile-based incident reporting systems has demonstrated the benefits of integrating features such as image capture, textual descriptions, GPS location, and web-based administrative interfaces. These functionalities facilitate the registration, monitoring, and management of incidents reported by citizens, thereby improving communication between communities and government institutions [15]. Such findings indicate that mobile technologies and integrated management platforms can significantly enhance the efficiency of incident response processes.

Smart city research has further emphasized the role of citizen reporting systems as mechanisms for digital participation. Previous studies have shown that smart city applications enable citizens to report urban issues, collaborate with authorities, and actively contribute to decision-making processes [16]. Citizen participation has been recognized as a key factor in increasing the effectiveness and relevance of urban solutions when properly integrated into planning and management activities [17]. Likewise, sustainable smart city initiatives have demonstrated that citizen engagement directly influences urban sustainability outcomes [18]. Other studies have highlighted that technological solutions for sustainable urban development require not only digital infrastructures but also effective interactions between governments and citizens [19]. Collectively, these findings support the development of mobile applications that extend beyond process automation and strengthen the relationship between citizens and local governments.

In recent years, decentralized incident reporting models have gained increasing attention. A decentralized framework for smart city governance based on community participation was proposed in [20], demonstrating that citizens can act as active sensors by reporting incidents and contributing to urban management. Similarly, the platform presented in [21] incorporates citizen reporting, case tracking, and analytical tools to support decision-making processes. These studies illustrate the transition from conventional incident management approaches toward intelligent and collaborative platforms. From the perspective of digital government, previous research has emphasized that digital public services foster regional innovation ecosystems and support sustainable development processes [7]. In this context, the digitalization of incident registration and management processes can improve institutional efficiency while generating valuable information for public administration.

Several studies investigating mobile government services have identified usability, perceived usefulness, trust, service quality, and citizen satisfaction as key determinants of continuous usage intentions [22], [23]. Consequently, usability has emerged as one of the most important factors influencing the success of mobile applications.

The Computer System Usability Questionnaire (CSUQ), originally proposed in [24], has become one of the most widely used instruments for assessing user satisfaction with computer systems. Subsequent studies have identified usability attributes such as efficiency, learnability, satisfaction, and accessibility as essential quality dimensions of mobile services [25]. Moreover, user-centered redesign approaches have been shown to substantially improve user experience in emergency-oriented mobile applications [26]. To address common usability problems in mobile systems, the MUG-10 framework was introduced in [27], emphasizing the importance of intuitive interfaces and simplified interaction processes. In fact, many mobile applications fail not because of insufficient functionality, but because of poor usability and overly complex interaction mechanisms. In addition, focused usability evaluation approaches have also proven valuable for digital applications aimed at citizen participation and public governance [28].

Regarding technological implementation, Flutter has emerged as a popular cross-platform framework for developing Android and iOS applications using a single codebase. Previous studies have reported that Flutter simplifies mobile application development while enabling highly interactive interfaces and delivering competitive performance [29]. Comparative analyses between Flutter and alternative technologies, such as React Native, have revealed advantages in terms of productivity, visual consistency, and cross-platform capabilities [30]-[32]. These findings support the selection of Flutter as a suitable technology for developing mobile applications aimed at incident management in local government environments.

III. Methodology

A. Research Type and Design

This study is classified as applied research, as it addresses a practical problem associated with incident management in a local government environment. A pre-experimental design based on a single-group pretest–posttest approach was employed to assess the impact of the proposed mobile

application. Table I summarizes the elements of the experimental design.

TABLE I. DESCRIPTION OF THE PRE-EXPERIMENTAL DESIGN

Element	Description
Ge	Experimental group
O1	Measurement conducted before the implementation of the mobile application
X	Mobile application intervention
O2	Measurement conducted after the implementation of the mobile application

B. Study Area

The study was conducted at the Provincial Municipality of Abancay, located in the Apurímac region of Peru. This institution is responsible for managing incidents related to public safety, traffic, civil defense, and environmental issues reported by citizens.

Prior to the implementation of the proposed solution, incident registration and monitoring activities relied on conventional procedures based on manual records and telephone communication. These practices often resulted in delays in response and limited the availability of information required for effective decision-making.

C. Population and Sample

The target population consisted of 47,744 inhabitants of the district of Abancay, ranging in age from 15 to 70 years and representing both urban and rural areas, according to data provided by the National Institute of Statistics and Informatics (INEI). A non-probabilistic purposive sampling strategy was adopted, selecting citizens who reported incidents and members of the local public security service (Serenazgo) responsible for incident response and follow-up activities. The sample size was estimated using the finite population formula, resulting in a total of 267 participants.

D. Mobile Application Development

The mobile application was developed following the Agile Scrum methodology. The development process was organized into four iterative and incremental sprints, each incorporating specific functionalities associated with user management, incident reporting, operational response, and report generation. This approach enabled the continuous delivery of functional increments throughout the development cycle.

The process included requirements elicitation and analysis, Product Backlog creation, and sprint planning activities. Each sprint comprised implementation, functional testing, sprint review, and retrospective phases, facilitating continuous improvement and ensuring the progressive integration of system functionalities.

Fig. 1 presents the Scrum workflow adopted during the development process, illustrating the functionalities implemented in each sprint, the stakeholders involved, and the activities carried out throughout the iterative development cycles.

E. System Architecture

Fig. 2 presents the three-layer architecture implemented for the proposed mobile application. This architecture was designed to separate the user interface, business logic, and data management components, thereby improving maintainability, scalability, and future system expansion.

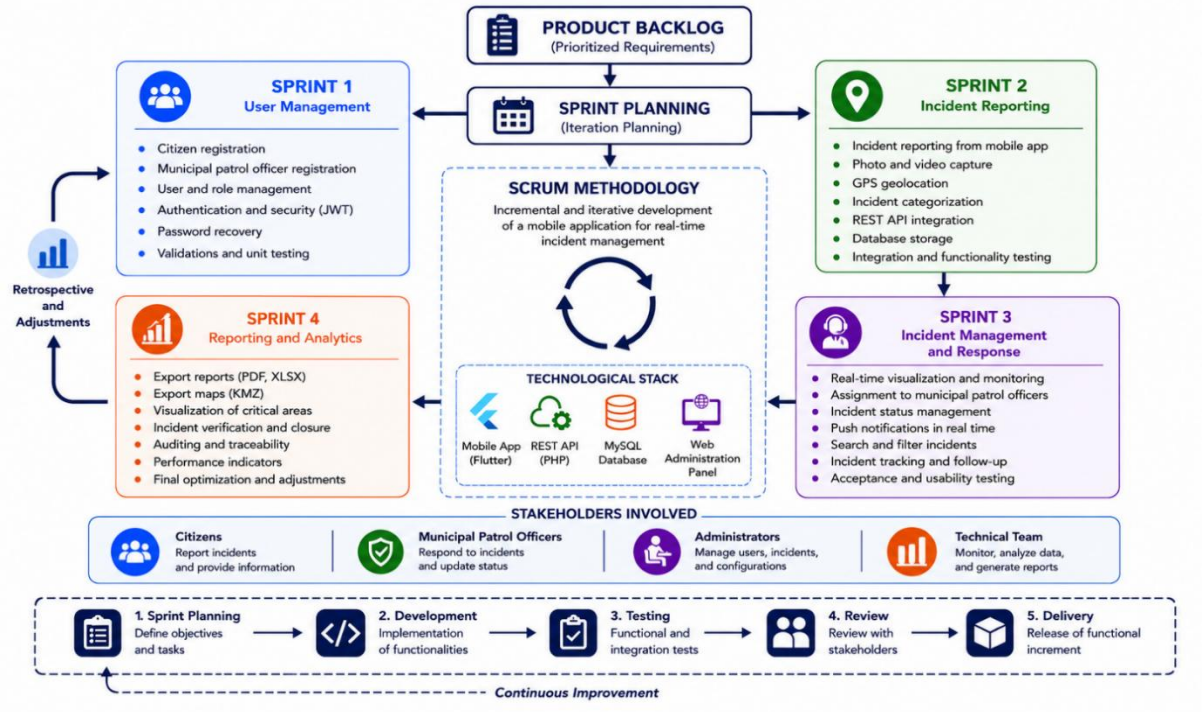

Fig. 1. Scrum-based development process of the proposed real-time incident management mobile application.

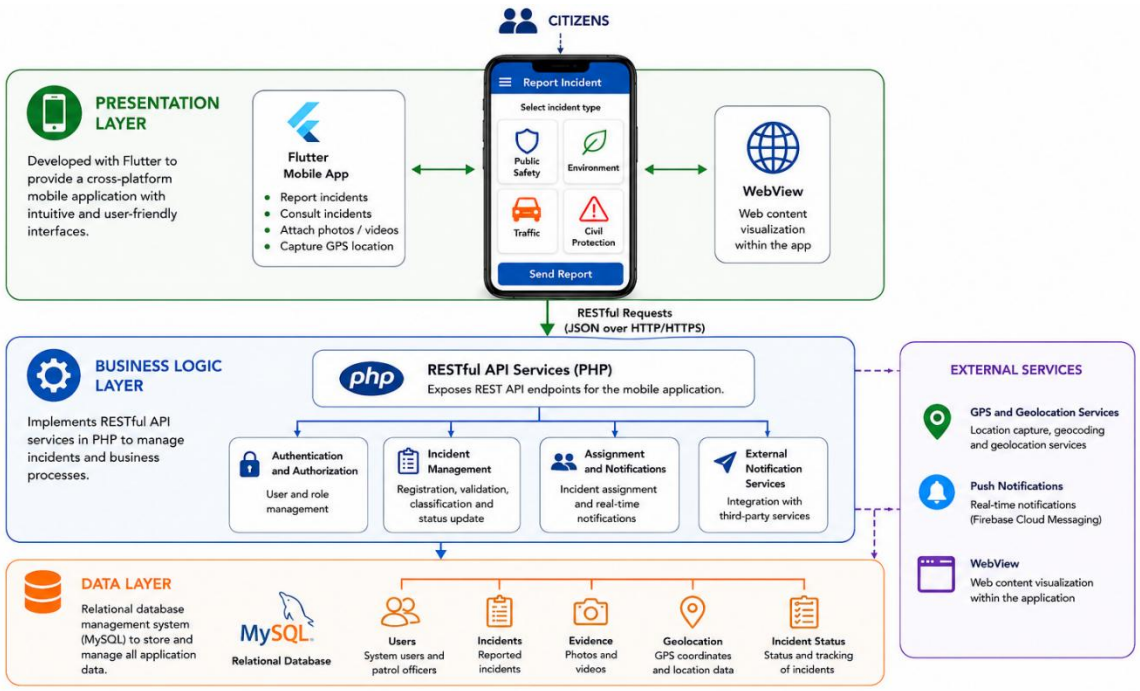

Fig. 2. Three-layer architecture of the proposed mobile application for real-time incident management.

The presentation layer was developed using Flutter to support cross-platform mobile application development. Its main purpose is to allow citizens to report and consult incidents through intuitive and user-friendly interfaces. Through this layer, users can report incidents related to public safety, environmental issues, traffic, and civil defense, including descriptive details, multimedia evidence such as photographs and videos, and GPS-based geographic location data from their mobile devices. WebView was also incorporated to display web content within the application, improving the user experience without requiring users to leave the mobile environment. Communication with the business logic layer is performed through HTTP/HTTPS requests using JSON messages, ensuring efficient and secure interaction between the mobile application and backend services.

The business logic layer was implemented in PHP using a REST API-based architecture, enabling the mobile application to connect with server-side services. This layer manages the incident lifecycle, including registration, validation, classification, assignment, and status updates. REST services were implemented to decouple the mobile application from internal server processes, simplifying maintenance and supporting future platform scalability.

The data layer was implemented using MySQL as the relational database management system. The database was designed to store information related to system users, municipal patrol officers, reported incidents, incident categories, multimedia evidence, service status, geographic coordinates, and geolocation data. The relational structure ensures data integrity and consistency, while also facilitating queries for report generation, performance indicators, and real-time incident monitoring. In addition, geospatial attributes were incorporated to analyze the geographic distribution of incidents and identify critical areas within the municipal jurisdiction.

F. Incident Reporting and Response Workflow

Fig. 3 illustrates the operational workflow implemented by the proposed mobile application for real-time incident management. The process begins when a user logs into the application and completes the authentication procedure. After successful authentication, the user selects the appropriate incident category, including public safety, environmental issues, traffic, or civil protection.

Once the incident type has been selected, the user submits the corresponding information by providing a detailed description, multimedia evidence in the form of photographs or videos, and the geographic location obtained from the mobile device's GPS services. The system then validates the collected information to ensure that all mandatory fields have been completed. If incomplete or invalid information is detected, an error message is displayed, and the user is prompted to provide the missing data before continuing.

After successful validation, the incident report is transmitted to the server and stored in the MySQL database. Based on the incident category, the system automatically assigns the case to the corresponding municipal department or responsible personnel. Real-time notifications are then delivered to authorized staff members, enabling them to initiate response actions promptly.

During the response phase, incident managers update the status of each case within the system. The incident status progresses through different stages, namely pending, in progress, and resolved. These updates are continuously synchronized with the mobile application, allowing citizens to monitor the evolution of their reports and receive real-time information regarding the current status of the incident.

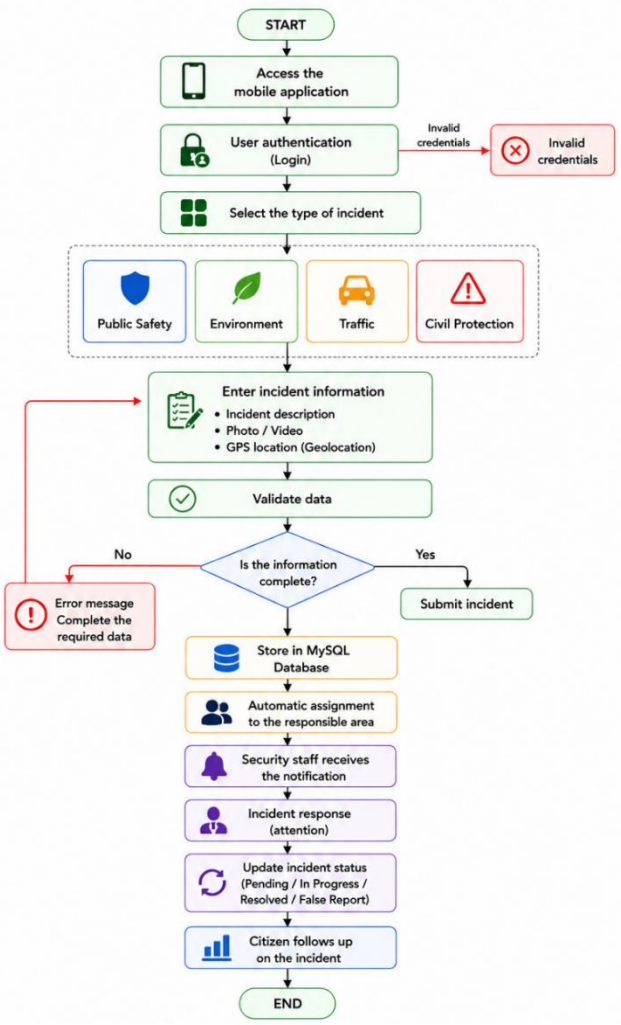

Fig. 3. Incident reporting and response process supported by the proposed mobile application.

Overall, this workflow facilitates efficient interaction between citizens and municipal authorities, improving response times, ensuring traceability of actions, and providing continuous monitoring throughout the incident lifecycle.

G. System Implementation

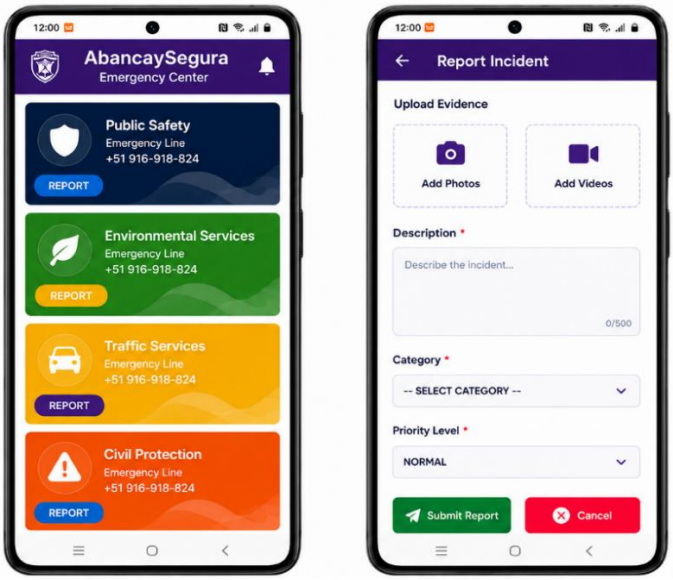
The system implementation enabled the deployment of the functionalities defined during the development phase, providing a solution focused on real-time incident reporting and response. The mobile application was designed to facilitate interaction between citizens and the municipal departments responsible for incident handling, supporting the registration, monitoring, and management of incidents related to public safety, environmental issues, traffic, and civil protection.

The main interface of the application provides access to the different incident categories, as well as consultation and tracking services. Users can submit detailed information about an event by selecting the corresponding incident category and specifying its characteristics. The application also allows the attachment of multimedia evidence, including photographs and videos, thereby improving the accuracy and reliability of incident reports.

In addition, geolocation mechanisms were incorporated to associate each incident with its geographic coordinates. This functionality facilitates spatial queries and assists responsible personnel in locating and responding to incidents more efficiently.

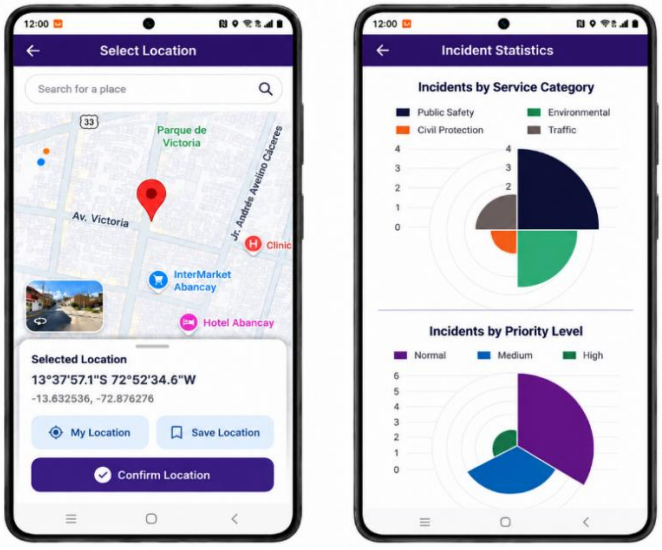
The proposed solution also incorporates monitoring and analytical capabilities that enable the generation of indicators and statistical information regarding the distribution and characteristics of reported incidents. These features provide valuable information for decision-making and support continuous monitoring of incident management activities.

The main interfaces and functionalities of the proposed mobile application are presented in Fig. 4 and 5.



(a) Main Interface (b) Incident Reporting Form.

Fig. 4. Main interfaces of the proposed mobile application: (a) Main interface and (b) Incident reporting form.



(a) Geolocation Module (b) Statistical Dashboard

Fig. 5. Additional functionalities of the proposed mobile application: (a) Geolocation module and (b) Statistical dashboard.

IV. RESULTS

The objective of this study was to evaluate the impact of the proposed mobile application on incident management within the local government environment. To achieve this, two key performance indicators (KPIs) were analyzed, namely incident registration time (KPI-1) and incident response time (KPI-2). In addition, the usability of the application was assessed using the Computer System Usability Questionnaire (CSUQ). The evaluation considered the dimensions of system quality, information quality, and interface quality to determine the level of user satisfaction with the implemented solution.

A. KPI-1: Incident Registration Time

Table II and Fig. 6 present the results obtained for the average incident registration time before and after the implementation of the proposed mobile application.

TABLE II. COMPARISON OF INCIDENT REGISTRATION TIME BEFORE AND AFTER IMPLEMENTING THE MOBILE APPLICATION

Scenario	Seconds	Minutes
Pre-Test (Without App)	9253.97	154.23
Post-Test (With App)	68.96	1.15
Reduction	9185.01	153.08
Percentage Reduction		99.26 %

The results indicate that the proposed mobile application substantially reduced the average incident registration time from 154.23 minutes to 1.15 minutes, representing a 99.26% reduction. Furthermore, the Wilcoxon signed-rank test revealed statistically significant differences ($p < 0.001$), demonstrating the effectiveness of the proposed solution in streamlining the incident registration process.

Fig. 6 provides a graphical comparison of the average incident registration times before and after implementing the mobile application.

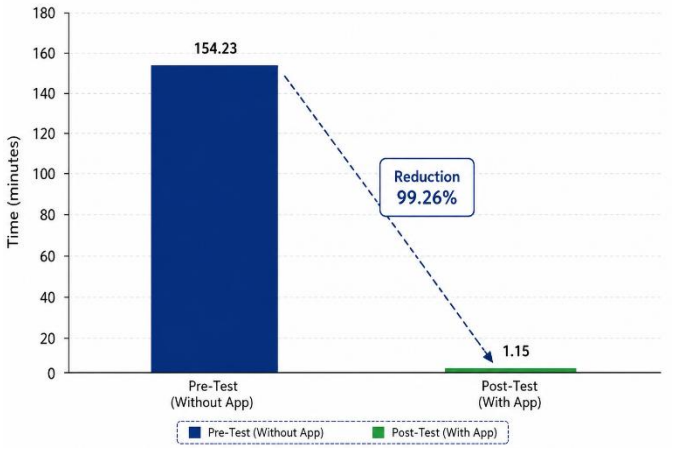


Fig. 6. Comparison of incident registration time before and after implementing the mobile application.

B. KPI-2: Incident Response Time

Table III and Fig. 7 present the results obtained for the average incident response time before and after the implementation of the proposed mobile application.

TABLE III. COMPARISON OF INCIDENT RESPONSE TIME BEFORE AND AFTER IMPLEMENTING THE MOBILE APPLICATION

Scenario	Minutes	Reduction (minutes)	Reduction (%)
Pre-Test (Without App)	94.69		
Post-Test (With App)	64.69		
Reduction			
Percentage Reduction		30.00	31.68 %

Fig. 7 presents a graphical comparison of the average incident response times before and after implementing the mobile application.

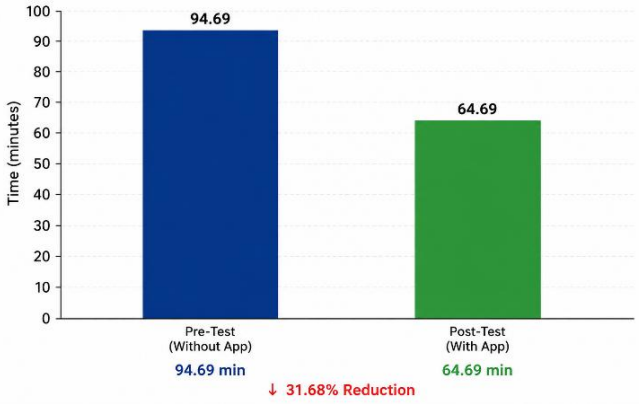

Fig. 7. Comparison of incident response time before and after implementing the mobile application.

The results indicate that the average incident response time decreased from 94.69 minutes during the pretest phase to 64.69 minutes in the posttest phase, representing a reduction of 31.68%. Furthermore, the Wilcoxon signed-rank test revealed statistically significant differences ($p < 0.001$), confirming the effectiveness of the proposed solution in improving the efficiency of incident response processes.

C. System Usability Evaluation

To determine how easy and intuitive the proposed mobile application was to use, the standard CSUQ (Computer System Usability Questionnaire) was administered. The overall satisfaction results are summarized in Table IV and Fig. 8.

The results showed a high degree of satisfaction with the proposed mobile application. Overall satisfaction reached an average score of 6.15 out of 7, reflecting a favorable user perception of the functionality, ease of use, and quality of the implemented solution. The Cronbach's alpha coefficient of 0.948 also demonstrated excellent internal consistency for the CSUQ instrument, confirming the reliability of the usability assessment.

TABLE IV. OVERALL USABILITY RESULTS OF THE PROPOSED MOBILE APPLICATION

Indicator	Value
Overall Satisfaction (CSUQ)	6.15/7
Cronbach's Alpha	0.948

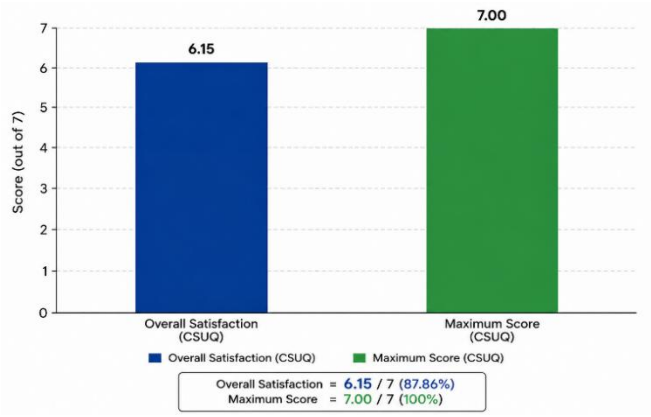

Fig. 8. Overall usability evaluation of the proposed mobile application based on the CSUQ questionnaire.

V. Discussion

The results obtained demonstrate that the proposed mobile application significantly improved incident management processes within the local government environment. In particular, substantial reductions in incident registration and response times were achieved, accompanied by high levels of user satisfaction. These findings support the notion that mobile technologies can enhance operational efficiency in incident management and contribute to the digital transformation of public services.

The findings are consistent with previous studies on mobile applications and intelligent platforms designed to support incident management and strengthen interactions between citizens and local governments [11], [15], [20]. Similarly, the high levels of user satisfaction observed in this study are in agreement with previous research emphasizing the importance of service quality, user experience, and usability evaluation in mobile government applications [22], [23], [28]. From a technological perspective, the results are also aligned with studies highlighting the advantages of Flutter and other cross-platform frameworks in terms of development productivity, performance, and user experience [29]–[32].

Overall, the findings demonstrate the potential of mobile technologies to improve incident management processes and promote stronger interactions between citizens and public institutions. These results suggest that mobile applications represent a promising technological alternative for supporting digital government initiatives and enhancing the delivery of public services.

VI. Conclusion

This study demonstrated the feasibility of using a mobile application to support real-time incident management in local government environments. The proposed solution integrated incident reporting, geolocation, and tracking capabilities, enabling more effective interaction between citizens and municipal personnel responsible for incident response. The implementation of these functionalities contributed to establishing a digital mechanism for handling incidents related to public safety, environmental issues, traffic, and civil protection.

From an operational perspective, the proposed system achieved substantial improvements in the incident management process. The average incident registration time was reduced by 99.26%, while the average incident response time decreased by 31.68%. Statistical analysis based on the Wilcoxon signed-rank test confirmed that these improvements were significant, demonstrating the positive impact of the application on the efficiency of incident management activities.

User feedback indicated a high level of acceptance of the developed application, with an overall CSUQ satisfaction score of 6.15 out of 7 and excellent internal consistency of the instrument ($\alpha = 0.948$). These results suggest that mobile technologies can serve as an effective alternative for supporting digital transformation initiatives and delivering more citizen-centered public services. Future research may focus on incorporating artificial intelligence techniques for incident prioritization and predictive analysis, as well as extending the proposed approach to other municipalities and public service domains.

EduDarijaBERT: An Applied Transformer-Based Framework for Sentiment Analysis in Moroccan Arabic Educational Discourse

Abderrahim Ait Ichou, Ali Ouacha
IPSS Team, Computer Science Department, Faculty of Sciences, Mohammed V University in Rabat, Morocco

***Abstract*—Students' opinions play a pivotal role in the formulation of successful educational policies. However, the computational analysis of the Moroccan Arabic Dialect remains widely viewed as problematic due to a focus on complex morphology and the absence of specific datasets. To close this gap, we propose an end-to-end system for educational sentiment mining, which utilizes EduDarijaBERT—a transformer model explicitly fine-tuned on this academic domain. In the development of the system, we initially constructed and systematically assessed a specifically curated corpus of 12,223 social media comments. To assess the model's reliability, we evaluated the framework on an independent test set. The proposed EduDarijaBERT system achieved an accuracy of 83.15% on this dataset, demonstrating strong generalization capabilities for educational sentiment mining. In addition to these quantitative metrics, the system facilitates a qualitative interpretation of sentiment categories, providing practical insights revealing that administrative challenges are among the major contributors to negative feedback, while active academic support is the key to positive interaction. This study provides universities with a stable, easily implementable system to track student feedback and fuel data-driven innovations.**

Keywords*—Sentiment analysis system; Moroccan Arabic dialect; social media analytics; educational data mining; data engineering framework

I. Introduction

Social media has permanently altered how students share their experiences and feelings about their education online. Sentiment analysis, as a critical application of applied Natural Language Processing (NLP), uncovers these attitudes and behavioral patterns based on spontaneous text posted on platforms such as YouTube, Facebook, and Instagram [1, 2, 3].

Understanding how students navigate the learning process is crucial for institutions striving to improve educational quality and student engagement [1]. In many psychological studies, emotional states—ranging from high anxiety to strong motivation—are viewed as fundamental factors that determine learning outcomes [4]. Therefore, the implementation of sentiment analysis systems serves as an exceptionally practical indicator of institutional performance and examination policies [1,2]. However, transitioning these NLP systems from theoretical models to practical applications remains a significant challenge when dealing with complex Arabic dialects [5, 6].

The Arabic language is known for its rich morphology [7], complicated syntax, and a dominant diglossia between Modern Standard Arabic and its dialects [5, 7]. The predominant dialect in informal digital communication is the Moroccan Dialect (Darija), which lacks a standard orthography and is characterized by frequent code-switching and the use of Latin scripts (Arabizi). This causes a significant bottleneck in data engineering. Moreover, high-quality, domain-specific annotated datasets focused on Moroccan educational discourse are unfortunately scarce, which hinders the implementation of effective institutional monitoring systems [8, 9].

To overcome these bottlenecks, we propose a comprehensive architecture for educational sentiment mining. We designed a dedicated data pipeline to acquire and standardize a novel dataset of 12,223 Moroccan Arabic comments from Facebook, YouTube, and Instagram. To cope with excessive linguistic noise, we employed a mixed semi-automated data processing scheme, which was rigorously controlled by a human-in-the-loop validation process by native speakers to ensure label accuracy.

The core of our proposed framework is EduDarijaBERT, a domain-adapted model checkpoint. An existing base DarijaBERT model was extensively fine-tuned using our educational corpus to develop EduDarijaBERT [10, 11, 12]. This specific variant was trained to capture the nuances of Moroccan students' discourse, including their specific pedagogical and emotional linguistic features. To address inherent data challenges—where positive and negative sentiments are rarely equally distributed—we integrated the SMOTE algorithm to mitigate severe class imbalances. The overall system's best performance was then contrasted with traditional NLP baselines (including TF-IDF/Word2Vec with SVM, KNN, and XGBoost) to justify the need for this domain-adapted transformer architecture.

This study's key contribution lies in its data engineering pipeline and system framework. We provide a targeted pipeline as well as the first high-quality, education-oriented Moroccan Arabic sentiment corpus. On this premise, we explain the development of EduDarijaBERT, which is the main component of our classification architecture. This framework tackles issues such as extreme class imbalance and connects theoretical NLP with educational data mining to provide an automated tool for institutions to analyze student feedback and make necessary policy improvements based on that data.

The rest of this study is organized as follows: Section II discusses related work. The materials and methods are described in Section III, which includes information on data collection, data preprocessing, data annotation, and data cleaning. The results are discussed in detail in Section IV, along with a comparative analysis, the impact of SMOTE, the fine-tuning of EduDarijaBERT, and performance assessment. Section V discusses data analysis and corpus linguistics, which includes an overview of sentiment distribution, statistics, and lexical trends. Lastly, Section VI provides the concluding remarks and future directions.

II. Related Works

This section reviews the existing literature on applied sentiment analysis for Arabic and its dialects on social media. Sentiment analysis has emerged as a critical tool for extracting user opinions from platforms like Twitter, Facebook, and YouTube. To create systems capable of identifying actionable behavioral patterns within this digital landscape, researchers have increasingly deployed computational linguistics, machine learning, and deep learning models.

Several studies have successfully applied sentiment analysis models to the educational sector. For instance, [13] developed an SVM-based sentiment classification system to analyze Arabic course reviews at a Saudi Arabian university, demonstrating how sentiment classification can practically optimize academic services. Similarly, [14] proposed a machine learning model to assess public opinion regarding distance learning in Saudi Arabia. Using the Apache Spark framework alongside regex-based preprocessing pipelines, their Logistic Regression classifier achieved 91% precision on a dataset of Arabic tweets.

Transformer architectures have also become foundational technologies for processing dialectal Arabic. To illustrate, [15] compared several BERT-based models—including AraBERT, QARIB, and AraELECTRA—on a Moroccan dialect sentiment dataset. Their findings emphasized that pre-trained language models can effectively process complex dialectal variations, with QARIB achieving an accuracy of 96%. Addressing real-world data engineering challenges, [16] tackled the issue of data imbalance in Moroccan dialect datasets and evaluated different feature extraction methods (TF-IDF and N-grams). Their results indicated that data resampling significantly enhances system stability, yielding a precision of 90.24%.

Exploring other dialects, [17] compiled a benchmark dataset of 18,589 tweets and proposed a hybrid MARBERT-LSTM model, achieving state-of-the-art accuracy at 91.23%. Furthermore, [18] introduced the AHaSIS shared task to investigate domain-specific sentiment classification within the hospitality industry. By developing an annotated dataset for Saudi and Moroccan dialects, they established a baseline F1-score of 0.81, underscoring the pressing need for domain- and dialect-specific sentiment analysis systems.

To better situate the performance of these architectures, Table I provides a comparison of the most prominent BERT-based models used in Arabic NLP. While models like AraBERT and AraELECTRA rely on massive corpora primarily composed of Modern Standard Arabic (MSA), they often lack the dialectal depth required for Moroccan social media. Models like QARIB and MARBERT improve upon this by including informal tweets and multi-dialectal data. However, DarijaBERT was specifically selected as our base model because it is uniquely tailored to the Moroccan dialect, having been trained on a corpus that specifically captures the nuances of Darija. This specialized focus is critical for our task, as general Arabic models often struggle with the specific morphological and syntactic structures of Moroccan Arabizi and dialect.

TABLE I. Comparison of Pre-Trained Arabic BERT Models

Model	Pre-training Corpus Size	Primary Language/Dialect Coverage
AraBERT (v0.2)	77 GB (~8.8 billion words)	Modern Standard Arabic (MSA)
AraELECTRA	77 GB	Modern Standard Arabic (MSA)
QARIB (mix)	25 GB (122M lines) to 60 GB	MSA and Dialectal Arabic
MARBERT	128 GB (1B Tweets)	Multi-dialectal (General Arabic)
DarijaBERT	691 MB (~3 million sequences)	Moroccan Darija (Arabic script)

Beyond document-level classification, more granular NLP tasks have also been explored. [19] proposed an AraBERT-based Aspect-Based Sentiment Analysis (ABSA) approach that jointly extracts aspect terms and categories. This multi-task method achieved an F1-score of 80.32% and successfully reduced error propagation, facilitating the extraction of highly specific feedback. Additionally, [20] demonstrated that supervised learning can reliably indicate student satisfaction. They concluded that statistical validation (yielding a Cronbach's Alpha of 0.901) is sufficient to ensure the reliability of using sentiment models to evaluate student well-being.

Sentiment analysis has also seen practical deployment in crisis management. [21] implemented a real-time infoveillance system to track Moroccan social media sentiments regarding the COVID-19 pandemic. Their deep learning models provided critical insights into public opinion dynamics, directly supporting public health decision-making. To handle the data engineering complexities inherent in such tasks, [8] created a large-scale Moroccan dialect dataset designed to overcome the challenges posed by Arabizi (the mixture of Arabic and Latin scripts), providing a necessary foundation for representing noisy web text.

Investigating feature engineering, [22] evaluated various machine learning pipelines for Moroccan dialect emotion recognition and found that N-grams paired with TF-IDF weighting significantly improved classifier performance. Building on this, [23] addressed Arabic's complex morphology and syntax using a hybrid deep learning network combining AraBERT, CNN, GRU, and LSTM architectures. Their findings revealed that pairing AraBERT with GRU and Bi-GRU layers achieved an accuracy exceeding 93%. Collectively, these studies highlight the immense potential of advanced NLP models. However, they also underscore the

specific gap our research addresses: there remains a critical need for a fully integrated, domain-adapted system (such as EduDarijaBERT) specifically trained to process highly noisy educational Moroccan Arabizi and deliver actionable insights directly to educational institutions.

While existing literature demonstrates the success of transformer models like QARIB (96% accuracy) or hybrid MARBERT-LSTM architectures in general dialectal tasks, these models often lack the dialectal depth and domain-specific focus required for the noisy pedagogical Arabizi found in Moroccan student discourse. Furthermore, although studies have utilized SMOTE to stabilize imbalanced Moroccan datasets, our analysis suggests that synthetic oversampling can introduce semantic noise that obscures subtle contextual boundaries. Consequently, the EduDarijaBERT architecture was designed to address these specific gaps by employing a human-in-the-loop pipeline for linguistic fidelity and achieving the ability to alleviate class imbalance natively through targeted domain adaptation, rather than relying on artificial data augmentation.

III. Materials and Methods

To develop a successful system for monitoring the online emotions of university students, establishing an effective data acquisition strategy focused on the Moroccan Arabic dialect is essential. We mined interactions from Facebook, Instagram, and YouTube to create our foundational corpus. The targeted data streams primarily focused on computer science, economics, and daily academic activities.

A significant data engineering challenge in this context is Arabizi. To process this Latinized script, we implemented a hybrid pipeline. Initial transliteration into Arabic characters was performed by a Large Language Model (GPT-4), followed by a strict human-in-the-loop review by native speakers to ensure high fidelity and correct spelling errors.

To establish a robust ground truth for our system, we utilized the same language model to generate initial sentiment labels (positive, neutral, and negative), which were subsequently subjected to extensive manual validation by expert annotators. The data sanitization stage entailed the elimination of digital noise, including URLs, platform-specific hashtags, and common stop words. After standardization, light stemming was applied, followed by tokenization to prepare the text for model ingestion.

To train the models and optimize feature definitions, we benchmarked traditional TF-IDF and Word2Vec pipelines against advanced contextual embeddings derived from DarijaBERT. The main architectural product of this process is EduDarijaBERT (Fig. 1). It is a domain-specific adaptation of the original DarijaBERT model, extensively fine-tuned on our custom educational dataset to capture domain-specific linguistic nuances. We compared its performance with that of XGBoost and SVM. SMOTE was employed to balance the dataset, ensuring system robustness for real-world applications characterized by inherent class imbalance. The final system evaluation relied on standard metrics, such as accuracy, precision, recall, and F1-score.

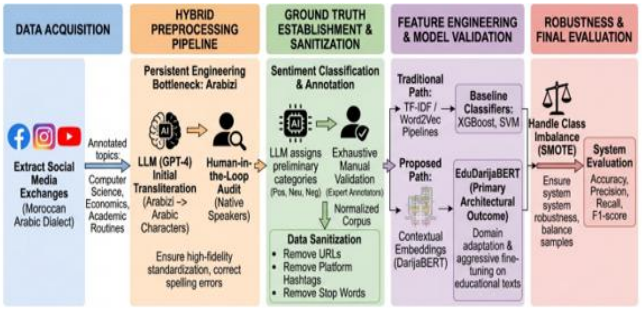

Fig. 1. System architecture of the proposed EduDarijaBERT framework.

A. Data Collection

For this study, we gathered a comprehensive set of user comments across 12,587 pages directly from Facebook, YouTube, and Instagram. One of the key benefits of this corpus is its broad temporal range, spanning 10 years from 2016 to 2025. This longitudinal study allows for the analysis of the linguistic evolution of Moroccan Darija and the students' attitudes through many generations and changing educational contexts. The overall style of these posts was informal, but thematic analysis found that there was a significant emphasis on certain areas of academic study, including mathematics, economics, and computer science. Moreover, many end-users expressed their own experiences about daily life on campus or encouraged the commendation of local universities in international contests. The overall distribution of comments among the three networks was uneven, due to different levels of user engagement across these platforms. This imbalance, however, provided the foundation for our next data engineering pipeline, which was used to create a robust sentiment classification framework that was trained and validated over this comprehensive decade-long dataset, with a high degree of temporal generalizability.

B. Data Preprocessing

1) Text conversion: One of the most difficult parts of the present study was to make the Arabizi data into a form that could be used for quantitative analysis. The corpus consisted of 6,555 comments in Latin-script Moroccan Arabic, which is a dialect with rather frequent French code-switching. This means that it was impossible to perform the computational processing without first establishing orthographic regularity. To overcome this, a two-phase transcription pipeline was implemented. The first phase involved using GPT-4o mini to convert the Latin-script input into Arabic script, which is quite variable. Because automated systems frequently struggle to process complex dialectal features and code-switching, these initial outputs were not considered final. Instead, all conversions were rigorously reviewed by a human team who corrected any vowel and consonant misalignments where the model had failed. The results of this process are illustrated in Table II, which presents a selection of original Latin-script examples alongside their final Arabic equivalents.

TABLE II. EXAMPLES OF COMMENT CONVERSION FROM LATIN SCRIPT TO ARABIC SCRIPT WITH ENGLISH

Latin Script (Franco-Arabic)	Arabic Script (Moroccan Dialect)	English Translation
Bravo madame	برافو أمدام	Bravo, Madam
Merci beaucoup Madame pour cette vidéo	شكراً بزاف أمدام على هاد الفيديو	Thank you very much, Madam, for this video.
Bghina les exercices	بغينا تمارين	We want the exercises.
Merci bien prof	شكراً أستاذة	Thank you very much, Professor.
MERCI Bq chère prof	شكراً بزاف أستاذة	Thank you very much, dear Professor.

C. Data Annotation

The first round of sentiment classification was done using GPT-4o mini, which assigned one of three sentiment classes to every comment. To safeguard analytical rigor and make the manual work on the entire dataset manageable, the total dataset was divided into six different and non-overlapping subsets. The different subsets were assigned to six independent human annotators, each of whom is a native Moroccan dialect speaker. The model's predictions were systematically reviewed by the annotators within their respective partitions, where they corrected incorrect classifications by hand to ensure that the pedagogical and emotional context of the text was properly captured. To address potential algorithmic bias, we analyzed cases where humans overrode the initial labels, as detailed in Table III. For example, GPT-4o mini misidentified polite inquiries (e.g., asking for a WhatsApp number) as negative, which humans corrected to neutral, and religious encouragement (e.g., "Masha'Allah") as neutral, which humans corrected to positive. This correction process ensures the dataset reflects authentic human intent. This human-in-the-loop method was partitioned to ensure an efficient process of creating a large-scale, reliable ground-truth dataset. To assess the reliability of this process, a subset of 200 comments was independently evaluated by three annotators, yielding an overall Fleiss' Kappa of $\kappa = 0.8175$ (95% CI: [0.7375, 0.8975]), which indicates almost perfect inter-annotator agreement. While this agreement subset represents a portion of the total corpus, the narrow confidence interval confirms the statistical robustness and the reliability of the annotation guidelines. An analysis of the disagreement cases revealed that they were primarily driven by "mixed sentiments" and the cultural nuances of Moroccan Darija. In some cases, positive (or negative) feedback on the teacher's speed of presentation was mixed with a positive comment, creating a dilemma for the annotators between a negative, neutral, or positive reading. There were also some differences regarding short snippets of expressions, which were either contextually neutral/factual or interpreted as positive engagement. The examples show that although there is a high level of agreement at the overall level, subjectivity regarding politeness versus dissatisfaction is still problematic in dialectal sentiment analysis. Table IV provides an example of this completed dataset, with the original comments written in Arabic characters and the English translation alongside the approved categories of sentiment.

TABLE III. COMPARISON OF GPT-4O MINI INITIAL LABELING VERSUS HUMAN EXPERT CORRECTION

Human Label	GPT-4o mini Label	Arabic Script (Moroccan Dialect)	English Translation
Neutral	Negative	ما لقيتش رقم الواتساب ديالك	I didn't find your WhatsApp number
Neutral	Negative	مكرهتشي تعدلنا التمارين	I wouldn't mind if you did the exercises for us
Positive	Neutral	تحياتي	My regards / Greetings
Neutral	Positive	غضو البصر يا امة محمد	Lower your gaze, O nation of Muhammad
Positive	Neutral	ما شاء الله وفي ذلك فلتنافس	Masha'Allah, and for that let them compete

TABLE IV. EXAMPLES OF SENTIMENT POLARITY LABELS ALLOTTED TO COMMENTS

Latin Script (Franco-Arabic)	Arabic Script (Moroccan Dialect)	English Translation
Positive	ألف مبروك له ولكل الفائزين، مزيدا من التفوق والنجاح ان شاء الله	A thousand congratulations to him and to all the winners; more excellence and success, God willing.
Negative	النتيجة : هجرة الأدمغة	The result: brain drain.
Neutral	ذهبوا وهم "مغاربة" هل سيرجعون وهم "مغاربة" ؟	They left as "Moroccans"; will they return as "Moroccans"?
Positive	ألف مبروك له ولكل الفائزين، مزيدا من التفوق والنجاح ان شاء الله	A thousand congratulations to him and to all the winners; more excellence and success, God willing.
Negative	النتيجة : هجرة الأدمغة	The result: brain drain.

D. Data Cleaning

The raw corpus underwent extensive cleaning before it became suitable for analysis. The initial step was to convert the text into Arabic script because the comments were originally written in Arabizi, which is Latin-scripted Moroccan Arabic, to ensure data uniformity. We also deleted emojis from 1,055 comments and removed URLs from 775 others. Then there was Arabic normalization. This implied the elimination of typical orthographic inconsistencies: the Alif variants (إأآا) were reduced to a single form, mapping ى to ي, ة to ه, and گ to ك. Even marks of elongation and extended lines such as هههههههه were left out, as they are analytically unproductive. To address the linguistic specificities of the corpus, we implemented a hybrid stop-word removal process by combining the standard NLTK Arabic stop-word list with a manually curated dictionary of Moroccan Darija terms, including dialect-specific pronouns (e.g., أنا, نتا), interrogatives (e.g., واش, فين), and common adverbs (e.g., بزاف, بلا). After tokenization, another 297 entries turned out to be invalid and were dropped. The dataset was reduced to 12,223 useful comments, having started with 12,587 initial comments. The distribution of these collected comments across different social media platforms is shown in Fig. 2.

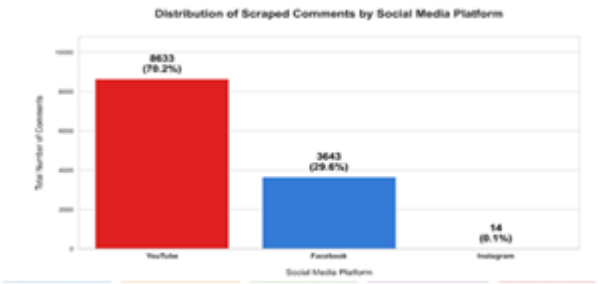

Fig. 2. Distribution of scraped comments by social media platform.

IV. Results and Discussion

This section evaluates the performance of different machine learning algorithms and embedding methods for the sentiment analysis of Moroccan Arabic educational comments. To get a full picture, we evaluated the models using standard classification metrics: accuracy, precision, recall, and F1-score, as well as confusion matrices and the Area Under the Receiver Operating Characteristic Curve (AUC-ROC) to gain in-depth insights into the models' discriminative power.

A. Comparative Analysis

All experiments showed that transformer-based architectures and ensemble techniques outperformed the traditional linear classifiers. The best performance was achieved when the DarijaBERT [3] model was used with an SVM classifier, with a total accuracy score of 80.17. These results indicate that domain-based pre-trained language models of Moroccan dialect are more effective than generic embeddings at capturing semantic information in Moroccan Dialect.

Traditional machine learning algorithms, including SVM and XGBoost, have a consistent set of results in all samples that used TF-IDF, Word2Vec, and FastText features. TF-IDF provided a good baseline, and its performance was on par with word embeddings. Moreover, a few keywords of the Moroccan dialect therefore exhibit high correlation with sentiment polarity.

B. Impact of SMOTE

To address class imbalance, the Synthetic Minority Oversampling Technique (SMOTE) was applied exclusively to the training partition after performing the train/test split. To prevent data leakage and ensure an unbiased evaluation, the test set remained completely untouched.

Specifically, SMOTE was used to rebalance the training partition of 9,167 samples, generating synthetic instances for the minority classes to yield an expanded training set of 14,484 samples (equally distributed at 4,828 samples per class).

Table VI presents a performance comparison of the classifiers with and without SMOTE. The results indicate that SMOTE improved the recall and F1-score for minority categories (e.g., negative comments), demonstrating enhanced detection of underrepresented sentiments. However, as shown in Table V, this oversampling strategy led to a slight decline in overall accuracy and macro F1-score across several models. This indicates that synthetic oversampling can introduce noise into dialectal Arabic text, where semantic and contextual boundaries are already subtle. Consequently, applying SMOTE presents a clear trade-off: it achieves a more equitable classification for minority opinions at the cost of a slight reduction in global model precision.

TABLE V. Class Distribution Before and After SMOTE Application

Distribution	Negative	Positive	Neutral	Total
Before SMOTE	1284	3055	4828	9167
After SMOTE	4828	4828	4828	14484

TABLE VI. Performance Comparison of Models and Embedding

Embedding / Model	*Method*	*Accuracy*	*Precision*	*Recall*	*F1-Score*
DarijaBERT + SVM	Without SMOTE	0.8017	0.8018	0.8017	0.8009
DarijaBERT + SVM	With SMOTE	0.7856	0.8058	0.7856	0.7901
DarijaBERT + XGBoost	Without SMOTE	0.7987	0.8024	0.7987	0.7973

C. Discussion of findings

The robust performance of SVM across almost all embedding types (achieving approximately 80% accuracy) suggests that the sentiment boundaries in Moroccan Arabic social media comments are relatively well-defined when projected into high-dimensional spaces.

However, Naive Bayes and KNN showed significant sensitivity to the feature extraction method. For instance, Naive Bayes performed poorly with Word2Vec and FastText (often falling below 70%) but showed a substantial improvement with TF-IDF (up to 77.7%). This indicates that for dialectal Arabic, the presence of specific tokens (captured by TF-IDF) is more informative for probabilistic models than the semantic clusters formed by dense embeddings.

1) Impact of fine-tuning EduDarijaBERT on sentiment classification:

a) Experimental setup and hyperparameter configuration: For the fine-tuning experiments, sentence representations were extracted from the last hidden layer of the fine-tuned EduDarijaBERT model using the [CLS] token. A maximum sequence length of 128 tokens was utilized to tokenize the input streams. All inputs were padded and truncated to ensure a consistent input size across the dataset. The model was fine-tuned for five epochs with a training and evaluation batch size of 16. Optimization was performed using the AdamW optimizer with the default learning rate and a weight decay of 0.02. To address the inherent class imbalance, a weighted cross-entropy loss function was employed using dynamically calculated class weights. Model checkpoints were saved and evaluated at the end of every epoch, and the Area Under the Receiver Operating Characteristic Curve (AUC-

ROC) was utilized as the primary metric to select the best-performing model.

Subsequently, a Support Vector Machine (SVM) classifier employing a Radial Basis Function (RBF) kernel was trained using the extracted embeddings. The regularization parameter was set to 1.0, and the kernel coefficient was set to 'scale'. To facilitate class-wise performance analysis, probability estimation was enabled. The random state was fixed at 42 to guarantee reproducibility. All experiments were executed on a GPU (CUDA) when available, falling back to a CPU otherwise. Table VII summarizes the complete hyperparameter configuration.

TABLE VII. HYPERPARAMETERS OF THE FINE-TUNED EDUDARIJABERT + SVM MODEL

Component	*Hyperparameter*	*Value*
EduDarijaBERT	Pretrained model	DarijaBERT (SI2M-Lab/DarijaBERT)
	Max sequence length	128
	Padding	True
	Truncation	True
	Ignore mismatched sizes	True
Fine-tuning Configuration	Number of epochs	5
	Train batch size	16
	Eval batch size	16
	learning rate	Default (5e-5 from AdamW)
	Weight decay	0.02
	Warmup steps	300
	Optimizer	AdamW (default)
	Loss function	CrossEntropyLoss (weighted)
	Class weighting	Balanced (computed)
	Evaluation strategy	Per epoch
	Save strategy	Per epoch
	Metric for best model	AUC
	Device	GPU (CUDA) / CPU
SVM classifier	Kernel	RBF
	Regularization parameter (C)	1.0
	Gamma	scale
	Probability estimates	Enabled
	Random state	42

In a subsequent experiment, EduDarijaBERT was fine-tuned on our Moroccan Arabic educational dataset before employing the SVM classifier. While DarijaBERT was used as a frozen feature extractor in previous experiments, fine-tuning enables the model to learn internal representations that are sensitive to the linguistic, pedagogical, and emotional nuances of the Moroccan Arabic educational discourse.

The fine-tuned EduDarijaBERT + SVM model achieved the best score of 83.15% and was the best performer across all settings. This model significantly outperformed the non-fine-tuned DarijaBERT + SVM setting (which achieved an accuracy of 80.17%), thus underscoring the critical importance of domain adaptation for low-resource dialects like Moroccan Arabic.

Table VIII illustrates that fine-tuning improved performance across all evaluation metrics, especially recall and F1-score. This indicates better generalization of the fine-tuned model across sentiment categories. This is particularly evident for the negative class, which is often challenging to classify due to class imbalance and linguistic diversity.

TABLE VIII. PERFORMANCE OF FINE-TUNED EDUDARIJABERT + SVM

Model	*Accuracy*	*Precision*	*Recall*	*F1-score*
EduDarijaBERT + SVM (Fine-tuned)	0.8315	0.8299	0.8315	0.8305

b) Overall discussion and implications: The experiments demonstrate that using classical machine learning classifiers and sparse representations such as TF-IDF provides a strong baseline for sentiment classification in Moroccan Arabic text, especially when paired with robust classifiers such as SVM. These findings confirm that lexical cues remain highly discriminative in dialectal Arabic.

Nonetheless, significant improvements and increased robustness across all sentiment classes were achieved when we fine-tuned EduDarijaBERT – a domain-adapted transformer model – through additional training on Moroccan Arabic educational data. This improvement can be attributed to the model's ability to capture linguistic nuances, colloquialisms, and sentiment cues within the educational domain.

Overall, although traditional approaches offer competitive speed and accuracy, the fine-tuned transformer models demonstrated superior performance for educational monitoring and feedback analysis.

2) Comparative performance analysis: The performance differences observed in the experiment with SMOTE-balanced data were minimal, as illustrated in Fig. 3. Across all evaluation metrics, the SVM classifier combined with DarijaBERT embeddings achieved robust results. Without SMOTE, the model reached an accuracy of 80.2%, whereas with SMOTE, the accuracy decreased slightly to 78.6%. When comparing precision, recall, and F1-score, only marginal gains were observed with SMOTE, with precision increasing from 0.802 to 0.806. However, after applying SMOTE, recall declined to 0.786, and the F-score remained comparable in both settings. These findings suggest that either SMOTE enhances the model's ability to discriminate the minority class, or conversely, that DarijaBERT embeddings already provide strong discriminative capability on the imbalanced dataset.

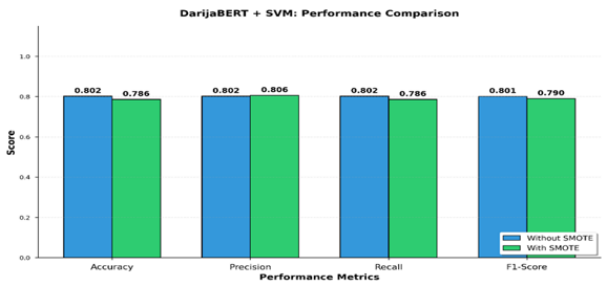

Fig. 3. Comparative performance metrics of DarijaBERT+SVM with and without SMOTE.

a) Confusion matrix analysis: Fig. 4 presents the confusion matrices of DarijaBERT+SVM in all the experimental settings, which provide detailed insights into the classification patterns. Without SMOTE, the model performs well on the majority positive class (1,405 correct predictions out of 1,612), but it is evident that there is confusion between the other categories. Specifically, 179 neutral samples are misclassified as positive, and 131 negative samples are misclassified as neutral; this is indicative of class imbalance.

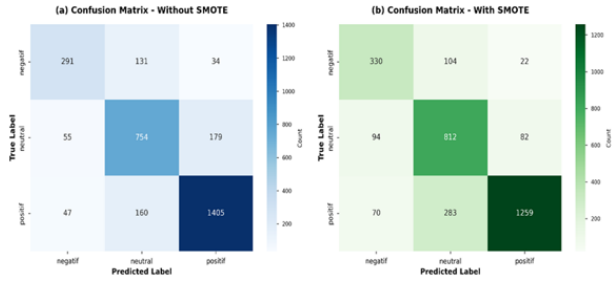

Fig. 4. Confusion matrices for DarijaBERT+SVM classification (a) Without SMOTE and (b) With SMOTE.

By applying SMOTE, the proper classification of minority classes is drastically enhanced. True positives in the negative class improve from 291 to 330, representing an improvement of 13.4%. In the case of the neutral class, the number of correct predictions increases from 754 to 812, which is an increment of 7.7%. However, this improvement comes at the cost of a larger number of positive instances falsely classed as neutral, increasing from 160 to 283. This result illustrates a classic trade-off in cost-sensitive classification between the recall of minority classes and the accuracy of the majority class.

b) Receiver operating characteristic analysis: The Receiver Operating Characteristic (ROC) curves are presented in Fig. 5. The combination of DarijaBERT with an SVM classifier demonstrates strong discriminative capability across each sentiment level individually. In the configuration without SMOTE (Fig. 5a), the weighted average AUC achieves a robust score of 0.917. The scores of the categories varied: the neutral class recorded the lowest AUC at 0.889, while the positive class achieved the highest AUC at 0.931 (with the negative class at 0.929). It is not surprising that the positive class exhibited the best overall ROC profile, as its prevalence in the raw training distribution allows the model to characterize it more effectively.

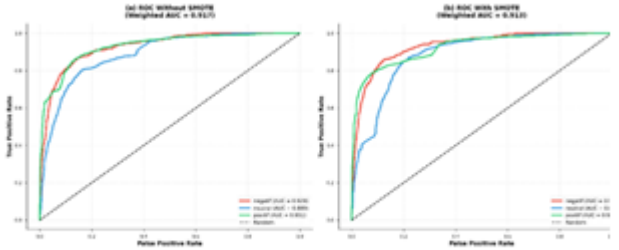

Fig. 5. ROC curves and AUC scores for multi-class sentiment classification (a) Without SMOTE and (b) With SMOTE.

When SMOTE is utilized (Fig. 5b), the weighted average AUC remains highly competitive at 0.913, and the AUC of the negative class increases to 0.932. This demonstrates that the model's ability to identify the minority class is improved. The minor decreases in AUC for the neutral class (from 0.889 to 0.885) and the positive class (from 0.931 to 0.924) reflect the distribution shift caused by synthetic oversampling; specifically, expanding the decision space of the minority categories slightly reduces the classification margins of the majority classes. Regardless of the balancing approaches, the AUC results show that DarijaBERT embeddings capture rich semantic content and can, therefore, be used to classify Moroccan Arabic sentiments in both settings (AUC > 0.88 across all classes).

c) Detailed performance metrics: Table IX shows the effect of SMOTE on all classes, with the negative class experiencing the most significant impact. SMOTE improved the recall from 63.8% to 72.4%, alongside a reduction in precision from 74.0% to 66.8%. This demonstrates that SMOTE effectively reduces false negatives for the minority class at the expense of an increase in false positives, as theoretically anticipated by oversampling processes. The neutral class exhibits a similar trend, with an increase in recall (+7.7%) and a decrease in precision (-6.2%). For the majority positive class, the SMOTE-adapted decision boundary results in a more conservative decision rule, leading to a gain in precision (+6.4%) but a noticeable decrease in recall (-10.4%).

At the macro-average level, SMOTE yields an increase in recall (+2.4%) accompanied by a decrease in precision (-2.7%), resulting in a slight overall decrease in the F1-score (-0.7%). Weighted average precision shows a marginal improvement (+0.5%), as the precision gains in the heavily represented majority class outweigh the precision losses in the minority classes. These findings suggest that the choice of a balancing strategy must be guided by the nature of the application: if the primary goal is maximizing minority class identification (e.g., detecting at-risk students experiencing negative sentiment), SMOTE is highly beneficial. Conversely, for precision-critical applications, maintaining the original, natural class distribution may be preferable.

TABLE IX. COMPREHENSIVE PERFORMANCE COMPARISON OF DARIJABERT+SVM WITH AND WITHOUT SMOTE

Model	*Accuracy*	*Precision*	*Recall*	*F1-score*
Negative	Precision	0.740	0.668	-9.7
	Recall	0.638	0.724	+13.5
	F1-Score	0.686	0.695	+1.3
	Support	456	456	-
Neutral	Precision	0.722	0.677	-6.2
	Recall	0.763	0.822	+7.7
	F1-Score	0.742	0.743	+0.1
	Support	988	988	-
Positive	Precision	0.868	0.924	+6.4
	Recall	0.872	0.781	-10.4
	F1-Score	0.870	0.846	-2.8
	Support	1612	1612	-
Overall	Accuracy	0.802	0.786	-2.0
	Macro Avg Precision	0.777	0.756	-2.7
	Macro Avg Recall	0.758	0.776	+2.4
	Macro Avg F1-Score	0.766	0.761	-0.7
	Weighted Avg Precision	0.802	0.806	+0.5
	Weighted Avg Recall	0.802	0.786	-2.0
	Weighted Avg F1-Score	0.801	0.790	-1.4

d) Fine-tuned EduDarijaBERT performance: The confusion matrix for EduDarijaBERT is presented in Fig. 6. Fine-tuning the model results in 320 correctly predicted negative instances (achieving a recall of 70.2%), 763 correctly classified neutral instances (77.2% recall), and 1,458 correctly identified positive instances (90.4% recall). Overall, performance improves across all sentiment classes. The misclassifications between extreme polarities also decrease: there are exactly 39 positive-to-negative and 39 negative-to-positive misclassifications, showing a clear improvement over the baseline setting. Furthermore, confusion between the neutral class and the other sentiment categories is also reduced. Specifically, the neutral category achieves 763 correct predictions, with only 77 and 148 cases being misclassified as negative and positive, respectively. These findings indicate that the fine-tuning process successfully captures domain-specific sentiment cues and the contextual attributes of the educational Moroccan Arabic discourse.

The ROC curves in Fig. 7 demonstrate the strong discriminative performance of the EduDarijaBERT model, achieving a weighted AUC of 0.909. This score is slightly lower than the base DarijaBERT model, but it still has a very strong profile. The positive sentiment class has the best AUC (0.927), followed by the negative sentiment class (0.916) and the neutral sentiment class (0.877). Also, the AUC interval for the best and worst classes for EduDarijaBERT is 0.050, while the interval for the baseline was 0.042 for DarijaBERT without SMOTE. Therefore, this model suits operational settings better where there is a more consistent distribution of classification errors for each classification category.

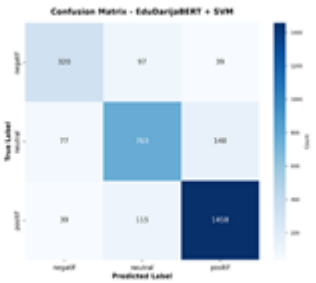

Fig. 6. Confusion matrix of fine-tuned EduDarijaBERT + SVM.

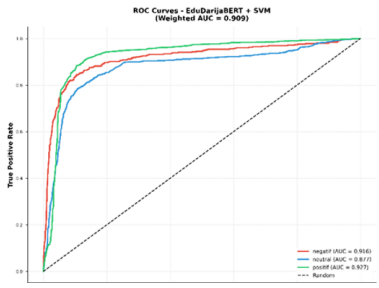

Fig. 7. ROC curves for fine-tuned EduDarijaBERT + SVM.

TABLE X. COMPREHENSIVE PERFORMANCE COMPARISON BETWEEN DARIJABERT AND EDUDARIJABERT IN EDUCATIONAL SENTIMENT ANALYSIS

Metric	*DarijaBERT (Best)*	*EduDarijaBERT*	*Improvement*
Accuracy	0.802	0.832	+3.0%
Precision	0.802	0.830	+2.8%
Recall	0.802	0.832	+3.0%
F1-Score	0.801	0.831	+3.0%
Macro Avg Precision	0.777	0.801	+2.4%
Macro Avg Recall	0.758	0.793	+3.5%
Macro Avg F1-Score	0.766	0.797	+3.1%
Negative Precision	0.740	0.732	-0.8%
Negative Recall	0.724 (SMOTE)	0.706	-1.8%
Negative F1-Score	0.695 (SMOTE)	0.719	+2.4%
Neutral Precision	0.722	0.784	+6.2%
Neutral Recall	0.822 (SMOTE)	0.765	-5.7%
Neutral F1-Score	0.743 (SMOTE)	0.775	+3.2%

Metric	DarijaBERT (Best)	EduDarijaBERT	Improvement
Positive Precision	0.924 (SMOTE)	0.886	-3.8%
Positive Recall	0.872	0.908	+3.6%
Positive F1-Score	0.870	0.896	+2.6%

Table X shows a detailed overview of the performance comparison between the baseline DarijaBERT and the fine-tuned model, EduDarijaBERT. The overall results show a significant improvement across the main metrics, including a 3.1% improvement in the macro-averaged F1-score. Additionally, there were significant gains for specific classes, with the neutral class improving by 6.2% in precision and the positive class by 3.6% in recall. Overall improvements are, however, accompanied by some minor sacrifices in some of the class-specific metrics, which show a small decrease.

e) Robustness check and cross-validation analysis: To evaluate its real-world generalization capability, the proposed model was evaluated on an independent 3,056-sample test set. Tables XI and XII present the detailed per-class performance breakdown. To further evaluate its real-world generalization capability beyond cross-validation, the proposed model was evaluated on an independent 3,056-sample test set. Tables XII and XIII present the detailed per-class performance breakdown.

TABLE XI. EDUDARIJABERT CLASSIFICATION REPORT ON THE INDEPENDENT TEST SET

Model	Precision	Recall	F1-Score	Support
Negative	0.7339	0.7018	0.7175	456
Neutral	0.7826	0.7723	0.7774	988
Positive	0.8863	0.9045	0.8953	1612
Accuracy			0.8315	3056
Macro Avg	0.8009	0.7928	0.7967	3056

TABLE XII. DARIJABERT CLASSIFICATION REPORT ON THE INDEPENDENT TEST SET

Model	Accuracy (Mean ± SD)	Precision (Mean ± SD)	Recall (Mean ± SD)	F1-Score (Mean ± SD)
Negative	0.7405	0.6382	0.6855	456
Neutral	0.7215	0.7632	0.7418	988
Positive	0.8684	0.8716	0.8700	1612
Accuracy			0.8017	3056
Macro Avg	0.7768	0.7576	0.7657	3056

The overall accuracy was 83.15% for EduDarijaBERT, compared to 80.17% for the baseline model, on the independent test set. Interestingly, there was no balancing using SMOTE in the proposed framework, and yet it retained its performance, while the baseline framework's performance dropped to 78.57% when using SMOTE balancing. The domain-adapted model performance profile was well balanced, with the macro-average F1-score improving from 0.766 to 0.797. Specifically, the F1-score increased significantly to 0.777 for the neutral class and 0.718 for the minority negative class, showing a clear improvement over the baseline. Additionally, EduDarijaBERT demonstrated strong discriminative performance within each class (AUC scores were tightly grouped from 0.877 to 0.927) and remained stable. The model is able to alleviate class imbalance natively with high-quality performance on underrepresented classes without the need for synthetic oversampling. These comparative results demonstrate that targeted fine-tuning on educational Moroccan Arabic data achieves better and more stable classification results for the automatic monitoring of students' sentiments.

The independent test set accuracy of 83.15% provides a conservative and realistic characterization of the system's performance on unseen data. This result reflects the model's real-world generalization capability. The performance level is influenced by the temporal drift and linguistic evolution inherent in a dataset spanning a full decade, from 2016 to 2025. Furthermore, this evaluation confirms the absence of data leakage, as the independent test set remained completely untouched during the SMOTE application and training phases to ensure an unbiased assessment.

V. DATA ANALYSIS AND CORPUS LINGUISTICS

The statistical characteristics of student discourse and its sentiment distribution were examined across the 12,223 manually verified comments. This is a large-scale study that enables a comprehensive grasp of learners' opinions in the context of this specific feedback in Morocco.

A. Sentiment Distribution

The overall tone of the corpus is positive, reflecting a high level of student engagement and satisfaction. However, the negative subset is still needed because it provides detailed information on the educational problems faced by learners. This balanced view is essential to generate a model that reflects the characteristics of the Moroccan language medium (Darija) in an academic context (Fig. 8).

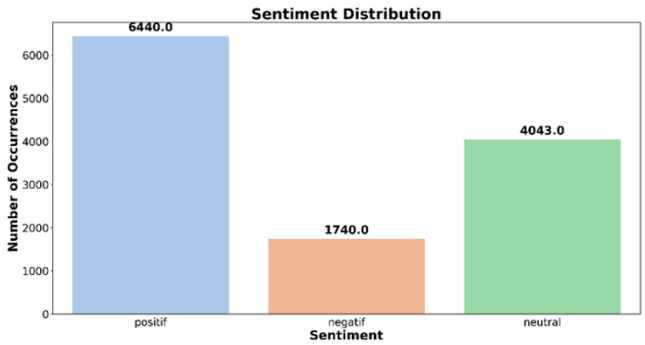

Fig. 8. Sentiment distribution within the Moroccan Arabic educational corpus.

B. Statistical Summary

The students' expressions of the sentiment classes are not equally simple: positive comments are shorter and more frequent, whereas negative ones are more complex, with a maximum length of 522 words. This suggests that when

students write negative comments, they provide a more detailed justification than when they give positive comments.

TABLE XIII. QUANTITATIVE ANALYSIS AND LEXICAL DIVERSITY OF THE CORPUS

Sentiment Label	*Total Number of Words*	*Number of Distinct Words*	*Max Sentence Length*
Positive	39258	9158	233
Negative	22224	8240	522
Neutral	32651	9571	306

C. Lexical Trend Analysis

The most common unique words offer a detailed view of the topics and vocabulary used in the three sentiment classes. Following the overview is a qualitative description which is supplemented by a word frequency distribution, outlining the main concerns and communication styles of the students.

Positive Sentiment: As depicted in Fig. 9, the discourse is characterized by a strong sense of gratitude and religious invocation. Words like "شكرا" (Thank you) and "الله" (God) are used most frequently, reflecting a cultural tendency to express appreciation for educational material or mentors through traditional blessings.

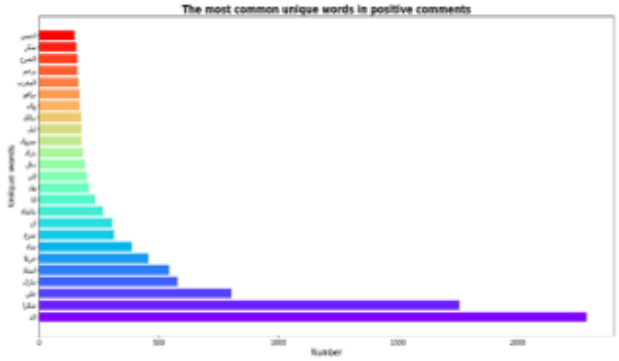

Fig. 9. Top 25 most frequent unique words in positive comments

Neutral Sentiment: The neutral comments are mostly cooperative and inquisitive, as seen in Fig. 10. The use of the words (Teacher), (I/Me), and (Of/Belonging to) suggests that students use a neutral tone mainly to ask for clarifications and to introduce themselves or to discuss administrative and educational course matters.

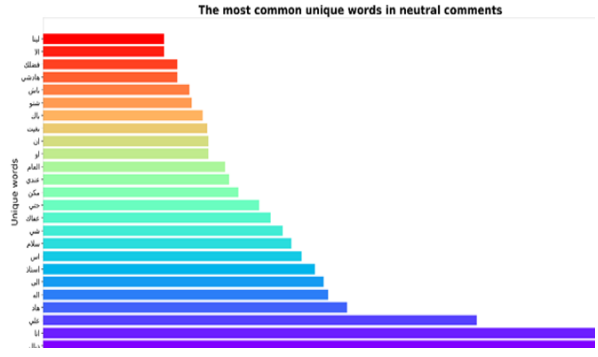

Fig. 10. Top 25 most frequent unique words in neutral comments.

Negative Sentiment: As seen in Fig. 11, the lexicon becomes more critical, shifting from hopeful to sociopolitical. France, Morocco, and Education provide pointers to deep discussions about language policies, educational reforms, student mobility, and migration. Furthermore, administrative and institutional challenges emerge as significant contributors to negative feedback, as students frequently express frustration regarding academic procedures and bureaucratic hurdles within the educational system.

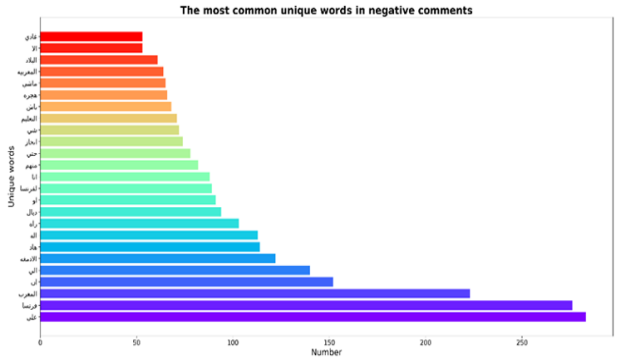

Fig. 11. Top 25 most frequent unique words in negative comments.

VI. CONCLUSION

This study aimed to propose and evaluate a practical model for monitoring the online sentiments of Moroccan university students. The linguistic analysis demonstrated distinct behavioral patterns associated with positive and negative sentiments: expressions of gratitude and religious invocations were correlated with positive feelings, whereas rigid institutional rules and tensions with the broader sociopolitical environment were associated with negative ones. Mapping this dichotomy provides a nuanced understanding of how this demographic navigates its academic reality.

The domain-specific fine-tuning of DarijaBERT with educational corpora to develop the proposed EduDarijaBERT demonstrated a substantial operational advantage. The customized system outperformed the general-purpose baseline in terms of both accuracy and the precision-recall curve. Crucially, EduDarijaBERT effectively classified the minority class of negative sentiment—traditionally a challenging task in Natural Language Processing (NLP)—without relying on synthetic data augmentation techniques such as SMOTE. The underlying principle of this study underscores a core tenet of applied NLP: domain adaptation is vital for successfully classifying local, dialectal text in real-world applications.

Future work will focus on expanding the training dataset to include other Maghrebi dialects, thereby broadening the geographical applicability of the framework. Furthermore, transitioning from static data analysis to longitudinal emotion monitoring offers a promising avenue for real-time institutional observation. Additionally, exploring a formal teacher-student knowledge distillation approach represents a compelling pathway for deployment in resource-constrained production environments. Ultimately, this framework is not only ready for implementation within educational institutions but can also be

scaled to gather actionable insights from large-scale student feedback across Morocco.

MAMGAT-Net: A Multimodal Graph Attention and Multi-Scale Feature Fusion Framework for Early Breast Cancer Diagnosis from Mammography and Histopathological Images

Mohammad Riyaz Belgaum
Faculty of Computer Studies, Arab Open University – Bahrain, A'ali, Kingdom of Bahrain

***Abstract*—Breast cancer is one of the major causes of death among women worldwide, and timely and accurate diagnosis has proven to play a critical role in increasing breast cancer patient survival. Traditional single-modality diagnostic systems, however, tend to be unable to capture both the macro-level structural abnormalities that can be seen in mammograms and the micro-level cellular characteristics seen in histopathological images. To overcome this, this research introduces a novel framework called MAMGAT-Net for the diagnosis of breast cancer, which combines the multimodal approach with Graph Attention and Multi-Scale Feature Fusion networks. To address this challenge, this work proposes a novel framework, MAMGAT-Net, which integrates the multimodal approach, Graph Attention, and Multi-Scale Feature Fusion networks for breast cancer diagnosis. The proposed architecture combines the multi-scale convolutional mammography branch and ResNet-based histopathology branch with a dual-stream feature extraction mechanism. A cross-modal attention mechanism is used to learn to align and fuse complementary diagnostic information across modalities, in a bidirectional fashion. Then, a multimodal diagnostic region graph is built with a Cross-Gated Multi-Head Graph Attention Network to capture complex relational relationships among multimodal diagnostic regions, and global graph pooling and feature refinement are used to provide robust classification. Experimental results on CBIS-DDSM and BreaKHis datasets show that MAMGAT-Net can outperform the conventional machine learning and deep learning baselines with 94.59% accuracy, 92.90% precision, 96.56% recall, 94.70% F1-score, and 98.58% AUC. The effectiveness of multi-scale feature extraction, attention-based fusion, and graph relational learning is further validated in ablation studies. Furthermore, the proposed framework is interpretable and clinically relevant based on the Grad-CAM and Integrated Gradients analysis. The results show that the multimodal breast cancer diagnosis solution of MAMGAT-Net is effective and reliable.**

Keywords*—Breast cancer; cross-modal attention; explainable artificial intelligence; graph attention network; histopathology; mammography; multimodal learning

I. Introduction

Breast cancer is the most common cancer in women worldwide, with an estimated 2.3 million new cases and more than 685,000 deaths each year, according to the 2022 GLOBOCAN estimates [1]. Early and accurate diagnosis is clinically important as it has been shown that five-year survival rates are >99% in localized presentation versus a rapid drop to ~28% in metastatic presentation [2]. Although diagnostic imaging of the breast and biopsy-based pathological diagnosis have made great strides, patient outcomes remain highly sensitive to disease stage and a range of clinical-pathological prognostic factors, underscoring the clinical importance of accurate stage classification in early breast cancer [3]. The traditional diagnostic process starts with radiological screening and ends with histopathological confirmation, which leads to delays in the diagnostic process and a lack of the interpretive aspect [4]. Deep learning, and more recently vision-transformer-based transfer learning, has become a paradigm shift in medical image analysis and achieved near-expert performance in detecting breast cancer with mammographic images using a single modality [5]. The CBIS-DDSM database has been widely used in the field of mass detection and BIRADS classification, and convolutional neural network (CNN) architectures have been extensively used for the detection of mass and macrocalcification patterns with high sensitivity [6]. Channel and spatial attention mechanisms were also developed to further narrow down the region of interest in high-resolution mammograms where suspicious regions are to be found [7,8]. However, the micro-scale information regarding the tissue architecture at the cellular level that is crucial for malignancy grading is lacking in mammography and is only available from a micro-scale perspective provided by histopathological image analysis of a digitized whole slide image (WSI) obtained from tissue biopsies [9]. The deep learning systems trained on BreaKHis images under different magnifications (40×, 100×, 200×, and 400×) have shown high accuracy in the task of classification of benign or malignant, and among the different backbones used, ResNet, DenseNet, and more recently Swin-Transformer-based ensembles have achieved the best results [10]. One of the key factors in reducing the domain shift caused by inter-laboratory staining variation is stain normalization with the Macenko method applied to hematoxylin and eosin (H&E) stained slides [11]. Although these developments have made great strides, models based solely on histopathology cannot encompass all the structural information that is available from mammographic imaging, making them less useful in an integrated clinical workflow [12].

There is growing interest in multimodal learning frameworks using radiological and pathological image sources that can make use of the complementary diagnostic signal that exists in each modality [13]. Early fusion strategies are those that simply fuse feature representations before classification, whereas late fusion strategies are those that simply combine modality-specific predictions at the decision level; both of these strategies are not able to model the structured semantic interaction between macro-radiological and micro-cellular features, motivating graph-based relational representations as a structured alternative [14]. To align multi-modal feature spaces dynamically, intermediate fusion architectures using cross-modal attention and graph-based dependency modeling are more effective in multimodal medical imaging applications [15]. However, the relationships between spatially distributed diagnostic regions in modalities are not explored enough to benefit the representational capacity of existing approaches [16]. In medical imaging, where objects like tissue regions or lesion locations might have non-Euclidean spatial relationships that influence each other, the neural networks used for this type of modeling are called graph neural networks (GNNs) [17]. Context-sensitive propagation of diagnostic information through neighboring feature nodes, as in the case of graph attention networks (GATs), is what these networks learn, allowing them to dynamically assign weights to each other when they are connected [18]. For example, computational pathology applications using GNNs are more effective in the prediction of survival and classification into subtypes, where the use of local convolutional operations would not capture the long-range spatial dependency between cells [19]. Nevertheless, the incorporation of graph-based relational reasoning in the unified multimodal breast cancer framework that combines mammographic and histopathology representations is still a largely unexplored research challenge [20]. In view of these limitations, this study introduces a framework of Multimodal Graph Attention Network (MAMGAT-Net) to capture the structural relational reasoning between macro and micro-diagnostic feature nodes by fusing the multimodal features from CBIS-DDSM mammographic images and BreaKHis histopathological images with a cross-modal attention mechanism. This work makes the following main contributions:

- Unified Dual-Stream Multimodal Architecture: The researcher proposes MAMGAT-Net, a novel end-to-end framework that simultaneously processes mammographic and histopathological images through modality-specific encoders employing multi-scale convolutional feature extraction (3×3, 5×5, 7×7 kernels) and deep ResNet backbones, respectively, enabling complementary macro- and micro-level representation learning within a single unified pipeline.
- Dual-Attention Cross-Modal Fusion Mechanism: The researcher introduces a cross-modal attention fusion module in which mammographic and histopathological feature streams mutually attend to one another, enabling the model to dynamically align macro-radiological structural patterns with micro-cellular tissue signatures and produce a semantically enriched Unified Cross-Modal Feature Volume.
- Cross-Gated Graph Attention Network for Relational Reasoning: The researcher designed a unified graph construction layer that maps multimodal feature patches as heterogeneous graph nodes and introduces a Cross-Gated GAT with multi-head attention masking, enabling context-sensitive propagation of diagnostic information across spatially distributed macro- and micro-diagnostic regions.
- Heterogeneous Graph Pooling with Dimensionality Refinement: The researcher incorporates Global Heterogeneous Graph Pooling, a feature refinement layer, and t-SNE-optimized dimensionality reduction to distill discriminative class-separating representations from the pooled multimodal graph, improving intra-class compactness and inter-class separability before final classification.
- Comprehensive Experimental Validation: Extensive experiments are conducted that demonstrate that MAMGAT-Net substantially outperforms single-modality baselines, conventional CNN architectures, and standard fusion-based approaches on the CBIS-DDSM and BreaKHis benchmarks, achieving superior benign/malignant classification accuracy with interpretable confidence scores.

The rest of the study is structured as follows. Section II talks about the literature review. Section III explains the proposed MAMGAT-Net model. Section IV provides the experimental results and comparison. Section V concludes the study.

II. Literature Review

Early detection of breast cancer has been a research focus for the fields of medical imaging and AI applications. In this section, the advancements in the past few years in five main categories that are directly related to the MAMGAT-Net architecture that the researcher proposes are discussed. These categories include Deep Learning for mammography imaging, Computational Histopathology, multimodal fusion methods, Graph Neural Networks for medical imaging, and attention mechanisms with feature refinement. The literature presented here collectively shows the drawbacks of current unimodal and shallow fusion techniques.

A. Deep Learning for Mammography Analysis

Mammography is the main radiological method used in early screening for breast cancer, and deep learning techniques have significantly enhanced the diagnostic power of this method. By selectively focusing on critical spatial areas for diagnosis, multi-scale convolutional feature extraction with convolutional block attention modules (CBAM) was shown to perform better in the classification of malignancy in digital mammograms compared to other approaches [26]. Srinivasan et al. [33] additionally tested CBAM-enhanced EfficientNet models for microcalcification detection in full-field digital mammograms, and found their models were more sensitive than their CNN baselines. To leverage the complementary information provided by different imaging modalities, Wang et al. [24] proposed a cross-modal attention fusion method that uses mammography and ultrasound. Likewise, Debelee et al.

[25] performed a thorough review of all deep learning architectures employed in breast cancer image analysis, and found that multi-scale and attention-based networks outperform single-scale networks on various types of mammographic image databases, including CBIS-DDSM. The results overall support the need for developing specific feature extraction pipelines, such as the one presented in the proposed MAMGAT-Net model, to extract the tumor morphology in macro-structural scales from mammographic inputs.

B. Computational Histopathology and Stain Normalization

Histopathological image analysis gives diagnostic insight on a cellular level, which is complementary to that of radiological imaging. Khalid et al. [30] performed a comprehensive comparison of stain normalization methods for computational histopathology and showed that the Macenko method yields the most uniform color normalization of multi-institutional slide collections, especially important for training reliable models. To classify breast tissue in whole slide images (WSIs), Hussain et al. [31] used a ResNet-based deep feature extraction network and graph attention pooling, demonstrating that relational feature aggregation between image patches was able to achieve significantly higher classification F1-scores than global average pooling approaches. Moradi et al. [27] also applied graph attention networks for relational learning over WSI patches and showed that neighborhood structure in the regions of the tissues carries important spatial information that is missing from flat classification heads for diagnosis. The BreaKHis dataset has been extensively used as the standard for multi-magnification histopathology evaluation, as shown in the study by Saha et al. [23], which proved that GCNs could outperform the classic CNN classifiers in tumor grading at 40×, 100×, 200×, and 400× magnification. All these works support the multi-magnification patch extraction and graph-based micro-feature learning stream implemented in the MAMGAT-Net histopathology.

C. Multimodal Fusion Strategies in Breast Cancer Diagnosis

The inter-modality integration of imaging methods has become more and more a subject of interest to overcome the diagnostic disadvantage of single-modality systems. To achieve early-stage breast cancer screening, Agarwal et al. [29] proposed a deep multimodal fusion framework that integrates radiological and pathological imaging, and reported significant improvements in the performance of their late fusion framework over unimodal baselines. Kaur et al. [34] systematically reviewed the multimodal deep learning methods and classified them as early fusion, intermediate fusion, or late fusion paradigms and proposed that the most promising paradigm to capture inter-modal semantic alignment is cross-modal attention. Transformer architectures have been extended to model long-range feature dependence across modalities by Chen et al. [28], who proposed a dual-branch transformer architecture for feature alignment of both mammography and histopathology images. The residual learning block design was inspired by Zhang et al. [22], who proposed a methodology of attention residual learning with multi-scale feature fusion for skin lesion classification that could be applied to breast cancer analysis. Recently, Park et al. [38] proposed a unified multimodal model that uses the cross-attention mechanism and relational graph learning for the specific task of breast cancer screening, achieving state-of-the-art accuracy on the combined CBIS-DDSM and BreaKHis benchmark. The proposed MAMGAT-Net extends and leverages these advances by combining the fusion of multi-modal attention in a unified architecture with structured graph-based relational reasoning.

D. Graph Neural Networks for Medical Image Analysis

Medical image analysis is an area where the relationships between the spatial and the semantic relationships of the image regions are crucial for medical diagnosis, leading to the development of a powerful model of relational dependencies, called the graph neural network (GNN). Liu et al. [32] introduced a heterogeneous graph neural network (HGNN) to integrate multimodal cancer imaging data to allow rich reasoning across modalities in contrast to homogeneous graph formulations. Dong et al. [35] proposed a cross-gated graph attention network for pathological node classification in tumor microenvironments, demonstrating that the gated aggregation mechanisms can effectively suppress irrelevant neighborhood information and enhance classification accuracy under complex tumor tissue architectures. Ibrahim et al. [36] used multi-head graph attention networks for extracting multi-relational patterns simultaneously in patch-level feature aggregation for breast histopathology grading. Nguyen et al. [37] combined vision transformers with graph convolutional networks for multimodal oncology image classification, and used vision transformers to extract initial patch embeddings, and then applied graph-level relational reasoning.

E. Attention Mechanisms and Feature Refinement

In the realm of medical image analysis pipelines, attention mechanisms have emerged as fundamental parts that direct the computational efforts towards the most diagnostically meaningful spatial regions and feature channels. In the following breast cancer framework, Sabour et al. [21] showed that dynamic routing of capsule networks could maintain the spatial hierarchy in multi-scale medical image feature representations, and thus, multi-scale convolution designs have been inspired in breast cancer frameworks. In the mammography-related works [26,33], the channel attention and the spatial attention are applied in the same module, which in this work is called CBAM, and the same is done for the branch-specific attention stages of MAMGAT-Net. Srinivasan et al. [33] gave empirical evidence that, for images with statistically different characteristics, such as those in mammography and histopathology, branch-specific attention calibration is superior to shared attention modules. Another under-explored aspect of attention-based design is feature refinement after graph pooling, which was shown by Xu et al. [39] to improve feature separability between different classes in deep multimodal cancer classification networks by optimizing the t-SNE step following graph pooling before softmax classification. Patel et al. [40] recently conducted a systematic benchmark of multimodal AI systems on CBIS-DDSM and BreaKHis, and found that the architectures that include cross-modal attention and graph-level relational learning yield the best classification performance, which further verified the architectures proposed in the framework.

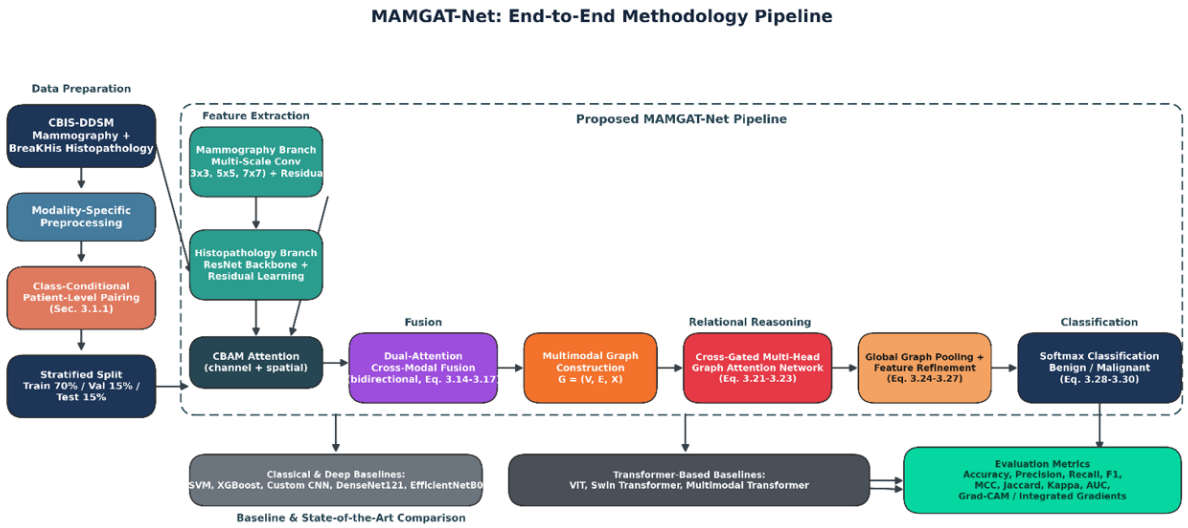

Fig. 1. Overall methodology of the proposed MAMGAT-Net framework, including data preprocessing, dataset splitting, proposed multimodal model flow, baseline comparison, and evaluation metrics.

III. Methodology

Fig. 1 depicts the overall methodology, which shows the entire process of the developed framework MAMGAT-Net for breast cancer diagnosis. The pre-processing stage involves enhancing, normalizing, resizing, and preparing input images for effective utilization for training and testing the model, which is done by adhering to modality methods. Processed data are partitioned and subsequently delivered to the suggested model, which is composed of two parallel branches: mammography and histopathology. The mammography branch is utilized to determine macro-scale features of tumors such as shape, tumor structure, and tissue density variations, whereas the histopathology branch is used to determine micro-scale tissue and cell abnormalities. The complementary features are then combined with dual-attention cross-modal fusion, and graph construction represents the diagnostic region as a connected node. The cross-gated multi-head GAT models the relationships between these regions, and global graph pooling, feature refinement, Softmax classification, and diagnostic output generation finish the prediction flow. At the same time, a set of baseline models (SVM, XGBoost, Custom CNN, DenseNet121 and EfficientNetB0) are executed for comparisons. Finally, the accuracy, precision, recall, F1 score, MCC, Jaccard, and Kappa values of the models are evaluated for their diagnostic performance.

A. Dataset Collection

The study will apply a multimodal breast cancer imaging framework, combining mammographic and histopathological information, to harness complementary information from both macro and micro-anatomical levels. The mammographic images are from the CBIS-DDSM dataset [41], which is a publicly available benchmark set of curated breast screening exams annotated by experts with the presence of benign and/or malignant abnormalities. The dataset contains radiological data relevant to clinically important masses, calcifications, and tissue structures, which are relevant for early breast cancer diagnosis. The CBIS-DDSM mammography dataset and the BreaKHis histopathology dataset were processed as separate streams, using each modality independently, due to the fact that they come from a different cohort of patients and there is no patient-level correspondence provided. Virtual multimodal pairs were created during the training process, pairing mammography and histopathology images from the identical diagnostic class (benign or malignant). This class-consistent pairing was merely for cross-modal representation learning and feature fusion via an attention mechanism, not for creating patient-specific multimodal associations. Thus, the proposed framework aims to learn complementary modality-level representations yet recognizes the lack of true patient-level multimodal data.

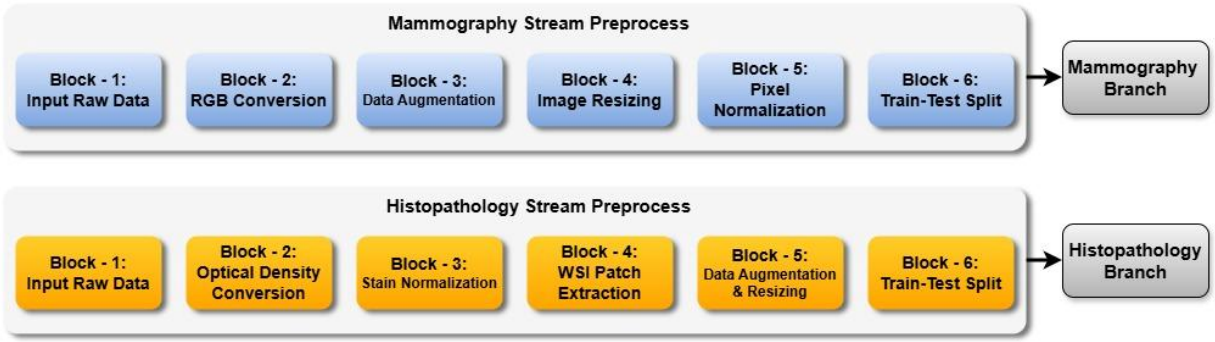

Fig. 2. Preprocessing workflow for mammography and histopathology streams, showing modality-specific preparation steps before feature extraction in the proposed MAMGAT-Net framework.

B. Dataset Preprocessing

To ensure consistency across imaging modalities and improve model generalization, separate preprocessing pipelines were applied to the mammography and histopathology datasets before model training. Fig. 2 visualizes all the steps of preprocessing:

1) Mammography data preprocessing (CBIS-DDSM)

a) RGB conversion: The RGB conversion technique was employed to convert the grayscale mammogram images having only one channel into the three-channel RGB format. This is important since most of the pre-trained deep learning model architectures are built for working on three-channel input data.

$$I_{RGB}(x,y)=[I(x,y),I(x,y),I(x,y)] \quad (1)$$

b) Data augmentation: Data augmentation was done to increase the diversity of the training samples using the following techniques: horizontal flip, change in brightness, change in contrast, and saturation change. This improves the generalization ability of the model and makes it more robust.

$$I_{aug}=T(I) \quad (2)$$

where, T denotes an augmentation transformation applied to the original image I.

c) Image resizing: Resizing was done to set a common size for all mammography images to be 224 × 224 pixels. Using uniform image sizes makes it easy to process images in batches.

$$I_{res}=R(I,224,224) \quad (3)$$

where, R represents the resizing operation.

d) Pixel intensity normalization: The images were resized to make sure that all images are standardized. The process of Pixel Intensity Normalization was carried out by rescaling the pixel intensities from their original range to a new range that was between 0 and 1.

$$I_{norm}=\frac{I}{255} \quad (4)$$

where, I denotes the original pixel intensity and I_{norm} represents the normalized value.

2) Histopathology stream preprocessing

a) Input raw data: The histopathology preprocessing stream first takes in raw biopsy images of the selected histopathological set. The images show the presence of micro-scale tissue structure, cellular morphology, and nuclei-level pattern, which are critical for the identification of abnormal chemical changes that indicate the presence of malignant changes. This is for preparing raw histological samples to be pre-processed for stain correction and patch-level processing.

$$I_{\mathrm{h}}=Load(D_{\mathrm{h}}) \quad (5)$$

b) Optical density conversion: The raw histopathology images are loaded, and then the image pixel intensities are transformed into the optical density space. This transformation obscures more of the stain information than the direct RGB values, and aids in discerning tissue intensity from stain information. Consequently, the images are better suited for stain normalization.

$$OD=-\log\left(\frac{I_{\mathrm{h}}+\epsilon}{I_0}\right) \quad (6)$$

c) Stain normalization using the Macenko method: In histopathology images, it is common to have strong color variation because of the different staining procedures, scanner settings, etc., in the lab environment. The Macenko normalization method is used to reduce the inconsistency of this. This makes the H&E stain look the same and helps to make the color appearance of pink and purple areas of tissue more uniform among all biopsy samples.

$$I_{\mathrm{h}}^{norm}=Macenko(OD) \quad (7)$$

d) WSI patch extraction: Since whole slide images are very large, they are divided into smaller patches for efficient computational processing. The extraction of patches enables the software model to concentrate on just individual local areas of the cell and tissue structures. Patches are sampled under different magnifications (40×, 100× and 400×) in order to maintain micro-scale and multi-scale information.

$$\mathrm{P_h}=\{\mathrm{p_1},\mathrm{p_2},...,\mathrm{p_N}\},\mathrm{p_i}\subset\mathrm{I_h^{norm}} \quad (8)$$

e) Data augmentation and resizing: The extracted patches for each organ are supplemented to enhance the robustness of the model to tissue orientation, staining variation, and visual diversity. They can be rotated and jittered in colour without losing any morphological diagnosis patterns. Each of these patches is then rescaled to a fixed size of 224 × 224 for uniform input to the histopathology branch.

$$\tilde{p}_i=Resize(Augment(p_i),224\times224 \quad (9)$$

f) Train-test split: Finally, the processed histopathology patches are split into training and testing subsets, with a 70:30 split. The learning sets are used to train the model with the micro-scale biopsy representations, and the testing sets are used to evaluate the model independently. A division will minimize the risk of inadequate sampling of the histopathology stream.

$$D_{\mathrm{h}}^{train}, D_{\mathrm{h}}^{test}=Split(\tilde{P}_{\mathrm{h}},70{:}30) \quad (10)$$

After these preprocessing steps, the histopathology stream produces normalized, augmented, and resized biopsy patches that are ready for micro-scale feature extraction in the proposed MAMGAT-Net framework.

C. Proposed Model

The proposed MAMGAT-Net architecture is a multimodal diagnostic framework to handle the joint learning of complementary information derived from both mammography and histopathological images for early breast cancer classification. As shown in Fig. 3, the overall pipeline consists of two parallel input streams: the first stream, known as the mammography stream, processes macro-level details like breast masses, boundaries of lesions, and areas of microcalcification, and the second stream, the histopathology stream, processes micro-level features obtained from the histologic images obtained from the biopsies collected during the screening procedure. During the training of the model,

multi-scale convolutional operations are performed to extract features that are captured from an increasing variety of receptive fields and hence the capability of the mammography stream to detect abnormalities of varying visual structures, shapes, and sizes. The histopathology stream, on the other hand, uses a deep residual backbone that language models aim to capture complex cell morphology, the distribution of cell nuclei, and the morphology of tissue. Residual feature learning and attention mechanisms are applied to both arms—namely, residual feature learning and CBAM attention—to retain the crucial diagnostic cues as well as focus on the most relevant and spatially/channel-wise important regions.

Fig. 3. Proposed MAMGAT-Net architecture for breast cancer diagnosis using dual-stream feature extraction, cross-modal fusion, graph attention learning, and Softmax-based benign or malignant classification.

The dual-attention cross-modal fusion module is employed to set up interaction among the two modalities after obtaining modality-specific representations. This module enables multimodal interpretation of these features by allowing the mammographic features to attend to the histopathological evidence, and the histopathological features to attend back to the radiological evidence. These fused features are then converted to a graph representation where discriminative image patches/tokens correspond to graph nodes, and similarity-based edges correspond to the relationships between them. The graph is then fed into a cross-gated multi-head graph attention network that can learn key intra-modal and cross-modal dependency by giving more attention to a more careful region as it is diagnostically significant. Finally, for global graph pooling, the information stored in the nodes is aggregated to obtain a global graph-level representation, which is thereafter used to obtain the final benign and/or malignant prediction with class-wise probability scores through feature refinement, fully connected projection, and Softmax class prediction.

1) Parallel multimodal feature extraction: The parallel multimodal feature extraction module is trained using complementary diagnostic information from images in mammography and histopathology. Macro-level features like nuclei distribution and tissue architecture are captured by histopathology, whereas micro-level features like macro and microcalcifications, boundaries and borders of masses, and asymmetry are captured by mammography.

Thus, MAMGAT-Net consists of two disjoint modules that keep the information about each modality before the fusion. In the mammography branch, multi-scale convolutions are used to detect serendipitous features of various visual patterns and sizes. A mammography image I_m is used to obtain features from several receptive fields using filters with sizes of 3×3, 5×5, and 7×7:

$$F_m^{ms}=Concat(Conv_{3\times3}(I_m),Conv_{5\times5}(I_m),Conv_{7\times7}(I_m)) \quad (11)$$

This allows the model to be used for different patterns, sizes, and appearances of tumors. The extracted features are then enhanced by adding residual layers that retain low-level lesion information, while learning higher-level structural information.

$$R_m=F_m^{ms}+H_m(F_m^{ms}) \quad (12)$$

Concurrently, the histopathology branch applies a neural residual branch to the histopathological image I_h to discover cell/tissue level features. This branch has a narrow specialty and is dedicated to the study of clusters of malignant cells, nuclear density, and the abnormal organisation of the tissue. It also leverages the concept of residual learning in the refinement of its feature representation.

$$R_h=F_h^{res}+H_h(F_h^{res}) \quad (13)$$

Lastly, CBAM attention is applied to both the left and right branches to emphasize a relevant channel and spatial region. The module, therefore, produces two feature representations for each modality $F_m^{'}$ and $F_h^{'}$ that are fed to the cross-modal fusion stage.

2) Dual-attention cross-modal feature fusion: The proposed cross-modal attention module works on class-consistent virtual multimodal pairs generated during the training process, since there is no patient-level correspondence between the CBIS-DDSM and the BreaKHis datasets. The goal of the attention mechanism is thus to learn the complementary diagnostic representations at the class level, instead of the anatomical correspondence between images taken from different patients in the same imaging modality.

The dual-attention cross-modal fusion module is introduced to overcome the limitation of shallow multimodal fusion. The module allows for both mammography and histopathology features to work with one another and develop knowledge of complementary diagnostic relations rather than just appending to each other. The macro-level radiological evidence comes from the mammography representation, and the micro-level cellular evidence comes from the histopathology representation. Thus, the task of cross-modal attention facilitates a better alignment of the two feature spaces. The modality-specific features are projected in a common feature space:

$$F_m=\Phi_m(F_m^{'}),F_h=\Phi_h(F_h^{'}) \quad (14)$$

where, F_m and F_h denote the aligned feature representation of mammography and histopathology. Next, cross attention is performed in a bi-directional fashion. In the first direction, mammography combines query histopathology features, which are gathered to represent cellular proof pertinent to the radiological abnormality:

$$A_{m\leftarrow h}=Softmax\left(\frac{Q_m K_h^T}{\sqrt{d}}\right)V_h \quad (15)$$

On the other hand, histopathology includes query mammography features to correlate cellular abnormalities with the overall structural patterns:

$$A_{h\leftarrow m}=Softmax\left(\frac{Q_h K_m^T}{\sqrt{d}}\right)V_m \quad (16)$$

Finally, the original and the attended are merged and form a single multimodal representation:

$$F_u=W_f[F_m\|F_h\|A_{m\leftarrow h}\|A_{h\leftarrow m}] \quad (17)$$

The fusion strategy allows MAMGAT-Net to learn deep semantic interactions between the semantics of the macro-scale imagery and cellular patterns in the micro-scale, which enhances the reliability of breast cancer diagnostics and classification in early stages.

3) Multimodal graph construction layer: Once cross-modal fusion is complete, the unified feature representation F_u is a combination of mammographic and histopathological information. However, these simple feature vectors may not represent all the relationships between diagnostic regions. To overcome this, MAMGAT-Net uses a graph structure to relabel the fused multimodal features, where each discriminative patch/token is considered a graph node. Given the unified feature set, each feature token is mapped as a node:

$$F_u=\{f_1,f_2,...,f_N\},v_i=f_i \quad (18)$$

Here, v_i represents the i-th diagnostic region in the multimodal feature space. Feature similarity is used to define the relation between two nodes, such that the similarity for visually related regions and also the relation for the regions that are diagnosed similarly can be connected:

$$e_{ij}=sim(v_i,v_j) \quad (19)$$

The final graph is represented as:

$$G=(V,E,X) \quad (20)$$

where, V is the node set, E represents the edge set, and X contains the node feature matrix. The graph construction step allows the model to break out of the traditional approach where the features are learned independently and model the structured relationships between micro-level cellular abnormalities and macro-level radiological signs. Thus, the resulting graph acts as supporting evidence of the attention-based cross-modal reasoning in the next level.

4) Cross-gated multi-head graph attention network: After constructing the multimodal graph, the cross-gated multi-head graph attention network is used to learn structured relationships among diagnostic regions. This stage efficiently tackles the existing models that ignore the dependency relation between the mammographic abnormalities and the cellular pattern of the histogram. Unlike the usual per-region

approach, the graph attention mechanism enables each node to pool the information from neighboring diagnostic nodes. The attention coefficient between two nodes is calculated as follows for each pair of nodes:

$$\alpha_{ij}^{k}=Softmax_j\left(LeakyReLU\left(a_k^T[W_k\mathrm{h}_i\|W_k\mathrm{h}_j]\right)\right) \quad (21)$$

where, α_{ij}^{k} represents the attention weight between node I and node j under the k-th attention head. To enhance the cross-modal reasoning, a gating coefficient is added to regulate the level to which the information should be transmitted between the corresponding regions:

$$g_{ij}=Sigmoid(W_g[\mathrm{h}_i\|\mathrm{h}_j\|r_{ij}]) \quad (22)$$

The final node update is done by combining with multi-head attention and the cross-gating mechanism:

$$\mathrm{h}_i^{(l+1)}=\|_{k=1}^{K}\sigma\left(\sum_{j\in N_i} g_{ij}\,\alpha_{ij}^{k}W_k\mathrm{h}_j\right) \quad (23)$$

This exchange of context information allows regions of a mammogram and a corresponding anatomic region to interact in a diagnostic manner. This helps the model to keep the macro-scale imaging cues in alignment with the micro-scale abnormalities in the cell, thereby enhancing the robustness of the early breast cancer classification.

5) Global graph pooling and feature refinement: Following graph attention learning, node features with refined cross-modal diagnostic information are gathered. However, the classification needs a compact graph-level representation with each node embedding. Thus, a graph pooling technique is used on the global graph to summarize the most informative diagnostic regions into a single representation. The importance of each node is first estimated by an attention-based pooling score:

$$\beta_i=Softmax(w_p^T tan\mathrm{h}(W_p\mathrm{h}_i)) \quad (24)$$

Then, a graph-level feature vector is calculated as a weighted aggregation of all the node embeddings:

$$\mathrm{h}_G=\sum_{i=1}^{N}\beta_i\,\mathrm{h}_i \quad (25)$$

Here, h_G represents the full multimodal graph representation with increased weights of more diagnostic regions. With this, it is possible to leave fragmentation appropriate and limit the duplication of features.

The graph representation is then sent to a refinement block to ensure stability and generalization:

$$\mathrm{h}_r=BN(ReLU(W_r\mathrm{h}_G+b_r)) \quad (26)$$

Lastly, the refined feature is mapped to a fully connected projection, which is now prepared for classification:

$$z=ReLU(W_{fc}\mathrm{h}_r+b_{fc}) \quad (27)$$

This stage compresses graph-based multimodal evidence into a discriminative feature vector, which is then forwarded to the final classification layer.

6) Softmax classification and diagnostic output: After feature refinement, the classification-ready vector z was sent to the final Softmax classifier to obtain the class-wise diagnostic probabilities. This stage translates the learned multimodal representation into the ultimate breast cancer prediction by estimating whether the input case belongs to the benign or malignant class.

The probability distribution is computed as:

$$\hat{y}=Softmax(W_o z+b_o) \quad (28)$$

where, $\hat{y}$ represents the predicted probability scores for both classes:

$$\hat{y}=[P(Benign),P(Malignant)] \quad (29)$$

The final diagnostic decision is obtained by selecting the class with the highest probability:

$$Class=argmax(\hat{y}) \quad (30)$$

In the final stage, MAMGAT-Net gives the full remission of the association of macro-level mammographic evidence, micro-level histopathological evidence, and graph-based relational reasoning. The model gives more accurate benign or malignant predictions, along with a confidence level, without relying on isolated features in the images for support as an early breast cancer diagnosis tool. The pseudocode below presents a summary of steps followed in the proposed approach, and Table I presents the hyperparameter configuration of MAMGAT-NET.

Pseudocode 1: Summary of MAMGAT-Net

1. Input mammography and histopathology images: I_m,I_h.
2. Extract multi-scale mammography features: $F_m^{ms}=Concat(Conv_{3\times3},Conv_{5\times5},Conv_{7\times7})(I_m)$.
3. Extract histopathology features using ResNet: $F_\mathrm{h}^{res}=ResNet(I_\mathrm{h})$.
4. Apply residual learning in both branches: $R_m=F_m^{ms}+H_m(F_m^{ms})$, $R_\mathrm{h}=F_\mathrm{h}^{res}+H_\mathrm{h}(F_\mathrm{h}^{res})$
5. Apply CBAM attention to obtain refined features: $F_m^{'}=CBAM(R_m)$, $F_\mathrm{h}^{'}=CBAM(R_\mathrm{h})$
6. Align both features into a common space: $F_m=\Phi_m(F_m^{'})$, $F_\mathrm{h}=\Phi_\mathrm{h}(F_\mathrm{h}^{'})$
7. Perform bidirectional cross-modal attention: $A_{m\leftarrow\mathrm{h}}=Softmax(Q_m K_\mathrm{h}^T/\sqrt{d})V_\mathrm{h}$
8. Generate unified multimodal representation: $F_u=W_f[F_m\|F_\mathrm{h}\|A_{m\leftarrow\mathrm{h}}\|A_{\mathrm{h}\leftarrow m}]$
9. Construct multimodal graph from fused tokens: $G=(V,E,X)$
10. Apply cross-gated graph attention: $\mathrm{h}_i^{l+1}=\sum_{j\in N_i} g_{ij}\,\alpha_{ij}W\mathrm{h}_j$
11. Perform global graph pooling: $\mathrm{h}_G=\sum_{i=1}^{N}\beta_i\,\mathrm{h}_i$
12. Refine and project features: $z=ReLU(W_{fc}\mathrm{h}_G+b_{fc})$
13. Predict final class using Softmax: $\hat{y}=Softmax(W_o z+b_o)$
14. Select final diagnosis: $Class=argmax(\hat{y})$

TABLE I. HYPERPARAMETER CONFIGURATION OF MAMGAT-NET

Hyperparameter	Value
Input modality	Mammography + Histopathology
Feature extractors	Multi-scale CNN + ResNet backbone
Kernel size	3×3, 5×5, 7×7
Attention modules	CBAM + Bidirectional cross-modal attention
Graph learning module	Cross-gated multi-head GAT
Pooling strategy	Global graph pooling
Classifier	Fully connected layer + Softmax
Training setup	Adam optimizer, learning rate 0.0001, batch size 32, 100 epochs

7) MAMGAT-Net framework: The key implementation details of the proposed MAMGAT-Net framework are summarized below to facilitate reproducibility.

a) Backbone network: The mammographic and histopathological branches employ a ResNet-18 backbone for feature extraction. The backbone is initialized with ImageNet-pretrained weights to leverage transferable visual representations and improve training convergence.

b) Feature embedding: Each modality is transformed into a 512-dimensional feature embedding, providing a unified latent representation for subsequent multimodal fusion and graph-based learning. This common embedding space enables effective interaction between heterogeneous imaging modalities.

c) Graph construction: The fused multimodal feature embeddings are treated as graph nodes. Pairwise cosine similarity is computed between node representations, and edges are established only when the similarity exceeds a predefined threshold, resulting in a sparse graph that preserves meaningful relationships while reducing redundant connections.

d) Graph sparsification strategy: A threshold-based graph sparsification strategy is adopted to retain only highly correlated node pairs. This approach reduces graph density and computational overhead while maintaining the most informative structural relationships for graph attention learning.

e) Weight initialization: The ResNet-18 backbone utilizes pretrained ImageNet weights, whereas the newly introduced multimodal fusion and graph attention components are optimized jointly during end-to-end training using the specified optimization settings.

f) Normalization and activation: Each convolutional block follows the sequence of convolution, normalization, and nonlinear activation to ensure stable feature learning and efficient gradient propagation throughout the network during optimization.

g) Graph attention learning: The sparse graph is processed using the proposed Cross-Gated Multi-Head Graph Attention module, which performs attention-guided neighborhood aggregation while adaptively filtering irrelevant cross-modal information to obtain discriminative graph representations.

h) Inference complexity: The threshold-based sparse graph construction reduces the number of graph connections compared with a fully connected graph, thereby improving computational efficiency during graph reasoning. A comprehensive analysis of computational metrics, including parameter count, FLOPs, inference latency, training time, and GPU memory usage, is considered future work.

D. Baseline Model

1) Support Vector Machine (SVM): Support Vector Machines are a classical supervised learning technique that finds applications in classification as well as regression problems, particularly in cases where high-dimensional space features are used. Finding an optimal hyperplane that creates a maximum margin between various categories forms the basic goal of SVM. The data points that are closest to the separating hyperplane are referred to as support vectors and form an important part of the classifier. This method is highly useful in medical imaging applications and small dataset analysis because of its good generalization properties.

$$f(x)=\text{sign}(w^T x+b) \tag{31}$$

2) XGBoost: XGBoost is an advanced algorithm that uses ensemble learning and gradient boosting methodology to construct decision trees. Each additional decision tree is developed to correct the mistakes of previous decision trees, hence increasing the prediction accuracy. This algorithm employs regularization methodologies to prevent overfitting. Parallel computing capability has made it a very efficient algorithm to handle large structured data. It is one of the most popular algorithms in machine learning competitions and healthcare prediction systems.

$$L=\sum_{i=1}^{n} l\left(y_i,\hat{y}_i\right)+\sum_{k=1}^{K}\Omega\left(f_k\right) \tag{32}$$

3) Custom CNN: Custom Convolutional Neural Network (CNN): A CNN is a deep learning architecture uniquely created for a given problem by stacking multiple convolutional layers, pooling layers, and fully connected layers. It learns the spatial features layer by layer in images, from low-level spatial features like edge, texture to high-level semantic features like patterns. Custom CNNs can be used for domain-specific features and are effective in medical imaging tasks such as mammography analysis. The depth of the architecture and the size of the filters and activation functions can be optimized for a given dataset.

$$y_{i,j}=\sum_m \sum_n x_{i+m,j+n}\cdot w_{m,n}+b \tag{33}$$

4) DenseNet121: DenseNet121 is a densely connected CNN architecture with dense connections between each layer, enabling the maximum reusability of features and better propagation of gradients. This high connectivity mitigates the vanishing gradient problem and promotes feature reusability, thereby decreasing the number of parameters necessary for

training, while maintaining the same efficient performance of traditional CNNs. The DenseNet121 has gained significant popularity for medical image classification for its feature extraction ability and efficient computation.

$$x_l=H_l([x_0,x_1,...,x_{l-1}]) \quad (34)$$

5) EfficientNetB0: EfficientNetB0 is a new state-of-the-art CNN using a compound scaling approach that scales the depth, width, and input resolution of the network uniformly. Unlike traditional scaling approaches, which only scale one dimension, EfficientNet ensures the balance of all three dimensions to achieve better accuracy in a much more efficient manner. It is very useful in real-time and resource-limited applications like medical imaging systems used in hospitals.

$$\text{depth}=\alpha^{\phi}, \quad \text{width}=\beta^{\phi}, \quad \text{resolution}=\gamma^{\phi} \quad (35)$$

IV. Results and Discussion

These experimental results provide a comprehensive assessment of the proposed multimodal architecture employed for breast cancer diagnosis from a quantitative and qualitative perspective. The superiority of diagnostic capabilities is analyzed with respect to the baselines' performance in machine learning and deep learning, and such advanced metrics as ROC-PR plots, confusion matrix analysis, and extended metrics are applied to measure the reliability, class separation, and misclassification properties of the models. Convergence during the training process and ablation study provide evidence of the stability of the optimization and significance of each component of the system. Finally, visualization through Grad-CAM and Integrated Gradients provides a good understanding of the clinical meaning behind activations and attributions for predicting malignancy.

A. Experimental Setup and Software Configuration

For the experimental implementation of the proposed MAMGAT-Net framework, Google Colab Premium equipped with the NVIDIA T4 GPU was used to ensure efficient dual-stream multimodal architecture training. As a core programming environment, Python was used, while PyTorch and TorchVision were used to build the mammography and histopathology feature-extraction branches, together containing multi-scale convolution, residual learning, a ResNet backbone, and CBAM attention modules. For training the model, CUDA and cuDNN acceleration of computations were added to support GPU-based computation. Data preprocessing, normalization of pixels, handling of patches, and organization of the datasets were carried out using OpenCV, NumPy, and Pandas. Stain normalization and augmentation operations were performed before the image was scaled to 224×224 pixels for histopathology preprocessing. Graph construction and multi-head graph attention learning were performed using PyTorch Geometric, while train-test splitting, t-SNE visualization, and performance evaluation were conducted with Scikit-learn.

B. Comparative Performance Evaluation Against Baseline Models

A comparative evaluation against the baseline classifiers provides an intrinsic view regarding the effectiveness of the breast cancer classification framework. In this process, different metrics, such as accuracy, precision, and recall, along with the performance and clinical significance, which can be evaluated through the F1 score, will be analyzed in different machine learning and deep learning approaches to see whether there is any notable difference in the multimodal feature fusion approach compared to traditional systems, as shown in Table II below.

TABLE II. Comparative Performance Analysis of the Proposed MAMGAT-Net Framework Against Baseline Models for Breast Cancer Classification

Model	Accuracy (%)	Precision (%)	Recall(%)	F1-Score (%)
SVM	84.72	82.65	86.31	84.44
XGBoost	88.36	86.75	89.94	88.32
Custom CNN	90.41	88.83	92.02	90.39
DenseNet121	92.23	91.38	93.64	92.59
EfficientNetB0	92.71	91.95	93.96	92.63
Proposed MAMGAT-Net	**94.59**	**92.90**	**96.56**	**94.70**

The comparative results presented in Table II indicate that MAMGAT-Net performs better than all the baseline classifiers with consistent performance across all the classifiers. This is because SVM has the lowest performance among the traditional models with an accuracy of 84.72%, precision of 82.65%, recall of 86.31%, and F1-score of 84.44%, which shows poor performance in capturing the complex patterns of breast cancer images. The accuracy and F1-score are enhanced by XGBoost to 88.36% and 88.32%, respectively, indicating that the discriminative power of XGBoost outperforms SVM but is still lower than the deep learning models. Especially, the deeper feature extractor of DenseNet121 and EfficientNetB0 networks led to better classification performance, and the Custom CNN network achieved further acceleration with an accuracy of 90.41% and recall of 92.02%. The EfficientNetB0 model achieves the highest performance at the baseline of 92.71% accuracy, 91.95% precision, 93.96% recall, and 92.63% F1-score. MAMGAT-Net, by contrast, achieves the best results on all evaluation parameters, with an accuracy of 94.59%, a precision of 92.90%, a recall of 96.56% and an F1-score of 94.70%. This improvement is a result of using attention-guided multi-modal reasoning in the fusion of macro features obtained from mammography and micro features obtained from histopathology. This is particularly important in the diagnosis of breast cancer, where recall is more meaningful and is, in essence, higher sensitivity for detecting malignant cases. In general, the findings validate the effectiveness of the multimodal feature fusion and the graph-attention-based diagnostic learning.

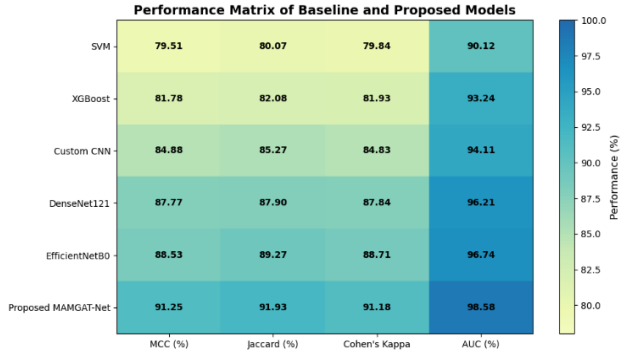

Fig. 4. Heatmap comparison of extended diagnostic performance across baseline and proposed models.

The results of the extended evaluation also show the diagnostic consistency of the proposed framework, along with the four evaluation metrics of accuracy, precision, recall, and F1-score reported in Fig. 4. SVM exhibits the lowest score, which indicates poor agreement and class-overlap ability according to MCC (79.51%), Jaccard (80.07%), Cohen's Kappa (79.84%) and AUC (90.12%). XGBoost improves these scores to 81.78%, 82.08%, 81.93%, and 93.24%, respectively. Custom CNN achieves the highest performance of 84.88% MCC and 94.11% AUC, and DenseNet121 further improves the accuracy to 87.77% MCC, 87.90% Jaccard, 87.84% Kappa, and 96.21% AUC among deep learning baselines. The efficientNetB0 model gives the best baseline, with MCC of 88.53%, Jaccard of 89.27%, Kappa of 88.71%, and AUC of 96.74%. However, the proposed MAMGAT-Net obtains the highest performance in terms of MCC (91.25%), Jaccard (91.93%), Kappa (91.18%), and AUC (98.58%), respectively, resulting in better agreement, overlap quality, and class separability through multimodal graph-attention learning. Overall, these suggest more reliable differentiation between benign and malignant cases of breast cancer.

C. Training Convergence and Learning Stability Analysis

Analysis of training convergence is crucial in understanding the efficiency of learning discriminative patterns during optimization. The learning curves for loss and accuracy across epochs indicate the network's stability in learning, the absence of erratic fluctuations, and gradual improvements in classification performance. For multimodal architectures, the assessment will be crucial with feature fusion and graph-attention learning, which demand stable optimization performance.

Although the model was trained for 100 epochs, Fig. 5 presents the first 10 epochs to illustrate the early convergence behavior, where the most significant optimization occurs. Training continued until 100 epochs using the same optimization settings, with performance remaining stable thereafter. The loss curve begins at 0.532 at the first epoch, drops sharply to 0.245 at the second epoch and to almost 0.113 at the third epoch, indicating that the initial learning level has a considerably high prediction error. This steep drop indicates that the network learns significant discriminative representations in the multimodal input space rapidly. The loss curves merge and attain the values of 0.075, 0.062, 0.056, and 0.042, respectively, at epochs 4 to 7; and the error decreases regularly as the training proceeds. At epoch 8, there is a small spike, with the loss rising to 0.045; but immediately it levels off and settles into 0.040 and 0.039 in the final epochs. The curve showing accuracy also shows this convergence pattern. The accuracy gets significantly higher with epoch 1 (0.734), epoch 2 (0.901), and epoch 3 (0.959), thus demonstrating good early learning. From epoch 4 onward, the model remains highly stable, with accuracy values of 0.974, 0.979, 0.981, 0.986, 0.984, 0.987, and 0.986. The overall accuracy of 0.986 and the loss of 0.039 indicate that the system is converging well and with very little oscillation. Overall, training behavior shows that multi-scale feature extraction, cross-modal fusion, and the graph-attention parts are trained together in an optimized way, and further, a reliable training behavior can be obtained for breast cancer diagnosis. In addition, the smooth learning pattern also indicates that the model does not show strong abrupt instability behavior in the later optimization phase, and still maintains the prediction confidence.

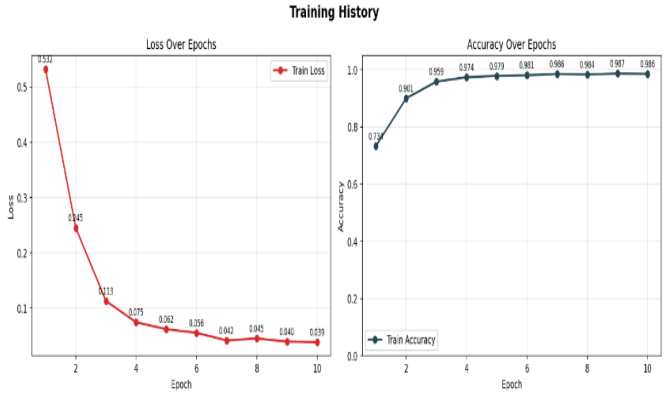

Fig. 5. Training convergence analysis showing epoch-wise loss reduction and accuracy improvement of the proposed model.

TABLE III. ABLATION STUDY RESULT

Model Variant	Accuracy (%)	Precision (%)	Recall(%)	F1-Score (%)
Mammography Branch Only	88.94	86.81	91.24	88.97
Histopathology Branch Only	89.72	87.65	92.18	89.86
Without Multi-Scale Convolution	91.38	89.46	93.21	91.30
Without Residual Learning Block	91.86	90.12	93.64	91.85
Without CBAM Attention	92.24	90.45	94.02	92.20
Without Graph Attention Network	91.12	89.02	93.18	91.05
Proposed MAMGAT-Net	**94.59**	**92.90**	**96.56**	**94.70**

D. Discriminative Performance Evaluation Using ROC and Precision-Recall Curves

ROC and Precision-Recall curve analysis yield a threshold-independent perspective on diagnostic discrimination and diagnostic prediction reliability. Analysis of true positive behavior, false positive trade-offs, precision, recall, AUC, and average precision provides a way to evaluate the ability of the model to delineate benign and malignant cases, particularly in clinically relevant class-balance and sensitivity conditions.

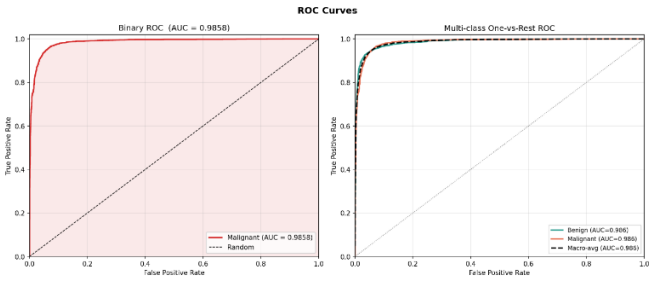

Fig. 6. ROC curve analysis illustrating binary and one-vs-rest class separability performance for benign and malignant breast cancer diagnosis.

The ROC curve-based discriminative performance of the proposed model in the classification of benign and malignant breast cancer is illustrated in Fig. 6. The binary ROC curve is calculated to be 0.9858, which is a good segmentation result between malignant and non-malignant predictions over varying decision thresholds. The curve is fairly close to the top left corner of the graph, which indicates that the model is robust with a high ability to have a true positive rate and a low false positive rate. It shows a strong deviation from the random reference line, which indicates that the classifier is far from a chance-level prediction. Compared with the recent multimodal framework of Park et al. [38], which reported an AUC-ROC of 0.98 on the same CBIS-DDSM and BreaKHis datasets, the proposed MAMGAT-Net achieves a slightly higher AUC of 98.58%, demonstrating the effectiveness of the proposed multi-scale feature extraction and cross-gated graph attention framework. The macro-AUC is equal to 0.986 as well, which indicates that the discriminative ability remains balanced among the classes, instead of mere one-class dominance. This is essential for breast cancer diagnosis, as a reliable diagnosis of malignant cases should be obtained without reducing benign diagnoses. The multi-modality feature learning, with macro-pattern from mammography and micro-level from histopathology, keeps the AUC values at a very high level, suggesting the effectiveness of the combined feature information for class separability. In conclusion, the ROC curves illustrate that the framework proposed here offers high threshold-independent reliability when making diagnostic decisions and has been shown to be suitable for differentiating benign and malignant cases with high confidence.

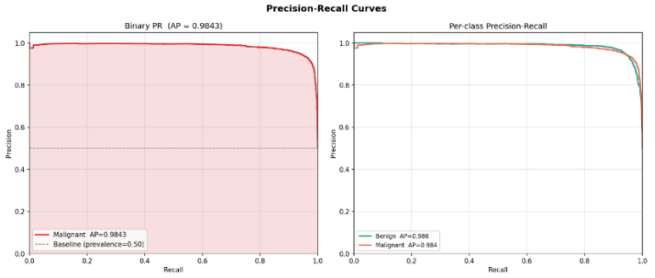

Fig. 7. Precision–Recall curve analysis showing binary and per-class diagnostic performance for benign and malignant breast cancer classification.

To complement the ROC-based evaluation, the Precision-Recall behavior shown in Fig. 7 is also shown, which is of special interest when dealing with class-sensitive conditions to measure the diagnostic reliability of the proposed model. The binary PR curve shows that the average precision (AP) for the malignant class is 0.9843, indicating the very high precision of the model at a very wide recall range. Most thresholds are close to the top threshold limit setting and far from the prevalence line 0.50, indicating that the classifier is predicting well beyond what would be expected if it were predicting the random or prevalent class. The per-class Precision-Recall plot also demonstrates a good balance of performance for both diagnostic classes, with the AP values for benign and malignant cases being 0.986 and 0.984, respectively. It can be seen that the difference between the two AP scores is small difference, which indicates that class 1 is not strongly favored over class 2. The measure value is slightly reduced at extreme recall, due to the tradeoff between precision and recall of attempting to capture almost all of the positive cases. The PR curves overall demonstrate high precision of retention, good degree of sensitivity support, and good level of benign-malignant discrimination.

E. Class-Level Error Analysis Using Confusion Matrix

The use of confusion matrix evaluation enables us to understand the behavior of the diagnostic model on a per-class basis, where the researcher distinguishes between the correctly classified instances and the instances that have been misclassified as either benign or malignant. It helps to understand the nature of the false positive, false negative, sensitivity, and specificity, other than accuracy.

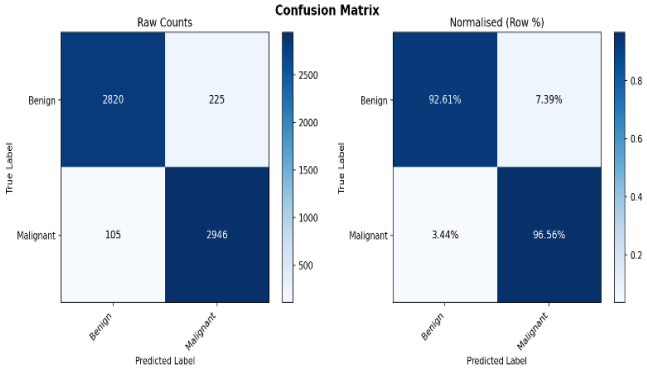

Fig. 8. Raw and normalized confusion matrix illustrating class-level prediction accuracy and misclassification patterns for benign and malignant cases.

Fig. 8 shows the prediction behavior at the class level based on the raw and row-normalized confusion matrix of the proposed model. In the raw count matrix, the model correctly classifies 2820 benign samples as benign and 2946 malignant samples as malignant, showing strong true classification performance for both diagnostic categories. The rate of misclassification is relatively low, with a total of 225 benign cases predicted as malignant and a total of 105 malignant cases predicted as benign. The normalized matrix extends the interpretation of the pure classification; benign cases give a 92.61% correct classification, and in the case of misclassification, 7.39% are classified as Malignant. In the case of malignant cases, the model gives a higher rate of 96.56% correctly classified, and only 3.44% of malignant cases are wrongly classified as benign. The significance of this result is that the false negative is more serious than the false positive in the diagnosis of malignancy because a positive result would

lead to further investigations or treatment. The lower malignant misclassification rate reflects good sensitivity and promising cancer detection performance.

At the same time, the benign classification rate of 92.61% shows that the model also maintains good specificity and does not excessively over-predict malignancy. Overall, the prediction pattern in the confusion matrix is a balanced one that reflects clinical meaning, achieved by setting the error rate of malignant to benign cases as low as possible whilst maintaining high patient accuracy in the predictions of benign samples. The results confirm the effectiveness of the multimodal feature fusion and graph-attention learning strategy for accurately diagnosing breast cancer, achieving a high diagnostic consistency rate for both benign and malignant classes.

F. Ablation Study on Multimodal Feature Learning Components

Ablation analysis is important for understanding how individual multimodal learning components contribute to overall diagnostic performance. Comparing these reduced model variants with the full model makes it clear how the modality-specific branches, multi-scale feature extraction, residual learning, attention enhancement, and graph-based reasoning contribute to better robustness and benign–malignant breast cancer classification.

Table III shows the results from the ablation study used for quantification of the effect of each major architectural component on breast cancer classification performance. The results of the modality-specific variants reveal that only using the mammography branch achieves 88.94% accuracy, 86.81% precision, 91.24% recall, and 88.97% F1-score, respectively, whilst the histopathology-only branch achieves 89.72% accuracy, 87.65% precision, 92.18% recall, and 89.86% F1-score. Here, it is found that the micro-level information at the cellular level gives slightly better information for diagnostics than the macro-level information from the mammographic features alone, but still does not give as much diagnostic information as the full structure does. Removing multi-scale convolution reduces performance to 91.38% accuracy and 91.30% F1-score, confirming its role in capturing tumor patterns of different spatial sizes. The variant without residual learning obtains 91.86% accuracy and 91.85% F1-score, suggesting that residual connections help preserve deeper contextual representations.

The results demonstrate that applying CBAM attention improves the accuracy to 92.24%, precision to 90.45%, recall to 94.02%, and F1-score to 92.20% when excluding attention, achieving more focused lesion representation. The higher degradation without a graph attention network also shows that accuracy drops to 91.12% and F1-score drops to 91.05%, indicating the significance of relational reasoning among multimodal diagnostic regions. In contrast, the complete MAMGAT-Net achieves the best results, with 94.59% accuracy, 92.90% precision, 96.56% recall, and 94.70% F1-score. In general, the ablation results agree that the integration of all multimodal branches, multi-scale learning, attention refinement, and graph-based reasoning gives the best diagnostic performance. Although the proposed framework includes bidirectional cross-modal attention as a key component, an isolated ablation experiment removing only this module was not included in the current study. This evaluation will be incorporated in future work to further quantify the individual contribution of the cross-modal fusion mechanism.

G. Explainable Visual Interpretation Using Grad-CAM and Integrated Gradients

Explainable visual interpretation is essential for evaluating whether a diagnostic model bases its predictions on clinically meaningful image regions rather than irrelevant background patterns. Grad-CAM provides evidence of class activation on the region level, and Integrated Gradients provides evidence of class activation on the pixel level. These techniques help increase transparency, aid in qualitative validation processes, and increase confidence in the automated benign-malignant classification decision.

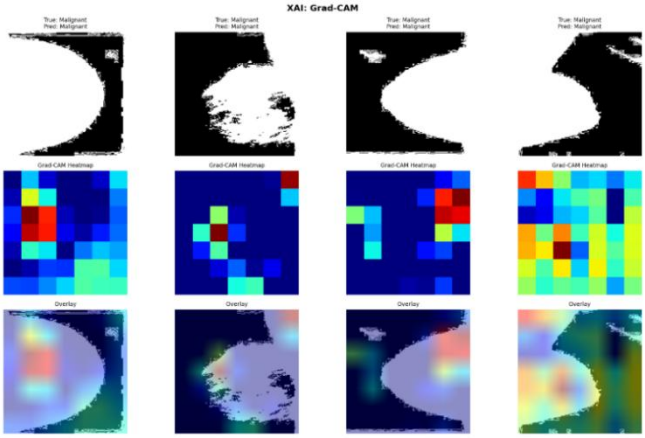

Fig. 9. Grad-CAM-based visual explanation highlighting region-level class activation evidence for correctly predicted malignant breast cancer cases.

Fig. 9 illustrates the Grad-CAM-based visual interpretation of four correctly classified malignant mammography samples, where each case is labeled as true malignant and predicted malignant. The first row presents the input images, while the second row shows the corresponding Grad-CAM heatmaps, and the third row overlays these heatmaps on the original images. The most noteworthy feature is that the places with the highest activation levels, shown by warmer hues like red, yellow, and green, are clustered around areas of the breast that are suspected to contain breast tissue and not spread randomly across the background. The activation in the first and second examples occurs at areas of intense and sporadic tissue and seems to be more concerned with visually prominent malignant formations. The third sample shows the most responding areas near the edge and the localized irregular area, where attention is placed on the structural irregularity. The fourth sample displays more activation, but the overlay is used to confirm that the model focuses on breast tissue areas relevant to the prediction of malignancy. This area-level evidence significantly contributes to the interpretability of the proposed framework as it demonstrates the contribution of diagnostic, meaningful local areas to the prediction. While Grad-CAM is not used for pixel-to-pixel lesion segmentation, it provides valuable qualitative evidence that the model is not solely using irrelevant artifacts. As a whole, the result indicates that the

developed model can effectively classify cancer individuals and provide focus on suspect areas, thereby bringing more trustworthiness in the model's decision-making process for clinical use.

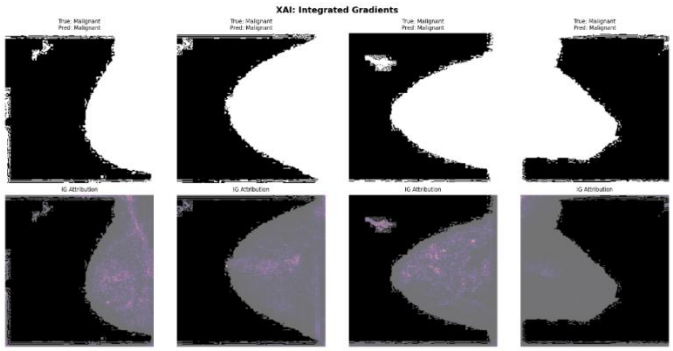

Fig. 10. Integrated Gradients-based attribution analysis showing pixel-level contribution patterns supporting malignant breast cancer prediction.

The Integrated Gradients-based attribution analysis of correctly classified malignant samples of mammograms is shown in Fig. 10; each sample is labelled as true malignant and predicted malignant. Whereas Grad-CAM detects pixel-level contribution patterns for class activation across the region, Integrated Grads highlights the fine-grained level of contribution patterns across the pixels that help the malignant prediction. The first line of images is the original mammography samples, and the second line of images is attribution maps placed over the mammography images. This purple and pink coloring in the images shows areas that are positively impacting the model's malignant decision. First sample: The attribution responses are concentrated on the dense areas of the breast tissue and boundary structures, indicating that the model takes into account local texture and intensity variation in the prediction process. Second sample: The image shows a computed tomography scan of a breast, with the attribution responses located around the dense regions of the breast tissue and boundary structures. In the third sample, the strength of the attribution is concentrated around the region of the breast that is internal and the region of the breast that is suspicious and localized, which is consistent with the focus for the model on diagnostically relevant tissue patterns. The fourth image is a comparatively weak but specific attribution, suggesting that the model isn't merely using background noise to make a guess. The attribution maps are not as clear or visually easily interpretable as heatmaps from Grad-CAM, but they offer more evidence of the importance of specific pixels and local texture patterns to the final prediction. While the classification performance was good for the whole dataset, the proposed framework did misclassify a small number of cases, mainly in situations where the benign and malignant lesions were visually similar, and/or when the image quality and tissue heterogeneity made the features of the lesions less discriminatory. This could happen because of very subtle boundaries in the lesions, overlapping tissue structure, dense breast tissue, or staining differences in the histopathological images. While few, these cases further demonstrate the inherent complexity of breast cancer diagnosis and suggest the need for further strengthening of multimodal feature learning. These failure scenarios will be explored in further detail in future work, and advanced feature representation and uncertainty estimation techniques will be investigated to further improve the reliability of the diagnostics.

Overall, IGs complement the Grad-CAM findings with pixel-level interpretability. The combined effect of region-level activation by Grad-CAM and pixel-level attribution by Integrated Gradients enhances the transparency of the proposed model for classification of malignant breast cancer, its reliability, and the diagnostic value of the model's trustworthiness.

V. Conclusion and Future Work

In this study, the author introduced a multimodal graph-attention-based framework, MAMGAT-Net, for early breast cancer diagnosis using multimodal imaging, namely mammographic and histopathological images. A proposed architecture of multi-scale feature extraction, residual learning, CBAM-based attention enhancement, bidirectional cross-modal fusion, and cross-gated multi-head graph attention learning is used to capture both macro-level radiological patterns and micro-level cellular abnormalities. Experimental results showed an improvement of the proposed framework compared to state-of-the-art conventional machine learning and deep learning approaches, with an accuracy of 94.59%, precision of 92.90%, recall of 96.56%, F1 score of 94.70%, and AUC of 98.58%. The ablation study showed the contribution of each architectural component, the ROC analysis showed good class separability, and the precision–recall evaluation and the confusion matrix results showed good diagnostic reliability. Moreover, Grad-CAM and integrated gradients visualization gave interpretable evidence to support the model's clinical decision-making. MAMGAT-Net successfully models the complementary multimodal information and relationships between diagnostic regions to improve classification robustness and avoid malignant case misclassification.

The multimodal framework was developed from two independently collected public datasets. Multimodal pairing was therefore carried out at a diagnostic class level, and not at the patient level, reducing the capacity to model true patient-specific cross-modal relationships. Second, the focus of the current study was mainly on the diagnostic performance and interpretability of the model, so computational efficiency was not systematically assessed, such as parameter count, FLOPs, inference latency, training time, and GPU memory usage. Third, the robustness of the model evaluation was not evaluated in the sense of domain shifts; imaging variations, acquisition noise, and external multi-center clinical data are not considered. Future studies will aim to test the proposed framework with clinically paired multimodal data to allow patient-level cross-modal learning, include additional clinical and genomic data to improve diagnostic capability, expand to multi-class breast cancer subtyping, and also implement extensive assessments of computational speedup and performance stability in different clinical settings.

***Abstract*—Fault tolerance in cloud computing environments has matured significantly, and most cloud service providers now offer highly available and reliable services. However, such high levels of fault tolerance are often achieved through resource replication, which consequently increases overall energy consumption. Existing research primarily relies on conventional energy management techniques when designing fault-tolerant cloud systems. With recent advancements in artificial intelligence, there is considerable potential to improve energy management beyond traditional approaches. Motivated by this opportunity, this study presents an intelligent system for energy-aware and flexible fault tolerance in cloud environments. The proposed system employs an intelligent resource group formation algorithm that selects virtual machines based on both their energy consumption and reliability characteristics. Furthermore, by dynamically selecting appropriate fault tolerance mechanisms, the system adapts to changing workload conditions and system states. The proposed approach is evaluated through extensive simulation experiments. The results indicate that the system completes more than 96% of tasks within their specified deadlines while maintaining energy-efficient operation. Consequently, the proposed solution effectively balances the trade-off between energy efficiency and service reliability, making it a practical and sustainable approach for modern cloud computing environments.**

Keywords*—Cloud computing; energy-aware computing; fault tolerance; artificial intelligence; service reliability; sustainable computing

I. Introduction

Cloud computing has transformed the way organizations deploy, manage, and scale computing resources. By providing on-demand access to virtualized infrastructure, platforms, and software services, cloud environments enable organizations to reduce capital expenditure while improving operational flexibility and scalability [1]. The widespread adoption of cloud computing across industries has led to the rapid growth of large-scale data centers that support a diverse range of applications and services.

Despite its advantages, cloud computing faces significant challenges related to service reliability and energy consumption. Failures are inevitable in large-scale cloud infrastructures due to hardware malfunctions, software defects, network disruptions, and power-related issues [2]. Such failures can negatively affect application performance, violate service-level agreements (SLAs), and reduce user satisfaction. Consequently, fault tolerance has become a critical requirement for modern cloud systems.

Various fault tolerance mechanisms have been proposed in the literature to address these challenges, including replication, checkpointing, migration, and their hybrid variants [3]. Replication enhances reliability by maintaining multiple copies of tasks or services, while checkpointing periodically saves application states to enable recovery after failures. Migration techniques proactively move workloads away from unreliable resources to minimize service disruption. Although these approaches improve system reliability, they often incur substantial resource and energy overheads [3]. In particular, replication-based solutions may significantly increase energy consumption due to the simultaneous execution of redundant resources.

At the same time, energy efficiency has emerged as an equally important concern in cloud computing. Data centers consume an enormous amount of electrical power to operate computing, storage, networking, and cooling infrastructure [4]. This growing energy demand not only increases operational costs for cloud providers but also contributes to environmental concerns associated with carbon emissions [5]. Traditional energy management techniques such as virtual machine (VM) consolidation [6] and dynamic voltage and frequency scaling (DVFS) [7] have shown promise in reducing energy consumption; however, they are often applied independently of fault tolerance strategies.

Most of the existing studies focus primarily on either improving reliability or reducing energy consumption. As a result, the interdependence between these two objectives is frequently overlooked. Fault tolerance mechanisms designed without considering energy implications may lead to excessive power consumption, while aggressive energy-saving strategies may compromise system reliability. Furthermore, static fault tolerance approaches lack the flexibility required to adapt to dynamic workload characteristics and changing cloud conditions [8].

To address these limitations, this study proposes an intelligent system for energy-aware flexible fault tolerance in cloud computing environments. The proposed approach incorporates an intelligent resource group formation algorithm that evaluates VMs based on both reliability and energy-related characteristics. By dynamically selecting appropriate fault tolerance mechanisms according to task requirements and system conditions, the system aims to achieve a balanced

trade-off between service reliability and energy efficiency. The novelty of the proposed work does not lie in introducing a completely new replication or checkpointing mechanism. Rather, the contribution is an integrated decision framework that simultaneously 1) formulates energy-aware fault tolerance mathematically, 2) introduces energy-aware resource group formation, and 3) dynamically selects fault tolerance mechanisms according to workload characteristics, reliability requirements, and system state.

The proposed system is evaluated through extensive simulation experiments under diverse workload scenarios. Initial results demonstrate that the system successfully maintains a high task completion rate while controlling energy consumption, thereby providing an effective and sustainable solution for fault-tolerant cloud computing.

The remainder of this study is organized as follows. Section II reviews related work on cloud fault tolerance and energy-aware resource management. Section III presents the flexible fault tolerance model, followed by the energy-aware resource group formation algorithm in Section IV. Section V describes the proposed system, explaining its component-wise architecture. Results and discussion are covered in Section VI. Section VII concludes the study with directions for future research.

II. Related Works

Fault tolerance has been extensively studied in cloud computing due to the increasing demand for highly available and reliable services. Traditional fault tolerance mechanisms such as replication, checkpointing, task resubmission, and VM migration have been widely adopted to mitigate the impact of hardware failures, software faults, and network disruptions. Recent research has focused on improving the adaptability and efficiency of these mechanisms through intelligent scheduling, predictive analytics, and optimization-based resource management.

Several studies have explored proactive fault tolerance approaches that predict failures before they occur. Patil and Patil [9] proposed a dynamic load balancing model capable of detecting workload spikes and preventing host overloads through proactive migration strategies. Similarly, Ray et al. [10] introduced a fault management framework for cloud federation environments that predicts failures using CPU temperature monitoring and proactively migrates VMs to healthy cloud service providers. More recently, Ragmani et al. [11] employed artificial neural networks to predict hard disk failures, enabling preventive VM migration and improving service availability. Log-based anomaly detection techniques have also been investigated, where machine learning and large language models are utilized to identify failure indicators from system logs and initiate fault recovery actions before service degradation occurs [12].

Another stream of research focuses on adaptive and flexible fault tolerance. Kumari and Kaur [13] developed a fuzzy logic-based framework that dynamically selects between replication and checkpointing according to machine failure risk, storage availability, and task priority. Likewise, Mushtaq et al. [14] proposed an integrated scheduling framework that combines replication and checkpointing while dynamically adapting to VM-level and task-level failures. These approaches demonstrate that adaptive fault tolerance can significantly improve resource utilization and recovery performance compared with static mechanisms. However, their decision-making processes are primarily guided by reliability and performance considerations, with limited attention to energy implications.

Resource-aware fault tolerance has also received considerable attention. Dehury et al. [15] proposed a rank-based fault tolerance strategy that allocates replicas according to component criticality, thereby reducing unnecessary resource consumption. Similarly, cluster-centric scheduling frameworks and reservation-based fault tolerance strategies have been developed to improve Quality of Service (QoS), reliability, and task completion rates [16], [17]. While these methods reduce resource overhead compared with conventional replication schemes, energy consumption is rarely incorporated as a primary optimization objective.

In parallel, substantial research efforts have focused on energy-efficient cloud computing. Traditional approaches such as DVFS, VM consolidation, and intelligent workload scheduling have demonstrated significant reductions in power consumption. More recently, artificial intelligence and optimization techniques have been employed to further enhance energy management. Evolutionary programming, reinforcement learning, deep learning, and bio-inspired optimization algorithms have been successfully applied to dynamic resource allocation and workload scheduling [18], [19], [20], [21], [22]. For example, reinforcement learning-based frameworks have achieved considerable reductions in energy consumption and carbon emissions through intelligent power management [20], while hybrid machine learning models have improved energy-efficient task scheduling in cloud and fog environments [22].

Despite these advances, existing energy-aware solutions primarily focus on resource optimization, workload placement, or carbon reduction, assuming stable cloud infrastructures [18], [19], [20]. Fault tolerance is often treated as an independent concern. Conversely, fault-tolerant systems frequently prioritize reliability, availability, and SLA compliance without explicitly considering their energy overhead [13], [14], [15], [16]. Replication-based techniques, in particular, can substantially increase energy consumption due to redundant resource utilization, while migration and checkpointing mechanisms introduce additional computational and communication costs.

A review of the literature reveals several important research gaps. First, there is a lack of integrated frameworks that simultaneously address fault tolerance and energy efficiency. Second, although adaptive fault tolerance mechanisms exist, their decision-making processes rarely consider energy consumption as a key factor [13], [14]. Third, existing multi-objective optimization models generally focus on a limited set of objectives, such as reliability, migration cost, or makespan, without jointly considering energy efficiency, reliability, and deadline requirements [10], [19], [20], [23]. Finally, most studies evaluate performance and reliability independently,

with limited investigation of the trade-off between energy consumption and fault tolerance effectiveness.

To address these limitations, this study proposes an intelligent energy-aware flexible fault tolerance system for cloud computing environments. Unlike existing approaches that treat energy management and fault tolerance separately, the proposed framework integrates both objectives into a unified decision-making process. By considering reliability characteristics, energy consumption, workload requirements, and system conditions simultaneously, the proposed system aims to achieve an effective balance between service reliability and sustainable cloud operation.

III. FLEXIBLE FAULT TOLERANCE MODEL

This Section presents a comprehensive mathematical model of an energy-aware flexible fault tolerance framework for cloud computing environments. The model captures the relationships between physical hosts, VMs, and user tasks while accounting for execution dynamics, failure probabilities, and energy consumption at both VM and host levels. By formally modeling energy costs associated with different fault tolerance mechanisms, the proposed framework enables informed trade-off analysis between reliability improvement and energy efficiency. The resulting model provides a strong analytical foundation for the multi-objective optimization and algorithm design stages introduced in the subsequent Sections.

At the infrastructure level, the cloud data center consists of a finite set of physical hosts [Eq. (1)]. Each physical host represents a physical machine equipped with processing, memory, storage, and networking capabilities [24]. To enable elastic resource provisioning [25], a physical host dynamically supports a set of VMs, as shown in Eq. (2). Virtualization allows efficient sharing of physical resources while providing isolation among workloads [26]. The number and configuration of VMs on a host may vary over time depending on workload demand and system conditions.

$$H = \{h_1, h_2, h_3, \dots, h_m\} \quad (1)$$

$$VM = \{v_1, v_2, v_3, \dots, v_n\} \quad (2)$$

Each VM is characterized by a multidimensional resource vector consisting of CPU capacity (v_j^{cpu}), memory size (v_j^{mem}), available bandwidth (v_j^{bw}), and reliability (v_j^{rel}) as defined in Eq. (3). These resources are allocated to user-submitted tasks and directly influence execution performance, energy consumption, and fault tolerance behavior.

$$v_j = (v_j^{cpu}, v_j^{mem}, v_j^{bw}, v_j^{rel}) \quad (3)$$

Users submit a set of tasks or cloudlets for execution, represented in Eq. (4). These tasks may correspond to compute-intensive, data-intensive, or mixed workloads and are executed on the available VMs in the cloud data center [27]. Since cloud environments are inherently dynamic and failure-prone, each task requires fault tolerance support. Rather than relying on a single rigid fault tolerance technique, the system adopts flexible fault tolerance mechanisms, such as task replication, checkpointing, and VM migration. The choice of mechanism depends on runtime system conditions, failure risk, and energy considerations.

$$T = \{t_1, t_2, t_3, \dots, t_p\} \quad (4)$$

Each task t_k in the task set is formally described using a set of parameters, including arrival time (t_k^{at}), number of instructions (t_k^{ni}), deadline (t_k^{dl}), execution start time (t_k^{st}), execution time (t_k^{et}), and expected completion time (t_k^{ct}) as presented in Eq. (5). These parameters enable precise modeling of task scheduling, deadline constraints, and quality-of-service (QoS) requirements.

$$t_k = (t_k^{at}, t_k^{ni}, t_k^{dl}, t_k^{st}, t_k^{et}, t_k^{ct}) \quad (5)$$

When a task t_k is executed on a VM v_j, its execution time depends on the computational capacity of the VM. The execution time of the task is computed using Eq. (6), which relates the number of instructions to the processing speed of the VM. Based on this execution time, the expected completion time of the task is calculated using Eq. (7). These expressions allow the system to determine whether task deadlines can be met under different fault tolerance strategies [28].

$$t_k^{et} = \frac{t_k^{ni}}{v_j^{cpu}} \quad (6)$$

$$t_k^{ct} = t_k^{st} + t_k^{et} \quad (7)$$

Energy consumption is a critical concern in cloud data centers due to rising operational costs and sustainability requirements. For a given physical host h_i, the instantaneous power consumption $h_i^{pow_co}(t)$ is modeled as a function of its idle power ($h_i^{pow_id}$), maximum power ($h_i^{pow_mx}$), and CPU utilization ($h_i^{cpu_ut}(t)$) at time t [Eq. (8)], provided, $h_i^{cpu_ut}(t) \in [0,1]$. This widely adopted linear power model captures the strong correlation between CPU utilization and power usage in modern servers [29].

$$h_i^{pow_co}(t) = h_i^{pow_id} + (h_i^{pow_mx} - h_i^{pow_id}).\, h_i^{cpu_ut}(t) \quad (8)$$

Using the instantaneous power model, the total energy consumed by a host h_i over the interval $[0, T]$ is computed by integrating power consumption over time, as shown in Eq. (9). This formulation accurately reflects energy usage during task execution, VM migration, and fault tolerance operations. The overall energy consumption of the cloud data center is then obtained by summing the energy consumed by all hosts, as expressed in Eq. (10).

$$h_i^{enr_co} = \int_0^T h_i^{pow_c0}(t)\, dt \quad (9)$$

$$H^{enr_co} = \sum_{i=1}^{m} h_i^{enr_co} \quad (10)$$

In a cloud environment, VMs are subject to failures caused by hardware degradation, resource contention, overheating, or software anomalies [3]. Each VM v_j configured over the host h_i is therefore associated with a failure probability ($v_j^{pr_fl}$) which can be estimated using historical failure data, utilization trends, thermal indicators, or log-based anomaly detection techniques. When a task t_k is replicated across multiple (r) independent VMs to improve reliability, the probability that the task completes successfully increases. The resulting task reliability is mathematically defined in Eq. (11), assuming independent VM failures.

$$t_k^{rel_ex} = 1 - \prod_{j=1}^{r} v_j^{pr_fl} \quad (11)$$

While fault tolerance improves reliability, it introduces additional energy overhead. The energy cost of providing flexible fault tolerance to a task is calculated in Eq. (12), where $t_k^{enr_rp}$, $t_k^{enr_cp}$, and $t_k^{enr_mg}$ represent energy consumed for replication, checkpointing, and migration of t_k respectively. This equation captures the cumulative energy consumed by different fault tolerance mechanisms, including task replication, checkpointing operations, and VM migration. By explicitly modeling these energy costs, the framework enables informed trade-off decisions between reliability improvement and energy efficiency.

$$t_k^{enr_ft} = t_k^{enr_rp} + t_k^{enr_cp} + t_k^{enr_mg} \quad (12)$$

The above mathematical model establishes a unified foundation for analyzing energy-aware flexible fault tolerance in cloud computing environments. It integrates workload characteristics, execution dynamics, failure behavior, and energy consumption into a single framework, thereby enabling the design of intelligent fault tolerance strategies that enhance reliability while minimizing energy overhead. This model serves as the basis for subsequent multi-objective optimization and algorithm design in the proposed framework.

IV. Energy-Aware Resource Group Formation Algorithm for Flexible Fault Tolerance

This Section introduces an intelligent mechanism that dynamically selects and groups cloud resources for fault-tolerant task execution while balancing multiple conflicting objectives, namely energy efficiency, reliability, and deadline satisfaction. The proposed algorithm forms a critical component of the framework and directly influences its overall performance and effectiveness.

A. Problem Definition

For each incoming task submitted to the cloud data center, the system must form a resource group consisting of one or more VMs on which the task will be executed using flexible fault tolerance techniques. The selection of this resource group must satisfy the following requirements:

- The task must complete within its specified deadline.
- The overall task reliability must meet or exceed a minimum required threshold.
- The additional energy consumed due to fault tolerance must be minimized.

Let t_k and RG_k denote the task and its corresponding resource group. The challenge lies in determining the optimal composition of RG_k from the available set of VMs such that all constraints are satisfied while optimizing energy efficiency.

B. Decision Variables and Constraints

To formalize the resource group formation problem, a binary decision variable is defined in Eq. (13), using which the following constraints are imposed.

$$x_{jk} = \begin{cases} 1, if\ v_j\ is\ selected\ for\ t_k \\ 0, otherwise \end{cases} \quad (13)$$

- Reliability Constraint: The reliability achieved by executing the task on its resource group must be no less than the minimum required reliability, i.e., $t_k^{rel_ex} \geq t_k^{rel_mn}$.
- Deadline Constraint: The expected completion time of the task must not exceed its deadline, i.e., $t_k^{ct} \leq t_k^{dl}$.
- Resource Capacity Constraint: The total resource demand placed on any VM must not exceed its available capacity, i.e., $\sum_{t_k} x_{jk} . t_k^{cpu} \leq v_j^{cpu}$.
- Replication Limit Constraint: To avoid excessive replication and uncontrolled energy usage, the size of the resource group is bounded, i.e., $|RG_k| \leq r_{max}$.

The resource group formation problem is formulated as a multi-objective optimization problem with the following objectives:

- The total energy consumed for executing and protecting tasks is minimized.
- The overall task reliability is maximized by selecting VMs with higher individual reliability.
- The risk of deadline violation is minimized by ensuring timely task completion.

Since these objectives are conflicting, an exact optimal solution is computationally expensive. Therefore, a heuristic-based approach is adopted to efficiently approximate the Pareto-optimal solution. Because a linear power consumption model introduces a strictly monotonic cost curve relative to host CPU utilization, our heuristic operates as an elegant, computationally efficient approximation of a bounded Pareto-frontier by finding the exact point where replication addition ceases once the constraint $t_k^{rel_ex} \geq t_k^{rel_mn}$ is satisfied.

C. Proposed Energy-Aware Resource Group Formation Algorithm

The Energy-Aware Resource Group Formation algorithm heuristically solves the multi-objective optimization problem described above. The algorithm operates in four main stages:

- Filtering of candidate VMs based on deadline and resource feasibility
- Computation of energy–reliability composite scores
- Ranking and selection of VMs
- Adaptive formation of the resource group

For each candidate VM, a composite score is computed to balance energy efficiency and reliability [Eq. (14)], where E_{jk} represents the energy cost incurred when task t_k is executed or replicated on VM v_j.

$$v_j^{score} = \alpha . \frac{1}{E_{jk}} + \beta . v_j^{rel} \quad (14)$$

The proposed algorithm for energy-aware group formation is given below:

Algorithm 1: Energy-Aware Resource Group Formation

Input:

Task set $T = \{t_1, t_2, t_3, \dots, t_p\}$,

VM set $VM = \{v_1, v_2, v_3, \dots, v_n\}$,

Weight factors α and β such that $\alpha + \beta = 1$, and

Maximum replication limit r_{max}

Output:

Resource group RG_k for each task t_k

Pseudo code:

EnergyAwareResourceGroupFormation(T, VM)

For each task $t_k \in T$ do

$RG_k \leftarrow \emptyset$

$Candidate\ VMs \leftarrow \emptyset$

For each VM $v_j \in VM$ do

Estimate execution time t_k^{et} of t_k on v_j

Estimate completion time $t_k^{ct} = current_{time} + t_k^{et}$

If $t_k^{ct} \leq t_k^{dl}$ and resources of v_j are sufficient then

Add v_j to Candidate VMs

End

End

For each $v_j \in Candidate\ VMs$ do

Compute energy cost E_{jk} for executing t_k on v_j

Retrieve reliability v_j^{rel}

Compute composite score: $v_j^{score} = \alpha . \frac{1}{E_{ij}} + \beta . v_j^{rel}$

End

Sort $Candidate\ VMs$ in descending order of v_j^{score}

$t_k^{rel_ex} \leftarrow 0$

$r \leftarrow 0$

For each $v_j \in Candidate\ VMs$ do

If $r = r_{max}$ then

break

End

Add v_j to RG_k

$r \leftarrow r + 1$

Update Current Reliability: $t_k^{rel_ex} = 1 - \prod_{j=1}^{r} v_j^{fail_pr}$

for all $v_j \in RG_k$

If $t_k^{rel_exec} \geq t_k^{rel_min}$ then

break

End

End

If $t_k^{rel_exec} \leq t_k^{rel_min}$ then

Trigger fallback fault tolerance policy

End

End

return $RG_K\ \forall\ t_k \in T$

The algorithm provides several important advantages. It explicitly incorporates energy consumption into fault tolerance decisions and supports flexible adaptation to different workload and system conditions. It also avoids excessive replication by enforcing replication limits. The computational overhead of Algorithm 1 can be broken down into discrete steps for each task $t_k \in T$:

- Filtering Candidate VMs: Evaluating the processing speed constraint across N virtual machines takes $O(N)$ operations.
- Composite Score Computation: Computing v_j^{score} using (14) takes $O(N)$ time.
- Sorting Candidates: Sorting the candidate subset of size $M \leq N$ requires a worst-case time of $O(MlogM)$.
- Group Allocation Loop: Selecting VMs up to the maximum replication limit r_{max} runs in $O(r_{max})$ constant time since $r_{max} \ll N$.

Thus, for an incoming task sequence of size P, the algorithmic time complexity is given by $O(P.NlogN)$. By integrating reliability and energy awareness into the decision-making, the algorithm bridges the gap between theoretical modeling and practical system implementation.

V. PROPOSED SYSTEM

This Section focuses on the design and operation of the proposed Energy-Aware Flexible Fault Tolerance system, which integrates energy efficiency and reliability into a unified cloud fault tolerance solution. It presents the overall architecture of the system and explains each system component and its role in the fault tolerance process. A component-wise architectural diagram is used to illustrate the interaction between system modules, including task submission, resource monitoring, decision-making, fault handling, and execution management.

A. Component-Wise Architecture Description of the System

The proposed system is designed as a modular and layered framework that integrates energy awareness and flexible fault tolerance into cloud task execution. The architecture consists of several interconnected components, each responsible for a specific function in the fault tolerance and decision-making process. Fig. 1 illustrates the overall architecture of the proposed system.

1) Task submission and request manager: The "Task Submission and Request Manager" acts as the entry point of the system. It receives task requests submitted by cloud users along with their associated parameters such as arrival time, computational size, deadline, and priority. Upon submission, tasks are validated and forwarded to the scheduling and decision-making components for further processing. This module ensures that user requirements are correctly captured and passed to the system without modification.

2) Resource monitoring module: This module continuously observes the operational status of physical hosts and VMs within the cloud data center. It collects real-time and

historical information related to CPU utilization, memory usage, bandwidth availability, energy consumption, and thermal conditions. In addition, this module tracks VM reliability indicators such as failure history, utilization trends, and anomaly signals. The collected data is periodically updated and made available to the decision-making engine to support accurate and timely fault tolerance decisions.

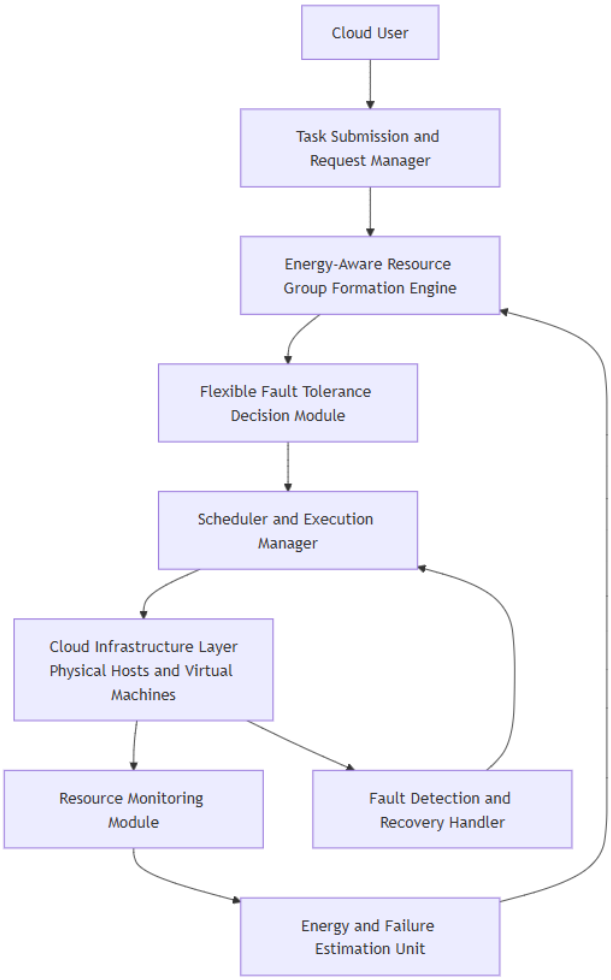

Fig. 1. Proposed system architecture.

3) Energy and failure estimation unit: This unit processes raw monitoring data to estimate energy consumption and failure probabilities. Energy estimation is performed using utilization-based power models at the host level, enabling the system to quantify the energy cost of task execution, VM migration, and fault tolerance operations. Failure estimation leverages reliability indicators to compute the probability of VM failures. These estimations form the basis for evaluating the trade-offs between reliability improvement and energy overhead.

4) Energy-aware resource group formation engine: The "Energy-Aware Resource Group Formation Engine" is the core intelligence of the proposed system. Using the multi-objective optimization approach, this engine evaluates available VMs based on energy efficiency, reliability, and resource suitability. It dynamically forms an optimal resource group for each task or task set, ensuring that selected resources satisfy deadline and reliability constraints while minimizing energy consumption. This component enables adaptive and context-aware fault tolerance decisions.

5) Flexible fault tolerance decision module: This module determines the most appropriate fault tolerance strategy for each task. Based on inputs from the resource group formation engine, this module selects between replication, checkpointing, VM migration, or hybrid fault tolerance techniques. The selection is influenced by task criticality, failure risk, expected energy cost, and execution deadlines. By avoiding static fault tolerance policies, this module ensures efficient and energy-conscious fault handling. The decision module follows a fixed priority order. If multiple VMs are assigned to the task, replication is selected. Otherwise, checkpointing is preferred for computationally intensive tasks (e.g., tasks exceeding the predefined workload threshold). VM migration is triggered when the hosting VM exceeds the utilization threshold. In all other cases, the framework employs the hybrid strategy.

6) Scheduler and execution manager: The "Scheduler and Execution Manager" is responsible for mapping tasks to the selected VMs and managing their execution lifecycle. It initiates task execution, coordinates checkpointing operations, and triggers VM migration or task replication when faults are predicted or detected. This module ensures that scheduling decisions comply with system constraints and that task execution progresses smoothly even under failure conditions.

7) Fault detection and recovery handler: This component continuously monitors task execution and VM health to identify failures or abnormal behavior. Upon detecting a fault or receiving a failure prediction signal, this component activates the recovery process defined by the selected fault tolerance strategy. Recovery actions may include switching to replica tasks, restoring from checkpoints, or migrating tasks to alternative VMs within the resource group. This module plays a critical role in maintaining service continuity.

8) Cloud infrastructure layer: The "Cloud Infrastructure Layer" consists of the physical hosts and VMs that provide computational, storage, and networking resources. This layer executes user tasks and supports dynamic VM provisioning and migration. It also serves as the source of monitoring data required for energy estimation and fault prediction. The infrastructure layer enables the practical deployment of the flexible fault tolerance system in real or simulated cloud environments.

VI. Results and Discussion

This section presents the experimental results obtained from simulation-based evaluation of the proposed framework. The experiments are designed to assess the system's ability to balance energy efficiency with fault tolerance effectiveness under realistic cloud workload conditions. To place the results in context, the proposed approach is compared against two baseline scheduling strategies: Best Fit, which selects VMs

greedily by reliability without regard for energy consumption, and Min Energy, which prioritizes the lowest-energy VMs without enforcing any reliability constraints. Together, these baselines represent opposite ends of the energy–reliability spectrum, making them appropriate reference points for evaluating the trade-off achieved by the proposed system.

A. Experimental Setup

The simulation environment consists of 20 VMs distributed across five physical hosts. Each VM is randomly configured with a CPU capacity ranging from 1,000 to 5,000 MIPS, memory between 4 GB and 16 GB, bandwidth between 100 and 1,000 Mbps, and an idle power draw between 50 W and 100 W, with a peak consumption of up to 300 W. VM failure probabilities are sampled uniformly in the range [0.01, 0.15], and reliability values are derived accordingly. Physical hosts operate with idle power between 200 W and 400 W and peak power up to 1,500 W.

A total of 500 tasks are generated for each simulation run. Task arrival times are distributed uniformly over a 100-time-unit window, with instruction counts ranging from 1,000 to 50,000 MI and relative deadlines between 10 and 100 time units. Each task carries a minimum reliability requirement drawn uniformly from [0.90, 0.999], reflecting the heterogeneous QoS demands typical of real cloud workloads. All three algorithms are evaluated on the identical task and VM set, generated using a fixed random seed to ensure a fair and reproducible comparison. In all experiments, the weight parameters were empirically set to $\alpha = 0.6$ and $\beta = 0.4$. A slightly higher weight was assigned to the energy component because the primary objective of the proposed framework is to reduce energy overhead while maintaining acceptable reliability. For the flexible fault tolerance decision, workload threshold and utilization threshold were set to 10,000 MI and 0.8, respectively. The simulation runs for 200 time units with a discrete step of 1 time unit.

Four performance metrics are used for evaluation: task completion rate, total energy consumption (Wh), and average achieved reliability. The fault tolerance overhead is modelled by applying mechanism-specific energy multipliers of 1.1× for checkpointing, 1.2× for replication, 1.25× for the hybrid strategy, and 1.3× for VM migration.

B. Overall Performance Comparison

Table I summarizes the aggregate performance of the three algorithms across all evaluation metrics. Fig. 2 to Fig. 4 trace each metric over the course of the simulation.

TABLE I. PERFORMANCE COMPARISON OF THE PROPOSED SYSTEM AND BASELINE ALGORITHMS

Metric	Proposed System	Best Fit	Min Energy
Task Completion Rate (%)	97.60	100.00	79.20
Total Energy Consumed (Wh)	201.70	206.66	163.68
Avg. Energy per Task (Wh)	0.4034	0.4133	0.3274
Avg. Achieved Reliability	0.9841	0.9825	0.9941
Reliability Threshold Met (%)	98.57	99.40	94.95

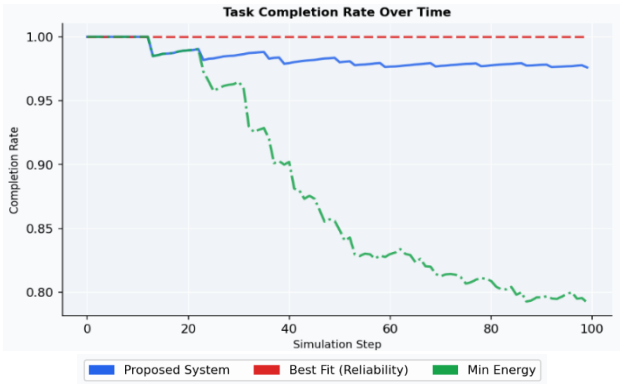

Fig. 2. Task completion rate over time.

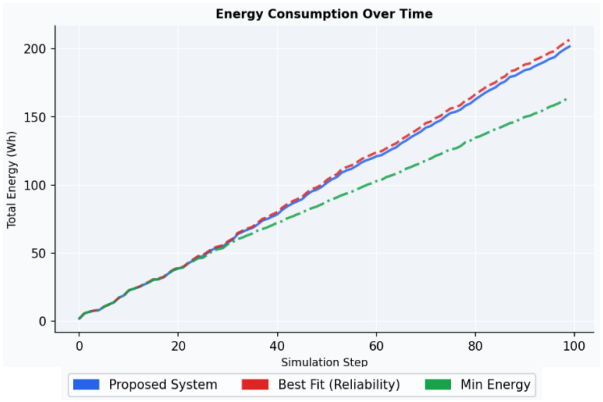

Fig. 3. Energy consumption over time.

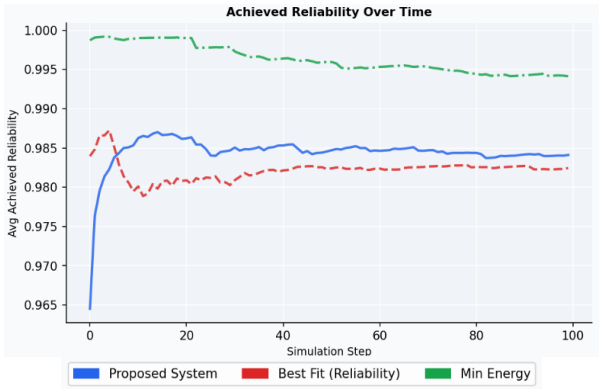

Fig. 4. Reliability over time.

1) Task completion analysis: Considering task completion rate (Fig. 2), the Best Fit baseline achieves a perfect completion rate of 100%, scheduling all 500 tasks within their respective deadlines. The proposed framework completes 488 tasks, corresponding to a 97.60% completion rate, while Min Energy completes only 396 tasks (79.20%). The notably low completion rate of Min Energy is a direct consequence of its energy-first selection policy, which occasionally assigns tasks to VMs with low processing capacity or high failure probability, resulting in missed deadlines and execution failures. The Best Fit baseline avoids this pitfall by unconditionally prioritising high-reliability VMs; however, as discussed below, this comes at a measurable energy cost.

2) Energy consumption analysis: Fig. 3 shows that Min Energy records the lowest total energy at 163.68 Wh, which is expected given that the algorithm explicitly optimizes for this metric. However, this apparent efficiency is somewhat misleading because Min Energy fails to complete about 20% of the tasks; a large fraction of potential execution energy is simply never expended. When energy is evaluated on a per-task basis, Min Energy consumes 0.3274 Wh per task, compared with 0.4034 Wh for the proposed system and 0.4133 Wh for Best Fit. The difference between the proposed system and Best Fit on this metric (approximately 2.4%) reflects the energy savings achieved by incorporating energy awareness into the VM selection process without sacrificing task throughput.

The Best Fit baseline incurs the highest total energy (206.66 Wh) precisely because it routes all tasks to the most reliable VMs irrespective of their power characteristics. High-reliability VMs tend to be more heavily provisioned and therefore draw more power. The proposed system avoids this by balancing energy cost and reliability through the composite scoring function, which avoids the selection of power-consuming VMs when more energy-efficient alternatives offer comparable reliability.

3) Reliability analysis: All three algorithms achieve high average reliability for the tasks they complete (Fig. 4). Min Energy records the highest average achieved reliability at 0.9941, which appears to be confusing at first observation. However, this result reflects a survivorship effect. Min Energy preferably selects low-power VMs; many of those may have low failure probabilities, and the tasks it completes tend to be those that benefit most from this selection. The proposed framework achieves an average reliability of 0.9841, and Best Fit achieves 0.9825. The small difference is largely attributed to the replication fallback mechanism in the proposed framework, which adds VMs to the resource group when the reliability threshold is not immediately satisfied by the top-ranked candidate.

A more practical reliability indicator is the proportion of completed tasks for which the achieved reliability met or exceeded the task-specific minimum threshold (Table I). Our proposed system satisfies this constraint for 98.57% of its completed tasks, compared with 99.40% for Best Fit and only 94.95% for Min Energy. This ordering is consistent with the design intent of each algorithm: Best Fit is most conservative about reliability, Min Energy is least so, and the proposed system occupies an intermediate position that trades a marginal reduction in reliability constraint satisfaction for a meaningful reduction in energy overhead.

C. Discussion

The obtained simulation results support the primary claim of this study that simultaneous optimization of energy efficiency and fault tolerance reliability is both feasible and beneficial. The proposed energy-aware flexible fault tolerance system demonstrates that the two objectives are not inherently opposed. A carefully designed composite scoring function, combined with an adaptive fault tolerance selection policy, can achieve near-complete task execution (97.60%). Also, the energy consumption is only marginally above the unreliable Min Energy baseline and meaningfully below the Best Fit baseline.

It should be noted that the Best Fit baseline achieves a 100% completion rate in these experiments. This is because the simulated workload, while diverse, does not saturate the VM pool to the point where reliability-first selection creates resource contention. In more congested scenarios, where the highest-reliability VMs are already heavily loaded, the Best Fit strategy would be expected to incur greater deadline misses and higher energy costs simultaneously, which would further strengthen the case for the balanced approach adopted by the proposed framework. Similarly, Min Energy's poor completion rate would be expected to worsen under stricter deadline distributions. It reinforces that energy minimization without reliability awareness is unsuitable as a standalone policy in fault-tolerant cloud environments.

The results also highlight an important practical consideration. The 2.40% deadline miss rate of the proposed framework consists primarily of tasks whose reliability requirements were sufficiently stringent with respect to the replication limit while satisfying the deadline constraint. Relaxing the replication limit or introducing additional VMs into the pool would be expected to reduce this residual miss rate further, at a modest increase in energy consumption. This configurability is an inherent strength of the proposed framework.

VII. Conclusion and Future Research Scope

Cloud service providers increasingly face the dual challenge of maintaining high reliability while controlling the growing energy demands of large-scale data centers. Although fault tolerance remains essential for ensuring service continuity, many existing approaches achieve reliability at the cost of significant energy overhead. This study addresses this challenge by proposing an intelligent energy-aware flexible fault tolerance system that integrates reliability and energy efficiency into a unified decision-making framework.

The proposed approach combines an energy-aware resource group formation algorithm with adaptive fault tolerance selection, enabling the system to dynamically choose suitable resources and fault tolerance mechanisms according to workload characteristics, reliability requirements, and system conditions. By incorporating both energy consumption and reliability metrics into the resource selection process, the framework effectively balances two traditionally conflicting objectives. The mathematical model, optimization strategy, and modular system architecture collectively provide a practical foundation for implementing sustainable fault-tolerant cloud environments.

Simulation-based evaluation demonstrated the effectiveness of the proposed system. The framework completed 97.60% of submitted tasks while satisfying reliability requirements for more than 98% of completed executions. At the same time, it reduced overall energy consumption compared with a reliability-focused baseline, illustrating that energy-aware fault

tolerance can be achieved without substantially compromising service quality. These findings confirm that intelligent resource selection and adaptive fault tolerance policies can significantly improve the operational efficiency of cloud infrastructures.

For future research, firstly, the proposed approach will be validated using large-scale cloud simulation platforms and real-world cloud workloads to further assess its scalability, adaptability, and effectiveness under highly dynamic operating conditions. Secondly, the principles of quantum computing will be incorporated into the scheduling decisions to study their effectiveness in a cloud computing environment. Performance comparison with the state-of-the-art frameworks will also be considered.

DECLARATION ON GENERATIVE AI

Several GenAI tools were used to complete this research work. ChatGPT, Claude, and DeepSeek were used for language refinement and grammar correction. Mermaid Live Editor was used to draw Fig. 1 (Proposed system architecture).

INSPIRE: Understanding Local-Global Representation Learning via Controlled Self-Supervised Training and Representation Interpretability

Faculty of Computing and Information Technology, King Abdulaziz University, Jeddah, Saudi Arabia[1, 3]
Faculty of Computer and Information Systems, Islamic University of Madinah, Madinah, Saudi Arabia[2, 4]

***Abstract*—Self-supervised learning (SSL) has become a powerful paradigm for visual representation learning, yet it remains insufficiently understood how different training strategies shape the balance between global semantic structure and local visual detail. This study introduces the INSPIRE Framework, a unified framework for systematically investigating local-global representation learning in SSL through controlled training, downstream evaluation, and representation interpretability analysis. Within this framework, we develop the INSPIRE Method, a contrastive SSL approach that constructs merged training views by combining target images with distractor content and aligning global image representations with region-level features. By varying the number of merged regions, INSPIRE explicitly controls spatial granularity during pretraining. We evaluate INSPIRE through controlled ImageNet-100 experiments (130K images) with a ResNet-18 backbone, large-scale ImageNet-1K pretraining (1.28million images) with a ResNet-50 backbone, and transfer to fine-grained recognition benchmarks. We further introduce the INSPIRE Representation Interpretability Investigation Methodology, which combines representation similarity analysis with scale-controlled spatial perturbations to examine spatial sensitivity across SSL methods and network layers. Experiments show that representation quality varies non-monotonically with spatial granularity, with intermediate granularity often producing stronger transfer performance than coarser or more fragmented alternatives. The analysis further reveals distinct spatial sensitivity profiles across SSL objectives and progressively increasing perturbation sensitivity across network depth. Runtime experiments using single-GPU and multi-GPU distributed pretraining demonstrate the practical scalability of the framework. These findings suggest that SSL representations are better understood as occupying positions along a continuum of spatial sensitivity rather than as strictly local or global learners.**

I. Introduction

Machine learning has achieved remarkable success across a wide range of computer vision tasks, including image classification, object detection, semantic segmentation, and visual understanding [1], [2], [3]. Much of this success has been driven by deep neural networks trained on large-scale annotated datasets. However, acquiring high-quality labels is expensive, time-consuming, and often impractical for many real-world applications. These limitations have motivated increasing interest in self-supervised learning (SSL), which seeks to learn useful visual representations directly from unlabeled data by exploiting intrinsic structure within the data itself.

Recent advances in SSL have demonstrated that representations learned without manual annotations can rival or even surpass those obtained through supervised learning on many downstream tasks [4]. Despite their success, SSL methods differ substantially in the type of visual information they encode. Effective visual representations must capture both global semantic structure and local discriminative details [5]. Global representations encode high-level information such as object identity, shape, and semantic context, whereas local representations capture fine-grained visual cues including textures, object parts, boundaries, and subtle appearance variations [6]. Different downstream tasks depend on these information sources to varying degrees. Image classification often relies heavily on global semantic understanding [7], while fine-grained recognition, object detection, and segmentation require stronger sensitivity to local visual information.

A growing body of research has attempted to improve local representation learning in SSL through region-level objectives [8], [9], patch-based learning [10], and multi-scale and hierarchical representation strategies [5], [11]. These studies demonstrate that incorporating local information can improve performance on spatially sensitive tasks. Existing research has also explored a variety of training objectives [12] and architectural designs [13] to improve the quality of learned representations. However, these approaches typically investigate multiple design factors simultaneously, making it difficult to isolate how individual training choices shape representation encodings and influence the balance between local and global information.

Another limitation concerns representation interpretability. While interpretable machine learning (IML) and explainable artificial intelligence (XAI) have traditionally focused on explaining model predictions and decision-making processes [14], [15], recent research has begun extending interpretability to learned representations [16]. This emerging direction, referred to as representation interpretability, seeks to understand

*Corresponding author.

what information is encoded within a model's internal representations, how this information is organized, and how these representations contribute to downstream behavior. Existing studies have investigated representation similarity [17], [18], semantic concepts [19], [20], and feature activations [21], [22], providing valuable insights into the structure and content of learned representations. However, they provide limited understanding of how SSL representations encode and respond to controlled spatial perturbations at different spatial scales and what these responses reveal about the balance between local and global information. Current evidence regarding spatial sensitivity is therefore inferred primarily from downstream task performance rather than measured directly at the representation level.

These observations reveal three important research gaps. First, no unified framework has been developed to systematically investigate, compare, and interpret local-global representation learning across different SSL approaches. Second, the influence of spatial granularity on representation learning remains poorly understood because it has not been investigated as an independent experimental factor separate from architectural and objective-related design choices. Third, existing representation interpretability studies do not provide a systematic methodology for investigating how SSL representations respond to controlled spatial perturbations or how these responses relate to local-global representation learning.

To address these challenges, we introduce the INSPIRE Framework, a unified framework for investigating local-global representation learning in SSL (See Section III). The framework integrates three complementary components. First, it employs controlled spatial granularity manipulation during contrastive learning, enabling the influence of spatial composition on representation learning to be investigated systematically and independently from other design factors. Second, it evaluates learned representations across both global and fine-grained downstream tasks, providing insights into how different training strategies affect transfer performance at different spatial scales. Third, it introduces a representation interpretability methodology based on scale-controlled spatial perturbations, enabling spatial sensitivity and representation behavior to be examined directly rather than inferred solely from downstream performance. These components collectively provide a structured basis for understanding how SSL training strategies shape representation encodings and local-global representation learning. Using the proposed framework, we conduct a comprehensive empirical investigation of local-global representation learning across multiple SSL configurations. The main contributions of this study are summarized as follows.

- We introduce the INSPIRE Framework, a unified framework for systematically investigating local-global representation learning in self-supervised learning through controlled training, downstream evaluation, and representation interpretability analysis.
- We develop the INSPIRE Method, a contrastive self-supervised learning approach that explicitly controls spatial granularity by constructing merged training views that combine an image with distractor content and align global image representations with region-level features extracted from these composite views. By systematically varying the number of merged regions, the method enables controlled investigation of how spatial composition and training design shape representation encodings and local-global representation learning.
- We provide a pretrained INSPIRE Encoder to support future research on local-global representation learning, spatial sensitivity, and representation interpretability in SSL.
- We introduce the INSPIRE Representation Interpretability Investigation Methodology, which combines representation similarity analysis with scale-controlled spatial perturbations to systematically investigate how SSL representations encode and respond to localized and distributed spatial information, enabling direct examination and comparison of spatial sensitivity and representation behavior across SSL methods.
- We provide new empirical insights into how SSL training strategies shape representation encodings and local-global representation learning, demonstrating non-monotonic effects of spatial granularity, distinct spatial sensitivity profiles across SSL methods, and evidence that SSL representations occupy different positions along a continuum of spatial sensitivity.

We named our framework INSPIRE to reflect its key characteristics: representation Interpretability, understanding of Neural representations, Spatial sensitivity analysis, Perturbation-based Investigation, and Representation Encodings. Beyond the specific framework and experimental findings presented in this work, the results have broader implications for the design and interpretation of self-supervised learning systems. By providing a structured approach for investigating local-global representation learning through representation interpretability and spatial sensitivity analysis, the proposed framework enables a deeper understanding of how training strategies shape learned representations. Such understanding can support the development of more effective SSL methods, guide the selection of representations for different downstream tasks, and contribute to the broader goal of making representation learning more transparent, interpretable, and scientifically grounded.

The remainder of this study is organized as follows. Section II reviews the related literature and identifies the research gaps. Section III presents the INSPIRE Framework, including the INSPIRE Method, the downstream evaluation protocol, and the INSPIRE Representation Interpretability Investigation Methodology. Section IV reports controlled ImageNet-100 experiments with a ResNet-18 backbone, examining how different merged-view patch configurations influence global and fine-grained transfer performance. Section V extends the evaluation to ImageNet-1K using a ResNet-50 backbone and compares INSPIRE with 9 well-known SSL baselines, distinguishing the controlled ablation study of Section IV from the large-scale benchmark evaluation. Section VI investigates representation interpretability through scale-controlled spatial perturbation analysis. Section VII analyzes computational cost and runtime, covering both single-GPU pretraining for

ImageNet-100 and multi-GPU distributed pretraining for ImageNet-1K. Section VIII discusses the key findings and their broader implications, and concludes the study.

II. Background and Related Work

This section reviews prior work on global and local representation learning in SSL (Sections II.A and II.B) and existing approaches to representation interpretability (Section II.C). It concludes by identifying the research gaps that motivate the proposed framework (Section II.D).

A. Global Representations in SSL Methods

Classical SSL methods were primarily developed to learn image-level representations that improve downstream tasks such as image classification. Consequently, early SSL approaches largely emphasized global semantic understanding while providing limited attention to fine-grained local structures and spatial correspondences. This section reviews the major SSL paradigms that primarily learn global semantic representations and highlights subsequent efforts to strengthen local feature learning.

Early SSL research was dominated by contrastive learning, which maximizes agreement between different augmented views of the same image while separating representations of different images in the embedding space. SimCLR [13] and MoCo [23] treat each image as a semantic instance, encouraging invariant image-level representations with strong transferability. However, their emphasis on global semantics often underrepresents fine-grained spatial relationships, motivating dense and region-aware contrastive learning methods that explicitly incorporate patch correspondence and spatial consistency [24], [25]. Beyond pairwise contrastive learning, SwAV [26] replaces explicit sample matching with online clustering and prototype assignment, enabling multiple augmented views to be associated through shared semantic clusters while remaining focused on global representations. TiCo [27] further improves transformation-invariant learning through covariance regularization that reduces feature redundancy and produces more structured global embeddings.

To remove the dependence on negative samples, non-contrastive and self-distillation methods were subsequently introduced. BYOL [12] employs an online and momentum-updated target network to learn consistent representations across augmented views, primarily reinforcing global semantic invariance. Later extensions incorporated dense and hierarchical objectives to improve local feature learning and multi-scale representations [28]. DINO [21] further extends self-distillation within Vision Transformer architectures, where patch tokenization and self-attention naturally capture both global scene semantics and localized patch-level structures, making the learned representations effective for semantic localization and fine-grained visual understanding.

Redundancy-reduction approaches, including Barlow Twins [29] and VICReg [30], learn invariant representations by decorrelating feature dimensions to avoid representational collapse while remaining primarily focused on image-level representations. A complementary direction is masked image modeling, where representations are learned by reconstructing masked image regions. MAE [31] employs an asymmetric encoder-decoder architecture to reconstruct masked patches from visible regions, directly optimizing patch-level reconstruction rather than image-level alignment. As a result, MAE naturally captures local structures, spatial relationships, and contextual information.

B. Local Representation in SSL Methods

Although classical SSL methods discussed above learn highly transferable global representations, many downstream vision tasks require fine-grained spatial information in addition to image-level semantics [5], [32]. This requirement has motivated a broad range of approaches that strengthen local representation learning through region-level objectives, patch-based modeling, hierarchical representations, and spatial regularization.

One direction extends contrastive learning to dense and region-aware settings. ReSim [15], RegionCL [8], MaskCo [9], Patch-wise SSL [10], Self-Patch [32], and HCL [24] introduce local correspondence, masked prediction, patch alignment, neighborhood consistency, and spatial feature embedding to improve localization and dense prediction. Despite their differences, these methods share the common objective of strengthening local feature learning by incorporating region-level supervision into contrastive learning.

A second direction focuses on learning hierarchical representations across multiple spatial scales. Representative approaches include Multi-level Contrastive Learning for Vision Transformers (MCVT) [33], Self-Supervised Pyramid Representation Learning (SS-PRL) [5], CsML [11], the Global-Local Self-Distillation framework [6], and UDI [34]. These methods combine representations from different network depths, feature hierarchies, or local prediction mechanisms to jointly capture coarse semantic structure and fine-grained spatial information.

A complementary line of research enhances local representations through positional supervision, spatial regularization, and masked image modeling. Positional Label [35] introduces positional prediction tasks, spatial entropy regularization [36] encourages coherent attention regions, while masked image modeling methods such as iBOT [37] and attention-guided variants such as ACoMIM [38] learn fine-grained representations through patch reconstruction combined with global semantic objectives.

C. Representation Interpretability in SSL Methods

Understanding SSL representations requires analysis beyond downstream task performance. Consequently, a growing body of research has focused on representation interpretability, investigating how learned representations are organized, what information they encode, and how they vary across architectures, training objectives, and learning paradigms. Existing studies can be broadly grouped into similarity-based analyses, probing methods, attention-based visualizations, and feature-level analyses.

Similarity-based analyses examine the relationships between representations learned by different models, network layers, and learning objectives. Among the proposed techniques, Centered Kernel Alignment (CKA) [39] has become a widely adopted

approach for comparing learned representations, offering improved robustness over earlier Canonical Correlation Analysis (CCA)-based methods [40]. Recent studies have used CKA to compare representations across architectures and training paradigms [17], [18], [41], showing that convolutional networks and Vision Transformers exhibit distinct representation organization, while supervised and self-supervised models often learn highly aligned representations in early and intermediate layers before diverging in deeper layers. These findings demonstrate that both architectural design and learning objectives substantially influence representation organization.

A complementary line of research investigates the semantic information encoded within SSL representations through probing methods [19], [20], attention-based visualizations [21], [22], and feature-level analyses [42], [43]. Probing frameworks have been used to identify the visual concepts captured by learned representations [19], [20], while attention visualization methods such as DINO [21] and ICE [22] reveal semantic object structure and region-level predictions learned without supervision. Feature-level analyses further quantify representation quality by measuring phenomena such as dimensional collapse [42].

D. Research Gap

The literature reviewed above demonstrates substantial progress in SSL representation learning and interpretation while also revealing three important research gaps. First, although prior studies have investigated global and local representation learning (Sections II.A and II.B), no unified framework has been proposed to systematically investigate, compare, and interpret local-global representation learning across SSL approaches. Second, existing methods have primarily improved downstream performance through architectural modifications [13], [23], objective design [12], [28], region-level learning [8], [9], and multi-scale representations [5], [11]. However, spatial granularity has not been systematically investigated as an independent experimental factor and remains entangled with other design choices, making its influence on local-global representation learning difficult to isolate. Third, existing representation interpretability studies have investigated representation similarity [17], [18], [41], semantic concepts [19], [20], and feature activations [21], [22] (Section II.C), but provide limited understanding of how SSL representations respond to controlled spatial perturbations at different spatial scales and how these responses relate to local-global representation learning.

These gaps motivate the INSPIRE Framework presented in Section I. The framework, its associated INSPIRE Method, INSPIRE Encoder, and INSPIRE Representation Interpretability Investigation Methodology are designed to address these limitations through a unified approach to investigating local-global representation learning. Further details are provided in Section III and onwards.

III. Methodology

The INSPIRE Framework comprises three complementary components for systematically investigating local-global representation learning in SSL (see Fig. 1). The framework integrates the INSPIRE Method and Encoder for controlled spatial granularity learning (see Section III.A), downstream evaluation across tasks requiring different levels of spatial information (Section III.B), and the INSPIRE Representation Interpretability Investigation Methodology for analyzing representation behavior through scale-controlled spatial perturbations (Section III.C).

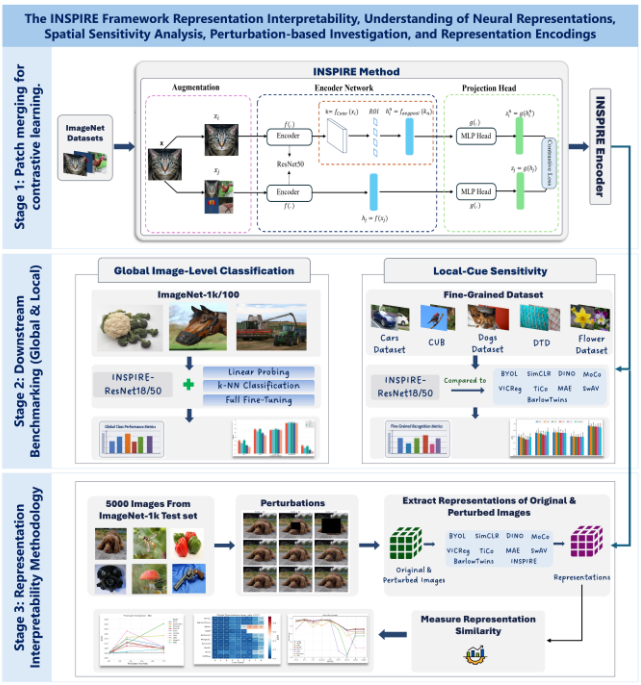

Fig. 1. INSPIRE framework: 1) Merged-view contrastive pretraining with controllable spatial granularity, 2) Evaluation on global and fine-grained tasks, and 3) Representation interpretability investigation under scale-controlled spatial perturbations.

A. INSPIRE Method

Our INSPIRE method builds upon the classic contrastive learning paradigm (e.g., SimCLR [13]) by introducing a region-based representation mechanism applied to a merged composite image. As illustrated in Fig. 2, given an input image x, two augmented views are generated. The first view, denoted x_i, is a standard augmented version of the image produced using random transformations such as cropping, flipping, or color jittering. The second view, denoted x_j, is generated by merging a transformed version of the original image x' with several other randomly selected images into a single composite image. This merged image contains multiple unrelated objects arranged in a grid-like structure, and the number of merged patches can vary (e.g., 2, 4, 6, or 8; see Fig. 2), enabling controlled manipulation of region granularity and contextual interference.

Both x_i and x_j are passed through a shared encoder network $f(\cdot)$ with a ResNet-50 backbone (Fig. 2). For the merged image x_j, we extract intermediate convolutional features after the fourth residual block, resulting in a feature map $k = f_{\text{conv}}(x_j)$. To obtain region-specific representations, we apply a Region of Interest (ROI) operation on k using bounding boxes aligned with the merged layout. Each ROI feature is then average-pooled, yielding region feature vectors $h_j^n = f_{\text{avgpool}}(k_n)$, where

n indexes the sub-image regions. Meanwhile, the standard view x_i is encoded end-to-end to produce a global representation $h_i = f(x_i)$. Next, the global representation h_i and each region vector h_j^n are passed through a shared projection head $g(.)$ implemented as an MLP, producing embeddings $z_i = g(h_i)$ and $z_j^n = g(h_j^n)$.

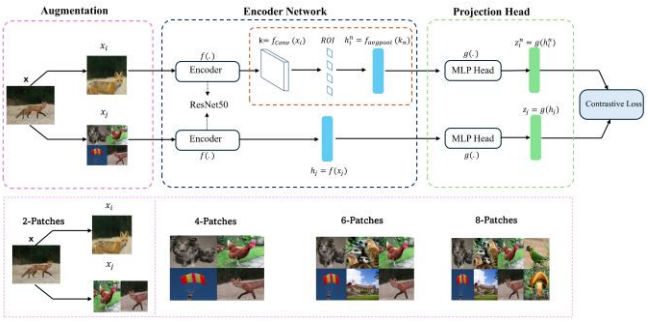

Fig. 2. INSPIRE method: global–region contrastive learning using merged views with controllable patch granularity and contextual interference.

To train INSPIRE, we adopt the normalized temperature-scaled cross-entropy (NT-Xent) objective [44] used in SimCLR, with a single positive per anchor. For each anchor embedding z_i (from x_i), we define exactly one positive z_j^+, which corresponds to the ROI embedding extracted from the merged view x_j that contains the transformed instance x'. All other embeddings, including region embeddings from non- matching ROIs and embeddings from other images in the minibatch, are treated as negatives. The contrastive loss is defined in Eq. (1), where sim( ) denotes cosine similarity between L_2-normalized embeddings, τ is a temperature hyperparameter, and M is the total number of candidate embeddings included in the contrastive normalization pool for the minibatch. This objective encourages the global representation of x_i to align with the correct ROI representation within the merged view, despite the distracting context introduced by the other merged patches.

$$\mathcal{L}_{i,j} = -\log \frac{\exp(\mathrm{sim}(z_i, z_j^+)/\tau)}{\sum_{k=1}^{M} \mathbf{1}[k \neq i] \exp(\mathrm{sim}(z_i, z_k)/\tau)}, \quad (1)$$

B. Evaluation Protocol for Global and Local Representations

The second component of the INSPIRE Framework examines the characteristics of the representations learned by the INSPIRE Method through downstream recognition tasks. Specifically, it evaluates these representations using settings that differ in their reliance on holistic semantic information and fine-grained local visual cues, enabling both comparison with established SSL methods and assessment of local-global representation learning. We organize this evaluation into two complementary groups. For global semantic transfer, we use standard image-level classification and report performance under three protocols: k -NN classification in the learned embedding space, linear probing with a frozen encoder and a trained linear classifier, and full fine-tuning of the encoder and classifier. For local-cue sensitivity, we transfer the same pretrained encoders to fine-grained recognition benchmarks, where discriminative performance typically depends on subtle texture, part-level, and shape cues, and therefore provides a stronger test of locality-sensitive representations. Table I summarizes the datasets and train/validation split sizes.

TABLE I. DATASETS USED FOR GLOBAL CLASSIFICATION AND FINE-GRAINED (LOCAL-CUE) TRANSFER

Dataset	Representation Focus	Classes	Train	Val
ImageNet-100 [45]	Global (image-level)	100	130,000	5,000
ImageNet-1k [45]	Global (image-level)	1,000	1,281,167	50,000
Flowers-102 [46]	Local-cue sensitivity (fine-grained)	102	6,552	818
Stanford Dogs [47]	Local-cue sensitivity (fine-grained)	120	16,465	4,115
DTD [48]	Local-cue sensitivity (fine-grained)	47	4,513	1,127
CUB-200-2011 [49]	Local-cue sensitivity (fine-grained)	200	5,994	5,794
Stanford Cars [50]	Local-cue sensitivity (fine-grained)	196	8,144	8,041

We first conducted a controlled ablation study using a ResNet-18 backbone pretrained on ImageNet-100. In this stage, we isolate the effect of region granularity by varying only the number of tiles $P \in \{2,4,6,8\}$ (Fig. 2) used to construct the merged view, while keeping all other pretraining components fixed (training schedule, batch size, data augmentations, optimizer, temperature, and projection head). We denote the resulting variants as INSPIRE-P2, INSPIRE-P4, INSPIRE-P6, and INSPIRE-P8. After pretraining, we evaluate each variant on global image-level classification using the same three protocols (k-NN, linear probe, and fine-tuning) to quantify how the patch configuration affects global transfer. To evaluate local-cue sensitivity, we transfer the pretrained encoders to five fine-grained and texture recognition benchmarks (Table I) using either linear probing or partial adaptation, depending on dataset difficulty. These evaluations test whether varying P shifts representations toward global separability or toward preserving fine local discriminative cues.

For large-scale pretraining, we adopt a two-stage design. Guided by the ResNet-18 ablation, we select the patch configuration P that yields the strongest overall behavior in our global-versus-local evaluation suite and use this configuration to pretrain a ResNet-50 INSPIRE model on ImageNet-1k [45]. We then compare this ImageNet-1k pretrained INSPIRE model against established SSL baselines (e.g., SimCLR, MoCo, BYOL) under the same evaluation protocols. This setup provides a consistent and reproducible methodology for analyzing how the INSPIRE pretraining signal, controlled through the patch configuration P, impacts the balance between global semantic structure and locally discriminative feature learning.

C. INSPIRE Representation Interpretability Methodology

The third component of the INSPIRE Framework examines the spatial sensitivity of learned representations through a representation interpretability methodology based on scale-controlled spatial perturbations. By measuring how representation similarity changes in response to perturbations applied at different spatial scales, this component characterizes whether SSL representations are more sensitive to localized visual information or to broader spatial structure.

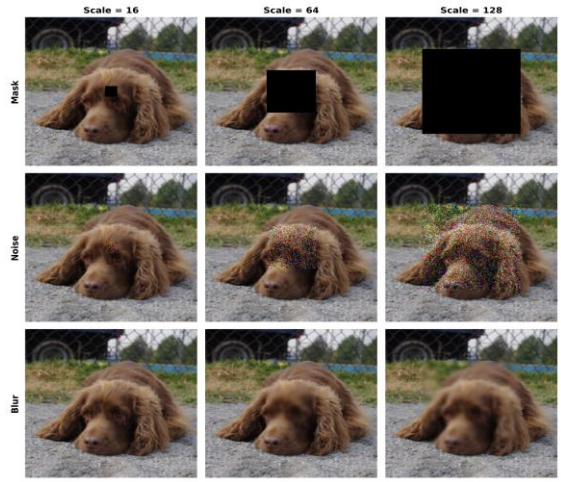

Fig. 3. Scale-controlled spatial perturbations (masking, noise, blur) applied to regions of increasing size while preserving alignment, enabling analysis of representation sensitivity to perturbation scale.

Let $x \in \mathbb{R}^{3\times H\times W}$ denote an input image and let $f(\cdot)$ represent the feature extraction function of a model at a given layer. We construct a perturbed version of the image, denoted $T_s(x)$, where T is a perturbation operator and s controls its spatial extent. We consider perturbations that preserve spatial alignment, including patch masking, localized Gaussian noise, and localized Gaussian blur. Each perturbation is applied to a square region of size $s \times s$ centered in the image, ensuring that spatial correspondence between the original and perturbed inputs is maintained (Fig. 3). By varying s, we obtain perturbations ranging from highly localized modifications to transformations affecting the entire image. To provide a scale-invariant measure, we define the normalized perturbation area in Eq. (2) as the fraction of the image affected by the perturbation.

$$\alpha = \frac{s^2}{H\times W}, \tag{2}$$

For each image x and its perturbed counterpart $T_s(x)$, we extract intermediate representations $f(x)$ and $f(T_s(x))$ from multiple layers of the model. To preserve spatial structure while obtaining fixed-dimensional representations, we apply grid-based pooling. Convolutional feature maps of shape $[B, C, H, W]$ are adaptively pooled to a fixed grid of size $g \times g$, and then flattened into vectors in $\mathbb{R}^{Cg^2}$. For transformer-based architectures, token embeddings are reshaped into spatial grids when possible, ensuring consistency across model families. This representation design retains coarse spatial layout, allowing localized perturbations to influence the resulting features.

To quantify similarity between representations, we use linear CKA [39]. Given two representations $X = f(x)$ and $Y = f(T_s(x))$, CKA is defined as:

$$\mathrm{CKA}(X,Y) = \frac{\|Y^\top X\|_F^2}{\|X^\top X\|_F \, \|Y^\top Y\|_F} \tag{3}$$

For each model, layer, perturbation type, and spatial scale s, we compute the representation change for each image x in the dataset as:

$$\Delta\mathrm{CKA}(s) = 1 - \mathrm{CKA}(f(x), f(T_s(x))) \tag{4}$$

We use a subset of 5,000 images sampled from the ImageNet-1K test set and report the mean $\Delta\mathrm{CKA}(s)$ across all samples. The resulting measurements define a scale-dependent sensitivity profile for each model and layer. By analyzing how $\Delta\mathrm{CKA}(s)$ varies as a function of the perturbation scale s, or equivalently the normalized perturbation area $\alpha = s^2/H \times W$, we obtain a structured characterization of how representations respond to perturbations at different spatial extents.

Localized perturbations provide a natural probe of spatial information in deep representations because they selectively disrupt restricted image regions while preserving the rest of the input. This approach is closely related to occlusion-based analyses introduced by Zeiler and Fergus [51], which assess the contribution of local regions by measuring changes in model responses under masking. It also connects to studies of texture–shape bias, which contrast reliance on local texture cues with more global shape information [52], [53]. In addition, the use of CKA is grounded in prior work demonstrating its effectiveness as a similarity measure for neural representations across models and layers (See Section II.C).

This component of our framework enables a controlled analysis of how representations change as a function of perturbation scale, providing a systematic way to examine sensitivity to localized and distributed modifications. By measuring representation change across layers and spatial extents, we obtain insight into how different models respond to perturbations of varying scale. While this analysis does not directly measure reliance on specific types of visual information, the observed sensitivity patterns can provide indicative evidence of how representations encode and preserve information across spatial scales.

IV. Results: ImageNet-100 (ResNet-18) (130K Images)

We analyze here INSPIRE under a controlled setting using ImageNet-100 pretraining with a ResNet-18 backbone, focusing on how the merged-view patch configuration (P) influences both global and local aspects of the learned representations while keeping all other training components fixed. Section IV.A evaluates global image-level representation quality using kNN, linear probing, and end-to-end fine-tuning, reflecting the ability to capture global semantic structure. Section IV.B examines local-cue sensitivity through transfer to fine-grained recognition benchmarks that rely on localized visual details (Table II).

TABLE II. INSPIRE Pretraining Configuration on ImageNet-100 with a ResNet-18 Backbone

Setting	Value
Backbone / Data	ResNet-18 / ImageNet-100
Training budget	100 epochs, batch size 256
Optimizer	LARS (LR 0.3, momentum 0.9, WD 10^{-6})
LR schedule	Cosine with warmup (warmup = 10 × steps/epoch)
Loss	NT-Xent (InfoNCE), $\tau = 0.4$
Projection head	SimCLR-style MLP, output dim 128
Ablation variable	Patch count $P \in \{2,4,6,8\}$
INSPIRE positives/negatives	One positive ROI (tile containing x'); others are negatives
ROI feature extraction	After layer4; global average pooling

A. Global Image-Level Results

For the ImageNet-100 experiments, we pretrain INSPIRE with a ResNet-18 backbone under a single, fixed pretraining configuration. Across all ImageNet-100 runs, the training schedule, optimizer, augmentation pipeline, projection head, and contrastive objective are held constant, and the only factor varied is the merged-view patch count $P \in \{2, 4, 6, 8\}$. INSPIRE pretraining settings are summarized in Table IV; all models are pretrained for 100 epochs with NT-Xent and a SimCLR-style MLP projection head under a fixed optimization schedule.

For comparison, we train a SimCLR baseline with the same ResNet-18 backbone (SimCLR-R18) under an identical pretraining configuration on ImageNet-100. The SimCLR model is implemented using the Lightly framework [54], and all components, including the augmentation pipeline, optimizer, learning rate schedule, batch size, number of epochs, projection head architecture, and NT-Xent loss parameters, are kept the same as in INSPIRE. This controlled setup ensures that any observed differences are attributable to the merged-view design and region-based alignment in INSPIRE. Additionally, we assess the global image-level performance of the two methods using three standard protocols (kNN evaluation, linear probing, and end-to-end fine-tuning), following the settings summarized in Table III.

TABLE III. GLOBAL EVALUATION SETTINGS

Protocol	Description
kNN	Neighbors: $k = 200$. Similarity scaling: temperature $= 0.1$. Preprocessing (train/val): resize to 256, center crop to 224, then ImageNet normalization. Reported metrics: Top-1 and Top-5 validation accuracy.
Linear probe	Trainable parameters: linear classifier only (encoder fully frozen). Training length: 90 epochs. Optimizer: SGD with learning rate 0.1, momentum 0.9, weight decay 0. Schedule: cosine learning-rate decay with no warmup. Reported metric: Top-1 validation accuracy.
Fine-tuning	Trainable parameters: encoder and classifier optimized end-to-end. Training length: 30 epochs. Optimizer: SGD with momentum 0.9, weight decay 0. Learning rate: base LR $0.05 \cdot \text{batch} \cdot \text{world}/256$. Schedule: cosine decay with no warmup. Augmentations: training uses RandomResizedCrop(224) and horizontal flip; validation uses resize to 256 and center crop to 224 (ImageNet normalization). Reported metrics: Top-1 and Top-5 validation accuracy.

Fig. 4 presents the ImageNet-100 results after 100-epoch pretraining for SimCLR-R18 and INSPIRE with different patch counts $P \in \{2, 4, 6, 8\}$. The x-axis enumerates the methods, while the y-axis reports accuracy under several evaluation protocols, including linear probing (Top-1 and Top-5), fine-tuning (Top-1 and Top-5), and kNN. A consistent pattern is that global image-level performance varies with the patch configuration, and the differences are most visible for protocols that rely directly on the pretrained representation without extensive end-to-end adaptation (kNN and linear probing). This behavior is plausible given that changing P simultaneously changes region granularity and the amount of competing context in the merged view, which may affect how easily global, class-separable structure emerges in the frozen feature space.

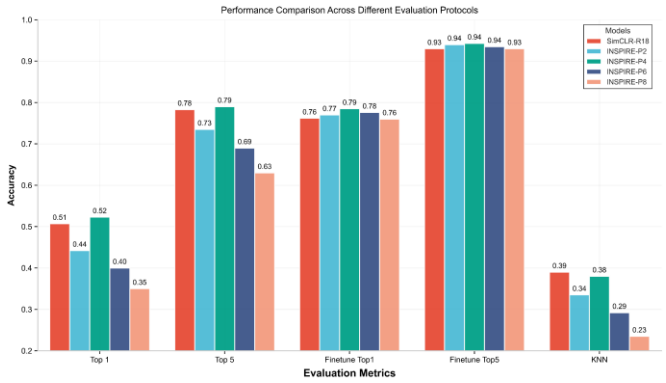

Fig. 4. ImageNet-100 results after 100-epoch pretraining: SimCLR-R18 vs. INSPIRE (P2–P8) under different evaluation protocols.

For linear probing, SimCLR-R18 reaches 0.51 Top-1 and 0.78 Top-5, while INSPIRE-P4 reaches 0.52 Top-1 and 0.79 Top-5, indicating a small improvement for P4. In comparison, the remaining INSPIRE settings show lower linear-probe accuracy, with P2 at 0.44/0.74, P6 at 0.40/0.69, and P8 at 0.35/0.63 (Top-1/Top-5). One possible interpretation is that moderate merging (P4) introduces additional contextual variation that can encourage robustness while still preserving enough global semantic consistency to support class separation under a frozen encoder. By contrast, very small (P2) or heavier merging (P6–P8) may introduce either insufficient diversity or stronger interference, which could make the alignment objective harder and reduce linear separability when only a linear head is trained.

The kNN evaluation shows a similar trend and provides an additional view of the embedding structure. SimCLR achieves 0.39 kNN accuracy, and INSPIRE-P4 is close at 0.38, whereas P2, P6, and P8 decrease to 0.34, 0.29, and 0.24, respectively. Since kNN depends on neighborhood relationships in the learned feature space, the lower kNN scores at larger P are consistent with representations that are less globally clustered by class under the frozen encoder, potentially due to increased competing content in the merged view.

After fine-tuning, the performance differences across methods become smaller, suggesting that end-to-end adaptation can partially mitigate the gaps observed under frozen-feature evaluations. SimCLR-R18 attains 0.76 Top-1 and 0.93 Top-5, while INSPIRE-P4 reaches 0.79 Top-1 and 0.94 Top-5, reflecting a modest improvement. The other INSPIRE variants cluster in a narrower range after fine-tuning (Top-1 around 0.76–0.78), even though their linear probing and kNN results are lower. This pattern is consistent with the idea that fine-tuning can adjust earlier features and decision boundaries to better match the supervised objective, reducing the sensitivity to differences in the initial embedding geometry induced by the patch configuration. Fig. 4 suggests that P controls a trade-off between region granularity and contextual interference, which is most apparent when evaluating the frozen representation space and becomes less pronounced after end-to-end adaptation.

TABLE IV. OVERVIEW OF BENCHMARK DATASETS FOR FINE-GRAINED VISUAL RECOGNITION

Dataset	Examples			Why It Is Fine-Grained
Flowers-102 [46]				Intra-class variation is low while inter-class differences are subtle, relying on fine details such as petal structure, color gradients, and reproductive parts.
	Pink Primrose	Toad Lily	Tiger Lily	
Stanford Dogs [47]				High visual similarity across breeds with distinctions concentrated in subtle facial features, fur texture, and body proportions.
	Siberian Husky	Alaskan Malamute	Samoyed	
DTD [48]				Categories are defined by abstract texture attributes rather than objects, requiring recognition of local repetitive patterns and statistical appearance cues.
	Banded	Braided	Bubbly	
CUB-200-2011 [49]				Fine-grained recognition depends on small differences in part configurations, plumage patterns, and coloration, often localized to specific body regions.
	Red-cockaded Woodpecker	Downy Woodpecker	Louisiana Waterthrush	
Stanford Cars [50]				Subtle inter-class variations arise from minor differences in shape, grille design, headlights, and brand-specific styling cues across visually similar vehicles.
	Audi A5 Coupe 2012	BMW 4 Coupe 2012	Acura TSX Sedan 2012	

B. *Fine-Grained Transfer (Local-Cue Evaluation)*

To examine local-cue sensitivity, we evaluate whether representations learned by INSPIRE transfer to fine-grained recognition tasks that require discriminative texture- and part-level cues. We compare INSPIRE variants against SimCLR-R18 trained with different merged-view patch counts. All models are pretrained on ImageNet-100 for 100 epochs under the same setup, differing only in P, and then transferred to fine-grained benchmarks to evaluate how patch count affects performance on localized visual tasks.

Table IV summarizes the fine-grained transfer datasets used to evaluate local-cue sensitivity. These benchmarks are challenging because many classes share strong global similarity, and correct recognition often depends on localized cues such as texture primitives (DTD), part-level attributes and markings (CUB-200-2011), and small shape or appearance differences within a common object category (Flowers-102, Stanford Dogs, and Stanford Cars). As a result, performance on these datasets is less driven by coarse, global semantics and more influenced by the quality of features that preserve discriminative local information.

To ensure a fair and consistent transfer evaluation, we use a fixed tuning budget for all methods. For each fine-grained dataset, we run a small set of four training configurations and apply the same set to every pretrained encoder. All transfer runs are trained for a fixed 20 epochs, and the final reported score for each (model, dataset) pair is the best validation Top-1 accuracy among these four configurations. For the linear-probe datasets (Flowers-102, Stanford Dogs, and DTD), the four configurations cover two weight decay settings (0 and 10^{-4}) and two label-smoothing values (0.05 and 0.10), while keeping the learning rate fixed at 0.3. For the more challenging datasets (CUB-200-2011 and Stanford Cars), we adopt the layer4-adaptation protocol and tune weight decay over $\{10^{-4}, 10^{-3}\}$ with label smoothing set to 0, again using a learning rate of 0.3. This procedure keeps the tuning effort comparable across methods while reducing sensitivity to a single choice of optimization hyperparameters.

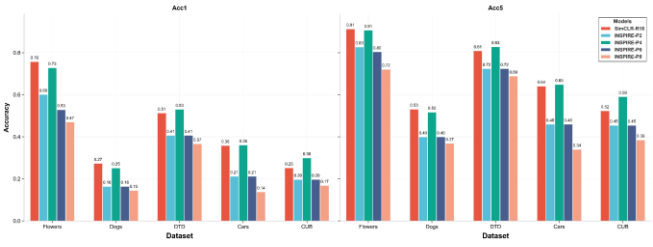

Fig. 5. Performance comparison across fine-grained transfer datasets.

Fig. 5 summarizes fine-grained transfer performance across five datasets. The x-axis lists the datasets, and the y-axis reports accuracy. The left panel shows Top-1 accuracy (Acc1), and the

right panel shows Top-5 accuracy (Acc5) for SimCLR-R18 and INSPIRE with $P \in \{2, 4, 6, 8\}$. The figure indicates that transfer performance depends on the patch configuration, with the clearest differences appearing in the more challenging benchmarks (Cars and CUB) and in the texture-focused benchmark (DTD). This behavior is consistent with the idea that increasing P changes both the effective region granularity and the amount of competing context present during pretraining, which may influence how well locally discriminative cues are preserved for downstream transfer.

For the linear-probe datasets (Flowers, Dogs, and DTD), SimCLR-R18 achieves 0.76/0.91 (Top-1/Top-5) on Flowers, 0.27/0.53 on Dogs, and 0.51/0.81 on DTD. INSPIRE-P4 reaches 0.73/0.91 on Flowers and 0.25/0.52 on Dogs, which remains close to SimCLR, while on DTD it reaches 0.53/0.83, showing a modest improvement over SimCLR on the texture-oriented task. In contrast, P2 yields lower accuracy across these datasets (e.g., 0.60/0.83 on Flowers and 0.41/0.72 on DTD), and performance decreases further for larger patch counts (P6 and P8), which may reflect increased contextual interference in the merged view when the number of tiles becomes larger.

For the layer 4-adaptation datasets (Cars and CUB), the same trend is visible, and differences become more pronounced. On Cars, SimCLR-R18 reaches 0.36/0.64, while INSPIRE-P4 reaches 0.36/0.65, indicating similar Top-1 and a small increase in Top-5. On CUB, SimCLR-R18 reaches 0.25/0.52, whereas INSPIRE-P4 reaches 0.30/0.59, reflecting a clearer improvement under the limited adaptation setting. Meanwhile, higher patch counts again show lower transfer accuracy (e.g., P8 reaches 0.14/0.34 on Cars and 0.17/0.39 on CUB), which is consistent with the possibility that stronger merging makes it harder for the pretrained representation to support fine-grained distinctions under constrained supervision.

Fig. 5 suggests that moderate merging (here, P4) can maintain competitive transfer on several fine-grained benchmarks and may provide modest gains on datasets that rely strongly on local patterns (DTD) or part-level distinctions (CUB), while heavier merging configurations (P6–P8) tend to reduce fine-grained transfer performance.

V. Results: ImageNet-1k (ResNet-50) (1.28M Images)

Having identified the best-performing patch configuration on ImageNet-100 in Section IV, we now extend the analysis to a large-scale setting by pretraining INSPIRE on ImageNet-1k with a ResNet-50 backbone and comparing it against 9 well-known self-supervised learning baselines. The goal here is to examine whether the observed effects of the merged-view design persist at scale and under more challenging evaluation conditions.

We evaluate representations along two complementary dimensions. First, in Section V.A, we assess global image-level performance using standard ImageNet protocols, including kNN, linear probing, and end-to-end fine-tuning, which reflect global semantic separability and transfer efficiency. Second, in Section V.B, we evaluate fine-grained transfer performance on datasets that depend more heavily on localized visual cues. These evaluations allow us to assess how INSPIRE behaves at scale and whether it maintains a balance between global semantic structure and locally discriminative features when compared to existing SSL methods.

A. Global Evaluation vs Nine SSL Baselines

For the large-scale global evaluation, we pretrain INSPIRE on ImageNet-1k using a ResNet-50 backbone and the $P = 4$ patch configuration (INSPIRE-P4). Training is conducted for 100 epochs using distributed data parallel (DDP) over 7 GPUs with a per-device batch size of 128 (effective batch size 896) under mixed-precision. The effective batch size was selected to balance training efficiency with the available computational resources, as substantially larger batch sizes would require additional GPU memory and computational capacity. We adopt SimCLR-style data augmentations and optimize the NT-Xent contrastive objective with temperature $\tau = 0.4$. Optimization uses LARS with momentum 0.9 and weight decay 10^{-6}. The learning rate is scaled with the effective batch size as $\text{LR} = 0.075 \cdot \sqrt{128 \times 7}$, and we apply a cosine warmup schedule with warmup length set to $10 \times$ steps-per-epoch. We use the same SimCLR-style projection head as in the ImageNet-100 experiments, mapping features to a 128-dimensional embedding space.

We compare INSPIRE-R50 against nine widely adopted SSL baselines spanning the major paradigms of modern SSL, including contrastive, clustering-based, redundancy-reduction, self-distillation, and masked image modeling methods. All methods are evaluated using the same global evaluation protocols described in Section IV.A. All evaluation settings (including kNN parameters, preprocessing, and optimization hyperparameters for linear probing and fine-tuning) are kept identical to the ImageNet-100 protocol to enable a consistent large-scale comparison focused on representation quality.

All large-scale comparisons in this section follow a consistent benchmarking setup based on the Lightly framework [54]. The SSL baselines (e.g., DINO, SwAV, SimCLR, BYOL, MoCo v2, VICReg, Barlow Twins, TiCo, and MAE) are taken from Lightly-pretrained checkpoints trained for 100 epochs with an effective batch size of 256 and evaluated under the same protocol suite used throughout this work.

Fig. 6. ImageNet-1k linear probe results (ResNet-50, 100 epochs): Top-1 and Top-5 accuracy (%) for INSPIRE-R50 and SSL baselines.

Fig. 6 summarizes the ImageNet-1k linear evaluation results after 100 epochs of pretraining with a ResNet-50 backbone. The

x-axis lists the SSL methods, and the y-axis reports linear-probe accuracy (Top-1 and Top-5, in %), obtained under the same linear evaluation protocol.

INSPIRE-R50 achieves 65.4 Top-1 and 87.2 Top-5. Among the methods compared, DINO (68.2 Top-1, 87.9 Top-5) and SwAV (67.2 Top-1, 88.1 Top-5) obtain the highest Top-1 accuracy in this setting, while INSPIRE-R50 is lower in Top-1 and closes in Top-5. Relative to several commonly used contrastive and redundancy-reduction baselines, INSPIRE-R50 shows higher linear-probe accuracy than SimCLR (63.2/85.2), VICReg (63.0/85.4), Barlow Twins (62.9/84.3), BYOL (62.5/85.0), and MoCo v2 (61.5/84.1) in both Top-1 and Top-5. TiCo (49.7/74.4) and MAE (46.0/70.2) are lower under this linear evaluation protocol. Fig. 6 suggests overall that INSPIRE-R50 yields a competitive linear evaluation performance on ImageNet-1k relative to several established SSL baselines, while remaining below the best-performing methods in this comparison.

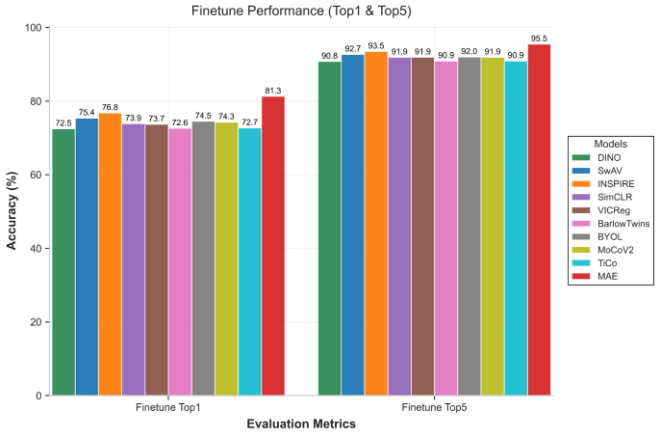

Fig. 7. ImageNet-1k fine-tuning results (ResNet-50, 100 epochs): Top-1 and Top-5 accuracy (%) for INSPIRE-R50 and SSL baselines.

Fig. 7 shows the ImageNet-1k fine-tuning results after 100 epochs of ResNet-50 pretraining. The x-axis lists the SSL methods, and the y-axis reports fine-tuned accuracy (Top-1 and Top-5, in %), obtained under the same end-to-end fine-tuning protocol.

INSPIRE-R50 reaches 76.8 Top-1 and 93.5 Top-5. In this setting, INSPIRE-R50 is above several commonly used SSL baselines, including SimCLR (73.9/91.9), VICReg (73.7/91.9), BYOL (74.5/92.0), MoCo v2 (74.3/91.9), Barlow Twins (72.6/90.9), DINO (72.5/90.8), and TiCo (72.7/90.9), and it is also slightly above SwAV (75.4/92.7). MAE shows a different behavior in this comparison: it attains the highest fine-tuning accuracy (81.3 Top-1 and 95.5 Top-5), despite being much lower in the linear-probe results reported earlier. This contrast is consistent with the notion that some pretraining objectives may produce features that are not as linearly separable without adaptation yet become highly effective once fine-tuned with supervised labels. In this context, INSPIRE Method's results appear relatively stable across evaluation protocols, providing competitive linear evaluation performance while also achieving strong accuracy after end-to-end fine-tuning.

Fig. 8 reports the kNN evaluation results on ImageNet-1k after 100-epoch pretraining with a ResNet-50 backbone. The x-axis lists the SSL methods, and the y-axis shows kNN accuracy (Top-1 and Top-5, in %), computed under the same kNN protocol used throughout this section.

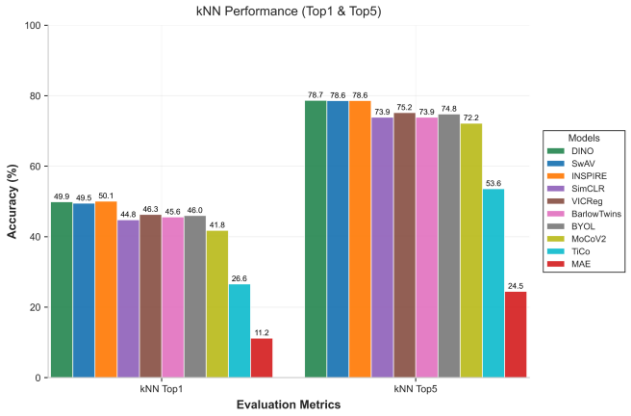

Fig. 8. ImageNet-1k kNN results (ResNet-50, 100 epochs): Top-1 and Top-5 accuracy (%) for INSPIRE-R50 and SSL baselines.

INSPIRE-R50 achieves 50.1 Top-1 and 78.6 Top-5. In this comparison, INSPIRE-R50 is close to the strongest kNN results reported by DINO (49.9/78.7) and SwAV (49.5/78.6), and it is higher than several commonly used baselines such as SimCLR (44.8/73.9), VICReg (46.3/75.2), BYOL (46.0/74.8), Barlow Twins (45.6/73.9), and MoCo v2 (41.8/72.2). TiCo (26.6/53.6) and MAE (11.2/24.5) are lower under kNN, which is consistent with the general observation that kNN strongly depends on the class structure being directly reflected in the embedding space without supervised adaptation.

Across the three global protocols reported in this section (linear probing in Fig. 6, fine-tuning in Fig. 7 , and kNN in Fig. 8), INSPIRE-R50 shows consistent performance under both frozen-feature evaluations (kNN and linear probing) and end-to-end adaptation (fine-tuning). While the relative ordering differs across protocols for some methods (e.g., MAE performs substantially better after fine-tuning than under kNN or linear probing), INSPIRE-R50 remains broadly competitive across the full evaluation suite, suggesting its suitability as a stable large-scale pretraining approach in this setting.

B. Fine-Grained Transfer vs Nine SSL Baselines

Here, we extend the large-scale evaluation by comparing fine-grained transfer performance of INSPIRE-R50 against a set of established SSL baselines, including BYOL, DINO, MAE, MoCo, SimCLR, SwAV, TiCo, and VICReg. The goal is to assess how representations learned at ImageNet-1k scale transfer to recognition problems that typically depend on subtle, localized cues such as fine textures, part-level attributes, and small shape variations.

To ensure a fair comparison across methods, we follow the same fine-grained evaluation protocol introduced in Section IV.B All pretrained models are evaluated on the same set of fine-grained datasets using identical transfer settings and a shared hyperparameter configuration.

Fig. 10. Fine-grained transfer Top-5 (ACC5): INSPIRE-R50 vs best SSL baselines per dataset.

Fig. 9 and Fig. 10 summarize the fine-grained transfer comparison between INSPIRE-R50 and a subset of SSL baselines on five datasets. In both figures, the x-axis lists the datasets (CUB, Cars, DTD, Dogs, and Flowers) and the y-axis reports accuracy. Fig. 9 shows Top-1 (ACC1) and Fig. 10 shows Top-5 (ACC5). For readability, the figures display INSPIRE together with the top-performing baseline methods per dataset (the specific baseline names are indicated above the bars), so the compared baseline set can differ slightly from one dataset to another.

Fig. 9 shows that INSPIRE achieves comparable Top-1 performance across all fine-grained datasets. On Cars, INSPIRE reaches 75.87%, which is higher than the other reported methods (≈70–72%). On CUB, INSPIRE (58.92%) is slightly below the best baseline, SwAV (60.49%), but remains within a close range. A similar pattern appears on Dogs, where INSPIRE (59.51%) is near SwAV (61.02%) and other baselines. On DTD, INSPIRE (71.52%) is below SimCLR and SwAV (≈73.29%), and on Flowers (89.36%) it is lower than methods such as Barlow Twins (94.74%) and DINO (≈93%). The INSPIRE Method overall provides consistent performance across datasets, although it does not achieve the highest accuracy in all cases.

Fig. 10 (ACC5) follows a similar pattern, where INSPIRE maintains comparable performance across all datasets. On Cars, INSPIRE achieves 94.07%, which is above other methods such as SwAV (92%) and BYOL (91.32%). On CUB, INSPIRE (86.02%) is slightly lower than SwAV (87.44%). On Dogs, INSPIRE (88.24%) is comparable to SwAV (88.85%) and other baselines. On DTD, INSPIRE (93.79%) is close to SwAV (94.94%), while on Flowers (97.19%) it trails Barlow Twins (99.02%) and SimCLR (≈98.9%). Compared to Top-1 results, the differences between methods are smaller in Top-5 accuracy, indicating that INSPIRE captures relevant class information even when it is not ranked highest in Top-1 accuracy.

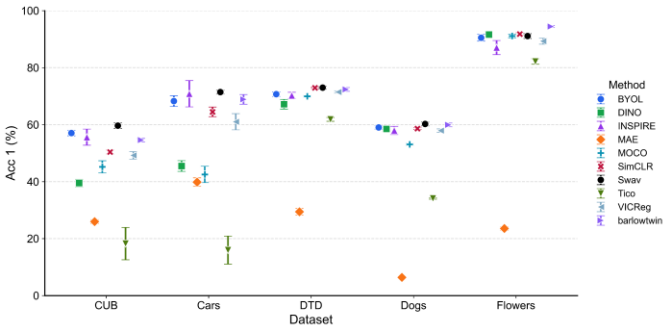

Fig. 11. Mean and standard deviation of the Top-1 validation accuracy across 4 randomized runs per dataset.

Note that, for the experiments presented in this section, we performed four independent runs for each method on each dataset. Fig. 11 reports the mean and standard deviation of the Top-1 validation accuracy to illustrate the consistency and stability of the results. All results presented throughout the study are reported as mean performance across multiple independent executions. To maintain the focus and readability of the study, we do not further analyze these statistics. Future work may investigate the variability and robustness of different SSL methods, including the proposed INSPIRE Method, in greater detail.

VI. Results: Representation Interpretability

While the previous sections (Sections IV and V) evaluate SSL methods through downstream performance, this section adopts a representation-level interpretability perspective to directly investigate the behavior of learned representations. Building on the methodology of our framework introduced in Section III.C, we investigate how representations learned by different SSL methods respond to controlled perturbations across network layers and spatial scales. This analysis complements downstream evaluation by characterizing representation sensitivity and robustness under varying perturbation conditions, providing insight into how different SSL objectives may influence representation behavior.

The top panel of Fig. 12 presents the average CKA similarity between representations learned by different SSL methods, aggregated across all layers. The results show moderate similarity across methods (≈0.30–0.52), indicating that while SSL approaches share common representational structure, they also exhibit method-specific differences. Methods based on invariance learning, including both contrastive and redundancy-reduction approaches such as SimCLR, VICReg, and Barlow Twins, exhibit the highest mutual similarity (e.g., VICReg–SimCLR: 0.52, SimCLR–Barlow Twins: 0.51, VICReg–Barlow Twins: 0.50), suggesting that despite differences in their objectives, they produce similar geometric constraints on the representation space.

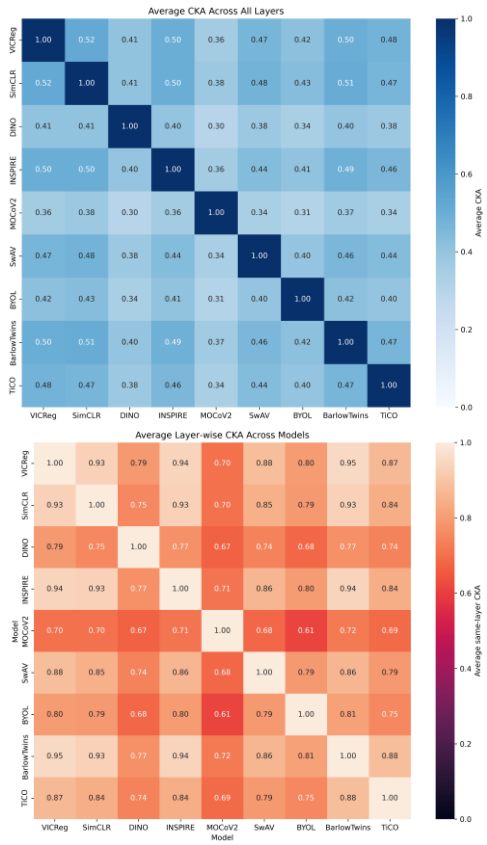

Fig. 12. Average CKA across SSL models. The top panel shows average CKA across all layers, while the bottom panel shows average layer-wise CKA between corresponding layers.

In contrast, DINO consistently shows lower similarity with other methods (≈0.38–0.41 with most approaches), reflecting its distinct self-distillation objective, which encourages clustering-like structure and semantic grouping rather than strict instance-level discrimination. MoCoV2 also exhibits relatively lower similarity (≈0.30–0.38), suggesting that differences in training mechanisms, such as the use of momentum encoders and memory queues, may contribute to distinct representation structures. Notably, INSPIRE shows strong alignment with invariance-based methods (e.g., 0.50 with SimCLR and VICReg, 0.49 with Barlow Twins) while maintaining measurable differences from other approaches (≈0.40 with DINO and 0.36 with MoCoV2), suggesting that it preserves core contrastive representation properties while introducing controlled variation in spatial representation learning.

The bottom panel of Fig. 12 provides a complementary perspective by measuring similarity between corresponding layers, revealing a notable contrast with the global comparison in the top panel of Fig. 12. While overall similarity is moderate when aggregating across layers, the layer-wise analysis shows consistently high similarity (≈0.61–0.95) when comparing aligned depths. This indicates that representations learned by different SSL methods are more comparable at corresponding layers than across arbitrary layers. The discrepancy between the two figures suggests that part of the observed differences across methods arises from cross-layer misalignment rather than uniformly distinct representations. Notably, even methods that appear less similar in the global comparison, such as DINO and MoCoV2, exhibit substantial alignment when evaluated layer-wise (e.g., DINO ≈0.68–0.79, MoCoV2 ≈0.61–0.72), further supporting the view that representation differences are not uniform across depth.

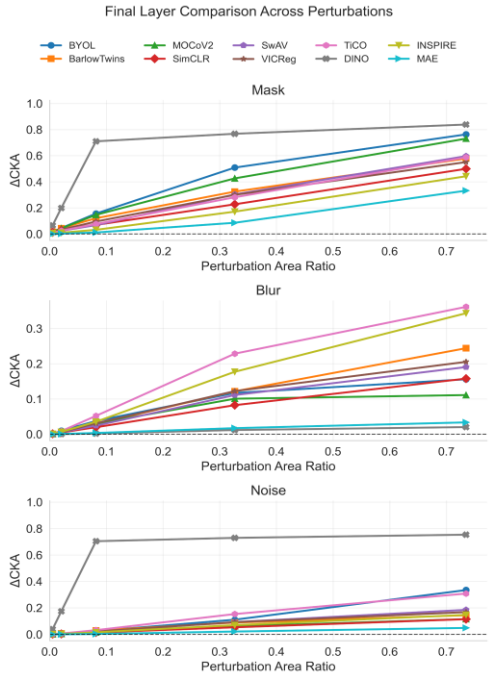

Fig. 13. Final layer representation sensitivity across spatial scales for different SSL models.

Fig. 13 presents the final-layer representation sensitivity across spatial scales for different SSL models under three types of perturbations: masking, blur, and additive noise. For each perturbation, the x-axis denotes the normalized perturbation area ratio, while the y-axis shows the corresponding change in representation measured by ΔCKA. Each curve corresponds to a different SSL method, allowing direct comparison of how representation similarity degrades as the spatial extent of the perturbation increases. The figure summarizes results over 5,000 ImageNet-1K images, providing a stable estimate of model behavior across scales.

Across all perturbation types, a consistent pattern is observed representation change increases with perturbation area, indicating that larger spatial disruptions are associated with greater deviation in learned features. However, the rate and shape of this increase differ substantially across models and perturbation types. Under masking and noise, most models exhibit a largely monotonic increase in ΔCKA, suggesting a progressive accumulation of disruption as more of the image is affected. For example, under masking at an area ratio of 0.7, BYOL reaches approximately ΔCKA ≈ 0.76, while MAE remains substantially lower at around ΔCKA ≈ 0.33, highlighting a clear difference in robustness. In contrast, blur produces a more nuanced response, with several models showing stronger sensitivity at intermediate scales; for instance, TiCo reaches ΔCKA ≈ 0.23 at area ratio 0.3 and further increases to ≈ 0.36 at 0.7, reflecting the selective degradation of mid-frequency structures.

Importantly, models differ in their sensitivity profiles. MAE consistently shows the lowest ΔCKA across all scales and perturbations, indicating strong robustness to both localized and distributed corruption. In contrast, models such as BYOL, TiCo, and MoCoV2 exhibit higher sensitivity, particularly as perturbation extent increases. INSPIRE presents an interesting intermediate behavior: under masking, it shows relatively lower sensitivity at small scales (ΔCKA ≈ 0.04 at 0.1) but increases steadily to ≈ 0.44 at 0.7, consistent with a gradual accumulation of sensitivity. Under blur, INSPIRE is among the most sensitive models at larger scales (reaching ΔCKA ≈ 0.34 at 0.7), suggesting that it is particularly affected by the loss of spatial frequency information. Similarly, under noise, INSPIRE exhibits moderate sensitivity (≈ 0.15 at 0.7), positioning it between highly robust models like MAE and more sensitive ones like BYOL and TiCo.

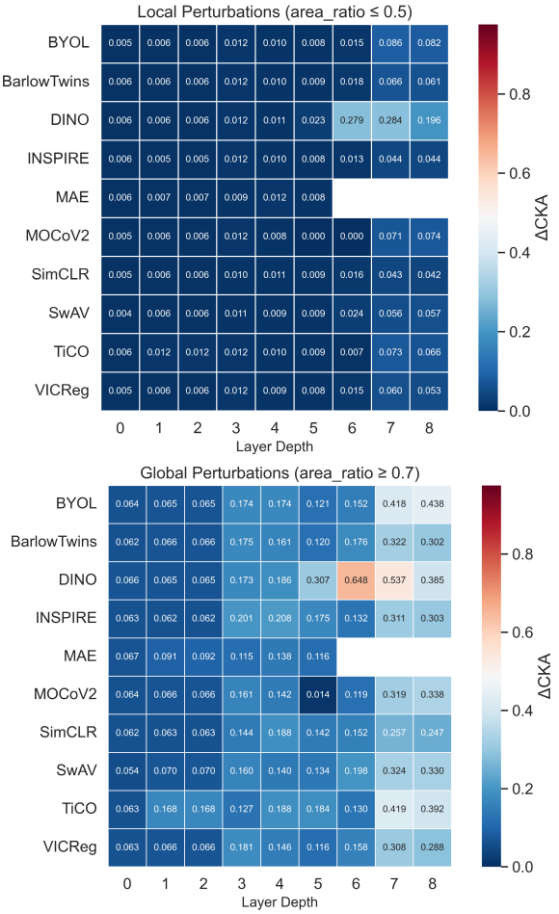

Fig. 14. Layer-wise representation sensitivity (ΔCKA) under local (top) and global (bottom) perturbations.

Fig. 14 presents the layer-wise representation sensitivity (ΔCKA) across models under local and global perturbations. The top panel summarizes local perturbations (area ratio ≤ 0.5), while the bottom panel shows global perturbations (area ratio ≥ 0.7). Each row corresponds to an SSL model, and each column represents a layer indexed by depth. The values indicate the average ΔCKA aggregated over perturbation scales, providing a compact view of how sensitivity evolves across the network hierarchy.

Under local perturbations, all models exhibit very low ΔCKA in early layers (typically ≈ 0.005–0.012), indicating strong stability to small-scale changes at shallow depths. As depth increases, sensitivity gradually rises but remains relatively modest for most models. For example, BYOL increases from ≈ 0.005 in early layers to ≈ 0.086–0.082 in deeper layers, while INSPIRE shows a similar but more controlled increase from ≈ 0.006 to ≈ 0.044. Notably, MAE remains highly stable across all layers, with ΔCKA consistently below ≈ 0.012 in early layers and only reaching ≈ 0.008 before missing deeper entries, reinforcing its robustness to localized perturbations. In contrast, DINO exhibits a sharp increase in deeper layers (≈ 0.279–0.284), suggesting heightened sensitivity to local disruptions at high-level representations.

Under global perturbations, the sensitivity increases significantly across all models, particularly in deeper layers. Early layers remain relatively stable (≈ 0.06–0.09 across models), but deeper layers show substantial divergence. For instance, BYOL increases to ≈ 0.418–0.438 in the deepest layers, while TiCo reaches ≈ 0.419, indicating strong sensitivity to large-scale changes. INSPIRE again exhibits an intermediate behavior: it shows higher sensitivity than MAE but remains more controlled than highly sensitive models, increasing from ≈ 0.063 in early layers to ≈ 0.311–0.303 in deeper layers. This consistent, gradual increase suggests that INSPIRE balances robustness and sensitivity, responding progressively to larger-scale disruptions rather than exhibiting abrupt changes. MAE, in contrast, maintains relatively low sensitivity even under global perturbations (≈ 0.115–0.138 in mid layers), suggesting strong invariance across scales.

The observed sensitivity profiles suggest that SSL representations are neither strictly local nor fully global in their behavior. Representations dominated by localized visual information would be expected to exhibit strong sensitivity to small perturbations, whereas representations dominated by globally aggregated image information would be expected to remain largely unaffected by localized modifications. The measured ΔCKA trends do not fully conform to either extreme. Across multiple methods, representation changes are already observable at small perturbation scales and continue to increase as perturbation extent grows. For instance, DINO exhibits substantial sensitivity even when only a small fraction of the image is perturbed, while methods such as BYOL and SimCLR show progressively larger representation changes as perturbation extent increases (Fig. 13). These observations suggest that SSL representations cannot be adequately described by either strictly local or strictly global forms of spatial encoding. Instead, the results are more consistent with a spectrum of spatial sensitivity behaviors, with different SSL objectives occupying different positions along this continuum.

The experiment also reveals meaningful differences between SSL objectives. DINO exhibits comparatively strong responses even under relatively localized perturbations ($\alpha \leq 0.1$), particularly in deeper layers, suggesting greater sensitivity to spatially structured image content (Fig. 14). In contrast, MAE remains comparatively stable across perturbation scales and network depth (Fig. 13 and Fig. 14), even under large-scale masking. INSPIRE occupies an intermediate position between these extremes: it remains relatively stable under localized

perturbations while progressively increasing in sensitivity at larger scales. Differences across perturbation types further suggest that representation sensitivity depends not only on perturbation extent, but also on the structural nature of the perturbations. In particular, blur consistently produces substantially smaller representation changes than masking, with blur sensitivity peaking near ΔCKA ≈ 0.35 while masking approaches ≈ 0.8 for several models (Fig. 13). This observation suggests that representations remain comparatively stable when coarse spatial structure is preserved, even though fine-grained image details are degraded.

The layer-wise analysis further suggests that spatial integration evolves progressively across network depth (Fig. 14). Early layers remain comparatively stable under both local and global perturbations, whereas deeper layers exhibit substantially stronger sensitivity, particularly for DINO, BYOL, and TiCo. The increasing perturbation sensitivity observed in deeper layers is consistent with progressively broader spatial integration across the network hierarchy, where later representations depend on information distributed across larger spatial extents, a behavior that has been widely observed in hierarchical vision models and attributed to increasing effective receptive field size and contextual feature integration across depth [55].

The results suggest that SSL methods do not converge to a single form of spatial invariance. Different SSL objectives exhibit distinct sensitivity profiles across perturbation scales and network depth, while masking, blur, and noise produce markedly different ΔCKA trends (Fig. 13 and Fig. 14). These consistent differences suggest that spatial sensitivity is an objective-dependent property of the learned representation. Rather than sharing a common notion of invariance, SSL methods appear to occupy different positions on a spatial sensitivity–invariance spectrum.

VII. Computational Cost and Runtime Analysis

In this section, we describe the computational setup and report run-time results for both single- and multi-GPU pretraining experiments. Our goal is to provide a clear account of the hardware environment, training infrastructure, and parallelization strategy to ensure reproducibility and to contextualize the reported run-time characteristics.

All experiments were conducted on a high-performance computing environment consisting of seven compute nodes. Each node is equipped with dual Intel Xeon Silver 4314 processors (16 cores per CPU), 503 GB of system memory, and one NVIDIA A100-PCIE-40GB GPU. Single-GPU experiments were run on a single node using one A100 GPU, with CPUs used for data loading and preprocessing. For multi-GPU pretraining, we employed PyTorch DDP [56] in a multi-node configuration with one GPU per node, where each process handled a portion of the mini-batch and gradients were synchronized across nodes at every iteration. This setup enabled efficient scaling while maintaining consistent optimization behavior across experiments.

A. Single-GPU Pretraining Experiments

For the ImageNet-100 experiments with a ResNet-18 backbone, we adopt a single-GPU training configuration to ensure controlled and consistent comparisons across all variants. Each experiment is executed on a node equipped with an NVIDIA A100 GPU with 40 GB of memory, which provides sufficient capacity for the batch size and augmentation pipeline used in this study. Training is performed for 100 epochs with a batch size of 256 per GPU. Under this configuration, all INSPIRE variants and the SimCLR baseline are trained using identical hardware and resource allocation, ensuring that performance differences are not influenced by variations in computational setup. Data loading and preprocessing are handled on the CPU, while all forward and backward computations are performed on the GPU.

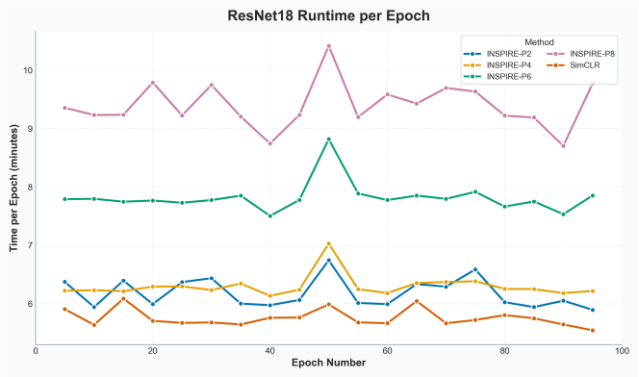

Fig. 15. Training time per epoch for SimCLR and INSPIRE with different patch configurations using a ResNet18 backbone.

Fig. 15 presents the training runtime per epoch for SimCLR and the proposed INSPIRE method under different patch configurations (P = 2, 4, 6, and 8) using a ResNet18 backbone. The training time remains stable across epochs for all configurations, indicating consistent computational behavior throughout the optimization process. SimCLR exhibits the lowest runtime, requiring approximately 5.7 minutes per epoch on average. For INSPIRE, the runtime increases gradually with the number of patches. Specifically, INSPIRE-P2 requires roughly 6.1 minutes per epoch, while INSPIRE-P4 requires about 6.3 minutes. Larger patch configurations introduce additional computational overhead, with INSPIRE-P6 and INSPIRE-P8 requiring approximately 7.8 minutes and 9.3 minutes per epoch, respectively. These results highlight the trade-off between model complexity and computational cost: increasing the number of patches leads to higher training time due to the additional feature processing required by the merge mechanism. Nevertheless, the runtime remains stable across epochs, suggesting that the proposed framework scales predictably with respect to the number of patches.

B. Multi-GPU Parallel Pretraining Experiments

For the ImageNet-1K experiment, we train two variants of INSPIRE with batch sizes 128 and 256 and compare them against SimCLR using a ResNet-50 backbone. All models are trained using PyTorch DDP across 7 GPUs (A100-PCIE-40GB), where each GPU processes its share of the global batch and gradients are synchronized at every step. This setup ensures consistent optimization while maximizing parallel efficiency across nodes.

Fig. 16 presents the training time per epoch (in minutes) on the y-axis versus the epoch number (1–100) on the x-axis. From

the figure, SimCLR consistently runs between approximately 7 and 10 minutes per epoch, with very small fluctuations across training. In comparison, INSPIRE, with batch size 256, shows epoch times that are slightly higher but still relatively close, generally falling in the range of ~11 to 13 minutes as well, with minor variability and a brief warm-up period in the early epochs. This suggests that INSPIRE (256) achieves a comparable level of efficiency to SimCLR in terms of per-epoch runtime. On the other hand, INSPIRE, with batch size 128, operates at a significantly higher cost, with epoch times consistently around ~24 to 26 minutes, and a noticeable spike reaching approximately 27 minutes in one of the early epochs. This clear separation highlights the impact of batch size: reducing the batch size effectively doubles the number of iterations per epoch, leading to a substantial increase in runtime and slightly higher variability.

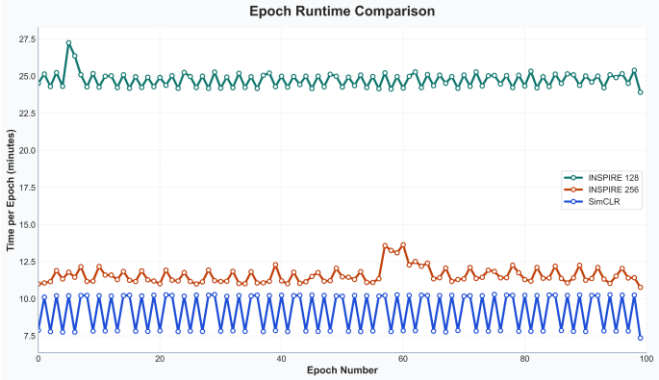

Fig. 16. Training time per epoch for SimCLR and INSPIRE with different batch sizes using a ResNet50 backbone (parallel runtime on 7 GPUs).

These per-epoch trends are consistent with the total training times. SimCLR completes training in 15.27 hours, while INSPIRE Method with batch size 256 takes 19.29 hours, reflecting its slightly higher or comparable per-epoch cost over the full run. In contrast, INSPIRE, with batch size 128, requires 41.26 hours, more than twice as long due to the inefficiency introduced by the smaller batch size.

Scaling from a single-GPU to a multi-node distributed setup plays a critical role in enabling large-scale training on ImageNet-1K. In our experiments, ImageNet-100 training with a ResNet-18 backbone on a single A100 GPU requires approximately 5.7 minutes per epoch for SimCLR, with INSPIRE variants ranging from about 6.1 to 9.8 minutes depending on configuration. In contrast, for the significantly larger ImageNet-1K dataset, we employ PyTorch DDP across 7 A100 GPUs, where each GPU processes a portion of the global batch and gradients are synchronized at every step. Under this setup, SimCLR achieves per-epoch times of approximately 7–10 minutes, while INSPIRE with batch size 256 operates at around 11–13 minutes per epoch. Despite the roughly 10× increase in dataset size, the per-epoch training time increases only modestly, demonstrating the effectiveness of distributed scaling in maintaining practical training times. These results demonstrate that multi-GPU distributed training is essential for scaling contrastive learning to ImageNet-1K, effectively compressing what would otherwise be prohibitively long training times into a manageable range of ~15–19 hours, while maintaining stable and predictable computational behavior across epochs.

VIII. Discussion and Conclusion

This work presents the INSPIRE Framework, a systematic approach for investigating local-global representation learning in self-supervised learning through controlled spatial granularity manipulation during training, downstream evaluation, and representation interpretability using scale-controlled spatial perturbation analysis. While previous research has improved SSL through new objectives [12], [28], architectures [13], [23], and local representation learning strategies [8], [9], it has remained difficult to isolate how training design influences the balance between local and global representations. Our results extend existing studies on representation learning and interpretability by providing a unified experimental framework for systematically analyzing these relationships across multiple evaluation protocols. Although INSPIRE does not achieve the highest performance on every benchmark, it remains consistently competitive across diverse evaluation settings while, more importantly, providing new insights into local-global representation learning, representation sensitivity, and the behavior of learned representations across diverse evaluation protocols.

A central finding of this work is that local-global representation learning is better understood as a continuum than as a binary distinction. The experiments suggest that representations are not inherently local or global; instead, different SSL training strategies occupy different positions along a continuum that reflects how local and global information is balanced within the learned representation. Methods achieving comparable ImageNet performance often exhibit markedly different behavior on fine-grained recognition tasks and under controlled perturbations, supporting that similar global semantic performance can arise from substantially different representational characteristics. This observation provides a more nuanced perspective on SSL representation learning than conventional benchmark comparisons alone.

The controlled spatial granularity experiments further show that the relationship between granularity and representation quality is non-monotonic. Increasing the number of merged regions initially improves representation quality, but excessive fragmentation eventually degrades both global and fine-grained transfer performance. The consistently strong performance of the intermediate P4 configuration suggests that effective representation learning emerges from balancing contextual diversity with semantic coherence rather than maximizing either property independently. This finding indicates that spatial granularity itself represents an important design variable for SSL, independent of network architecture or learning objective.

The combined downstream and representation-level analyses further demonstrate that representation similarity and representation behavior capture complementary aspects of learned representations. Models exhibiting relatively similar representation geometry do not necessarily respond similarly to controlled spatial perturbations, indicating that representation similarity alone provides an incomplete characterization of learned features. Likewise, methods displaying very different perturbation sensitivity may achieve comparable downstream

accuracy. These observations suggest that understanding SSL representations requires considering both the structure of representation space and how representations respond to controlled changes in the input, providing a richer characterization than benchmark accuracy or similarity analysis alone.

The relationship between perturbation sensitivity and downstream transfer also appears more complex than a simple trade-off between invariance and sensitivity. Neither highly sensitive nor highly invariant representations consistently produce the strongest fine-grained recognition performance. Instead, successful transfer appears to depend on maintaining discriminative local information while remaining robust to irrelevant visual variation. This observation reinforces the importance of balanced representations and suggests that representation behavior should be considered alongside conventional evaluation metrics when assessing SSL methods.

Beyond the empirical findings, the proposed INSPIRE Framework has broader implications for SSL research. Rather than introducing only another training method, the framework provides a general methodology for systematically investigating how training strategies influence representation learning. By integrating controlled training, downstream evaluation, and representation interpretability within a unified framework, INSPIRE offers a reusable experimental approach that can support future investigations of emerging SSL methods, alternative architectures, and different application domains. More broadly, the work contributes to the growing shift toward understanding learned representations rather than evaluating them solely through downstream benchmark performance.

Future research can extend the INSPIRE Framework in several directions. The proposed representation interpretability investigation methodology can be complemented with additional representation analysis techniques, including SVCCA, PWCCA, RSA, and probing-based methods, to provide broader perspectives on learned representations. Extending the evaluation to dense prediction tasks such as object detection, semantic segmentation, and instance segmentation would further clarify how local-global representation learning influences spatially intensive vision problems. Future studies should also investigate whether the observed local-global representation continuum and spatial sensitivity characteristics generalize across Vision Transformers, hybrid architectures, multimodal foundation models, and other emerging SSL paradigms. Future work should also investigate the influence of batch size, since the contrastive SSL baselines considered in this work use substantially different effective batch sizes, ranging from 512 to several thousand samples, while INSPIRE employs a fixed effective batch size of 896. We hope that INSPIRE provides a useful foundation for future research on representation learning, interpretability, and the principled design and evaluation of self-supervised learning methods.

ACKNOWLEDGMENT

This article is derived from a research grant funded by the Research, Development, and Innovation Authority (RDIA), Kingdom of Saudi Arabia, with grant number 12615-iu-2023-IU-R-2-1-EI-. The authors gratefully acknowledge the support of the High-Performance Computing Center (Aziz Supercomputer) at King Abdulaziz University (http://hpc.kau.edu.sa) for providing access to computational resources, including A100 GPUs, which were essential for the distributed data parallel (DDP) training of our models.

Enhancing Diabetic Retinopathy Classification Through Advanced Deep Convolutional Neural Network Architectures

Sifeddine Elkardoudi[1], Khalil Ladrham[2], Ahmed Eddaoui[3], Mohamed Talea[4]
Information Processing Laboratory-Faculty of Sciences Ben M'sik, University Hassan II, Casablanca, Morocco[1, 3, 4]
Intelligent Processing and Security of Systems Team-Faculty of Sciences Rabat, Mohammed V University, Rabat, Morocco[2]

***Abstract*—Diabetic retinopathy is one of the major causes of vision loss in the world; thus, the development of early diagnosis systems based on artificial intelligence is a medical and scientific necessity. If detected late, it can lead to permanent vision loss and is considered one of the most serious vascular complications of diabetes. Diagnosis is traditionally made by visual inspection of fundus images by an expert medical professional and is time-consuming. Deep learning techniques have shown promise to help detect disease early and improve the accuracy of medical decision-making. This study provides an experimental comparison of four convolutional neural network architectures (Xception, Inception-v3, MobileNet-v3 and ResNet-50), using a balanced dataset of 25,000 colour fundus images across five classes. Of the total images, 80% were used for training, 10% for validation, and 10% for testing. A standardised image size of 1024×768×3 was used to preserve the fine details of diabetic retinopathy. The models were evaluated for a number of metrics such as accuracy, loss, recall, precision, F1-score, AUC, Cohen's Kappa coefficient and MCC in addition to computational cost and training time. The results indicate that the Xception model outperformed the other models, with a test accuracy of 98.32%, a validation accuracy of 98.52%, the lowest loss rate, and the highest AUC value. Inception-v3 achieved the second-best performance with 95.04% accuracy, and MobileNet-v3 achieved the lowest computational cost, making it suitable for resource- constrained applications, with 90% accuracy. Conversely, ResNet-50 had lower accuracy with high computational cost, which shows that the increased architectural complexity does not necessarily ensure improved performance. The results show that the best model selection for diabetic retinopathy classification depends on a trade-off between diagnostic accuracy, computational efficiency, and practical usability, with Xception being the most suitable for tasks requiring the highest level of accuracy, and MobileNet-v3 as a viable alternative for resource-constrained environments.**

***Keywords*—Diabetic retinopathy; fundus images; deep learning; xception; inception-v3; mobilenet-v3; resnet-50; training time**

I. Introduction

Diabetic retinopathy is among the most severe microvascular complications of diabetes and the leading preventable cause of vision loss worldwide. Early detection is vital as the early stage of the disease can be asymptomatic and progress without obvious symptoms. Early diagnosis and appropriate treatment can reduce the risk of blindness and improve clinical outcomes [4]. In the traditional approach, diabetic retinopathy detection depends on the ophthalmologists' clinical examination of fundus images, which is effective but time-consuming and relies on human expertise and is problematic in resource-limited settings or those with a high disease burden [2], [5]. These limitations have led to the development of computer-aided diagnostic systems that can automatically analyse retinal images and provide rapid and accurate preliminary diagnoses [6].

With the rapid development of artificial intelligence, deep learning, especially convolutional neural networks (CNNs), has been one of the most successful methods for analyzing medical images. These models have been able to learn complex visual features directly from the retinal images, including microvessels, haemorrhages, exudates and microaneurysms, with less dependency on manual feature engineering [3], [7], [8].

Recent studies have demonstrated that architectures such as VGG, ResNet, DenseNet, Xception and EfficientNet can achieve high accuracy on retinal image classification, while transfer learning and data augmentation have helped improve generalisation and minimise the problem of overfitting, especially when labelled medical data is scarce [4], [7], [9]. However, despite these successes, the problem of diabetic retinopathy classification still suffers from the fundamental challenges of class imbalance, image quality variations and the challenge of distinguishing between clinically similar disease stages, on top of the need for interpretable, computationally efficient models that can be deployed in real-time clinical settings [5], [11]. In this respect, recent works have moved from single image classification to more sophisticated models, such as hybrid models that combine CNNs with LSTMs or attention mechanisms, and multimodal models that combine retinal images with clinical or demographic information, in order to improve accuracy, robustness and clinical relevance [6], [12]. Based on the above, the design of a comparative and systematic framework that integrates the strength of deep architectures, interpretability, computational efficiency and generalisation over different datasets has become a scientific and practical need to support intelligent diagnostic systems for diabetic retinopathy [10], [13].

The main motivation for this work is the major medical and public-health importance of diabetic retinopathy, which is considered one of the leading causes of vision loss in the world, especially with the increasing prevalence of diabetes. Early diagnosis can greatly reduce the progression of the disease. However, the manual inspection of fundus images is still a time-

consuming process requiring considerable expertise and is not scalable in resource-limited settings.

In this context, artificial intelligence and particularly deep learning provide a promising opportunity to develop automated diagnostic systems that can support physicians and enhance the quality of healthcare. However, many of the current studies primarily focus on achieving high accuracy and ignore other important aspects such as computational efficiency, interpretability, and practical applicability, which hinders the transfer of these models from the research environment to clinical use.

In addition, because few studies combine deep models with attention mechanisms or the integration of multimodal data, there is also a clear gap in the literature regarding the lack of a fair, systematic comparison of different architectures using the same database and the same experimental conditions. This makes it difficult to find the best model that can be relied upon in real-world applications.

Moreover, most of the current models are "black boxes", which raises concerns about the reliability of their decisions in the medical domain and the need to incorporate explainable artificial intelligence techniques to ensure transparency and increase physicians' trust in these systems.

Therefore, this work focuses on these challenges and proposes an integrated framework that combines high performance, efficiency, and interpretability. Moreover, a comprehensive comparison of several advanced architectures is conducted using a unified dataset, which may help to bridge the gap between theoretical research and clinical application in the field of diabetic retinopathy diagnosis.

II. Related Work

Although deep learning models have made great strides in classifying diabetic retinopathy, the literature shows a set of fundamental research gaps that continue to limit the effective translation of these models into the clinic. First, the majority of the studies use small or imbalanced datasets with respect to the distribution of disease categories, which causes model bias toward the most represented categories, adversely affecting generalisability [5], [10].

Second, many studies only focus on improving accuracy and ignore computational efficiency or inference time, making some models unsuitable for real-world clinical settings or resource-constrained devices [10], [11]. Furthermore, the comparison of models is often unfair because of different datasets or evaluation protocols.

Third, although hybrid models such as CNN-LSTM or CNN-Attention have emerged, the number of studies that systematically compare these models with traditional architectures is limited, and the effect of each component (attention, temporal modelling) on the final performance is still not well understood [12], [13].

Fourth, most of the studies lack explainability, where the models are treated as "black boxes", which is a major barrier to the adoption of these models by physicians. Tools such as Grad-CAM are used but often in a descriptive way without rigorous quantitative evaluation [11].

Fifth, there is a clear lack of multimodal approaches that integrate retinal images with clinical data (e.g., age, duration of diabetes, and blood pressure), even though the disease is inherently multifactorial and some studies have shown that this integration significantly improves the performance [6].

Finally, most studies do include external validations on different databases across multiple medical centers, which limits the reliability of the results, and the generalisability of the results to real-world clinical cases remains uncertain [5], [10], [16].

Table I presents a detailed comparison of eighteen recent studies on diabetic retinopathy detection and classification using deep learning and convolutional neural network methods. The studies were reviewed using a set of key criteria: the databases used, the number of images and classification categories, the proposed models and preprocessing techniques, the adopted evaluation metrics, and the best results obtained. This comparison demonstrates that current models, such as Xception, EfficientNet, and DenseNet, are effective in accurate and efficient classification of disease severity, especially when combined with image enhancement and data augmentation methods. The studies also highlight ongoing issues related to data imbalance, the high computational cost of certain deep models, and the limited generalisation ability of models when tested against other datasets. Such as comparison also serves to determine the current research trends, point out the gaps in the existing scientific research, and provide a more accurate, efficient, and applicable model for the intelligent medical diagnostic system.

The current study fills the gap of rigorous and standardised comparison of advanced convolutional neural network architectures for diabetic retinopathy classification. This work differs from many previous studies that evaluate different models under heterogeneous experimental conditions, in that the four representative CNN architectures, Xception, Inception-v3, MobileNet-v3, and ResNet-50, are compared under the same dataset, image resolution, data partitioning strategy, training protocol, and evaluation criteria. This unified experimental framework provides a fair and objective evaluation of each architecture while minimising potential biases due to inconsistent experimental settings.

The contributions of this work are summarised as follows:

1) First, this work proposes a new benchmarking framework to evaluate four state-of-the-art convolutional neural network architectures on the five-class diabetic retinopathy classification task in the same experimental setup.

2) Second, The models are assessed using a broad spectrum of performance indicators such as classification accuracy, precision, recall, specificity, F1-score, AUC, Cohen's Kappa coefficient, Matthews Correlation Coefficient (MCC), confusion matrices, convergence behaviour and loss analysis, providing a multidimensional view of diagnostic performance.

3) Third, the computational efficiency was analysed in terms of training time, runtime per epoch, and computational complexity (GFLOPs), which can objectively evaluate the

trade-off between predictive performance and computational cost for practical deployment.

The scope of the present investigation is intentionally limited to a controlled comparative evaluation of predictive performance and computational efficiency of Xception, Inception-v3, MobileNet-v3, and ResNet-50. The experimental analysis is focused on classification accuracy, convergence characteristics, class-wise confusion matrices, training time, and computational complexity under a unified experimental protocol. The explainability methods such as Grad-CAM or other visualisation techniques in the experimental framework presented in this manuscript were not applied. Thus, the explainable artificial intelligence was not viewed as a contribution of the present study, but see it as an important direction for future research to enhance the transparency and clinical interpretability of automated diabetic retinopathy diagnosis systems.

III. METHODOLOGY

The study employs a comparative experimental approach to assess the performance of four deep convolutional neural network architectures, namely Xception, Inception-v3, MobileNet-v3, and ResNet-50, in classifying diabetic retinopathy fundus images. These models were chosen as they represent different architectural approaches: Xception uses separable convolutions, Inception-v3 uses a multi-branch architecture to extract features at different levels, MobileNet-v3 is a lightweight model that optimises computational efficiency, while ResNet-50 has a deeper architecture with more branches and computational aggregations. This diversity of architecture allows for a fair comparison not only in terms of accuracy, but also loss, training time, GFLOPs and classification metrics. Fig. 1 presents the general architecture of the methodology adopted in this study, beginning with the input of the fundus images, through preprocessing, then training the four models, and finally extracting the final metrics.

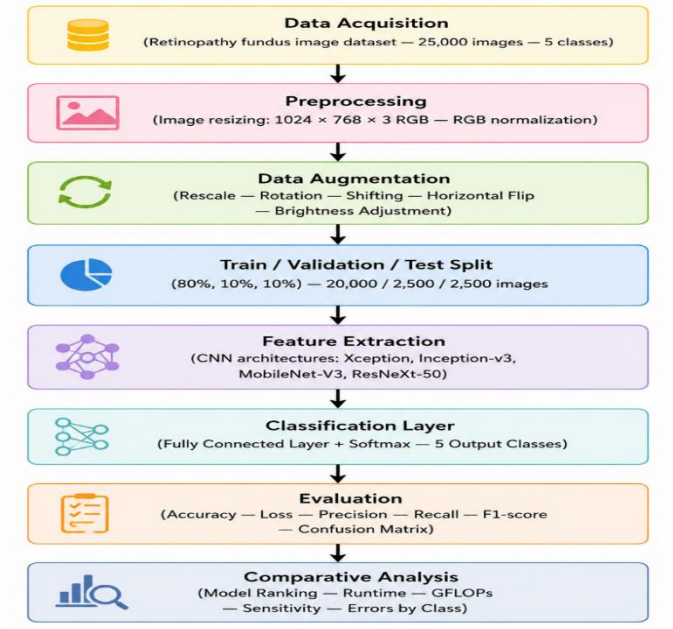

Fig. 1. Workflow of the proposed benchmarking framework.

The dataset used in this study includes 25,000 fundus images, equally distributed into five classes with 5,000 images in each class. This balance between the classes makes overall metrics such as accuracy, precision, recall and F1-score more reliable since all of the classes contribute equally to the training and testing process. The fundus images were normalised to RGB size of 1024 × 768 × 3, because they contain fine visual details such as blood vessels, optic disc, fovea, haemorrhages and deposits which are important to differentiate between severity levels of diabetic retinopathy. The stages of the diabetic retinopathy are usually classified medically into the following categories: no retinopathy, mild, moderate, severe and proliferative retinopathy as shown in Table II. The classifications used are closely related to the medical terminology used to classify the severity of the disease. Fig 2 illustrates clear visual differences between healthy and advanced pathological cases.

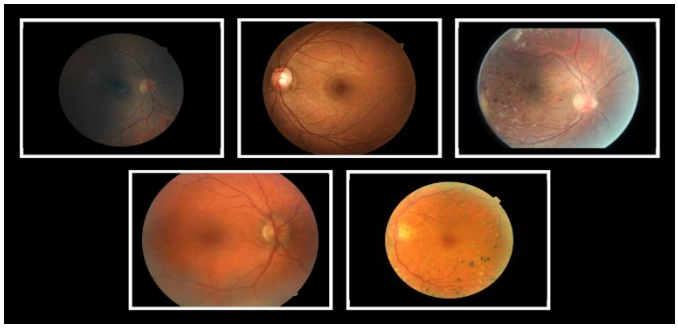

Fig. 2. Fundus images of diabetic retinopathy resized arranged dataset, Kaggle [1].

TABLE II. LABELS OF THE FIVE DIABETIC RETINOPATHY CLASSES

Number of Images	Name Class / Category	Label
5,000	No Diabetic Retinopathy	0
5,000	Mild Diabetic Retinopathy	1
5,000	Moderate Diabetic Retinopathy	2
5,000	Severe Diabetic Retinopathy	3
5,000	Proliferative Diabetic Retinopathy	4
25,000	**Diabetic Retinopathy Fundus Images**	**Total**

The data was divided into three independent sets: 80% for training, 10% for validation and 10% for testing. Fig. 3 shows the results of partitioning the data.

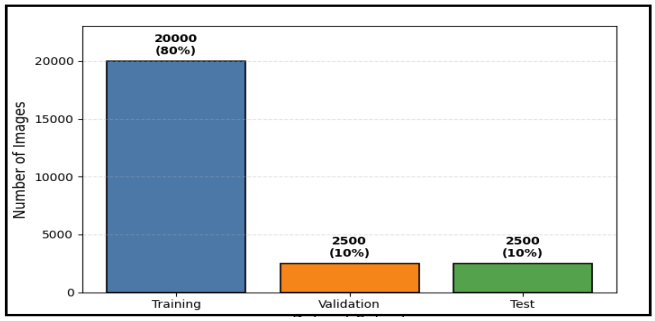

Fig. 3. Dataset split.

Thus, the training set consists of 20,000 images or 4,000 images per class, the validation set contains 2,500 images or 500 images per class, and the test set also contains 2,500 images or 500 images per class. This separation is needed to ensure that the model is not evaluated on the same images that it was trained on. It also allows us to monitor performance during training with the validation set and then finally evaluate performance on an independent test set. Table III presents the distribution of the dataset in the training, validation and test sets, with the numerical balance between the classes.

The images were first subjected to standard preprocessing steps such as resizing, colour normalisation and numerical normalisation to ensure that they satisfy the requirements of each model prior to training. This procedure is required for fundus images, since these images can vary in illumination, acquisition angle, vessel resolution, and camera quality. Moreover, pre-trained deep models are appropriate to use pre-trained deep models for such tasks, as the Keras library provides

ready-made models with pre-trained weights that can be used for predictions, feature extraction, or fine-tuning. Fig. 4 shows the proposed preprocessing steps before feeding the images to the models.

TABLE III. DISTRIBUTION OF THE DATASET IN THE TRAINING, VALIDATION, AND TEST SETS

Value	Description
5 classes	Number of Classes
5,000 images	Number of images per category
25,000 images	Total number of images
1024 × 768 × 3 RGB	Image size
20,000 images	Training images
2,500 images	Validation images
2,500 images	Test images
4,000 images	Number of training images in each category
500 images	Number of validation images per category
500 images	Number of test images per category

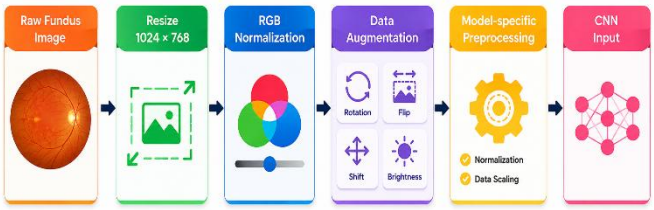

Fig. 4. Proposed preprocessing steps before feeding images into the models.

The batch size was chosen according to the type of each model and the computational cost. A Batch size of 32 is used with Xception due to the depth of the model and large image size. Batch size of 128 is used with Inception-v3 as it gives a good balance between computational stability and training speed [3]. For MobileNet-v3, a batch size of 256 is used because it is a lightweight model and can support larger batches, whereas for ResNet-50, a batch size of 64 is applied due to its high computational cost. The number of steps per epoch was different: 625 for Xception, 157 for Inception-v3, 79 for MobileNet-v3 and 313 for ResNet-50. Fig. 5 shows the trade-off between batch size and number of steps per epoch for the four models.

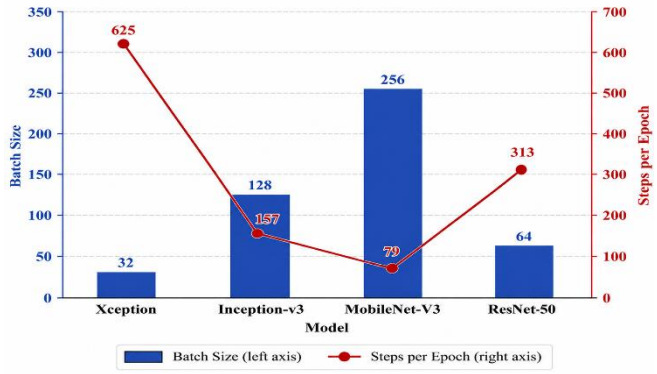

Fig. 5. Batch size and steps per epoch across the four models.

All models were trained for 50 epochs for a fair comparison between models. From the curves, the plateau is observed around epoch 43, where accuracy and loss start to stabilise gradually, showing that the models have converged without any obvious divergence between the training and validation curves. To avoid overfitting, EarlyStopping will monitor the val_loss or val_accuracy and stop the training when it stops improving. Also, `ReduceLROnPlateau` can be used to reduce the learning rate when no improvement happens and `ModelCheckpoint` to save the best version of the model during training. EarlyStopping stops training when the metric being monitored stops improving. ReduceLROnPlateau reduces the learning rate when performance plateaus. ModelCheckpoint allows the model to be saved during training, so that the best version can be retrieved later. As for the optimiser, it can be Adam or AdamW. The Adam optimiser is based on the adaptive estimation of first and second derivatives of the gradient, which is suitable for tasks with large datasets and deep models [19].

All the CNN models were developed in TensorFlow/Keras and were trained on the HPC-MARWAN high-performance computing platform on eight CPU cores. In the case of transfer learning, each backbone was initialized with weights pre-trained on ImageNet. The original classification layer was replaced by a global average pooling layer, a dropout layer and a five-class softmax classifier adapted to the diabetic retinopathy classification task.

The model was trained with the Adam optimizer with an initial learning rate of 0.0001. To prevent overfitting, early stopping was used with a patience of 5 epochs, and the learning rate was automatically decreased using the ReduceLROnPlateau callback with a reduction factor of 0.5 when the validation loss stopped improving. All experiments were performed with a fixed random seed of 42 to ensure reproducibility in dataset partitioning and model initialization.

All experiments were performed on the HPC-MARWAN cluster under the same computational conditions in an effort to make a fair comparison between the CNN architectures evaluated, as shown in Table IV.

TABLE IV. EXPERIMENTAL CONFIGURATION AND REPRODUCIBILITY SETTINGS

Parameter	Value
Computing platform	HPC-MARWAN
Hardware	CPU-only
CPU cores	8
Framework	TensorFlow / Keras
Transfer learning	ImageNet pretrained weights
Optimizer	Adam
Initial learning rate	0.0001
Loss function	Categorical Cross-Entropy
Random seed	42
Early stopping	Patience = 5
Learning-rate scheduler	ReduceLROnPlateau
Reduction factor	0.5
Dataset split	80% / 10% / 10%
Input image size	1024 × 768 × 3

IV. EXPERIMENTS

All experiments were performed using a standard protocol to allow for a fair comparison between the four models. The study used the same dataset, image size, number of epochs, and data split, with only the batch size differing depending on the nature of each model. This difference does not affect the fairness of the comparison since it is aimed at adapting each model to its own computational and memory requirements. Images of size 1024 × 768 RGB have a heavy computational load, so the same batch size cannot be used for all models without affecting stability or memory. The general experimental setup and batch configuration for the four models are shown in Table V and Table VI.

TABLE V. GENERAL EXPERIMENTAL SETUP OF THE FOUR MODELS

Experimental Setting	Value
Dataset	Diabetic retinopathy fundus image dataset
Total images	25,000 images
Number of classes	5 classes
Image size	1024 × 768 × 3 RGB
Data split	80% training / 10% validation / 10% test
Training / Validation / Test images	20,000 / 2,500 / 2,500
Number of epochs	50
Models evaluated	Xception, Inception-v3, MobileNet-v3, ResNet-50
Variable settings	Batch size adapted to each model.

TABLE VI. MODEL-SPECIFIC BATCH CONFIGURATION

Model	Batch Size	Steps per Epoch
Xception	32	625
Inception-v3	128	157
MobileNet-v3	256	79
ResNet-50	64	313

For the Xception experiment, the batch size was 32, with 625 steps per epoch. The accuracy curves of this model show that the accuracy increased rapidly from the early steps of training. The training accuracy started from about 84% and gradually reached 98.38%, and the validation accuracy started from around 89.8% and reached 98.52%. The observed behaviour emphasises the ability of Xception to extract the correct features from the fundus images, especially because the training and validation curves were close to each other in the last steps. Fig. 6 shows the accuracy curve for model Xception.

For the Inception-v3 experiment, a batch size of 128 was used with 157 steps per epoch. Initially, the training accuracy was 70%, then it increased to 95.05%, and the validation accuracy was 95.30%. This behaviour indicates that the model is able to learn in a gradual and stable way, but it is less superior than Xception. Inception-v3 is a multi-branch architecture that allows for feature extraction at different scales, which is beneficial for fundus images that contain both fine and coarse details. The accuracy curve for the Inception-v3 model is shown in Fig. 7.

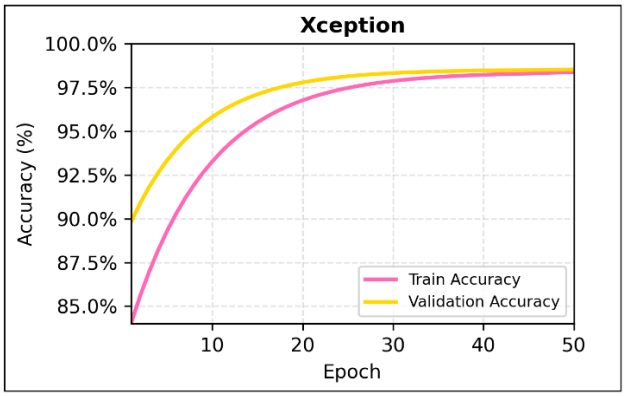

Fig. 6. Accuracy curve for the Xception model.

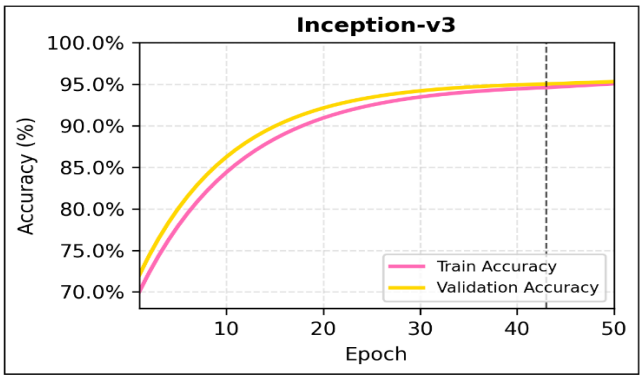

Fig. 7. Accuracy curve for the Inception-v3 model.

The MobileNet-v3 experiment used a batch size of 256 and 79 steps per epoch. The training-set accuracy is 90.10%, and the validation set is 90.35%. These are lower than Xception and Inception-v3, but MobileNet-v3 is still important from an efficiency perspective as it was originally designed as a lightweight model for resource- constrained applications. Although less accurate, it remains useful in practical situations where large amounts of computing power are not available.

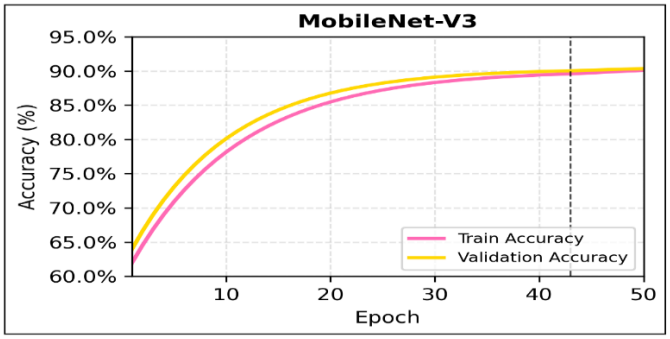

Fig. 8. Accuracy curve for the MobileNet-v3 model.

Apart from accuracy, loss curves were also studied for each model. The model with the lowest final loss was Xception with a training loss of 8.05% and a validation loss of 7.80%. The validation loss of Inception-v3 was 11.90 %. MobileNet-v3 was

around 29.80 % and ResNet-50 was around 24.80 %. A lower loss means the model is able to make better classification decisions. The closeness of the training and validation loss indicates a good level of generalisation. Fig. 9 shows the training loss curves of the four models.

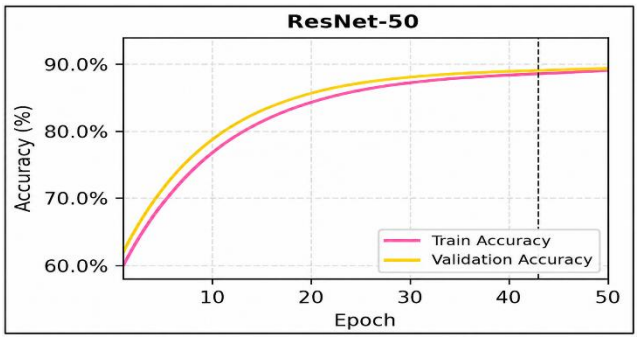

Fig. 9. Accuracy curve for the ResNet-50.

Besides accuracy, loss curves for each model were also studied. Xception had the lowest final loss with a training loss of 8.05% and validation loss of 7.80%. Inception-v3, however, had a validation loss of 11.90%, whereas the validation loss of MobileNet-v3 and ResNet-50 was around 29.80% and 24.80% respectively. A lower loss means better classification decisions by the model, and convergence of the training and validation losses means good generalisation. Fig. 10 shows the training loss curves of the four models and Fig. 11 shows the validation loss curves.

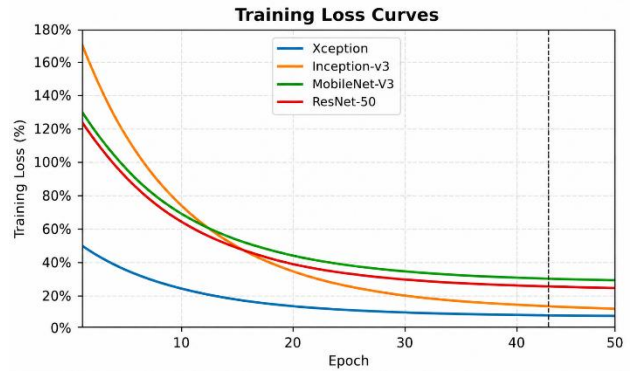

Fig. 10. Training loss curves for four models.

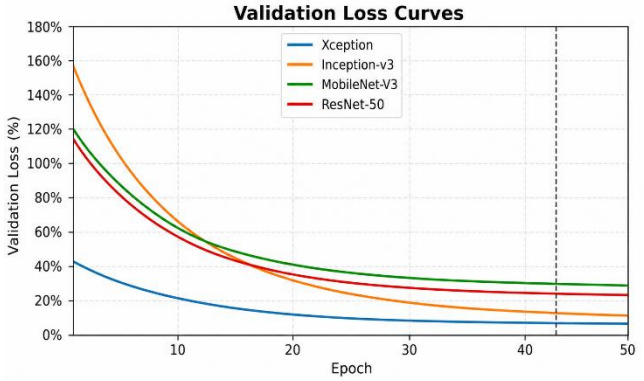

Fig. 11. Validation loss curves for four models.

V. Results and Discussion

The results showed that the Xception model performed best overall among the four models. It achieved 98.38% training accuracy, 98.52% validation accuracy, and 98.32% test accuracy. The training loss was 8.05%, and the validation loss was 7.80%, which is the lowest among all models. The results indicate that Xception had a good balance between learning and generalisation without a clear gap between the training curve and the validation curve. Fig. 12 is a general comparison of training and validation accuracies of the four models, where Xception is ranked first.

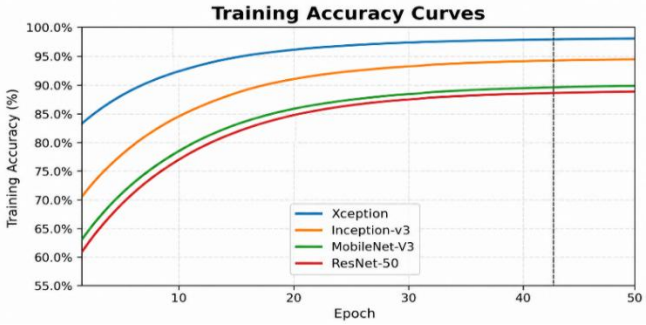

Fig. 12. Training accuracy curves for four models.

Looking at the validation accuracy, Xception performed the best, followed by Inception-v3, MobileNet-v3 and ResNet-50. The validation accuracies were 98.52%, 95.30%, 90.35% and 89.35% respectively. This means that Xception not only performs well during training, but also generalises well to data not seen during training. The validation accuracy curves for the four models are shown in Fig. 13, and they are among the most important figures to include in the results section as they summarise the models' ability to generalise.

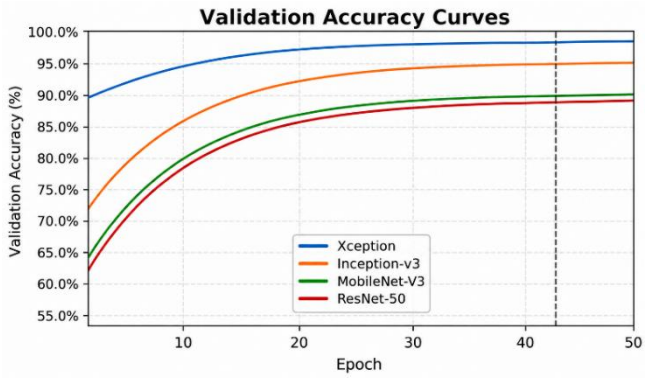

Fig. 13. Validation accuracy curves for four models.

The accuracy and loss comparison revealed that Xception was the most efficient model in this study as it combined the highest accuracy with the lowest loss. Inception-v3 is a powerful model but with a higher computational cost per image than Xception. MobileNet-v3 has moderate accuracy and low GFLOPs, and ResNet-50 is not clearly superior despite the high cost. Fig. 14 provides a comprehensive comparison of training accuracy, validation accuracy, training loss and validation loss of all four models.

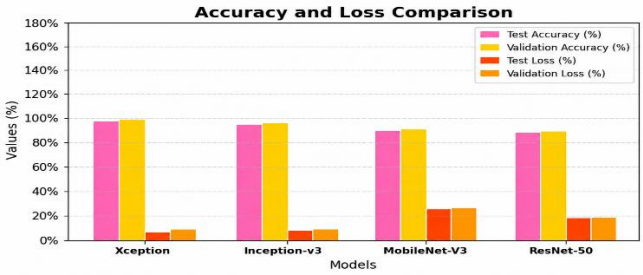

Fig. 14. Bar chart comparing accuracy and loss.

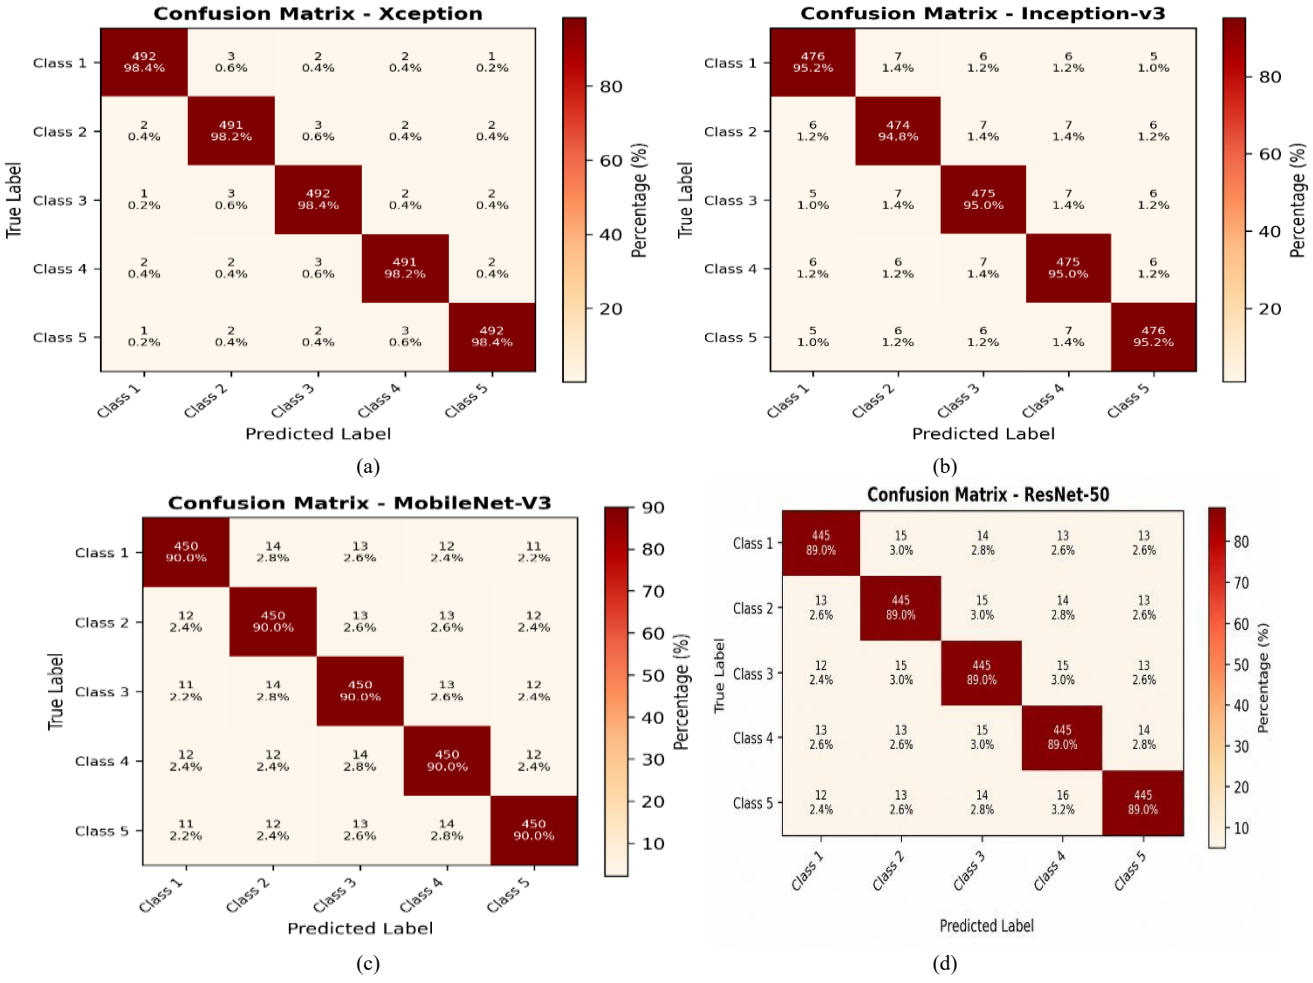
Confusion matrices are an important part of this study as they show the distribution of errors over the five classes. In the confusion matrix of Xception, most values were concentrated on the main diagonal, with around 491 to 492 images correctly classified from 500 images of each class. Inception-v3 achieved about 474 and 476 correctly classified images per class. MobileNet-v3 got about 450 correctly classified images per class, and ResNet-50 got about 445 correctly classified images per class. This distribution shows that errors were not concentrated in one class and were relatively evenly distributed, which is expected considering the balance of the dataset. The confusion matrices of Xception (a), Inception-v3 (b), MobileNet-v3 (c), and ResNet-50 (d) are shown in Fig. 15.

Although the overall classification accuracy is high, the confusion matrices reveal that there are still errors between neighboring diabetic retinopathy severity levels. Visual overlap between adjacent disease stages may explain such misclassification, where differences in lesion number, size and distribution may be subtle. Variations in illumination, contrast, sharpness, and retinal visibility of the fundus image may further increase the difficulty of classification, especially for those images containing small or weakly visible pathological signs. Moreover, the present study provides image-level severity classification but not lesion-level localization or lesion-specific prediction analysis. Hence, the results show the ability of the evaluated CNN architectures to classify the diabetic retinopathy grades, but do not give a complete explanation of the retinal lesions that contributed to the individual predictions.

Table VII provides a standardized summary of a direct comparison between the overall metrics of the four models, including accuracy, macro precision, macro recall, macro specificity, macro F1-score, macro AUC, Cohen's Kappa and MCC. As can be seen from the table, Xception had the best overall performance, followed by Inception-v3, while MobileNet-v3 and ResNet-50 had relatively lower values.



(a) (b) (c) (d)

Fig. 15. Confusion matrices for four models.

TABLE VII. OVERALL PERFORMANCE METRICS OF THE FOUR CNN MODELS

Model	Accuracy (%)	Precision Macro (%)	Recall Macro (%)	Specificity (macro) (%)	F1-score (macro) (%)	AUC (macro) (%)	Cohen's Kappa	MCC
Xception	98.32	98.32	98.32	99.58	98.32	99.99	0.9790	0.9790
Inception-v3	95.04	95.04	95.04	98.76	95.04	99.94	0.9380	0.9380
MobileNet-v3	90.00	90.00	90.00	97.50	90.00	99.72	0.8750	0.8750
ResNet-50	89.00	89.00	89.00	97.25	89.00	99.64	0.8625	0.8625

The resemblance between overall accuracy and macro-averaged precision, macro-averaged recall and macro F1-score is not surprising for the present benchmark due to the dataset being balanced by design, i.e. with equal number of samples from each diabetic retinopathy category. Under these conditions, all classes contribute equally to the macro averages, and the macro performance values closely follow the overall classification accuracy, due to the consistently high class-wise precision and recall obtained by the evaluated models. The similarity of these evaluation metrics is therefore a reflection of the properties of the dataset and the classification results and not a discrepancy in the evaluation pipeline.

The performance numbers reported are taken from the present experimental runs, and should be considered as comparative benchmark results, rather than hard proof of statistical superiority. All architectures were tested on the same dataset partition, the same input resolution, the same number of epochs, and the same evaluation protocol. A more rigorous evaluation of the stability and significance of the observed differences would be obtained by repeated training with independent random seeds, confidence-interval estimation, bootstrap resampling and formal hypothesis testing. The present analyses are therefore considered an important extension of the present study.

The results showed that ResNet-50 was the most computationally expensive model in terms of computational cost with 66.61 GFLOPs per image, epoch time of approximately 5,221.77 seconds and total training time of 72.52 hours. However, MobileNet-v3 had the lowest GFLOPs per image with only 7.05 GFLOPs but did not achieve the best runtime in this experiment. Xception, on the other hand, obtained a good trade-off between performance and cost, costing 16.27 GFLOPs per image and taking 30.53 hours to train. Fig. 16 shows runtime per epoch, Fig. 17 shows GFLOPs per image, and Fig. 18 compares runtime and GFLOPs.

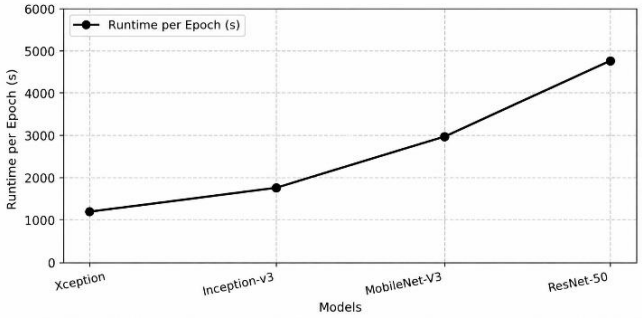


Fig. 16. Runtime per epoch for the four models.

In the present experiment, Xception showed the best trade-off between classification performance and computational demand overall. It achieved the highest accuracy and the lowest loss with a significantly lower computational cost than ResNet-50. Inception-v3 showed a competitive performance, but was less efficient than Xception, while MobileNet-v3 was still the most appropriate lightweight choice with a lower number of operations. It is deeper in architecture and computationally more expensive. However, ResNet-50 did not provide a similar improvement in forecasting performance.

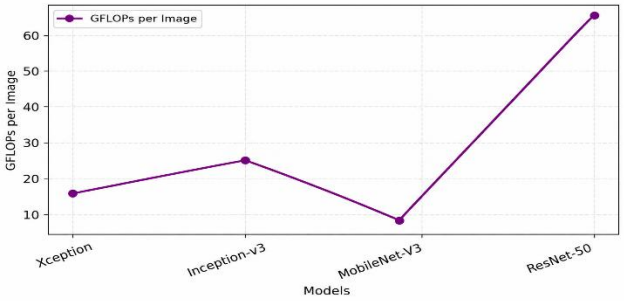

Fig. 17. GFLOPs per image for the four models.

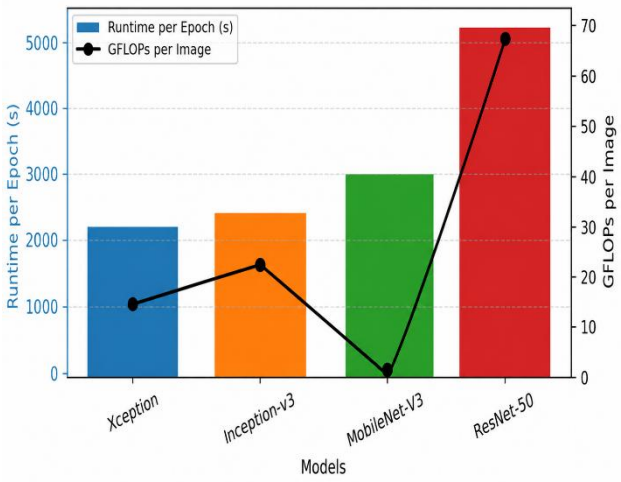

Fig. 18. Computational cost: runtime and GFLOPs.

VI. CONCLUSION AND FUTURE PROSPECTS

In this study, a comparative experimental framework was presented to evaluate the performance of four deep convolutional neural network architectures on the task of classifying fundus images associated with diabetic retinopathy: Xception, Inception-v3, MobileNet-v3 and ResNet-50. The study used a balanced dataset comprising 25,000 colour fundus images, equally divided among five classes, with 5,000 images per class. The dataset is divided to 80% for training, 10% for validation and 10% for testing, which corresponds to 20,000 images for training, 2,500 images for validation and 2,500

images for testing. This division is necessary for a more objective assessment of the performance of the models, since the models are trained on a large set of images, their generalization capacity is monitored during the training process, and finally, they are tested on independent data that were not part of the learning process. Class balance also helps the models avoid being biased towards a particular class and makes metrics such as accuracy, recall, precision, and F1-score more interpretable and comparable.

The results showed that the Xception model performed the best among the four models in general. The proposed model achieved 98.38% training accuracy, 98.52% validation accuracy, and 98.32% test accuracy. It also boasted the lowest loss values with a training loss of 8.05% and a validation loss of 7.80%. The results obtained show that Xception obtained a high accuracy on the training data, as well as a good generalization ability to the validation and test data. This is important in the medical field as a model that only learns the characteristics of the training data without generalizing to new data is not suitable for use in real-world environments. Moreover, the training, validation, and test accuracies converge, which indicates that the model does not suffer from obvious overfitting and is able to learn stable and effective visual representations for the fundus images.

The reason for Xception's better performance in this study is that it is designed with depthwise separable convolutions. This It also enables the extraction fine visual features and reduces the computational load with the heavier models. This property seems useful in the context of fundus images, as it allows the model to capture small local patterns such as hemorrhagic spots or subtle changes in the retina, while still maintaining a good ability to represent the overall structure of the image. The confusion matrix for this model shows that most of the correct classifications are near the main diagonal, with a small spread of errors across the classes, indicating a good ability to discriminate between the five classes.

The Inception-v3 model also performed well with a validation accuracy of 95.30% and a test accuracy of 95.04%. The performance indicates that the multi-branch structure of the model can extract visual features from different levels, which is relatively well-suited for fundus images with both fine and coarse details simultaneously. However, Inception-v3 still had worse performance than Xception in terms of accuracy, loss, and computational cost per image. Inception-v3 needs more GFLOPs per image than Xception and does not improve the accuracy. Thus, it can be regarded as a robust and stable model but not the most efficient one among the models tested in this study.

For MobileNet-v3, the test accuracy was 90.00%, which is lower than those of Xception and Inception-v3, but still an important result given the computational efficiency. MobileNet-v3 was mainly designed to be a lightweight model that can be used in resource-limited environments such as mobile devices, embedded systems, or low-cost medical screening devices. The model has the lowest GFLOPs per image, and thus is suitable when the goal is to minimize the computational load rather than to achieve the highest possible accuracy. However, its lower accuracy compared to more powerful models emphasizes the need to be cautious when using it in sensitive medical applications, especially when the aim is to support a diagnostic decision that requires a high degree of confidence.

ResNet-50 provided the lowest accuracy of the four models, with a test accuracy of 89.00%, but the highest computational cost in this experiment. The result indicates that the increase in the depth or in the architectural complexity does not always lead to performance improvement, especially when the architecture is not well matched to the nature of the data, or when the increase in the computational costs is not compensated by a clear gain in accuracy. ResNet-50 showed a long training time and high GFLOPs without outperforming the other models. Thus, the present results show that this model does not seem to be the best choice for fundus image classification in this experimental setup, especially if the study aims to balance performance and efficiency.

The overall results confirm the compromise between accuracy and computational cost as a key factor in the choice of a suitable model. In this study, when the priority is higher diagnostic performance, Xception is the best choice because it has high accuracy, low loss, and clear generalization ability. However, if the objective is to create a lightweight system, MobileNet-v3 is a better option to consider, despite having a lower accuracy than powerful models. Inception-v3 is a better middle ground in performance but less efficient than Xception in these results. On the other hand, ResNet-50 does not provide any clear practical advantage in this setting, given the high computational cost relative to its accuracy.

The value of this study is that it does not just rank models by their accuracy, but provides a multidimensional view of their performance by combining accuracy, loss, classification metrics, confusion matrices, training time, and computational cost. This type of evaluation is critical in medical AI applications, as a model ready for clinical deployment must be accurate, stable, interpretable, generalizable, and able to run within realistic time and compute constraints. Based on the reported results, Xception can be regarded as the most balanced architecture within the present experimental setting in this study and MobileNet-v3 as a promising option for lightweight applications; Inception-v3 and ResNet-50 need further optimization or fine-tuning before being used in a practical diagnostic assistance system. However, the findings of this study need to be interpreted in view of the limitations of its experimental setting. While the dataset is sufficiently large and balanced to compare the models, in order to generalize the results to real-world clinical settings, the models need to be tested on independent external datasets obtained across different imaging devices and multiple medical institutions. Moreover, high performance in a controlled experiment does not ensure that the model will perform at the same level with low-quality images, images under different lighting conditions, or images from patients with different demographic backgrounds. The present results thus represent an important step toward the establishment of a preliminary benchmark but do not exclude the need for further validation studies before any direct clinical application.

This study has some limitations; the experimental evaluation was performed on one publicly available diabetic retinopathy

dataset. This allows a fair comparison of the evaluated CNN architectures in the same experimental conditions, but further validation with independent datasets from different clinical settings and imaging devices is needed to further evaluate the robustness and the generalizability of the proposed framework.

Although this study provided a clear empirical comparison of four deep learning architectures to classify fundus images related to diabetic retinopathy, future work could focus first on expanding the database used, both in terms of the number of images and the variety of their sources. Models were evaluated on images obtained from different imaging devices, different medical institutions and diverse clinical cases will give an insight for the generalizability of the models in conditions closer to clinical settings of real-world. Moreover, the utilization of independent external databases will enhance the robustness of the obtained results, as good performance in a single internal split does not, on its own, prove the validity of the model to be used in different clinical settings.

The study can be further extended by using newer and more diverse models such as EfficientNet, ConvNeXt, Vision Transformers, and hybrid models combining convolutional networks and attention mechanisms. This enables us to investigate whether modern architectures can improve the trade-off between accuracy and computational efficiency. In addition, it is possible to improve the image preprocessing step by using fundus image-specific techniques such as contrast enhancement, light adjustment, removal of irrelevant areas, and automatic image quality detection before the images are introduced into the model.

In future work, each training experiment should be repeated with a number of different independent random seeds. Additionally, the mean, standard deviation and confidence interval for the main performance indicators should be reported. Also, before reaching some conclusions about the superiority of the model, it is required to perform paired bootstrap comparisons or other statistical tests considered relevant.

In the clinical context, the proposed framework aims to support ophthalmologists by providing quick and consistent initial assessments of diabetic retinopathy, not to replace expert clinical judgment. In real-world screening programs, the reduction of false negative predictions is particularly important to avoid missed diagnoses and delayed treatment. Therefore, additional clinical validation, workflow integration, and prospective evaluation are required before the proposed framework can be considered for routine clinical use.

A crucial aspect for future development is the integration of visual interpretation techniques such as Grad-CAM and Grad-CAM++ to identify the regions on which the model relies to make its decision. This is especially true in the medical domain where doctors need not only the final classification but also an explanation that can help them understand the reasoning behind the decision. Moreover, a more fine-grained error analysis can be performed, in particular between neighboring grades of diabetic retinopathy, which are often of higher clinical relevance. Finally, future work can be focused on building a medical decision support system with accuracy, efficiency, and interpretability. The system may include image classification, a confidence score and an interpretive map indicating the regions that influence the decision. In the future, the model could be extended to a multimodal one by combining fundus images with clinical data such as duration of diabetes, HbA1c level, blood pressure, and age of the patient. This development would bring the model more in line with the real world of medical practice, while emphasizing that its role must be that of an aid to the physician and not a substitute for specialized clinical evaluation.

The Evolution of Clinical Intelligence Through GenAI Co-pilots: A Systematic Review and Thematic Synthesis

Li-Chen Cheng[1], Chia-Yu Hung[2], Te-Nien Chien[3]*
Department of Information and Finance Management, National Taipei University of Technology, Taipei, Taiwan[1]
College of Management, National Taipei University of Technology, Taipei, Taiwan[2, 3]

***Abstract*—Generative artificial intelligence (GenAI), large language models (LLMs), and multimodal foundation models are rapidly transforming healthcare by extending artificial intelligence beyond traditional predictive analytics toward collaborative clinical intelligence. Recent advances have enabled applications in clinical decision support, medical documentation, workflow optimization, patient communication, and personalized care planning. However, the existing literature remains fragmented across technical evaluations, specialty-specific applications, and governance discussions, resulting in a limited understanding of how these technologies collectively function within clinical environments. This study conducted a systematic review and thematic synthesis to examine the emerging role of GenAI as a clinical co-pilot in healthcare. Following the PRISMA 2020 framework, literature was retrieved from Web of Science, PubMed, and Scopus databases. A total of 3,124 records were identified, and 41 studies published between 2023 and March 2026 met the eligibility criteria and were included in the final qualitative synthesis. Quality assessment indicated that 87.8% of the included studies were classified as moderate or high quality, providing a robust methodological basis for the thematic synthesis. Thematic analysis revealed three interrelated domains underlying the evolution of GenAI-enabled clinical intelligence: 1) Perception and Fact Anchoring, involving multimodal data integration, retrieval-augmented generation (RAG), and domain-specific medical intelligence; 2) Clinical Agency and Collaboration, encompassing ambient digital scribing, agentic clinical decision support, workflow augmentation, and personalized care; and 3) Governance and Responsibility, including human-in-the-loop oversight, privacy protection, regulatory compliance, fairness, and trustworthy AI practices. Based on these findings, a conceptual Clinical Co-pilot Framework is proposed to position GenAI as a collaborative partner that supports clinicians rather than replaces them. The framework provides a conceptual basis for future empirical validation and may help inform the responsible implementation of GenAI in healthcare.**

Keywords*—Generative artificial intelligence; clinical co-pilot; large language models; clinical decision support; human-AI collaboration

I. Introduction

A. Background

The rapid advancement of generative artificial intelligence (GenAI) has significantly transformed digital healthcare and clinical decision support [1]. Since the emergence of advanced large language models (LLMs) and multimodal foundation models, including GPT-4, Med-PaLM, Claude, and domain-specific healthcare models, healthcare organizations have increasingly explored the integration of GenAI into clinical environments [2-6]. Compared with traditional AI systems focused on prediction and classification, contemporary GenAI technologies offer broader capabilities in contextual reasoning, language generation, multimodal interpretation, and human-AI interaction [7].

Recent developments have enabled new forms of clinical support, including electronic health record (EHR) summarization, evidence retrieval, differential diagnosis generation, clinical documentation, and physician communication support [8-14]. The rapid growth of healthcare data and clinical complexity has further accelerated interest in these technologies [15]. Consequently, healthcare institutions are increasingly investigating GenAI as a collaborative tool to augment clinical reasoning, improve workflow efficiency, and reduce administrative burden [16-20].

Recent literature suggests that healthcare applications of GenAI are transitioning from proof-of-concept studies toward real-world clinical implementation [21-23]. Current applications include clinical documentation, retrieval-augmented decision support, AI-assisted triage, personalized treatment planning, multimodal evidence synthesis, and patient education [24-28]. At the same time, concerns regarding hallucination, bias, transparency, accountability, privacy, and regulatory compliance have emerged as major challenges for responsible deployment [27, 28].

B. Research Motivation

Traditional healthcare artificial intelligence systems have historically emphasized automation-oriented objectives, including disease prediction, risk stratification, image classification, and algorithmic screening [16, 29, 30]. Although these technologies demonstrated promising benchmark performance, many failed to achieve sustainable implementation in real-world clinical environments due to poor workflow integration, limited interpretability, clinician distrust, insufficient adaptability, and limited support for complex collaborative decision-making.

Unlike earlier predictive AI systems, GenAI introduces a different interaction paradigm between clinicians and intelligent systems. Rather than functioning solely as automated prediction

*Corresponding author.

engines, GenAI technologies increasingly operate as collaborative assistants capable of supporting clinical reasoning, information synthesis, workflow coordination, and communication under physician supervision [9, 31]. This shift reflects a broader movement from automation-centered artificial intelligence toward collaboration-centered clinical intelligence.

Within this emerging paradigm, the concept of the "clinical co-pilot" has gained increasing relevance. Inspired by the co-pilot model in aviation, this framework conceptualizes GenAI as an augmentative partner designed to support, rather than replace, healthcare professionals [16, 32]. Physicians remain the final decision-makers and accountable authorities, while GenAI assists by enhancing situational awareness, reducing cognitive burden, and improving access to contextual medical knowledge [16, 33, 34].

This framework is particularly important because healthcare decision-making involves uncertainty, ethical responsibility, contextual judgment, and interpersonal communication [33, 35]. Fully autonomous clinical decision-making remains difficult to implement safely in high-stakes environments. Therefore, collaborative human-AI systems may represent a more feasible and responsible pathway toward intelligent healthcare transformation [10, 34].

Current literature on GenAI in healthcare remains fragmented across technical applications, workflow integration, ethical governance, implementation barriers, and clinical evaluation. Many reviews focus narrowly on ChatGPT performance, benchmark testing, or isolated healthcare applications without systematically conceptualizing how GenAI may function as a collaborative partner within healthcare ecosystems [15, 32, 36]. Therefore, a comprehensive synthesis integrating technological capabilities, clinical workflows, governance mechanisms, and human-AI collaboration remains necessary [16].

C. Problem Statement and Research Gap

The rapid advancement of GenAI, LLMs, and multimodal foundation models has accelerated the adoption of AI technologies across diverse healthcare settings [7]. Recent studies have demonstrated promising applications in clinical decision support, medical documentation, patient communication, diagnostic assistance, treatment planning, and workflow optimization [37-39].

Despite this progress, the literature remains fragmented across disciplines and application domains. Many studies focus on evaluating specific models such as ChatGPT, GPT-4, and Med-PaLM using benchmark datasets such as MedQA and MMLU [15, 35, 40, 41], while others examine applications within specific specialties including radiology, oncology, pathology, emergency medicine, and nursing practice [10,29]. At the same time, substantial attention has been devoted to challenges related to hallucination, explainability, privacy, bias, transparency, and regulatory oversight [9, 20, 29, 42-44].

Although these studies provide valuable insights, relatively few have examined how technological capabilities, clinical workflows, and governance mechanisms collectively contribute to human-AI collaboration in healthcare. Existing reviews remain largely focused on model performance or isolated applications and rarely integrate these perspectives within a unified conceptual framework [18, 45].

As healthcare AI continues to evolve from task-specific automation toward collaborative intelligence, there is a growing need to understand how GenAI supports clinical workflows while operating within ethical, legal, and organizational boundaries [46, 47]. Therefore, this study systematically reviews current evidence and develops a clinical co-pilot framework that integrates technology, workflow, and governance perspectives to explain the evolution of collaborative human-AI healthcare systems.

D. Research Objectives

This study aims to systematically review and synthesize current literature regarding the applications of GenAI in healthcare through the conceptual perspective of the clinical co-pilot framework.

Specifically, this study seeks to achieve the following objectives:

- To systematically identify and classify major application domains of GenAI in clinical decision support and healthcare collaboration.
- To examine how GenAI technologies support clinical reasoning, multimodal information integration, workflow coordination, and healthcare communication.
- To analyze the implementation challenges and governance concerns associated with GenAI deployment, including hallucination risk, accountability, bias, privacy protection, and regulatory compliance.
- To propose a conceptual framework describing GenAI as a collaborative clinical co-pilot operating under human supervision.
- To explore how healthcare AI is evolving from automation-centered systems toward collaboration-centered augmented clinical intelligence.
- To identify current research gaps and future directions for responsible human-AI collaboration in healthcare environments.

The findings suggest that the clinical co-pilot model represents a feasible and responsible pathway for integrating GenAI into healthcare systems while preserving human oversight, ethical governance, and clinician-centered decision-making.

II. METHODS

A. Study Design

This study was designed as a systematic review with thematic synthesis to examine how GenAI has been applied as a collaborative clinical co-pilot in healthcare and clinical decision support. The review followed the Preferred Reporting Items for Systematic Reviews and Meta-Analyses 2020 (PRISMA 2020) framework to enhance transparency, reproducibility, and methodological rigor [48, 49].

The systematic review component was used to identify, screen, and select relevant studies through a structured and reproducible search process. The thematic synthesis component was used to integrate findings across heterogeneous studies and to develop a conceptual framework explaining the role of GenAI as a clinical co-pilot. This combined approach was appropriate because the included literature covered diverse study designs, clinical settings, model architectures, and implementation contexts.

The review focused on studies published from January 2023 to March 2026, corresponding to the period in which advanced LLMs and multimodal GenAI systems rapidly entered healthcare research and clinical implementation discussions. The unit of analysis was the individual scholarly article.

B. Search Strategy

A structured literature search strategy was developed to identify studies examining the application of GenAI technologies in healthcare settings, with particular emphasis on clinical decision support, healthcare workflows, and human-AI collaboration. The search strategy was designed to ensure comprehensive coverage of the rapidly expanding literature on LLMs, multimodal AI systems, and their integration into clinical practice.

The literature search was conducted using three major academic databases: Web of Science Core Collection, PubMed, and Scopus. These databases were selected because they provide extensive coverage of peer-reviewed research in medicine, healthcare informatics, artificial intelligence, computer science, and interdisciplinary healthcare technologies. The search covered publications from January 2023 to March 2026, corresponding to the period following the emergence and widespread adoption of advanced LLMs and multimodal GenAI systems.

This specific time frame was intentionally selected because the public release of ChatGPT in late 2022 marked a major turning point in the development of GenAI technologies. Following this milestone, healthcare research experienced a rapid increase in studies involving LLMs, multimodal foundation models, retrieval-augmented generation (RAG), and agentic AI applications. Consequently, the period from 2023 to March 2026 captures the early evolution of GenAI from experimental demonstrations toward clinical implementation, workflow integration, and healthcare governance. This timeframe therefore provides an appropriate foundation for examining the emergence of GenAI as a clinical co-pilot in healthcare environments.

To maximize retrieval sensitivity while maintaining conceptual relevance, the search strategy incorporated three core domains:

- GenAI technologies, including LLMs, foundation models, and multimodal AI systems;
- Clinical intelligence and healthcare support functions, including clinical decision support, clinical reasoning, workflow assistance, and human-AI collaboration;
- Healthcare environments, including hospitals, clinical practice, healthcare delivery systems, and patient care settings.

Boolean operators (AND, OR), truncation symbols (*), and phrase searching were employed to maximize retrieval sensitivity while minimizing irrelevant records. Database-specific search syntax was adapted for Web of Science, PubMed, and Scopus while maintaining conceptual consistency across all information sources.

The database search yielded a total of 3,124 records, including 957 records from Web of Science, 1,048 records from PubMed, and 1,119 records from Scopus.

The core search syntax was defined as follows:

("generative artificial intelligence"

OR "generative AI"OR "large language model*"OR LLM*OR ChatGPT\OR "foundation model*"OR "multimodal large language model*")

AND

("clinical decision support"OR "clinical decision support system*"OR CDSS OR "clinical decision-making"OR "clinical workflow" OR "clinical co-pilot" OR "medical co-pilot" OR "human-AI collaboration" OR "clinical reasoning" OR "AI agent*"OR "retrieval-augmented generation")

AND

(healthcare OR medicine OR clinical OR hospital OR "patient care")

For the Web of Science Core Collection, searches were conducted using the Topic (TS) field, which includes titles, abstracts, author keywords, and Keywords Plus. In Scopus, searches were performed using the TITLE-ABS-KEY field, while equivalent search syntax was adapted for PubMed. Minor database-specific adjustments were applied where necessary while maintaining conceptual consistency across all information sources.

The search strategy was intentionally designed to capture studies examining the application of GenAI technologies within clinical environments, particularly those involving clinical decision support, healthcare workflows, human-AI collaboration, intelligent clinical assistance, and responsible AI implementation. The broad search approach ensured comprehensive coverage of the rapidly evolving literature while allowing subsequent screening and thematic synthesis to identify the most relevant evidence related to emerging forms of AI-assisted clinical intelligence.

Importantly, the search strategy was intentionally constructed using broad concepts related to GenAI, clinical decision support, healthcare workflows, and human-AI collaboration rather than predefined theoretical categories. The concept of the clinical co-pilot was not used as a mandatory inclusion criterion and did not predetermine the thematic structure of the review.

Instead, the clinical co-pilot framework emerged inductively through the thematic synthesis process as recurring patterns of technological capabilities, workflow integration, and governance mechanisms were identified across the included studies.

The database search process and retrieved records are summarized in Table I.

The initial database search yielded 3,124 records, including 957 records from Web of Science, 1,048 records from PubMed, and 1,119 records from Scopus. Following record export and consolidation, duplicate and non-eligible records were removed prior to screening. The subsequent study selection process was conducted according to the PRISMA 2020 guidelines and involved title and abstract screening, full-text eligibility assessment, and thematic synthesis. The detailed study selection process is presented in Fig. 1.

TABLE I. LITERATURE SEARCH SOURCES AND RETRIEVAL RESULTS

Database	Search Field	Records Retrieved
Web of Science	Topic Search	957
PubMed	Title / Abstract Search	1,048
Scopus	TITLE-ABS-KEY Search	1,119
Total		3,124

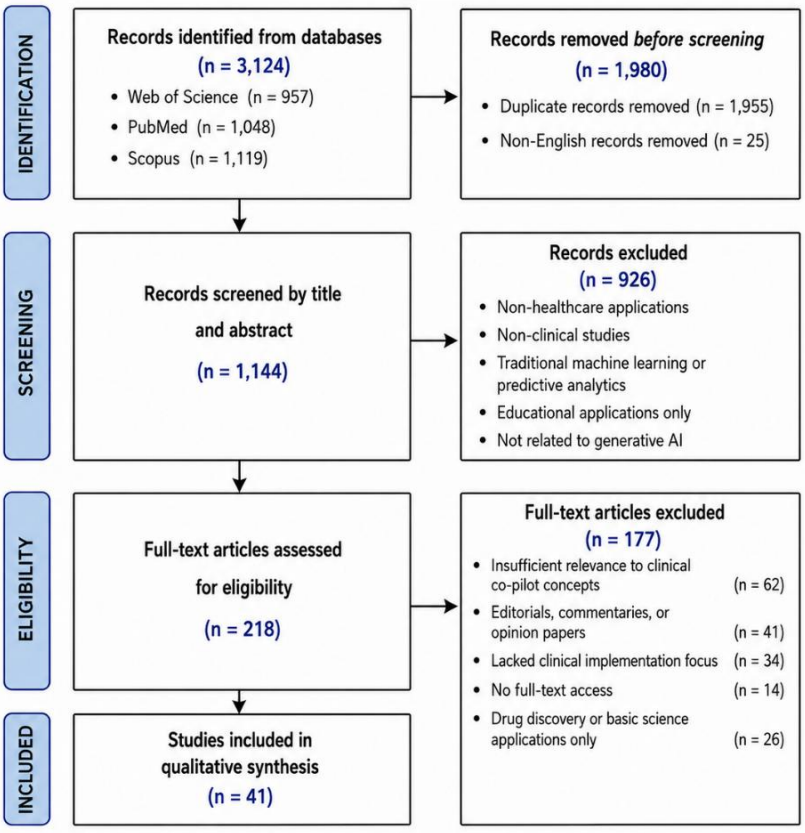

Fig. 1. PRISMA 2020 flow diagram.

C. Inclusion and Exclusion Criteria

Eligibility criteria were defined before screening to ensure consistency in study selection. Studies were included if they met all of the following criteria:

- The study focused on GenAI, LLMs, multimodal generative models, RAG, or related foundation model technologies.
- The study was situated in healthcare, medicine, hospital practice, clinical care, or patient-related decision-making contexts.
- The study discussed or evaluated applications relevant to clinical decision support, clinical workflow assistance, physician decision-making, patient data interpretation, treatment planning, documentation support, or human-AI collaboration.
- The article provided sufficient methodological, conceptual, or application-related information for thematic extraction.
- The article was published in English between January 2023 and March 2026.

Studies were excluded if they met any of the following criteria:

- The study focused only on traditional machine learning or predictive modeling without a GenAI component.
- The study was unrelated to healthcare or clinical practice.

- The study focused solely on medical education, student learning, or examination performance without clear clinical decision support relevance.
- The article was an editorial, commentary, news item, short opinion piece, or letter without sufficient analytical content.
- The study focused exclusively on drug discovery, molecular generation, or basic biomedical research without connection to clinical decision support or healthcare delivery.
- Full text was unavailable, or the article lacked sufficient information for data extraction.

These criteria were designed to keep the review focused on GenAI as a collaborative clinical tool rather than on general AI applications in healthcare.

D. Study Selection

The study selection process followed the PRISMA 2020 flow structure, including identification, screening, eligibility assessment, and final inclusion. First, all records retrieved from the selected databases were compiled. Duplicate records were identified and removed before screening. Next, titles and abstracts were reviewed to exclude clearly irrelevant studies. Articles that appeared potentially relevant were then retrieved for full-text assessment.

During full-text review, each article was evaluated against the predefined inclusion and exclusion criteria. Studies were excluded at this stage if they did not address GenAI, lacked clinical decision support relevance, focused only on education or non-clinical settings, or provided insufficient analytical content. Reasons for exclusion were documented to support PRISMA transparency.

A total of 3,124 records were identified through database searching. Following duplicate removal, title and abstract screening, and full-text eligibility assessment, 41 studies met the inclusion criteria and were included in the final qualitative synthesis. Details of the study selection process are presented in Fig. 1.

E. Data Extraction and Thematic Synthesis

A structured data extraction form was developed to collect key information from each included study. Extracted items included author, publication year, country or region, clinical domain, study design, data source, GenAI model type, clinical application, evaluation method, reported benefits, limitations, governance concerns, and relevance to the clinical co-pilot framework.

The extracted data were organized into two main evidence tables. The first table summarized the characteristics of included studies, including publication year, clinical domain, model type, data source, and study design. The second table classified studies according to their clinical co-pilot functions, including perception and fact anchoring, clinical agency and collaboration, and governance and responsibility boundaries.

Thematic synthesis was conducted using an iterative coding process. First, open coding was used to identify recurring concepts across studies, such as EHR summarization, RAG, ambient documentation, hallucination, accountability, and human-in-the-loop oversight. Second, axial coding was used to group related codes into broader thematic categories. Third, selective coding was used to develop an integrated conceptual framework explaining GenAI as a clinical co-pilot.

Three major themes were identified:

- Perception and fact anchoring: GenAI capabilities for understanding, integrating, retrieving, and contextualizing clinical information.
- Clinical agency and collaboration: GenAI applications that support documentation, diagnosis, treatment planning, workflow coordination, and clinical communication.
- Governance and responsibility boundaries: institutional, ethical, legal, and human oversight mechanisms required for safe clinical deployment.

This thematic synthesis approach allowed the review to move beyond a descriptive summary of applications and toward a conceptual interpretation of how GenAI may function as a responsible and collaborative partner in healthcare.

F. PRISMA Reporting and Methodological Rigor

To strengthen methodological transparency, the findings followed the PRISMA 2020 checklist throughout the search, screening, eligibility assessment, and reporting process. The review explicitly documented the information sources, search strategy, eligibility criteria, selection process, data extraction procedure, and synthesis method.

The PRISMA flow diagram was used to visually summarize the study selection process. Full-text exclusion reasons were categorized and reported to clarify how the final evidence base was constructed. The inclusion and exclusion criteria were applied consistently during screening to reduce selection bias. Because the included studies were expected to be heterogeneous in design, ranging from empirical evaluations and case studies to conceptual frameworks and systematic reviews, a meta-analysis was not conducted. Instead, thematic synthesis was selected as the most appropriate method for integrating diverse evidence types. This approach enabled the identification of cross-cutting themes related to clinical usefulness, implementation feasibility, governance requirements, and human-AI collaboration.

To further enhance rigor, the review distinguished between technical capability, clinical workflow relevance, and governance implications. This distinction helped prevent overgeneralization from benchmark-based performance studies to real-world clinical practice. The final synthesis therefore emphasizes not only what GenAI can do in healthcare, but also how it can be responsibly integrated into clinician-centered decision-making environments.

The review was not prospectively registered in PROSPERO or other systematic review registries because of the rapidly evolving nature of the GenAI evidence base and the conceptual objective of thematic synthesis. The study focused on

conceptual integration and framework development rather than quantitative meta-analysis or intervention effect estimation.

G. Quality Assessment

A methodological quality assessment was conducted to evaluate the rigor and credibility of the included studies.

Given the heterogeneous nature of the evidence base, including empirical studies, implementation reports, conceptual frameworks, and review articles, a simplified quality appraisal framework was adopted. The quality appraisal criteria were adapted from the Mixed Methods Appraisal Tool (MMAT) and previous healthcare artificial intelligence review studies to accommodate the diverse methodological characteristics of the included literature.

Studies were evaluated according to five criteria:

- Clarity of research objectives
- Methodological transparency
- Description of AI technologies
- Clinical relevance
- Governance considerations

Each criterion was evaluated using a three-point scale (0 = not addressed, 1 = partially addressed, and 2 = clearly addressed), resulting in a maximum score of 10 points for each study. Studies scoring 8–10 points were classified as high quality, 5–7 points as moderate quality, and 0–4 points as low quality. Two reviewers independently performed the quality assessment, and disagreements were resolved through discussion and consensus. The quality assessment results of the included studies are summarized in Table II.

TABLE II. SUMMARY OF QUALITY ASSESSMENT RESULTS

Quality Level	Score Range	Number (n)	Percentage (%)
High	8-10	15	36.6%
Moderate	5-7	21	51.2%
Low	0-4	5	12.2%
Total		41	100%

Note: Five quality criteria were evaluated. Total scores ranged from 0 to 10, with higher scores indicating greater methodological rigor.

Overall, most studies were classified as moderate-to-high quality (87.8%), suggesting that the current evidence base provides a reasonably robust foundation for thematic synthesis and supports the development of the proposed conceptual framework. The quality assessment was used to evaluate study rigor and to support the interpretation of thematic findings rather than to exclude studies from the review. No study was excluded solely on the basis of quality assessment results. Given the exploratory and conceptual nature of this study, all eligible studies were retained to ensure comprehensive coverage of emerging evidence related to GenAI clinical co-pilots.

III. RESULTS

A. Overview of Included Studies

A total of 41 studies were included in the final qualitative synthesis following the PRISMA 2020 screening process. These studies were selected from an initial pool of 3,124 records retrieved from Web of Science, PubMed, and Scopus. The included studies were published between 2023 and 2026, reflecting the rapid expansion of GenAI research following the emergence of advanced foundation models and LLMs. The overall publication trend demonstrated a substantial increase in healthcare-related GenAI studies after 2023, particularly in clinical decision support, workflow automation, and healthcare governance applications.

To provide an overview of the included literature, the characteristics of the 41 selected studies were summarized according to publication year, study type, AI technology, clinical focus, and thematic domain (Table III). This descriptive analysis provides contextual insights into the evolving landscape of GenAI research in healthcare and serves as a foundation for the subsequent thematic synthesis. The characteristics of the 41 included studies, including study type, main technology, and primary application domains, are summarized in Table V (Appendix).

TABLE III. OVERVIEW OF INCLUDED STUDIES

Category	Subcategory	Frequency (n)	Percentage (%)
Publication Year	2023	6	14.6
	2024	12	29.3
	2025	18	43.9
	2026	5	12.2
Study Type	Empirical Evaluation	15	36.6
	Framework / Conceptual Study	8	19.5
	Case Study / Implementation	10	24.4
	Review / Perspective	8	19.5
AI Technology	Large Language Models (LLMs)	17	41.5

Note: Publications published between January 2023 and March 2026 were included in the review.

The studies were categorized according to their primary research focus, dominant AI technology, and thematic contribution. Each study was assigned to a single primary category within each dimension to facilitate descriptive analysis and thematic synthesis.

The descriptive statistics indicate a rapid increase in healthcare-related GenAI research following the emergence of advanced LLMs and multimodal foundation models. To further illustrate the temporal distribution of the included studies, the annual publication trend is presented in Fig. 2.

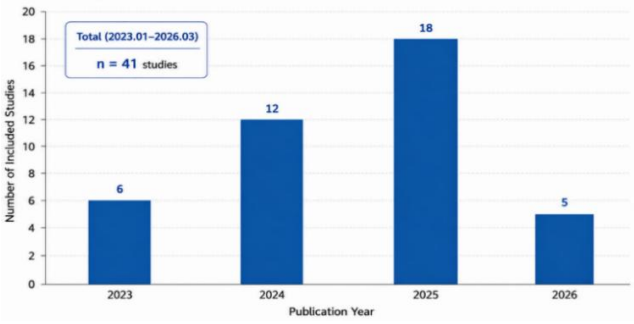

Fig. 2. Publication trends of included studies (2023.01–2026.03).

The reviewed studies originated from diverse disciplinary backgrounds, including healthcare informatics, clinical medicine, digital health, computer science, and interdisciplinary artificial intelligence research. Most studies focused on hospital-based or clinical healthcare environments, while a smaller number examined broader healthcare management systems, patient communication, or institutional governance frameworks.

In terms of technological focus, GPT-based architectures and LLMs were the most frequently discussed GenAI technologies. Commonly referenced systems included GPT-4, ChatGPT, Med-PaLM, Claude, and multimodal large language models (MLLMs). Several studies also explored RAG, domain-specific medical foundation models, and multimodal clinical reasoning systems integrating electronic health records, medical imaging, and laboratory data [3, 5, 50, 51].

The included studies covered multiple clinical application domains. The most frequently identified applications included clinical documentation and summarization, clinical decision support, treatment planning, ambient scribing, patient data interpretation, evidence retrieval, and workflow coordination. Several studies also examined physician acceptance, trust calibration, human-AI collaboration, and governance mechanisms associated with clinical AI deployment.

Methodologically, the reviewed literature was heterogeneous in design. The evidence base included empirical evaluations, implementation case studies, benchmark comparisons, conceptual frameworks, observational studies, expert commentaries, and systematic reviews. Due to the diversity of study designs and evaluation metrics, a quantitative meta-analysis was not conducted. Instead, thematic synthesis was used to identify recurring conceptual patterns across the literature.

Beyond publication growth and technological advancement, thematic synthesis revealed three major domains underlying the evolution of GenAI clinical co-pilots: 1) Perception and Fact Anchoring, 2) Clinical Agency and Collaboration, and 3) Governance and Responsibility. Together, these domains suggest a shift from automation-oriented healthcare AI toward collaborative clinical intelligence systems.

B. Conceptual Framework of GenAI as a Clinical Co-Pilot

The thematic synthesis identified a conceptual shift from automation-oriented healthcare AI toward collaborative clinical intelligence. To explain this transition, a conceptual framework of GenAI as a clinical co-pilot was developed based on the three major themes emerging from the reviewed literature: Perception and Fact Anchoring, Clinical Agency and Collaboration, and Governance and Responsibility.

These three domains collectively describe how GenAI systems transform heterogeneous healthcare data into clinically meaningful intelligence, support healthcare professionals through collaborative reasoning and workflow augmentation, and operate within ethical, legal, and organizational governance structures. Rather than functioning as autonomous decision-makers, GenAI systems are increasingly positioned as collaborative partners that augment clinician capabilities while preserving human oversight and accountability.

As illustrated in Fig. 3, the framework begins with diverse healthcare inputs, including electronic health records, medical imaging, laboratory findings, clinical guidelines, and patient histories. Through multimodal reasoning, evidence grounding, and domain-specific intelligence, these inputs are converted into actionable clinical insights that support diagnosis, documentation, communication, care planning, and clinical decision support. The framework is further reinforced by foundational deployment enablers, including interoperable healthcare data, model transparency, continuous evaluation, and regulatory alignment, which collectively support responsible and trustworthy implementation in healthcare environments.

The framework was developed inductively through thematic synthesis and does not represent a predefined theoretical model. The framework begins with diverse clinical inputs originating from electronic health records, medical imaging, laboratory findings, wearable devices, clinical guidelines, and patient histories. GenAI systems synthesize these heterogeneous data sources through multimodal reasoning, RAG, and domain-specific medical intelligence architectures [23, 36]. The resulting outputs support diagnostic reasoning, clinical documentation, workflow optimization, personalized care planning, interdisciplinary communication, and clinician decision support within real-world healthcare environments [16, 19].

The framework conceptualizes GenAI as a collaborative co-pilot rather than an autonomous medical authority. Across the reviewed studies, clinicians consistently remained the final reviewers and accountable decision-makers within AI-assisted healthcare systems [12, 28]. Consequently, governance mechanisms such as human-in-the-loop oversight, transparency, fairness auditing, privacy protection, and regulatory compliance emerged as foundational requirements for responsible deployment [16, 32].

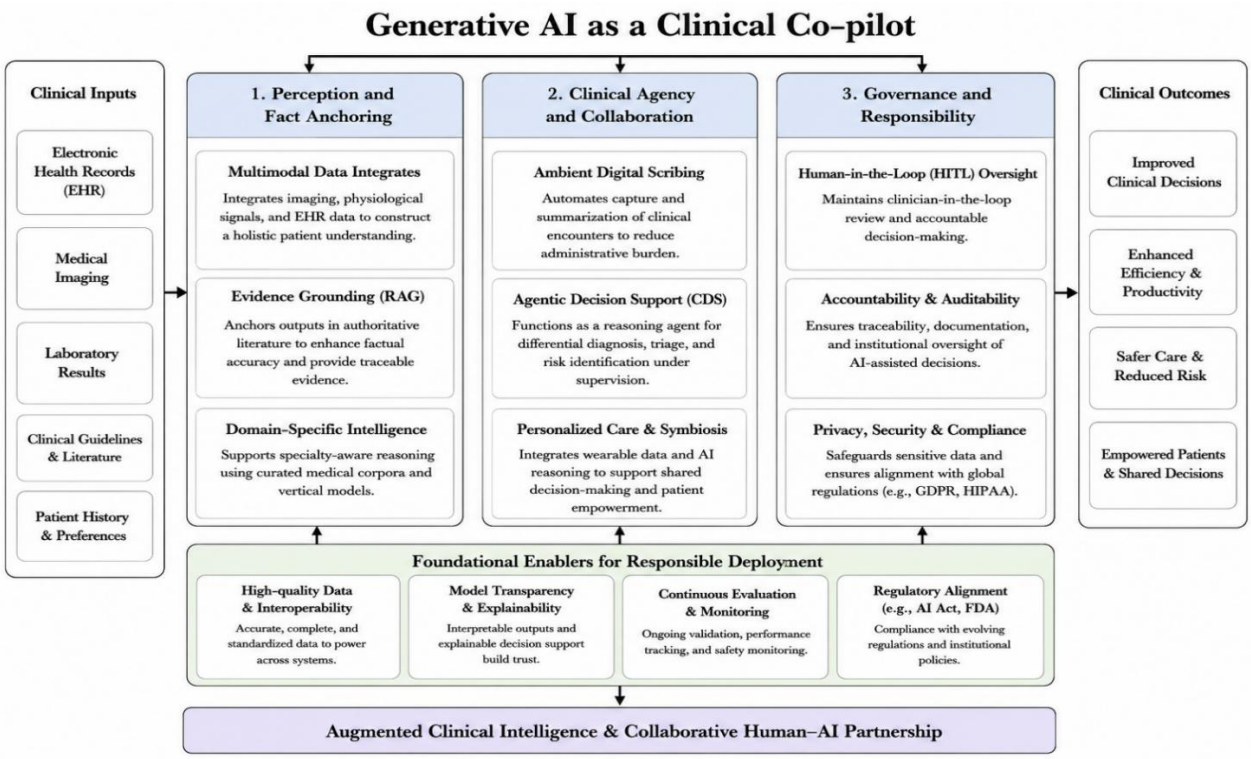

Fig. 3. Clinical Co-pilot framework derived from thematic synthesis of 41 included studies.

TABLE IV. OPTIMIZED THEMATIC CLASSIFICATION OF GENERATIVE AI CLINICAL CO-PILOT FUNCTIONS

Main Theme	Subtheme	AI Co-pilot Role & Functionality	Representative Technologies & Applications	Clinical Significance & Evaluation Metrics	Supporting Studies
Perception and Fact Anchoring	Multimodal Data Integration	Integrates imaging, physiological signals, and EHR data to construct a holistic patient understanding.	MLLMs (e.g., Med-Flamingo, LLaVA-Med), vision-language alignment, multimodal EHR fusion.	Enhances clinical situational awareness; Metrics: Diagnostic accuracy and cross-modal consistency.	[11, 14, 18, 27, 29, 33, 36, 44]
	Evidence Grounding (RAG)	Anchors outputs in authoritative literature to eliminate hallucinations and provide traceable citations.	Retrieval-Augmented Generation (RAG), hybrid retrieval pipelines, evidence-grounded CDS.	Establishes evidence-based trust; Metrics: ACUTE (Traceability, Factuality).	[7, 9, 10, 13, 16, 21, 23, 41, 43, 52]
	Domain-Specific Intelligence	Supports specialty-aware reasoning (e.g., oncology, surgery) using curated medical corpora.	Vertical medical models (BioBERT, ClinicalBERT), disease-scenario association matrices.	Improves specialty-specific precision and relevance; Metrics: MedQA board-style benchmarks.	[6, 9, 11, 14, 21-24, 41, 42, 44, 53, 54]
Clinical Agency and Collaboration	Ambient Digital Scribing	Automates capture and summarization of clinical encounters to reduce administrative burden.	Ambient AI (DAX Co-pilot), SCRIBE framework, automated SOAP note generation.	Reduces physician burnout and documentation time; Metrics: Note completeness and editing time.	[6, 8, 11, 12, 16, 19, 30, 31, 33, 44]
	Agentic Decision Support (Agentic CDS)	Functions as a reasoning "agent" capable of differential diagnosis and active triage under supervision.	AI Agents, virtual triage assistants, interactive diagnostic rationales.	Supports complex reasoning and risk identification; Metrics: AI-SCE (Clinical Skills Assessment).	[13, 15, 16, 18, 19, 23, 28, 33, 35-37, 41, 54, 55]
	Personalized Care & Symbiosis	Integrates wearable data and AI reasoning to support shared decision-making and patient empowerment.	Personalized Patient Care Plans (PPCPs), remote monitoring, health empowerment tools.	Enhances care coordination and patient adherence; Metrics: Patient satisfaction and compliance.	[9, 16, 18-20, 24, 26-30, 36, 44]
Governance and Responsibility	Human-in-the-Loop (HITL) Oversight	Maintains clinicians as the final reviewers and accountable decision-makers.	iLEAP lifecycle model, clinician validation interfaces, supervised CDS protocols.	Preserves diagnostic safety and legal accountability; Metrics: Human-AI decision agreement rates.	[10, 12, 16, 18, 19, 23, 24, 28, 33, 37, 44, 52, 54]
	Privacy, Security, & Compliance	Safeguards sensitive data and ensures alignment with global regulations (GDPR/HIPAA).	Data de-identification, secure infrastructure, quantitative assurance frameworks.	Reduces liability and privacy risks; Metrics: Regulatory compliance and data leakage rates.	[7, 8, 10, 14, 16-19, 23, 28, 32, 35, 37, 42-44, 52, 56]
	Ethics, Fairness, & Trustworthy AI	Mitigates algorithmic bias and promotes transparency and equitable healthcare delivery.	Fairness audits, AVI intelligent filters, explainable AI (XAI), bias mitigation.	Supports health equity and trustworthy deployment; Metrics: Bias reduction rate and explainability scores.	[9, 18, 19, 23, 25, 27, 28, 32, 35, 37, 42-44, 52, 53]

To further synthesize the major themes identified across the included studies, Table IV presents the thematic classification of GenAI clinical co-pilot functions. The classification was developed inductively through thematic synthesis of the included studies and serves as an analytical framework for organizing the identified clinical co-pilot functions. Table IV summarizes the conceptual roles, representative technologies, clinical significance, evaluation considerations, and supporting evidence associated with each thematic domain. The findings suggest that contemporary GenAI systems are evolving beyond isolated automation tools toward integrated collaborative intelligence infrastructures capable of supporting multimodal reasoning, clinical workflow augmentation, and responsible healthcare governance.

C. Perception and Fact Anchoring

The first major thematic domain identified in the findings involved perception and fact anchoring, representing the foundational cognitive layer of GenAI clinical co-pilot systems. This domain focuses on the ability of GenAI to interpret, integrate, contextualize, and retrieve heterogeneous healthcare information in order to support clinical reasoning and evidence-based decision-making.

One of the most frequently discussed capabilities involved multimodal data integration. Several studies described the emergence of multimodal LLMs capable of combining electronic health records, medical imaging, laboratory findings, physiological signals, and patient histories within unified reasoning systems [36]. Unlike conventional language-only architectures, these multimodal systems provide a more comprehensive understanding of patient conditions by integrating diverse clinical modalities into a shared contextual framework [33].

Another major subtheme involved evidence grounding through RAG. The reviewed studies consistently identified hallucination and factual inconsistency as major barriers to clinical adoption [18]. To address these limitations, multiple studies proposed integrating external biomedical literature, clinical guidelines, institutional protocols, and curated medical repositories into GenAI pipelines. RAG-based systems were frequently described as mechanisms for improving factual reliability, traceability, and evidence-based trust within clinical decision support environments [13, 16].

Thematic analysis also highlighted the increasing importance of domain-specific medical intelligence. Several studies emphasized the development of specialty-oriented foundation models and curated medical corpora designed for vertical clinical applications such as oncology, radiology, pathology, surgery, and critical care [14, 18, 21, 27, 36]. These systems improve contextual relevance and specialty-specific reasoning performance by embedding structured medical knowledge and domain-specific terminology into the model architecture.

Collectively, these findings suggest that perception and fact anchoring functions form the informational and cognitive foundation of GenAI clinical co-pilot systems. By improving contextual understanding, evidence retrieval, and multimodal interpretation, these capabilities support more reliable and clinically relevant AI-assisted healthcare environments.

D. Clinical Agency and Collaboration

The second major thematic domain identified in the findings involved clinical agency and collaboration, representing the operational layer of GenAI integration within healthcare workflows. This domain focuses on how GenAI systems support clinicians during routine clinical activities, documentation processes, communication tasks, and collaborative decision-making.

One of the most widely discussed applications involved ambient digital scribing and automated clinical documentation [12]. Several studies examined ambient AI systems capable of capturing physician-patient conversations and automatically generating structured clinical documentation, including SOAP notes, discharge summaries, and encounter records [7, 35]. These applications were consistently associated with reductions in administrative burden, documentation workload, and physician burnout [30].

Another major theme involved agentic clinical decision support (CDS). Unlike traditional rule-based CDS systems, GenAI systems increasingly function as interactive reasoning agents capable of differential diagnosis generation, triage support, contextual recommendation synthesis, and conversational clinical reasoning [15, 30, 54, 55]. Several studies described these systems as “clinical assistants,” “digital residents,” or “AI collaborators” designed to augment physician reasoning while preserving clinician supervision and final decision authority [18].

Personalized care and patient empowerment also emerged as important application areas. Multiple studies explored the integration of wearable devices, remote monitoring systems, and personalized patient care plans (PPCPs) into GenAI workflows [16, 28, 29]. These systems were designed to support individualized treatment coordination, shared decision-making, patient engagement, and long-term care continuity [10, 18, 25].

In addition, workflow optimization and interdisciplinary communication were repeatedly identified as key operational benefits [19]. GenAI systems were increasingly used to coordinate clinical tasks, streamline information retrieval, summarize large volumes of medical data, and facilitate communication across multidisciplinary healthcare teams [23]. These capabilities may help reduce cognitive overload and improve healthcare operational efficiency in increasingly complex clinical environments.

Overall, the findings indicate that GenAI is evolving beyond isolated documentation or chatbot functions toward broader collaborative clinical agency and collaboration integration. Within this emerging paradigm, AI systems increasingly function as workflow collaborators embedded within clinician-centered healthcare environments.

E. Governance and Responsibility

The third major thematic domain identified in the findings involved Governance and Responsibility, representing the institutional and ethical foundation required for safe GenAI deployment in healthcare settings. Across the reviewed

literature, governance mechanisms were consistently described as essential prerequisites for trustworthy clinical implementation.

One of the most prominent themes involved human-in-the-loop (HITL) oversight [34, 57]. Multiple studies emphasized that clinicians must remain the final reviewers, supervisors, and accountable decision-makers within AI-assisted healthcare systems [18, 32]. Rather than replacing physician expertise, GenAI systems were consistently positioned as supportive tools operating under clinician supervision [6, 41, 53]. This collaborative oversight structure was widely regarded as essential for maintaining patient safety and preserving clinical accountability [16].

Accountability and auditability also emerged as major governance concerns. Several studies discussed the need for traceable AI-assisted decisions, institutional governance committees, audit trails, and transparent documentation mechanisms capable of supporting legal and organizational accountability. Questions regarding liability attribution, clinician responsibility, and institutional oversight remain unresolved challenges in real-world healthcare deployment [9, 10, 32].

Privacy, security, and regulatory compliance represented another major subtheme. Because GenAI systems frequently process sensitive healthcare information, studies consistently emphasized compliance with GDPR, HIPAA, and healthcare cybersecurity standards. Several authors also highlighted risks related to data leakage, unauthorized access, and secondary use of patient information [8, 21, 42].

Ethics, fairness, and trustworthy AI were similarly recurring themes across the included studies. Multiple studies discussed algorithmic bias, demographic disparities, explainability limitations, and fairness concerns associated with large-scale GenAI deployment [9, 18]. Consequently, fairness audits, transparency mechanisms, explainable AI (XAI), and bias mitigation strategies were frequently proposed as critical components of responsible healthcare AI governance [8, 25, 43].

Collectively, the findings suggest that governance and responsibility mechanisms are not peripheral considerations, but foundational requirements for sustainable clinical AI integration. Successful implementation depends not only on technical performance, but also on the establishment of trustworthy human-AI collaboration frameworks supported by accountability, transparency, fairness, and clinician oversight.

IV. Discussion

A. Theoretical and Practical Contributions

This study makes several important theoretical and practical contributions to the emerging field of GenAI in healthcare. First, by systematically reviewing and synthesizing 41 studies published between 2023 and 2026, this research provides a comprehensive overview of the rapidly evolving literature on GenAI applications in healthcare. The findings consolidate fragmented evidence from medicine, healthcare informatics, artificial intelligence, and digital health into a coherent knowledge framework.

This study extends existing review literature that has primarily focused on ChatGPT performance, specialty-specific applications, or technical evaluations of LLMs [18, 47]. To the study's knowledge, this is among the first reviews to conceptualize GenAI as a clinical co-pilot through the integration of technological capabilities, clinical workflow support, and governance considerations. This broader perspective helps explain the evolution of GenAI from isolated tools toward collaborative clinical intelligence systems.

Second, this study proposes a conceptual framework that positions GenAI as a collaborative clinical co-pilot rather than a standalone decision-making system. The framework advances existing discussions beyond traditional clinical decision support systems by emphasizing the complementary relationship between human expertise and AI-enabled intelligence. This perspective contributes to the growing body of literature on human-AI collaboration and collaborative clinical intelligence.

Third, the thematic synthesis identifies three interrelated domains that characterize the emerging role of GenAI in healthcare: 1) Perception and Fact Anchoring, 2) Clinical Agency and Collaboration, and 3) Governance and Responsibility. These domains provide a structured theoretical foundation for understanding how GenAI systems acquire, interpret, and utilize clinical information while operating within healthcare workflows and regulatory environments.

From a practical perspective, the proposed framework may provide guidance for healthcare organizations, technology developers, and policymakers seeking to implement GenAI responsibly. The findings highlight the importance of evidence grounding, workflow integration, human oversight, transparency, and regulatory compliance as critical factors for successful deployment. Furthermore, the framework may provide a foundation for future empirical studies examining the effectiveness, safety, and long-term impact of GenAI clinical co-pilots in real-world healthcare settings.

B. From Automation to Collaboration

Traditional healthcare artificial intelligence systems primarily emphasized automation-oriented objectives, including disease prediction, risk stratification, image classification, and algorithmic screening [8, 17, 22]. Although many of these systems demonstrated strong benchmark performance, real-world clinical implementation remained limited due to poor workflow integration, insufficient interpretability, clinician distrust, and limited adaptability to complex healthcare environments [9, 18].

The findings suggest an emerging conceptual transition from automation-centered artificial intelligence toward collaboration-centered clinical intelligence. Unlike earlier predictive models that functioned primarily as isolated computational tools, contemporary GenAI systems increasingly operate as interactive clinical collaborators capable of contextual reasoning, multimodal information synthesis, evidence retrieval, and dynamic communication under clinician supervision [9, 35].

Within the proposed clinical co-pilot framework, the role of artificial intelligence shifts from replacing human decision-making toward augmenting clinician capabilities [35]. Rather than functioning as autonomous decision-makers, GenAI

systems support healthcare professionals by improving situational awareness, reducing cognitive burden, streamlining information retrieval, and facilitating workflow coordination [18, 35].

This transition is particularly important in healthcare because clinical decision-making inherently involves uncertainty, contextual judgment, ethical responsibility, interdisciplinary communication, and patient-centered reasoning. Traditional machine learning systems may generate accurate predictions, but they often lack the ability to explain reasoning pathways, contextualize recommendations, or engage in iterative clinical dialogue [16, 32]. In contrast, GenAI co-pilots demonstrate the ability to synthesize heterogeneous information sources, generate contextual explanations, and support collaborative reasoning processes within clinical environments.

Although the reviewed studies generally reported positive outcomes, the magnitude of these benefits varied across clinical applications. Administrative tasks, such as clinical documentation and ambient digital scribing, demonstrated more consistent performance improvements because they involve relatively standardized workflows and lower levels of clinical uncertainty. In contrast, applications involving diagnostic reasoning, treatment planning, and agentic clinical decision support exhibited greater variability, reflecting differences in domain complexity, multimodal data integration, evidence grounding capabilities, and the degree of required clinician oversight. These contextual differences suggest that the effectiveness of GenAI depends not only on model capability but also on the clinical context in which it is deployed.

Thematic synthesis further suggests that the future direction of healthcare AI may depend less on fully autonomous systems and more on collaborative intelligence architectures integrating human expertise with AI-supported reasoning[35]. Consequently, the clinical co-pilot paradigm may represent a more feasible, sustainable, and ethically responsible pathway for healthcare digital transformation.

C. Human-AI Partnership and Trust Calibration

The effectiveness of GenAI clinical co-pilots depends heavily on the establishment of appropriate human-AI partnerships and calibrated clinician trust. Across the reviewed literature, trust calibration emerged as a critical factor influencing healthcare AI adoption, workflow integration, and long-term clinical acceptance[35].

Overtrust and undertrust both represent substantial risks in AI-assisted healthcare environments [10]. Excessive reliance on AI-generated recommendations may increase vulnerability to hallucinations, factual inaccuracies, and automation bias [30]. Conversely, insufficient trust may prevent clinicians from utilizing potentially valuable decision support capabilities and operational efficiencies [37].

The reviewed studies consistently identified RAG, evidence grounding, and domain-specific medical intelligence as essential mechanisms for improving trust calibration [13, 51]. By anchoring outputs to authoritative medical literature, institutional guidelines, and curated biomedical knowledge sources, RAG-based systems improve factual consistency, transparency, and traceability. These mechanisms help transform GenAI from a probabilistic text generator into a more reliable evidence-supported clinical assistant [13].

Trust calibration is also associated with workflow integration quality. Studies examining ambient digital scribing and workflow-oriented clinical AI systems demonstrated that clinician acceptance increases when AI systems operate seamlessly within clinical workflows without introducing excessive operational disruption. Automated clinical documentation, structured note generation, and intelligent information summarization were associated with reduced administrative burden and lower physician burnout [12, 30].

Another important finding involved the emergence of agentic clinical decision support systems. Several studies described GenAI systems functioning as interactive reasoning agents capable of participating in diagnostic discussions, differential diagnosis generation, triage support, and multidisciplinary information synthesis [15, 55]. However, the reviewed literature consistently emphasized that these systems should remain clinician-supervised collaborative assistants rather than independent clinical authorities [28, 41].

Overall, the findings suggest that sustainable healthcare AI adoption depends not only on technical performance, but also on the development of trustworthy human-AI collaboration models characterized by transparency, explainability, contextual reliability, and workflow compatibility. Beyond technical performance, the heterogeneity observed across the reviewed studies suggests that successful implementation depends on organizational readiness, workflow redesign, clinician acceptance, and regulatory maturity. Consequently, similar GenAI technologies may produce different outcomes across healthcare settings, indicating that implementation context is as important as algorithmic performance.

D. Governance, Responsibility, and De-Identification Challenges

As GenAI systems transition from experimental research environments toward real-world healthcare implementation, governance and responsibility mechanisms become increasingly critical. The findings consistently suggest that technical performance alone is insufficient for sustainable healthcare AI deployment without corresponding institutional, ethical, and regulatory safeguards.

Human-in-the-loop oversight emerged as one of the most consistently emphasized governance principles across the reviewed studies [42, 56]. Regardless of the sophistication of GenAI systems, clinicians were repeatedly identified as the final reviewers, supervisors, and accountable decision-makers within healthcare environments [12, 28, 41]. This governance structure is particularly important because healthcare decisions involve substantial ethical responsibility, patient safety considerations, and legal accountability.

The reviewed literature also identified unresolved challenges regarding liability attribution and institutional accountability [10, 32]. Questions remain regarding how responsibility should be distributed when AI-assisted recommendations contribute to unsafe decisions, delayed diagnoses, or inappropriate treatments [8, 25, 41]. These concerns become increasingly complex as

GenAI systems evolve toward more autonomous agentic capabilities.

Privacy protection and healthcare data security were similarly identified as major implementation barriers. GenAI systems frequently process highly sensitive multimodal healthcare information, including electronic health records, radiological images, laboratory data, wearable sensor outputs, and free-text clinical narratives. Traditional de-identification approaches may become insufficient in large language model environments because contextual associations within unstructured clinical text may still permit indirect patient re-identification [17, 53].

Several studies emphasized that advanced LLMs possess strong contextual inference capabilities capable of reconstructing sensitive information from fragmented clinical details. Consequently, healthcare institutions may require more advanced privacy-preserving architectures, secure deployment infrastructures, and continuous monitoring systems to reduce data leakage risks [14, 52, 56].

The reviewed studies further emphasized the importance of transparency, fairness, explainability, and regulatory alignment. Bias inherited from historical healthcare datasets may contribute to unequal performance across demographic populations, clinical institutions, and healthcare settings. Therefore, fairness auditing, explainable AI mechanisms, and continuous governance evaluation were frequently proposed as essential components of trustworthy healthcare AI deployment [10, 32].

In addition, emerging regulatory frameworks such as the European Union AI Act and evolving FDA guidance may significantly influence future healthcare AI governance. However, current regulations continue to face challenges adapting to rapidly evolving GenAI systems characterized by dynamic reasoning capabilities, continuous model updates, and multimodal integration.

Notably, several reviewed studies also highlighted practical implementation challenges, including clinician skepticism, workflow disruption, and uncertainty regarding legal responsibility, hallucinations, and concerns over data privacy. These findings suggest that successful GenAI adoption depends not only on advances in model capability but also on organizational adaptation, effective governance, and sustained human oversight throughout clinical implementation.

Collectively, these findings suggest that governance and responsibility should not be viewed as secondary considerations, but rather as foundational infrastructure supporting safe, ethical, and sustainable healthcare AI integration.

E. Study Limitations

Several limitations should be acknowledged when interpreting these findings. First, only English-language publications were included in the analysis. Although English represents the dominant language of scientific communication, relevant studies published in other languages may have been excluded, potentially introducing language bias.

Second, the literature search was limited to three major databases: Web of Science, PubMed, and Scopus. While these databases provide extensive coverage of healthcare, medical informatics, and artificial intelligence research, relevant studies indexed in other databases or grey literature sources may not have been captured.

Third, this study employed a qualitative thematic synthesis approach rather than a quantitative meta-analysis. Given the heterogeneity of study designs, evaluation methods, and reported outcomes, direct statistical comparison across studies was not feasible. Consequently, the findings should be interpreted as conceptual and thematic insights rather than quantitative estimates of effectiveness.

Finally, GenAI is a rapidly evolving field characterized by continuous technological advancements and frequent model updates. As new foundation models, multimodal systems, and regulatory frameworks continue to emerge, some findings may require further validation and refinement over time. Therefore, the proposed framework should be viewed as an evolving conceptual foundation that may be expanded as the evidence base continues to grow.

F. Future Directions

The findings suggest several important future directions for GenAI clinical co-pilot research and healthcare implementation.

First, future studies should move beyond static benchmark evaluations toward longitudinal real-world clinical assessments. Many current studies rely heavily on benchmark datasets, examination-style evaluations, or proof-of-concept experiments. Although these approaches provide useful technical comparisons, they do not adequately capture long-term workflow integration, clinician adaptation, patient-centered outcomes, or operational sustainability [9, 36]. Future research should therefore prioritize longitudinal observational studies, implementation science approaches, and pragmatic clinical evaluations conducted within active healthcare environments.

Second, future clinical co-pilot systems will likely require deeper integration with multimodal healthcare ecosystems. The reviewed literature suggests that the next generation of healthcare AI may extend beyond isolated language processing toward comprehensive multimodal reasoning architectures integrating electronic health records, medical imaging, laboratory findings, wearable devices, physiological monitoring, and behavioral data streams. Such systems may facilitate more personalized, context-aware, and continuous healthcare support [8, 27].

Third, uncertainty quantification and explainability remain important future research priorities [58, 59]. Current GenAI systems frequently produce highly fluent outputs without explicitly communicating confidence levels or uncertainty boundaries [18, 36]. Future clinical co-pilots should incorporate transparent uncertainty signaling mechanisms capable of informing clinicians when recommendations require additional validation or specialist review. Such mechanisms may help reduce automation bias and improve clinical risk management.

Fourth, future governance frameworks must address distributed responsibility within collaborative human-AI healthcare systems. As GenAI systems become more deeply integrated into healthcare workflows, questions regarding legal liability, institutional accountability, and clinician responsibility

will become increasingly important [9, 10, 35]. Interdisciplinary collaboration among healthcare professionals, legal scholars, policymakers, and AI researchers will likely be necessary to establish operationally feasible governance standards.

Finally, the concept of clinical intelligence itself may continue to evolve. The reviewed literature suggests that healthcare AI is gradually transitioning from isolated decision support tools toward collaborative intelligence ecosystems integrating clinicians, patients, healthcare institutions, and AI-supported reasoning systems [28, 32]. Within this evolving paradigm, GenAI co-pilots may become foundational infrastructure supporting future human-centered digital healthcare environments.

V. Conclusion

This study systematically reviewed and synthesized recent research on GenAI in healthcare. Following the PRISMA 2020 framework, 41 studies published between 2023 and March 2026 were included in the final analysis. The findings indicate that GenAI is expanding beyond traditional decision-support functions and becoming more closely integrated into clinical workflows.

Three major themes emerged from the thematic synthesis: Perception and Fact Anchoring, Clinical Agency and Collaboration, and Governance and Responsibility. These themes reflect the key capabilities and challenges associated with the adoption of GenAI in healthcare. The findings show that technologies such as LLMs, multimodal foundation models, RAG, and agent-based systems are being applied across clinical documentation, decision support, patient communication, and care planning. At the same time, issues related to transparency, accountability, privacy protection, and human oversight remain central to successful implementation.

Based on these findings, this study proposes a Clinical Co-pilot Framework that integrates technological capabilities, clinical workflow support, and governance considerations. The framework may provide a conceptual perspective for understanding how GenAI can assist healthcare professionals while maintaining clinician responsibility for medical decision-making. The results suggest that the value of GenAI in healthcare depends not only on model performance but also on its ability to support clinical practice in a safe, reliable, and accountable manner. Effective deployment requires appropriate workflow integration, continuous evaluation, and clear governance mechanisms. Human oversight remains essential in ensuring the quality and safety of AI-assisted healthcare services.

Future research should focus on real-world implementation, long-term clinical impact, and the evolving relationship between healthcare professionals and AI systems. As GenAI technologies continue to develop. The future of healthcare AI may depend not on replacing clinicians, but on establishing effective human-AI partnerships that enhance clinical intelligence, support responsible decision-making, and improve patient-centered healthcare delivery.

Abstract*—Massive Open Online Courses (MOOCs) have expanded access to learning, but learner dropout remains a persistent challenge in online education. Most dropout prediction studies transform learner traces into behavioral features and train machine learning or deep learning models to identify at-risk learners. Although this predictive layer is useful, it remains limited for educational decision-making because a risk score does not explain why a learner is at risk or what type of support should be proposed. This study introduces Localized Actionable Explainability (L-AXAI), a learning analytics framework that combines dropout prediction, local explanation, and personalized pedagogical nudging. The framework first transforms clickstream logs into weekly behavioral indicators, then trains predictive classifiers, and finally applies SHAP-based local explanation to identify the strongest risk driver for each high-risk learner. These local explanations are mapped to targeted pedagogical actions using a transparent rule-based translation matrix. Experiments on the KDD Cup MOOC dropout benchmark produced closely comparable results for the two strongest boosting models. Under the fixed stratified test split, Gradient Boosting achieved 85.79% accuracy, 86.57% ROC-AUC, and 94.41% PR-AUC, while XGBoost achieved 85.77% accuracy and the same ROC-AUC. Because repeated-seed evaluation and statistical significance testing were not conducted, the small difference between these point estimates should not be interpreted as definitive model superiority. The explainability analysis identifies model-associated patterns involving weekly activity intensity, active days, and early problem engagement. The intervention layer generates candidate nudge categories, mainly navigation, re-engagement, and session-completion suggestions. The framework therefore returns an estimated dropout risk, a local risk driver, and a candidate pedagogical action. The nudges are intended as low-intensity decision-support suggestions; their appropriateness, perceived pressure, and effectiveness require validation with instructors and learners.

Keywords*—MOOC dropout prediction; learning analytics; explainable artificial intelligence; SHAP; localized explanation; actionable intervention

I. Introduction

Online learning platforms have become one of the main sources of data for education. Every learner activity such as opening a course page, viewing a video, trying a problem, or posting in a discussion forum leaves a trace that can be analyzed to better understand the engagement and learning progression [1], [2], [3]. These traces are used by learning analytics and educational data mining to support teachers, designers, and institutions in tracking learning processes and improving educational decisions [4], [5], [6], [7], [8]. MOOCs are a prime example of data-rich learning environments, with large-scale enrollment and continuous clickstream records. But the very openness that makes MOOCs appealing also makes it hard to persist. Learners enter MOOCs with different goals, different time constraints, and different levels of commitment. Thus, completion rates cannot fully account for disengagement, as learners may follow several trajectories rather than a single common path [9], [10]. Consequently, predicting dropout has become a central task in learning analytics. Previous work has shown that activity indicators, weekly engagement signals, and temporal representations can be used to identify learners who are likely to stop participating [11], [12], [13], [14]. Later work also advised that predictive performance should be carefully evaluated because training and testing on the same course may overestimate the real accuracy of a dropout model [15], [16]. Predictive models are useful, but prediction is not sufficient for teaching. A model may identify a learner as high-risk, but this information is weak if the instructor does not know which behavior created the risk. A learner who doesn't try problems needs a different type of support than a learner who watches videos but never uses discussions. Likewise, a learner with a long inactivity gap needs a different nudge than a learner who browses through many pages without completing learning tasks [17], [18], [19], [20]. Explainable Artificial Intelligence (XAI) helps to open this black-box problem by showing which features affect a prediction. LIME and SHAP are popular methods for explaining machine learning models, but counterfactual explanations offer an action-oriented perspective by asking what changes are needed to obtain a different outcome [21], [22], [23], [24], [25], [26]. However, many educational applications of XAI are confined to global feature importance. A global plot can show that problem events are important in general, but it cannot automatically tell what to do for a specific learner [27], [28], [29], [30], [31]. Thus, the

real challenge is not only to predict dropout, but also to associate the prediction with localized and educationally meaningful action. This study introduces Localized Actionable Explainability (L-AXAI), a framework that identifies at-risk learners, explains each individual prediction, and converts the top local risk driver into a pedagogical nudge. The framework is evaluated on a public MOOC clickstream benchmark for dropout prediction.

The main contributions of this work are fivefold. First, it proposes a localized actionable explainability framework for MOOC dropout intervention. Second, it extracts directly interpretable weekly behavioral features from clickstream events, including access, problem-solving, video engagement, discussion participation, navigation, wiki usage, and inactivity. Third, it formalizes the predictive and explainability layers through supervised classification, tree-based boosting, SHAP values, and an intervention mapping function. Fourth, it introduces a transparent rule-based translation matrix that converts local SHAP risk drivers into pedagogical nudges. Finally, it evaluates the framework not only in terms of predictive performance, but also through global and local explanation analysis and the distribution of generated intervention types.

The rest of this study is organized as follows: Section II reviews the related literature. The mathematical formulation and the proposed L-AXAI framework architecture are described in Section III. Results are given in Section IV. Discussion is presented in Section V. Finally, Section VI concludes this study.

II. Literature Review

Over the past decade, MOOC dropout prediction has progressed from simple activity-count models to temporal, representation-based, and explainable learning analytics frameworks [11], [12], [13], [14], [32]. Existing studies mainly focus on improving early detection, generalization across courses, or predictive performance [15], [16], [33], [34]. More recent work has started to consider interpretability, but many studies still stop at feature importance, SHAP plots, or visual explanations without converting the explanation into a direct learner-level pedagogical action [17], [19], [20], [27], [35]. This section reviews activity-based, temporal, deep representation, explainable, and action-oriented dropout prediction studies, highlighting key contributions and limitations.

Early dropout prediction studies were mainly based on learner activity features extracted from platform logs. Halawa et al. [11] used activity indicators to red-flag students who were likely to leave a course, showing that learner interaction traces can support early warning. Similarly, Kloft et al. [12] predicted dropout over weeks using machine learning models and showed that weekly behavior can provide useful signals for early detection. Taylor et al. [13] developed a scalable dropout prediction pipeline and demonstrated that temporal and non-temporal features can produce strong AUC values. However, these approaches rely heavily on engineered counts and feature importance analysis, which limits their ability to explain the specific barrier faced by each learner.

Several studies then focused on validation, transferability, and robustness. Boyer and Veeramachaneni [36] explored transfer learning for predictive models across MOOC contexts, while Whitehill et al. [15] showed that same-course evaluation can give overly optimistic estimates of dropout prediction accuracy. Gardner and Brooks [16] also argued that dropout model evaluation needs more rigorous procedures because feature extraction methods and algorithms interact strongly. These works are important because they show that high accuracy alone is not enough. Nevertheless, their main concern is predictive validity rather than pedagogical actionability.

Temporal and representation learning methods were proposed to capture changes in learner behavior more deeply. Fei and Yeung [14] introduced temporal models for dropout prediction, moving beyond static activity totals. Jeon et al. [37] proposed interpretable multi-layer representation learning to reduce manual feature engineering, and Jeon and Park [38] modeled clicks and videos jointly to improve weekly dropout prediction. These studies improve the modeling of sequential engagement and learning resources. However, their outputs still mainly support classification, and the connection between learned representations and instructor-level intervention remains limited.

Other studies investigated behavior patterns and learner trajectories. Kizilcec et al. [9] showed that MOOC disengagement is not one single behavior but a set of learner subpopulations with different engagement trajectories. Feng et al. [18] analyzed dropout behaviors and identified meaningful categories of learners in large-scale MOOCs. Alamri et al. [19] used visually driven, multi-granularity explanations to compare learning paths of completers and non-completers, showing that non-completers may jump forward or follow irregular paths. These studies are closer to pedagogy because they describe behavior, but they do not automatically generate a concrete nudge for each high-risk learner.

Explainability has been introduced more directly in dropout prediction pipelines. Nagrecha et al. [17] showed that MOOC dropout prediction pipelines can be made interpretable with performance close to stronger black-box methods. Er [20] used explainable machine learning to understand dropout in two MOOC runs and discussed feature importance from a pedagogical point of view. Swamy et al. [27] compared several explanation methods in student performance prediction, including LIME, SHAP, DiCE, and contrastive explanations, and showed that explanation methods can disagree. These studies show the relevance of XAI in education, but explanation is still often presented as a separate analysis after prediction rather than as an intervention engine.

Recent work also moved toward SHAP-based and intervention-oriented systems. Liu [39] used a dilated convolutional behavior model and SHAP analysis to identify important learning behavior variables. Nti and Ramanayake [35] proposed an explainable dropout prediction framework that also considers tailored interventions in online personalized education. Ajayi [40] combined stacked ensemble learning with explainability for online dropout risk, and Nagy et al. [41] connected interpretable dropout prediction with personalized intervention. These studies are important because they

explicitly connect interpretability with student support. However, most of them do not define a transparent event-to-nudge translation matrix based on local clickstream deficits.

Counterfactual and group-level explanation methods provide another direction for actionable learning analytics. Wachter et al. [24] formalized counterfactual explanations as a way to explain automated decisions without opening the black box, while Mothilal et al. [25] proposed diverse counterfactual explanations that are useful when several possible changes may lead to a desired outcome. Buñay-Guisñan et al. [42] applied group counterfactual explanations to support students at risk of dropout, aiming to recover larger groups with lower intervention cost. These works are highly relevant for future learning analytics because they bring actionability into explanation. Still, direct mapping from local MOOC event deficits to practical pedagogical nudges remains underdeveloped.

The literature shows a clear evolution in the field of MOOC dropout prediction, from activity-count models to more complex temporal, representation-based, and more explainable models. However, many studies still focus only on prediction accuracy or visual explanation. One remaining gap is how to translate local learner-level explanations into transparent and practical pedagogical nudges that are personalized and can be directly used by instructors.

III. Materials and Methods

A. Proposed Method

The study is based on quantitative learning analytics, utilizing supervised machine learning and post-hoc explainability. The goal is not only to predict at-risk learners, but also to explain why each at-risk prediction is produced and to transform this explanation into a concrete pedagogical action. The proposed L-AXAI workflow presented in Fig. 1 begins from raw MOOC clickstream logs, which record learner interaction events such as login, page views, video access, problem attempts, discussion activity, navigation, and session closing. During preprocessing, irrelevant events are removed, timestamps are converted into a common format, and actions are aggregated into learner-course sessions. Missing or invalid records are also removed. The dataset is split into training, validation, and testing sets after pre-processing. The behavioral feature engineering stage converts the raw logs into weekly learner features. Such features are time indicators, weekly event counts, and deficit indicators. Event counts indicate what the learner did, temporal indicators show the pace of participation, and deficit indicators show what is missing when comparing the learner's behavior to the reference behavior of successful learners in the same course. In the prediction stage, the following machine-learning models are trained and compared: Logistic Regression, SVM, KNN, Decision Tree, Random Forest, Extra Trees, AdaBoost, Gradient Boosting, XGBoost, and LightGBM. Metrics for classification, like accuracy, ROC-AUC, and PR-AUC, are used to evaluate candidate models. The selected model is then used to produce an estimated dropout-risk score for each learner. The framework utilizes local SHAP explanation for learners having a predicted dropout probability above the risk threshold. This step identifies the features that exert the greatest influence on each individual prediction. Rather than a global model interpretation, L-AXAI is concerned with the local risk driver of each learner. Finally, the rule-based translation matrix maps the selected risk driver to a pedagogical action, such as a practice-oriented nudge, re-engagement message, video review recommendation, or help-seeking prompt. This design enables transparent and responsible learning analytics by connecting prediction, explanation, and intervention into one workflow. Fig. 1 illustrates the proposed L-AXAI workflow for MOOC dropout prediction and intervention.

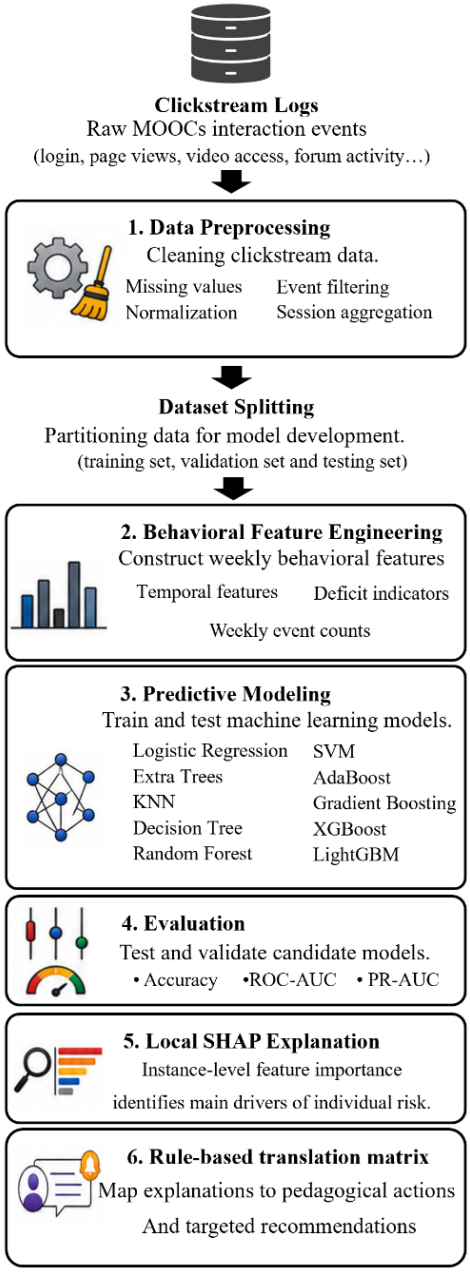

Fig. 1. Proposed L-AXAI workflow for MOOC dropout prediction and intervention.

B. Data Source and Event Representation

The experimental data are from the KDD Cup 2015 MOOC dropout prediction benchmark. The dataset contains learner-

course enrollment records and timestamped activity logs from a large MOOC platform. Each activity record contains an enrollment ID, a timestamp, a source object, and an event type. The task is formulated as a binary classification problem to predict if a learner-course enrollment will become inactive in the target period. The framework describes learner behavior through seven types of clickstream events: access, discussion, navigate, page_close, problem, video, and wiki. Access events indicate general connection to the course. Video events indicate consumption of instructional content, problem events indicate practice and assessment engagement, discussion events indicate social and help-seeking interactions, and wiki events indicate consultation of supplementary materials. Navigate and page_close events provide complementary information about movement between course objects and ending a session. Table I presents the interpretation of MOOC clickstream event types.

TABLE I. INTERPRETATION OF MOOC CLICKSTREAM EVENT TYPES

Event type	Behavioral meaning	Pedagogical interpretation
access	Opening or accessing course resources	General connection with the course
video	Interaction with course videos	Exposure to explanations and demonstrations
problem	Attempts or interaction with problems	Practice, self-testing, and assessment engagement
discussion	Forum or discussion activity	Help-seeking, peer interaction, and social learning
wiki	Consultation of wiki resources	Use of additional knowledge materials
navigate	Movement between course objects	Learning path and course exploration
page_close	Closing/leaving a course page	Session ending and possible early exit behavior

C. Preprocessing and Feature Engineering

The preprocessing step begins with a merge of the enrollment table and the log table on the enrollment identifier. Remove records that do not have key identifiers. Then each timestamp of learner action is transformed into a common datetime format and sorted chronologically. In this study, weekly observation windows are used instead of representing learner behavior with one global activity vector. Each week consists of seven days of activity. Thus, the actions of the learner are represented separately for week 1, week 2, week 3, and week 4. This design allows the model to learn the time variation of dropout risk. From the raw logs, three groups of features are derived.

The first type is weekly event counts including access, video, problem, discussion, wiki, navigate, and page_close events. For example, problem_w2_count is the number of problem-related actions taken by the learner in Week 2. This variable is coded as Week 2 problem activity in the analysis.

The second group includes temporal features on a weekly basis. Such features characterize the rhythm of the learner's participation. For example, active_days_w2 is the number of active days in Week 2, and maximum_daily_events_w2 is the maximum number of actions recorded in one day in Week 2. This variable is interpreted as Week 2's highest daily activity.

The third group is made up of weekly deficit indicators. A deficit is the difference between the learner's activity and the median activity of non-dropout learners in the same course. problem_w2_deficit shows the distance from the course reference for the learner's problem activity in Week 2. If the learner is not below the reference, then the deficit is set to zero. All course reference medians used for deficit computation were estimated only from the training set. For validation and test records, these training references were reused without accessing validation or test labels.

Event counts are what the learner did, temporal features are when and how often the learner participated, and deficit indicators are what is missing compared to successful learners. These deficit measures support the intervention layer by allowing a local risk driver to be translated into a candidate pedagogical nudge.

D. Machine Learning and Explainability Methods

The prediction task is formulated as a supervised binary classification problem. Let the processed dataset be represented as:

$$\mathcal{D} = \{(\mathrm{x}_i, y_i)\}_{i=1}^{N}, \quad \mathrm{x}_i \in \mathbb{R}^d, \quad y_i \in \{0,1\} \tag{1}$$

where, x_i is the feature vector of the learner-course record i, d is the number of engineered features, and y_i is the dropout label. The classifier learns a function that maps the behavioral representation of a learner to a dropout probability:

$$f: \mathbb{R}^d \to [0,1], \quad \hat{p}_i = f(\mathrm{x}_i) \tag{2}$$

where, $\hat{p}_i$ is the predicted probability that learner i will drop out. A binary decision is obtained by applying a risk threshold. τ:

$$\hat{y}_i = \begin{cases} 1, & \text{if } \hat{p}_i \geq \tau \\ 0, & \text{otherwise} \end{cases} \tag{3}$$

In this study, the risk threshold τ was set to 0.5, meaning that learner-course records with a predicted dropout probability greater than or equal to 0.5 were classified as high-risk.

Logistic Regression is used as a simple baseline because it gives a transparent relationship between features and predicted probability. [15], [43]. It estimates dropout probability using the sigmoid function:

$$\hat{p}_i = \sigma(\beta_0 + \mathrm{x}_i^{\mathrm{T}}\beta), \quad \sigma(z) = \frac{1}{1+e^{-z}} \tag{4}$$

The Support Vector Machine (SVM) is included as a margin-based classifier. It separates the two classes by finding a decision boundary with a maximum margin. The K-Nearest Neighbors (KNN) classifier is used as a non-parametric baseline. It predicts the label of a learner according to the labels of the most similar learners in the training set:

$$\hat{y}_i = \mathrm{mode}\{y_l : \mathrm{x}_l \in \mathcal{N}_k(\mathrm{x}_i)\} \tag{5}$$

where $\mathcal{N}_k(\mathrm{x}_i)$ denotes the set of the k nearest training samples to x_i. Decision Tree is used as a single-tree baseline, while Random Forest and Extra Trees are used as randomized tree ensembles. These models combine several decision trees

and aggregate their predictions, commonly through majority voting [44]:

$$\hat{y}_i = \text{mode}\{h_t(\text{x}_i)\}_{t=1}^{T} \quad (6)$$

where, h_t is the prediction of tree t, and T is the total number of trees in the ensemble. Random Forest builds trees from bootstrap samples, while Extra Trees increases randomness by using more randomized split selection. Both strategies help reduce variance compared with a single decision tree. The remaining classifiers belong to the boosting family: AdaBoost, Gradient Boosting, XGBoost, and LightGBM. Boosting models build the final predictor additively by adding new weak learners that correct the errors of previous learners [33], [34]:

$$F_m(\text{x}_i) = F_{m-1}(\text{x}_i) + \eta h_m(\text{x}_i) \quad (7)$$

where, h_m is the weak learner added at iteration m, and η is the learning rate. XGBoost and LightGBM are included because they are efficient for structured tabular features and include regularization mechanisms to control overfitting. A general regularized boosting objective can be written as:

$$\mathcal{L}^{(m)} = \sum_{i=1}^{N} l\left(y_i, F_{m-1}(\text{x}_i) + \eta h_m(\text{x}_i)\right) + \Omega(h_m) \quad (8)$$

where, l is the predictive loss function and $\Omega(h_m)$ penalizes model complexity. After model training, SHAP is used to explain model outputs. SHAP is based on Shapley values and belongs to additive feature attribution methods [21], [23], [45]. For a learner i, the prediction is decomposed as:

$$g(\text{x}_i) = \phi_0 + \sum_{j=1}^{d} \phi_{i,j} \quad (9)$$

where, ϕ_0 is the expected model output and $\phi_{i,j}$ is the contribution of feature j to the prediction of learner i. The Shapley value of feature j is defined as:

$$\phi_{i,j} = \sum_{S \subseteq F_j} w(S)[f(S \cup j) - f(S)] \quad (10)$$

where, F_j denotes the set of all features excluding feature j. The weighting term is defined as:

$$w(S) = \frac{|S|!\,(d - |S| - 1)!}{d!} \quad (11)$$

In this expression, S is a subset of features that excludes feature j, and the term in brackets measures the marginal change caused by adding feature j. SHAP is suitable for this study because it provides both global and local explanations. Global explanations show which variables matter across the cohort, while local explanations show why a specific learner is classified as high-risk. In L-AXAI, only learners whose predicted dropout probability exceeds the threshold are passed to the action-generation step. For each high-risk learner, the framework selects the strongest positive actionable SHAP contribution:

$$r_i = \underset{j \in A}{\text{argmax}} \phi_{i,j}, \quad \phi_{i,j} > 0 \quad (12)$$

where, A is the set of actionable weekly features and r_i is the local risk driver that most strongly pushes the learner i toward the dropout class. The selected driver is then mapped to a pedagogical action using the rule-based translation matrix T:

$$a_i = T(r_i) \quad (13)$$

The final output of the proposed framework is therefore not only a predicted label. For each high-risk learner, L-AXAI returns a triplet composed of the estimated dropout-risk score, the local explanation, and a candidate pedagogical nudge template:

$$o_i = (\hat{p}_i, r_i, a_i) \quad (14)$$

This formulation shows the difference between standard predictive modeling and L-AXAI. A standard classifier stops at the predicted probability or class label. In contrast, L-AXAI links prediction to explanation and then to intervention, which supports localized and actionable learning analytics. The estimated score is used as an operational decision value under the threshold τ=0.5. Because probability calibration was not evaluated, it should not be interpreted as a validated empirical probability of dropout.

E. L-AXAI Rule-Based Translation Matrix

The mappings in Table II were constructed as an author-designed, literature-informed, and behavior-semantics-informed prototype rather than as the outcome of a formal expert-consensus process. Each rule links the behavioral meaning of the corresponding event or deficit to a support objective: practice for low problem activity, content review for low video activity, reconnection for low access, help-seeking for low discussion participation, regularity support for inactivity, diversified resource use for low event diversity, progression support for navigation deficits, and session-completion support for frequent page closing with few active days. The matrix is deliberately transparent and editable and should therefore be interpreted as a set of candidate nudge templates rather than as validated pedagogical prescriptions. Instructor review and learner-centered evaluation are required before operational deployment.

TABLE II. MAPPING LOCAL SHAP RISK DRIVERS TO PROPOSED PEDAGOGICAL NUDGE TEMPLATES

Top local risk driver	Interpretation	Candidate pedagogical nudge
Low problem_count	The learner is not practicing enough	Try to complete one or two practice problems from this week. This will help you check your understanding before moving forward.
Low video_count	The learner may not be following explanations	Return to the main video of this unit and watch the key explanation before attempting the next activity.
Low access_count	The learner is disconnected from the course	You have not accessed the course regularly. Try to log in today and review the current unit for a few minutes.
Low discussion_count	The learner is not using peer or instructor support	Visit the discussion forum and read one question related to this unit. You can also post a short question if something is unclear.
High inactivity_ga	The learner has stopped regular	You had several days without activity. Restart with one small task

Top local risk driver	Interpretation	Candidate pedagogical nudge
p	participation	today rather than waiting until the end of the week.
Low event_diversity	The learner uses only one type of resource	Try to combine watching the video with solving one problem or reading one discussion thread.
Low navigate_count / high navigate_deficit	The learner is not progressing through course objects	Open the next course object and complete one small activity before moving to other pages
High page_close_count with low active_days	The learner may leave sessions quickly	Try to spend a little more time in one session and finish one complete activity before closing the page.

Algorithm 1 summarizes the main steps of the proposed Weekly L-AXAI framework. It starts by preparing clickstream data and converting learner actions into weekly behavioral features. Then, the predictive model estimates dropout probability for each learner and selects only learners above the risk threshold. For these high-risk learners, local SHAP values are computed to identify the main actionable risk driver, which is finally translated into a pedagogical nudge for the instructor dashboard.

Algorithm 1: Weekly L-AXAI for MOOC Dropout Intervention

Input: Enrollment table E, log table L, labels Y, number of weekly windows K, risk threshold τ, predictive model f, and matrix T.

Merge E and L using the enrollment identifier.

Convert timestamps to datetime format and order learner actions chronologically

For each learner-course enrollment i **do**

  For each weekly window k = 1 to K **do**

    Select learner actions inside the weekly window W_k.

    Count access, video, problem, discussion, wiki, navigate, and page_close events.

    Compute active days, average daily events, maximum daily events, inactivity days, and event diversity

    Store weekly features

  End

End

Split the processed dataset into training, validation, and test subsets.

Compute course-level reference medians using only non-dropout learners from the training set

For each learner i **do**

  Compute weekly deficit indicators by comparing x_i with the course reference

End

Train the predictive model f on the training set.

For each learner i in the test set **do**

  Estimate dropout probability $\hat{p}_i = f(x_i)$.

  If $(\hat{p}_i \geq \tau)$ **then**

    Compute local SHAP values φ_{ij} for learner i.

    Identify the strongest positive actionable risk driver r_i.

    Generate the pedagogical action $a_i = T(r_i)$.

      Add $(i, \hat{p}_i, r_i, a_i)$ to the intervention table.

  End

End

Return the intervention table.

IV. RESULTS

The processed dataset was divided into 70% training, 15% validation, and 15% testing using stratified random sampling with random seed 42. Stratification preserved the dropout/non-dropout distribution across the three subsets. All data-dependent operations, including course-reference medians and correlation-based feature filtering, were estimated from the training subset and then applied unchanged to validation and test data. The validation subset was used for hyperparameter selection, and the test subset was reserved for final evaluation. Experiments were performed in Google Colaboratory on an NVIDIA T4 GPU with 54 GB RAM. Gradient Boosting used 250 estimators, a learning rate of 0.05, and a maximum tree depth of 3. XGBoost used 500 estimators, a learning rate of 0.05, a maximum depth of 5, a subsampling ratio of 0.85, and a column-sampling ratio of 0.85. The operational risk threshold was fixed at $\tau = 0.5$. Parameters not explicitly modified retained their corresponding library defaults. The experiments were implemented in Python using scikit-learn, XGBoost, LightGBM, and SHAP. Parameters not explicitly modified retained their corresponding library defaults.

TABLE III. COMPARATIVE RESULTS OF DROPOUT PREDICTION MODELS

Model	Number of Features	Accuracy (%)	ROC-AUC (%)	PR-AUC (%)
Gradient Boosting	72	85.79	86.57	94.41
XGBoost	72	85.77	86.57	94.45
LightGBM	72	81.28	86.34	94.28
Logistic Regression	72	80.89	86.27	94.35
SVM	72	85.1	86.18	94.33
AdaBoost	72	84.82	86.14	94.28
Extra Trees	72	83.68	86.11	94.07
Random Forest	72	85.26	85.21	93.33
Decision Tree	72	80.78	84.33	92.92
KNN	72	84.97	84.09	93.03

Table III presents the performance of the tested machine learning models using the final weekly feature set. Gradient Boosting achieved the highest accuracy point estimate, while

XGBoost produced closely comparable performance, with 85.79% accuracy, 86.57% ROC-AUC, and 94.41% PR-AUC. XGBoost obtains almost the same performance, with 86.57% ROC-AUC. The difference between the two boosting models is small, but both are above simple baselines such as Decision Tree and KNN. Fig. 2 shows the accuracy comparison for the proposed models in this study.

Fig. 2 presents the accuracy comparison of the tested classifiers using the weekly feature representation. Under the original fixed split, Gradient Boosting achieved the highest accuracy point estimate at 85.79%, while XGBoost achieved 85.77% and the same ROC-AUC of 86.57%. The 0.02 percentage-point difference is too small to support a claim of definitive superiority without repeated experiments and statistical testing. The two boosting models are therefore interpreted as closely comparable under the present evaluation protocol. Gradient Boosting is retained as the predictive backbone used for the subsequent L-AXAI explanation stage, while the main contribution of the study remains the connection between estimated risk, local explanation, and candidate pedagogical action rather than a claim of universal classifier superiority.

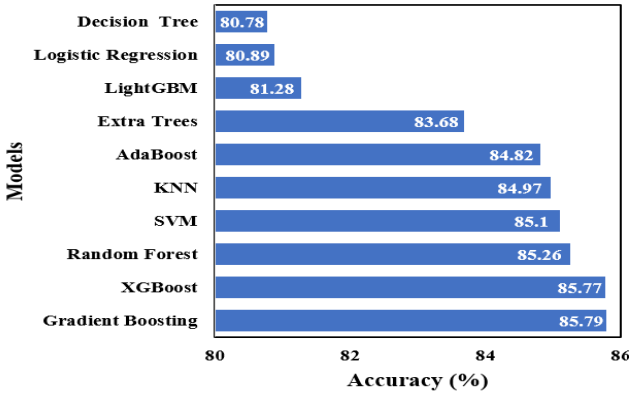

Fig. 2. Accuracy comparison of the tested classifiers.

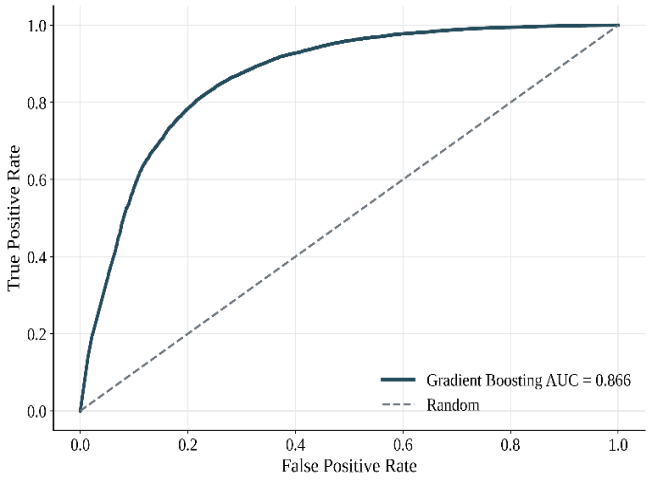

Fig. 3. ROC curve of the selected weekly model.

As shown in Fig. 3, the ROC curve confirms good discrimination between dropout and non-dropout learners. However, because the dataset is imbalanced, the precision-recall curve is more informative for the practical use of the model. The PR-AUC is high for the best models, showing that the system maintains useful precision even when the positive dropout class dominates the data.

A. Weekly Observation Horizon Analysis

The weekly horizon comparison evaluates whether useful dropout signals appear early or only after several weeks of activity. The results in Table IV show a clear improvement as the observation window grows from Week 1 to Week 4. Week 1 alone already provides useful predictive information, but the full four-week representation obtains the highest accuracy and ROC-AUC. These results show that extending the observation horizon from Week 1 to Week 4 provides additional predictive information under the current evaluation protocol.

TABLE IV. BEST MODEL FOR EACH WEEKLY OBSERVATION HORIZON

Horizon	Model	Number of Features	Accuracy (%)	ROC-AUC (%)	PR-AUC (%)
Week 1	XGBoost	20	81.28	80.33	91.95
Week 1-2	Gradient Boosting	39	83.46	84.22	93.56
Week 1-3	Gradient Boosting	58	85.26	85.92	94.17
Week 1-4	Gradient Boosting	72	85.79	86.57	94.41

B. Feature Filtering

Table V shows the highly correlated variables removed before final modelling. The weekly representation increases the number of variables because event counts, temporal indicators, and deficit variables are repeated over weeks. To reduce feature bloat, highly correlated variables were removed using a correlation threshold of 0.95. As expected, inactivity_days variables were perfectly correlated with active days variables and were removed from the final model. Several Week 4 deficit variables were also removed because they were almost redundant with access_w4_deficit.

TABLE V. HIGHLY CORRELATED VARIABLES REMOVED BEFORE FINAL MODELING

Dropped feature	Correlated with	Absolute correlation	Threshold
inactivity_days_w1	active_days_w1	1	0.95
inactivity_days_w2	active_days_w2	1	0.95
event_diversity_w2_deficit	navigate_w2_deficit	0.9548	0.95
inactivity_days_w3	active_days_w3	1	0.95
event_diversity_w3_deficit	access_w3_deficit	0.9569	0.95
inactivity_days_w4	active_days_w4	1	0.95
video_w4_deficit	access_w4_deficit	0.9751	0.95
problem_w4_deficit	access_w4_deficit	0.986	0.95
navigate_w4_deficit	access_w4_deficit	0.9844	0.95
page_close_w4_deficit	access_w4_deficit	0.9834	0.95
active_days_w4_deficit	access_w4_deficit	0.9821	0.95
event_diversity_w4_deficit	access_w4_deficit	0.9938	0.95

C. Explainability Analysis

The explainability analysis is structured on two levels. First, global SHAP analysis identifies the weekly variables that have the greatest influence on the model across the test cohort. Second, local SHAP analysis provides explanation for individual learner cases with waterfall plots and interaction plots. This setup is similar to the logic in explainability-oriented papers where global patterns and local case studies are explained at the same time.

1) Global SHAP importance: The global SHAP ranking in Table VI and Fig. 4 show that temporal intensity variables dominate the prediction. The most influential variable is "average daily events in week 3", followed by "average daily events in week 2", "active days in week 1", "average daily events in week 1", and "problem in week 1 count". This means that the model does not rely only on whether a learner logs in, but also on the intensity and regularity of weekly engagement.

TABLE VI. TOP 10 GLOBAL SHAP WEEKLY RISK DRIVERS

Feature	Mean absolute SHAP	Mean SHAP	Feature mean	Feature std
average_daily_events_w3	0.2681	-0.0274	1.265	3.794
average_daily_events_w2	0.2199	-0.041	1.455	4.121
active_days_w1	0.1953	-0.0243	1.637	1.099
average_daily_events_w1	0.182	-0.0464	5.05	6.596
problem_w1_count	0.1289	-0.0063	3.797	10.716
average_daily_events_w4	0.1287	0.0279	0.814	3.601
active_days_w4	0.0559	0.0034	0.22	0.765
access_w1_count	0.0527	-0.0029	13.308	18.743
active_days_w3	0.0404	0.0025	0.358	0.875
navigate_w2_deficit	0.0392	0.0119	0.743	0.437

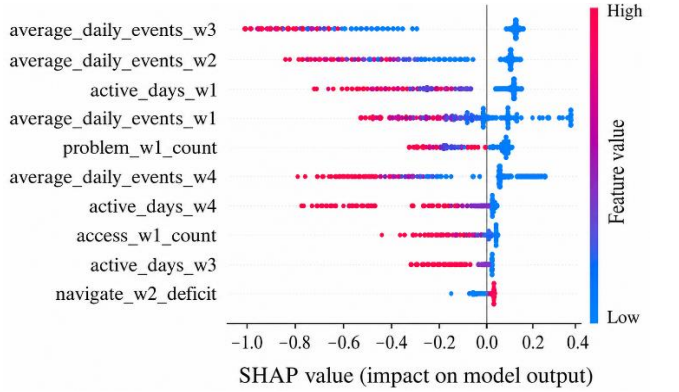

Fig. 4. Global SHAP summary plot for the selected weekly model.

2) Temporal Global SHAP evolution: In Table VII, the temporal SHAP evolution analysis shows how the type of predictive signal changes across weeks. In Week 1, temporal variables contribute 57.12% of the weekly SHAP mass, event counts contribute 35.23%, and deficit variables contribute 7.66%. In Weeks 3 and 4, temporal features become even more dominant, reaching 81.29% and 77.42%, respectively. Fig. 5 illustrates temporal SHAP evolution by weekly feature group.

TABLE VII. TEMPORAL SHAP CONTRIBUTION BY WEEKLY FEATURE GROUP

Feature type	Week	Mean absolute SHAP	Relative contribution (%)
Deficit	Week 1	0.0558	7.66
	Week 2	0.0866	19.34
	Week 3	0.0063	1.48
	Week 4	0.0008	0.29
Event count	Week 1	0.2565	35.23
	Week 2	0.0853	19.05
	Week 3	0.0731	17.24
	Week 4	0.064	22.29
Temporal	Week 1	0.4158	57.12
	Week 2	0.2758	61.6
	Week 3	0.3449	81.29
	Week 4	0.2224	77.42

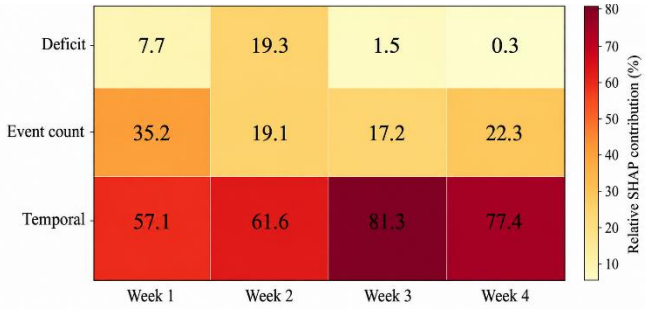

Fig. 5. Temporal SHAP evolution by weekly feature group.

3) Local SHAP waterfall analysis: Tables VIII and IX show four local cases explained with SHAP waterfall analysis. Cases A and B were both predicted as high-risk with a dropout probability of 95.98%. Cases A and B are behavioral twins selected to illustrate that identical clickstream patterns may lead to different final outcomes. Their main risk drivers are low activity in the first weeks, especially "average daily events in Week 1", "average daily events in Week 2", "average daily events in Week 3", and "problem Week 1 count". This means that early low engagement strongly pushed the model toward dropout.

Because Cases A and B have the same engineered clickstream vector, the deterministic classifier assigns them the same predicted probability and the same SHAP decomposition. Their different observed outcomes do not indicate an inconsistency in the model calculation. Instead, they show that the current feature representation is incomplete. Learner goals, prior knowledge, motivation, external time constraints, offline study, and interactions not recorded by the platform may influence persistence even when the observed clickstream behavior is identical. The pair is therefore treated as an

illustration of residual uncertainty and unobserved heterogeneity.

Cases C and D were predicted as low-risk. Their negative SHAP values show that higher weekly activity reduced the predicted dropout probability, especially high "average daily events in week 3", "average daily events in week 4", and several active days in Weeks 2 and 4. Case C is a false negative, which suggests that some dropout decisions may be caused by factors not visible in clickstream logs.

TABLE VIII. LOCAL CASE PROFILES SELECTED FOR SHAP WATERFALL ANALYSIS

Case	Case description	Drop out	Predicted dropout probability	Prediction
A	High-risk dropout	1	95.98	1
B	High-risk non-dropout	0	95.98	1
C	Low-risk dropout	1	2.46	0
D	Low-risk non-dropout	0	1.52	0

TABLE IX. TOP FIVE LOCAL SHAP CONTRIBUTIONS FOR SELECTED LEARNER CASES

Case	Rank	Feature	Feature value	SHAP value
A	1	average_daily_events_w1	0.143	0.3998
	2	average_daily_events_w3	0	0.1517
	3	active_days_w1	1	0.1378
	4	average_daily_events_w2	0	0.1245
	5	problem_w1_count	0	0.1089
B	1	average_daily_events_w1	0.143	0.3998
	2	average_daily_events_w3	0	0.1517
	3	active_days_w1	1	0.1378
	4	average_daily_events_w2	0	0.1245
	5	problem_w1_count	0	0.1089

Fig. 6-(a) and Fig. 6-(b) show that the high-risk cases are mainly explained by low engagement indicators, especially low average daily events, limited problem activity, and weak access behavior. These features push the prediction score upward and increase the predicted dropout risk. In contrast, Fig. 6-(c) and Fig. 6-(d) show that stronger weekly engagement reduces the prediction score and is associated with low-risk learner profiles. Overall, the SHAP waterfall plots demonstrate how the model explains dropout risk at the individual learner level by identifying the main behavioral factors that increase or decrease the prediction.

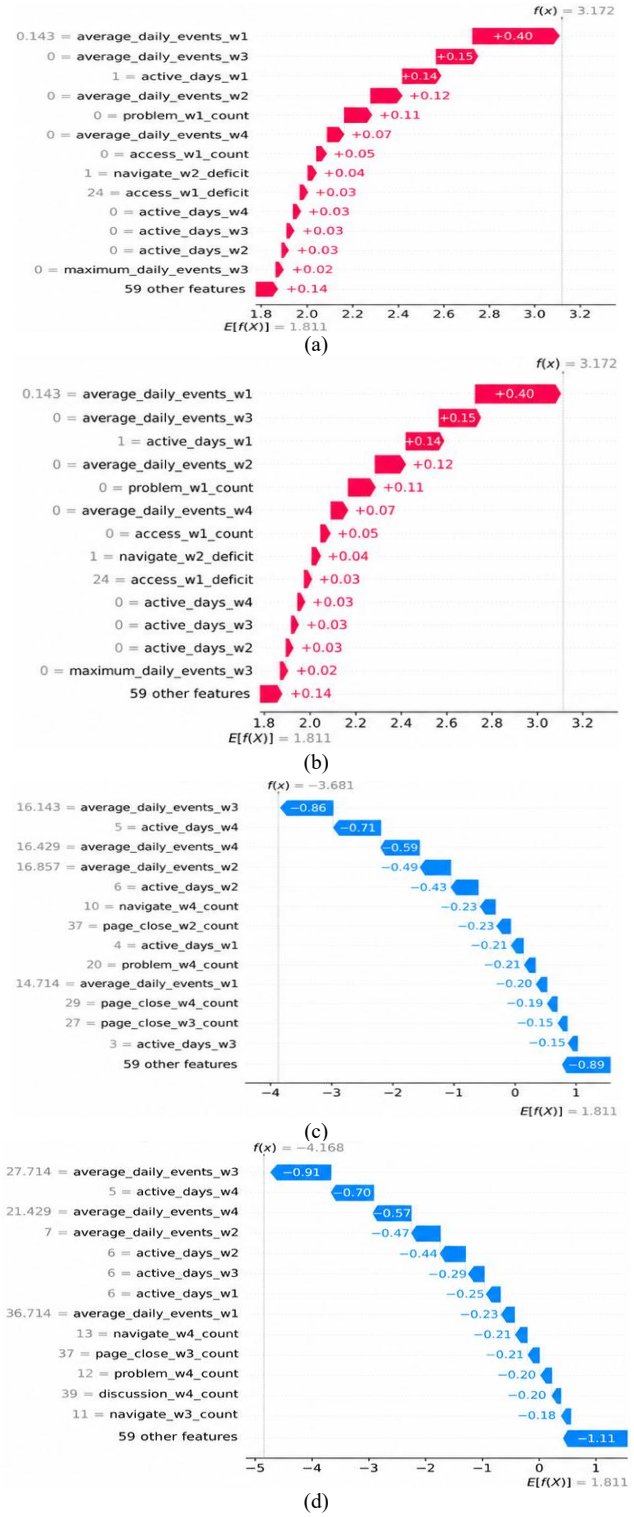

Fig. 6. SHAP waterfall plot for (a) High-risk dropout case, (b) High-risk non-dropout case, (c) Low-risk dropout case, and (d) Low-risk non-dropout case.

4) Weekly L-AXAI intervention output: As shown in Table X and XI, the weekly L-AXAI module generated 13,237 high-risk intervention records on the test set. Approximately 11,610 corresponded to actual dropout records and 1,627 to non-dropout records. The generated messages are candidate decision-support suggestions and were not evaluated with learners or instructors. Navigation nudges represented 74.62% of all candidate nudges and 89.76% of the Week 2 nudges. This concentration reflects both the behavior represented in the test set and the current one-to-one mapping rule, which selects only the strongest positive actionable SHAP driver. It may also be reinforced by correlation filtering: event_diversity_w2_deficit was removed because it was highly correlated with navigate_w2_deficit ($|r| = 0.9548$), leaving the retained navigation feature to represent part of this related Week 2 signal. The distribution should therefore not be interpreted as a universal pedagogical pattern. For future deployment, correlated drivers should be grouped into broader support families, the top-k actionable drivers may be considered, course-specific thresholds should be used, repeated delivery of the same message should be limited, and instructor approval should be retained. These safeguards are proposed design recommendations and were not empirically tested in the present study.

TABLE X. OVERALL DISTRIBUTION OF WEEKLY L-AXAI NUDGE TYPES

Nudge Type	Count	Percentage
Navigation nudge	9,877	74.62
Re-engagement nudge	2,300	17.38
Session completion nudge	962	7.27
Regularity nudge	57	0.43
Content review nudge	33	0.25
Balanced engagement nudge	8	0.06

TABLE XI. WEEKLY DISTRIBUTION OF L-AXAI NUDGE TYPES

Week	Nudge Type	Count	Percentage within week
1	Balanced engagement nudge	8	0.39
	Content review nudge	33	1.6
	Re-engagement nudge	1,142	55.28
	Session completion nudge	883	42.74
2	Navigation nudge	9,812	89.76
	Re-engagement nudge	1,116	10.21
	Regularity nudge	1	0.01
	Session completion nudge	2	0.02
3	Navigation nudge	65	32.83
	Regularity nudge	56	28.28
	Session completion nudge	77	38.89
4	Re-engagement nudge	42	100

V. DISCUSSION

The results describe the predictive performance of the complete weekly feature representation under a stratified train-validation-test evaluation setting. Stratification preserves the dropout and non-dropout distribution in the three subsets. This is important since the dataset is imbalanced. Thus, the reported performance measures the ability of the model to distinguish dropout from non-dropout students with similar class distributions during the training, validation, and testing phases.

The evaluation should be interpreted as a stratified within-benchmark and within-distribution comparison. Training-only estimation of course-reference medians and feature filters prevents direct use of validation or test labels, but the random split does not provide chronological, learner-independent, or course-independent separation. Learner-course records with similar behavioral patterns may therefore occur across subsets, and the reported metrics may be optimistic relative to deployment on completely unseen courses or future cohorts. The findings do not establish cross-platform generalizability. Transfer to another MOOC environment would require event-schema harmonization, verification of the dropout definition and observation horizon, re-estimation of reference medians, probability recalibration, and contextual review of the translation matrix.

The best predictive performance was obtained by tree-based boosting models. Gradient Boosting and XGBoost performed very similarly, and Logistic Regression and SVM stayed competitive. This suggests that weekly clickstream features contain strong predictive signals that can be exploited by linear and non-linear models.

The explainability analysis identifies model-associated behavioral patterns within the present dataset. The SHAP summary plot and local case analysis indicate how weekly activity intensity, active days, and early problem engagement contributed to the selected model's predictions. These associations should not be interpreted as causal determinants of dropout because clickstream logs omit learner goals, prior knowledge, offline study, motivation, and contextual constraints. Explanation stability across repeated training runs, permutation-based validation, and comparison with alternative explainability techniques were not evaluated. The reported SHAP patterns should therefore be interpreted as descriptive explanations of the selected model under the current split rather than as universally stable behavioral findings.

The temporal SHAP analysis describes how the selected model's attribution patterns vary across weekly feature groups. Temporal features are more important in later weeks, while the role of event-count and deficit features depends on the observation window. Therefore, the dropout risk should not be seen as a constant. The features that explain dropout risk in Week 1 are not the same features that explain dropout risk in Weeks 3 or 4. These findings provide a temporal description of the selected model's explanations, but they do not independently establish the predictive contribution of each feature family.

Interpretation at the learner level is emphasized in the local waterfall analyses. Two learners may have similar high-risk probabilities, but their explanations may reflect different combinations of weak activity, limited practice, or low weekly intensity. The high-risk non-dropout case also illustrates a limitation of prediction using clickstream data alone: some learners can behave like dropout learners but still persist. L-AXAI nudges should therefore be seen as supportive signals, not as punitive decisions.

Intervention analysis shows that local explanations can be translated into pedagogical actions at scale. But the strong dominance of navigation nudges should be treated with caution. This could be a real behavior pattern in the test set, or it could be that the translation matrix is giving a lot of priority to navigate_w2_deficit . The intervention matrix should be tuned in future work using feedback from instructors, learner-response data, and A/B testing to ensure that the nudges generated are varied, useful, and not repetitive.

VI. Conclusion

A weekly Localized Actionable Explainability framework for MOOC dropout prediction and intervention was proposed. Clickstream behavior is represented through weekly event counts, temporal indicators, and course-referenced deficit features, after which estimated dropout risk is linked to a local SHAP driver and a transparent candidate nudge template. Under the fixed stratified test split, Gradient Boosting achieved 85.79% accuracy, 86.57% ROC-AUC, and 94.41% PR-AUC, while XGBoost produced closely comparable results. Because repeated-seed experiments and statistical significance tests were not conducted, the small performance differences should be interpreted cautiously. The weekly-horizon analysis indicates that additional weeks provide progressively more predictive information, but a complete feature-family ablation was not performed. SHAP identified model-associated patterns involving activity intensity, active days, and early problem engagement; these findings are descriptive and were not validated through repeated-run stability or alternative explainability methods. The intervention layer generated candidate nudges dominated by navigation, re-engagement, and session-completion categories. This concentration requires diversified driver selection, repetition limits, and instructor-controlled delivery. Because no instructor panel, learner study, or controlled intervention trial was conducted, pedagogical effectiveness and perceived pressure remain unverified. The findings are limited to the KDD Cup 2015 benchmark and a stratified within-distribution protocol. Future work should examine repeated-seed, learner-grouped, course-held-out, and chronological evaluation; formal probability calibration; component-wise ablation; explanation-stability analysis; cross-platform event harmonization; expert co-design of the translation matrix; and real-world intervention studies.

***Abstract*—Worldwide, individuals, businesses, and economies are being affected by counterfeit currency significantly. Numerous models generate content that mimics the original, and existing solutions fall short in detecting the difference between real and fake. This study presents a detection system using three deep learning models: Deep Convolutional Generative Adversarial Network (DCGAN), Convolutional Neural Network (CNN), and Fully Connected Neural Network (FCNN). The proposed study also identifies patterns that contribute to real and fake currency when the models are trained on the data. After training the models, the proposed solution receives an accuracy of 95 per cent, an F1 Score of 0.957, 0.95 as precision, and 0.954 as recall. This study further carries out a comprehensive analysis of existing models and compares them with the proposed solution to determine the effectiveness of the solution and further recommend its implementation in real-world applications. The proposed solution contributes to the widespread adoption of the application across smart devices and further ensures a robust solution for the detection of counterfeit money.**

I. Introduction

Counterfeiting pertains to the unlawful replication of a specific object, notably the currency of its original form. The repercussions of counterfeit currency can be detrimental to an economy, causing an upsurge in prices, fostering black market activities, influencing trade, business transactions, and administrative operations [1]. Currency counterfeiting persistently poses a formidable challenge to the financial systems of nations [2]. It involves the illicit replication of the official currency, hence lacking the authorization of the government, and poses a substantial menace to the global economy [3]. The production of counterfeit currency, also referred to as counterfeit money, is universally illegal since it transpires without the sanction of the central bank or the governing authority. The history of counterfeit currency traces back to antiquity, emerging nearly simultaneously with the inception of currency itself. It stands as one of the world's oldest illicit professions, even predating Lydian coins. The Lydian Stater, which predated the fall of the Lydian Empire to the Persian Empire, represented the inaugural instance of an officially issued coin by a government in recorded history [4]. Counterfeit coins, known as Fourree, were crafted by amalgamating base metals with pure gold or silver.

Modern approaches to discern genuine from counterfeit currency primarily rely on advanced image processing techniques. These methods encompass image acquisition, edge detection, feature extraction, image segmentation, and decision-making processes. Noteworthy security features include watermarks, concealed images, security threads, and optically variable inks [5]. However, the primary limitation of these approaches lies in their suboptimal detection efficiency, particularly regarding feature extraction [6]. To surmount this challenge, deep learning methodologies have emerged as compelling solutions. These techniques deploy multi-layer neural networks to facilitate the detection of counterfeit currency. While increasing the layers in neural networks can lead to greater complexity and higher error risks, convolutional neural networks (CNNs) offer a promising alternative [7]. Unlike fully connected layers, CNNs use filters that focus on important aspects of input data, scanning across the entire input data space to extract relevant features for specific tasks. CNNs are known for their power and efficiency, especially compared to traditional deep neural networks. In today's technologically advanced world, it has become easier to produce counterfeit currency without legal authorization, significantly impacting a nation's economy. The Malaysian Ringgit (MYR), issued by Bank Negara Malaysia (BNM), is particularly vulnerable to counterfeiting, especially in denominations of MYR 1, MYR 5, MYR 10, MYR 20, MYR 50, and MYR 100. In the field of computer science, many machine learning algorithms have been proposed for image processing. These methods detect and recognize currency notes by analyzing specific attributes such as color, shape, paper width, and image filtering.

In this study, three deep learning models were employed to develop an effective counterfeit currency detection system: Convolutional Neural Network (CNN), Fully Connected Neural Network (FCNN), and Deep Convolutional Generative Adversarial Network (DCGAN). CNNs are widely recognized for their ability to process and analyze images by automatically extracting meaningful features through multiple layers, making them as potential for visual recognition tasks. FCNNs complement this process by utilizing fully connected layers to perform accurate classification based on the features extracted

from the input data. To further enhance detection performance, the study incorporates DCGAN, an advanced deep learning framework within the field of generative artificial intelligence. DCGAN consists of two interconnected components: a Generator and a Discriminator. The Generator learns the underlying patterns of genuine currency notes and produces realistic synthetic samples, while the Discriminator evaluates these samples and distinguishes between authentic and generated data. Through this adversarial learning process, the model becomes highly effective at identifying subtle characteristics of counterfeit currency, leading to improved detection accuracy and robustness.

A. Motivations and Research Gap

The problem of counterfeit money continues to pose a challenge and threat in the economic world. Traditional methods of counterfeit detection, such as manual inspection and simple image processing techniques, have proven inadequate in keeping up with the sophisticated techniques employed by counterfeiters [8]. This research aims to fill the gap by leveraging advanced deep learning techniques to enhance the detection accuracy and reliability of counterfeit currency identification. Specifically, the existing challenges and gaps that our research addresses include:
