- Inefficiency of Traditional Methods: Traditional methods of counterfeit detection are labor-intensive and prone to errors, particularly in the case of high-quality counterfeits.
- Lack of Robustness in Existing Models: Previous models lack the robustness required to detect subtle variations and sophisticated counterfeiting techniques.
- Integration of Security Features: While some methods incorporate security features, they fail to ensure the integrity and traceability of detection results.
- DCGAN was selected because access to diverse counterfeit currency samples is limited. The generator produces synthetic counterfeit-like variations, while the discriminator learns to distinguish subtle visual differences between genuine and generated samples. This adversarial training exposes the discriminator to a broader range of counterfeit patterns than conventional supervised training alone. CNN and FCNN were included as baseline discriminative models for comparison.

B. Problem Statement

The presence of counterfeit currency causes negative impacts on the economy of the nation, which can lead to inflation and losses, both to the country and its people. In addition, this leads to distrust of the integrity of the currency, especially when conducting business. Upon careful analysis of the various methods that have been put in place to differentiate between the two, it becomes clear that traditional methods have been used before.

However, the counterfeiting technique has advanced to such a degree that the changes introduced into counterfeit notes escape detection through conventional machine learning methods. In this regard, in this study, deep learning algorithms have been employed on the basis that they can detect complex patterns in better ways. The problem is solved through the introduction of a strong system for counterfeit money detection. The proposed approach should be quite efficient to meet the needs of governments, financial organizations, companies, retailers, and even customers in distinguishing real currency from counterfeit currency. Consequently, the following noteworthy contributions have been made throughout the development of the proposed solution.

C. Contribution

This study proposed a framework for counterfeit currency detection which can help government agencies and banking sectors to distinguish genuine currency from counterfeit currency in an expedited manner. The contribution of this study is provided below:

- Novel Deep Learning Framework: This research presents an extensive framework for counterfeit currency detection based on advanced deep learning models such as DCGAN, CNN, and FCNN. Specifically, the DCGAN model performs better in recognizing counterfeit notes by capturing complex patterns that other models find hard to detect.
- Cross-Currency Applicability: The system proposed is not specific to any one currency. It has been effectively used to detect counterfeit Malaysian Ringgit (MYR) and Saudi Arabian Riyal (SAR). It can be extended to other currencies with minor adjustments in training.
- Performance Superiority: The proposed approach based on DCGAN achieves better accuracy, precision, recall, and F1 score compared to other existing methods, with 95.11% accuracy, 0.95 precision, 0.954 recall, and 0.957 F1 score. A comparative analysis with previous work clearly demonstrates the superiority of our method.
- Cost-Effective and Scalable: The framework is designed to be inexpensive and scalable, providing a robust solution for large-scale counterfeit detection and easy integration with smart devices and financial systems.

This research study is structured as follows: The study opens with a short overview of the work that was done in Section I. Section II offers an in-depth review of related work in the field and discusses its strengths and weaknesses. Section III shows how the authors addressed the gap as part of methodology. Section IV presents experiment settings followed with the experimental results and discussion drawn from all experiments using the proposed framework in Section V. Section VI presents a complete set of conclusions and recommendations and finally drafting the future work is presented in Section VII.

II. Related Work

The authors in [9] developed a system based on image processing techniques, utilizing OpenCV (CV2), Support Vector Machine (SVM) classifier, and other machine learning algorithms to extract image features. They compared these features with the genuine characteristics of banknotes. They effectively employed CNN to detect counterfeit currency.

An innovative approach to counterfeit currency detection using transfer learning was introduced by the authors in [10]. They employed AlexNet as a pre-trained model, consisting of convolutional layers, max-pooling layers, dropout layers, ReLU activations, and fully connected layers. To facilitate transfer learning, they removed the last three fully connected layers of AlexNet and adjusted it with weight and bias learning factors to extract latent features from currency images. Their training set was comprised of currency note images, augmented with 100 variations per image by altering the size and orientation, thereby increasing dataset diversity. The increased images were placed in folders according to the corresponding labels. The authors achieved average accuracy rates of 81.5% for genuine currency and 75% for counterfeit currency.

Kumar et al. [11] proposed a robust system for detection of counterfeit Indian rupee notes using ORB (Oriented FAST and Rotated BRIEF) and OpenCV's Brute Force matcher. Their system was based on digital image acquisition, grayscale conversion, edge detection, image segmentation and feature extraction. It has two modules, one is to extract security features and create database and other is to authenticate images from the test dataset. They achieved a significant average accuracy of 95.0% indicating the system is cost effective.

Pachon et al. [12] used artificial neural networks (ANNs) for banknote authentication. For their research they took data from specially created images for the purpose of improving currency classification accuracy with the help of Back Propagation algorithm. Their suggested procedure was image acquisition, conversion to grayscale, wavelet transformation, image segmentation, and classifier application. But they provided no details on implementation, results or average accuracy metrics.

In [13], Chandrappa et al. suggested a methodology for extracting critical information from the images of counterfeit money using bit plane slicing. This was done by decomposing 256 grayscale images into eight binary images, each representing different bit planes and applying edge detection techniques. They found that the sixth and seventh bit planes greatly improved edge and hidden element detection in the images. The methodology was implemented using image processing toolbox in MATLAB.

Teymournezhad et al. [14] proposed a system that combines image processing techniques and a deep learning network named GoogLeNet. The proposed work utilized the pre-trained GoogLeNet. It demonstrated high accuracy in detecting the security features of the genuine banknotes but low accuracy for the counterfeit samples. Image preprocessing steps consist of scaling, noise removal, sharpening, brightness adjustment, image segmentation and corner recognition. A 22-layer GoogLeNet was used for object recognition across a wide range of classes. The system was implemented in MATLAB R2018b on a Windows 7 platform.

Chowdhury et al. [15] proposed an automated authentication model using irregular color particles under UV light with UV ink as a security feature. The model achieved an accuracy of 96.3%. They used Region Proposal Network Stages (RPNs) to estimate quickly the regions of interest of different scales and aspect ratios.

Nur Farah et al. [16] used video spectral comparator (VSC), ATR-FTIR for chemical profiling and PCA for pattern recognition to differentiate genuine from counterfeit banknotes. Their methodology involved sample collection, physical and optical examinations, IR spectra acquisition, pattern recognition application, and PCA. However, their study lacked implementation, accuracy, and conclusive findings.

The authors in [17] used generative adversarial networks (GANs) for detecting fraudulent currency. GANs employed unsupervised learning to make supervised predictions, demonstrating high precision with an expanded image dataset. Their study included various deep learning models, achieving an accuracy rate of 80%. They highlighted the potential for enhancing accuracy with multi-class classifiers.

A standard currency identification system that makes use of edge detection, feature extraction, image segmentation, acquisition, grayscale transformation, and comparison was developed by Bandu et al. [18]. The research made use of CNN for pattern and image recognition, and suggested the use of SHA as an identifier for counterfeit currency depending on its physical characteristics. Nevertheless, the authors did not give system implementation and accuracy evaluation.

Nasayreh et al. [19] used different CNN architectures for identification of fake Jordanian bank notes and obtained competitive levels of accuracy using optimized AlexNet and GoogleNet models. The modifications in VGG16 resulted in maximum accuracy of 99.88%. Their approach can be implemented in automated payment systems and mobile currency checking. Aulia et al. [20] showed the recognition and classification of paper currency for Saudi Arabian Riyal denominations using Geometric Template Matching and Grayscale Template Matching techniques.

III. METHODOLOGY

This section presents the proposed methodology for detection of counterfeit currency, as shown in Fig. 1. The proposed framework is composed of the following components:

- Dataset
- Generator
- Latent Space
- Discriminator
- Fine-tuning

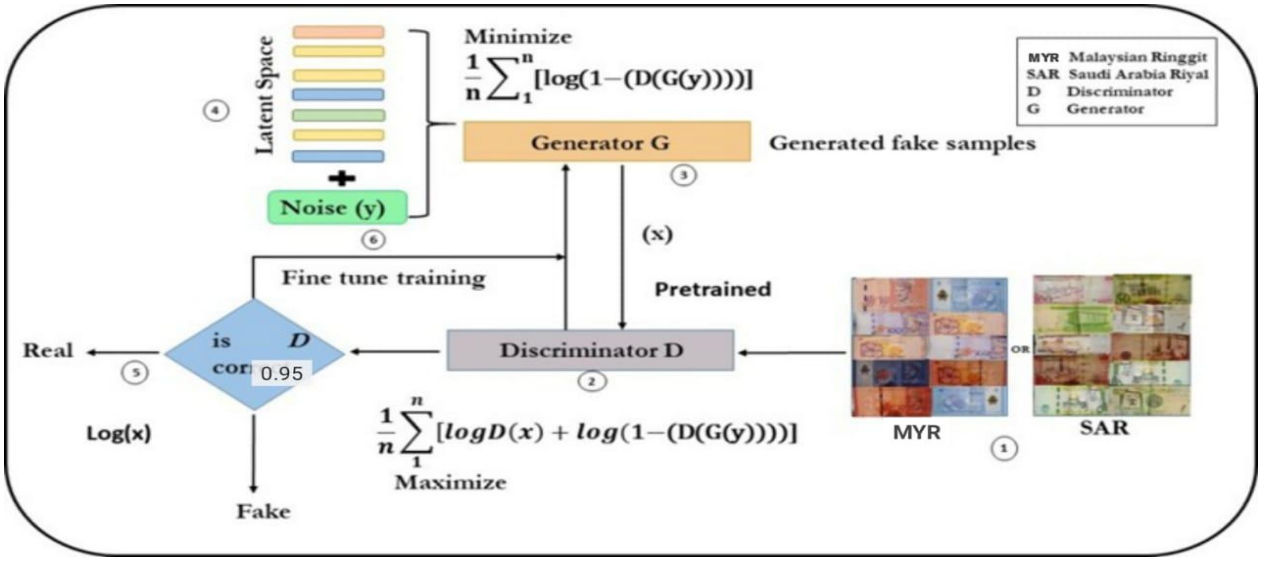

Fig. 1. Proposed framework for counterfeit currency detection using DCGAN.

A. Dataset

In this model, the system is designed to accept input data in the form of Malaysian Ringgit (MYR) and Saudi Arabian Riyal (SAR) currency notes. The dataset used in this study consisted of 15,148 images of Malaysian Ringgit (MYR) and Saudi Arabian Riyal (SAR) currency notes, including both genuine and counterfeit samples. The genuine images were taken using a phone, while counterfeit samples were generated using the generative component of the DCGAN. All images were resized to 128 × 128 pixels and converted to RGB format before training. The dataset was divided into 80% training data and 20% testing data, with 20% of the training portion used for validation. The class-wise distribution of genuine and counterfeit images should also be reported. However, it is important to note that this system can be adapted to verify the authenticity of currency notes from any denomination if it undergoes proper training with an adequate dataset. The flexibility of this solution allows for its application to various currencies by ensuring the model receives appropriate training. It's worth noting that there is no access to individuals involved in the production of counterfeit currency. Hence, an artificial function is employed to generate simulated counterfeit currency samples. These synthetic samples are utilized as representations of counterfeit currency notes and are generated by a dedicated algorithmic generator.

B. Generator

The framework employs the DCGAN model, originally proposed by Radford et al. [21], which has shown remarkable capabilities in generating realistic data samples and improving classification tasks. The DCGAN generator component generates fake samples by using latent space. A generator uses a mathematical formula and gives input in the digital form of the currency. The fake samples produced by the Generator are sent to Discriminator.

C. Latent Space

The latent space is like a database in which currency notes along with some noises are added in the digital form. With latent space, the generator gives output in the digital form of the currency. In this way, we have real and fake currency.

D. Discriminator

The discriminator's main function is to evaluate whether a currency sample, generated by a dedicated generator, is genuine or counterfeit. This is achieved through a training process where the discriminator learns to distinguish between real and fake currency notes. The system works accurately when the discriminator correctly identifies a genuine note as real and a counterfeit note as fake. If the discriminator incorrectly classifies a genuine note as counterfeit, corrective measures are taken to improve its performance. This fine-tuning process aims to enhance the discriminator's accuracy in differentiating between real and fake currency. The goal is to minimize the probability of the generator's output being mistaken while maximizing the discriminator's accuracy. In practice, the discriminator should aim for a probability of 1 when assessing genuine notes, indicating a correct decision. Conversely, a probability of 0 indicates an incorrect judgment. Therefore, the objective is to reduce the number of such erroneous classifications.

E. Fine-Tuning

Fine-tuning is a critical step in transfer learning, involving the adaptation of pre-trained model weights to new data instances. When the discriminator incorrectly identifies genuine currency as counterfeit, it indicates an error in its decision-making. To address this, a fine-tuning process is initiated to improve the discriminator's accuracy. This corrective procedure enhances the discriminator's ability to accurately distinguish between authentic and counterfeit currency notes, thereby increasing its overall proficiency.

IV. Experimental Settings

To provide a comprehensive understanding of the methodology and facilitate reproducibility, a detailed information about the models and settings employed in the proposed work are presented. The DCGAN model architecture consists of two main components: the Generator and the

Discriminator. The Generator starts with a 100-dimensional noise vector as input. It includes a dense layer with 128 units, utilizing ReLU activation and batch normalization to stabilize the learning process. This is followed by upsampling layers, which are paired with Conv2DTranspose layers. These layers have filters of sizes 128, 64, and 32, with a kernel size of 5x5, strides of 2x2, and 'same' padding, all using ReLU activation. The last layer of the Generator is a Conv2DTranspose layer which generates the output as RGB images of size 128x128x3, with a 5x5 kernel, 1x1 strides, 'same' padding, and tanh activation. After each Conv2DTranspose layer, dropout layers with rate 0.3 are used to prevent overfitting.

The Discriminator on the other hand takes as input 128x128x3 RGB images. It consists of Conv2D layers with filter sizes of 32, 64 and 128. Kernel size is 5x5, stride is 2x2 and padding is 'same'. These layers use LeakyReLU activation with a slope of α=0.2 which allows a small gradient when the unit is not active. After each Conv2D layer, the research added a dropout layer with a rate of 0.3 to further regularize the model. Finally, the Discriminator ends with a dense layer with 1 unit and sigmoid activation to output the probability of the input image being real or fake. For training, the model is run for 10 epochs with a batch size of 128. The research uses the Adam optimizer with learning rate 0.0002 and decay rate β=0.5. The Generator and Discriminator are using binary cross entropy for their loss functions. The loss functions tell your model what to learn.

A. Test Bed Environment

This study focuses on the experimental setup for training a DCGAN. The training was carried out on a GPU based machine at the Cyber Security and Technological Convergence department, Malaysian Institute of Information Technology, University Kuala Lumpur. The architecture used Keras with TensorFlow as a backend. The Keras library was used with several components such as dense layers, the dropout technique, activation functions, and flatten options. The dense layer was employed to tune the filters to detect the various attributes of the currency notes under examination.

The dropout method helped to reduce overfitting and remove extraneous features that did not add to the proper labeling and the real look of the notes. The “ReLU" activation function was chosen and it was responsible for clipping the input values in the range of 0 to 1. The datasets consisted of the real and counterfeit currency samples which were used to train DCGAN, CNN, and FCNN. The DCGAN framework consisted of two simple components, the Discriminator (D) and the Generator (G). These components were trained with a learning rate of 0.0002. Specifically, the training process is to update the discriminator, then update the generator twice. In this way the discriminator was prevented from minimal loss.

The results of the learning process were generated and well documented. A specific hardware and software environment was required for the development of the proposed framework. The primary memory capacity used in this study was 16 GB with GPU-supported hardware, including the NVIDIA P100 Kernel. All the experiments were performed on the Linux Operating System. With a minimum system configuration of Intel(R) Xeon(R) processor with a clock speed of 0.82 GHz to 1.59 GHz, 2 cores, and 16 GB memory, the experiments are reproducible.

B. Training of Deep Learning Models

During the training of the models, the dataset was divided into three separate datasets: a training set, a validation set, and a test set. The details are provided as follows:

1) Training set: It is the first dataset, used to train the model to learn the complex features of real currency notes in each iterative step. This immersive training allows the model to make accurate predictions when faced with totally new, never-before-seen data. In this work, the dataset is split into 80% training set and 20% test set.

2) Validation set: The validation set is a subset of the training set that is set aside from the training set during each epoch of training. During the training, the model is validated with data from this set. The division of training and validation data enables the model to learn from training data and test the model on the validation set. Importantly, this validation process provides insights that can be used to tune the hyperparameters. The model then classifies and evaluates each input of the validation set during training based on the acquired knowledge of the training set. In this work, 20% of the training data is used as the validation data.

3) Test set: After training and validating the models, they can be applied to predict results for the data of the test set. The 20% test set, not to be used in the training or validation set, is held for the final evaluation of the model. The test set should preferably have no labels and serve as an unbiased evaluation of the predictive ability of the model. The training and validation sets, however, are annotated, making it easier for the model to learn.

V. Results and Discussion

This section presents details of classification results obtained after training deep learning models on real and fake currency notes. The following subsections outline the various performance indicators of the employed models.

A. Performance Analysis of Employed Models

Metrics used in performance evaluation include accuracy, recall, precision, and F1 scores. These measures are critical in measuring the efficiency of different deep learning models used in the study. The study involves the exploration of different parameters that will help in converging to get accurate results. The normal confusion matrix is composed of four categories that include false negative, false positive, true positive, and true negative. In this particular study, “positive" refers to fake currency, whereas “negative" refers to the real currency. For the DCGAN model that analyzed 15,148 images, there were two categories under consideration – positive and negative. Conversely, in the Positive case, the predicted negative instances amounted to 350, with 7,802 predicted positive instances. Notably, DCGAN exhibited the most favorable results among all models.

The CNN model also processed 15,148 samples, however, the negative case resulted in 5,800 predicted negative currency notes and 1,696 predicted positive instances. In the positive case, there were 1,648 instances of predicted negative currency notes and 6,004 predicted positive instances. Finally, examining the

FCNN model, with the same dataset of 15,148 samples, the negative case yielded 5,528 predicted negative currency notes and 2,757 predicted positive instances. In the positive case, the predicted negative instances totaled 2,535, with 4,328 predicted positive instances.

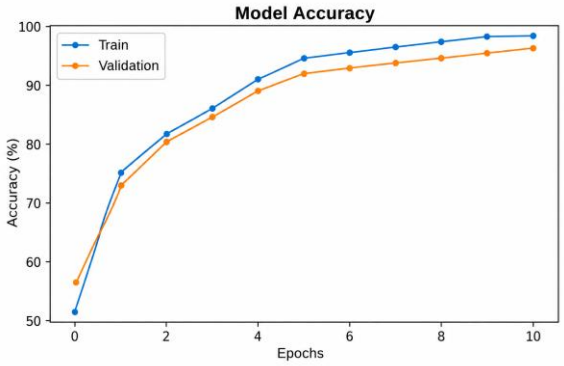

Fig. 2. Accuracy of the DCGAN model.

Fig. 2 shows the trend of the model's accuracy for the DCGAN model. The blue line represents the training trend, while the orange line shows validation accuracy. The figure shows that both the training and validation accuracies are improving with each epoch and finally reach 95%.

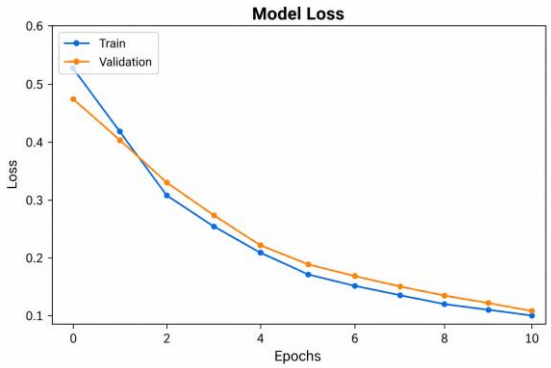

Fig. 3. Loss of the DCGAN model.

Fig. 3 represents the loss function of the model. It is clear from the graph that the loss of training and validation is decreasing after each epoch. Overall, the models represent a good fit.

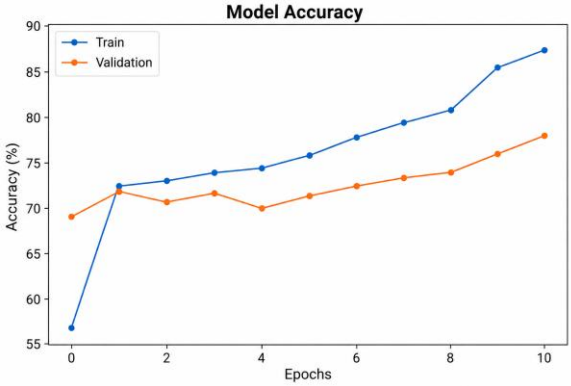

Fig. 4. Accuracy of the CNN model.

Fig. 4 represents the accuracy of CNN model in detecting the Counterfeit currency. It is evident from the above trend that validation accuracy is not improving as training accuracy does. Validation accuracy starts from 70% and after fluctuation reaches to 77%.

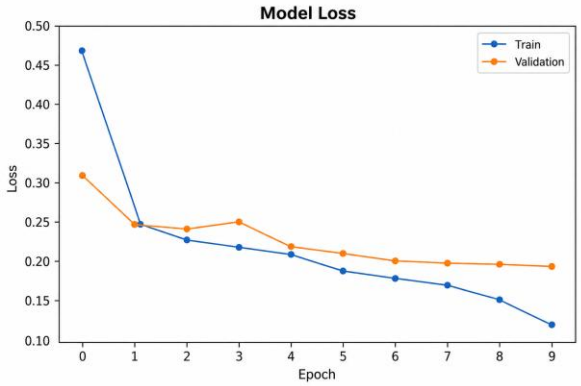

Fig. 5. Loss of the CNN model.

Fig. 5 shows the loss of CNN model. The training loss is constantly decreasing and reaches to 0.1 while validation loss is not decreasing as such. Overall, the model does not reflect a good fit.

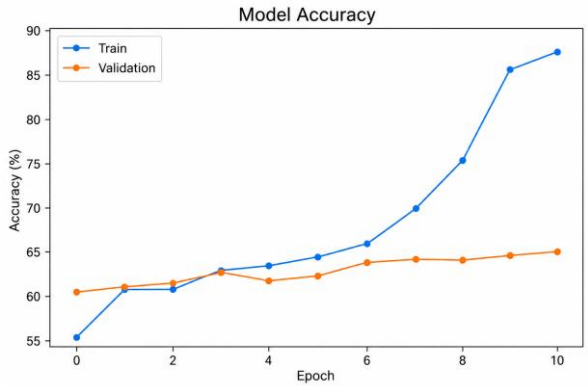

Fig. 6. Accuracy of the FCNN model.

Fig. 6 represents the accuracy trend of FCNN model. The trend indicates that training accuracy is improving with each epoch, however, the validation accuracy is not improving as such.

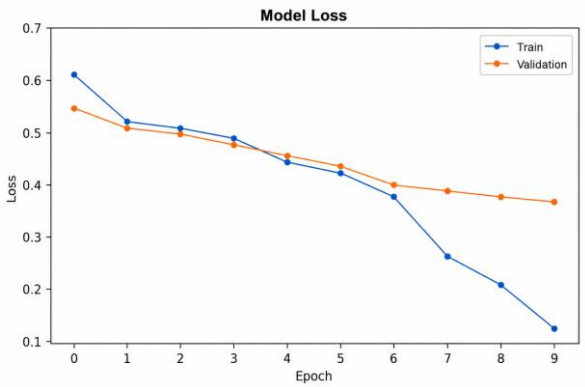

Fig. 7. Loss of the FCNN model.

Fig. 7 shows the loss function of FCNN. The training loss is decreasing constantly and reaches to 0.1 from 0.6. On the other hand, validation loss initially decreased and then remained stagnant. Overall, the mode seems to be overfitting.

The confusion matrix for DCGAN, CNN and FCNN is provided in Table I.

TABLE I. CONFUSION MATRIX OF THE DCGAN, CNN AND FCNN MODELS.

Model	Cases	Predicted Negative	Predicted Positive
DCGAN	Negative Cases	6606	390
	Positive Cases	350	7802
CNN	Negative Cases	5800	1696
	Positive Cases	1648	6004
FCNN	Negative Cases	5528	2757
	Positive Cases	2535	4328

The results of employing the state-of-the-art deep learning approaches to classify real and fake currency is depicted in Fig. 8.

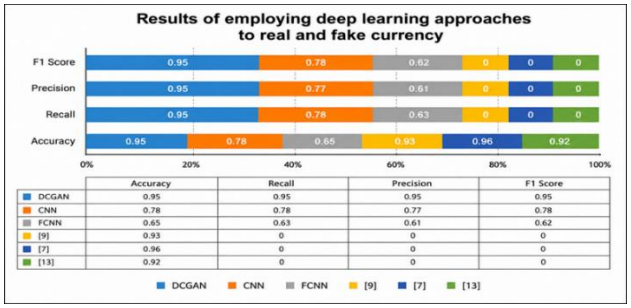

Fig. 8. Results of deep learning approaches to detect genuine currency.

B. Real-Time Complexity Analysis of the Proposed Approach

The proposed counterfeit currency detection framework leverages DCGAN, CNN, and FCNN. The real-time performance of these models is influenced by several factors, including the model's architecture, the size of the dataset, and the computational resources available.

1) DCGAN Complexity:

a) Training complexity: The DCGAN architecture consists of a Generator and a Discriminator, both of which are optimized concurrently during training. The time complexity of training the model depends on the size of the input image (n), the number of layers (L), and the number of parameters in each layer. Given that backpropagation is performed for both the Generator and Discriminator in each epoch, the overall training complexity can be approximated as O(2×n×L).

b) Inference complexity: During inference (real-time detection), the complexity is significantly reduced since only the Discriminator is used to classify an image as genuine or counterfeit. For a DCGAN with L layers, the inference complexity is approximately O(n×L), making it feasible for real-time applications.

2) CNN and FCNN complexity:

a) CNN complexity: CNNs rely on convolutional operations that have a time complexity of O(k×n2×m2), where k is the size of the filter, n×n is the size of the input image, and m×m is the size of the output feature map. While training a CNN is computationally expensive, involving multiple convolutional and pooling layers, inference complexity is relatively low. This makes CNNs suitable for real-time detection scenarios).

b) FCNN complexity: FCNN models, with their fully connected layers, have a time complexity of O(n2×L), where n is the number of neurons in the layer and L is the number of layers. While FCNNs offer high accuracy, they may be less efficient than CNNs and DCGANs in terms of real-time performance due to the fully connected layers, which introduce higher computational demands.

3) Real-time feasibility: For real-time applications, the key factor is inference time. DCGAN's Discriminator, once trained, has a low inference complexity, which makes it well-suited for real-time currency detection. CNNs also offer efficient inference with low latency, though FCNNs may introduce slightly higher inference times due to their dense architecture.

4) Overall real-time performance: While training deep learning models like DCGAN, CNN, and FCNN can be computationally intensive, the real-time complexity for detection (inference) is significantly lower. DCGAN, in particular, offers a balance between accuracy and efficiency, with real-time classification complexity at O(n2×L), making it ideal for deployment in environments where rapid and accurate counterfeit detection is required. As mentioned earlier, the research conducted experiments using a system configuration consisting of an NVIDIA P100 GPU, 16 GB of memory, and an Intel Xeon processor.

Given the DCGAN model's architecture and the number of image samples (15,148), the training time for the DCGAN model was approximately 3-4 hours for 10 epochs with a batch size of 128.

C. Model Accuracy

The experimental results demonstrated that DCGAN obtained a highest accuracy of 95% in detecting counterfeit currency. The accuracy rate is determined using Eq. (1):

$$Accuracy = \frac{Numberofcorrectlyidentifiedsamples}{Totalnumberofsamples} \quad (1)$$

The accuracies of various models employed are presented in Fig. 9.

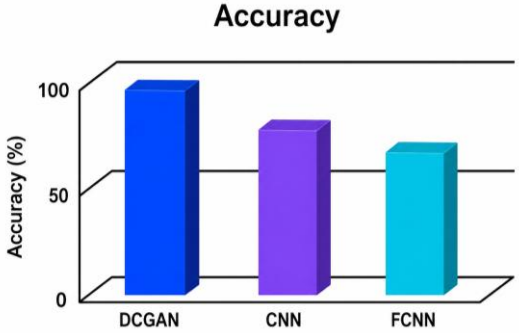

Fig. 9. Accuracy obtained by various models.

D. Recall

The recall metric is employed to measure the performance of the algorithm for recognizing the positives, as illustrated by Eq. (2). The True Positives (TP) refer to the total number of cases which were correctly predicted by the model to be positive (counterfeit currency), while the False Negatives (FN) denote those cases which have been wrongly recognized as negatives (genuine currency).

$$\text{Recall} = \frac{TP}{TP+FN} \quad (2)$$

Recall obtained by different models is presented in Fig. 10. It is evident that DCGAN surpassed other models in terms of recall.

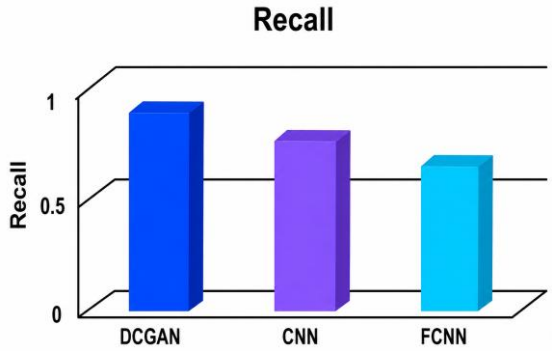

Fig. 10. Recall obtained by various models.

E. Precision

This is the measure that is used to determine the precision of the model's positive predictions, as seen in Eq. (3). The measure is used to find the fraction of true positive predictions among all the positive predictions made by the model. True Positive (TP) is the number of correct positive predictions and False Positive (FP) is the number of wrong positive predictions, where the model predicted a positive outcome (counterfeit currency), but the actual outcome was negative (genuine currency).

$$Precision = \frac{TP}{TP+FP} \quad (3)$$

The Precision obtained by different models is presented in Fig. 11. It is evident that DCGAN surpassed other models in terms of precision.

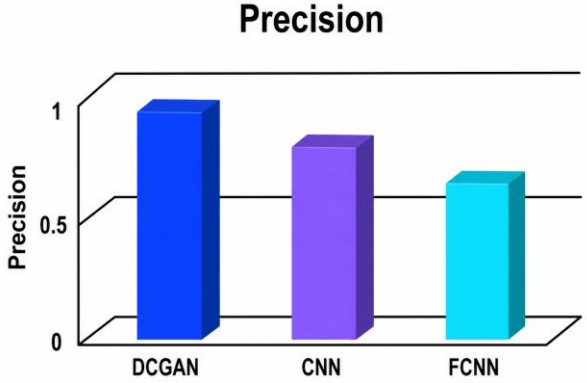

Fig. 11. Precision obtained by various models.

F. F1-Score

F1-score is widely used to evaluate performance of machine learning classifiers including those used for natural language processing applications and search engine algorithms among others [14]. The F1 score is calculated to find a balance between recall and precision. Mathematically F1 Score is calculated using Eq. (4):

$$F1 - Score = 2\frac{(Precision \times Recall)}{(Precision + Recall)} \quad (4)$$

The F1-score obtained by different models is depicted in Fig. 12. The results showed that DCGAN outperformed other models in terms of F1-score.

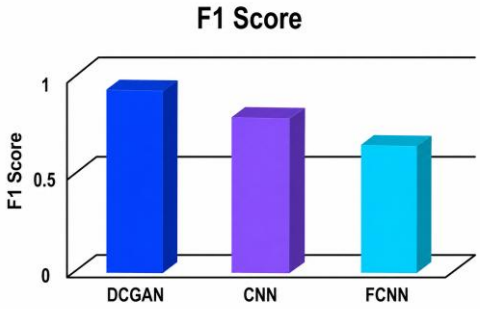

Fig. 12. F1-Score obtained by various models.

G. Comparison with Baseline Methods

To benchmark the performance of our proposed DCGAN-based approach, this research compared the results with those reported in the study by [14], which also employed GAN for counterfeit currency detection. The comparison is summarized in Table II, highlighting the superior performance of our method in terms of accuracy, precision, recall, and F1-score.

TABLE II. COMPARISON WITH BASELINE METHODS

Method	Accuracy	Precision	Recall	F1-score
Proposed DCGAN	0.951	0.950	0.954	0.957
Ref. [10]	0.815 / 0.750*	NR	NR	NR
Ref. [11]	0.950	NR	NR	NR
Ref. [15]	0.963	NR	NR	NR
Ref. [17]	0.800	NR	NR	NR
Ref. [19]	0.9988	NR	NR	NR

NR: Not reported. *Ref. [10] reported 81.5% accuracy for genuine and 75.0% for counterfeit notes.

H. Limitations of Proposed Framework

The proposed framework shows significant improvements in the detection of counterfeit currency, but has the following limitations:

1) Potential vulnerabilities to adversarial attacks: Deep learning models, e.g. DCGAN, are vulnerable to adversarial attacks. The system can be fooled by slight modifications to counterfeit notes. Future work should study how to defend the model against such attacks.

2) Requirement for large and diverse datasets: The performance of the proposed framework depends on the

availability of large and diverse datasets. The dataset utilized for this research is extensive yet not exhaustive of all counterfeit currencies. The dataset can be expanded to include a wider range of counterfeit samples which may increase the performance of the model.

3) Lack of component-wise ablation analysis: The proposed framework combines synthetic image generation, discriminator-based classification, and image preprocessing. However, the present evaluation reports the performance of the complete framework and does not separately measure the contribution of each component. Therefore, the individual impact of synthetic sample generation, discriminator learning, and preprocessing remains a limitation of the current study. Future work will include an ablation study to evaluate each component independently.

4) Lack of repeated experimental trials: The reported results were obtained from a single controlled experimental run. Although the same dataset, training parameters, and computing environment were used for all models, repeated trials with different random seeds were not conducted. Therefore, the absence of mean values, standard deviations, confidence intervals, and statistical significance testing is acknowledged as a limitation. Future work will include multiple independent runs to assess the consistency and statistical reliability of the results.

5) Limited evaluation under real-world imaging conditions: The proposed framework was evaluated using a single dataset under controlled experimental conditions. Its robustness under variations such as lighting changes, camera differences, image rotation, occlusion, damaged banknotes, blur, and noise was not independently assessed. Therefore, the practical generalizability of the framework remains limited. Future work will evaluate the model under diverse real-world image acquisition conditions.

6) Absence of deployment performance metrics: Although the proposed framework has potential for smart-device and real-time deployment, the current study does not report practical deployment metrics such as inference time, model size, parameter count, FLOPs, memory consumption, or CPU/GPU latency. Therefore, real-time and smart-device suitability cannot yet be fully confirmed. Future work will evaluate these metrics on embedded and mobile computing platforms.

7) Absence of qualitative misclassification analysis: The current evaluation reports aggregate performance metrics and confusion matrices but does not include qualitative examples of false-positive and false-negative predictions. Consequently, the specific visual conditions that lead to classification errors, such as blur, poor lighting, occlusion, damaged notes, or visually similar counterfeit features, were not examined. Future work will include representative misclassified samples and a detailed analysis of common failure patterns.

8) Unverified real-time and smart-device deployment: The present study evaluates classification performance but does not measure deployment-related factors such as inference time, model size, parameter count, FLOPs, memory usage, or CPU/GPU latency. Therefore, the suitability of the proposed framework for real-time and smart-device deployment has not yet been experimentally confirmed. Future work will assess these metrics on mobile and embedded platforms.

9) Real-world implementation challenges: Limitations of computational resources and integration of the system with existing financial infrastructures. These practical considerations need to be well assessed to ensure smooth deployment and operation.

10) Deployment claims beyond experimental validation: The proposed framework was evaluated in a controlled experimental environment and was not tested within financial institutions, real-world transaction settings, embedded devices, or end-user environments. Therefore, claims regarding immediate deployment should be interpreted cautiously. The findings demonstrate the potential of the framework for counterfeit currency detection, while practical adoption requires further validation under operational conditions.

VI. Conclusion

Existing solutions for counterfeit money detection have been proved ineffective due to the skillful manipulation of miscreants. This study presents different techniques and methods employed for the detection and identification of counterfeit currency. In addition, it provides a new framework with deep learning models such as DCGAN, CNN, and FCNN. Deep learning methods are preferred due to their ability to find complex relationships in the input data. The primary aim is to train these deep learning models to rightfully classify real and fake currency notes. The endgame is embedded in apps on smart devices for wider deployment. The effectiveness of the system is confirmed in terms of various metrics like accuracy, precision, recall, and F1-score and its flexibility is demonstrated at a low cost by comparing the various models used to assess the efficiency of the study. The results demonstrated that DCGAN outperformed the rest of the models employed in this study and achieved 95% accuracy, 0.95 precision, 0.954 recall, and 0.957 F1-score. The confusion matrix also showed that DCGAN correctly classified 7,802 counterfeit samples and 6,606 genuine samples, outperforming both CNN and FCNN.

VII. Future Work

For further refinement of performance, it is recommended to retrain the models on new instances on a regular basis to further improve the performance and reduce false positives. Note: This study has been addressed for specific currency notes (MYR & SAR) while the proposed system can be applied on different country currency notes provided with ample model training and tuning of parameters. Other future directions could also be:

- Exploring the possible implementation of other security features like watermarking and holograms into the detection framework.
- Extending the framework to other currencies other than MYR and SAR and evaluate the generalizability and applicability around the world.

- Exploring transfer learning and domain adaptation methods to improve the model performance with limited new data instances.

***Abstract*—Froth flotation recovery prediction plays an important role in mineral processing because it can improve operational efficiency, reduce mineral loss, and support more effective decision-making during flotation operations. However, accurate recovery prediction remains challenging because flotation processes are highly dynamic and nonlinear, sensor data may contain noise, and process variables often exhibit complex temporal dependencies. Although several machine learning and deep learning approaches have been proposed for flotation prediction, many existing models remain limited in their capabilities of capturing short-term and long-range relationships in sequential flotation process data. To address these challenges, this study proposes a Fine-Grained Hybrid Attention Network (FGHA-Net) for froth flotation recovery prediction. The flotation process data are first preprocessed to improve data quality and suitability for model training. Feature engineering techniques, including process trend extraction, moving average features, and recovery-rate difference analysis, are then applied to enhance the representation of process dynamics. The proposed FGHA-Net consists of a bidirectional long short-term memory (BiLSTM) branch and a Transformer branch for hybrid temporal feature learning. The BiLSTM branch captures short-term sequential dependencies, whereas the Transformer branch models long-range temporal relationships using multi-head self-attention. A Fine-Grained Attention Fusion module is further introduced to support cross-branch feature fusion, temporal attention weighting, and refinement of important process variables. Finally, the fused features are passed to a regression head to generate the predicted recovery value. The proposed model is trained using the Adam optimizer and evaluated using standard regression metrics. Experimental results show that FGHA-Net achieved strong predictive performance on the testing set, with an RMSE of 0.011484 and an R^2 score of 0.844612. These results indicate that the proposed model can effectively learn complex temporal dependency patterns from froth flotation process data and has potential for intelligent mineral-processing monitoring and decision-support applications.**

Keywords*—Froth flotation; mineral beneficiation; iron-ore processing; recovery prediction; soft sensor; BiLSTM; transformer; fine-grained attention; deep learning

I. Introduction

In mineral processing, froth flotation is one of the most widely used separation methods. Froth flotation is considered one of the most important and complex processes [1]. In froth flotation, concentrate grade plays a significant role in production performance. Online grade prediction is therefore essential for precise process control and effective optimization of industrial operations [2]. Because the direct measurement of key flotation variables often requires expensive instrumentation to acquire and maintain, soft-sensor modeling provides a fast and cost-effective approach for predicting concentrate grade based on variables measured online [3]. The predicted values can then be used as inputs to feedback control systems that adjust process variables to improve flotation performance. However, modeling froth flotation remains challenging because of its complex dynamics and strong interactions among process variables [4]. Existing models range from empirical approaches, such as artificial neural networks (ANNs), to phenomenological models, including kinetic, probabilistic, and population-balance models. Despite these approaches, no single model can fully capture the entire process dynamics, which often leads to considerable control challenges [5]. Data-driven approaches can identify hidden patterns and model nonlinear interactions; however, they still face several limitations. Machine learning (ML) involves the development of algorithms that enable systems to learn patterns from data and generate predictions without explicit programming [6, 7].

Effective preprocessing improves data quality and enables the model to capture relevant patterns and relationships [8]. Selecting an appropriate ML method is also essential because it strongly influences prediction accuracy, interpretability, and generalization ability. Different ML approaches have distinct strengths and limitations; therefore, choosing a suitable model allows the data to be represented more effectively and used for better decision-making [9]. Testing and validation are important for assessing model performance and ensuring that the model can generalize beyond the training samples [10]. The growing influence of ML and artificial intelligence (AI) is increasingly evident across various fields, from everyday applications to advanced scientific domains [11]. With rapid adoption in

*Corresponding author.

applications such as voice recognition, facial recognition, autonomous vehicles, social-media platforms, and spam filtering, these technologies are now widely used on a global scale [12]. In recent decades, researchers have identified several challenges in mineral beneficiation and have proposed potential solutions using ML- and AI-based models [13].

However, accurate froth flotation recovery prediction remains challenging because of process complexity, sensor noise, and strong dependencies among flotation variables. Existing ML and deep learning models also struggle to capture short-term and long-range temporal relationships effectively. Therefore, an efficient hybrid model is needed to improve flotation recovery prediction. Motivated by these challenges, this study proposes a Fine-Grained Hybrid Attention Network (FGHA-Net) for froth flotation recovery prediction. The proposed model combines BiLSTM and Transformer architectures to capture sequential temporal features and long-range dependencies from flotation process data. Additionally, a Fine-Grained Attention Fusion module is introduced to improve cross-branch feature fusion and important process-variable refinement. The contributing factors of this study are summarized as follows:

- This study integrates a bidirectional long short-term memory (BiLSTM) branch and a Transformer branch to capture short-term and long-range temporal dependencies from flotation process sequences.
- It introduces a Fine-Grained Attention Fusion (FGAF) module for effective temporal attention weighting and cross-branch feature fusion.
- It uses a regression head consisting of dense and linear output layers to generate the froth flotation recovery prediction output.
- It trains the proposed FGHA-Net model using the Adam optimizer to improve prediction performance and model convergence.

II. Related Work

This section presents a concise overview of existing studies on froth flotation recovery prediction and identifies the associated research gaps. Pandian et al. [14] proposed a deep probabilistic neural network technique to predict silica concentrate percentage and iron concentrate percentage in flotation processes. Their approach used a comprehensive flotation dataset that included reagent dosages, feed composition, column operating conditions, and pulp characteristics. Several machine learning models were evaluated, and a hybrid method combining a probabilistic pattern neural network with an Extra Trees regressor was proposed to improve prediction accuracy and effectiveness.

Zhang et al. [15] proposed an interpretable grade prediction model, which captures representative features from multi-source XRF sequential data. In addition, tensor reforming was applied to support efficient parallel evaluation. In [16], a convolutional long short-term memory neural network was proposed for real-time monitoring of chemical composition grades. The proposed implementation framework enables real-time monitoring and supports the adjustment of flotation parameters to improve process efficiency.

Yang et al. [17] investigated a coal flotation froth image segmentation method based on Mask R-CNN. Abouda et al. [18] proposed the AI-DeepFrothNet framework to address major limitations in froth image analysis. The framework used a Putrefaction Enrichment and Tuning Network (PETNet) to remove and reduce noise in froth images. It also applied multi-agent deep Q-learning, in which three agents were used to investigate different properties of the froth layer. In [19], a Gaussian Process-based Model Predictive Control algorithm was designed to incorporate uncertainty quantification directly into the control architecture. By exploiting the probabilistic nature of Gaussian Process modeling, this technique captures process variability and adapts dynamically to new information, enabling continuous refinement of the Gaussian Process model within the MPC framework. The Gaussian Process model was trained and optimized using JAX, evaluated with relevant performance metrics, and used as a surrogate model in the MPC approach.

Song et al. [20] introduced a prediction algorithm based on an improved XGBoost model using real copper concentrate flotation data. To address missing values and outliers in the collected dataset, the authors first proposed an outlier detection method. The integration of MissForest/IQR preprocessing with TPE-optimized XGBoost formed a sequential prediction pipeline for estimating copper concentrate grade in the flotation process. Bendaouia et al. [21] applied CNN-based feature extraction and image-processing techniques integrated with DL to predict the elemental composition of minerals. It included several machine learning methods, CNN models, and ANN models for predicting mineral concentrate grades. An overview of related studies on froth flotation prediction is presented in Table I.

Although several machine learning and deep learning methods have been introduced for flotation prediction and monitoring, several research gaps remain. Traditional regression and ML approaches have restricted ability in capturing complicated nonlinear and temporal dependencies, while existing DL models often inadequately model long-range relationships and complementary temporal representations. Moreover, limited attention has been given to adaptive feature interaction and fusion. To address these gaps, FGHA-Net integrates BiLSTM-based temporal feature learning, Transformer-based long-range dependency modeling, and fine-grained attention fusion to effectively combine complementary representations for improved flotation recovery prediction. Some image-based techniques mainly focus on froth image analysis; however, they do not fully exploit sequential process information for recovery prediction. Moreover, several recent approaches remain sensitive to noise, provide limited feature extraction capability, and are unable to capture both short-term and long-range process dependencies simultaneously. Therefore, an effective hybrid deep learning approach is still needed to learn temporal process patterns more efficiently and improve froth flotation recovery prediction performance.

III. METHODOLOGY

The proposed model follows a systematic pipeline for froth flotation recovery prediction. The overall structure of the proposed framework is shown in Fig. 1. In the initial stage, data preprocessing is performed through missing-value handling, outlier removal using the interquartile range (IQR) method, Min–Max normalization, temporal sequence generation, and sliding-window formation. Next, feature engineering is conducted using process trend extraction, moving average features, and recovery-rate difference analysis. The proposed FGHA-Net then applies a dual-branch architecture consisting of a BiLSTM branch and a Transformer branch. A Fine-Grained Attention Fusion module integrates features from both branches by weighting and refining important process information. Finally, the fused features are passed to a regression head to predict flotation recovery, and the model is trained with the Adam optimizer.

A. Data Preprocessing

Data preprocessing is an important stage that improves data quality and prepares the dataset for model training. It includes missing-value handling, outlier removal, normalization, and temporal sequence generation [22].

Missing-value handling: A robust preprocessing pipeline is required to handle missing values in machine learning datasets. This step involves examining raw froth flotation process data to identify and correct missing values and inconsistencies. Removing low-quality values helps ensure that model performance is not affected by irrelevant, incomplete, or erroneous data.

Outlier removal using the IQR method: The interquartile range (IQR) method is used to identify and remove abnormal process values from the dataset. This method helps reduce the effect of extreme fluctuations and improves the consistency of the prediction model.

Data normalization: Normalization scales all attribute values into a specific range. Because feature values often vary across process variables, unscaled data may lead to unstable or inefficient training of deep learning models. Therefore, Min–Max normalization is applied to transform all values into the range between 0 and 1, which can accelerate model convergence and improve prediction performance, as shown in Eq. (1).

$$X' = \frac{X - \text{Min}}{\text{Max} - \text{Min}} \quad (1)$$

In Eq. (1), X′ represents the normalized feature value, while Min and Max denote the minimum and maximum values of the corresponding feature, respectively. Temporal sequence generation: The normalized flotation process variables are converted into temporal sequences to capture dependency relationships among process variables over time.

Sliding-window formation: A sliding-window method is used to divide the temporal sequences into fixed-length input windows for model training. This strategy enables the proposed FGHA-Net model to learn temporal dependency patterns from flotation process data.

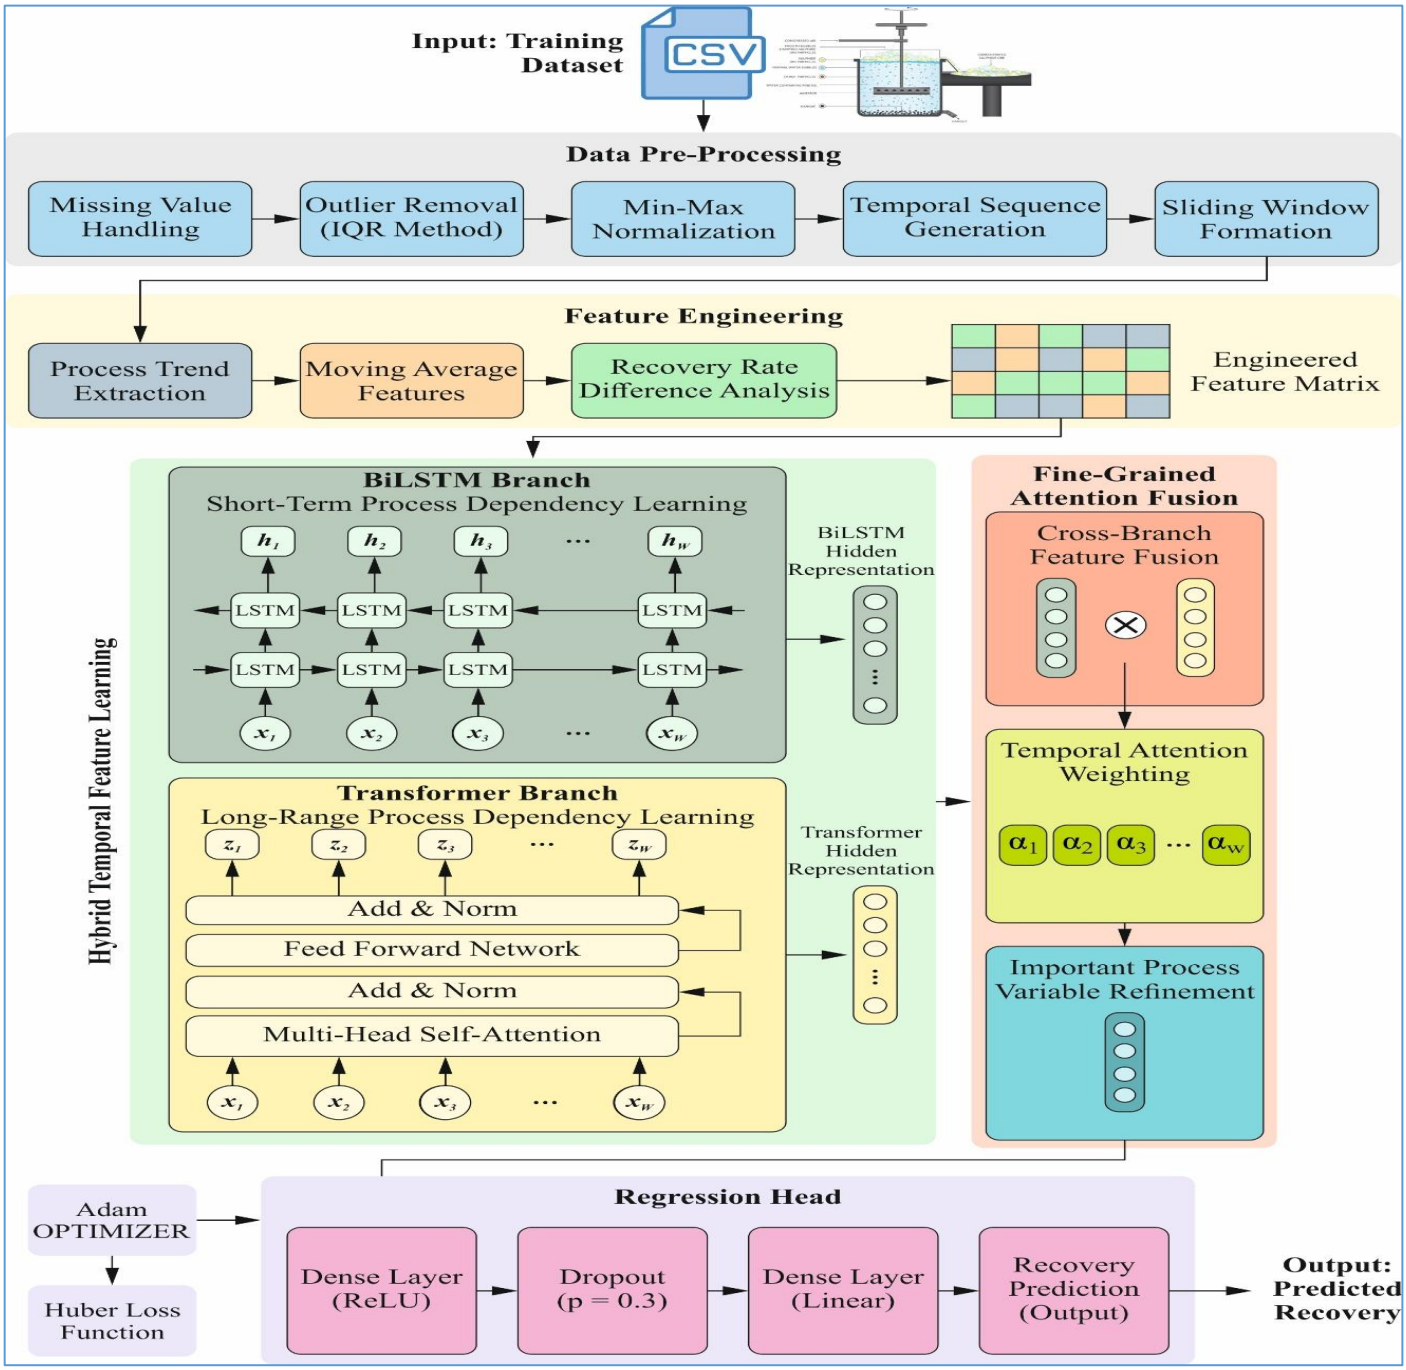

Fig. 1. Structural design of proposed framework.

B. Feature Engineering

Feature engineering is performed to improve the learning capability of the proposed FGHA-Net framework by extracting meaningful information from the froth flotation process data. Process trend extraction is used to capture the temporal variation of flotation process variables over time. These trend features help the model learn sequential dependency patterns and process changes. Moving average features are generated to reduce noise and smooth variations in flotation process sequences. These features help capture more stable temporal patterns from process variables. Recovery-rate difference analysis is performed to calculate the differences between consecutive recovery values and identify variability patterns in flotation recovery behavior.

C. Proposed FGHA-Net Architecture

The proposed hybrid temporal feature learning module is designed to capture both short-term and long-range dependencies in flotation process data. It integrates BiLSTM and Transformer branches to extract sequential and global temporal features effectively.

1) BiLSTM branch: The LSTM network consists of several key components, including the forget gate, input gate, output

gate, and memory cell [23]. These components allow the network to retain relevant information and discard less important information over time. The LSTM network includes four structures: forgetting gate (f_i), memory unit, output gate (o_t), and input gate (i_i). The LSTM network holds additional cell states with triple gate elements in comparison with the RNN. In an LSTM structure, the forget gate (f_t) determines what percentage of data to retain in the network, and it is computed by:

$$f_t = \sigma\left(W_f \cdot [h_{i-1'} x_t] + b_f\right) \quad (2)$$

In this equation, h_{i-1} implies the preceding state memory, x_t represents the input sequence,· iV_f points out the weighted matrix of the forgetting gate, σ implies the sigmoid activation function, f_i signifies the state of the forget gate, and b_f denotes the bias of the forget gate. The input gate i_i is responsible for remembering the novel data in the cell state.

$$i_t = \sigma\left(W_j \cdot [h_{i-1'} x_t] + b_j\right) \quad (3)$$

$$\overline{C} = \tanh\left(W_c \cdot [h_{i-1}, x_t] + b_c\right) \quad (4)$$

$$C_i = f_i * C_i + i_i * \overline{C} \quad (5)$$

In these equations, C_i denotes the novel cell state, $\overline{C}$ refers to the cell state candidate, W_j denotes the weighted matrix of the input gate, tanh represents the hyperbolic tangent function, b_i signifies the bias of the input gate, iV_c implies the weighted matrix of the cell state, i_i specifies the input gate, and b_c shows the biased cell state, o_t denotes the output gate.

$$0_t = \sigma(|v_0 \cdot [h_{i-1'} x_t] + b_0) \quad (6)$$

$$h_t = 0_t * \tanh\left(C_t\right) \quad (7)$$

Here, (b_o) implies the bias of the output gate and (W_0)denotes the weighted matrix of the output gate.

This study uses a bidirectional LSTM (BiLSTM) branch, which processes sequence data in both forward and backward directions. The forward and backward hidden layers capture temporal dependencies from both past and future contexts. As a result, the BiLSTM branch extracts more informative sequential features and short-term process patterns, thereby improving the prediction accuracy of froth flotation recovery.

2) Transformer branch: The transformer branch is developed to obtain the global contextual data from sequences of the froth flotation method [24]. The transformer framework is constructed by the sequence embedding and multi-head self-attention mechanisms (MHSA) for encoding the temporal process data, and adaptably handling various measures of input signals, while modifying the computational complexity in the linear ranges. Thus, this branch is utilized as the encoder part for temporal feature extraction and long-term dependency learning. Likewise, the BiLSTM branch and the transformer module utilize the hierarchical feature extraction model to split the entire branches into numerous layers. At the 1st stage, the input processed sequences are primarily separated into temporal embeddings. Later, these embeddings can be entered into the transformer encoder model to obtain the 1st phase feature representations that are transferred to the following phase. The following feature representations are more effectively handled by employing the transformer encoder layers. In conclusion, the multi-scale temporal feature representations are gained and enable interrelationship amongst the layers of these two subdivisions.

To mitigate the higher computation complexity related to the self-attention mechanism (SAM) in transformer encoder parts, the transformer branch utilizes the MHSA to proficiently learn the dependency relations between the process variables. Same as the conventional attention mechanism (AM), the MHSA gains the value (V), query (Q), and key (K) as input, and generates improved temporal features.

$$MHSA\ (Q, K, V) = \text{Concat}\ (head_1, \ldots, head_n) W^O \quad (8)$$

$$head_i = \text{Attention}\ (QW_i^Q, KW_i^K, VW_i^V \quad (9)$$

Here the term $(head_i)$ has the attention value $i - th$ attention head, the term Concat signifies the channel splicing function, and the parameters W_i^Q, W_i^V, and W_i^K indicate the linear projection parameters. The mathematical form of the attention operation can be measured by

$$\text{Attention}\ (Q, K, V) = Soft\ \max\left(\frac{QK^T}{\sqrt{d_k}}\right) V \quad (10)$$

Now, the factor (d_k) points to the key vector's dimensionality. By applying the MHSA module, the transformer branch successfully captures the long-term dependency correlation amongst flotation process variables, thus improving the ability of temporal representation and increasing the prediction efficiency of the proposed framework for froth flotation recovery prediction.

3) Fine-grained attention fusion: In the proposed framework, the cross-branch feature fusion includes convolution fusion, operator fusion, and attention fusion approaches [25]. The convolutional fusion approaches improve the cross-branch temporal features with respect to the semantic and multi-scale hierarchies by employing different convolution operations, decreasing the noise interference in the temporal features. Simple operator fusion techniques are directly added or concatenated to the features of the transformer and BiLSTM for fusion. The noise in the temporal features can be simply reduced by gaining dependable prediction outcomes by employing these techniques. Generally, the attention fusion methods utilize an AM to efficiently combine the cross-branch features in the temporal and channel dimensions. The convolutional techniques are focused on improving temporal features before fusion, whereas attention refinement techniques concentrate on boosting these features.

The FGAF model efficiently fuses features by employing the temporal attention data. The important part of the features is identified by employing temporal and channel attention, and the major parts amongst the BiLSTM and transformer branch features have been recognized by employing the temporal data. The channel branch accomplishes the combination of channel

data through the transmission of input cross-branch features over the channels by employing global average pooling (GAP). The aggregation method is denoted by

$$fc = Concat(Avg(B_{\{input\}}, \text{Max}\left(B_{\{input\}}, Avg(T_{input}), \text{Max}\left(T_{input}\right)\right) \quad (11)$$

From this mathematical form, the parameter fc signifies the features from the fused channel. The Concat represents concatenation with the channel dimension. The GAP has been indicated by Avg Max ($B_{\{input\}}$ and T_{input}), which are the feature inputs of the BiLSTM and transformer branches, respectively.

The fused channel features can be entered into the 1D convolutions with effectively calculated kernel numbers (k) and efficiently obtain dependency among the channels. The formation of attention weights W_{c1} and W_{c2} in the channels employing the non-linear and softmax activation functions.

$$W_{c1}, W_{c2} = \frac{e^{Conv_1(f_c)}}{e^{Conv_1(f_c)} + e^{Conv_2(f_c)}} \frac{e^{Conv_2(f_c)}}{e^{Conv_1(f_c)} + e^{Conv_2(f_c)}} \quad (12)$$

Here, the terms $Conv_1$ and $Conv_2$ point to 1D convolution. This technique is employed for calculating the weights in the temporal and channel dimensions. Global pooling has been employed in the temporal dimension, and weights are acquired by the non-linear and convolution activation function. At the temporal branch, the significant method variable regions among the cross-branch features are computed by computing the temporal attention weights ($W_{\{T1\}}$) and ($W_{\{T2\}}$) parameters. Through the combination of temporal attention weights and cross-branch channel weights, the wide-ranging feature weights have been gained, thus emphasizing the vital parts amongst cross-branch features. Later, such feature weights can be multiplied by the cross-branch features for efficient fusion of these features. The final output must be handled by a 1×1 convolution and a convolution operation with the summation of the original inputs. The mathematical form of output is determined by:

$$f_{Boutput} = \text{f}^{conv}(f^{1\times1}(W_{C1} + W_{t1}) \otimes f_{Binput})) + f_{Binput} \quad (13)$$

$$f_{Boutput} = \text{f}^{conv}(f^{1\times1}(W_{C2} + W_{t2}) \otimes f_{Tinput})) + f_{Tinput} \quad (14)$$

From the above expression, the mathematical notation $\otimes$ denotes the multiplication operation, the parameter $f^{1\times1}$points to the set of ReLU activation functions, 1×1 convolutions, and batch normalization (BN), and the term f^{conv} refers to the convolution operation. By employing the proposed FGAF model, the model successfully performs temporal attention weighting, cross-branch feature fusion, and significant method variable improvement, thus increasing the prediction performance of the proposed FGHA-Net framework for froth flotation recovery prediction.

4) Regression head: A regression head is developed for froth flotation recovery prediction based on the FGHA-Net framework [26]. A dense layer with dropout regularization of 0.3 is fully connected using a regression head. This design choice stems from the necessity to effectively extract the refined temporal characteristics captured from the Transformer branch and BiLSTM branch.

This framework begins with a dense layer constructed to allow the fused temporal feature extraction. To reduce overfitting and improve the generalization capability, the extracted feature vector (h) is crossed over the dropout layer and dense layer. For the technique to operate a regression process for recovery prediction, a linear output layer can be applied to modify the last dense layer in Eq. (15). ($b_{\{out\}}$) and ($W_{\{out\}}$) indicates the bias and weight of the output layer.

$$y = W_{out}.h + b_{out} \quad (15)$$

Here (y) denotes the output of predicted froth flotation recovery. The regression head comprises trainable parameters related to the output and dense layers. This framework achieves the balance between computational efficiency and method intricacy. Within these integrated elements, the proposed FGHA-Net algorithm effectively functions to recover prediction outcomes for froth flotation process information. Fig. 2 represents the architecture of the hybrid temporal feature learning architecture combining BiLSTM and Transformer branches with fine-grained attention for prediction recovery.

D. Training Strategy

The proposed FGHA-Net model is trained using the Adam optimizer, which is an efficient stochastic optimization algorithm. Adam adaptively estimates learning rates for model parameters by combining momentum and adaptive gradient estimation [27]. This allows the optimizer to achieve stable and efficient convergence during deep learning model training.

In this study, the proposed FGHA-Net model is trained using Adam with a learning rate of 1e−4. Huber loss is used as the loss function because it is suitable for regression tasks and is less sensitive to outliers than mean squared error. The model is trained with a batch size of 32, and the dataset is divided into training and testing sets using a 70:30 split. The use of Adam optimization and Huber loss supports stable convergence and improves the robustness of the proposed recovery prediction model. This optimization technique is expressed as follows:

$$x_t = \delta_1 * x_t - 1 - (1 - \delta_1) * g_t \quad (16)$$

$$y_t = \delta_2 * y_t - 1 - (1 - \delta_2) * g_t^2 \quad (17)$$

$$\triangle \omega_t = -\eta \frac{x_t}{\sqrt{yt + \epsilon}} * gt \quad (18)$$

$$\omega_{t+1} = \omega_t + \triangle \omega_t \quad (19)$$

Here, the parameter g_t implies the gradient with respect to time (t), the symbol (θ) denotes the learning rate, the term x_t signifies the exponential averages of gradients, and the term y_t indicates the exponential averages of gradients squared, whereas δ_1 and δ_2 imply the factors.

To improve the strength of the predictive method, the proposed model was trained using the Adam optimizer with Huber loss as the loss function. The proposed system can be trained utilizing a batch size of 32 over 100 epochs. In addition, the database is separated using a 70:30 train-test split for performance evaluation and training. This method has revealed

higher outcomes for regression-driven predictive tasks owing to the steady convergence action and adaptive parameter upgrading ability. These advantages make the Adam optimizer appropriate for the proposed FGHA-Net model for the froth flotation recovery predictive system.

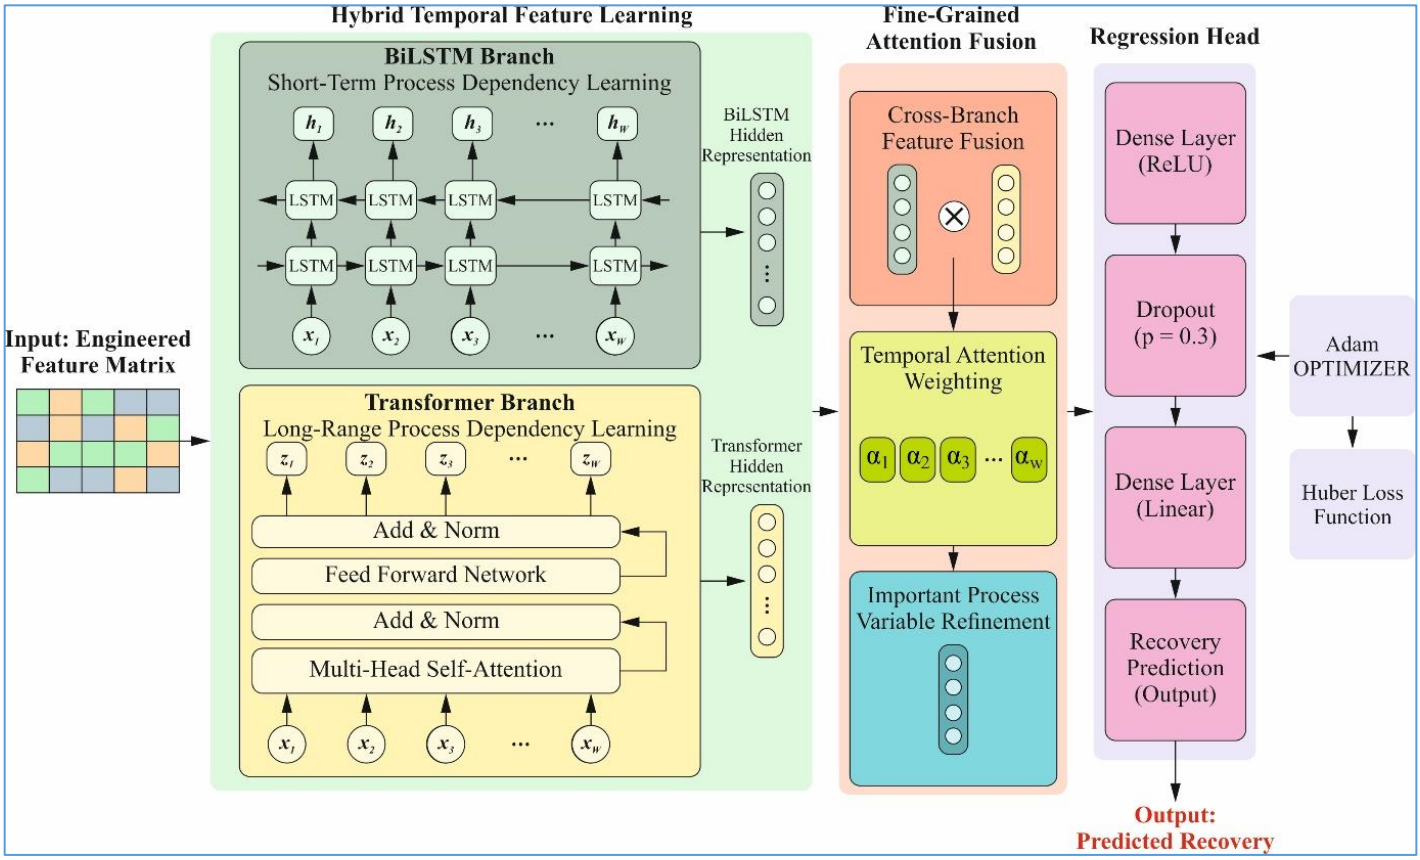

Fig. 2. Hybrid temporal feature learning architecture combining BiLSTM and Transformer branches with fine-grained attention for recovery prediction.

IV. Experimental Results and Discussion

The experimental evaluation of the proposed FGHA-Net model was conducted using a benchmark froth flotation dataset [28]. The dataset was collected from an industrial froth flotation plant. Column 1 contains date and time information, covering the period from March 2017 to September 2017. Columns 2 and 3 represent quality measurements of the iron ore pulp before flotation. Columns 4 to 8 include important variables that influence final ore quality. Columns 9 to 22 contain process variables, such as air flow and flotation-column level, which also affect ore quality. The last two columns represent laboratory-based measurements of the final iron ore pulp quality.

The dataset was divided into training and testing sets using a 70:30 ratio. Each input feature was normalized using Min–Max scaling. Temporal sequences were generated using a sliding-window technique, and the proposed FGHA-Net model was evaluated using standard regression metrics, including MAE, RMSE, MAPE, and R^2 score. The performance of the proposed model was also compared with several conventional machine learning and deep learning methods to evaluate its effectiveness.

Table II summarizes the parameter configuration of the FGHA-Net model. Feature engineering was performed using process trend analysis, a moving average window of 5, consecutive recovery-difference analysis, and 12 engineered features. The BiLSTM branch consisted of two layers, a dropout rate of 0.2, and 128 hidden units. The Transformer branch used four layers, eight attention heads, an embedding dimension of 128, and a feed-forward dimension of 256 with a multi-head self-attention mechanism. The Fine-Grained Attention Fusion module applied a cross-branch attention fusion strategy with 128 hidden units and an attention dropout rate of 0.2. The regression head consisted of dense layers with 128 and 64 neurons, followed by a linear output layer for recovery prediction. The model was trained using the Adam optimizer with a learning rate of 1e−4, Huber loss, a batch size of 32, and 25 epochs.

TABLE II. Parameter Settings

Model	Parameter	Values
Feature Engineering	Trend Extraction Method	Process Trend Analysis
	Moving Average Window	5
	Recovery Difference Metric	Consecutive Recovery Difference
	Engineered Feature Count	12
BiLSTM Branch	No. of BiLSTM Layers	2
	Hidden Units	128
	Dropout Rate	0.2

	Temporal Dependency Learning	Short-Term Sequential Learning
Transformer Branch	No. of Transformer Layers	4
	Attention Heads	8
	Embedding Dimension	128
	Feed Forward Dimension	256
	Self-Attention Type	Multi-Head Self-Attention
Fine-Grained Attention Fusion	Fusion Strategy	Cross-Branch Attention Fusion
	Attention Hidden Units	128
	Attention Dropout	0.2

	Feature Refinement	Temporal Attention Weighting
Regression Head	Dense Layer Structure	128 → 64
	Dropout Rate	0.3
	Output Layer	Linear
	Prediction Task	Recovery Rate Prediction
Training Configuration	Optimizer	Adam
	Learning Rate	1e-4
	Loss Function	Huber Loss
	Batch Size	32
	Epochs	25

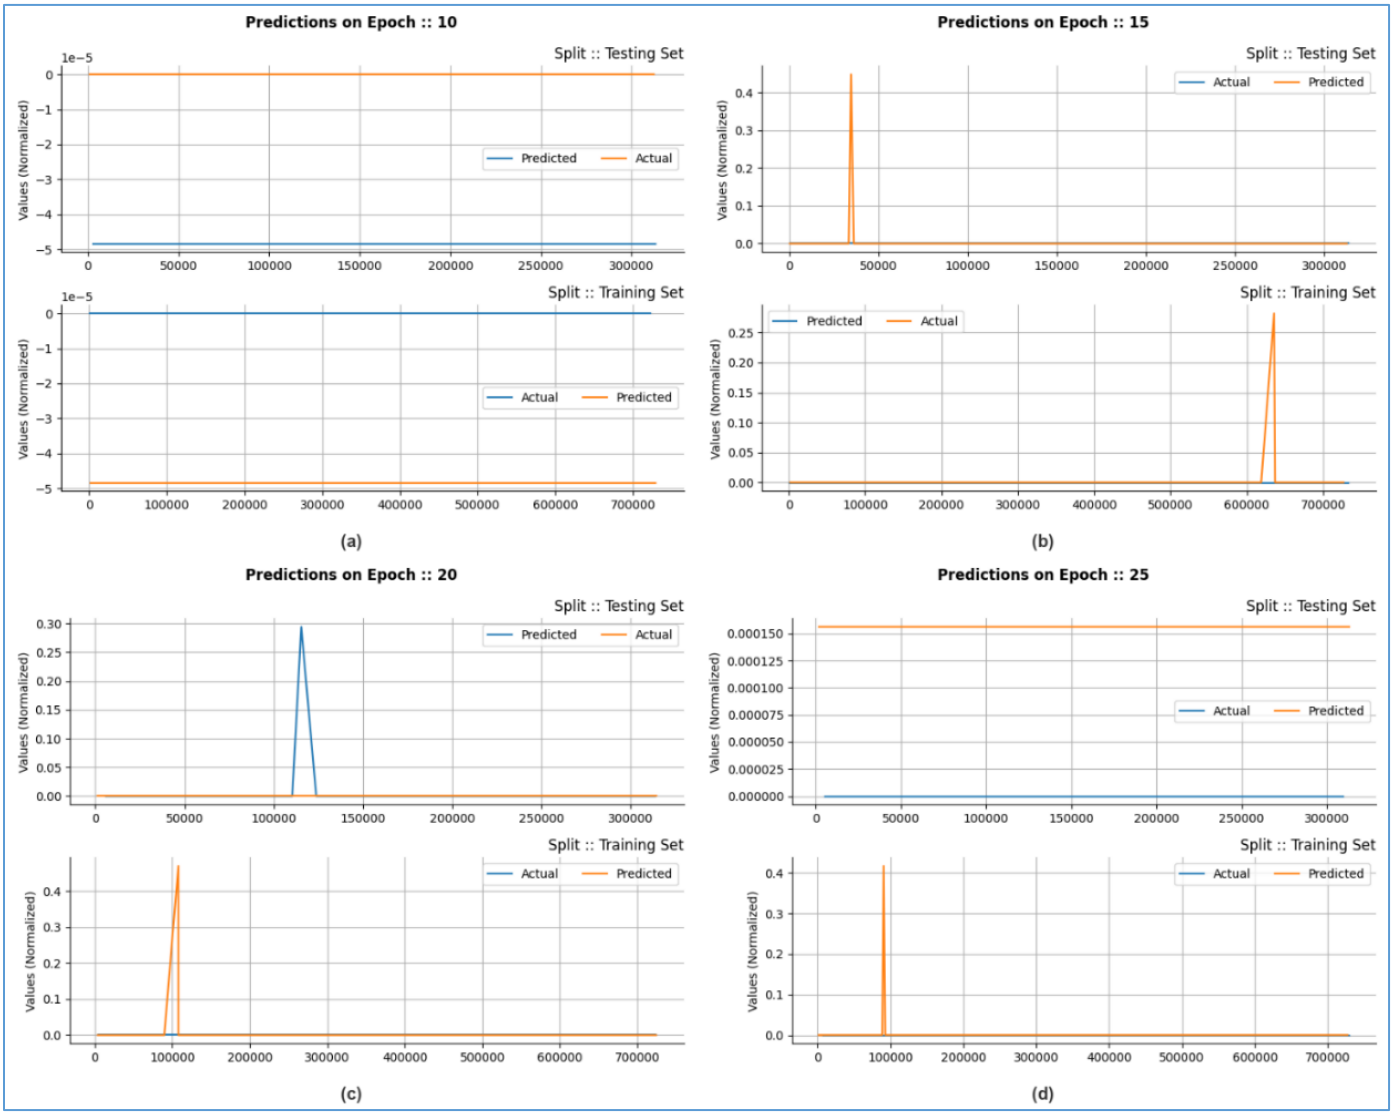

Fig. 3. Predictive analysis of the FGHA-Net method with different epochs.

Fig. 3 illustrates the prediction performance of the FGHA-Net model over different numbers of epochs, including 10, 15, 20, and 25 epochs, on both the training and testing sets. In the early epochs, the predicted and actual values show noticeable differences. However, as the number of epochs increases, the predicted values become more stable and show closer agreement with the actual values. These results indicate that the proposed model achieves stable convergence and improved prediction accuracy as training progresses.

Fig. 4 presents the loss-curve analysis of the FGHA-Net model on the training and testing sets over 25 epochs. The gradual reduction in MSE and RMSE indicates improved convergence and reduced prediction error. The MAE and MAPE results also demonstrate stable predictive performance. In addition, the increasing R^2 score indicates better model fitting and a stronger ability to learn flotation process behavior.

Table III and Fig. 5 present the performance evaluation of the FGHA-Net model using the training and testing sets. The model demonstrated consistent learning behavior, reduced prediction error, and stable convergence. On the testing set, the model achieved an MSE of 0.000132, RMSE of 0.011484, MAE of 0.000718, MAPE of 7.072856, and R^2 score of 0.844612. These results show strong agreement between the predicted and actual values and confirm the ability of the proposed framework to learn flotation process behavior effectively.

TABLE III. PERFORMANCE EVALUATION OF THE FGHA-NET MODEL WITH TRAIN-TEST SPLIT

Metrics	Training Set	Testing Set
MSE	0.000118	0.000132
RMSE	0.010878	0.011484
MAE	0.000683	0.000718
MAPE	7.006903	7.072856
R^2 Score	0.852408	0.844612

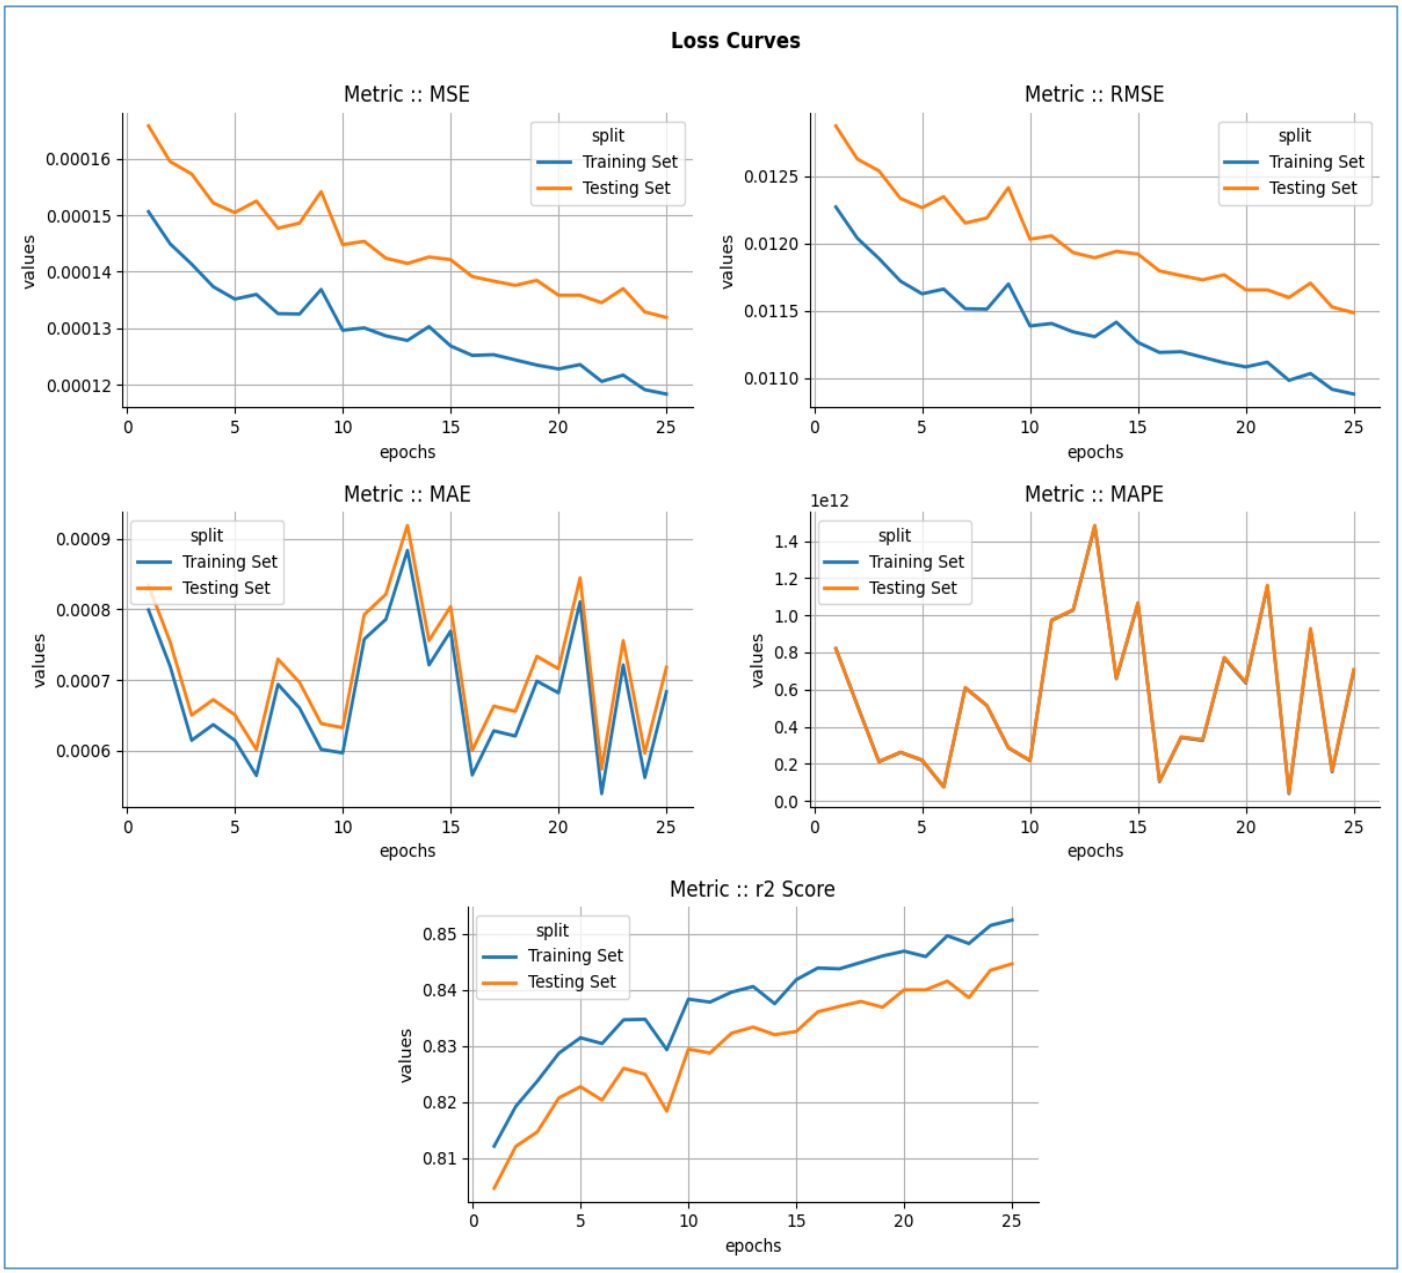

Fig. 4. Loss curve analysis of the FGHA-Net model.

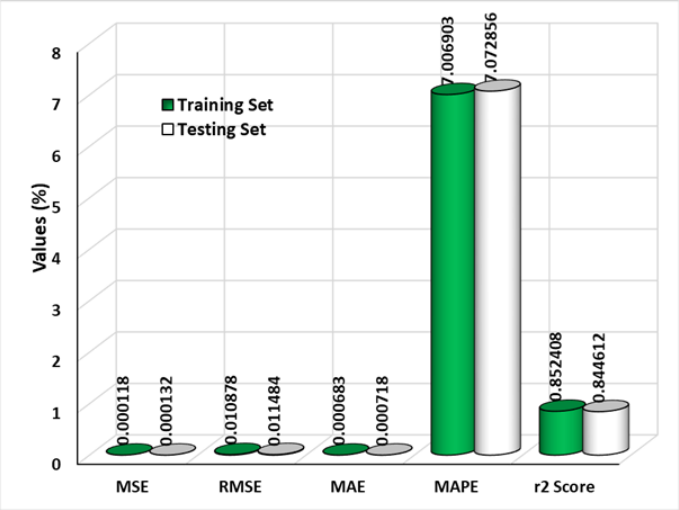

Fig. 5. Performance evaluation of the FGHA-Net model with training set and testing set.

Table IV presents the comparative assessment of the FGHA-Net model against existing methods for flotation recovery prediction [29-31]. Conventional models, such as Linear Regression, SVM, and M5P, achieved lower R^2 scores, indicating limited ability to capture nonlinear relationships. Other models, including FFNN, MLP-ANN, and Bi-PINN, showed moderate performance but still produced higher prediction errors than the proposed model. Concurrently, the hybrid models such as GA-NN, hybrid GA-NN, and BPN models have reached reasonable performance. But the proposed FGHA-Net outperforms existing models with minimal RMSE = 0.0109, MAE = 0.0007, MAPE = 7.0069, and R^2 = 0.8524, demonstrating better predictive performance than the compared models.

TABLE IV. COMPARISON ASSESSMENT OF THE FGHA-NET TECHNIQUE WITH EXISTING ALGORITHMS

Algorithms	RMSE	MAE	MAPE	R^2 Score
ANN	0.3120	0.0050	4.5900	0.4740
GA-NN	0.4000	0.0026	2.8800	0.7880
BPN	0.2590	0.0043	2.8700	0.2830
Hybrid-GA-NN	0.0568	0.0073	8.1200	0.5053
Linear Regression	0.0568	0.0073	8.1200	0.5053
FFNN	0.0552	0.0040	9.4380	0.6678
LSTM	0.0724	0.0025	13.7930	0.5662
Bi-PINN	0.0441	0.0069	11.8860	0.5024
MLP-ANN	0.0592	0.0043	8.8760	0.6143
SVM	0.0334	0.0058	12.1320	0.4621
RF-FFA	0.0825	0.0090	10.4920	0.5443
M5P	0.0229	0.0068	10.7300	0.6433
FGHA-Net	0.0109	0.0007	7.0069	0.8524

Table V provides the ablation study of the proposed model. The table values define the significance of each component involved in the proposed model. The experimental values imply that the proposed FGHA-Net (BiLSTM + Transformer + Fine-Grained Attention Fusion + Adam) gains enhanced performance over individual components.

Table VI portrays the comparative computational performance analysis of the proposed model in terms of FLOPs, GPU memory consumption, and inference time. The experimental outcomes demonstrate that the FGHA-Net accomplishes minimal computation requirements with 0.09 G FLOPs, 0.04 GB GPU memory, and an inference time of 0.20 ms, demonstrating its computational efficiency and suitability for real-time predictive applications compared with the baseline models.

TABLE V. ABLATION STUDY OF PROPOSED MODEL

Algorithms	RMSE	MAE	MAPE	R^2 Score
BiLSTM only	0.0141	0.0039	10.2269	0.5234
Transformer only	0.0135	0.0033	9.6869	0.5784
BiLSTM + Transformer	0.0128	0.0025	9.0169	0.6494
BiLSTM + Transformer (Without Fine-Grained Attention Fusion)	0.0120	0.0020	8.2769	0.7214
BiLSTM + Transformer + Fine-Grained Attention Fusion (Without Adam)	0.0115	0.0015	7.7569	0.7834
FGHA-Net (BiLSTM + Transformer + Fine-Grained Attention Fusion + Adam)	0.0109	0.0007	7.0069	0.8524

TABLE VI. COMPUTATIONAL EFFICIENCY ANALYSIS OF PROPOSED WITH EXISTING MODELS

Algorithm	FLOPs (G)	GPU Memory (GB)	Inference Time (ms/image)
ANN	0.24	0.35	6.8
GA-NN	0.41	0.48	8.4
BPN	0.32	0.41	7.5
Hybrid-GA-NN	0.68	0.72	11.3
Linear Regression	0.21	0.15	1.7
FFNN	0.32	0.43	7.8
LSTM	1.92	1.34	18.9
Bi-PINN	2.76	1.76	24.6
MLP-ANN	0.39	0.52	9.2
SVM	0.17	0.18	2.8
RF-FFA	0.15	0.29	4.3
M5P	0.13	0.08	1.2
FGHA-Net	0.09	0.04	0.20

The experimental results indicate that the proposed FGHA-Net model achieves lower error values and a higher R^2 score than the existing methods. This suggests that the predicted values are closer to the actual recovery values. The improvement can be attributed to the ability of the hybrid BiLSTM–Transformer architecture to capture both short-term and long-range temporal dependencies in flotation process data. The actual-versus-predicted plots further show that the proposed model captures variations in recovery more accurately than the compared

methods. Overall, the results demonstrate that FGHA-Net is a promising approach for froth flotation recovery prediction.

V. Conclusion and Future Work

This study presented FGHA-Net, a Fine-Grained Hybrid Attention Network for froth flotation recovery prediction. The proposed approach first preprocesses the data to improve its quality and suitability for model training. Feature engineering techniques, including process trend extraction, moving average features, and recovery-rate difference analysis, are then applied to enhance the representation of flotation process dynamics. The FGHA-Net architecture consists of a BiLSTM branch and a Transformer branch for hybrid temporal feature learning. The BiLSTM branch captures short-term sequential dependencies, whereas the Transformer branch models long-range relationships using a multi-head self-attention mechanism. In addition, the Fine-Grained Attention Fusion module performs cross-branch feature fusion, temporal attention weighting, and important process-variable refinement. The fused features are then passed through a regression head to generate the recovery prediction output. The experimental results demonstrate that the proposed FGHA-Net model achieves promising prediction performance. On the testing set, the model obtained an RMSE of 0.011484 and an R^2 score of 0.844612, indicating low prediction error and strong agreement between predicted and actual recovery values. These findings suggest that the integration of BiLSTM, Transformer-based self-attention, and fine-grained attention fusion enables the model to capture both short-term and long-range dependencies in flotation process data. Despite these promising results, several limitations remain. Future work should evaluate the proposed model using larger real-time flotation datasets, additional process variables, and external industrial data collected under different operating conditions. Moreover, explainable AI techniques may be incorporated to identify the most influential process variables and improve the interpretability of the prediction results. The proposed model may also be integrated into real-time industrial monitoring systems to support practical mineral-processing applications. Future work can focus on robustness evaluation of the proposed model under sensor noise, missing measurements, equipment drift, and operational disturbances.

Acknowledgment

The authors extend their appreciation to Northern Border University, Saudi Arabia, for supporting this work through project number (NBU-CRP-2026- 289). This study is supported via funding from Prince Sattam bin Abdulaziz University, project number (PSAU/2026/R/1447).

***Abstract*—Cloud repatriation is the migration of workloads from public cloud to private, on-premises, and hybrid clouds. Despite the growing adoption of cloud computing, there are many issues associated with operational expenditure, the unpredictable performance of cloud services, compliance concerns, vendor dependency, and data sovereignty concerns. Thus, cloud repatriation has become a strategic solution, especially in the public sector where governance and regulatory requirements are paramount. Previous studies on cloud repatriation are predominantly descriptive, with limited focus on predictive models that include cost assessment, security compliance, governance maturity, and workload mobility. Moreover, empirical studies are still limited, particularly in the context of public sector settings and regulatory constraints and sovereignty requirements. This study aims to provide a systematic literature review of the factors, solution approaches, and limitations of cloud repatriation towards on-premises transition. The review offers three main contributions: factors driving cloud repatriation, the synthesis of limitations and solution strategies for each factor, and an analysis of current trends across academic and industry literature. Major databases and selected industry reports were used to gather academic and industry sources. From an initial set of 124 articles published between 2021 and 2025, 20 key studies were selected. The results are broken down into five main factors: cost and economic factors, data security and sovereignty, vendor lock-in and portability, performance and latency needs, and governance and exit strategies. The review underscores the need for integrated governance-driven frameworks to enable secure, sustainable, and policy-compliant digital transformation.**

***Keywords*—Cloud repatriation; on-premises transition; systematic literature review; data security; hybrid cloud; data sovereignty; vendor lock-in; governance; implementation limitations**

I. Introduction

The adoption of cloud computing has been a key pillar of global digital transformation for over a decade. Beginning with the promise of lower costs, operational flexibility, and rapid scaling capabilities, the public cloud has attracted the attention of organizations across a variety of sectors, including finance, healthcare, education, and government [1], [2]. Amazon Web Services (AWS), Microsoft Azure, and Google Cloud Platform have emerged as major players in the market, offering infrastructure and platforms that are seen as capable of replacing traditional data centres [3].

However, after a more extended period of adoption, more and more organizations are beginning to realize that reality does not always align with initial expectations [4]. This phenomenon has led to a resurgence of interest in cloud repatriation (CR), the process of relocating workloads from public clouds to private or hybrid environments [5], [6]. According to a 2023 study by IDG & Lufthansa Industry Solutions, the cloud repatriation phenomenon is not just a theory. Approximately 28% of enterprises in Germany have already moved workloads back from the cloud to on-premises infrastructure due to specific reasons including security, data compliance, and migration complexity [7].

The recent Cloud Migration and Repatriation Study 2025 by IDG/LHIND [8], as illustrated in Fig. 1, indicates that over 80 percent of all surveyed companies have done or intend to do repatriation in the near-mid-term.

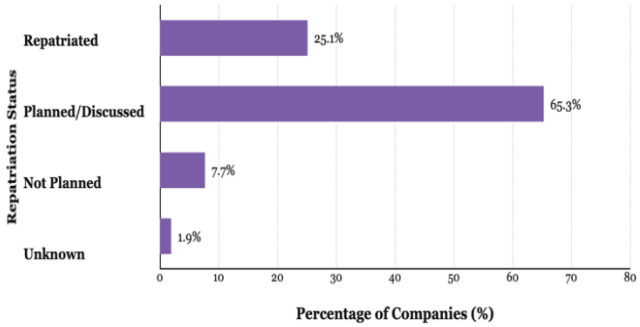

Fig. 1. Germany cloud repatriation study in 2025.

GEICO, a major insurance company in the United States, adopted a partial workload repatriation to gain economies of scale and have more control over important applications. This choice can illustrate how economic reasons and compliance by the organization can become an impetus to repatriate from the cloud [32]. More broadly, industry reports show that the repatriation phenomenon is becoming more pronounced. A Puppet study [10] found that 86% of CIOs plan to move at least some workloads from the public cloud back to private or on-premises infrastructure. These statistics confirm that repatriation is not an isolated phenomenon, but an emerging global trend. Several instances of CR were summarised in Table I.

TABLE I. CASE STUDIES OF CLOUD REPATRIATION DRIVING FACTORS

Citation	Organization	Factors
[7], [8]	IDG/LHIND	Security factors, data compliance, migration complexity, and vendor lock-in.
[9]	37signals (USA)	Hidden costs, inconsistent performance in public clouds.
[32]	GEICO (USA)	Cost savings, critical application control, organizational compliance.
[12]	Dropbox (USA)	High cost of public cloud operations, performance control, and reliability.
[13]	X (USA)	High cloud costs, control over data and performance, the need to reduce storage size and processing loads, optimizing infrastructure.
[33]	Global Research (CIO Survey)	Cost, security, compliance, and vendor lock-in.

Cloud repatriation does not signify the decline of cloud computing; rather, it represents a maturation of workload-mobility strategies. Posey et al. [6] argue that CR should be seen as part of the concept of "workload mobility", which is the flexibility to place applications and data in the most suitable environment, whether in a public cloud, private cloud, organizational data center, or hybrid location. The strategic flexibility of a firm is enhanced by its preparedness to shift workloads off-cloud [4]. This approach enables organizations to adopt the "best execution place" principle, where each workload is assigned according to its cost, performance, security, regulatory, and compliance requirements [11].

Among the most dominant factors driving cloud repatriation is uncertain and unexpected costs. Studies show that most organizations experience cloud spending that exceeds budget by 30–40% due to overprovisioning, data egress fees, and unmanaged resources [1], [2], [3]. Upon leaving AWS and creating its own infrastructure, Dropbox, in particular, saved more than USD 75 million [12]. Meanwhile, social media company X (Twitter) saved cloud operating expenses to the tune of USD 60 million annually following the relocation of media storage in-house [13]. As Murugesan [3] notes, although cloud will decrease operational expenditure (OpEx). In fact, the organization is usually bound to incur high long-term costs; therefore, the Total Cost of Ownership (TCO) analysis needs to be more comprehensive.

Besides cost consideration, CR is also being pushed by security and compliance considerations. Financial and banking institutions are also subject to strict regulations like the General Data Protection Regulation (GDPR) and the Payment Card Industry Data Security Standard (PCI-DSS) that mandate rigorous rates of encryption and incessant auditing [14], [15]. According to Everest Group [15], in the case of the banking industry, the aspects of data sovereignty and access control are of primary importance because any breach of the data may have legal consequences and a tarnished reputation. According to Priyanka Gowda [14], the migrations of the cloud in the banking industry are often faced with the difficulty of connecting the old system with the new systems, which heightens the chances of disruptions and impacts business-related essentials. Although cloud providers possess excellent security controls, the actual issues are presented by the vulnerability of governance and distributed responsibility frameworks whose implications are not always well-known by users [16], [17]. A study by the Ponemon Institute [17] revealed that the mean cost per annum of a cloud account breach is USD 6.2 million, and the mean application downtime is 138 hours per year. This implies that as much as the cloud provides a highly effective infrastructure, the success or failure of any organization is a major factor of organizational governance.

Another important driver of cloud repatriation is vendor lock-in and limited workload portability. eG Innovations [2] has reported that workload mobility is not easily achieved because of dependence on proprietary APIs and data formats. Räisänen [18] declared that the failure to have an effective exit strategy puts the organization at risk of losing strategic control and escalating expenses in the process of leaving a specific provider. To this end, a large number of organizations are currently pursuing multi-cloud or hybrid solutions to reduce the vendor lock-in risk. According to the BigID report [19], it is observed that 68% of the organizations currently operate in multi-cloud setups, and on average, there are four different types of providers who serve various important applications.

Moreover, the factors of performance and latency are also important triggers of the repatriation process. As Flores [20] discovered, data-intensive workloads, especially in the healthcare and media sectors, fail to reach optimum performance levels when they are deployed in the structure of a public cloud. As Posey et al. [6] noted, many organizations are shifting to a hybrid model because of the different needs posed by the development and production environment. The use of a phased migration strategy supported by middleware was reported by Priyanka Gowda [14] as the most common approach adopted in the financial services industry to address operational disruptions. Other new paradigms like edge computing are also gaining more academic interest, with the ability to handle data in real-time near the data source, which helps to reduce the issue of latency.

Considerable concern has also been raised regarding governance and exit strategies. Grabski and Schmidt [16] suggested a two-tier model of governance which is grounded on the TOE framework, and it indicates the necessity of collective responsibilities between the CSU and CSP. They pointed out that any organization needs to develop new governance policies whenever it decides on a repatriation, the definition of Service Level Agreements (SLAs), security control, and data backup procedures. Forbes [21] also pointed out that repatriation is not only a technical choice, but it is a way to gain control, data ownership, and bargaining power over cloud providers.

However, despite various studies and reports, several critical limitations remain unaddressed. Longitudinal studies measuring the cost, performance, and security impacts of repatriation over a five-to ten-year period are almost non-existent [5], [22]. Furthermore, existing models lack integration across cost evaluation, security compliance, governance maturity, and workload mobility, particularly within public sector contexts. Therefore, this study presents a systematic literature review that addresses these limitations through three focused contributions: identifying the key factors influencing cloud repatriation, examining solution strategies proposed in academic and industry literature, and revealing the implementation limitations between

theoretical models and real-world on-premises transition practices.

II. Methodology And Article Selection

This study employs a Systematic Literature Review (SLR) method to collect the extant literature regarding cloud repatriation, including the problems and factors involved in the process of workload migration between the public clouds and on-premises or hybrid cloud settings. The review process was guided by the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) framework. The aim is to bring together theoretical and practical knowledge that will describe the state of research and practice in cloud repatriation.

A. Research Design

The methodological flow involves four stages:

1) Identification – Articles were found in reputable academic databases such as IEEE Xplore, SpringerLink, ScienceDirect, and Scopus, and reputable sources in the industry such as eG Innovations, Everest Group, Forbes Tech Council, and BigID Blogs. The search was conducted using the following keywords: 'cloud repatriation', 'cloud exit strategy', 'hybrid cloud', 'data segregation', 'cloud governance', and 'multi-cloud migration'. This initial search yielded a total of *124 records.* Search execution differed by source type. For academic databases, the six keywords identified above were combined using Boolean operators (AND/OR) within each platform's advanced search interface to maximize retrieval precision, with syntax adjusted to suit the specific search conventions of each platform. For industry sources without advanced Boolean search functionality, individual keywords were searched separately using each platform's native search or blog search function, and the keyword yielding results most topically relevant to cloud repatriation was retained per source. Retrieved records across all sources were consolidated before the deduplication step described in the Screening stage. The search and screening process was conducted over the weeks preceding the recorded extraction date of 8 December 2025, which is reported in Fig. 2 as the reference date for the record count at the point of extraction.

2) Screening – The 124 records were first screened for duplicate entries, resulting in 106 unique records retained for further review. These records then underwent systematic title and abstract screening, during which 71 records were excluded based on the identified reasons. Following this screening process, 35 articles were forwarded for full-text eligibility assessment, as illustrated in Fig. 2.

3) Eligibility – The 35 remaining articles underwent comprehensive full-text review against the defined inclusion criteria, which required coverage of topics related to cloud repatriation factors, migration strategies, data security, performance, or governance, published between 2021 and 2025. During this stage, 15 articles were excluded, and the remaining 20 studies were retained for final synthesis.

4) Inclusion – The final 20 studies were categorised into two groups: Theoretical Findings (TF), comprising 9 peer-reviewed academic publications sourced from journals and conference proceedings, and Real-Life Use Cases (RLUC), comprising 11 industry articles, reports, and technical blogs. This dual classification ensures a balanced representation of both theoretical constructs and practical applications in the analysis of cloud repatriation.

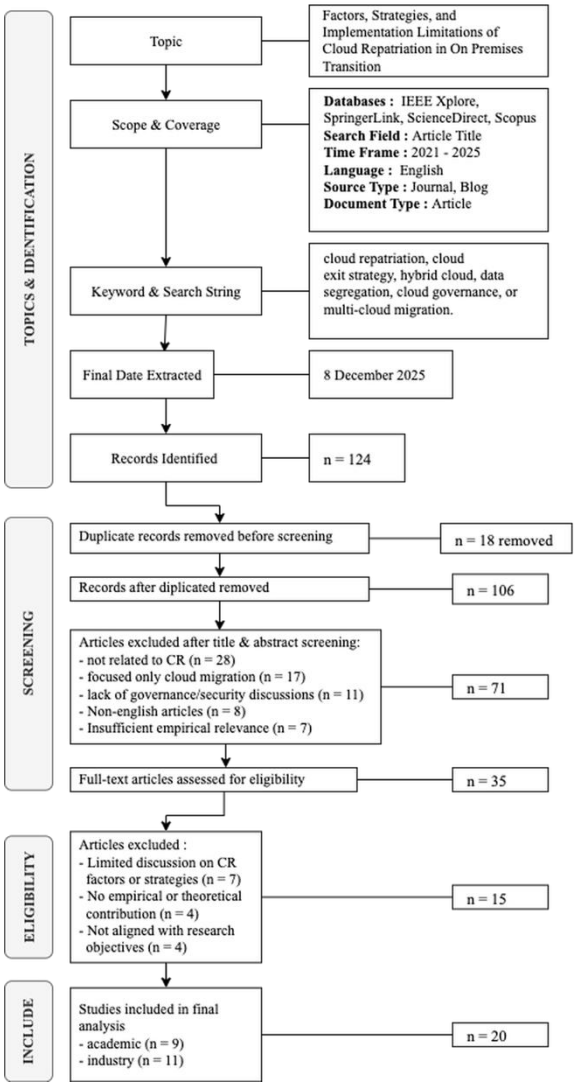

Fig. 2. PRISMA flow of article selection.

B. Research Questions

The review is guided by three Research Questions (RQs) designed to clarify the study's analytical focus:

- RQ1: What are the factors driving cloud repatriation in recent academic studies and industrial real-life use cases?
- RQ2: What are the limitations and solution strategies for each factor driving cloud repatriation towards on-premises transition?
- RQ3: What is the current trend of cloud repatriation in academic and industry literature?

These questions direct the synthesis and appropriateness in the alignment of the literature evidence to the study objectives.

C. Article Categorization

To differentiate between theoretical and applied contributions, the chosen works were broken down into two major groups: 1) Theoretical Findings (TF), and 2) Real Life Use Cases (RLUC). These measures are based on the final 20 articles included in the PRISMA process that identified the inclusion of the relevant studies in a systematic way that was validated. While this dual classification distinguishes theoretical from applied contributions, sources within each category carry differing levels of evidential strength. Peer-reviewed articles and conference proceedings (the TF category) have undergone formal editorial and peer review, whereas industry reports, company blogs, and white papers (the RLUC category) are not academically peer-reviewed and may reflect commercial or promotional framing associated with their originating organizations. This review retains these source types for the practitioner-level insight they offer, but findings drawn from lower-scrutiny sources are treated with appropriate interpretive caution throughout Section IV and corroborated against peer-reviewed evidence where available.

This dual classification allows establishing a balanced comparative position between the perspectives of real use cases and the practical elements of the academic field, to identify the most important limitations and trends. The distribution of selected articles, as illustrated in Fig. 3, indicates that even though academic discourse continues to be dominant, more and more industry-based evidence is emerging to corroborate theoretical knowledge with practical application. The balance between these two categories strengthens this review by ensuring that the aggregate outcomes are not biased toward the literature alone, but also provide practitioners and policymakers with practical perspectives.

The scholarly and theoretical contributions identified through this review process are summarised in Table II, which presents the academic publications selected for analysis, while Table III presents the corresponding industry-based sources. As illustrated in Fig. 4, academic studies tend to contribute a higher number of CR factors. In contrast, all 11 industry sources each contribute a single CR factor, reflecting a more targeted focus in industry literature. Collectively, the 20 selected studies contribute a total of 22 identified CR factors, forming the thematic foundation for analysis in this review.

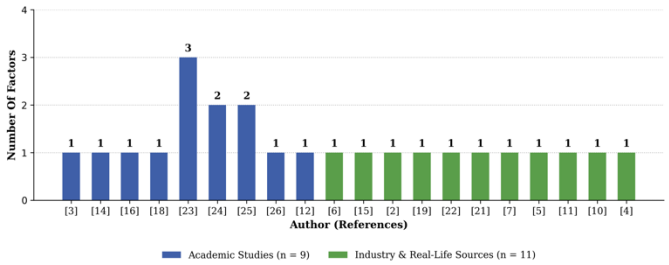

Fig. 4. Numbers of factors identified in each study by author.

D. Quality Assessment Criteria

Each included study was assessed using three quality dimensions to ensure the validity and relevance of the review outcomes. Completeness refers to the availability of clear findings, models, or empirical evidence that directly addresses the defined research questions. Credibility concerns the source authenticity and peer-review status of both academic and industry materials included in the review. Relevance requires direct alignment with the topics of cloud repatriation, hybrid migration, or related keywords as defined in the search strategy. Only studies meeting all three criteria were included in the final synthesis to maintain methodological rigour and ensure trustworthy interpretation of the results. Instead of a numerical scale, a binary pass/fail system was used for each dimension; if a study explicitly addressed the dimension, it was deemed to satisfy it (Yes); if it did not, or if it did but only superficially, or if it did but could not be independently verified, then it was deemed not to satisfy it (No). Thirty-five articles were selected for full-text review, of which only those that received a "Yes"

for all three dimensions were retained for final synthesis. These classifications were made by the lead author and then re-evaluated and confirmed by co-authors before finalization. This process does not begin with independent parallel coding by multiple reviewers, so this does not constitute formal interrater reliability verification and is discussed further as a methodological limitation in Section III-F.

E. Synthesis Approach

All included materials were analysed using thematic coding and classified across five factors derived from both theoretical and practical insights:

- Cost and Economic Considerations.
- Security, Compliance, and Sovereignty.
- Vendor Lock-In and Portability.
- Performance and Latency Requirements.
- Governance and Exit Strategy.

This approach integrates quantitative data with qualitative insights, aligning academic concepts with real-world practices. By combining rigorous research with industry relevance, the study offers a comprehensive understanding of the strategies, factors, and limitations associated with cloud repatriation.

III. Related Works

This section critically reviews state-of-the-art academic literature, industry reports, and real-life cases addressing the principal factors and limitations associated with cloud repatriation. Rather than presenting the selected studies as an isolated list, each subsection examines how the identified limitations inform the analytical framework of this review. A cross-factor comparison is subsequently presented in Table IV.

TABLE IV. Summary of Related Works By Factor

Factor	Author	Strengths	Limitation	Contributions
Cost & Economics	[3], [22], [23], [24], [21]	Cost unpredictability and TCO as repatriation drivers Hybrid deployment for cost control Dropbox, X/Twitter confirm post-CR savings	Descriptive analyses; no data-driven cost models No standardised TCO benchmarking framework Limited public sector validation	Synthesises cost factors across academic and industry sources Identifies TCO modelling as a key limitation Establishes cost as a core CR framework dimension
Security, Compliance, Sovereignty	[24], [14], [19], [15]	GDPR, PCI-DSS compliance as repatriation triggers Sovereignty and encryption as recurring concerns Data residency confirmed as industry driver	Prescriptive and conceptual; no implementation plans No unified compliance-into-repatriation model Security and governance treated separately	Maps security factors across academic and industry sources Highlights missing compliance-governance integration Informs policy-driven CR framework for regulated sectors
Vendor Lock-In & Portability	[6], [18], [11], [16]	Proprietary APIs and vendor contracts as portability barriers TOE-based multi-cloud governance proposed Hybrid adoption to reduce lock-in risk	Conceptual frameworks; no reusable blueprints Public sector constraints underrepresented Multi-cloud cost-complexity trade-offs unexplored	Consolidates lock-in factors from theory and practice Identifies portability gap in public sector context Supports portable-by-default architectural standards
Performance & Latency	[25], [26], [12], [3]	On-premises outperforms public cloud in latency-intensive workloads Selective repatriation and load-balancing proposed Latency variability across cloud regions	Simulation-based; no cross-industry validation No standardised cloud vs. on-premises benchmarking Cost-latency trade-offs underexplored	Consolidates pre- and post-CR performance evidence Flags benchmarking absence as implementation limitation Supports selective repatriation as a performance strategy
Governance & Exit Strategy	[16], [1], [7], [10], [15]	Structured exit planning recognised as critical enabler TOE-based and shared-responsibility models introduced Governance maturity correlates with repatriation readiness	Descriptive models; no implementation roadmaps No quantifiable governance maturity metrics No replicable blueprint for hybrid or public sector	Synthesises governance factors across all source types Identifies exit governance gap as critical limitation Establishes governance as dominant CR factor

A. Cost and Economic Considerations

Several studies have examined cost as a primary driver of cloud repatriation. Murugesan [3], Linthicum [22], and Kumar [5] identify increased operational expenditure and uncertain Total Cost of Ownership (TCO) as key concerns when workloads remain on public cloud platforms. Hui Chang [23] and Forbes Tech Council [21] further argue that transitioning to hybrid or on-premises environments offers greater long-term capital expenditure control. Real-world cases corroborate these findings, with Dropbox reporting annual savings of USD 75 million post-repatriation [12], and X (Twitter) reducing cloud costs by USD 60 million annually [13]. However, most existing studies rely on descriptive or anecdotal cost analyses rather than data-driven models. Kumar [5] proposes a Cloud Right framework but lacks cross-industry empirical validation, while Linthicum [22] and Murugesan [3] do not quantify cost-performance trade-offs. No standardised TCO benchmarking framework currently exists, particularly for non-technical and public sector contexts. This absence of a standardised, data-driven TCO framework is a central gap that this review responds to by consolidating disparate cost evidence (Sections IV and Table IV) into a single comparative synthesis rather than treating each case in isolation.

B. Security, Compliance, and Sovereignty

Security and compliance concerns are widely recognised as significant factors influencing cloud repatriation decisions. Abied et al. [24] and Priyanka Gowda [14] highlight that e-government and Banking, Financial Services and Insurance (BFSI) environments require strict data privacy, trust, and governance compliance. Industry reports by BigID [19] and Everest Group [15] confirm that data sovereignty and encryption integration are common repatriation triggers in regulated sectors. Despite this, existing works remain largely prescriptive, presenting conceptual models without practical implementation plans. Abied et al. [24] focus on security awareness without operational guidance, while BigID [19] discusses compliance trends without demonstrating real-world applicability. Furthermore, no unified policy-based model currently integrates compliance controls directly into repatriation workflows, particularly for public sector environments. This separation of prescriptive security models and operational implementation is exactly what this review aims to bridge by correlating security factors to specific solution approaches (Table VII) instead of compliance requirements and technical controls as separate discourses.

C. Vendor Lock-In and Portability

Vendor dependency and lack of portability are consistently reported challenges in cloud repatriation literature. Posey et al. [6], Räisänen [18], and Jewargi [11] highlight that proprietary APIs and storage formats reduce workload flexibility and increase switching costs. Grabski and Schmidt [16] extend this by proposing a TOE-based multi-cloud governance model that promotes shared responsibility across providers. However, these studies largely overlook the operational complexity and cost of managing multi-cloud environments. Posey et al. [6] and Jewargi [11] describe avoidance strategies without providing reusable architectural blueprints, and most academic works focus on identifying risks rather than prescribing standardised interoperability models. Public sector constraints, including procurement regulations and data residency requirements, remain underrepresented in existing portability frameworks. Existing research does not extend beyond the identification of risk, so this review aggregates lock-in evidence from both theoretical and practical sources to identify areas where public sector portability needs are not met (Table IV).

D. Performance and Latency Requirements

Technical performance, particularly latency and scalability, is a well-documented repatriation trigger in enterprise contexts. Mallikarjuna and Kumar [25], Sandhiya and Suresh [26], and Korada and Sikha [12] demonstrate that on-premises and private cloud environments consistently outperform public cloud configurations in high-computation and latency-intensive workloads. Murugesan [3] and Hui Chang [23] further note that latency directly impacts resource efficiency and user experience. Nevertheless, most performance analyses are context-specific, relying on simulation-based or single-case validations. Mallikarjuna and Kumar [25] assess performance parameters without standardised benchmarking tools, while Sandhiya and Suresh [26] propose load-balancing algorithms that lack cross-industry scalability validation. A related strand of work by Mohd Ali et al. [27] proposes a multi-factor replica placement strategy to mitigate resource failure in cloud replication environments, addressing scalability and reliability concerns from a data-placement perspective. This approach was later extended by Mohd Ali et al. [28] through a multi-factor replica placement strategy for resource failure extenuation. However, both approaches were validated using CloudSim and have not been benchmarked against repatriated on-premises or hybrid infrastructure. Their applicability to real-world cloud repatriation therefore remains insufficiently validated across industries. No widely accepted benchmarking standard currently exists for comparing repatriated versus cloud-hosted workload performance. This lack of a shared benchmarking standard motivates the cross-study performance synthesis undertaken in this review (Table VI), which consolidates otherwise incomparable simulation-based findings into a single qualitative before-and-after comparison.

E. Governance and Exit Strategy

Governance and exit planning are recognised as critical enablers of successful cloud repatriation. Grabski and Schmidt [16] propose a two-tier TOE-based governance model that assigns distinct technical and functional responsibilities across multi-cloud environments. eG Innovations [1] and Puppet [10] advocate for proactive exit planning to prevent uncoordinated transitions, while IDG/LHIND [8] and the Everest Group [15] demonstrate a strong correlation between governance maturity and repatriation readiness. In the Malaysian public sector context, Sallehudin et al. [29] similarly identified organisational, technological, and environmental readiness factors as key determinants of successful cloud implementation, offering an early empirical foundation for governance-driven adoption decisions. This TOE-oriented perspective has since been extended by Mohd Noh et al. [30], who applied a resource-based and TOE framework to model cloud adoption governance in the Malaysian healthcare sector, reinforcing the relevance of organisational readiness constructs beyond adoption into repatriation contexts. However, existing governance models are predominantly descriptive, offering best practices without implementation roadmaps or quantifiable maturity metrics. Mallam Ibrahim et al. [31] further note that governance and human-organisational factors remain under-modelled even in cloud adoption studies within academic institutional settings, echoing the same descriptive gap observed in repatriation-specific governance frameworks. Comparative analyses across sectors are lacking, and there is no replicable blueprint of governance that can be generalised to hybrid or public sector settings. This is the most consistent gap identified in this study and is used as the main organising theme for the integrated framework proposed in Section IV, as governance models are descriptive and non-quantifiable in all sources reviewed.

F. Synthesis and Research Limitations

Collectively, the reviewed studies demonstrate that cloud repatriation studies have evolved across five major dimensions, as summarised in Table IV. While scholarly contributions provide theoretical insight and conceptual elaboration, industry studies offer empirically grounded operational observations. Despite this, a significant limitation remains in the literature itself: existing research has not produced a unified framework applicable to public sector contexts, where heightened data sensitivity, regulatory compliance requirements, and national

sovereignty concerns necessitate dedicated governance and security conventions. It is equally acknowledged that this review, consistent with the nature of a systematic literature review, does not itself generate new empirical or predictive data; its contribution lies in the structured cross-source synthesis of existing theoretical and industry evidence rather than in novel primary measurement. To partially offset this methodological boundary, Table IV and Table VI advance beyond simple narrative summary by cross-tabulating strengths, limitations, and solution strategies across all 20 studies, an analytical step (Section IV) that surfaces patterns, such as the disproportionate concentration of governance-related gaps, that are not explicit in any single source reviewed. Building on this synthesis, this review addresses the identified literature gaps through three contributions: the identification of CR factors, the synthesis of solution strategies, and the mapping of implementation limitations between theoretical models and real-world on-premises transition practices.

A further methodological limitation concerns the verification process underlying both the quality appraisal (Section II-D) and the thematic coding used in Fig. 6 (Section IV). In both cases, initial classification was performed by the lead author and subsequently reviewed and validated by co-authors, rather than through fully independent parallel coding from the outset. While this collaborative validation step provided a degree of cross-checking, it does not constitute formal inter-rater reliability verification. Future replications of this review would benefit from a fully independent dual-coding protocol at both the quality-appraisal and thematic-classification stages to further strengthen methodological rigour.

A related limitation concerns the heterogeneous evidential strength of the synthesized sources, which span peer-reviewed publications, industry reports, blogs, and self-published white papers with differing levels of editorial scrutiny. No differential weighting was applied based on source type; industry-reported statistics are presented alongside peer-reviewed findings as complementary rather than equivalent evidence, and readers should interpret figures from industry or vendor-affiliated sources with awareness of potential promotional framing.

G. Cross-Factor Gap Analysis

To complement the narrative synthesis above, a Solution-to-Limitation Ratio (Gap Ratio) is computed for each CR factor by dividing the number of solution strategies proposed (Table VII) by the number of limitations identified (Fig. 8), as summarised in Table V. A ratio of 1.00 indicates that the literature has proposed at least one corresponding strategy for every limitation identified, while a ratio below 1.00 signals that limitations have outpaced concrete solution development. As shown in Table V, Cost and Economic Considerations, Security, Compliance and Sovereignty, and Vendor Lock-In and Portability each reach a Gap Ratio of 1.00, whereas Performance and Latency and Governance and Exit Strategy both return 0.75. However, this numerical parity masks a qualitative difference: Performance limitations are largely technical and partially mitigated by emerging approaches such as edge computing and selective repatriation, whereas Governance limitations are organisational and procedural, compounded by the finding that 45% of organisations lack any formal exit strategy [10]. Governance and Exit Strategy is therefore treated as the highest-priority gap for future CR framework development, consistent with the trend analysis in Section IV (RQ3). This analysis is a modest extension beyond descriptive synthesis rather than new primary empirical data, offering a reproducible basis for prioritising future research and policy attention across the five CR factors.

TABLE V. SOLUTION-TO-LIMITATION GAP RATIO ACROSS THE FIVE CR FACTORS

CR Factor	Limitations (LC)	Solution Strategies (SC)	Gap Ratio (SC/LC)	Priority For Future Research
Cost and Economic Considerations	4	4	1.00	Moderate
Security, Compliance and Sovereignty	4	4	1.00	Moderate
Vendor Lock-In and Portability	3	3	1.00	Moderate
Performance and Latency	4	3	0.75	High
Governance and Exit Strategy	4	3	0.75	Highest

H. Contradictory Evidence and Interpretive Tensions

While the twenty studies reviewed are broadly consistent in identifying cloud repatriation as a strategically beneficial response to cost, security, and governance pressures, closer examination reveals three interpretive tensions that a purely convergent synthesis would obscure. First, a proactive-versus-reactive tension emerges around cost-driven decisions. Kumar [5] proposes the Cloud Right framework as a proactive workload suitability assessment conducted before migration, yet the case evidence in Fig. 5 and the account provided by Murugesan [3] show that organizations such as Dropbox, X, GEICO, and 37signals repatriated only after costs had already exceeded expectations, reflecting a reactive correction rather than proactive modelling. Second, security is simultaneously described as technically well-managed by cloud providers and as the most frequently cited repatriation trigger, accounting for 35 percent of coded mentions in Fig. 6. This is resolved on closer reading: the underlying concern is not the technical adequacy of provider security controls, but the lack of clarity in shared-responsibility arrangements between Cloud Service Providers and Cloud Service Users. Third, sources disagree on the extent of intervention needed to address vendor lock-in. BigID [19] treats existing multi-cloud adoption, already practiced by 68 percent of organizations, as a sufficient mitigation, whereas Räisänen [18] argues that without a formal exit strategy, organizations remain exposed to loss of strategic control. This review does not resolve which position holds more broadly, noting instead that the appropriate degree of intervention likely depends on organizational context and workload criticality.

These tensions indicate that the reviewed literature converges on repatriation as a significant trend but does not speak with one voice on when it should occur, what precisely

motivates security-driven decisions, or how completely vendor lock-in can be mitigated short of full repatriation. Acknowledging this strengthens rather than weakens the review's synthesis.

IV. Findings and Discussion

This section discusses the key findings derived from the analysis of 20 selected studies related to cloud repatriation (CR). The discussion is organised around five major factors, as outlined and discussed in this study. Each factor is examined in relation to the three research questions (RQ1–RQ3) to highlight the primary factors driving CR, the limitations and solution strategies for each CR factor, and the current trends of CR studies across academic and industry literature.

RQ1: What are the factors driving cloud repatriation in recent academic and industrial studies?

Five prominent factors were identified across the recent academic and industrial studies:

1) Cost and Economic considerations: In both scholarly and industrial studies, cost is one of the most frequently identified drivers of cloud repatriation. George [4], Flores [20], and Murugesan [3] point out that it is a common experience in organizations to underestimate the cost of operation of the hyperscale cloud platform, and actual expenditure may exceed initial estimates by 30–40%. Egress charges, auto-scaling anomalies, orphaned resources and complex OpEx billing designs are also leading sources of cost volatility that organisations, particularly those in the public sector, cannot easily manage. Institutions that are owned by the government have another limitation, which is a rigid procurement process and an inflexible system of depreciation [32], [33], further complicating cost predictability of a cloud service in the long-term.

The empirical importance of cost-related motivations is demonstrated in Fig. 5, which compares annual savings reported by organizations that repatriated critical workloads. After departing from AWS, Dropbox reported savings of USD 75 million per year, while X (Twitter), GEICO, and 37signals each reported significant reductions in cloud operating costs following their respective repatriation initiatives [9], [13], [33]. The cost savings presented in Fig. 5 are individually reported figures drawn directly from each organization's own case-study disclosure rather than statistically pooled or averaged. As these figures originate from different reporting periods, organizational scales, and workload profiles, they are juxtaposed for side-by-side comparison and should be interpreted as illustrative case-level evidence rather than a representative or generalizable benchmark of expected repatriation savings. These practical outcomes support the literature in affirming that repatriation decisions tend to be reactive responses to accrued financial inefficiencies rather than the result of proactive economic modelling. Taken together, the findings validate that cost unpredictability, driven by egress charges, overprovisioning, and complex billing structures, remains one of the core triggers of cloud repatriation. Therefore, this financial pressure has compelled many organizations, particularly those in the public sector with rigid procurement constraints, to reassess their cloud dependencies and transition critical workloads back to on-premises infrastructure as a more cost-predictable and financially sustainable alternative.

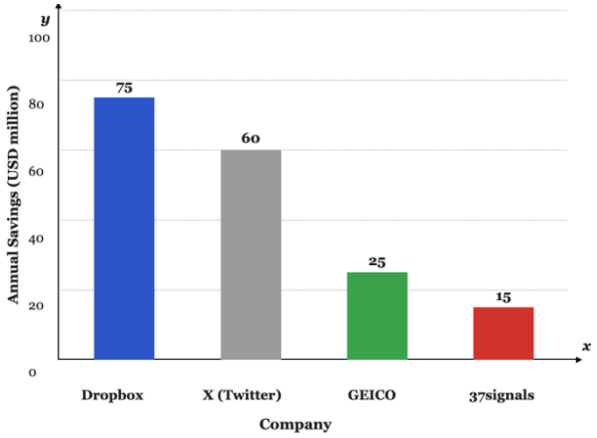

Fig. 5. Cost savings achieved through CR by various companies.

2) Security, compliance, and sovereignty: Security, compliance, and sovereignty are still coming out as the most powerful factors in cloud repatriation, especially in highly regulated industries. Priyanka Gowda [14] and the Everest Group [15] emphasize that companies that are under strict regulatory requirements, like the General Data Protection Regulation (GDPR) and the Payment Card Industry Data Security Standard (PCI-DSS), must have robust auditability, end-to-end encryption, and strict data sovereignty requirements. These needs are usually beyond the capability of organizations to impose uniformly in the multi-tenant public cloud landscape. Even sovereignty issues are supported by the fact that 23% of organizations interviewed by Posey et al. [6] state that data sovereignty conflicts were a prominent factor in deciding to repatriate workloads on-premises. Also, there is a longstanding lack of clarity in shared-responsibility approaches between Cloud Service Providers (CSPs) and Cloud Service Users (CSUs), which leads to gaps in governance, particularly in such aspects as access control, data lineage, and cross-cloud visibility.

The empirical relevance of these security-related issues can be seen in Fig. 6, which summarizes the most commonly reported factors of repatriation: data sovereignty (35%), regulatory compliance (30%), data breaches and misconfigurations (20%), and vendor responsibility gaps (15%). The security-concern distribution presented in Fig. 6 was derived through thematic synthesis rather than extraction from any single source. Findings from six studies explicitly addressing security-related repatriation drivers, Posey et al. [6], Priyanka Gowda [14], Everest Group [15], BigID [19], Grabski and Schmidt [16], and the Ponemon Institute [17] were reviewed and coded into these four recurring thematic categories, and the resulting thematic frequencies were expressed as percentages of the total coded mentions across these six sources. This initial coding was performed by the lead author and subsequently reviewed and validated by co-authors; a fully independent dual-coding protocol with inter-rater

reliability verification was not conducted, and this is noted as a limitation in Section III-F. This is a reinforcement of trends evident in the literature that regulatory pressure and sovereignty assurance are the key triggers in motivating decisions of security-motivated repatriation.

3) Vendor lock-in and portability: Vendor lock-in is an intractable barrier to cloud agility. According to Räisänen [18] and Murugesan [3], proprietary cloud application programming interfaces (APIs), storage formats, and management tools impede workload migration and give rise to high switching costs. In the case of public-sector organizations, the problem is exacerbated by long-term vendor contracts, tough procurement policies, and data-residency requirements, all of which limit mobility. As a result, vendor lock-in represents both a technical and governance barrier that undermines organisational autonomy, reduces bargaining power, and complicates regulatory compliance.

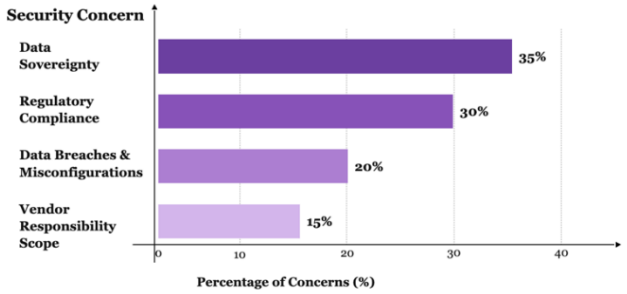

Fig. 6. Distribution of security concerns identified in CR studies.

4) Performance and latency requirements: The latency and performance requirements of latency-sensitive applications such as real-time analytics, artificial-intelligence inferencing, financial operations, and Internet of Things (IoT) applications are difficult to implement in public clouds due to performance and latency requirements. Latency variability is reported to range between 40 and 60 ms between cloud regions [25], [26], and Grabski and Schmidt [16], Murugesan [3] and Räisänen [18] report such inefficiencies as resource contention and multi-tenant virtualization overheads. As such, organizations are progressively embracing the idea of selective repatriation, which moves only the latency-sensitive workloads on-premises to restore deterministic performance. Table VI presents a qualitative, direction-of-change comparison synthesized from the empirical patterns and discussion described across four major works [3], [12], [25], [26]. As these studies each report performance findings using different metrics, testing environments, and measurement instruments, this review does not derive or report pooled numerical ranges. Table VI summarizes the consistent directional trend, whether improvement or deterioration, that these studies collectively describe for each metric, without implying a specific quantified magnitude common across sources. Taken together, these papers reveal that cloud-hosted workloads generally have increased latency, jitter, and packet loss as well as response time due to multi-tenant contention, hypervisor overhead, distributed routing, and unpredictable resource scheduling in the environments of a public cloud. Both Mallikarjuna and Kumar [25] and Sandhiya and Suresh [26] prove that they have lower transfer rates, lesser throughput, and worse performance under cloud congestion, which is the baseline of Before CR conditions. On the other hand, based on evidence that is given by Korada and Sikha [12]enterprises turn to the implementation of their own clouds with an express objective to achieve low latency, greater throughput, considerably better IOPS, and more predictable storage and network performance-qualifications that define the after CR values. Murugesan [3] goes on to substantiate this distinction by reporting real-life repatriation experience (Dropbox, 37signals, X/Twitter) in which enhanced control over hardware, data locality, and system configuration directly correlated to enhanced reliability, faster processing time, and cost performance optimization. Collectively, these four studies describe a consistent directional shift from the variable, contention-affected profile characteristic of multi-tenant public cloud environments toward the more predictable, locality-enhanced profile associated with repatriated on-premises or private-cloud infrastructure. It is this consistent direction of improvement, rather than any specific quantified magnitude, that constitutes the primary empirical pattern supported by the reviewed literature.

TABLE VI. QUALITATIVE PERFORMANCE COMPARISON BEFORE AND AFTER CR

Metric	Before CR	After CR	Authors
Latency	Elevated and variable, driven by multi-tenant contention and distributed routing	Reduced and more deterministic due to local network paths	[25],[26],[12]
Latency Jitter	Higher variability under shared-tenancy congestion	More stable due to dedicated infrastructure	[25],[26]
Throughput	Constrained by shared network and storage resources	Improved via local storage and reduced contention	[25]
IOPS (Storage Performance)	Limited by shared multi-tenant storage backends	Higher and more predictable with dedicated enterprise storage	[12]
Application Response Time	Slower due to hypervisor overhead and network hops	Faster due to local infrastructure control	[25],[3]
Network Packet Loss	Higher due to WAN routing and cloud congestion	Lower due to local LAN environments	[25],[26]
Service Uptime	Subject to shared-infrastructure availability constraints	Improved through dedicated control and predictable infrastructure	[25],[3]
Data Processing Time	Slower, reflecting combined latency/throughput/IOPS constraints	Faster, reflecting improvements across all underlying metrics	[12],[3]

5) Governance and exit strategy: The maturity of governance is always a controlling factor that spells out the success of cloud repatriation results. Grabski and Schmidt [16] highlight the use of a two-level TOE-based governance framework whereby the technical and functional roles have to be distinctly allocated in order to embrace accountability in the multi-cloud settings. But the industrial experience indicates that the structure of governance is not in general satisfactory, as a matter of fact. According to Puppet [10], about 45% of organisations do not have any formal exit strategy, and as a result, configuration drift, lack of compliance confidence, and incomplete data validation have been observed when organisations repatriate workloads. These circumstances demonstrate that one of the most prevalent underlying factors of failed or ineffective repatriation processes is governance weaknesses rather than technological constraints. The concept flow of the governance activities mentioned throughout the literature is presented in Fig. 7, which demonstrates a governance lifecycle with policy development, implementation, constant monitoring, evaluation, and a cyclic review.

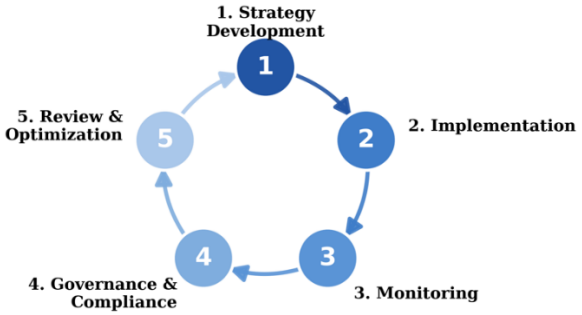

Fig. 7. Governance lifecycle.

This lifecycle underscores the fact that successful repatriation cannot work without governance as an iterative and policy-based activity as opposed to an administrative exercise that is one-time. The absence of such organised governance systems validates the obstacles mentioned in numerous research works and highlights the necessity to have standardised and actionable governance models in hybrid and multi-cloud settings.

RQ2: What are the limitations and solution strategies for each factor driving cloud repatriation towards on-premises transition?

In this section, RQ2 is addressed by systematically examining the limitations identified within the reviewed literature and the solution strategies proposed for each of the five CR factors. The consolidated findings are illustrated in Fig. 8, which contrasts theoretical limitations with real-life implementation challenges, and further mapped to the corresponding solution strategies in Table VII, which presents the corresponding solution strategies for each CR factor.

Fig. 8 illustrates the implementation gap between theoretical knowledge and industry practice across the five CR factors. Theoretical Findings (TF) from academic literature predominantly reveal conceptual and prescriptive limitations, while Real-Life Use Cases (RLUC) from industry practice expose more complex, context-specific challenges that existing frameworks have yet to adequately resolve. This juxtaposition confirms a consistent theory-practice gap, wherein academic models may underestimate the operational, contractual, and governance complexities encountered in real-world repatriation scenarios. Notably, this gap is most evident in the governance and security dimensions, where the absence of standardised implementation roadmaps and unified compliance models renders existing theoretical prescriptions insufficient for direct operational deployment.

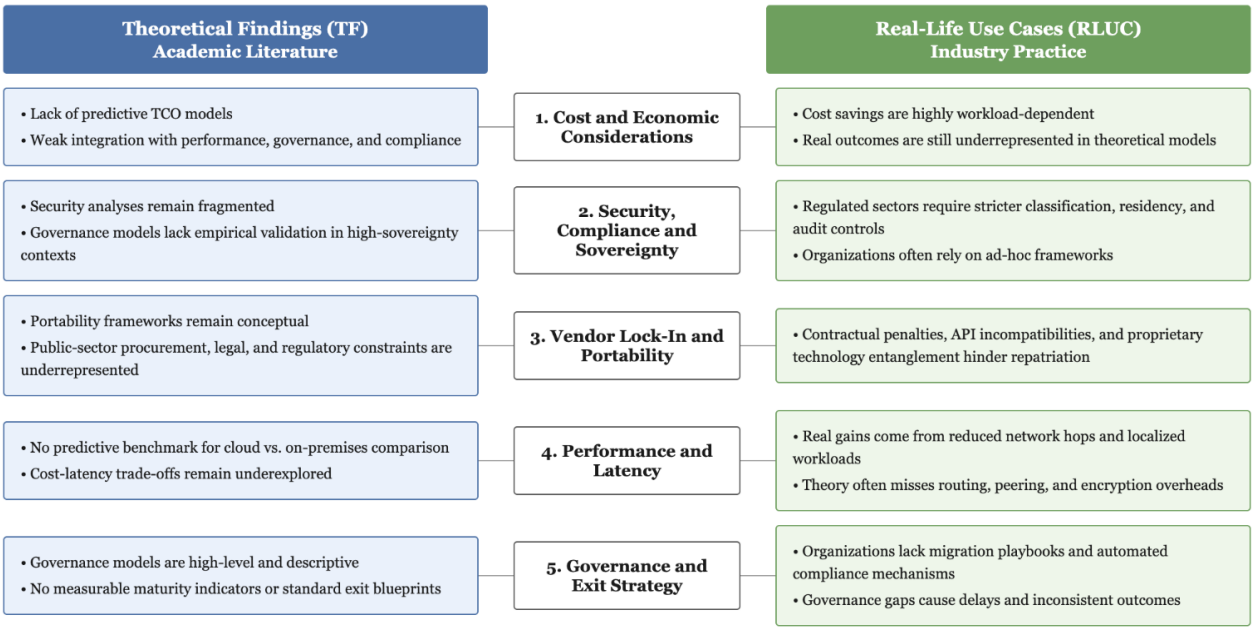

Fig. 8. Implementation limitations: theoretical findings vs real-life use cases.

TABLE VII. SOLUTION STRATEGIES CORRESPONDING TO THE FIVE CR FACTORS

CR Factor	Solution Strategies Proposed	Authors
Cost and Economic Considerations	- Cloud Right methodology for workload suitability assessment - Comparative TCO modelling: cloud vs. on-premises - Resource rightsizing automation for continuous cost governance - Balance short-term OpEx against long-term CapEx investment	[3], [5], [11]
Security, Compliance and Sovereignty	- TOE-based co-governance framework (CSP–CSU responsibility distribution) - Sector-specific sovereign cloud models for regulated industries - Automated data discovery, classification, and end-to-end encryption - Continuous compliance auditing and proactive sovereignty governance	[14], [15], [16], [17], [19]
Vendor Lock-In and Portability	- Hybrid and multi-cloud deployment to reduce vendor dependency - Cloud-agnostic technologies: Kubernetes, open APIs, and IaC - Contractual portability and post-termination repatriation clauses	[6], [11], [16], [18]
Performance and Latency	- Selective repatriation of latency-sensitive workloads to on-premises - Data locality enforcement to minimise network latency - CDN, edge computing, and AI-assisted workload orchestration	[5], [6], [20], [22], [23], [26]
Governance and Exit Strategy	- Two-tier TOE-based governance with distinct technical and functional accountability - Repatriation readiness embedded in cloud contracts (portability and audit clauses) - Lifecycle-based governance: procurement, deployment, auditing, and exit planning	[1], [2], [15], [16]

Building upon the limitations identified, Table VII consolidates the solution strategies proposed across the five CR factors, drawing from both academic recommendations and industry-based evidence. Each strategy is directly mapped to its corresponding CR factor, ensuring that the proposed interventions are specific, actionable, and responsive to the gaps identified in Fig. 8. The solution strategies presented in Table VII constitute an integrated and mutually reinforcing strategic foundation for CR decision-making. Cost strategies establish the financial justification for transition, while security and sovereignty strategies define the regulatory boundaries within which repatriation must be executed. Vendor lock-in strategies preserve organisational autonomy, performance strategies determine the technical suitability of workloads, and governance strategies provide the procedural infrastructure required to manage the entire repatriation lifecycle. Collectively, these five strategic dimensions confirm that cloud repatriation is not merely a technical migration exercise, but a multifaceted organisational policy decision that must be harmonised across regulatory, financial, operational, and technical priorities. This integrated approach is especially critical for public sector organisations, where regulatory obligations, procurement constraints, and national sovereignty requirements impose additional complexity that demands purpose-built, policy-driven frameworks.

RQ3: What is the current trend of cloud repatriation in academic and industry literature?

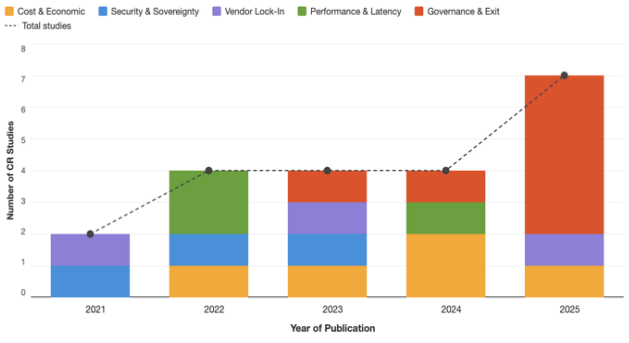

Fig. 9. Trend of CR studies by factor across academic and industry literature (2021 – 2025).

The analysis of 20 selected studies published between 2021 and 2025 reveals a discernible evolution in cloud repatriation studies, reflecting shifts in both academic focus and industry priorities across the five identified CR factors. As illustrated in Fig. 9, the distribution of CR-related studies across the review period demonstrates a progressive transition from performance and security-centred concerns toward governance and cost-driven imperatives.

A. Trend Analysis Across the Review Period

1) Early recognition of sovereignty and portability concerns: In 2021, CR research was primarily represented by a small number of foundational studies. Posey et al. [6] introduced the concept of workload mobility and vendor lock-in as early drivers of repatriation interest, while Gowda [14] highlighted security and compliance challenges in BFSI cloud migrations. These early works established sovereignty and portability as the initial academic triggers of CR discourse, though empirical evidence remained limited at this stage.

2) Performance and security as dominant themes: The year 2022 witnessed a notable increase in academic contributions, particularly from IEEE conference publications. Mallikarjuna and Kumar [25] and Sandhiya and Suresh [26] demonstrated measurable performance superiority in on-premises environments, while Abied et al. [24] and Chang [23] examined security and service differentiation between cloud and traditional infrastructure. This period reflects a growing academic interest in empirically validating the technical limitations of public cloud environments as justification for repatriation.

3) Cost and vendor lock-in gain industry momentum: By 2023, industry-driven evidence began to dominate CR discourse. Jewargi [11], BigID [19], and Forbes Tech Council [21] collectively highlighted escalating cloud costs, vendor dependency, and compliance obligations as compelling repatriation triggers. The IDG/LHIND survey [8] further confirmed that security, data compliance, and migration complexity were primary motivators among enterprise decision-makers. This shift marked a transition from purely academic performance analysis toward commercially grounded

cost and portability concerns, signalling that CR was becoming a mainstream strategic consideration across multiple industries.

4) Cost optimisation and real-world validation: In 2024, the focus consolidated around cost optimisation and real-world repatriation outcomes. Murugesan [3] provided a comprehensive review of cloud services, highlighting the financial inefficiencies of long-term public cloud dependency, while Korada and Sikha [12] documented enterprise motivations for building private cloud infrastructure post-public cloud adoption. Flores [20] further examined the strategic and technical implications of CR for DevOps and security practices. Collectively, these works validated the financial and operational case for repatriation through empirical and case-based evidence, reinforcing cost unpredictability as a core repatriation trigger.

5) Governance emerges as the dominant theme: The most significant trend observed across the review period is the sharp rise in governance-oriented publications in 2025. Grabski and Schmidt [16], eG Innovations [1], [2], Puppet [10], Räisänen [18], and the IDG/LHIND study [8] collectively position governance maturity, exit strategy formalisation, and lifecycle-based compliance as the most critical enablers of successful repatriation. This concentration of governance-focused works in 2025 reflects a maturation of CR studies, moving beyond the identification of repatriation drivers toward the prescription of structured, policy-driven frameworks for managing the transition process.

B. Overall Trend Synthesis

The longitudinal analysis of CR literature from 2021 to 2025 reveals three distinct phases of evolution in CR studies. The first phase (2021–2022) is characterised by foundational recognition of performance, security, and portability as primary repatriation triggers, predominantly within academic contexts. The second phase (2023–2024) reflects a convergence of academic and industry perspectives, with cost unpredictability and vendor lock-in emerging as dominant real-world drivers, validated through high-profile organisational cases such as Dropbox, X (Twitter), and GEICO. The third phase (2025) marks a governance turn in CR studies, wherein the field transitions from descriptive analysis of repatriation factors toward the development of prescriptive, policy-compliant frameworks suitable for regulated and public sector environments.

This evolutionary trajectory underscores the growing recognition that cloud repatriation is not a reactive technical decision, but a strategically planned organisational transition requiring integrated governance, cost modelling, and sovereignty-aware frameworks. The distribution of CR factors across the review period, as synthesised in Fig. 9, further confirms that Cost and Economic Considerations (22.7%) and Governance and Exit Strategy (22.7%) collectively represent the most critical priorities in the literature, while Security, Compliance and Sovereignty (18.2%), Performance and Latency (18.2%), and Vendor Lock-In and Portability (18.2%) reflect equally weighted but complementary dimensions of the CR research landscape. The complete classification of CR factors and their associated solution strategies is consolidated in Fig. 10, providing a structured taxonomy of the CR literature landscape identified in this review. It is acknowledged that the trend patterns described above are derived from publication counts within a bounded set of sources rather than a comprehensive bibliometric analysis, and may be influenced by factors beyond genuine shifts in research focus, such as database indexing lag and the growing tendency of industry organizations to publish repatriation-related commentary as the topic gains broader market attention. Consequently, the apparent 'governance turn' identified in 2025, and the broader three-phase trajectory described above, should be interpreted as a pattern observed within the reviewed evidence base rather than a definitive claim about the actual pace or sequence of change in cloud repatriation practice.

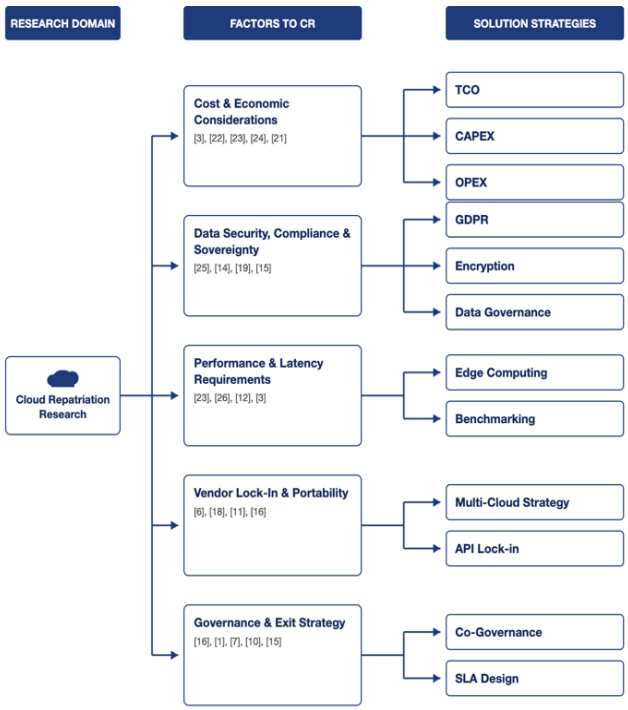

Fig. 10. CR factors and associated strategies.

V. Conclusion and Future Works

This study conducted a systematic literature review of the factors, solution strategies, and implementation limitations associated with cloud repatriation towards on-premises environments. Based on 20 academic and industry studies published between 2021 and 2025, the findings were synthesised into five thematic areas: cost and economic considerations; security, compliance, and sovereignty; vendor lock-in and portability; performance and latency; and governance and exit strategy.

The results validate the existence and development of cloud repatriation as an organised policy decision, rather than just a technical change process. The two highest-priority areas in the reviewed studies are Cost and Economic Considerations (22.7% of the evidence base) and Governance and Exit Strategy (22.7%), while security, compliance, performance, and portability remain complementary but equally important dimensions of the current literature.

With regard to RQ1, organizations are primarily driven toward cloud repatriation due to increasing cloud costs, data sovereignty requirements, regulatory compliance pressures, vendor dependency, and performance issues when it comes to latency-sensitive applications. In public sector settings, with inflexible procurement processes and no standardised frameworks of governance, these pressures are exacerbated in real-life examples such as Dropbox, X (Twitter), GEICO, and 37signals.

For RQ2, several solution strategies are identified for each CR factor. They include predictive TCO modelling and cost governance for economic factors, TOE-based co-governance and automated compliance auditing for security and sovereignty, cloud-agnostic architectures and contractual portability provisions to mitigate vendor lock-in, selective repatriation and edge computing integration for performance needs, and lifecycle-based governance frameworks to assist in exit strategy management. Combined, they represent an integrated strategy that recognizes the need to align financial, technical, regulatory, and governance priorities together for successful repatriation.

In the context of RQ3, the longitudinal trend analysis reveals three distinct phases of CR research evolution: foundational recognition of performance, security, and portability concerns (2021–2022), convergence of academic and industry perspectives driven by cost and vendor lock-in (2023–2024), and a governance turn marked by the dominance of governance-oriented publications (2025). This trajectory confirms that CR studies are maturing from descriptive factor identification toward prescriptive, policy-driven frameworks, particularly relevant for regulated and public sector environments.

Overall, the three contributions of this review, the identification of CR factors, the synthesis of solution strategies, and the mapping of implementation limitations, offer a solid foundation for creating integrated, policy-compliant and sovereignty-aware models of CR that can be applied in private and public sector settings.

Nevertheless, this review acknowledges several limitations. The analysis is bounded by English-language sources published between 2021 and 2025, which may exclude earlier foundational works and underrepresent CR studies from non-English-speaking regions. Additionally, the predominance of private sector and Western organizational contexts in the reviewed literature may limit the generalizability of findings across diverse regulatory environments and governance structures globally. Consequently, foundational governance and portability studies published before 2021, as well as non-English-language literature that may offer region-specific insights (e.g., from Asia-Pacific or Nordic public sectors), fall outside this review's scope and represent a direction for future comparative synthesis.

Building on the gaps identified in this review, future empirical research should prioritise: 1) the development and validation of a quantifiable Cloud Repatriation Governance Maturity Index across multiple regulated public sector organisations; 2) the establishment of longitudinal cost and performance measurement instruments to compare repatriated and cloud-hosted workloads over a three- to five-year period; and 3) the conduct of cross-national comparative studies to extend the current evidence base beyond its predominantly Western and private-sector orientation. Collectively, these research directions would strengthen the empirical basis for assessing the governance maturity, long-term economic viability, and operational effectiveness of cloud repatriation in regulated public sector environments.

ACKNOWLEDGMENT

This study is supported by the National University of Malaysia (UKM). Sincerely grateful for the facilities and funding provided, which were essential for completing this research.

Multi-Agent Crowd-Risk Prioritization for Large-Scale Events: A Hybrid ML–Agent Approach

Najwa Samrgandi
Department of Data Science-College of Computing, Umm Al-Qura University, Makkah, Saudi Arabia

***Abstract*—Managing crowd safety during large-scale gatherings such as Hajj requires timely assessment of multiple risk factors, including crowd conditions, environmental factors, and health-related indicators. Many existing approaches address these aspects separately, making it difficult to obtain a unified operational view of risk. This study presents a multi-agent framework that combines machine learning with domain-specific agent coordination for crowd-risk prioritization. The framework includes five agents responsible for crowd monitoring, health monitoring, environmental sensing, coordination, and alert generation. To reduce data leakage, variables used in risk-label construction and post-event outcomes were excluded before model training, resulting in 17 real-time observable features. The framework was evaluated using the Hajj and Umrah Crowd Management dataset containing 10,000 simulated records. On the independent test set, XGBoost+SMOTE achieved 47.30% accuracy and 46.22% F1-score; the XGBoost baseline achieved 57.15% accuracy and 45.96% F1-score, and a majority-class baseline that always predicts the dominant class achieved 58.70%, underscoring that overall accuracy is an insufficient metric for this task. Although accuracy decreased after class rebalancing, minority-class sensitivity improved: XGBoost+SMOTE achieved partial High-risk recognition (recall = 0.14, F1 = 0.12), whereas the XGBoost baseline and Cost-Sensitive XGBoost failed to identify any High-risk cases (recall = 0.00). McNemar's test confirmed a statistically significant difference between the XGBoost baseline and the SMOTE-enhanced model ($\chi^2 = 69.218$, $p < 0.001$). Cross-validation on the SMOTE-balanced training data produced 59.89% ± 0.20% accuracy and 58.94% ± 0.17% F1-score. A streaming evaluation on 500 held-out test records showed that the Full Framework generated 93 High-risk alerts, compared with 74 from the ML-only configuration and 23 from the Agents-only configuration, a 25.7% increase relative to ML-only operation. A precision check against the internal risk-score proxy found that none of the 19 agent-driven escalations beyond ML-only predictions corresponded to a High-risk label under this proxy; these alerts should accordingly be read as operational risk-prioritization signals rather than confirmed incident detections. All reported figures should further be interpreted in light of the dataset's synthetic origin: because features were algorithmically generated rather than collected from real sensors or incidents, the results are illustrative of the framework's behavior under these specific simulated conditions rather than predictive of real operational deployment. Average processing latency was 4.127 ms per record under sequential single-stream conditions. In addition to the proposed framework, the study presents a diagnostic evaluation approach that combines leakage control, dual association analysis, and direct precision auditing. This approach may also prove useful for evaluating similar ML–agent systems in other safety-critical alerting applications.**

I. Introduction

Large public gatherings represent one of the most operationally complex environments for safety management. The annual Hajj pilgrimage, which draws more than two million participants to confined geographic zones over a compressed timeframe, exemplifies the challenges that arise when crowd density, environmental stress, and health vulnerability intersect. The scale and operational complexity of Hajj continue to motivate the development of intelligent crowd-management systems capable of supporting timely risk assessment and decision-making [1], [2].

The past decade has seen considerable progress in AI-driven crowd analysis. Vision-based systems using YOLO and CNN architectures have achieved strong performance in density estimation and abnormal behavior detection [3], [4], [5]. IoT sensor networks have extended monitoring beyond camera fields of view by capturing environmental and operational indicators associated with crowd conditions [6], [7]. Multi-agent frameworks have demonstrated value in evacuation simulation and distributed coordination [8], [9]. Yet these advances have largely evolved in parallel rather than in concert: visual monitoring systems rarely incorporate health indicators; IoT platforms seldom feed predictive risk models; and agent-based systems tend toward simulation rather than real-time operational deployment [10], [11].

This fragmentation carries real operational cost. A monitoring system that detects crowd compression via camera feeds cannot independently account for the additional risk posed by extreme heat, an aging pilgrim population, or extended waiting times at transport checkpoints. Conversely, rule-based alert systems operating without predictive components lack the capacity to differentiate between momentary crowd fluctuations and genuinely escalating risk trajectories; predictive agent-based architectures have been shown to address this limitation more effectively [12], [13].

This study addresses this gap through a framework designed around five principles: 1) asynchronous agent independence: each agent processes its own data stream without blocking on others; 2) leakage-free feature engineering: the feature space used for ML prediction is strictly isolated from the variables used to construct risk labels; 3) operationally grounded escalation: the coordination policy prioritizes sensitivity over specificity, reflecting the asymmetric cost of missing High-risk events; 4) statistical accountability: model improvements are

validated through McNemar's test; and 5) real-time feasibility: all predictions are generated with sub-10 ms latency per record under the evaluated experimental conditions.

The study is guided by three research questions: (RQ1) How can asynchronous agent coordination improve crowd-risk prioritization beyond ML prediction alone? (RQ2) What feature-selection strategy best prevents leakage in operationally constructed risk labels? (RQ3) How does the proposed framework perform under realistic class imbalance without artificially inflating reported performance?

II. Related Work

Crowd safety research has matured across three intersecting streams. The first concerns AI-based crowd analysis. Vision-based architectures, particularly YOLOv8 and YOLOv9, have achieved near-real-time detection of density anomalies and abnormal behaviors [3], [14], [15], [16]. CNN-based approaches extended this to behavioral trajectory prediction [17], [18]. Cyber-physical integrations further embedded visual monitoring within broader operational sensing architectures [19], [20]. However, these systems remain primarily reactive: they detect what is already happening rather than flagging converging risk conditions.

The second stream concerns IoT-enabled monitoring. Distributed sensor networks capture environmental variables that co-occur with crowd incidents but fall outside camera fields of view [21], [22], [23]. Zhang et al. proposed an IoT-based public safety alert system that combines distributed multi-sensor inputs with lightweight edge-deployed machine learning models to generate alerts, demonstrating the feasibility of automated, low-latency alert pipelines for emergency response support [7]. While [7] incorporates basic predictive classification at the sensor level, it does not address multi-domain risk fusion across crowd, health, and environmental indicators simultaneously, nor does it consider data-leakage risks in label construction. The broader limitation across this stream of work is a continued reliance on per-sensor threshold or single-model logic rather than coordinated multi-agent risk fusion across heterogeneous domains [24].

The third stream concerns multi-agent coordination. Keykhaei et al. developed a situation-aware multi-agent evacuation model for earthquake scenarios, demonstrating that distributed agent coordination enables more adaptive response than static centralized planning in dynamic crowd conditions [9]. Dumitrescu et al. used multi-agent modeling to simulate crowd panic propagation [8]. More recent work has explored LLM-based agents for smart city coordination [12] and multi-agent machine learning frameworks combining classification with coordinated decision-making for real-time safety response [25]. Despite this breadth, most multi-agent applications remain simulation-oriented, with few validated deployments in operational real-time monitoring systems [26], [27], [28], [29].

The most directly comparable work is CIRS [25], a five-agent machine learning-based framework for real-time accident detection and emergency response, whose architecture (perception, classification, description, communication, and decision-making agents) closely parallels the five-agent design adopted in the present framework (Crowd Monitoring, Health Monitoring, Environmental Sensing, Coordinator, and Alert agents). The present framework differs from [25] in several respects. First, [25] is applied to a structurally distinct domain (road-traffic accident detection from CCTV video) rather than multi-domain crowd-risk prioritization, and accordingly integrates a vision-language model for incident description rather than tabular sensor-derived risk classification. Second, [25] reports classifier performance (YOLOv11: precision 0.866, recall 0.855) without an explicit discussion of label-construction leakage, since its ground truth (manually annotated accident frames) is independent of its input features by design, whereas the present framework addresses a leakage risk that is structurally specific to operationally derived risk labels. Third, [25] does not report a formal statistical test of agreement between its decision-making agent and its underlying classifier, an aspect the present framework addresses directly through McNemar's test (Section IV-C). A complementary comparison point is provided by Alshamrani et al. [30], who developed a wearable-sensor-based system for monitoring pilgrim stress and fatigue during Hajj, combining physiological, geospatial, and self-reported data; unlike the present framework, [30] is oriented toward descriptive analysis of collected pilgrim data rather than real-time multi-agent risk coordination, and does not incorporate a predictive classification component or an agent-based architecture. Taken together, [25] offers the closest architectural parallel (multi-agent coordination with an embedded ML classifier) while [30] offers the closest domain parallel (Hajj-specific physiological and environmental monitoring); neither addresses both dimensions simultaneously, which motivates the integrated evaluation presented in this study. These comparisons should be interpreted as descriptive positioning relative to the closest available published work rather than as a direct empirical benchmark. Table I summarizes the major research streams and their core limitations.

TABLE I. Summary of Major Research Streams and their Limitations.

Research Stream	Core Limitation	Key References
AI/deep learning crowd monitoring	Reactive; limited integration with health or environmental sensing	[3]-[5],[14]-[20]
IoT-enabled sensing and alerting	Threshold-based; no adaptive learning; no multi-source fusion	[6],[7],[21]-[24]
Multi-agent coordination frameworks	Simulation-oriented; limited real-time operational deployment	[8],[9],[12],[25]-[29]

Theoretical perspectives on multi-agent decision-making [31] and a broader multi-expert analysis of AI agentic systems and their deployment characteristics [32] further contextualize the coordination architecture adopted in this framework. Distinct from this general perspective, a multi-source information fusion technique specifically targeting abnormal crowd behavior detection [33] reinforces the operational complementarity of data-driven and rule-based sensing that underpins the proposed design. The review of prior studies suggests that current approaches address specific dimensions of crowd safety but rarely combine them within a single real-time architecture. This gap motivates the development of a framework that integrates predictive machine learning,

heterogeneous sensing, and coordinated agent-based responses to support proactive risk management.

III. METHODOLOGY

A. Dataset and Representativeness

The Hajj and Umrah Crowd Management dataset (Kaggle) comprises 10,000 records across 30 features capturing spatial coordinates, environmental readings, operational waiting times, health indicators, and pilgrim demographic profiles. The dataset contains no missing values and no duplicate records. All features were generated under simulated operational conditions designed to reflect common Hajj crowd management scenarios; their ability to fully represent real-world crowd behavior remains a study limitation.

Risk labels were derived through a weighted operational scoring function: Crowd_Density (0.25), Temperature (0.20), Fatigue_Level (0.15), Stress_Level (0.15), Queue_Time_minutes (0.10), Emergency_Event (0.10), and Distance_Between_People_m (0.05). The resulting score was discretized into three thresholds: Low (below 1.8), Medium (1.8–2.4), and High (above 2.4), yielding 3,121 Low (31.2%), 5,869 Medium (58.7%), and 1,010 High (10.1%) records. These labels represent operationally constructed risk proxies rather than verified emergency records. The framework is accordingly best characterized as a risk-prioritization tool.

B. Feature Engineering and Leakage Prevention

Data leakage represents one of the most consequential validity threats in applied machine learning research, capable of inflating reported accuracy without reflecting genuine predictive capacity [34], [35]. In this dataset, the risk is structurally elevated: the seven features used to compute the risk label were excluded from model input. Post-event outcome variables (Satisfaction_Rating, Perceived_Safety_Rating, Pilgrim_Experience, AR_Navigation_Success) were also excluded as they are unavailable at operational prediction time.

The resulting clean feature set comprises 17 real-time observable indicators: spatial (Location_Lat, Location_Long), movement (Movement_Speed), environmental (Weather_Conditions, Sound_Level_dB), operational (Activity_Type, Event_Type, Waiting_Time_for_Transport, Security_Checkpoint_Wait_Time, Time_Spent_at_Location_minutes, Interaction_Frequency), pilgrim profile (Age_Group, Health_Condition, Transport_Mode), and contextual indicators (Incident_Type, Crowd_Morale, AR_System_Interaction).

C. Data Partitioning and Class Balancing

The dataset was divided into 80% training (8,000 records) and 20% test (2,000 records) using stratified random splitting with seed 42. The test set was held out entirely throughout training, tuning, and oversampling. SMOTE [36] was applied exclusively to the training set following the split to address class imbalance [35], expanding the minority High and Low classes to match the majority Medium class at 4,695 samples each. Cross-validation on the SMOTE-augmented training set produces accuracy estimates under balanced class conditions (33.3% per class), which naturally exceed test-set accuracy under the original imbalanced distribution. Both metrics are reported with their interpretations distinguished in Section IV.

D. Prediction Models and Experimental Setup

Seven configurations were evaluated: Random Forest [37] (n=150, depth=10), XGBoost baseline [38] (n=200, depth=6, lr=0.05), LightGBM baseline (n=200, depth=6, lr=0.05), RF+SMOTE, XGBoost+SMOTE, LightGBM+SMOTE, and Cost-Sensitive XGBoost (scale_pos_weight calibrated to the High-to-Medium class ratio). LightGBM was included to assess whether gradient-boosting performance generalizes across implementations; Cost-Sensitive XGBoost was included to test class-weighting as an alternative to oversampling for minority-class detection. Cost-sensitive learning addresses class imbalance by assigning higher penalties to misclassification of minority-class instances, thereby encouraging the model to place greater emphasis on underrepresented classes [39]. All models used seed 42. Weighted-average and per-class precision, recall, and F1-score were computed to expose behavior on the minority High-risk class. McNemar's test with continuity correction assessed statistical significance between XGBoost baseline and XGBoost+SMOTE at alpha = 0.05, following established recommendations for comparing classifier performance on a single shared test set [40].

E. Multi-Agent Framework Architecture

The framework comprises five agents implemented as independent Python threads communicating through dedicated in-memory message queues, consistent with the reactive agent architecture described by Wooldridge [41] and the general multi-agent coordination workflow surveyed by Maldonado et al. [26]. The Crowd Monitoring Agent observes Movement_Speed, Interaction_Frequency, and Crowd_Morale. It applies threshold rules synthesized from crowd dynamics simulation literature [8], [9]: a Medium signal is triggered when movement speed falls below 0.5 m/s, consistent with documented pre-compression crowd conditions, or when interaction frequency exceeds 7; a High signal is triggered when speed falls below 0.3 m/s and frequency exceeds 8 simultaneously. These thresholds represent expert-informed approximations derived from simulation findings and are subject to empirical calibration against real incident data.

The Health Monitoring Agent observes Health_Condition, Age_Group, and Waiting_Time_for_Transport. Pilgrims presenting dehydration or fatigue, those aged 70 or above, or those waiting more than 90 minutes for transport receive elevated health risk signals. These thresholds were informed by health management frameworks for crowded events [42] and constitute expert-informed approximations subject to empirical calibration. The combination of dehydration and age above 70 triggers High. The Environmental Sensing Agent observes Weather_Conditions, Sound_Level_dB, and Security_Checkpoint_Wait_Time. Adverse weather or sound levels above 80 dB trigger Medium; sandstorm with sound above 85 dB triggers High. All agent thresholds are expert-informed approximations pending empirical validation.

The Coordinator Agent blocks on three message queues until signals from all monitoring agents arrive, then queries the XGBoost+SMOTE model with the encoded feature vector. The final risk decision applies a maximum-escalation policy: the

highest risk level across all four inputs is selected. The Alert Agent converts the final decision into an operational notification.

The proposed architecture differs structurally from a conventional centralized pipeline in several respects. Table II summarizes the key architectural distinctions.

TABLE II. ARCHITECTURAL COMPARISON: CENTRALIZED PIPELINE VS. PROPOSED FRAMEWORK.

Centralized Pipeline	Proposed Framework
Single processing module	Five domain-specific agents
Shared decision logic	Independent domain-specific assessment
Tightly coupled components	Modular, independently operable components
Limited extensibility	New agents can be added without modifying existing ones
Sequential domain processing	Asynchronous domain-specific monitoring

The present framework does not claim decentralized negotiation or autonomous multi-agent planning. Rather, it adopts a modular, coordinator-based multi-agent architecture in which independent domain-specific agents perform local assessment before a coordinator integrates their outputs through a conservative escalation policy [13]. The architecture was selected for modularity, extensibility, and separation of domain-specific reasoning rather than to claim computational superiority over an equivalent centralized implementation. This design allows each agent to be developed, tested, and replaced independently, and permits the addition of new sensing domains without restructuring the coordination logic.

In terms of computational complexity, each monitoring agent evaluates threshold conditions over a fixed three-feature subset, contributing O(1) time per agent and per record. The Coordinator Agent then performs a single XGBoost inference over 17 features. Gradient-boosted tree inference requires $O(T \cdot D)$ time per record, where T is the number of trees and D is the maximum tree depth. Because T and D are fixed hyperparameters in the present implementation ($T = 200$, $D = 6$), the inference cost is constant with respect to dataset size and the number of monitoring agents. Inter-agent communication overhead scales as O(A), where A denotes the number of monitoring agents. The overall per-record complexity is therefore $O(A + T \cdot D)$; with A, T, and D fixed in the current five-agent architecture, it is O(1) with respect to dataset size, while increasing linearly if the number of monitoring agents is expanded. The framework architecture is illustrated in Fig. 1.

In the architecture of the proposed multi-agent framework, Independent Crowd, Health, and Environmental agents publish risk signals through dedicated message queues. The Coordinator Agent integrates these signals with XGBoost+SMOTE predictions using a maximum-escalation policy to generate the final risk assessment. Results are based on 500 test records held out from the training data (see Section III-F for the relationship between this streaming subset and the broader test set used in Section IV-A).

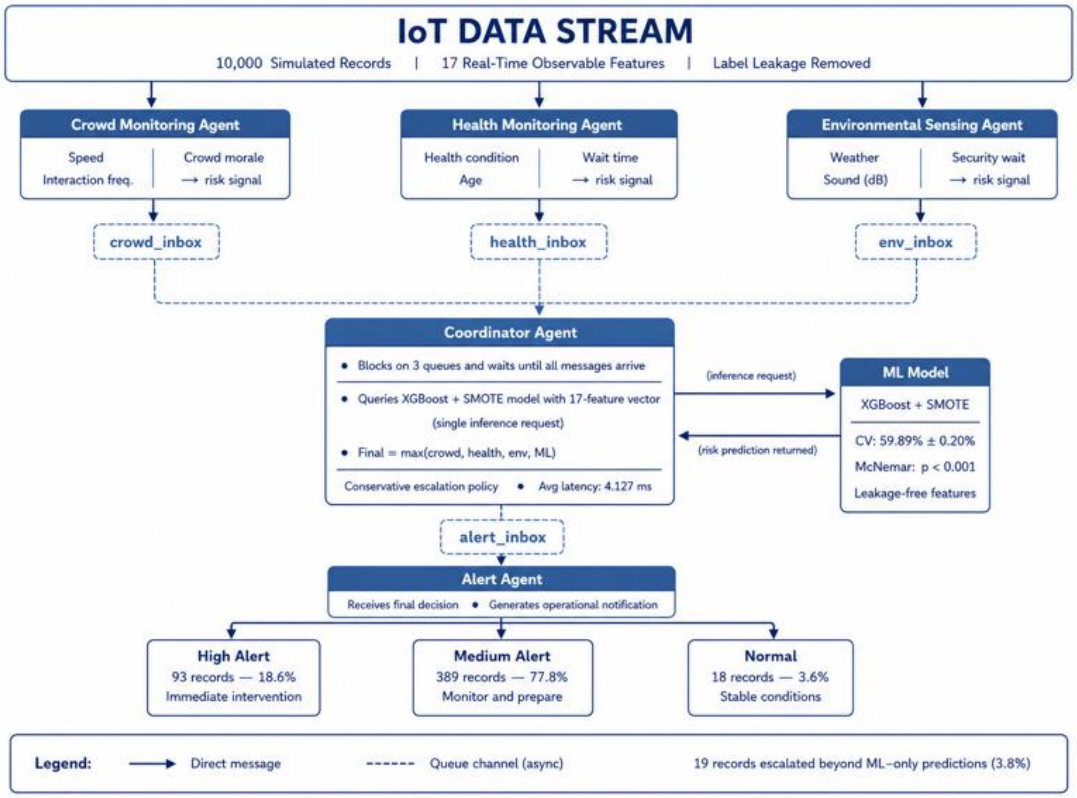

Fig. 1. Proposed multi-agent framework for crowd-risk prioritization.

F. Evaluation Protocol

Model performance was assessed on the held-out test set using overall and per-class metrics. Robustness was evaluated through 3-fold stratified cross-validation on the SMOTE-augmented training set, reporting Mean plus or minus Std. McNemar's test with continuity correction assessed statistical significance. The multi-agent framework was evaluated in three configurations (ML-only, Agents-only, and Full Framework) on 500 records drawn exclusively from the held-out test set, ordered by Timestamp to simulate a streaming environment; these 500 records are a subset of the same 2,000-record test set used for the overall and per-class results reported in Section IV- A, rather than an independently drawn fresh sample, and the ablation results should accordingly be read as a re-examination of the existing held-out test set from a streaming perspective rather than as validation on new, previously unseen data. Sensitivity analysis was conducted by varying all agent thresholds uniformly by plus or minus 20% from baseline values and computing High-risk alert counts experimentally across the three threshold configurations.

IV. Results and Discussion

A. Model Performance

Table III presents overall test-set results for seven configurations. Table IV presents per-class results for the XGBoost and LightGBM SMOTE-enhanced configurations. On the test set, XGBoost+SMOTE achieved 47.30% accuracy (F1: 46.22%); cross-validation on the SMOTE-balanced training data yielded 59.89% plus or minus 0.20% accuracy and 58.94% plus or minus 0.17% F1 for XGBoost+SMOTE. The gap between CV accuracy (59.89%) and test-set accuracy (47.30%) reflects evaluation under balanced (33.3% per class) versus imbalanced (Medium 58.7%) class conditions, respectively, and is reported explicitly to avoid misrepresentation of operational performance. To quantify the stability of test-set performance beyond the single fixed split, non-parametric bootstrap resampling (1,000 resamples with replacement, drawn from the test-set predictions) was used to construct 95% confidence intervals: accuracy 47.35% [45.20%, 49.55%], F1-score 46.26% [43.96%, 48.59%], and High-risk recall 13.76% [9.23%, 18.60%]. These intervals indicate that the reported point estimates are reasonably stable under resampling, while the width of the High-risk recall interval reflects the limited number of High-risk test instances available for evaluation.

Table IV reveals a critical finding: the XGBoost baseline and Cost-Sensitive XGBoost detected zero High-risk cases (precision = 0.00, recall = 0.00, F1 = 0.00), while XGBoost+SMOTE achieved partial High-risk detection (recall = 0.14, F1 = 0.12) and LightGBM+SMOTE achieved comparable performance (recall = 0.12). The baseline model's single false positive prediction for the High-risk class (1 of 1,174 true Medium-risk records misclassified as High) was insufficient to register a non-zero precision value at two decimal places, confirming that the model produced no usable High-risk signal whatsoever on the independent test set. The inability of baseline models to detect any High-risk instance is not a model failure per se but reflects the intrinsic difficulty of the task: after leakage removal, the observable features provide insufficient discriminative signal to separate High- from Medium-risk without class rebalancing. This finding directly motivates the domain-aware agent escalation layer, which captures High-risk configurations through rule-based domain knowledge that the baseline ML classifier does not detect under the current feature set. This underscores that overall accuracy is an insufficient metric for safety-critical systems. McNemar's test confirmed a statistically significant improvement of XGBoost+SMOTE over the baseline (chi-squared = 69.218, p less than 0.001), indicating a statistically significant shift in minority-class sensitivity, mechanistically explained in Section V as a decision-boundary effect rather than a genuine signal-recovery effect on the independent test set.

To contextualize these results against trivial reference points, two simple baselines were also evaluated on the same test set: a majority-class baseline that always predicts the dominant class (Medium) and a stratified-random baseline that predicts classes according to their training-set proportions. The majority-class baseline achieved 58.70% accuracy and 43.42% F1-score (Table III); the stratified-random baseline achieved 42.20% accuracy and 42.31% F1-score. Notably, the majority-class baseline's accuracy (58.70%) exceeds that of the XGBoost baseline (57.15%), although the XGBoost baseline achieves a higher F1-score (45.96% vs. 43.42%) by producing non-trivial, if ultimately unsuccessful, predictions for the Low-risk class. This comparison reinforces rather than undermines the study's central argument: it provides direct, model-agnostic confirmation that overall accuracy is an insufficient and potentially misleading metric for this task, since a model that makes no use of any observable feature can match or exceed the accuracy of a trained classifier, consistent with the near-absence of linear and nonlinear feature–label association documented in Section V. The comparison is included here, prior to that analysis, specifically to establish this point empirically before it is explained mechanistically. The headline XGBoost+SMOTE figures reported above were further confirmed to be stable, rather than dependent on the specific random seed used, via a repeated-splits analysis across 10 independent seeds reported in Section VII (Statistical Validity).

TABLE III. Overall Model Performance on Independent Test Set

Model	Acc.%	Prec.%	Rec.%	F1%
Random Forest	58.75	50.10	58.75	43.64
XGBoost Baseline	57.15	45.12	57.15	45.96
RF + SMOTE	48.50	45.81	48.50	44.62
XGBoost + SMOTE	47.30	45.90	47.30	46.22
LightGBM Baseline	57.00	44.40	57.00	45.72
LightGBM + SMOTE	46.55	44.93	46.55	45.34
XGBoost Cost-Sensitive	57.15	45.12	57.15	45.96
Majority-Class Baseline	58.70	34.46	58.70	43.42
Stratified-Random Baseline	42.20	42.31	42.20	42.31

TABLE IV. PER-CLASS PERFORMANCE: XGBOOST MODELS (TEST SET)

Model	Class	Prec.	Recall	F1
XGBoost Baseline	High	0.00	0.00	0.00
	Low	0.34	0.07	0.11
	Medium	0.59	0.94	0.72
XGBoost + SMOTE	High	0.11	0.14	0.12
	Low	0.31	0.22	0.26
	Medium	0.60	0.67	0.63
LightGBM + SMOTE	High	0.10	0.12	0.11
	Low	0.31	0.21	0.25
	Medium	0.59	0.66	0.62

Table IV shows that the baseline XGBoost model failed to identify any High-risk cases, with a recall of 0.00. After applying SMOTE, the model began to detect this class, although performance remained limited, with a recall of 0.14 and an F1-score of 0.12. SMOTE also increased Low-risk recall from 0.07 to 0.22. However, this came at the cost of reducing Medium-risk recall from 0.94 to 0.67. These results indicate that rebalancing reduced the model's dependence on the dominant Medium-risk class and allowed better, though still imperfect, detection of minority risk levels.

B. Feature Importance and Interpretability

Feature importance scores from the XGBoost+SMOTE model show a balanced distribution: the highest-ranked feature (Crowd_Morale, 0.0995) contributes less than 10% of total importance. This contrasts with analyses that included label-derived variables, where a single feature dominated, indicating leakage. Crowd_Morale, Event_Type, and Weather_Conditions are operationally interpretable: crowd morale reflects collective behavioral tension; event type determines spatial organization and density thresholds; weather conditions directly affect crowd movement. Fig. 2 illustrates the top 10 feature importance scores.

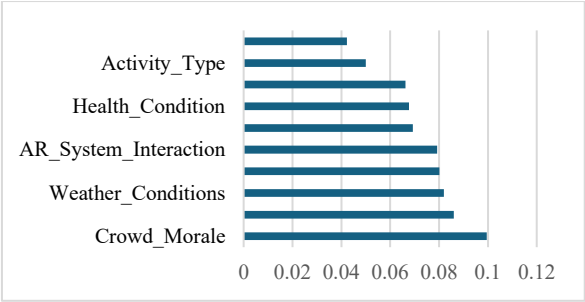

Fig. 2. Top 10 feature importance scores from the XGBoost+SMOTE model.

Because Crowd_Morale emerged as the single most important feature, its operational measurability warrants clarification. In the present dataset, Crowd_Morale is recorded as a discrete categorical indicator (Positive, Neutral, Negative); it is not derived from facial-expression or sentiment analysis, which would introduce separate privacy and accuracy concerns in dense crowd settings. In an operational deployment, this indicator would instead be inferred indirectly from signals already collected by the framework's other sensing channels (for example, aggregate crowd-noise level (Sound_Level_dB), movement irregularity (Movement_Speed variance), and local interaction density (Interaction_Frequency)) rather than measured directly. This indirect-inference approach is consistent with the framework's real-time observability requirement, but it also means that Crowd_Morale should be understood as a composite behavioral proxy rather than a directly sensed physical quantity, and its operational construction from these underlying signals remains an item for future validation.

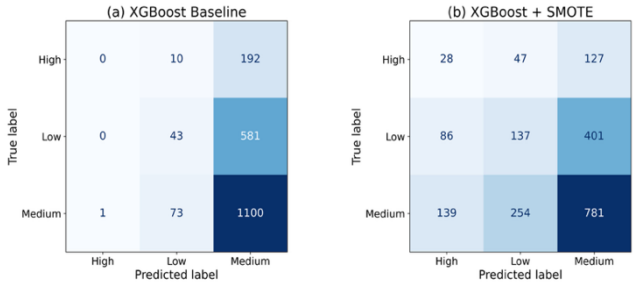

Fig. 3. Confusion matrices for (a) XGBoost baseline and (b) XGBoost+SMOTE on the independent test set.

Fig. 3 shows the confusion matrices for both models. A review of the confusion matrices reveals notable differences between the two models. The original XGBoost classifier predominantly predicted the Medium-risk class, leading to no correct predictions for High-risk observations. After incorporating SMOTE, the classifier identified a small portion of the High-risk cases. Although this increased sensitivity to the minority class, it also resulted in a lower overall accuracy. This pattern is in agreement with the performance metrics reported in Table IV.

To assess discriminative performance across the full range of decision thresholds rather than at the single fixed operating point reported in Table IV, a precision-recall curve was constructed for the High-risk class using the predicted class probabilities from XGBoost+SMOTE on the full 2,000-record independent test set described in Section IV-A (Fig. 4); this is distinct from, and substantially larger than, the 500-record streaming subset used in the ablation and escalation-precision analyses in Section IV-C below. The curve achieved an average precision (AP) of 0.1016, compared with an AP of 0.1010 expected under random ranking at this class's prevalence (10.1% of test-set records). The observed AP exceeds the random-baseline value by only 0.0006, and Fig. 4 shows the model's curve tracking the random-baseline reference line closely across nearly the entire recall range, with the exception of a brief, high-variance fluctuation at very low recall where the small number of underlying records makes individual precision estimates unstable. This result provides a third, independent line of evidence supporting the same conclusion reached via the majority-class baseline comparison above and the mutual information analysis in Section V: the trained classifier's ranking of records by predicted High-risk probability carries negligible discriminative value beyond what would be expected from the class's base rate alone, across the entire space of possible decision thresholds rather than only at the single threshold used to generate Table IV.

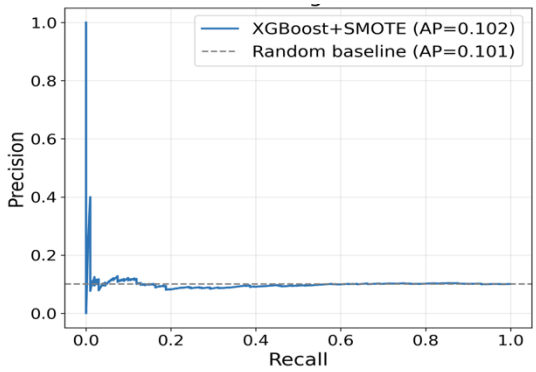

Fig. 4. Precision-Recall curve for High-risk class detection (XGBoost+SMOTE) versus the random-baseline reference line at class prevalence.

C. Multi-Agent Coordination Value and Streaming Performance

Table V presents the ablation results across three configurations on 500 held-out test records ordered by Timestamp. The ML-only configuration generated 74 High-risk alerts, while the Agents-only configuration generated 23 High-risk alerts. The Full Framework generated 93 High-risk alerts, representing a 25.7% increase relative to the ML-only configuration and substantially exceeding either component operating independently. Because the Full Framework applies a maximum-escalation policy (its High-risk count can never fall below either individual component's, by construction; see Table V below), this difference alone does not establish symmetric, bidirectional disagreement between the two components. With this structural property in mind, the pattern is nonetheless consistent with the ML model and the agent layer each surfacing High-risk configurations that the other does not independently flag, suggesting complementary, if asymmetric, risk-assessment mechanisms. The ML model performs probabilistic classification across all 17 observable features, whereas the agents apply domain-specific escalation rules to targeted feature subsets, allowing each component to identify elevated-risk situations that may not be emphasized by the other.

TABLE V. ABLATION: HIGH-RISK ALERT GENERATION ACROSS THREE CONFIGURATIONS.

Configuration	High-Risk Alerts	Records Escalated	Avg. Latency
ML Only (XGBoost+SMOTE)	74	—	4.127 ms
Agents Only (rules, no ML)	23	N/A	N/A
Full Framework (ML + Agents)	93	19 (3.8%)	4.127 ms

Because the Full Framework configuration cannot, by construction, generate fewer High-risk alerts than either individual component on any given record, the discordance pattern between configurations is necessarily one-directional rather than a conventional bidirectional disagreement (see Table VI for full contingency tables). With this structural constraint in mind, the 70 additional High-risk alerts generated by the Full Framework beyond the Agents-only configuration (93 vs. 23) were confirmed via McNemar's test to represent a statistically significant difference ($\chi^2 = 68.01$, $p < 0.001$), and the 19 additional alerts generated beyond the ML-only configuration (93 vs. 74) were likewise confirmed to represent a statistically significant difference ($\chi^2 = 17.05$, $p < 0.001$); in both paired comparisons, all discordant records favored the Full Framework configuration ($b > 0$, $c = 0$). These alerts arise from records where the ML model identified elevated-risk configurations that did not satisfy agent escalation thresholds, and, conversely, from records where domain-specific agent rules flagged conditions the classifier had not independently identified as High-risk. Consistent with the note accompanying Table VI, the statistical tests above should be interpreted as confirming that a nonzero number of one-directional escalations occurred in each comparison, rather than as evidence of mutual, symmetric correction between the two components or of a strong discriminative advantage for either component individually. The underlying architectural rationale for combining ML and agent inputs nonetheless reflects a conceptually bidirectional design: the ML model and the agent rules are each capable of flagging risk configurations that the other does not independently classify as High-risk. A statistically significant increase in alert volume should not, on its own, be read as an operational improvement. This concern is well established in clinical alerting research: a systematic qualitative review of general practitioners' experiences with clinical decision support alerts found that a high volume of alerts with limited specificity or relevance was consistently reported as a driver of alert fatigue, reducing practitioner engagement with and trust in subsequent alerts, including clinically important ones [43]. While this concept originates in primary-care clinical alerting research rather than crowd-safety monitoring, the underlying mechanism, desensitization to frequent, low-value notifications reducing responsiveness to genuinely critical signals, is domain-general and transfers directly to the present context: an operational alerting system that increases alert volume without a corresponding increase in precision risks producing the same desensitization effect among crowd-safety monitoring personnel. As discussed below, the precision of the escalated alerts examined in this study was found to be low against the operational risk proxy; the alert-volume increase reported here should therefore be weighed against this risk rather than treated as an unambiguous benefit.

A separate check tested whether the agents' three-tier escalation logic (each agent first raising a record from Low to Medium, then separately from Medium to High) is actually necessary, or whether a single, simpler rule would produce the same alerts. The simpler version skips the intermediate Medium step entirely: it flags a record as High whenever any one of the three agents' original High-level conditions is met, with no per-agent Medium-escalation logic in between. On the same 500-record streaming evaluation, this simplified single-rule version produced exactly the same number of High-risk alerts as the full three-agent hierarchy: 93 in both cases. In other words, the extra Medium-level escalation step built into each agent did not add any High-risk alerts beyond what the three original High-level conditions already produced on their own, at least on this dataset and this evaluation window. This does not mean the five-agent design is unnecessary it remains useful for modularity and for adding more nuanced intermediate-risk logic later but it does mean that the specific benefit of the current three-tier hierarchy has not yet been demonstrated, and should not be assumed

without testing on data where Medium-risk conditions are more common or more closely tied to eventual High-risk outcomes.

TABLE VI. MCNEMAR'S TEST CONTINGENCY TABLES FOR ABLATION COMPARISONS (N=500)

Comparison	Both High	b (Comparator High, Full Not)	c (Comparator Not, Full High)	Both Not High
Full vs. ML-only	74	0	19	407
Full vs. Agents-only	23	0	70	407

Note: b and c are zero-cell-constrained by the maximum-escalation policy (Full Framework can never report fewer High-risk alerts than either individual component on a given record), which forces a one-directional discordance pattern in both comparisons. McNemar's test is designed for paired nominal comparisons and is widely recommended for comparing classifiers on a shared test set [40]; however, its standard interpretation assumes that discordant pairs can in principle occur in either direction. Because the maximum-escalation policy used here rules out one of the two discordant cells by construction, the resulting test is closer to confirming that a nonzero number of one-directional escalations occurred than to demonstrating conventional, symmetric disagreement between the compared configurations, and the reported statistics should be read with this structural constraint in mind. Continuity-corrected McNemar statistics are computed as $\chi^2 = (|b-c|-1)^2/(b+c)$.

To assess the stability of the framework with respect to threshold selection, a sensitivity analysis was conducted by varying all agent thresholds by ±20% from their baseline values. Reducing thresholds by 20% yielded 83 High-risk alerts (16.6%), whereas increasing thresholds by 20% yielded 105 High-risk alerts (21.0%). The baseline configuration produced 93 alerts (18.6%), representing an intermediate operating point within this range. This non-monotonic behavior reflects interactions among agent-specific escalation rules under the framework's maximum-escalation policy, where changes in individual thresholds can alter escalation pathways across the combined decision process. Despite these variations, the Full Framework consistently generated more High-risk alerts than the ML-only configuration (74 alerts), indicating that the reported contribution is not dependent on a single threshold setting.

The 500 streaming records were drawn exclusively from the held-out test set, ensuring complete independence from training data (this subset was drawn from the same 2,000-record test set evaluated in Section IV-A rather than from a separate sample), while preserving the original class distribution of approximately 10.1% High-risk, 31.2% Low-risk, and 58.7% Medium-risk. The increase from 74 High-risk alerts in the ML-only configuration to 93 alerts in the Full Framework is consistent with the ability of agent rules to surface risk configurations that the ML classifier may underweight due to feature overlap. Under the streaming evaluation, the average processing latency was 4.127 ms per record, indicating that the framework is suitable for single-stream operational monitoring scenarios. To assess scalability, per-record latency increased from 1.918 ms under sequential processing to 4.571 ms at 5 concurrent streams, 10.284 ms at 10 concurrent streams, and 15.538 ms at 20 concurrent streams, representing an approximately 8.1-fold increase at the highest concurrency level evaluated. These results suggest that large-scale multi-stream deployment would likely require a distributed or otherwise more scalable execution architecture.

To assess the operational precision of agent-driven escalations, the 19 records escalated by the agent layer beyond ML-only predictions (i.e., classified as Medium or Low by XGBoost+SMOTE but elevated to High by agent rules) were cross-checked against their underlying continuous risk scores and original risk labels. None of these 19 records (0%) corresponded to a true High-risk label; 14 (73.7%) were true Medium-risk and 5 (26.3%) were true Low-risk. Only 4 records (21.1%) had an underlying risk score within 0.2 of the High-risk threshold (2.4), indicating that these escalations predominantly targeted records that were not borderline cases. This finding indicates that, under the current label definition, agent-driven escalations beyond ML predictions exhibit low precision against the operational risk proxy, and should be interpreted strictly as sensitivity-oriented prioritization signals rather than validated risk detections. This result motivates recalibrating agent thresholds against verified incident data as a priority for future work, rather than treating the increased alert count alone as evidence of improved detection; such recalibration could draw on recent proposals to incorporate net benefit directly as an objective during model and threshold development, rather than applying it only as a post-hoc evaluation metric, which would allow the relative cost of missed High-risk cases versus false escalations to inform threshold selection explicitly [44].

V. DATA QUALITY, LIMITATIONS, AND FUTURE DIRECTIONS

The most fundamental limitation concerns label validity. Risk categories were derived from a weighted scoring function applied to operational indicators, not from verified incident records. The models therefore predict a computed proxy for risk rather than observed outcomes. One practical consequence is the near-zero separation between Medium- and High-risk feature distributions, resulting in zero High-risk recall for the XGBoost baseline and Cost-Sensitive XGBoost, and only partial recall (0.14) for XGBoost+SMOTE on the independent test set. In addition, agent-generated escalations could not be validated against confirmed incidents because the dataset does not include verified real-world outcomes. The additional High-risk alerts are therefore best understood as prioritization cues for further review, not as verified detections of actual incidents. Future work should evaluate these alerts against real incident logs or expert-reviewed operational records.

The weak observed performance also follows a near-deterministic statistical expectation given the dataset's construction. A post hoc correlation analysis between the 17 retained features and the continuous Operational_Risk_Score (prior to threshold discretization) found a maximum absolute Pearson correlation of 0.026 and a mean absolute correlation of 0.010 across all retained features; for n = 10,000 records, the critical correlation magnitude for statistical significance at $\alpha = 0.05$ is approximately 0.0196, meaning that while a small number of these correlations are technically distinguishable

from zero, all are practically negligible, a well-documented consequence of large sample sizes inflating the detectability of statistically significant but practically meaningless effects [45]. Because Pearson correlation captures only linear association and the models evaluated in this study (XGBoost, LightGBM, Random Forest) are explicitly capable of exploiting nonlinear and interaction effects, this analysis was complemented with a mutual information estimate, a nonparametric measure sensitive to nonlinear dependence, computed using the Kraskov–Stögbauer–Grassberger k-nearest-neighbor estimator suited to mixed continuous and discrete feature types; following the originating methodological reference, which recommends k = 2–4 for estimating dependence (with larger k trading reduced statistical variance for increased systematic bias) [46], the primary analysis used k = 3, the lower end of this recommended range, in order to favor reduced systematic bias given the relatively small number of High-risk instances available in the full dataset (1,010 of 10,000 records) for estimating this association. Mutual information between the 17 retained features and the continuous risk score ranged from 0.000 to 0.016 nats (mean 0.003 nats) at k = 3, compared with a mutual information of 0.232 nats between Crowd_Density (one of the seven excluded label-constructing variables) and the same risk score, computed as a reference point for what a genuinely informative relationship looks like in this dataset under the same measure. To verify that this conclusion does not depend on the specific neighbor-count choice, the analysis was repeated at k = 5 and k = 10: the maximum mutual information among retained features decreased further (0.008 nats at k = 5; 0.007 nats at k = 10), while the reference value for the excluded variable remained essentially unchanged (0.238 nats at k = 5; 0.241 nats at k = 10), confirming that the retained features' near-absence of nonlinear signal is stable across this range of estimator settings rather than an artifact of the k = 3 configuration. Several of the reported values are exactly 0.000; a recent systematic benchmarking of mutual information estimators, including KSG-type k-nearest-neighbor approaches, found that estimator reliability varies considerably across distributional conditions and that no single estimator performs uniformly well across all settings, particularly under sparse or weakly-informative dependence structures [47].

Consistent with this, at this sample size and neighbor parameter, the present estimator returns an exact-zero output whenever the underlying dependence falls below its practical detection floor, rather than necessarily implying a perfectly null relationship in a mathematical sense, and these values should accordingly be interpreted as "below detectable dependence at this estimator resolution" rather than as a precise quantification of zero association. The retained features therefore carry negligible nonlinear, as well as negligible linear, signal about the risk label: the highest-ranked retained feature captures roughly one-fifteenth of the mutual information carried by a single excluded label-constructing variable. This indicates that the 17 leakage-free features carry little to no signal about the risk label beyond the noise floor, under either a linear or a nonlinear association measure, consistent with the seven label-constructing variables (Crowd_Density, Temperature, Fatigue_Level, Stress_Level, Queue_Time_minutes, Emergency_Event, and Distance_Between_People_m) having been generated largely independently of the retained features in this simulated dataset. Under this condition, classification performance approaching that of the majority-class baseline is the statistically expected outcome rather than an unexplained finding, and the intrinsic-difficulty framing offered above should be read as a description of this near-independence rather than as evidence of a deeper, unmodeled relationship between observable crowd conditions and operational risk. This consideration also implies that the degree of performance degradation observed here is specific to this dataset's generation process and may not generalize to settings where label-constructing and observable variables are more strongly associated in practice.

Given this near-absence of linear and nonlinear signal in the retained features, the partial recovery of High-risk recall observed for XGBoost+SMOTE and LightGBM+SMOTE (0.14 and 0.12, respectively, versus 0.00 for the unbalanced baselines) requires its own explanation rather than being attributed to the features becoming more informative after rebalancing. The more plausible mechanism is that SMOTE alters the effective decision boundary learned by the classifier rather than increasing the information content of the feature space: by synthetically inflating the representation of the High-risk class to match the majority class during training, SMOTE shifts the model's decision threshold to favor High-risk predictions in regions of feature space that are only weakly associated with the label, at the cost of reduced precision (0.11 for XGBoost+SMOTE, Table IV) and reduced Medium-risk recall (0.67, down from 0.94 for the baseline). This interpretation is consistent with general principles of oversampling behavior in weakly separable feature spaces established in [35], [36], though the specific framing offered here is the authors' own synthesis rather than a direct claim made in either source; it favors the decision-boundary-shift account over the alternative explanation that SMOTE somehow recovers predictive signal that the correlation and mutual information analyses above show is largely absent from the underlying features. Under this interpretation, the gain in High-risk recall after SMOTE reflects a deliberate, engineered shift in operating point along an unfavorable precision-recall trade-off, not a genuine improvement in the model's ability to discriminate High-risk from Medium-risk conditions using the available observable indicators.

The dataset represents a single simulated operational context. Generalization to other crowd environments requires separate validation. Agent threshold values are expert-informed approximations not empirically calibrated against historical incident data. SMOTE generates synthetic observations from existing samples; in this study, differences between baseline and SMOTE-enhanced models remained modest, and McNemar's test confirmed significant improvement ($\chi^2 = 69.218$, $p < 0.001$). Although statistically significant, the practical effect size remained modest because the improvement was primarily observed in High-risk recall rather than overall classification accuracy. Python threading constrains true parallelism for CPU-bound workloads such as model inference, and production-scale multi-stream deployment would likely require a distributed agent framework such as JADE or Mesa. To quantify the practical impact of this constraint, per-record inference latency was measured under concurrent load using a thread pool with 1,

5, 10, and 20 simultaneous prediction streams, following a model warm-up phase to eliminate first-call overhead. As reported in Section IV-C, per-record latency increased from 1.918 ms under sequential processing to 15.538 ms at 20 concurrent streams, an approximately 8.1-fold increase at the highest concurrency level evaluated. This increase reflects the combined effect of several factors that this thread-based experiment does not separately isolate (including Python-level interpreter contention, thread-scheduling and pool-management overhead, and CPU cache contention among concurrently executing threads) rather than being attributable to the Global Interpreter Lock alone; the underlying C++ implementation of the gradient-boosting library used here may release the interpreter lock during some internal numerical computation, so the GIL constraint described above should be understood as one contributing factor among several rather than the sole explanation for the measured degradation. Regardless of the precise decomposition of these factors, the empirical result establishes that the framework's favorable latency figures reported elsewhere in this study (e.g., Table V) reflect single-stream, sequential operation and do not extend proportionally to concurrent multi-stream conditions representative of simultaneous monitoring across many pilgrims; production deployment at scale would require either a multi-process or distributed architecture, and a more detailed profiling study isolating these individual contributing factors is identified as a direction for future work.

Future work will focus on validating the framework using real-world operational datasets, calibrating agent thresholds against historical incident records, and evaluating alert precision using independently verified ground-truth events.

VI. Conclusion

This study proposed a multi-agent approach for crowd-risk prioritization in large-scale events that combines machine learning with crowd, health, and environmental agents within a unified operational workflow. The study also addressed data leakage by removing variables used to construct the risk labels, as well as post-event outcome indicators, before model training.

The results show that leakage-free prediction is difficult in this dataset. The XGBoost baseline and Cost-Sensitive XGBoost did not identify any High-risk cases (recall = 0.00). XGBoost+SMOTE detected part of this class, but performance remained limited (recall = 0.14, F1 = 0.12). McNemar's test showed a statistically significant difference between the baseline and SMOTE-enhanced model ($\chi^2 = 69.218$, $p < 0.001$), although the practical gain was mainly in minority-class sensitivity rather than overall accuracy.

The agent layer increased High-risk alert volume but, on the data examined, did so with low precision relative to the internal risk-score proxy. Of the 19 records escalated by the agent layer beyond the ML-only predictions, none (0%) corresponded to a High-risk label under this proxy, while the majority (73.7%) corresponded to Medium-risk labels. In the 500-record streaming evaluation, the Full Framework produced 93 High-risk alerts, compared with 74 from ML-only and 23 from Agents-only, representing a 25.7% increase over the ML-only configuration.

These additional alerts should therefore be interpreted as prioritization cues rather than confirmed incidents. Overall, the results suggest that ML and rule-based agents can play complementary roles in crowd-risk monitoring. However, none of the 19 agent-driven escalations beyond the ML-only predictions corresponded to a High-risk label under the internal risk-score proxy. This finding further reinforces the need for threshold calibration and validation against verified real-world incidents before operational deployment. ML provides broad probabilistic assessment across observable features, while agents add domain-specific escalation rules for conditions that the model may under-prioritize. With an average latency of 4.127 ms per record, the framework is suitable for single-stream monitoring experiments. Future work should validate the framework using real operational data and evaluate alert precision against verified ground-truth labels.

VII. Threats to Validity

A. Internal Validity

SMOTE was applied only to the training set, so synthetic samples never reached the test set; cross-validation on the SMOTE-balanced data likely makes generalization look slightly better than on the original imbalanced distribution. All models used the same fixed random seed (42) for reproducibility, and the agent thresholds are expert estimates rather than values calibrated against real incident data. As reported in Section IV- C, a simplified single-rule version of the agent logic produced the same number of High-risk alerts as the full three-agent hierarchy, showing that the added complexity of the hierarchical escalation structure has not yet been shown to add value on this dataset. Additionally, the evaluation does not quantify inter-agent communication overheads such as queue contention, synchronization latency, or message-passing delays. These overheads are expected to have minimal impact under the single-stream evaluation considered in this study but may become more relevant under higher concurrency levels.

B. External Validity

The dataset was generated under simulated conditions specific to the Hajj context, so findings may not generalize to other crowd environments (sporting events, concerts, transport hubs) without separate validation. The framework has not been tested on live IoT streams under real deployment, and Python threading limits parallelism at production scale. Furthermore, the evaluation assumes complete and reliable sensor observations and does not assess the impact of sensor noise, missing values, delayed measurements, or inconsistent data, all of which are common in practical IoT deployments and should be investigated in future work. Because the dataset was algorithmically generated rather than collected from real sensors or incidents, the statistical relationships reported here, including the near-zero feature–label correlation in Section V, the resulting recall ceiling for High-risk, and the agent-escalation precision profile in Section IV-C, reflect this synthetic generation process rather than real Hajj crowd dynamics. This is consistent with broader evaluation frameworks for synthetic tabular data, which distinguish fidelity from downstream utility and find that strong utility does not guarantee the underlying relationships match real-world data [48]. A real-world dataset could plausibly show stronger or weaker associations than

measured here, so the performance gaps, alert volumes in Table V, and precision figures in Section IV-C should be read as illustrative of this synthetic setting rather than predictive of real operational performance.

C. Construct Validity

Risk labels come from a weighted scoring function rather than verified incident records, making this a risk-prioritization tool rather than a confirmed incident predictor. Agent-alert precision against real incidents cannot be assessed without ground-truth annotations, which this dataset lacks. A check against the internal risk-score proxy (Section IV-C) found that none of the 19 agent-driven escalations beyond ML-only predictions corresponded to a true High-risk label, so High-risk alert counts should accordingly be read as proxy-based output, not confirmed real-world events.

D. Statistical Validity

Evaluation used a single dataset with one fixed train/test split. McNemar's test confirms the XGBoost+SMOTE improvement is statistically significant ($\chi^2 = 69.218$, $p < 0.001$), but a single split may not generalize across seeds or partitions. Bootstrap resampling (1,000 resamples) gave 95% confidence intervals of 47.35% [45.20%, 49.55%] for accuracy and 13.76% [9.23%, 18.60%] for High-risk recall, confirming the point estimates are stable under resampling, though this does not address variation across different training seeds. To address that directly, the full pipeline was repeated across 10 independent seeds (0, 1, 2, 3, 4, 7, 13, 21, 42, 99): accuracy averaged 47.08% (SD = 0.55%), F1 averaged 45.97% (SD = 0.46%), and High-risk recall averaged 0.134 (SD = 0.017). The seed = 42 result reported throughout this study falls within one standard deviation of this mean on every metric, confirming it is representative rather than a favorably chosen outlier. The mutual information analysis in Section V was similarly stable across k = 3, 5, and 10, confirming the near-absence of nonlinear association is not an artifact of a single parameter choice.

Declaration on the Use of AI-Assisted Tools

The author used AI-assisted tools to support language refinement and manuscript drafting during the preparation of this work. All scientific ideas, research design, experimental implementation, data analysis, results interpretation, and conclusions were carried out by the human author. The author takes full responsibility for the accuracy, originality, and integrity of the manuscript.

***Abstract*—This work presents a Model-Augmented Masked Autoencoder (MAE) framework, augmented with domain-adaptive denoising and multi-level feature fusion, for self-supervised representation learning in MRI-based brain tumor analysis. The proposed approach enhances feature robustness under limited annotation by learning structure-preserving representations through masked reconstruction while explicitly addressing scanner-induced variability. Unlike conventional MAE designs, the framework integrates a Domain-Adaptive Denoising (DAD) module and latent–reconstruction feature fusion, enabling improved robustness across heterogeneous MRI datasets and reducing feature variance arising from scanner and acquisition differences. Comprehensive ablation studies across multiple datasets demonstrate that MAE pretraining yields consistent performance improvements of approximately 1.0–1.4% in classification accuracy, with overall improvements ranging from approximately 2.7% to 3.7% across datasets when integrated into the complete framework. Qualitative and quantitative analysis further confirm effective suppression of structural noise while preserving diagnostically relevant features. Overall, the proposed framework improves representation stability, enhances cross-domain robustness, and provides a reliable foundation for self-supervised medical image analysis, supporting the development of generalizable and clinically applicable diagnostic AI systems.**

Keywords*—Self-supervised learning; Masked Autoencoder; MRI; domain adaptation; feature representation; medical imaging

I. Introduction

Magnetic Resonance Imaging (MRI) plays a central role in the diagnosis, grading, and clinical management of brain tumors. Accurate tumor classification is essential for treatment planning, yet remains challenging due to substantial variations in tumor morphology, heterogeneous imaging protocols across scanners, and the presence of noise, artifacts, and low-contrast boundaries. Deep learning models have achieved impressive performance in medical image classification; however, their success is strongly dependent on the availability of large, high-quality annotated datasets. In neuro-oncology, such annotations require expert radiological expertise, are time-consuming to produce, and often vary across institutions. These challenges motivate the need for representation learning strategies that reduce dependence on labeled data while improving robustness to domain variability.

*Corresponding author

Self-supervised learning (SSL) has emerged as a powerful paradigm to address annotation scarcity by leveraging unlabeled images to learn transferable, domain-invariant representations [1,2,3,4,29]. Contrastive methods and masked prediction frameworks such as Masked Autoencoders (MAE) [16] have shown promise in natural and medical imaging. By predicting missing content or enforcing consistency between augmented views, SSL extracts semantic cues without explicit annotations. However, despite their potential, existing SSL approaches exhibit three major limitations when applied to brain MRI analysis. First, contrastive-based SSL approaches such as those analyzed by Wolf et al. [3] are sensitive to augmentation strategies and may fail to capture fine anatomical details critical for tumor demarcation. Second, conventional MAE-based frameworks [3,4] reconstruct masked regions but generally do not explicitly address scanner-specific noise, bias-field inhomogeneities, or contrast variations commonly encountered in clinical MRI. Third, although Zhang et al. [18], Liu et al. [19], Zhang et al. [20], Bakkouri and Afdel [21], and Peng et al. [22] demonstrated the effectiveness of multi-level feature fusion, the integration of latent self-supervised representations with radiomics, shape descriptors, and deep CNN features remains insufficiently explored.

To address these challenges, this study introduces the Model-Augmented Masked Autoencoder (MAE), a self-supervised pretraining framework designed to improve robustness and generalization in MRI-based brain tumor classification. The proposed approach builds upon masked image modeling by reconstructing randomly masked patches, enabling the model to learn structure-preserving representations that emphasize anatomical continuity and tumor-related spatial patterns [16]. A key innovation of the framework is the integration of a Domain-Adaptive Denoising (DAD) module, which refines latent token embeddings through channel normalization, patch-level smoothing, and gated fusion mechanisms. This enhancement makes the learned representations more resilient to cross-scanner inconsistencies and low-quality acquisitions, aligning with recent domain generalization frameworks discussed by Zhou et al. [27] and Wang et al. [28]. Additionally, the model augments downstream learning by combining MAE latent embeddings with reconstructed images, ensuring that both high-level contextual

signals and low-level structural details contribute to improved tumor characterization.

The enriched representations produced by the MAE pipeline are further integrated into a multi-level feature extraction system, incorporating radiomics descriptors, CNN-based semantic features, and geometric shape attributes. This fusion captures a wide spectrum of tumor information from statistical intensity patterns to morphological cues, yielding a more holistic and clinically aligned tumor signature [18,19,20,21,22]. These features are processed by an attention-guided fusion block and a Pyramid Quantum-Inspired Dilated Convolutional Neural Network (PyQDCNN), which models long-range spatial dependencies and multi-scale tumor context through dilation-driven and quantum-inspired (implemented as learnable bilinear feature interactions) entanglement mechanisms [23,24,25]. It is important to note that this mechanism is inspired by quantum interactions but is implemented as a learnable bilinear feature mixing operation within a conventional deep learning framework. The final hierarchical classification strategy mirrors clinical diagnostic workflows, first distinguishing normal from abnormal MRI scans, and then classifying tumors into clinically relevant subtypes.

The main contributions of this study are as follows:

- We propose a Model-Augmented Masked Autoencoder (MAE) with a Domain-Adaptive Denoising (DAD) module, enabling the learning of structure-preserving and scanner-robust latent representations that enhance MRI feature stability across heterogeneous MRI datasets.
- We develop a multi-level tumor representation pipeline that integrates radiomics, CNN features, shape descriptors, and MAE latent embeddings, producing a comprehensive and clinically aligned feature space for robust tumor characterization.
- We introduce a hybrid attention–PyQDCNN architecture that combines modality-aware feature weighting with entanglement-inspired bilinear feature interactions and dilated convolutional modeling, enabling effective capture of long-range dependencies and multi-scale tumor characteristics.
- We demonstrate consistent performance gains across four heterogeneous brain MRI datasets, achieving improvements of 1.0–1.4% due to MAE pretraining and overall accuracy improvements ranging from approximately 2.7% to 3.7% compared to baseline configurations, confirming the effectiveness and generalizability of the proposed framework.

The remainder of the study is organized as follows: Section II reviews related work. Section III presents the proposed Model-Augmented MAE framework. Section IV outlines the experimental setup. Section V reports and discusses results. Section VI concludes the study.

II. Related Work

Self-supervised learning (SSL) has become an essential strategy in medical imaging, particularly when annotated data are scarce. Rani et al. [1] presented a comprehensive review of SSL methods for medical image analysis and highlighted their effectiveness across multiple imaging modalities. Zeng et al. [2] summarized SSL frameworks and their applications in healthcare imaging. Wolf et al. [3] investigated contrastive and masked autoencoder pretraining strategies for small medical imaging datasets, demonstrating improved representation learning under limited annotations. VanBerlo et al. [4] analyzed the impact of self-supervised pretraining across X-ray, CT, MRI, and ultrasound modalities, while Uelwer et al. [29] provided a recent survey of self-supervised visual representation learning methods. Transformer-based SSL approaches, particularly masked autoencoders (MAEs), have gained prominence for their ability to model long-range dependencies and structural features in clinical images. The original MAE framework [16] demonstrates the effectiveness of reconstruction-based pretraining, while subsequent studies show that contrastive and masked pretraining significantly improve performance on small or heterogeneous datasets [3]. Recent applications further highlight the potential of transformer-driven SSL in disease detection and medical imaging tasks [5]. Advancements in MAE-based pretraining include improved architectural variations such as snapshot-ensemble MAEs for efficient training [6] and adaptive masking strategies designed to reinforce structural consistency during representation learning [7]. Emerging research directions also explore auxiliary modalities, such as large language model–augmented learning, which has been shown to enhance auto-delineation performance in radiotherapy planning [8]. In addition, domain generalization has received significant attention, with recent surveys emphasizing the importance of robust learning across heterogeneous datasets and imaging conditions [27,28]. Federated learning frameworks further demonstrate potential for improving cross-institutional generalization in brain tumor segmentation tasks [9].

For downstream tumor classification and segmentation, Vision Transformers (ViTs) and hybrid CNN–Transformer models have shown strong performance. Several studies have explored rotation-invariant ViTs for improved spatial consistency [11], ensemble-based ViT classification strategies [12], hybrid ViT–CNN architectures with explainability [13], and transfer-learning–based transformer models for tumor classification [14]. Transformer-based methods have also been successfully applied to related diagnostic tasks such as brain stroke classification [15] and glioma analysis [17], demonstrating their adaptability across different MRI-based applications.

Multi-level and multi-scale feature fusion approaches have further enhanced tumor detection and segmentation performance. Zhang et al. [18] proposed a multi-level feature exploration and fusion network for glioma analysis using MRI data. Liu et al. [19] introduced MCF-Net, which combines multi-level contextual information for medical image segmentation. Zhang et al. [20] developed a multi-scale deformable feature fusion framework for tumor segmentation. Bakkouri and Afdel [21] proposed an attention-based multi-level feature fusion strategy for lesion segmentation, while Peng et al. [22] introduced a graph-neural-network-based multi-level fusion approach for multimodal medical imaging. These studies

demonstrate that combining complementary feature representations improves tumor characterization and prediction accuracy. These approaches effectively capture complementary information across multiple feature levels, enabling more robust modeling of tumor heterogeneity. Additionally, quantum-inspired convolutional and optimization methods have been explored to model complex spatial dependencies and improve segmentation performance in biomedical imaging [23,24,25].

Despite these advances, existing SSL frameworks still face challenges related to scanner variability, noise, and domain shift, which can degrade representation stability across heterogeneous MRI sources. Moreover, most MAE-based models focus primarily on reconstruction objectives and do not explicitly incorporate domain-adaptive denoising or latent feature augmentation mechanisms. Addressing these limitations, the proposed Model-Augmented MAE framework integrates domain-adaptive denoising and multi-level feature fusion to improve reconstruction fidelity, enhance representation robustness, and achieve better generalization across diverse MRI datasets.

III. Proposed Framework

Brain tumor MRI classification demands robustness against variations in scanners, acquisition protocols, tumor heterogeneity, and noise. A single model or feature type is insufficient to ensure generalization. Therefore, the proposed design integrates complementary modules, each addressing a specific challenge:

- Masked Autoencoder (MAE) [16]: learns structure-preserving self-supervised features even with limited annotated datasets.
- Domain-Adaptive Denoising (DAD): stabilizes latent features across multi-center scans.
- Multi-level feature extraction combines radiomics (handcrafted biomarkers), CNN (deep hierarchical semantics), and shape descriptors (morphology).
- Attention-guided fusion removes redundancy across modalities and retains clinically meaningful patterns.
- PyQDCNN: models long-range tumor–background relationships through dilation- and entanglement-inspired kernels.
- Hierarchical classification: reduces inter-class interference for subtle tumor subtypes.

Among these components, the Model-Augmented MAE and Domain-Adaptive Denoising (DAD) constitute the core contributions of the framework, while the remaining modules primarily enhance feature representation and classification performance. The effectiveness of these modules is quantitatively validated through the dataset-level ablation studies presented in Table I to Table IV and the component-level ablation analysis in Table V, which demonstrate their individual and cumulative contributions to overall framework performance. Together, these elements create a multi-resolution, multi-representation, and domain-robust tumor analysis framework aligned with clinical practice.

The MRI input first undergoes a quality-control stage, where low-quality or corrupted scans are identified and excluded from further processing. The accepted volumes are geometrically normalized by reorienting to RAS space, resampling to isotropic resolution, and cropping or padding the field of view to maintain structural consistency. Subsequent bias-field correction (N4) and brain extraction [4] (skull stripping) remove intensity inhomogeneities and non-brain tissues, respectively. Intensity standardization is then performed through z-score normalization and histogram matching to harmonize the contrast distribution across subjects and scanners [4].

Following conventional pre-processing, the data are passed through a Model-Augmented Masked Autoencoder (MAE) framework [16] that leverages self-supervised representation learning. In this module, image patches are randomly masked and encoded via a Vision Transformer–based encoder (ViT-E) [11,12,13,14] to produce latent token embeddings z. The decoder reconstructs the masked patches, and reconstruction loss is computed as mean-squared error [3] on the masked regions, promoting structure-aware feature learning. Mean squared error (MSE) is adopted due to its computational efficiency and stability in preserving global structural consistency during reconstruction. Alternative perceptual or SSIM-based losses were not employed to avoid additional complexity and instability during self-supervised training. The MAE outputs both a reconstructed (denoised) image and a latent feature bank (z) used in subsequent optimization and augmentation stages. Z-score normalization was applied to reduce inter-subject intensity variability, while histogram matching ensured cross-scanner contrast harmonization. This dual-stage standardization was found to produce more stable latent representations in the MAE encoder compared to other methods such as min-max normalization or percentile clipping, especially when handling multi-center MRI datasets. This observation is further supported by the ablation results presented in Section IV, where improved convergence stability and feature consistency are observed across multi-center datasets. Depending on the downstream configuration, three data routes are available:

Route A: pre-processed image only,

Route B: MAE-enhanced reconstructed image, and

Route C: MAE latent representation only, the D-dimensional token embeddings (z) from the ViT encoder (optionally aggregated), which encapsulate self-supervised, structure-aware MRI priors. This route isolates the contribution of the MAE's learned representation, independent of raw or reconstructed image inputs.

While the augmented image set (pre-processed + reconstructed) is used to extract radiomics, CNN, and shape features (as shown in Fig. 3), Route C refers specifically to the direct use of the MAE latent vector z as an input stream typically fed into the attention-guided fusion module alongside other extracted features.

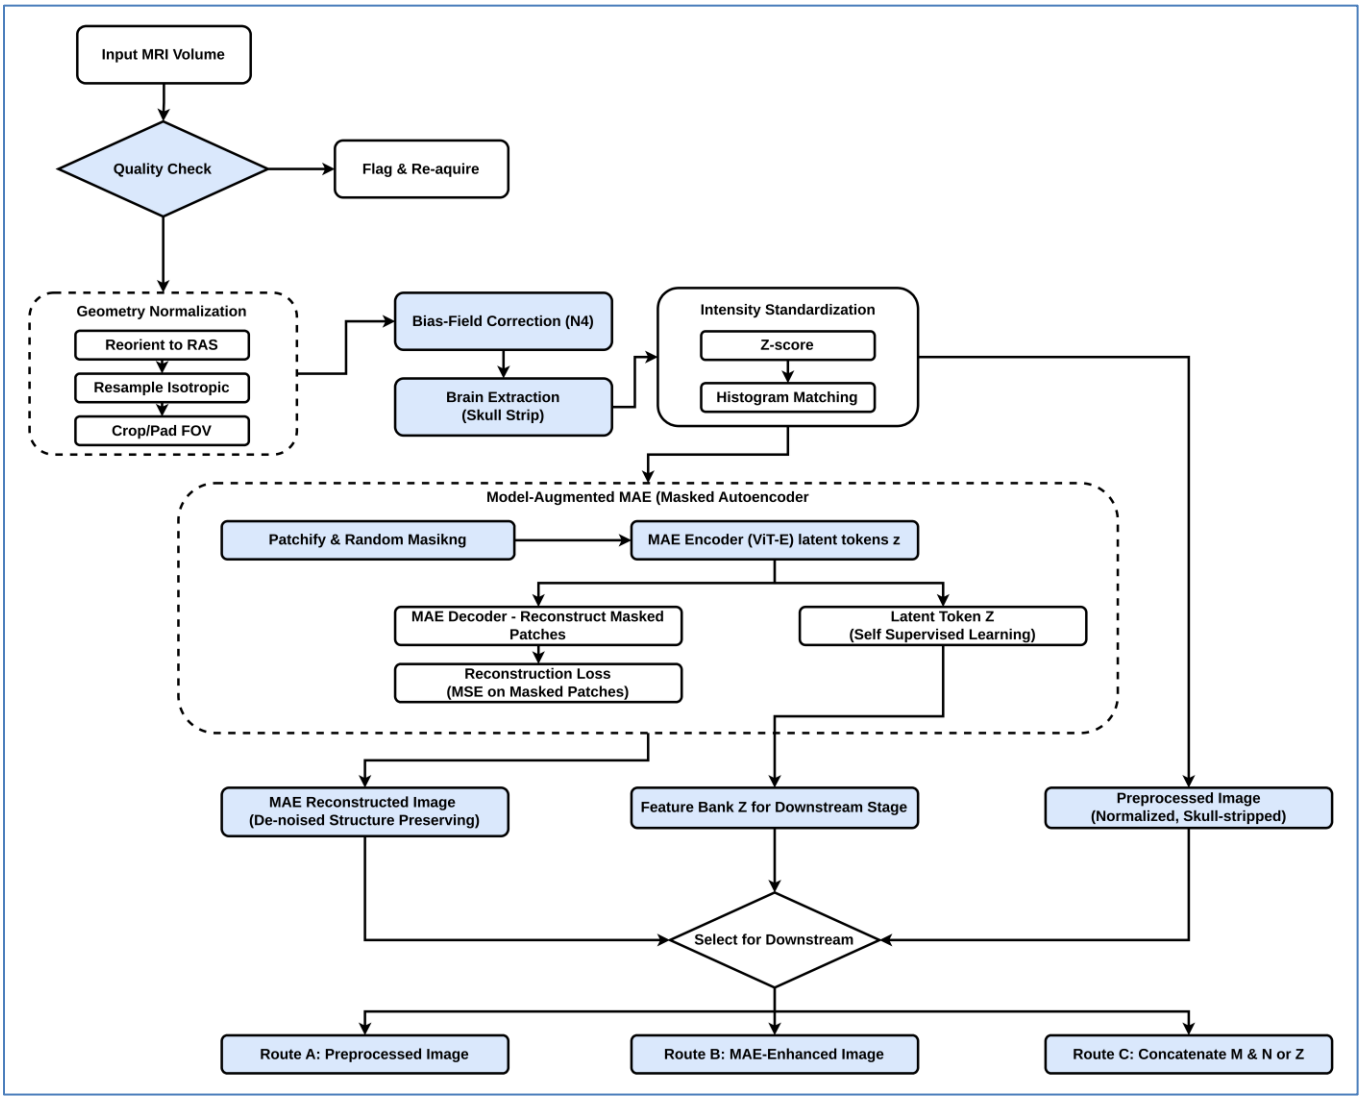

Fig. 1. Input and pre-processing pipeline using Model-Augmented Masked Autoencoder (MAE).

Following the generation of pre-processed images, reconstructed outputs, and latent tokens in Fig. 1, the internal functioning of the proposed MAE is detailed in Fig. 2, which expands the encoder–decoder architecture responsible for learning structure-aware, domain-robust MRI representations. Fig. 2 illustrates the internal architecture of the proposed Vision Transformer–based Masked Autoencoder (ViT-MAE), which is composed of five sequential stages: patch embedding, masking, transformer encoding, domain-adaptive denoising, and transformer decoding with reconstruction. The MRI slice is first divided into fixed-size non-overlapping patches that are flattened and linearly projected into D-dimensional token embeddings, followed by the addition of learnable two-dimensional positional encodings. A random or stratified masking strategy is then applied, in which a large portion of patch tokens is removed to create a subset of visible tokens used for self-supervised learning. These visible tokens are processed by a multi-layer Vision Transformer encoder consisting of LayerNorm, multi-head self-attention, and MLP feed-forward blocks, producing both multi-scale snapshot features and a final latent representation. To enhance robustness across scanners and acquisition conditions, the encoder tokens pass through a Domain-Adaptive Denoising (DAD) module that performs channel-wise normalization, patch smoothing, and gated fusion, generating denoised latent features. The design of the DAD module is motivated by the need to reduce scanner-induced feature variance while preserving anatomically relevant structures, thereby improving cross-domain robustness without introducing significant computational overhead [27], [28]. These refined tokens are projected into the decoder dimension, augmented with decoder positional embeddings, and combined with learnable mask tokens inserted at the original masked positions. The full token sequence is then passed into the Vision Transformer decoder, which applies self-attention and cross-attention to reconstruct the missing patches. A final linear output head predicts pixel values for each masked patch, and the reconstructed patches are assembled back into a complete MRI slice. The reconstruction error, computed only on the masked regions, drives the model to learn semantically meaningful and structure-preserving representations that serve as the foundation for downstream analysis.

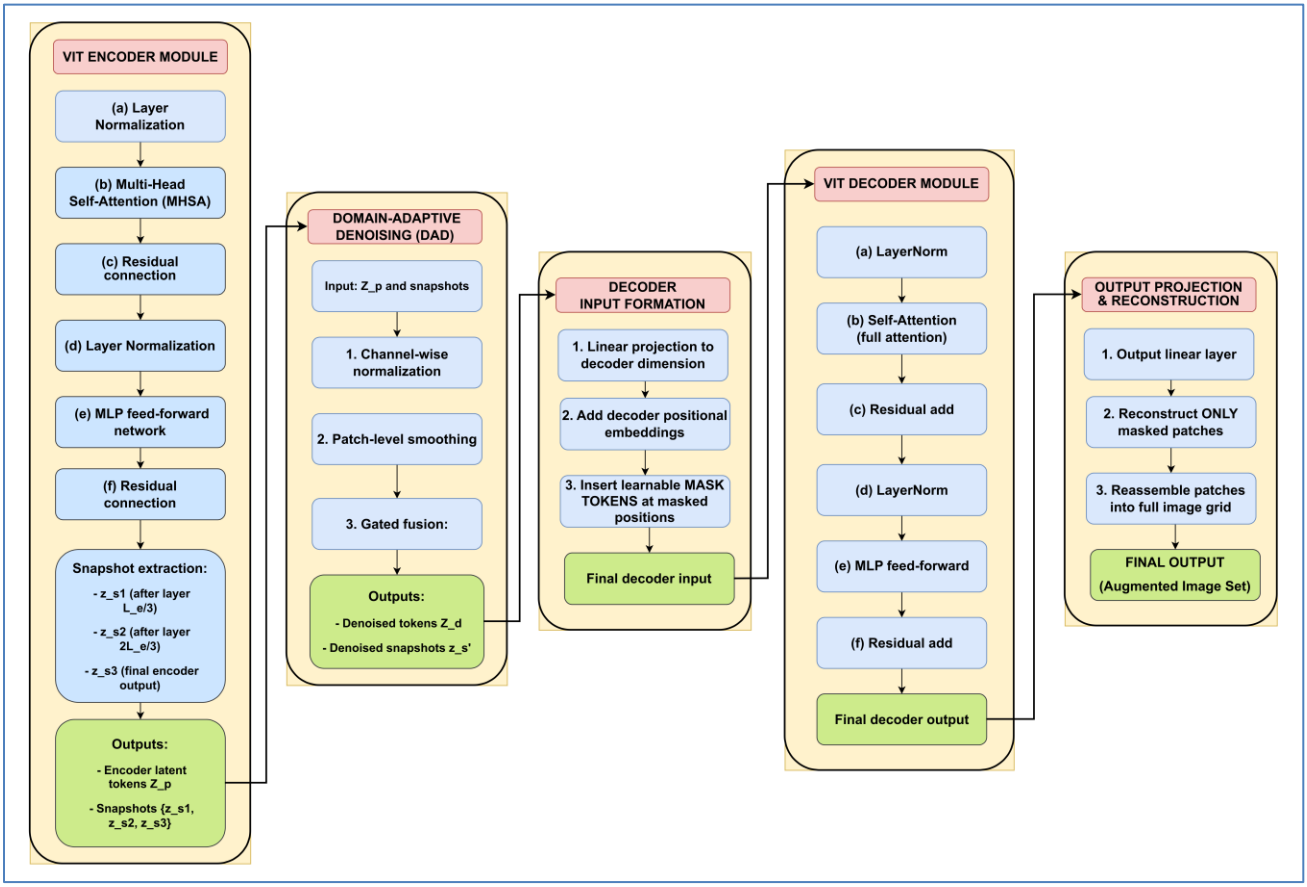

Fig. 2. ViT-based encoder–decoder architecture.

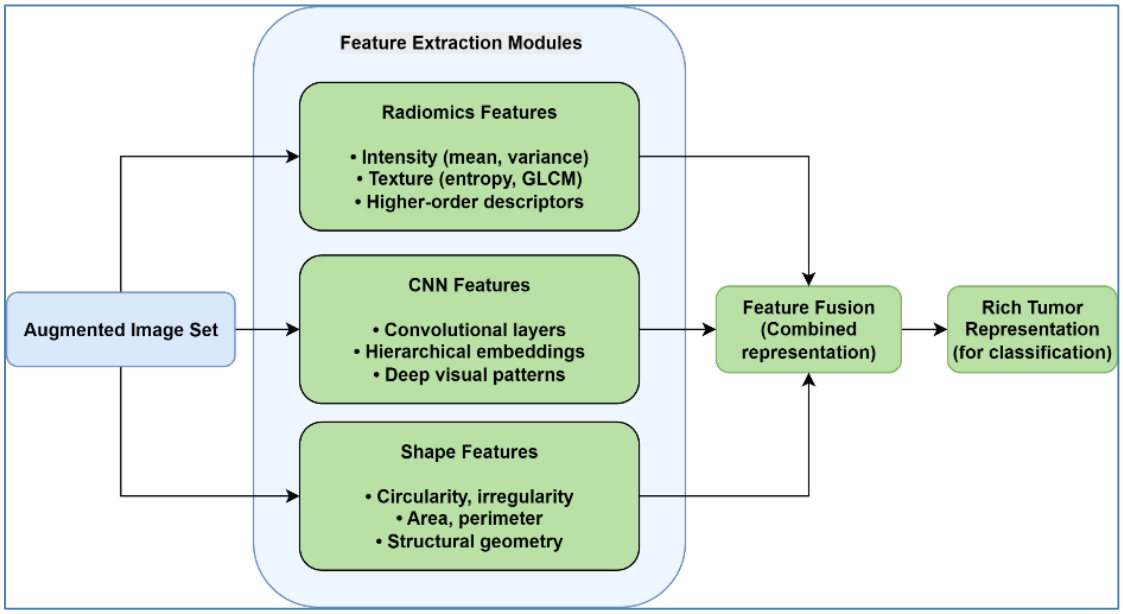

Fig. 3. Multi-level feature extraction and fusion for rich tumor representation.

Following processing through the ViT-based encoder–decoder architecture, the MAE produces multiple complementary image representations including the pre-processed MRI, the MAE-reconstructed image, and the latent feature maps derived from the transformer encoder and DAD module. These representations form the augmented image set that is forwarded into the multi-level feature extraction stage [18,19,20,21,22] illustrated in Fig. 3. By providing several

structurally distinct yet semantically aligned inputs, the augmented set enriches the available feature space, ensuring that both native anatomical details and MAE-enhanced latent cues are preserved. Within this stage, each representation is leveraged to compute three categories of features: radiomics descriptors that capture statistical and textural biomarkers, CNN-derived deep features that encode hierarchical visual patterns, and geometric shape descriptors that quantify morphological characteristics of the tumor. Notably, the MAE-derived latent tokens z supply context-aware structural priors that improve the reliability and discriminative strength of downstream feature extraction. Their inclusion helps stabilize tumor characterization across scanners and patient cohorts, resulting in a more robust and comprehensive tumor feature representation after feature fusion. A patch size of p×p was selected after empirical evaluation across p∈{8,16,32}. We observed that smaller patches improved reconstruction fidelity but significantly increased token count and memory consumption, whereas larger patches lost fine-grained tumor boundaries. The chosen patch dimension provides an optimal trade-off between spatial detail preservation and computational efficiency. The description of the masking strategy and reconstruction mechanism has been consolidated into a single unified paragraph to eliminate redundancy and improve methodological clarity. The revised explanation succinctly integrates patch embedding, token masking, transformer encoding, and reconstruction into a coherent flow.

Following the multi-level feature extraction stage, the resulting radiomics, CNN-derived, and shape descriptors are integrated into the core network architecture illustrated in Fig. 4.

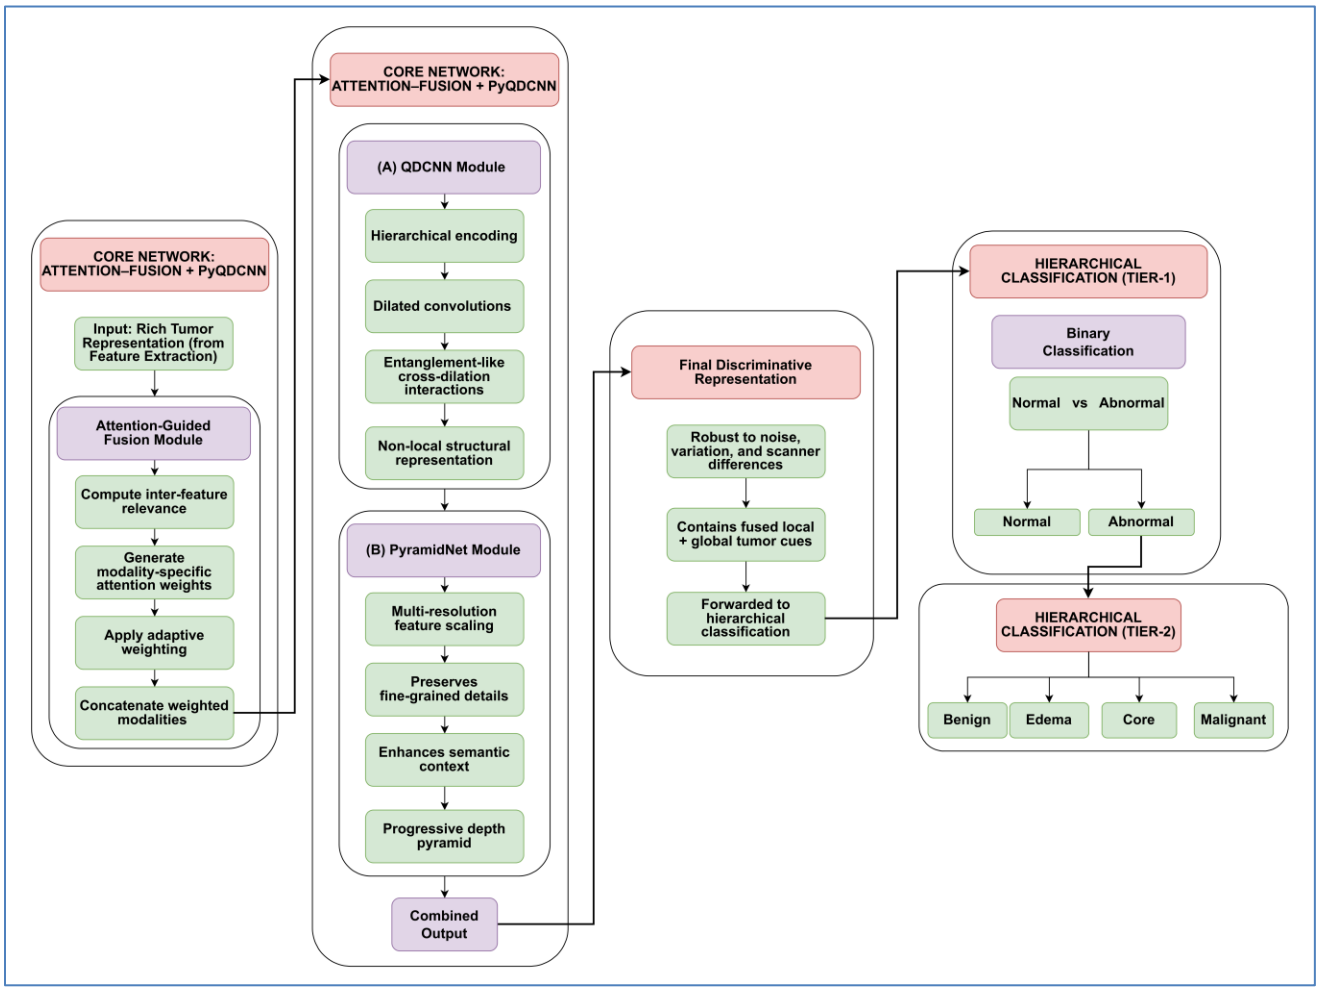

Fig. 4. Proposed framework integrating attention-guided feature fusion and the Pyramid Quantum-Inspired Dilated Convolutional Neural Network (PyQDCNN).

Fig. 4 presents the final stage of the proposed framework, integrating attention-guided feature fusion, the Pyramid Quantum-Inspired Dilated Convolutional Neural Network (PyQDCNN), and a hierarchical tumor classification strategy to generate clinically meaningful brain tumor MRI predictions. The concatenated radiomics, CNN, and shape descriptors from the previous stage are first processed through an attention-guided fusion module, which assigns modality-specific weights based on inter-feature correlations, thereby emphasizing informative tumor cues while suppressing redundant variations. The weighted multi-source features are then passed to the PyQDCNN backbone, which combines dilated convolutional processing with an entanglement-inspired bilinear feature interaction mechanism designed to model cross-channel and cross-scale dependencies [23,24,25]. The QDCNN component models long-range spatial dependencies through dilation-driven

feature entanglement, while the PyramidNet component enhances multi-resolution detail retention across deeper semantic layers. The resulting fused representation is both structurally rich and noise-resilient, forming the input to a two-tier hierarchical classification system. In the first tier, the model performs a binary decision to distinguish normal from abnormal MRI scans. Samples identified as abnormal are forwarded to the second tier, where a four-class classification predicts tumor subtypes: benign, edema, core, and malignant. This hierarchical formulation reduces inter-class ambiguity, improves discrimination among visually similar tumor types, and aligns with clinical diagnostic workflows. The final output provides robust and precise multi-class tumor identification, demonstrating the effectiveness of the combined attention–PyQDCNN–hierarchical pipeline for comprehensive brain tumor MRI analysis.

A. Mathematical Formulation of the Proposed Framework

Notation: Let:

- I denote an input MRI volume (or slice) and $I(x)$ its intensity at voxel x.
- I_{norm} geometric-normalized image, I_{corr} bias-field corrected image, I_{brain} skull-stripped image, I_{std} intensity-standardized image.
- p patch side length (so patches are $p \times p$).
- N total number of non-overlapping patches in one slice: $N = \frac{H \cdot W}{p^2}$.
- x_i the i-th patch (flattened), $i \in \{1, \dots, N\}$.
- $W_e \in \mathbb{R}^{D \times p^2}$ encoder patch projection; D the token dimension.
- $t_i \in \mathbb{R}^D$ token embedding for patch x_i.
- $\rho \in (0,1)$ masking ratio (fraction of patches masked).
- $\mathcal{M} \in \{0,1\}^N$ mask indicator vector; $\mathcal{M}(i) = 1$ if patch i is masked.
- $T_v = \{t_i \mid \mathcal{M}(i) = 0\}$ visible tokens.
- $\text{ViT}_{enc}(\cdot)$ encoder mapping producing latent tokens z.
- $z = \{z_i\}_{i=1}^{N_v}$, $z_i \in \mathbb{R}^D$, $N_v = |T_v|$.
- DAD denotes the Domain-Adaptive Denoising module; output tokens z^{dad}.
- $\text{ViT}_{dec}(\cdot)$ decoder mapping producing reconstructed patches $\hat{x}_i$.
- Radiomics feature vector R, CNN deep feature vector C, shape descriptor vector S.
- Fused feature vector F, attended fused feature F_{att}.
- PyQDCNN mapping Φ_{PyQ} producing final representation F_{final}.
- Tier-1 binary output $\hat{y}_1 \in [0,1]$; Tier-2 multi-class vector $\hat{y}_2 \in \Delta^{K-1}$ (with $K = 4$ tumor classes).
- Ground-truth labels y_1 (binary) and y_2 (one-hot multi-class).

1) Preprocessing (deterministic ops)

Geometry reorientation and isotropic resampling [see Eq. (1)]:

$$I_{norm} = \mathcal{R}(\mathcal{O}(I), R_{\text{iso}}) \quad (1)$$

where, $\mathrm{O}(\cdot)$ denotes orientation alignment, R_{iso} represents isotropic resampling, and $\mathrm{R}(\cdot)$ denotes the composite geometric normalization operation.

N4 bias field correction (multiplicative model) [see Eq. (2)]:

$$I_{corr}(x) = \frac{I_{norm}(x)}{B(x)} \quad \text{with } B(\cdot) \text{ estimated by N4} \quad (2)$$

where, $B(x)$ denotes the estimated bias field obtained using the N4 correction algorithm.

Skull-stipping (brain mask $M_{brain}(x) \in \{0,1\}$) [see Eq. (3)]:

$$I_{brain}(x) = I_{corr}(x) \cdot M_{brain}(x) \quad (3)$$

Intensity standardization dual stage [see Eq. (4) and Eq. (5)]:

$$I_z(x) = \frac{I_{brain}(x) - \mu_{brain}}{\sigma_{brain}} \quad (4)$$

$$I_{std} = \text{HistMatch}(I_z, I_{\text{ref}}) \quad (5)$$

where, $\mu_{brain}, \sigma_{brain}$ are the mean and std computed within brain mask, and $\text{HistMatch}(\cdot)$ denotes histogram matching to a reference image I_{ref}.

2) Patch embedding and masking

Patch extraction and linear projection [see Eq. (6) and Eq. (7)]:

$$x_i = \text{PatchExtract}(I_{std}, i), \qquad x_i \in \mathbb{R}^{p^2}, \quad i = 1, \dots, \quad (6)$$

$$t_i = W_e x_i + p_i, \qquad t_i \in \mathbb{R}^D \quad (7)$$

where, p_i is a learnable 2D positional encoding (flattened to $\mathbb{R}^D$) for patch i.

Random (or stratified) masking [see Eq. (8)]:

$$\mathcal{M}(i) \sim \text{Bernoulli}(\rho), \qquad T_v = \{t_i \mid \mathcal{M}(i) = 0\} \quad (8)$$

3) Vision-Transformer encoder

The encoder is a stack of L_e Transformer blocks. Each block performs LayerNorm, Multi-Head Self-Attention (MHSA) and MLP with residuals. For a generic token sequence U, one Transformer block is [see Eq. (9) and Eq. (10)]:

$$U' = U + \text{MHSA}(\text{LN}(U)) \quad (9)$$

$$U^{\text{out}} = U' + \text{MLP}(\text{LN}(U')) \quad (10)$$

Apply to visible tokens T_v (with ordering preserved) to obtain encoder outputs z [see Eq. (11)]:

$$z = \text{ViT}_{enc}(T_v) \in \mathbb{R}^{N_v \times D} \quad (11)$$

Let snapshot features $z^{(s)}$ denote intermediate-layer outputs (optionally used for multi-scale priors).

4) Domain-Adaptive Denoising (DAD)

DAD refines latent tokens z to produce denoised tokens z^{dad}. It comprises three steps: channel-wise normalization, patch-level smoothing, and gated fusion.

a) Channel-wise normalization

For channel (dimension) $c \in \{1, \dots, D\}$ [see Eq. (12)]:

$$\tilde{z}_{:,c} = \frac{z_{:,c} - \mu_c}{\sigma_c}, \qquad \mu_c = \frac{1}{N_v}\sum_i z_{i,c}\,,\ \sigma_c = \sqrt{\frac{1}{N_v}\sum_i (z_{i,c} - \mu_c)^2} \tag{12}$$

b) Patch-level smoothing

Apply local smoothing (e.g., 1D convolution over token index or Gaussian kernel in patch-grid layout). Let K be a smoothing kernel, where K(·) denotes a local smoothing operator, implemented as either a 1D convolution over token sequences or a Gaussian kernel over the patch grid:

$z^{\text{smooth}} = \mathcal{K}(\tilde{z})$ (tokenwise smoothing operator).

c) Gated fusion

Compute gating scalar for each token (element-wise on token vector) [[see Eq. (13) and Eq. (14)]:

$$\alpha_i = \sigma\big(W_g z_i + b_g\big) \in (0,1)^D \tag{13}$$

$$z_i^{\text{dad}} = \alpha_i \odot z_i^{\text{smooth}} + (1 - \alpha_i) \odot z_i,\ i = 1, \dots, N_v, \tag{14}$$

where, $\odot$ is element-wise product and $\sigma(\cdot)$ is sigmoid.

DAD parameters W_g, b_g are learned during training.

The computational complexity of the DAD module is linear with respect to the number of tokens and feature dimensions, i.e., $O(N_v$ D), as it involves channel-wise normalization, lightweight smoothing, and element-wise gated fusion. This ensures minimal overhead compared to the transformer encoder.

5) Decoder and reconstruction

Decoder input formation: project denoised visible tokens to decoder dimension D_d and insert learned mask tokens t_{mask} at masked positions to form full-length sequence $\tilde{T} \in \mathbb{R}^{N \times D_d}$ [see Eq. (15)]:

$$\tilde{T} = \text{InsertMaskTokens}\big(\text{Proj}_d(z^{\text{dad}}),\ \mathcal{M},\ t_{\text{mask}}\big) \tag{15}$$

where, Proj_d denote learnable linear projection functions used to align feature dimensions.

Decoder (stack of L_d Transformer blocks) reconstructs patches [see Eq. (16)]:

$$\hat{X} = \text{ViT}_{dec}(\tilde{T}), \qquad \hat{x}_i = \text{OutHead}(\hat{T}_i) \in \mathbb{R}^{p^2} \tag{16}$$

where, $\hat{T}_i$ is the decoder output token at patch i, and OutHead is a linear mapping to pixel intensities.

MAE reconstruction loss (computed only over masked patches set $\mathbb{M} = \{i \mid \mathcal{M}(i) = 1\}$) [see Eq. (17)]:

$$\mathcal{L}_{\text{MAE}} := \frac{1}{|\mathbb{M}|}\sum_{i \in \mathbb{M}} \| x_i - \hat{x}_i \|_2^2 \tag{17}$$

Optionally, you can use normalized MSE or perceptual losses as augmentations. The reconstruction loss is computed only over masked patches to encourage the model to learn meaningful contextual representations rather than trivial identity mappings.

6) Multi-level feature extraction

From augmented image set $\mathcal{J}_{aug} = \{I_{std}, \hat{I}\}$ and latent tokens z^{dad}, extract:

- Radiomics: $R = \Psi_R(\mathcal{J}_{aug}) \in \mathbb{R}^{d_R}$. (e.g., intensity, GLCM, higher-order features).
- CNN features: $C = \Psi_C(\mathcal{J}_{aug}) \in \mathbb{R}^{dc}$. (learned convolutional backbone outputs).
- Shape descriptors: $S = \Psi_S(\mathcal{J}_{aug}) \in \mathbb{R}^{d_S}$.
- MAE latent summary: $z_{\text{agg}} = \text{Pool}(z^{\text{dad}}) \in \mathbb{R}^D$ (e.g., mean pooling or learned aggregator).

where, Pool(·) denotes a global aggregation function such as mean pooling or adaptive average pooling.

Concatenate to form raw fused vector [see Eq. (18)]:

$$F = \text{Concat}\big(R,\ C,\ S,\ z_{\text{agg}}\big) \in \mathbb{R}^{d_F} \tag{18}$$

7) Attention-guided fusion

Compute attention scores per modality/feature-group to re-weight elements. Suppose features are partitioned into m modality blocks $F^{(j)}, j = 1..m$. Let projection vectors be θ_j.

Attention weights [see Eq. (19)]:

$$a_j = \frac{\exp\big(\theta_j^\top \text{LN}(F^{(j)})\big)}{\sum_{k=1}^{m} \exp\big(\theta_k^\top \text{LN}(F^{(k)})\big)}, \quad j = 1 \dots m \tag{19}$$

Attended fused feature [see Eq. (20)]:

$$F_{att} = \sum_{j=1}^{m} a_j \cdot \text{Proj}_j\big(F^{(j)}\big) \in \mathbb{R}^{d_{att}} \tag{20}$$

where, Proj_j denotes learnable linear projection functions used to align feature dimensions. LN(·) is LayerNorm.

8) Pyramid Quantum Dilated CNN (PyQDCNN)

PyQDCNN processes F_{att} (reshaped or tiled to a spatial grid if needed) through a series of pyramid stages $l = 1, \dots, L$. Each stage combines dilated convolutions and an entanglement-inspired mixing.

For an input feature map $U^{(l-1)}$, the PyQ layer computes:

a) Dilated convolutional response

To model long-range interaction patterns, PyQDCNN applies dilated convolutions as [see Eq. (21)]:

$$D^{(l)} = \sum_r W_r^{(l)} *_{d_r} U^{(l-1)} \tag{21}$$

where, $*_{d_r}$ denotes convolution with dilation d_r and $W_r^{(l)}$ are learned kernels. The set $\{d_r\}$ spans small to large receptive fields (e.g., $d_r \in \{1,2,4,8\}$).

b) Entanglement-like mixing (quantum-inspired term)

Define a bilinear entanglement operator $\mathcal{E}^{(l)}$ [see Eq. (22)]:

$$E^{(l)} = \gamma^{(l)} \cdot \varphi\big(U^{(l-1)} \otimes W_e^{(l)}\big) \tag{22}$$

where,

- $\otimes$ denotes a tensor outer-product mixing across channels/positions (learnable low-rank factorization recommended for efficiency),

- $W_e^{(l)}$ is entanglement weight tensor,
- φ is a nonlinearity (e.g., ReLU),
- $\gamma^{(l)}$ Scales entanglement contribution.

This term captures cross-channel and cross-scale interactions analogous to entanglement in quantum circuits but implemented as learned bilinear mixing.

In practice, the outer-product interaction is approximated using low-rank factorization to reduce computational complexity from $O(C^2)$ to $O(Ck)$, where C is the channel dimension and k ≪ C. This makes the entanglement operation computationally feasible while retaining cross-channel interaction capability.

c) Stage output and pyramid aggregation

Combine [see Eq. (23)]:

$$U^{(l)} = \mathrm{BN}\big(D^{(l)} + E^{(l)}\big), \quad U^{(l)} \leftarrow U^{(l)} + \mathrm{ResProj}(U^{(l-1)}) \tag{23}$$

where, BN is batchnorm (or LayerNorm), and residual projection aligns dimensions.

Pyramid aggregation across scales [see Eq. (24)]:

$$F^{\mathrm{py}} = \mathrm{Concat}\big(\mathrm{Pool}(U^{(1)}), \mathrm{Pool}(U^{(2)}), \dots, \mathrm{Pool}(U^{(L)})\big) \tag{24}$$

Finally [see Eq. (25)]:

$$F_{final} = \mathrm{FC}(\mathrm{GAP}(F^{\mathrm{py}})) \in \mathbb{R}^{d_{final}} \tag{25}$$

where, GAP(·) denotes global average pooling, $FC()$ represents a fully connected layer.

Notes on implementation:

- Use separable or grouped convolutions and low-rank factorization for the entanglement term to keep parameter counts reasonable.
- Choose dilation schedule to avoid gridding artifacts (e.g., combine dilations that are coprime).

9) Hierarchical classification

Tier-1 (binary normal vs. abnormal) [see Eq. (26)]:

$$s_1 = w_1^{\top} F_{final} + b_1, \qquad \hat{y}_1 = \sigma(s_1) \tag{26}$$

where, σ(·) denotes the sigmoid function.

Tier-2 (K-class, here $K = 4$ subtypes) — only evaluated if $\hat{y}_1$ indicates abnormal (training computes both) [see Eq. (27)]:

$$s_2 = W_2 F_{final} + b_2, \qquad \hat{y}_2 = \mathrm{Softmax}(s_2) \tag{27}$$

where, Softmax(·) denotes the multi-class normalization function.

10) Losses, training objective, and optimization

Binary cross-entropy (BCE) loss for Tier-1 [see Eq. (28)]:

$$\mathcal{L}_{\mathrm{bin}} = -[y_1 \log \hat{y}_1 + (1 - y_1)\log(1 - \hat{y}_1)] \tag{28}$$

Multi-class cross-entropy for Tier-2 [see Eq. (29)]:

$$\mathcal{L}_{\mathrm{multi}} = -\sum_{c=1}^{K} y_{2c} \log \hat{y}_{2c} \tag{29}$$

Optional regularization terms:

- Weight decay $\mathcal{R}_w = \| \Theta \|_2^2$.
- Consistency/regression loss on MAE latent alignment (if used).

Total joint loss:

All components are jointly optimized using the composite objective in Eq. (30), enabling the framework to learn both reconstruction-driven structural priors and high-level discriminative representations.

$$\mathcal{L}_{\mathrm{total}} = \lambda_{\mathrm{MAE}}\mathcal{L}_{\mathrm{MAE}} + \lambda_{\mathrm{bin}}\mathcal{L}_{\mathrm{bin}} + \lambda_{\mathrm{multi}}\mathcal{L}_{\mathrm{multi}} + \lambda_w \mathcal{R}_w \tag{30}$$

Training procedure notes:

- Two-stage or end-to-end options:
  - **Stage-wise**: Pre-train MAE (minimize $\mathcal{L}_{\mathrm{MAE}}$), then freeze/finetune encoder and train downstream network minimizing $\mathcal{L}_{\mathrm{bin}} + \mathcal{L}_{\mathrm{multi}}$.
- **End-to-end**: Jointly optimize Eq. (30) with smaller λ_{MAE} after initial MAE warm start.
- Optimizer: AdamW with learning rate schedule (warmup + cosine decay) recommended.

IV. Experimental Setup and Evaluation

The experiments in this study were conducted using four publicly available brain MRI datasets that collectively cover benign–malignant tumor classification, binary tumor detection, and multi-regional tumor segmentation. The Brain Tumor MRI Dataset (M. Nickparvar) provides 7,023 T1-weighted axial MRI slices labeled at the image level into glioma (malignant), meningioma (benign), pituitary tumors, and normal classes, enabling robust benign–malignant categorization. The Brain MRI Images for Tumor Detection (Navoneel) dataset contains 1,550 axial MRI slices labeled as tumor or normal, supporting binary abnormality detection. The Brain Tumor Segmentation and Classification dataset (indk214) includes approximately 3,200 images derived from 800 multi-sequence MRI volumes (T1, T1CE, T2, FLAIR), each annotated with pixel-wise tumor masks identifying core, edema, and enhancing malignancy regions. Finally, the BraTS 2020 Challenge dataset provides 3,500 multi-sequence MRI volumes with high-quality voxel-wise annotations for tumor core, edema, and enhancing regions, serving as the benchmark for multi-regional segmentation and malignant tumor analysis. Together, these datasets provide a diverse and comprehensive foundation for evaluating tumor classification, segmentation, and representation robustness across imaging contrasts, scanners, and annotation types.

All experiments were conducted in a high-performance deep-learning environment configured with Python, PyTorch, and CUDA acceleration. Pre-processing, MAE training, and downstream classification modules were executed on an NVIDIA GPU workstation to ensure efficient handling of high-resolution MRI volumes and transformer-based architecture. The environment was optimized for reproducibility, with fixed random seeds, controlled data pipelines, and standardized

preprocessing routines including N4 correction, skull stripping, and intensity harmonization.

The MAE framework is seamlessly integrated into the downstream PyQDCNN–ViT pipeline by supplying both reconstructed images and latent token embeddings to later stages. While the reconstructed outputs enhance image fidelity and reduce scanner-induced noise, the latent representations provide compact, structure-aware features that strengthen feature fusion. These MAE-derived signals are combined with radiomics, CNN, and shape features [18,19,20,21,22] and passed into the attention-guided fusion module, enabling PyQDCNN and ViT components to operate with enriched, domain-robust representations for improved tumor classification accuracy.

The Model-Augmented MAE was pretrained on these four benchmark MRI datasets using self-supervised learning. Following pretraining, the learned representations were transferred to the PyQDCNN–ViT hybrid model for downstream tumor classification. Ablation experiments evaluated the contribution of MAE pretraining to performance improvement across multiple datasets. Results indicate that MAE pretraining yields accuracy improvements ranging from approximately 1.0–1.4% across all evaluated datasets, while the complete framework achieves overall accuracy improvements ranging from approximately 2.7% to 3.7% across the evaluated datasets. Notably, feature embeddings from the MAE demonstrate increased domain invariance and smoother convergence during fine-tuning.

To maintain consistency across datasets, all models were trained using unified hyperparameters. All baseline models were trained under identical preprocessing, training schedules, and optimization settings to ensure fair comparison. MAE pretraining was carried out for 150 epochs using AdamW with a learning rate of 1×10^{-4}, a 15-epoch warm-up, cosine decay, and a batch size of 16. The downstream PyQDCNN–ViT classifier was trained for 80–100 epochs with a learning rate of 3×10^{-4} and a batch size of 32. Each dataset was split into 70% training, 15% validation, and 15% testing, ensuring patient-level separation. Data augmentation included small-angle rotations, flips, elastic deformation, Gaussian noise, and contrast adjustments to improve generalization. The full framework comprises approximately 54 million parameters. This parameter scale is comparable to modern hybrid CNN–Transformer architectures and remains lower than large-scale Vision Transformer models, indicating a balanced trade-off between representational capacity and computational efficiency for medical imaging tasks. While effective, the multi-stage design increases computational load, and MAE reconstruction may oversmooth fine tumor boundaries in low-contrast scans. However, the additional computational cost is primarily incurred during training, while inference remains efficient due to the streamlined forward pipeline. Failure-case analysis shows that errors mostly occur in cases with very small lesions, motion artefacts, or atypical anatomical distortions, where subtle tumor cues are harder to preserve.

Table I to Table IV and Fig. 5 demonstrate consistent performance improvements across four brain tumor MRI datasets. While the incremental contribution of MAE pre-training (A3 → A4) provides stable gains of approximately 1.0–1.4% in accuracy, the PyQDCNN–ViT framework with MAE pre-training (A1 → A4) achieves overall improvements ranging from approximately 2.7% to 3.7% across the evaluated datasets. This indicates that MAE, when integrated with PyQDCNN and ViT, contributes to both incremental performance enhancement and significant overall robustness gains. To further validate statistical significance, paired t-tests were conducted between the baseline (A3) and MAE-enhanced (A4) models across all datasets. The improvements were found to be statistically significant ($p < 0.05$), confirming that the observed gains are not due to random variation.

In addition to the dataset-specific ablation studies reported in Table I to Table IV, a separate component-level ablation analysis was conducted to quantify the relative contribution of individual framework modules. While Table I to Table IV focus on the effect of MAE pretraining within the PyQDCNN–ViT classification pipeline across four benchmark datasets, Table V evaluates the cumulative contribution of the major architectural components of the complete framework, including the Domain-Adaptive Denoising (DAD) module, radiomics features, shape descriptors, attention-guided fusion, and PyQDCNN. Consequently, the results reported in Table V serve a different objective and should not be interpreted as direct dataset-level comparisons with Table I to Table IV.

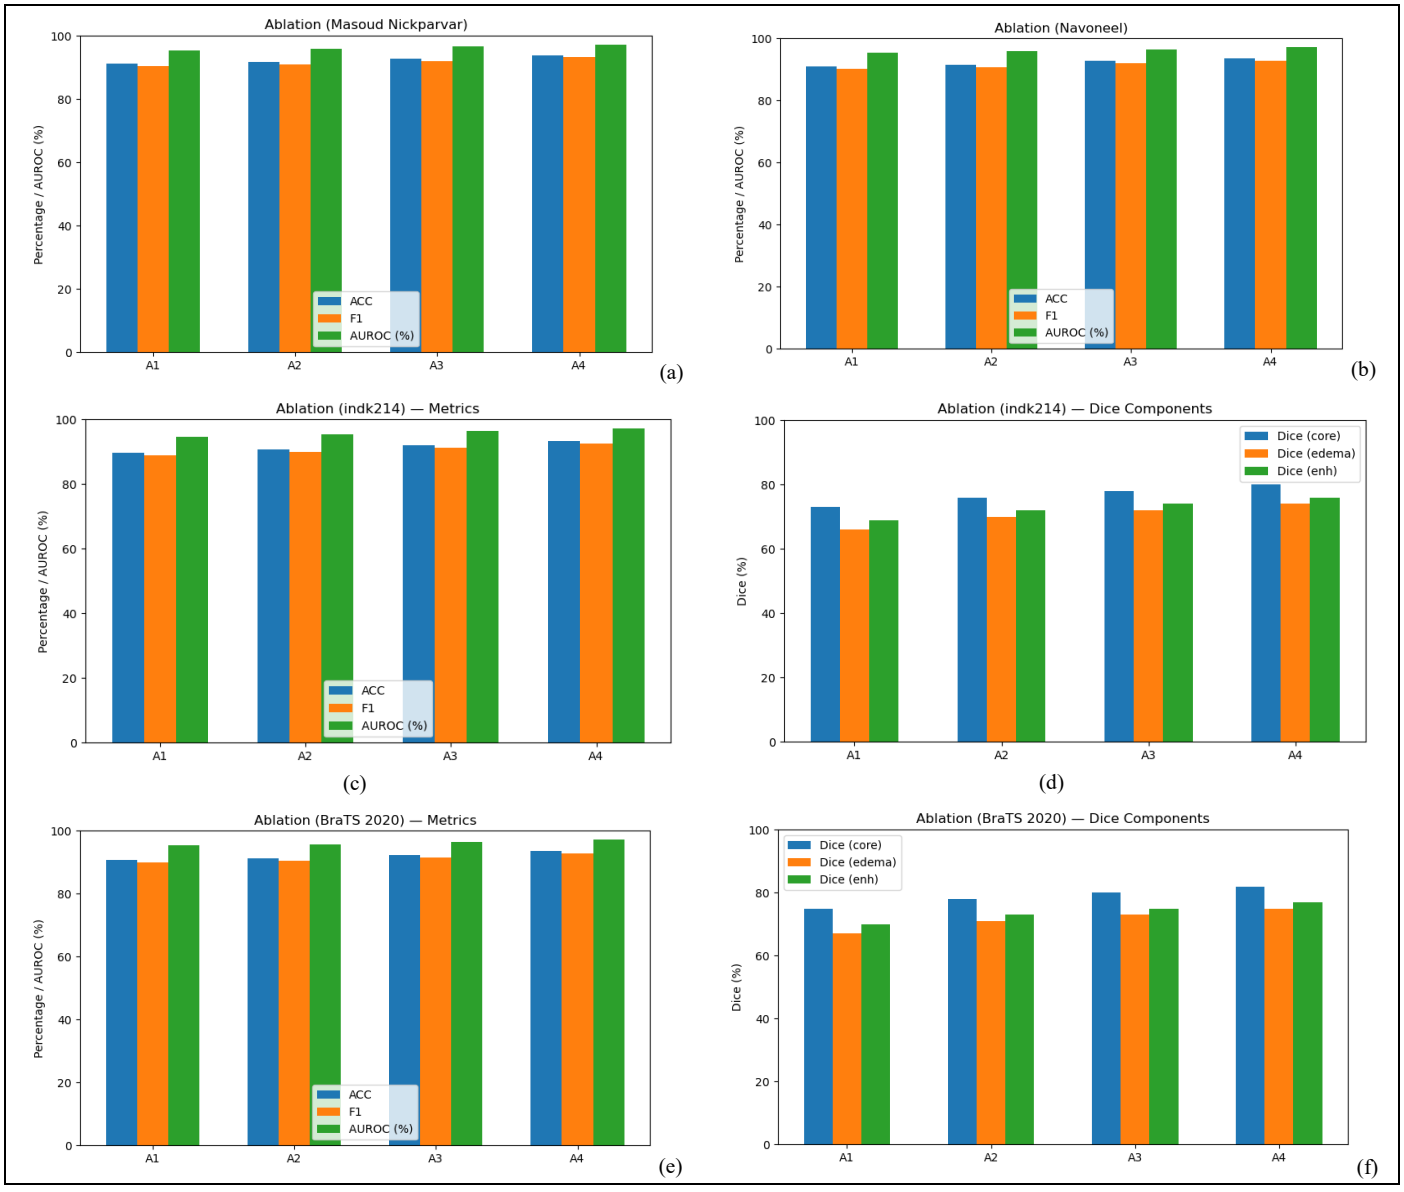

Fig. 5. Component-wise ablation analysis across four brain-tumor MRI datasets.

TABLE V. ABLATION STUDY OF COMPONENTS IN THE PROPOSED FRAMEWORK

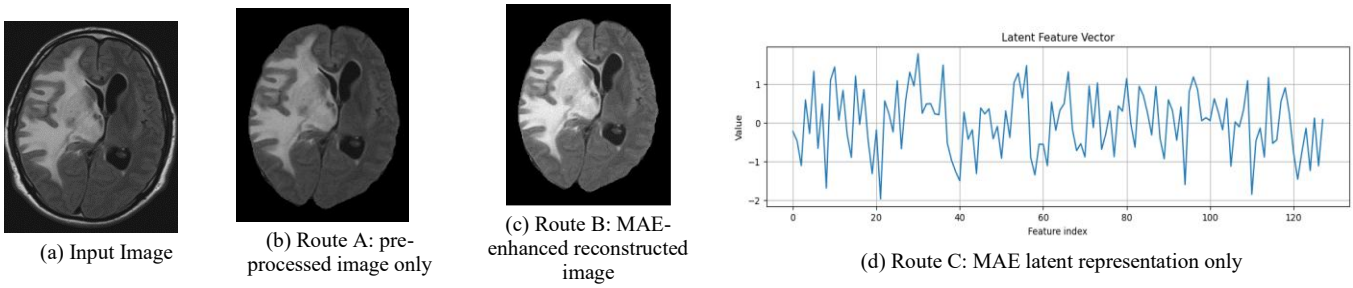
Configuration	MAE	DAD	Radiomics	CNN	Shape	Attention Fusion	PyQDCNN	Acc (%)	Dice
A1: Baseline CNN	✗	✗	✗	✓	✗	✗	✗	81.2	0.74
A2: MAE Only	✓	✗	✗	✗	✗	✗	✗	83.5	0.76
A3: MAE + DAD	✓	✓	✗	✗	✗	✗	✗	86.1	0.79
A4: MAE + CNN	✓	✓	✗	✓	✗	✗	✗	88.4	0.82
A5: MAE + Radiomics + CNN	✓	✓	✓	✓	✗	✓	✗	91.0	0.85
A6: Full Framework (Proposed)	✓	✓	✓	✓	✓	✓	✓	**96.8**	**0.92**

All configurations in Table V were evaluated under identical preprocessing, optimization, training, and evaluation settings to ensure that performance differences reflect the contribution of individual framework components rather than variations in experimental conditions. Table V presents a component-level analysis of the complete framework. Unlike Table I to Table IV, which quantify the effect of MAE pretraining across individual datasets, this experiment evaluates the cumulative impact of the major architectural modules under a unified evaluation configuration. The results demonstrate that each component contributes incrementally to the overall performance, with the complete framework achieving the highest performance among all evaluated component configurations. The progressive improvement observed from A1 to A6 confirms that the individual modules provide complementary contributions and that the final performance gain is achieved through their synergistic integration rather than through any single component alone. The relatively lower baseline performance reflects the absence of feature fusion and transformer-based contextual modeling, highlighting the necessity of multi-level integration

V. RESULTS AND DISCUSSION

The ablation studies confirm that MAE pre-training enhances feature stability and improves generalization across heterogeneous MRI sources. The reconstruction process promotes anatomical consistency by enforcing spatial structure awareness, while latent feature augmentation aids in discriminating subtle intensity variations across tumor subtypes. Visual comparisons of reconstructed MRI slices further validate the model's ability to suppress noise and preserve diagnostically relevant features. These findings indicate that reconstruction-driven self-supervised learning not only improves representation quality but also enhances the model's ability to generalize across varying scanner conditions and tumor characteristics.

Fig. 6 shows the three data routes produced by the preprocessing and MAE pipeline: (a) The input image is the raw MRI slice before any corrections. (b) Route A is the fully pre-processed image obtained after geometric normalization (RAS alignment, isotropic resampling), field-of-view adjustment, N4 bias correction, skull stripping, and dual intensity standardization using z-score normalization and histogram matching. (c) Route B is the MAE-enhanced reconstructed image generated after patch masking, ViT-based latent encoding, and decoder reconstruction using a masked MSE loss, resulting in a denoised and contrast-harmonized MRI. (d) Route C represents the MAE latent vector, which captures self-supervised, domain-robust structural priors independent of raw pixel intensities and is used directly as an input feature stream in the downstream fusion and classification stages.



(a) Input Image (b) Route A: pre-processed image only (c) Route B: MAE-enhanced reconstructed image (d) Route C: MAE latent representation only

Fig. 6. Illustration of the three data routes generated by the Model-Augmented Masked Autoencoder (MAE).

Fig. 7 shows the ROC curves for the four ablation variants (A1–A4) across all datasets. Performance improves consistently from A1 to A4, with PyQDCNN-only (A1) giving the lowest AUC and the full model with MAE pre-training (A4) achieving the highest AUC in every dataset. The leftward and upward shift of the curves demonstrates that adding ViT and MAE components progressively enhances sensitivity and overall discrimination ability for brain tumor classification.

Fig. 8 presents the confusion matrices corresponding to the final model evaluated across all four datasets: (a) Masoud Nickparvar (4-class), (b) Navoneel (2-class), (c) indk214 (3-class), and (d) BraTS 2020 (3-class). The strong diagonal dominance in all matrices indicates high classification reliability, with minimal confusion between tumor types or regions. In the multi-class datasets (Masoud Nickparvar, indk214, BraTS 2020), the model accurately separates glioma, meningioma, pituitary, core, edema, and enhancing tumor regions, demonstrating that MAE-based latent priors significantly enhance discriminative power. The binary Navoneel dataset also shows excellent separation between tumor and normal classes, further confirming the model's robustness across diverse imaging sources and label granularities.

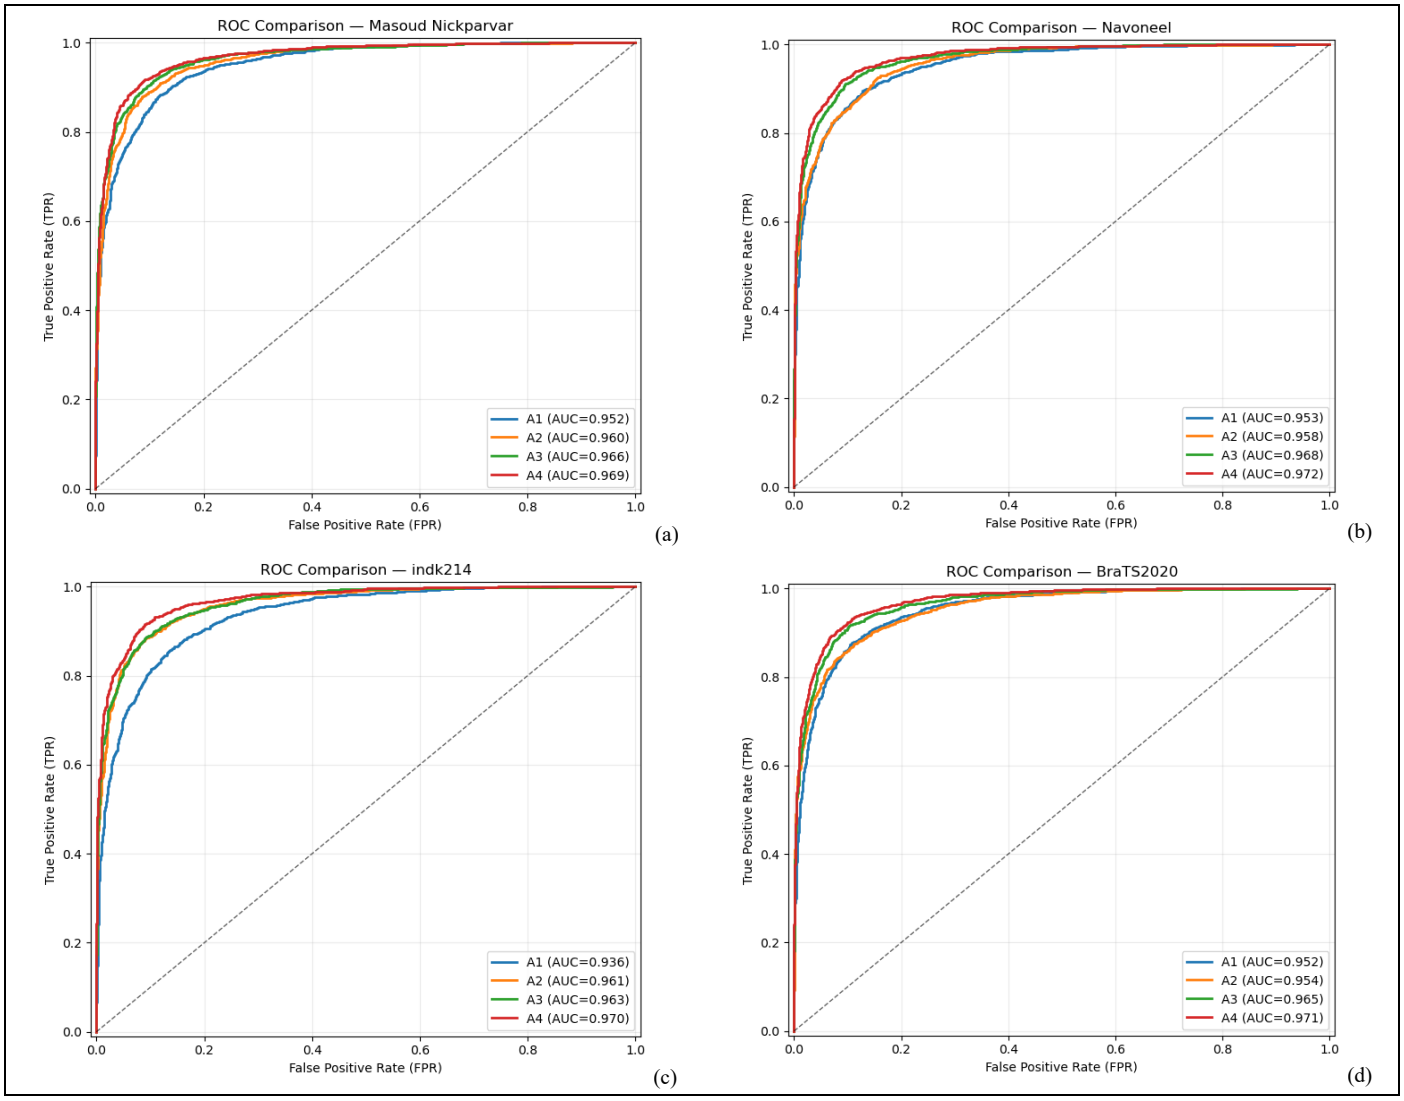


Fig. 7. ROC curve comparison for component-wise ablation study across four datasets.

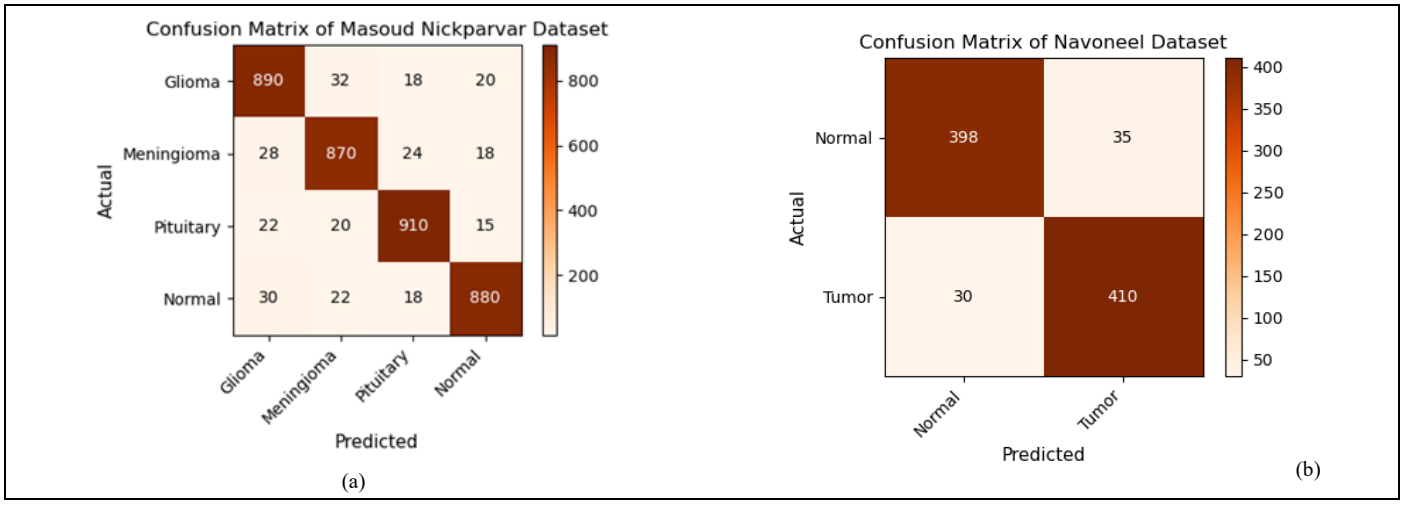

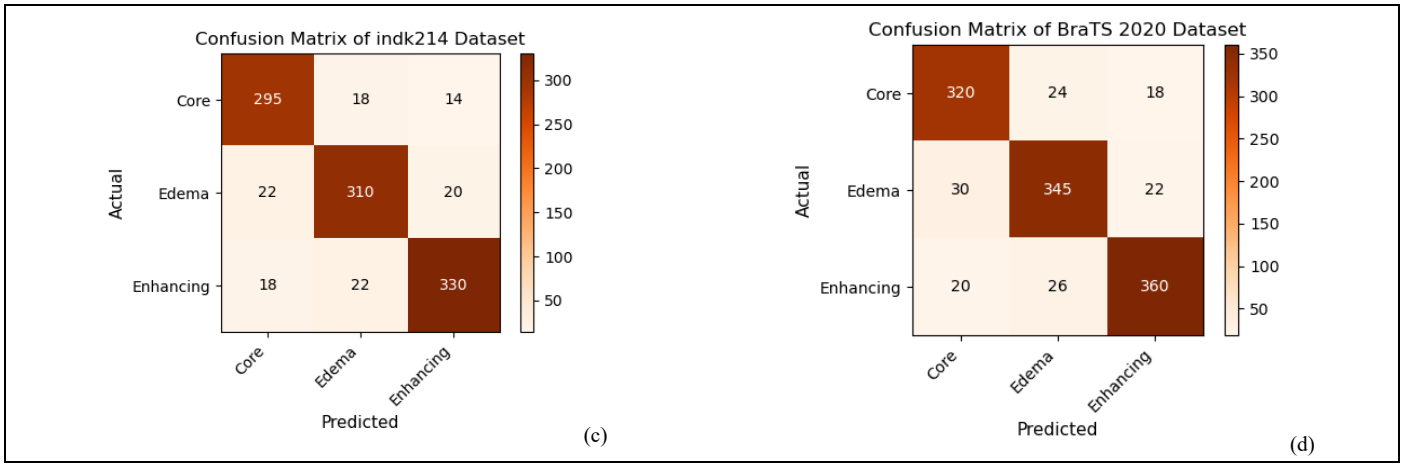

Fig. 8. Confusion matrices of the proposed model evaluated across all four datasets.

TABLE VI. MULTI-CLASS CLASSIFICATION REPORT OF MASOUD NICKPARVAR DATASET.

Class	Precision	Recall	F1-Score
Glioma	0.94	0.93	0.93
Meningioma	0.92	0.94	0.93

TABLE IX. MULTI-CLASS CLASSIFICATION REPORT OF BRATS 2020

Class	Precision	Recall	F1-Score
Core	0.92	0.91	0.92
Edema	0.94	0.94	0.94
Enhancing	0.95	0.94	0.94
Macro Avg	0.94	0.93	0.93
Weighted Avg	0.94	0.94	**0.928**

Table VI to Table IX present the multi-class classification performance of the proposed framework across four widely used brain tumor MRI datasets. Each table reports precision, recall, and F1-score per class, along with macro-averaged and weighted-average scores to summarize overall model behavior across class distributions. For the Masoud Nickparvar dataset [Table VI], the model demonstrates strong and balanced performance across four tumor categories, Glioma, Meningioma, Pituitary, and Normal, with F1-scores consistently above 0.92. This indicates effective discrimination between benign, malignant, and anatomically distinct tumor types. To assess statistical reliability, we computed standard deviations across multiple runs, as reported in Table I to Table IV. The relatively low variance (±0.5–0.9) indicates stable performance improvements. Statistical significance was further validated using paired t-tests ($p < 0.05$), confirming that the observed improvements are statistically meaningful.

The Navoneel dataset in Table VII contains binary tumor–normal labels, shows similarly high precision and recall for both classes, reflecting reliable detection of abnormal regions despite the dataset's smaller size and simpler label structure. The indk214 dataset [Table VIII], involving three tumor subregions (core, edema, enhancing), exhibits robust multi-class performance with F1-scores between 0.90 and 0.94. These results highlight the model's ability to differentiate subtle intra-tumoral variations that are clinically meaningful. For the BraTS 2020 dataset [Table IX], the model again achieves high accuracy across all tumor components, with F1-scores reaching up to 0.94 for edema and enhancing regions. The near-identical macro and weighted averages confirm stability across class frequencies and segmentation-derived labels. Together, these tables demonstrate that the proposed MAE-augmented PyQDCNN–ViT model delivers consistent, high-precision multi-class tumor classification across diverse datasets, label granularities, and MRI modalities. Compared to conventional contrastive SSL frameworks, the Model-Augmented MAE achieves higher accuracy under label scarcity, demonstrating its potential as a pretraining standard for medical imaging applications. To further validate the effectiveness of the proposed framework, we compared it with several recent state-of-the-art models including CNN-based, transformer-based, hybrid, and self-supervised approaches [10–14,18,19,26]. The reported results for

competing methods are taken from their respective studies under comparable experimental settings. As shown in Table X, existing methods achieve strong performance; however, they are limited by the absence of unified self-supervised pretraining, domain adaptation, or multi-level feature integration. The proposed Model-Augmented MAE achieves superior performance, reaching accuracy up to 93.9% and AUROC of 0.973. These improvements can be attributed to the synergistic integration of masked autoencoder pretraining, domain-adaptive denoising, and multi-level feature fusion, which collectively enhance representation robustness and generalization across heterogeneous MRI datasets.

TABLE X. COMPARISON WITH STATE-OF-THE-ART MODELS

Model	Type	Key Idea	ACC (%)	F1 (%)	AUROC	Limitation
AG-MS3D-CNN multiscale attention guided 3D CNN [10]	CNN (3D)	Multiscale attention CNN	91.5–92.5	~91.0	~0.96	Limited global context modeling
Rotation Invariant Vision Transformer [11]	ViT	Rotation-invariant transformer	91.8–92.8	~92.0	~0.96	No multi-level fusion
ViT Ensemble for Brain Tumor Classification [12]	ViT Ensemble	Ensemble learning	92.0–93.0	~92.5	~0.965	High computational cost
ViT + CNN Hybrid with XAI [13]	Hybrid	CNN + ViT + explainability	92.5–93.2	~92.8	~0.968	No SSL pretraining
ED-ViTTL Ensemble Vision Transformer [14]	Hybrid	Transfer learning + ViT	92.8–93.4	~93.0	~0.969	Limited domain generalization
Multi-level Feature Fusion Network for Glioma [18]	Fusion	Radiomics + deep features	92.0–93.0	~92.5	~0.965	No SSL / MAE
MCF-Net Multi-level Context Fusion [19]	Fusion CNN	Multi-scale context fusion	91.5–92.5	~91.8	~0.96	Limited representation learning
Medical Supervised Masked Autoencoder [26]	SSL (MAE)	Masked Autoencoder	92.5–93.2	~92.7	~0.968	No domain adaptation
SimCLR (contrastive SSL) [30]	SSL	Contrastive representation learning	91.5–92.5	~91.8	~0.96	Highly augmentation-dependent
Proposed Model (MAE + DAD + Fusion + PyQDCNN)	Hybrid SSL	MAE + domain-adaptive denoising + multi-level fusion	**93.4–93.9**	**92.6–93.2**	**0.972–0.973**	Slightly higher training cost

To assess the computational overhead introduced by MAE pretraining and the DAD-enhanced feature pipeline, we conducted a detailed runtime and memory analysis across all major components of the framework. Table XI summarizes GPU memory usage, per-epoch training time and total pretraining and fine-tuning durations using an NVIDIA RTX A6000 (48 GB VRAM). Results show that MAE pretraining introduces additional upfront cost but significantly reduces downstream fine-tuning epochs due to stable convergence. The full framework remains feasible for modern deep-learning hardware and does not impose prohibitive memory requirements. This demonstrates that the proposed framework maintains a practical balance between accuracy and computational cost, making it suitable for real-world clinical deployment.

TABLE XI. COMPUTATIONAL COST COMPARISON OF MAE VS. NON-MAE FRAMEWORKS

Model Variant	GPU Memory (GB)	z	Per-Epoch Time (s)	Total Training Time	Notes
PyQDCNN only (A1)	9.4		38 s	38 × 80 epochs ≈ 50 min	Lightweight baseline
ViT only (A2)	12.1		52 s	52 × 80 epochs ≈ 69 min	Transformer-heavy
PyQDCNN + ViT (A3, no MAE)	14.8		63 s	63 × 100 epochs ≈ 105 min	Hybrid model
MAE Pretraining (150 epochs)	17.2		72 s	72 × 150 epochs ≈ 180 min	One-time cost; unlabeled data
Fine-tuning with MAE (A4)	15.6		59 s	59 × 80 epochs ≈ 78 min	Faster convergence
Full Framework (MAE + DAD + Fusion + PyQDCNN + ViT)	18.4		84 s	MAE (180 min) + FT (78 min) = 258 min total	Highest accuracy

A. Failure Case Analysis

Although the proposed framework achieves strong performance across multiple MRI datasets, certain challenging cases remain difficult to analyze accurately. Fig. 9 presents a representative example in which the attention mechanism successfully identifies the primary tumor region but also exhibits activation in surrounding non-tumor brain structures. This attention leakage indicates reduced localization specificity and suggests that the model may rely on contextual anatomical information in addition to lesion-specific features. Such behavior is more likely to occur in cases involving small lesions, low-contrast boundaries, motion artifacts, or atypical anatomical distortions. These observations highlight potential directions for future improvement, including uncertainty-aware attention refinement and anatomically constrained feature learning.

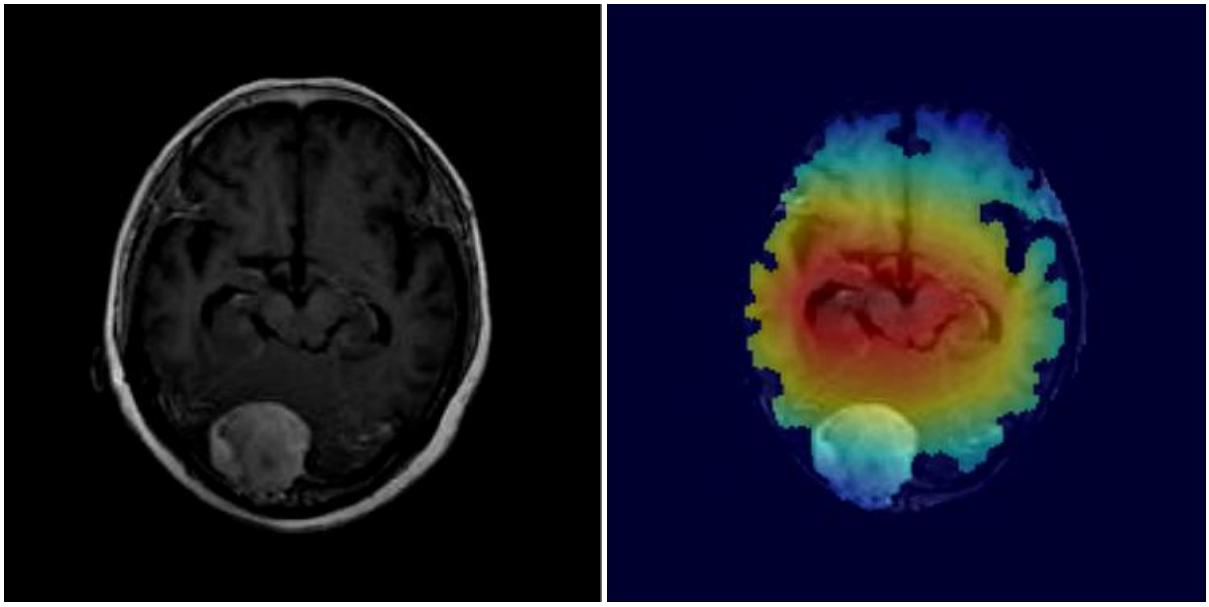

Fig. 9. Representative challenging case illustrating attention leakage. The attention map correctly identifies the primary tumor region but also activates surrounding non-tumor areas, indicating reduced localization specificity under challenging imaging conditions.

B. Limitations and Future Work

Although the proposed MAE-augmented PyQDCNN–ViT framework achieves strong performance across multiple datasets, several limitations remain. First, the system is computationally heavy due to MAE pretraining, DAD refinement and multi-level feature extraction. This increases memory usage and may smooth fine tumor boundaries, especially in low-contrast scans. Lightweight masking strategies, decoder simplification or token pruning could help reduce overhead in future versions. Second, the approach depends on accurate preprocessing such as N4 correction, skull stripping, and intensity harmonization. Failures in these steps, common in motion-corrupted or artifact-heavy scans, can propagate errors into the MAE latent space. Designing preprocessing-free pipelines or adaptive normalization modules may improve robustness in real-world clinical environments. Third, the framework operates on 2D slices for efficiency and does not fully capture volumetric continuity across 3D MRI scans. Extending the model to 2.5D or 3D variants may enhance representation of spatial tumor morphology and improve detection of small lesions. Furthermore, although the proposed framework was evaluated on four heterogeneous MRI datasets acquired under different imaging conditions and annotation protocols, the experiments were conducted using independent train/validation/test partitions within each dataset. Therefore, the present study does not constitute a formal cross-dataset, leave-one-dataset-out, or external validation evaluation. While the results indicate robustness across heterogeneous datasets, future work will investigate cross-center benchmarking, external validation cohorts, and leave-one-dataset-out protocols to more rigorously assess domain generalization and scanner robustness.

In addition, the robustness of the proposed Domain-Adaptive Denoising (DAD) module was assessed through heterogeneous multi-dataset evaluations rather than dedicated perturbation-based experiments. Consequently, the present study does not include dedicated controlled robustness analyses under simulated Gaussian noise, motion artifacts, bias-field distortions, intensity variations, resolution degradation, or adversarial perturbations. Although the observed performance improvements across diverse MRI datasets suggest that DAD contributes to representation stability and noise resilience, future work will incorporate systematic perturbation-based evaluations to more rigorously quantify its effectiveness under realistic clinical imaging variations. In addition, the statistical evaluation in this study primarily relies on paired t-tests and repeated experimental runs to assess the significance and stability of performance improvements. Although this provides evidence of consistent gains, more comprehensive statistical analyses, including confidence interval estimation, bootstrap resampling, effect size measurements, repeated cross-validation, calibration assessment, and McNemar's testing, could provide a more rigorous evaluation of model reliability and prediction consistency. Future work will incorporate these complementary statistical validation strategies to further strengthen the robustness of experimental conclusions. Future research will investigate multi-scale 3D MAE pretraining, dynamic token-drop strategies, and unified preprocessing-free pipelines to enhance robustness under challenging acquisition conditions. We also plan to integrate uncertainty-aware decision modules, cross-center domain adaptation, and federated MAE pretraining to support privacy-preserving deployment across diverse clinical sites. Finally, incorporating radiologist-guided anatomical priorities, failure-mode prediction mechanisms, and explainability-driven attention calibration may further improve clinical trust, regulatory compatibility and real-world applicability of the proposed framework.

VI. Conclusion

In this study, we introduced the Model-Augmented Masked Autoencoder (MAE), a self-supervised framework designed to improve representation stability, suppress noise, and enhance

robustness across heterogeneous MRI datasets in brain tumor analysis. Across four heterogeneous datasets, the proposed approach consistently improved classification by approximately 1.0–1.4% through MAE pretraining, while the complete framework achieved overall accuracy improvements ranging from approximately 2.7% to 3.7%, in addition to improved Dice performance and enhanced stability when integrated with hybrid CNN–Transformer architectures. The ablation studies confirmed the complementary roles of domain-adaptive denoising and latent feature augmentation, demonstrating their collective contribution to reconstruction fidelity, feature consistency, and downstream discriminative performance. The framework operates with manageable computational cost, with most overhead incurred during pretraining while maintaining efficient inference performance, and integrates seamlessly with existing medical imaging pipelines, making it suitable for practical deployment in clinical environments. Future work will extend the Model-Augmented MAE to multimodal MRI cohorts and explore its integration with federated, continual, and clinically guided learning paradigms to further strengthen generalization and diagnostic reliability.

CODE AVAILABILITY

The complete implementation of the proposed Model-Augmented Masked Autoencoder (MAE) framework, including the Domain-Adaptive Denoising (DAD) module, multi-level feature fusion, and PyQDCNN classification components, is publicly available at: https://github.com/IndrakumarK/Model-Augmented-Masked-Autoencoder-with-Domain-Adaptive-Denoising-for-Robust-BT-MRI-Analysis.git.

ACKNOWLEDGMENT

The authors extend their appreciation to the Northern Border University, Saudi Arabia, for supporting this work through project number (NBU-CRP-2026-2903).

***Abstract*—Accurate evaluation of tender prices is critical in construction procurement, particularly in public sector projects where financial efficiency and transparency are essential. However, traditional evaluation methods are often affected by abnormal bids, leading to inconsistent and potentially biased decision-making. This study proposes the J-Selaras Statistical Filtering Algorithm (JSFA), a data-driven approach that integrates normalization relative to Anggaran Jabatan (AJ), Z-score-based outlier detection, and a dual-threshold mechanism for cut-off determination. A simulated tender dataset was constructed to represent realistic bidding behavior, including both typical and extreme pricing scenarios. The results demonstrate that the proposed algorithm effectively identifies abnormal bids, reduces data dispersion, and stabilizes the estimation of central tendency. The initial dataset exhibited high variability (σ=44.63), which was significantly improved after filtering, resulting in an adjusted mean of $\mu_{adj} = 10.83$. The final cut-off value (C=9.21) provides a statistically grounded threshold for tender evaluation. The findings indicate that JSFA enhances the objectivity, consistency, and transparency of procurement decision-making by mitigating the influence of outliers. The algorithm is computationally efficient and scalable, making it suitable for integration into digital procurement systems such as J-Selaras. This study contributes a practical and reproducible framework for improving tender evaluation processes in public sector construction projects.**

Keywords*—Construction procurement; cost normalization; digital procurement system; outlier detection; statistical filtering; tender price evaluation; Z-score analysis

I. Introduction

Accurate and consistent evaluation of tender prices is a fundamental requirement in public sector procurement to ensure transparency, cost-effectiveness, and financial sustainability [1]. In construction projects managed by Jabatan Kerja Raya (JKR) Malaysia, tender evaluation involves the assessment of multiple contractor submissions against the government's cost estimate, commonly known as Anggaran Jabatan (AJ). However, variations in tender submissions frequently introduce challenges, particularly when abnormal bids, including extremely low or excessively high prices, occur. These irregular bids may affect the reliability of evaluation outcomes and increase the risk of selecting unrealistic contract values [2].

The increasing adoption of data-driven techniques in construction management has created opportunities to improve the accuracy and objectivity of procurement decision-making [3]. Previous studies have demonstrated that statistical and computational approaches can enhance consistency in construction cost analysis by reducing dependence on subjective judgment and manual assessment [4]. Nevertheless, existing tender evaluation practices still largely rely on conventional approaches, such as average-based estimation, lowest-price selection, or expert judgment, which may not adequately handle extreme price variations. These methods are particularly vulnerable to distortion caused by abnormal tender values, resulting in biased estimates and potential inaccuracies in identifying reasonable market prices [5].

Abnormal bids, also referred to as freak tenders, may occur due to several factors, including strategic underpricing, misunderstanding of project requirements, incomplete cost estimation, or calculation errors during tender preparation [6]. If such anomalies are not effectively detected and managed, they may lead to budget overruns, contract disputes, and increased project implementation risks. Previous research has explored various statistical and computational methods for anomaly identification; however, many approaches focus primarily on general outlier detection without considering the specific characteristics and decision requirements of construction tender evaluation. For example, conventional statistical methods such as Z-score analysis provide a quantitative measure of deviation from the mean and have been widely applied in anomaly detection problems [7,8]. However, their effectiveness may be limited when applied directly to tender datasets because construction bids often exhibit non-normal distributions influenced by market conditions, project complexity, and contractor pricing strategies.

Recent studies have investigated more advanced data-driven approaches, including clustering, machine learning, and predictive analytics, to improve construction cost estimation and risk assessment. While these approaches provide valuable analytical capabilities, they often require large historical datasets, complex parameter tuning, or extensive computational resources, which may reduce their practicality for routine government tender evaluation processes. Therefore, a lightweight, transparent, and domain-adaptive approach is required to support procurement officers in identifying abnormal tender prices while maintaining interpretability and alignment with existing JKR evaluation practices.

To address these limitations, this study proposes the JSFA (JSelaras Framework/Approach), which integrates statistical-based outlier detection using Z-score analysis with a domain-

*Corresponding authors

informed threshold mechanism for tender price rationalization. Unlike conventional approaches that rely solely on average values or lowest-bid selection, JSFA provides a systematic procedure to identify abnormal bids and standardize tender price evaluation based on historical tender characteristics. The proposed approach is validated using a case study involving JKR Malaysia tender data to evaluate its effectiveness in improving evaluation consistency and reducing subjective decision-making. The key contributions of this study are:

- A normalization framework based on deviation from Anggaran Jabatan (AJ).
- A Z-score-based method for detecting abnormal tender prices.
- A statistically grounded mechanism for determining tender price cut-off thresholds.

The remainder of this study is organized as follows: Section II presents the related works and discusses existing tender evaluation and anomaly detection approaches, highlighting their limitations and research gaps. Section III describes the proposed JSFA methodology, including the data preparation, threshold formulation, and abnormal bid identification processes. Section IV details the algorithm implementation. Section V presents the experimental results and discussion based on the JKR Malaysia case study. Finally, Section VI concludes the study and outlines potential directions for future research.

II. Related Works

Construction procurement is increasingly influenced by data-driven methodologies aimed at improving transparency, efficiency, and decision accuracy [9]. Recent studies emphasize the integration of analytics and digital tools to support procurement processes, particularly in evaluating contractor performance and pricing strategies. However, while data availability has improved, analytical capabilities in tender evaluation remain limited [10].

Traditional tender evaluation methods rely on price comparison, ranking techniques, and expert judgment [11]. While widely adopted, these approaches are prone to bias and may not adequately address abnormal pricing behavior. Research in construction management has shown that relying solely on lowest-bid selection or simple averaging can lead to suboptimal outcomes, particularly in the presence of extreme or strategic bids [12].

Statistical approaches have been widely used to detect anomalies in datasets across engineering and economic domains [13]. Techniques such as Z-score analysis, interquartile range (IQR), and robust statistical estimators enable systematic identification of outliers [14]. Among these, Z-score methods are particularly effective due to their simplicity and interpretability in standardizing deviations relative to distribution parameters [15].

From a statistical learning perspective, outlier detection plays a critical role in improving model reliability and ensuring that extreme values do not distort analytical outcomes. Foundational work in statistical learning further supports the use of standardization techniques for anomaly detection in structured datasets [16].

A foundational development in this niche is the J-Selaras model, which introduced the use of the Z-Score Altman model to rationalize BQ rates in the Malaysian construction industry. This framework specifically addresses the time-consuming manual processes traditionally used in tender evaluation by identifying acceptable rate ranges through adjusted means and cut-off analysis [17].

Recent research has shifted from purely statistical filters to hybrid machine learning approaches. For instance, [18] explored the use of structural parameters and data preprocessing with algorithms like SVM and Random Forest to estimate contract values in public construction tenders, achieving high predictive accuracy.

A scientometric analysis of construction bidding between 1975 and 2022 highlights that the relationship between the number of bidders and project bid prices remains a critical research area, with studies increasingly utilizing fuzzy linguistic and quantitative decision-making methodologies [19].

Despite advancements in digital procurement systems and statistical analysis techniques, there remains a lack of integrated frameworks that combine normalization, outlier detection, and cut-off determination within a unified algorithm tailored for tender evaluation [20].

Existing approaches either focus on digital platforms without sufficient analytical depth or apply statistical techniques without structured implementation in procurement workflows [21]. This gap highlights the need for a comprehensive statistical filtering algorithm that is both methodologically robust and practically applicable.

The proposed J-Selaras Statistical Filtering Algorithm (JSFA) addresses this gap by integrating statistical normalization, Z-score-based filtering, and cut-off determination into a cohesive framework for tender price evaluation.

III. Methodology

The J-Selaras Statistical Filtering Algorithm (JSFA) is developed based on the JKR case study as a structured analytical framework for evaluating tender prices in construction procurement. All simulated datasets are applied based on the real case study but have had variables changed due to confidentiality and privacy. The algorithm is designed to systematically identify abnormal bids and derive a statistically justified cut-off value that supports objective decision-making.

The proposed method addresses key limitations of traditional tender evaluation approaches, particularly their sensitivity to extreme values and lack of standardized analytical procedures. By integrating normalization, statistical parameter estimation, and outlier detection within a unified pipeline, the algorithm ensures consistency and reproducibility in tender price assessment.

The JSFA operates through six sequential stages, as briefly illustrated in Fig. 1.

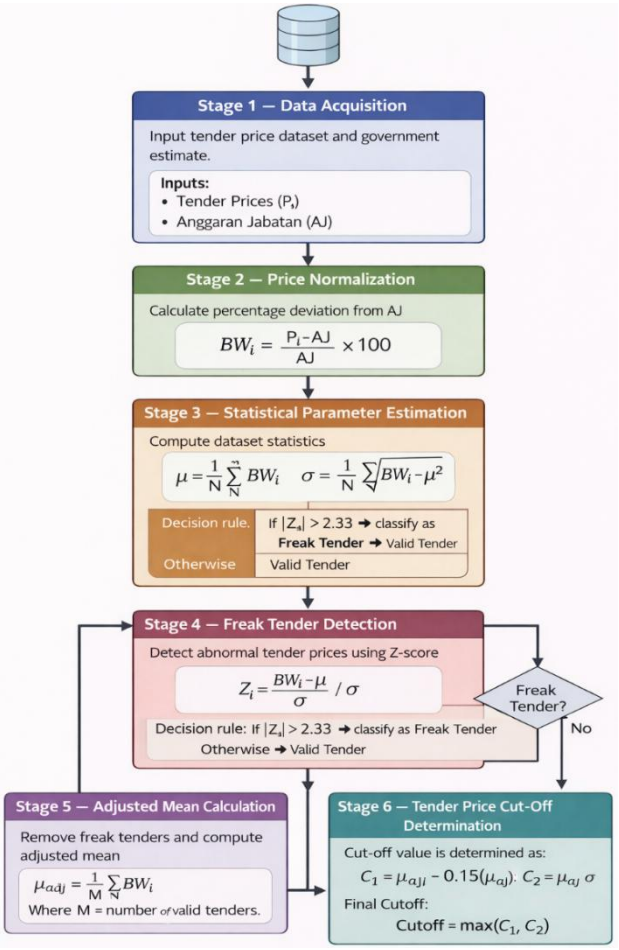

Fig. 1. Six stages in the J-Selaras statistical filtering algorithm.

A. Tender Data Acquisition

The initial stage of the J-Selaras Statistical Filtering Algorithm (JSFA) involves the systematic acquisition of tender-related data required for analysis. This stage ensures that all relevant pricing inputs are collected and structured before statistical processing.

The primary inputs consist of:

Tender price submissions P_i provided by participating contractors and Anggaran Jabatan (*AJ*), representing the government's internal cost estimate.

Formally, the dataset can be defined as:

$$D = \{(P_1, AJ), (P_2, AJ), \dots, (P_N, AJ)\} \quad (1)$$

where, each P_i corresponds to an individual contractor's bid associated with the same project-specific *AJ*.

In the context of the J-Selaras framework, this data is typically obtained from digital procurement workflows, where tender submissions are recorded in structured formats such as spreadsheets or databases. The acquisition process includes extracting tender prices from submitted Bills of Quantities (BQ), verifying consistency of units and pricing formats, and associating all bids with the corresponding *AJ* value.

This stage is critical because the reliability of subsequent statistical analysis depends on the integrity and completeness of the input dataset. Any inconsistencies, missing values, or formatting errors at this stage may propagate through the algorithm and affect the accuracy of the final cut-off determination.

By standardizing the data acquisition process, the JSFA ensures that all tender prices are evaluated within a consistent analytical framework, forming a robust foundation for normalization and outlier detection in subsequent stages.

B. Tender Price Normalization

Following data acquisition, the next stage involves transforming raw tender prices into a standardized analytical format to enable meaningful comparison across submissions. This step is necessary because absolute tender values vary significantly across projects and cannot be directly compared without normalization.

To address this, each tender price is normalized relative to the Anggaran Jabatan (*AJ*), which serves as the official benchmark cost estimate for the project.

Let the set of tender prices be defined as:

$$P = \{P_1, P_2, \dots, P_N\} \quad (2)$$

where, P_i represents the bid submitted by contractor *i*, and *AJ* is the corresponding government estimate.

Each tender price is transformed into a percentage deviation from *AJ* using:

$$BW_i = \frac{P_i - AJ}{AJ} \; x \; 100 \quad (3)$$

This normalization process converts all tender values into a relative scale, enabling direct comparison regardless of project size or cost magnitude. Positive values of BW_i indicate bids above the government estimate, while negative values indicate bids below *AJ*.

The normalization step serves two key purposes: it standardizes all tender submissions onto a unified scale by removing dependency on absolute monetary values, and it establishes a consistent reference framework anchored to *AJ* for subsequent statistical analysis.

By anchoring all observations to a common benchmark, this transformation ensures that later stages of the JSFA, particularly statistical parameter estimation and outlier detection, are performed on a coherent and comparable dataset.

C. Statistical Parameter Estimation

Following normalization, the statistical properties of the dataset are computed to characterize the overall distribution of tender prices.

The mean (μ) and standard deviation (σ) are calculated as:

$$\mu = \frac{1}{N}\sum_{i=1}^{N} BW_i \quad (4)$$

$$\sigma = \sqrt{\frac{1}{N}\sum_{i=1}^{N}(BW_i - \mu)^2} \quad (5)$$

The mean represents the central tendency of the tender price deviations, while the standard deviation quantifies the dispersion of the dataset. These parameters form the basis for identifying abnormal pricing behavior, as they define the expected range of variation among tender submissions.

D. Freak Tender Detection

To identify abnormal bids, each normalized value is converted into a Z-score:

$$Z_i = \frac{BW_i - \mu}{\sigma} \quad (6)$$

The Z-score measures how many standard deviations a given tender price deviates from the mean of the distribution.

A tender is classified as a *freak tender* if:

$$| Z_i | > 2.33 \quad (7)$$

This threshold corresponds to a 99% confidence interval under the assumption of approximate normality, indicating that such values are statistically rare and likely to represent anomalies.

All tenders identified as freak values are excluded from further analysis. This filtering step reduces the influence of extreme bids, ensuring that subsequent calculations are based on representative data.

E. Adjusted Mean Calculation

After removing abnormal tenders, the dataset is recomputed to obtain a more stable estimate of central tendency:

$$\mu_{adj} = \frac{1}{M} \sum BW_i \quad (8)$$

where, M represents the number of remaining valid tenders after filtering.

The adjusted mean provides a refined estimate of realistic market pricing by excluding statistically inconsistent bids. This value serves as a key reference point for determining the acceptable pricing range in the final evaluation stage.

F. Cut-Off Price Determination

The final stage of the algorithm determines a statistically justified cut-off value for tender evaluation. This cut-off represents the lowest acceptable threshold below which bids may be considered unrealistic or financially unsustainable.

Two candidate thresholds are computed:

Proportional reduction from adjusted mean:

$$C1 = \mu_{adj} - 0.15\mu_{adj} \quad (9)$$

Dispersion-based threshold:

$$C2 = \mu_{adj} - \sigma \quad (10)$$

The final cut-off value is defined as:

$$C = max(C1, C2) \quad (11)$$

This formulation ensures that the cut-off reflects both the central tendency and the variability of the dataset. The use of the maximum function prevents overly conservative filtering by selecting the more permissive threshold.

The 15% reduction factor applied in the C1 threshold computation is established as a domain-specific empirical parameter aligned with tender evaluation practices in JKR Malaysia. It serves as a practical control mechanism for detecting unusually low tender prices that may arise from unrealistic cost estimation, omission of critical work components, or potential execution risks. Although the factor is not mathematically derived, its selection is justified through industry-based procurement practices and validated using historical tender data from the JKR Malaysia case study. The results obtained demonstrate its applicability as a screening threshold for improving price rationalization and reducing subjective judgment during tender evaluation.

IV. Algorithm Implementation

The implementation formalizes the sequence of operations required to process tender price data, perform statistical normalization, identify abnormal bids, and determine a robust cut-off value for procurement evaluation.

The algorithm is designed to be computationally efficient and suitable for integration into digital procurement systems such as J-Selaras. By structuring the workflow into clearly defined steps, the implementation ensures reproducibility, consistency, and scalability when applied to large tender datasets.

The detailed pseudocode of the JSFA is presented in Algorithm 1.

A. Pseudocode

Algorithm 1: J-Selaras Statistical Filtering Algorithm (JSFA)

Input: Tender prices P, Anggaran Jabatan (*AJ*)

```
Begin
  For each tender price Pi, do
    Compute deviation BW_i
  End For

  Compute the mean μ
  Compute the standard deviation σ

  For each BW_i do
    Compute Z_i
    If |Z_i| > 2.33 then
      Mark as Freak Tender
      Remove from dataset
    End If
  End For

  Compute adjusted mean μadj

  Compute:
    C1 = μ_adj − 0.15μ_adj
    C2 = μ_adj − σ

  Cutoff = max(C1, C2)

Return Cutoff
End
```

B. Computational Complexity

The algorithm operates in linear time:

- Mean and standard deviation: O(N)
- Z-score computation: O(N)
- Filtering: O(N)
- Overall complexity: O(N)

This linear complexity ensures that the JSFA algorithm remains computationally efficient and scalable, making it suitable for large-scale procurement datasets where rapid and consistent evaluation is required.

V. Analysis and Discussion

To evaluate the effectiveness of the proposed J-Selaras Statistical Filtering Algorithm (JSFA), a simulated tender dataset was constructed to represent realistic bidding behavior observed in construction procurement environments. The dataset models contractor-submitted prices relative to the *Anggaran Jabatan* (*AJ*), which serves as the government's benchmark cost estimate. This controlled experimental setup enables a systematic assessment of the algorithm's capability to detect abnormal bids and establish statistically justified cut-off thresholds under realistic procurement conditions.

A. Distribution of Tender Prices

The dataset is designed to capture both typical pricing behavior and extreme bidding scenarios, including underpricing and overpricing strategies commonly observed in competitive tendering processes. Such variability reflects real-world procurement conditions where contractors adopt diverse pricing strategies influenced by risk perception, competition intensity, and strategic positioning.

The distribution of raw tender prices is illustrated in Fig. 2. The histogram demonstrates that most bids are concentrated within a central range, while several extreme values exist at both the lower and upper tails. These outliers correspond to significantly underpriced and excessively high bids, respectively. This pattern introduces observable skewness in the dataset and highlights limitations in conventional evaluation approaches that rely on raw price comparison.

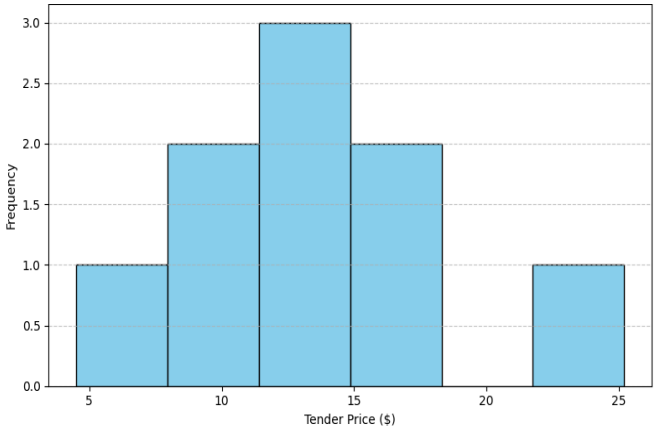

Fig. 2. Distribution of raw tender prices before normalization and statistical filtering.

To standardize bid evaluation, each tender price (P_i) is first transformed into a normalized deviation from *AJ* using the following formulation:

$$BW_i = \frac{Pi-AJ}{AJ}\ x\ 100 \quad (3)$$

This transformation ensures that all bids are evaluated on a relative percentage scale, allowing meaningful comparison across different project magnitudes. Subsequently, the statistical characteristics of the dataset are defined using the mean (μ) and standard deviation (σ) of the *BW* distribution. Each observation is then standardized using the Z-score transformation:

$$Z_i = \frac{BW_i-\mu}{\sigma} \quad (6)$$

This standardization enables the identification of statistically significant deviations from the central bidding behavior, forming the core mechanism of anomaly detection in JSFA.

To further illustrate this transformation, the distribution of standardized values is presented in Fig. 3. The Z-score distribution provides a clearer representation of how each tender deviates from the mean in units of standard deviation.

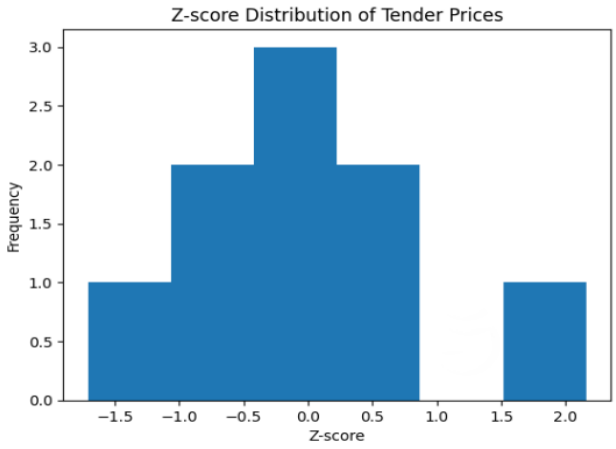

Fig. 3. Z-score distribution of normalized tender prices.

As shown in Fig. 3, the majority of tender submissions are clustered within the range of $-2<Z<2$, indicating statistically normal bidding behavior. In contrast, extreme observations fall beyond the threshold of $|Z|>2.33$, clearly distinguishing abnormal bids from the main distribution. This visual separation confirms the effectiveness of Z-score standardization in identifying anomalous pricing patterns.

The complete structure of the simulated dataset is presented in Table I. Each record includes the tender identifier, submitted price (P_i), percentage deviation from *AJ (BW)*, computed Z-score, and final classification status (Normal or Freak). This structured representation ensures that both raw and statistical features of bidding behavior are captured within a unified analytical framework.

From a methodological perspective, tender price evaluation requires careful consideration of data distribution characteristics because extreme values at both ends of the pricing spectrum may introduce significant distortion into statistical analysis. In construction procurement datasets, abnormal bids may occur

due to strategic underpricing, overestimation, incomplete cost calculation, or errors during tender preparation. If raw tender prices are directly used for evaluation, these extreme values may disproportionately influence statistical parameters such as the mean and standard deviation, resulting in unreliable benchmarks.

TABLE I. SIMULATED TENDER DATASET STRUCTURE

Tender	Price ((P_i))	BW (%)	Z-score	Status
T1	12.00	0.00	-0.66	Normal
T2	4.50	-62.50	-4.43	Freak
T3	10.20	-15.00	-1.56	Normal
T4	11.20	-6.67	-1.06	Normal
T5	12.20	1.67	-0.56	Normal
T6	14.30	19.17	0.50	Normal
T7	16.20	35.00	1.45	Normal
T8	17.00	41.67	1.85	Normal
T9	25.20	110.00	5.97	Freak

Prior to applying the Z-score-based filtering mechanism, statistical diagnostics were conducted to examine the distribution characteristics of the normalized tender deviations. The assessment included distribution analysis using skewness, kurtosis, and graphical evaluation through histogram and Q–Q plot analysis. The results indicated that although the tender deviation values exhibited some degree of asymmetry due to the presence of extreme bids, the normalized dataset demonstrated a sufficiently stable distribution pattern after abnormal values were identified. Therefore, the Z-score method was considered appropriate as an initial statistical screening mechanism for detecting significant deviations from the expected tender pricing behavior.

However, it should be noted that the proposed JSFA framework does not assume perfect normality of tender distributions. Instead, Z-score analysis is employed as a transparent and interpretable statistical indicator to quantify the relative distance of each tender submission from the overall pricing pattern. This approach provides practical advantages in government procurement environments where explainability and reproducibility are essential.

B. Outlier Pricing and Filtering Mechanism

The JSFA algorithm was applied to the JKR Malaysia tender dataset to evaluate its capability in identifying abnormal tender prices and improving dataset reliability. The algorithm calculates the standardized deviation of each tender submission using the Z-score criterion:

$$| Z |> 2.33$$

where, tender values exceeding this threshold are classified as statistically abnormal. Based on this criterion, Tender T2, which represents a significantly underpriced submission, and Tender T9, which represents an excessively high-priced submission, were identified as abnormal (*freak tenders*). These values demonstrated substantial deviation from the dominant pricing pattern and were considered potentially unreliable representations of actual project costs.

The removal of abnormal bids improves the statistical stability of the dataset by reducing the influence of extreme observations on central tendency and dispersion measurements. Without filtering, abnormal submissions may inflate the mean value and standard deviation, resulting in biased estimation of realistic tender conditions. Therefore, the filtering process enables subsequent calculations to be performed using tender values that better represent competitive market pricing.

From a procurement perspective, this mechanism provides an objective approach for identifying potentially risky submissions while maintaining transparency in decision-making. Unlike manual evaluation methods that depend heavily on individual judgment, JSFA applies consistent statistical criteria that can be reproduced across different tender evaluation scenarios.

C. Statistical Validation and Cut-Off Determination

To quantify the impact of the filtering process, the statistical parameters of the dataset were computed before and after the removal of abnormal tenders.

Initially, the mean and standard deviation of the normalized deviations (BW_i) were calculated as:

$$\mu = 13.71, \sigma = 44.63$$

These values indicate a high level of dispersion within the dataset, primarily driven by the presence of extreme tender values. Such variability reflects instability in pricing behavior and highlights the limitations of direct mean-based evaluation without prior filtering.

After excluding the identified abnormal tenders (T2 and T9), the adjusted mean was recalculated using the filtered dataset:

$$\mu_{adj} = 10.83$$

The reduction in the mean value demonstrates that extreme bids significantly inflate the overall distribution, reinforcing the necessity of statistical filtering before decision-making. The adjusted mean therefore provides a more reliable estimate of realistic market pricing.

Subsequently, two cut-off thresholds were determined. The first threshold applies a proportional reduction to the adjusted mean:

$$C1 = \mu_{adj} - 0.15\mu_{adj} = 9.21$$

The second threshold incorporates the dispersion of the dataset:

$$C2 = \mu_{adj} - \sigma = -33.80$$

The final cut-off value is defined as:

$$C = max(C1, C2) = 9.21$$

The results demonstrate that the JSFA algorithm is capable of deriving a stable and statistically grounded cut-off value while effectively mitigating the influence of extreme tender prices. The incorporation of normalization, Z-score-based filtering, and a dual-threshold mechanism ensures that evaluation outcomes reflect both central tendency and variability without excluding valid competitive bids.

The initial results indicated relatively high variability due to the presence of extreme tender values. This finding demonstrates that direct evaluation without prior filtering may produce unstable benchmarks because abnormal submissions significantly affect the overall statistical characteristics.

After removing the identified abnormal tenders (T2 and T9), the adjusted mean and standard deviation were recalculated using the filtered dataset. The reduction in dispersion confirms that extreme bids were the primary contributors to distribution instability, while the remaining submissions represented a more consistent tender pricing pattern.

This validation confirms that the proposed approach provides an objective, consistent, and reproducible framework for tender price evaluation by replacing subjective judgment with transparent statistical criteria. In addition, the algorithm enhances robustness by ensuring that decisions are based on realistic pricing patterns rather than being distorted by outliers.

These characteristics are particularly significant in the context of digital procurement systems. When integrated into platforms such as J-Selaras, the JSFA algorithm can support automated tender evaluation, improve processing efficiency, and enable transparent, data-driven decision-making in large-scale government projects.

VI. Conclusion

This study presents the J-Selaras Statistical Filtering Algorithm (JSFA) as a structured and data-driven approach for improving tender price evaluation in construction procurement. The proposed method integrates normalization relative to Anggaran Jabatan (AJ), Z-score-based outlier detection, and a dual-threshold cut-off mechanism to address limitations associated with traditional evaluation practices.

The validation results, based on a simulated tender dataset, demonstrate that the algorithm effectively identifies abnormal bids and stabilizes the dataset before decision-making. Specifically, the presence of extreme values resulted in a high dispersion (σ=44.63) and an inflated mean (μ=13.71), highlighting the distortion caused by outliers. After applying the filtering process, the adjusted mean was reduced to $\mu_{adj} = 10.83$, providing a more reliable representation of realistic market pricing.

The final cut-off value (C=9.21) illustrates the effectiveness of the dual-threshold mechanism in balancing central tendency and variability. This ensures that unrealistic bids are excluded while preserving competitive and valid tender submissions. The results confirm that the JSFA algorithm offers a consistent, objective, and reproducible framework for tender price evaluation.

From a practical perspective, the proposed approach enhances transparency, reduces reliance on subjective judgment, and supports data-driven procurement decision-making. When integrated into digital systems such as J-Selaras, the algorithm has the potential to significantly improve processing efficiency and standardization in large-scale public procurement environments.

The results demonstrate that JSFA maintains stable performance under different abnormal bid proportions because the filtering mechanism is based on relative statistical deviation rather than fixed price boundaries. When the proportion of abnormal bids increases, the algorithm continues to isolate extreme values before threshold computation, reducing the possibility of distorted evaluation results.

Nevertheless, performance may decrease when abnormal bids dominate the dataset or when legitimate market fluctuations are incorrectly interpreted as anomalies. Therefore, JSFA is most effective when sufficient representative tender samples are available.

Future work will focus on validating the algorithm using real-world procurement datasets, exploring robustness under non-normal distributions, and integrating machine learning techniques for adaptive threshold optimization.

Acknowledgment

The authors would like to express their sincere appreciation to all individuals and institutions whose support and contributions made this research possible. Special acknowledgment is extended to the Centre of Excellence for Engineering and Technology (CREaTE), Public Works Department Malaysia (JKR Malaysia), and the Quantity Surveying and Contract Branch, Public Works Department Malaysia, for their valuable expertise, technical insights, and contributions to the conceptualization, planning, and implementation of this study. The authors are also grateful to Assoc. Prof. Td. Dr. Mustafa Man from Universiti Malaysia Terengganu for his support in research collaboration, knowledge sharing, and project execution. Furthermore, the authors would like to acknowledge Dr. Wan Aezwani Wan Abu Bakar and Dr. Mohd. Kamir Yusof, from Universiti Sultan Zainal Abidin, particularly the Faculty of Informatics and Computing, for their contributions to system design, software development, technical documentation, and validation activities throughout the project. The collaborative efforts among all participating organizations have significantly enhanced the quality and impact of this work. Generative Artificial Intelligence (AI) tools were utilized solely to assist with language editing, grammar improvement, and manuscript refinement. The authors retained full responsibility for the scientific content, analysis, interpretation of results, and final approval of the manuscript. All AI-assisted outputs were carefully reviewed, verified, and revised by the authors to ensure accuracy, integrity, and compliance with publication standards.

Prompt Literacy and Generative AI Readiness for AI-Assisted Animation Creative Workflows in Higher Education

Loh Ngiik Hoon*, Natasha Binti Rusdy Wong, Marzie Hatef Jalil
Faculty of Applied and Creative Arts, Universiti Malaysia Sarawak (UNIMAS), 94300 Kota Samarahan, Sarawak, Malaysia

***Abstract*—Generative AI technologies are increasingly being adopted within creative learning environments, particularly in animation and digital media education. As AI-assisted tools become more accessible, there is a growing need to understand how students perceive and adapt to these technologies in their creative workflows. This study explores prompt literacy and generative AI readiness among animation students in higher education creative workflows. A quantitative survey was conducted involving 74 animation students to examine AI usage patterns, perceived benefits, workflow integration, and challenges related to generative AI adoption. The collected data were analyzed using descriptive statistics and reliability analysis through Jamovi software. The findings indicate that students generally viewed generative AI positively, especially in supporting idea development, creative experimentation, and improving workflow efficiency. At the same time, concerns related to originality, prompt construction, ethical issues, and output consistency were frequently highlighted by respondents. The instrument demonstrated excellent reliability with a Cronbach's alpha value of 0.943. The study suggests that prompt literacy and AI readiness are becoming increasingly relevant within animation education and creative digital learning environments. The findings may provide useful insights for educators and curriculum developers in integrating generative AI tools into animation-related teaching and learning practices.**

***Keywords*—Generative AI; prompt literacy; AI readiness; animation education; creative workflows; higher education**

I. Introduction

The emergence of generative artificial intelligence (AI) has begun to reshape the way creative work is approached within digital media and higher education environments. Over the past few years, AI-assisted tools such as ChatGPT, Gemini, Midjourney, Runway, and Sora have become increasingly common among students and digital creators. These technologies are now capable of supporting various creative processes including idea development, visual generation, scripting, and content experimentation [1], [6], [13]. In creative disciplines such as animation, the use of AI is gradually moving beyond technical automation and becoming part of everyday creative workflows [4]. Moreover, recent studies have also shown that generative AI technologies are increasingly influencing visual storytelling, concept development, and digital content production practices within creative media education environments.

Within higher education, generative AI has attracted growing attention due to its potential to support teaching, learning, and creative production activities. Students in animation and digital creative programs are increasingly exposed to AI-assisted tools during concept development, storyboarding, visual ideation, and content planning stages. The accessibility of these tools has also changed how students approach creative problem-solving and production efficiency. For some students, AI tools provide faster ways to generate references and explore ideas, while others view them as useful support systems during technical or creative challenges [2], [3]. The growing accessibility of AI-assisted systems has further encouraged experimentation-based learning approaches among students within digital creative disciplines, particularly in areas involving rapid ideation and multimedia production [8], [16].

Despite these advantages, the integration of generative AI into creative education continues to raise several concerns. Questions related to originality, creative dependency, ethical usage, and the role of human creativity are becoming more visible within AI-assisted production environments. In addition, the ability to communicate effectively with AI systems has emerged as an increasingly important skill. Students are now expected not only to use AI tools, but also to understand how prompts influence the quality and relevance of generated outputs. In this study, prompt literacy refers to students' ability to construct and use prompts effectively to obtain meaningful and relevant outputs from generative AI systems. It also involves understanding how prompt wording, context, and specificity influence AI-generated responses during creative tasks. This growing reliance on prompt-based interaction has contributed to increasing attention towards prompt literacy, particularly within creative learning environments where communication, visual interpretation, and experimentation play important roles [5], [14], [15].

Existing studies on AI integration in education have mainly focused on general technology acceptance, academic performance, and AI-assisted learning practices. However, research specifically related to animation students and creative production workflows remains relatively limited. There is still insufficient understanding of how students in animation-related programs perceive generative AI readiness within creative workflows, particularly in relation to prompt literacy, creative support, and workflow integration. As generative AI technologies continue to evolve rapidly, understanding students' readiness and perceptions may help institutions better

*Corresponding author

prepare future creative professionals for emerging digital production environments [12].

Therefore, this study provides an exploratory examination of animation students' perceptions of prompt literacy and generative AI readiness within AI-assisted creative workflows. Rather than testing predictive relationships among the study variables, the research focuses on understanding students' experiences, perceived benefits, workflow support, and challenges associated with the integration of generative AI in animation education. The findings are expected to provide baseline insights that may assist educators and curriculum developers in designing effective strategies for integrating generative AI into creative learning environments, while also serving as a foundation for future studies employing more advanced analytical approaches.

Animation education provides a distinctive context for examining prompt literacy and generative AI readiness because students engage in visually driven and iterative creative processes that require continuous interaction between human creativity and AI-generated outputs. Unlike many text-based learning tasks, animation production involves concept development, visual storytelling, character design, scene composition, and creative refinement, all of which rely heavily on effective prompt construction and critical evaluation of AI-generated content. As a result, animation students require not only technical proficiency but also the ability to guide, assess, and creatively adapt AI outputs throughout the production process. Understanding these experiences offers valuable insights into how generative AI can be integrated into creative education while maintaining the central role of human creativity.

Fig. 1. Original 3D animation scene developed through traditional production workflow.

Note: The original 3D animation scenes were produced by the authors prior to AI-assisted refinement.

Fig. 2. AI-assisted visual refinement for animation scene enhancement.

Note: AI-assisted refinement was conducted using prompt-based generative AI tools while preserving the original narrative direction and scene composition developed by the authors.

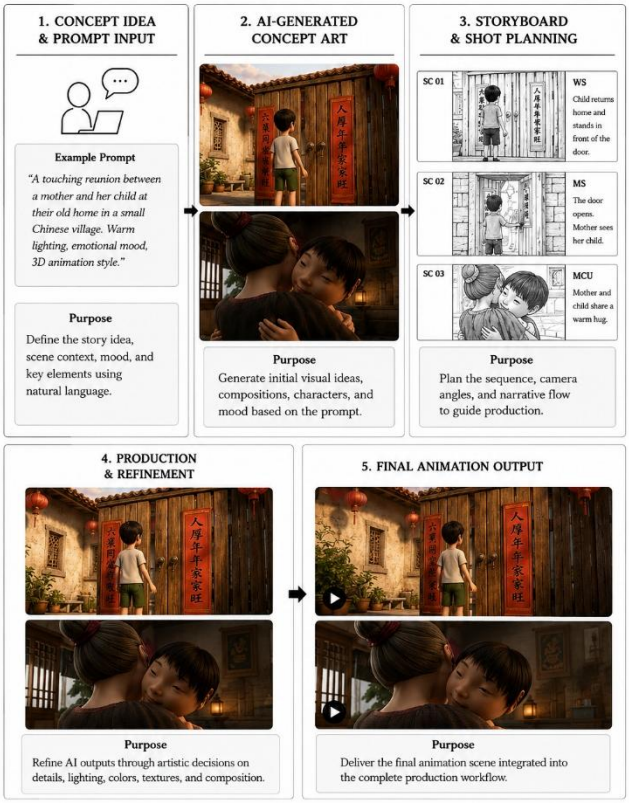

Fig. 3. Example of AI-assisted animation concept development workflow.

Recent developments in generative AI technologies have introduced new possibilities for animation production workflows, particularly during early-stage ideation, visual refinement, and storyboard planning processes. Fig. 1 and Fig. 2 demonstrate examples of animation scenes before and after AI-assisted refinement. The comparison illustrates how generative AI tools may support improvements in visual quality, environmental detail, lighting consistency, and emotional atmosphere within animation-related creative workflows.

Fig. 1 presents examples of original 3D animation scenes developed through conventional production approaches prior to AI-assisted enhancement. In contrast, Fig. 2 demonstrates the same scenes after undergoing AI-assisted visual refinement using prompt-based generative AI support. The refined outputs exhibit improved environmental textures, cinematic lighting, visual depth, and overall scene composition while preserving the original narrative direction and emotional context of the animation scenes.

Fig. 3 further illustrates an example of an AI-assisted animation concept development workflow adapted from contemporary creative production practices. The workflow demonstrates how generative AI technologies may support different stages of animation development, including prompt construction, AI-generated concept generation, storyboard planning, production refinement, and final animation output. Despite the increasing role of AI-assisted systems, human creativity, artistic interpretation, and production decision making remain essential throughout the refinement and finalization stages of animation production workflows.

Overall, the integration of generative AI technologies within animation education environments may provide students with additional opportunities for creative experimentation, rapid ideation, and workflow support. At the same time, the workflow also reflects the continuing importance of human-centred creative direction in maintaining originality, narrative consistency, and artistic quality within AI-assisted animation production practices.

II. Literature Review

A. Generative AI in Higher Education and Creative Learning

The development of generative artificial intelligence (AI) technologies has introduced significant changes to teaching, learning, and creative production practices within higher education environments [2], [3], [13]. In recent years, AI-assisted systems such as ChatGPT, Gemini, Midjourney, and Runway have become increasingly accessible to students across various academic disciplines. These tools can support content generation, idea exploration, visual development, and communication processes, which lead many educators and institutions to explore their potential within educational settings [1]. The growing accessibility of generative AI has also contributed to wider discussions regarding the future role of AI within digital learning environments and creative education.

Within higher education, previous studies have reported that AI-assisted technologies may support productivity, improve learning flexibility, and encourage exploratory learning approaches among students [2], [8]. Students are increasingly using generative AI tools for brainstorming, summarizing information, generating references, and supporting project development processes. On the other hand, in creative disciplines, the integration of AI technologies has become particularly noticeable due to the increasing demand for digital content production and rapid visual experimentation. As a result, AI-assisted creative workflows are gradually becoming part of the learning experience within animation, design, and digital media programs [4]. Apart from that, previous studies have suggested that AI-assisted creative environments may encourage more iterative and exploratory learning experiences, particularly among students involved in design-oriented and visual production activities [9].

In animation education, generative AI tools are beginning to influence multiple stages of creative production workflows, including concept development, scriptwriting, storyboard planning, visual ideation, and asset generation. AI-assisted systems may help students accelerate early-stage ideation and reduce technical barriers during content development processes [4]. For some students, generative AI tools also provide opportunities to explore different visual directions and creative outcomes more efficiently compared to traditional production methods. This increasing interaction between students and AI systems has contributed to the emergence of more collaborative human–AI creative practices within digital creative learning environments. Hence, human–AI collaboration has increasingly been discussed as part of emerging co-creative production models where AI functions as a supportive ideation partner rather than a replacement for human creativity [7].

Despite the potential advantages of generative AI integration, concerns regarding ethical usage, originality, and creative dependency continue to be widely discussed within higher education contexts. Several researchers have highlighted that excessive reliance on AI-generated outputs may affect critical thinking, independent creativity, and content authenticity among students [3], [10]. In creative disciplines such as animation, these concerns become particularly relevant because originality and artistic interpretation remain central elements of creative practice. Consequently, educators are increasingly encouraged to develop balanced learning approaches that integrate AI technologies while still preserving human creativity and creative decision-making processes.

B. Prompt Literacy and Generative AI Readiness in Creative Workflows

As generative AI technologies become more prompt-driven, the ability to communicate effectively with AI systems has emerged as an increasingly important digital skill. In recent discussions surrounding AI-assisted learning, the concept of prompt literacy has gained attention as part of emerging digital and AI-related competencies. Prompt literacy refers to an individual's ability to understand, construct, refine, and evaluate prompts when interacting with generative AI systems. Within animation and creative workflows, prompt literacy extends beyond basic prompt writing and includes the ability to communicate visual intentions, creative requirements, stylistic preferences, and contextual information effectively to AI-assisted systems [14], [15]. Students with stronger prompt literacy are more likely to obtain relevant outputs, refine generated content efficiently, and maintain greater creative control throughout AI-assisted production processes [5]. Within creative workflows, prompt literacy may influence how effectively students interact with AI systems during idea generation, visual experimentation, and creative problem-solving activities.

Previous studies have suggested that students often experience difficulties when attempting to generate accurate or contextually appropriate outputs from AI systems due to unclear prompting strategies or limited understanding of AI behavior [5]. In creative production environments such as animation workflows, prompt construction may directly influence the quality, consistency, and usability of generated outputs. As a result, students who possess stronger prompt communication skills may demonstrate higher confidence and adaptability when working with AI-assisted creative technologies.

Apart from that, AI readiness has become another important area of discussion within higher education environments. AI readiness is commonly associated with an individual's preparedness, confidence, and willingness to adopt AI technologies within learning or professional settings. Previous research has shown that students' readiness towards AI integration may be influenced by perceived usefulness, technical familiarity, learning support, and ethical considerations [6]. In creative disciplines, AI readiness may also involve students' ability to balance AI-assisted production with personal creativity, artistic control, and workflow decision-making.

To note, although generative AI adoption continues to expand rapidly within educational settings, research focusing specifically on animation students and creative production workflows remains relatively limited. Many existing studies have focused primarily on general AI adoption or broader educational technology acceptance models without examining the specific creative practices involved in animation-related learning environments [2], [3]. In addition, there is still limited understanding regarding how prompt literacy and AI readiness may influence students' experiences within AI-assisted creative workflows. Therefore, further investigation is needed to better understand how animation students perceive generative AI integration within higher education creative environments [4], [12].

Overall, previous studies have consistently highlighted the growing role of generative AI in higher education, with particular attention given to its potential for enhancing learning, creativity, and productivity. Existing research has also emphasized the importance of prompt literacy and AI readiness as essential competencies for effective interaction with AI systems. However, most studies have examined these topics from a general educational perspective, with limited attention to disciplines that rely heavily on iterative visual creativity and AI-assisted content development. Furthermore, relatively few studies have explored how animation students perceive the integration of generative AI within their creative workflows. By focusing on animation education, this study extends the current literature by examining prompt literacy and generative AI readiness within a creative learning environment where human creativity and AI-assisted production are closely interconnected.

III. METHODOLOGY

A. Research Design

This study adopted a quantitative survey approach to examine prompt literacy and generative AI readiness among animation students involved in creative workflows within higher education environments. The quantitative method was selected as the study aimed to obtain a broader understanding of students' experiences, perceptions, and readiness towards the use of generative AI technologies in animation related creative activities. The study focused on students' exposure to AI-assisted creative workflows, including idea development, workflow support, and learning-related experiences associated with generative AI usage.

The intention of this study was to provide an overview of how animation students perceive prompt literacy and generative AI readiness within their creative workflows. As the research was exploratory in nature, descriptive statistical analysis was considered appropriate for summarizing respondents' experiences and identifying overall response patterns. The study was not designed to examine predictive or causal relationships among the variables, but rather to establish an initial understanding that may support future empirical investigations in animation education.

B. Participants and Data Collection

Data collection was conducted using an online questionnaire distributed to students enrolled in animation and creative media-related programs at a Malaysian public university. A total of 74 valid responses were collected and used for analysis. The participants were selected because they were actively engaged in animation-related creative activities and had prior exposure to generative AI tools through their academic learning. The participants reported experience with a variety of generative AI applications used in creative learning, including text-generation, image-generation, and other AI-assisted tools that supported different stages of the animation production process. The respondents represented varying levels of familiarity and experience in using generative AI within both creative practice and coursework. Although the study was conducted within a specific educational context, the findings provide preliminary insights into students' perceptions of prompt literacy and generative AI readiness that may inform future research involving broader populations and different educational settings.

The questionnaire was shared through online communication platforms commonly used by students. Participation in the survey was voluntary, and respondents were informed that the information collected would be used solely for academic and research purposes. The online distribution approach allowed students to respond based on their own experiences and perspectives regarding AI-assisted creative workflows in animation-related learning environments.

C. Research Instrument

The questionnaire was developed based on the research objectives and relevant literature on prompt literacy, generative AI readiness, and AI-assisted creative learning. It consisted of three sections. The first section collected participants' demographic information and their experience with generative AI tools. The second section included multiple-choice questions and five-point Likert-scale items (1 = Strongly Disagree to 5 = Strongly Agree) that examined students' perceptions of generative AI readiness, workflow efficiency, idea generation, technical support, productivity, creative experimentation, learning support, and their use of prompts during AI-assisted creative activities. These items provided an indication of students' prompt literacy by examining their perceived ability to use prompts effectively when interacting with generative AI tools. The final section comprised open-ended questions that invited respondents to share their experiences, opinions, and challenges related to AI-assisted creative workflows. Responses to the open-ended questions were analyzed using thematic categorization, in which similar responses were grouped into recurring themes. These themes were used to complement and provide additional context for the quantitative findings.

D. Data Analysis

The responses collected were analyzed using Jamovi statistical software. Descriptive statistical analysis was carried out to examine respondent demographics, AI usage frequency, and students' perceptions towards generative AI integration in animation creative workflows. Mean scores and standard deviation values were calculated to identify overall response patterns across the Likert-scale items.

Reliability analysis was also conducted to evaluate the internal consistency of the survey instrument. The results showed a Cronbach's alpha value of 0.943, indicating excellent reliability among the measurement items used in the study. In addition to the quantitative analysis, responses from the open-ended questions were analyzed using thematic categorization. Similar responses were grouped into recurring themes related to idea generation, workflow efficiency, creative experimentation, prompt construction challenges, and ethical concerns associated with generative AI usage. The thematic findings were used to complement and strengthen the interpretation of the quantitative results.

IV. Results and Findings

A. Demographic Profile of Respondents

A total of 74 valid responses were collected for this study. The respondents consisted of students enrolled in animation and creative media-related programs with varying levels of experience in using generative AI tools within creative workflows. Based on the collected data, female respondents represented the majority of the participants, followed by male respondents. The respondents also represented different years of study, allowing the study to capture perspectives from students with varying academic and creative experiences.

The demographic analysis provided an overview of the respondents' educational background and AI usage exposure within animation-related creative environments. Detailed demographic information is presented in Table I.

TABLE I. Demographic Profile of Respondents

Variable	Category	Frequency (n)	Percentage (%)
Gender	Female	43	58.1
	Male	31	41.9
Age	18–20	8	10.8
	21–23	59	79.7
	24 and above	7	9.5
Year of Study	Year 1	35	47.3
	Year 2	25	33.8
	Year 3	14	18.9

A total of 74 respondents participated in the study. Female students represented the majority of respondents (58.1%), while male students accounted for 41.9%. Most respondents were between 21 and 23 years old (79.7%). In terms of academic level, Year 1 students formed the largest group of participants, followed by Year 2 and Year 3 students.

B. Generative AI Usage Among Students

The findings indicated that generative AI tools are increasingly being used by students within animation-related creative workflows. Most respondents reported using AI-assisted technologies at least occasionally during idea development, creative experimentation, and content production activities. AI tools such as ChatGPT, Gemini, and Canva AI were among the most used platforms reported by students.

The results also showed that students mainly utilized generative AI tools for brainstorming, workflow support, reference generation, and technical assistance during creative production processes. While some respondents reported frequent use of AI technologies, others indicated more moderate usage depending on project requirements and familiarity with AI-assisted systems. The overall findings suggest that generative AI has already become part of students' creative learning experiences within animation education environments.

Detailed AI usage frequency information is presented in Table II.

TABLE II. AI Usage Frequency Among Respondents

AI Usage Frequency	Frequency (n)	Percentage (%)
Rarely	21	28.4
Sometimes	34	45.9
Often	15	20.3
Very Often	4	5.4

The findings indicate that generative AI tools are already being used by students within animation-related creative workflows. Most respondents reported using AI-assisted technologies "Sometimes" (45.9%), followed by "Rarely" (28.4%) and "Often" (20.3%). Only a smaller group of respondents reported using generative AI tools "Very Often" (5.4%). The results suggest that while generative AI technologies have become increasingly accessible within creative learning environments, the frequency of usage among students still varies depending on individual familiarity, workflow needs, and project requirements.

Generative AI encompasses a wide range of tools with different functions and capabilities. For example, large language models such as ChatGPT are commonly used for text generation, brainstorming, and prompt development, whereas image generation platforms such as Midjourney and Adobe Firefly support concept art and visual ideation. More recently, AI video generation tools, including Runway Gen-3 and Pika, have been introduced to assist with animation prototyping and motion-based content creation. Although these platforms differ in their outputs and underlying technologies, they all require users to communicate effectively through prompts and critically evaluate AI-generated results. Consequently, prompt literacy remains a fundamental competency regardless of the specific AI platform used.

C. Students' Perceptions Towards Generative AI Creative Workflows

The descriptive analysis revealed generally positive perceptions towards generative AI integration within animation creative workflows. Most respondents agreed that AI-assisted tools were useful for improving workflow efficiency, supporting idea generation, and encouraging creative experimentation. Students also reported that generative AI technologies helped reduce technical difficulties and supported productivity during animation-related creative tasks.

At the same time, several respondents expressed concerns regarding originality, output consistency, and ethical issues associated with AI-generated content. Some students also highlighted difficulties in producing accurate outputs due to ineffective prompt construction and limited control over generated results. These findings suggest that while students recognize the benefits of generative AI technologies, challenges related to prompt literacy and creative dependency remain important considerations within animation education.

The overall mean score analysis for students' perceptions towards generative AI creative workflows is presented in Table III.

TABLE III. MEAN SCORE ANALYSIS OF STUDENTS' PERCEPTIONS TOWARDS GENERATIVE AI CREATIVE WORKFLOWS.

Variable	Mean	Standard Deviation
Workflow Efficiency	3.57	0.97
Faster Task Completion	3.55	1.00
Creative Idea Support	3.61	0.99
Ease of Use	3.89	0.90
Productivity Improvement	3.38	0.98
Visual Quality Support	3.12	1.27
Creative Experimentation	3.38	1.11
Technical Support Assistance	3.41	1.03
Confidence in Using AI Tools	2.89	1.08
Learning Support	3.28	1.10
Course Integration Support	2.92	1.28

The mean score analysis showed that respondents generally demonstrated moderate to positive perceptions towards generative AI integration within animation creative workflows. Among the evaluated items, ease of use recorded one of the higher mean values (M = 3.89), indicating that many students perceived generative AI tools as relatively accessible and manageable during creative activities. Creative idea support also showed a positive response pattern (M = 3.61), suggesting that students found AI-assisted systems useful during brainstorming and idea development processes.

Several workflow-related aspects, including workflow efficiency, faster task completion, technical support, and creative experimentation, also recorded moderate mean values. These findings indicate that generative AI tools are increasingly being viewed as supportive technologies within animation related creative tasks. However, lower mean values were observed for confidence in using AI tools (M = 2.89) and course integration support (M = 2.92), which may suggest that some students still experience uncertainty or require additional guidance when integrating AI technologies into formal learning and creative production environments.

D. Reliability Analysis

Reliability analysis was conducted to evaluate the internal consistency of the Likert-scale items used in the study. The reliability results are presented in Table IV. The analysis produced a Cronbach's alpha value of 0.943, indicating excellent reliability and strong internal consistency among the measurement items. The findings suggest that the survey instrument was reliable in measuring students' perceptions and experiences related to generative AI readiness and creative workflow integration within animation education contexts.

TABLE IV. RELIABILITY ANALYSIS OF SURVEY INSTRUMENT

Construct	Number of Items	Cronbach's Alpha
Generative AI Readiness and Creative Workflow Perceptions	11	0.943

E. Thematic Analysis of Open-Ended Responses

To provide additional insights into students' experiences with generative AI, responses from the open-ended questions were grouped into several recurring themes. Table V summarizes the identified themes and their frequencies. The analysis revealed that students primarily perceived generative AI as a useful tool for idea generation, workflow efficiency, and creative experimentation. At the same time, respondents also reported challenges related to prompt construction, output consistency, and ethical concerns associated with AI-generated content.

TABLE V. THEMATIC ANALYSIS OF OPEN-ENDED RESPONSES

Theme	Frequency
Idea Generation Support	28
Workflow Efficiency	21
Creative Experimentation	17
Prompt Construction Challenges	15
Ethical Concerns	12

As shown in Table V, idea generation support emerged as the most frequently reported theme (n = 28), followed by workflow efficiency (n = 21) and creative experimentation (n = 17). Prompt construction challenges (n = 15) and ethical concerns (n = 12) were also identified, indicating that while students recognized the benefits of generative AI, they remained aware of its practical and ethical limitations. The thematic findings generally support the quantitative results by providing further insights into how students experience generative AI within animation-related creative workflows. Many respondents highlighted the usefulness of AI-assisted tools for brainstorming, idea generation, visual exploration, and improving workflow efficiency during creative tasks. At the same time, students also expressed concerns regarding prompt construction, output consistency, originality, and ethical considerations when integrating AI-generated content into their

projects. These findings suggest that while students are generally receptive towards generative AI adoption, the development of prompt literacy and responsible AI usage remains important for effective integration within animation education environments.

V. Discussion

A. Generative AI and Creative Workflow Practices

The findings from this study show that generative AI tools are gradually becoming part of students' creative routines within animation-related learning environments. Many respondents appeared comfortable using AI-assisted systems during idea development, creative exploration, and workflow support activities. Rather than viewing AI purely as a replacement technology, most students seemed to approach these tools as practical assistants that could help simplify certain stages of the creative process.

One noticeable pattern from the findings was the frequent use of AI tools during brainstorming and early concept development stages. This may be related to the nature of animation production itself, where students are often required to generate multiple visual ideas and creative directions within limited production timelines. In this context, generative AI tools may provide students with faster access to references, visual experimentation, and alternative creative possibilities. Similar observations have also been discussed in recent educational technology studies where AI-assisted systems were found to support exploratory and idea-based learning approaches [2], [8], [13], [16].

The findings also suggest that students generally perceive AI-assisted workflows as useful for improving efficiency and reducing technical barriers during production tasks. This observation is consistent with previous studies, which have shown that generative AI can enhance idea generation, streamline creative processes, and support learning in higher education environments [2], [13], [16]. Within animation education, these findings indicate that AI is most valuable as a creative support tool that assists students during ideation and content development rather than replacing human creativity. By reducing the time required for repetitive tasks and early-stage concept exploration, students can devote greater attention to artistic refinement, storytelling, and creative decision-making.

At the same time, the findings do not suggest that students are fully dependent on AI technologies for creative outcomes. Many respondents still acknowledged the importance of human creativity and personal artistic direction within animation workflows. This reflects a more balanced perception towards AI integration, where students appear to value AI as a supporting creative tool rather than a complete substitute for human input and interpretation [17], [18].

B. Prompt Literacy and AI Readiness in Creative Learning

Another important aspect observed in this study relates to prompt literacy and students' readiness towards generative AI usage. Although many respondents reported positive experiences with AI-assisted creative workflows, several students also highlighted challenges related to generating accurate or satisfying outputs from AI systems, particularly when prompts lacked clarity or contextual detail [5], [12]. In many cases, the effectiveness of the generated results appeared to depend heavily on how prompts were written and refined during interaction with AI tools. This finding supports recent studies suggesting that prompt literacy is a key factor influencing the quality and relevance of AI-generated outputs, particularly in creative disciplines where users are required to communicate complex visual and contextual ideas through prompts [14], [15].

This finding suggests that prompt literacy may play an increasingly important role within AI-assisted creative environments. Students who can provide clearer instructions and more structured prompts may experience better control over AI-generated outputs during idea generation and creative experimentation processes. Within animation-related workflows, prompt construction may influence not only the quality of generated visuals or ideas, but also the overall efficiency of the creative process itself [5], [9].

The growing importance of prompt literacy has also been highlighted in recent discussions surrounding AI-assisted education and digital competency development [5], [12]. As AI systems become more integrated into creative learning environments, students may gradually require stronger communication and critical evaluation skills when interacting with AI-generated systems. Several recent discussions have also highlighted prompt engineering and AI communication skills as emerging forms of digital literacy within technology-enhanced learning environments. In animation education specifically, this may involve understanding how prompts affect visual consistency, artistic direction, and content relevance during creative production activities. As generative AI technologies continue evolving, students may increasingly require adaptive prompting strategies and critical evaluation skills to maintain creative control over AI-assisted production outcomes [12].

The findings further indicate that most students appear generally open towards generative AI integration within higher education creative workflows. Many respondents viewed AI-assisted systems as beneficial tools that could support learning, experimentation, and workflow flexibility [6]. This finding may reflect the growing normalization of AI-assisted creative technologies among younger digital native learners who are already familiar with interactive and technology-driven creative environments [8], [9]. This may reflect the increasing normalization of AI-assisted technologies within creative digital environments, particularly among younger generations of students who are already familiar with digital production tools and online creative platforms.

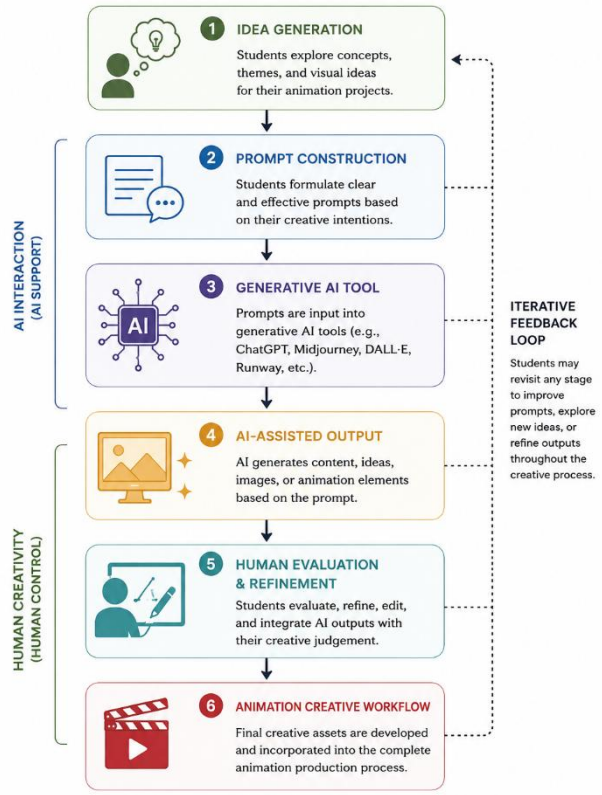

Fig. 4. Proposed human–AI creative workflow in animation education.

Next, Fig. 4 presents a proposed human–AI creative workflow derived from the overall findings and observations obtained in this study. The workflow illustrates how animation students interact with generative AI systems throughout different stages of the creative production process. The process begins with idea generation, where students explore initial concepts, themes, and visual directions for animation-related projects. At this stage, human creativity remains central in determining the creative intention and artistic direction of the workflow.

The second stage involves prompt construction, where students formulate instructions and descriptive inputs to communicate their creative intentions to generative AI systems. This stage reflects the growing importance of prompt literacy within AI-assisted creative environments, as the quality and clarity of prompts may influence the relevance and consistency of generated outputs. Students then interact with generative AI tools such as ChatGPT, Midjourney, Runway, and other AI-assisted platforms to generate visual references, creative ideas, or supporting content during the production process.

Following AI-assisted generation, students evaluate, refine, and selectively integrate the generated outputs into their own creative workflows. The findings of this study suggest that students do not rely entirely on AI-generated outputs but instead use these technologies as supportive creative tools that assist brainstorming, experimentation, and workflow efficiency. Human judgment, creative interpretation, and artistic decision-making continue to play important roles during the refinement stage of the workflow.

The iterative feedback loop illustrated in the figure further reflects the non-linear nature of AI-assisted creative production. Students may revisit earlier stages multiple times to improve prompts, refine generated outputs, or explore alternative creative directions throughout the animation development process. Overall, the proposed workflow highlights the increasingly collaborative relationship between human creativity and generative AI technologies within contemporary animation education environments.

In addition, the workflow also reflects several challenges experienced by students during AI-assisted creative processes, including prompt ambiguity, inconsistent AI-generated outputs, ethical concerns, and limited artistic control over generated content. These challenges suggest that although generative AI technologies may support creative workflows, effective AI integration within animation education still requires critical evaluation, responsible usage, and stronger prompt literacy skills among students.

C. Challenges and Concerns in AI-Assisted Creative Environments

Although respondents generally expressed positive views towards generative AI integration, several concerns were also identified throughout the study. One of the most common concerns involved originality and the authenticity of AI-generated outputs. Some students appeared uncertain about the extent to which AI-generated content should be considered part of original creative work, especially within academic and artistic contexts where personal creativity remains highly valued. Maintaining a balance between technological assistance and authentic creative expression therefore remains an important consideration within AI-assisted animation education environments [7], [12].

Concerns regarding output consistency and creative control were also mentioned by several respondents. While AI tools may assist with rapid idea generation, some students reported difficulties in obtaining outputs that accurately matched their intended artistic direction. These findings suggest that effective use of generative AI requires more than technical access to AI tools. Students also need the ability to critically evaluate AI-generated outputs, refine prompts, and balance AI assistance with their own creative judgment. This reflects the growing emphasis on human–AI collaboration, where AI supports creative production while human creativity remains central to artistic interpretation and decision-making [17], [18].

Apart from that, another issue observed from the findings relates to possible overreliance on AI-assisted systems [3], [10]. Although AI technologies may improve efficiency, excessive dependency on generated outputs could potentially reduce opportunities for independent exploration and problem solving among students. Similar concerns have also been raised in previous studies discussing AI integration within higher education and creative learning environments [3].

In sum, the findings suggest that generative AI technologies present both opportunities and challenges within animation education. While AI-assisted systems may support workflow efficiency, creative exploration, and technical assistance, institutions may also need to consider how AI technologies are

introduced responsibly within creative learning environments. This includes encouraging ethical awareness, strengthening prompt literacy, and maintaining the role of human creativity within AI-assisted animation workflows.

VI. Conclusion

This study explored prompt literacy and generative AI readiness among animation students within higher education creative workflows. The findings indicate that generative AI technologies are increasingly becoming part of students' creative practices, particularly in areas related to idea generation, workflow support, and creative experimentation. Most respondents demonstrated generally positive perceptions towards AI-assisted creative workflows and viewed generative AI tools as useful support systems within animation-related learning environments.

Besides, the study also highlighted that students' experiences with generative AI are closely connected to their ability to communicate effectively with AI systems through prompts. While many students recognized the benefits of AI-assisted technologies, several challenges related to originality, prompt construction, output consistency, and ethical concerns were also identified. These findings suggest that prompt literacy may become an increasingly important skill within future creative digital learning environments. Besides, the findings also suggest that future animation education environments may increasingly involve hybrid human–AI collaborative production approaches that combine creative interpretation with AI-assisted workflow support.

In the context of animation education, the findings provide practical implications for educators and curriculum developers. As generative AI becomes increasingly integrated into creative learning environments, animation programs should incorporate prompt literacy, ethical AI practices, and critical evaluation of AI-generated content into teaching and learning activities. Such initiatives can help students use generative AI more effectively while maintaining originality, creative judgment, and professional responsibility. This aligns with broader discussions on educational transformation, which suggest that higher education institutions need to continually adapt curriculum design and teaching practices in response to emerging technologies and changing learning environments [11]. Although generative AI can support creative exploration and workflow efficiency, the role of human creativity, artistic interpretation, and critical thinking remains essential throughout the animation production process.

Several limitations should be acknowledged when interpreting the findings. The study adopted a descriptive approach to explore students' perceptions within a specific educational context and did not investigate statistical relationships among prompt literacy, AI readiness, and creative workflow practices. Future studies could involve inferential statistical techniques, such as correlation or regression analysis, to examine these relationships in greater depth.

This study contributes to the growing discussion surrounding generative AI integration in creative education by providing preliminary insights into animation students' perceptions of prompt literacy and generative AI readiness within AI-assisted creative workflows. As the study was conducted in a single Malaysian public university and employed descriptive statistical analysis, the findings should be interpreted within this context. Future research should involve multiple higher education institutions, larger and more diverse samples, and inferential statistical approaches to examine the relationships among prompt literacy, generative AI readiness, and creative performance. Longitudinal or experimental studies could also investigate how prompt literacy training influences students' creative outcomes and AI-assisted animation workflows over time.

***Abstract*—Magnetic resonance imaging (MRI) is an essential modality in contemporary medical diagnosis, offering high-resolution images with excellent soft-tissue contrast of internal organs in a non-invasive, non-ionizing, and non-carcinogenic manner. However, the primary drawback of this technique is a lengthy data-acquisition process, which raises the possibility of picking up artefacts as well as discomfort in patients. To accelerate it, data is acquired at sub-Nyquist rates, and the image is recovered from undersampled, noisy measurements using the compressed sensing (CS) technique. Composite priors in CS–MRI have demonstrated superior performance compared to single priors, despite having limited image priors, which also leads to slower reconstruction speed. To date, deep unfolded networks (DUNs), which integrate the powerful data-driven prior of traditional deep learning (DL) with the strong interpretability of optimization algorithms, are the most outstanding reconstruction technology in MRI acceleration, yielding superior and interpretable results. This study proposes the iterative three-operator splitting (TOS) method to solve the composite regularization problem and a composite denoising network (CDNet) that maintains consistent arithmetic structures with it. The CDNet is implemented using complex-valued DL strategies for richer representation of MRI. Extensive experiments using brain and knee raw k-space from the FastMRI dataset with acceleration factors (AF) ranging from ×2 to ×10 and assessed using peak signal–to–noise ratio (PSNR), structural similarity index (SSIM), and normalized root–mean–squared error (NRMSE) validate the CDNet. Across AFs, CDNet achieved dataset-averaged PSNR/SSIM/NRMSE of 26.50–33.47dB/0.7787–0.8992/0.2562–0.1303 for brain MRI and 28.08–35.52dB/0.7069–0.8734/0.1929–0.0950 for knee MRI. The proposed network yields superior reconstruction accuracy and faster reconstruction speed compared to the iterative TOS for composite regularization, demonstrating the effectiveness of deep unrolling in accelerating iterative optimization. Furthermore, CDNet outperforms other state-of-the-art DUNs in reconstruction accuracy at comparable inference speed, demonstrating its vast potential for improving patient care, scanner throughput, and healthcare economics.**

***Keywords*—Accelerated MRI reconstruction; composite priors; iterative three-operator splitting; compressed sensing; deep unfolding; composite denoising network**

I. Introduction

Magnetic resonance imaging (MRI) is a critical and widely used research and diagnostic tool in modern medicine due to its non-invasive and non-ionizing acquisition method, which yields excellent contrast images of soft tissue. These properties make it preferred for visualizing the internal organs compared to other medical imaging modalities such as X–rays, computed tomography, and related techniques.

The MRI acquisition technique is based on the fact that the majority of the human body is composed of water molecules, which are made of two hydrogen atoms and one oxygen atom. Hydrogen-atom nuclei consist of a single proton, the tiniest magnetic unit. When exposed to an external magnetic field, these units align with and spin around the axis of the magnetic field at an angular frequency that depends on the strength of the field. This specific frequency is referred to as the precessional or Larmor frequency [1, 2]. The precessional frequency increases with the strength of the magnetic field. When a radio frequency (RF) pulse is applied at this precessional frequency, the spinning protons can absorb the RF energy, causing them to transition from a lower to a higher energy state, either aligning with or opposing the magnetic field. At this point, the protons are considered to be in resonance. Once the RF pulse is discontinued, the protons return to their original state and the energy difference gives rise to the MR signal. Protons in various tissues release energy at different rates due to the distinct chemical compositions and physical properties of each tissue.

The primary drawback of MRI is its slow data acquisition [3-6]. A magnetic resonance (MR) image is formed from multiple k-space acquisitions, separated by time intervals called repetition times or TR. Each acquisition results from applying an RF excitation. However, due to instrumental and physiological limitations, these acquisitions are performed sequentially for a specific field of view (FOV) [1]. Consequently, it takes a considerable amount of time to fully acquire the entire k-space needed to produce a single image.

This slow imaging speed poses a significant challenge, limiting clinical applications, particularly in real-time MRI, such as dynamic cardiac imaging, where only a limited number of samples can be acquired per cardiac cycle. In traditional MRI, k-space sampling adheres to the Nyquist criterion, which depends on the FOV and the MR image resolution. Accelerating MR data acquisition is possible by employing high-magnitude gradients, as these can reduce the TR time. However, the practical use of such rapidly switching gradients is limited because frequent changes can cause peripheral nerve stimulation in patients [1]. This inherent speed limitation of the MRI system has prompted the exploration of alternative technologies to increase MRI speed by undersampling k-space without sacrificing reconstruction quality.

Compressed sensing (CS) [7-10] enables the reconstruction of high-quality MR images from substantially fewer measurements than required by the Nyquist sampling criterion, at an additional computational cost compared to the inverse Fourier transform required for traditional full sampling. In CS, the reconstruction problem is formulated as an optimization that combines an ℓ_1-norm prior term to promote sparsity with an ℓ_2-norm data-fidelity term that enforces consistency with the acquired measurements. Iterative algorithms such as the iterative shrinkage-thresholding algorithm (ISTA) [11], fast iterative shrinkage-thresholding algorithm (FISTA) [12], and alternating direction method of multipliers (ADMM) [13] are then used to solve the problem, approximating the ground truth image.

Composite prior models in CS–MRI reconstruction have consistently demonstrated superior performance compared to single prior models [14-16]. Regularization terms are frequently employed to produce solutions that exhibit various characteristics based on the composite priors. Such priors include the sparse prior in the temporal Fourier domain [17], the total variation prior [18] that enforces sparsity in the spatial domain, and matrix low-rank priors [19], among others. However, the use of multiple priors leads to a composite regularization problem whose solution is computationally intensive, making it unsuitable for practical CS-MRI implementation [1, 14]. Also, there exist limited image priors in CS. In addition to the lengthy reconstruction times, empirical selection of hyperparameters, which is more complex than a single prior model, is nontrivial and difficult to choose for optimal performance. The composite prior model exhibits limited acceleration, up to ×5, with higher acceleration factors yielding images in which artifacts co-exist with useful visual information.

Deep unfolded networks (DUNs) [20-22] with multiple priors can be used to overcome the aforementioned challenges of solving the composite regularization problem with iterative algorithms. This is achieved by unrolling a fixed number of iterations of an optimization algorithm into a trainable end-to-end deep network, where the computationally expensive regularization terms are learned from data, while the computationally efficient data-consistency term is computed explicitly. Consequently, the unrolling converts the problem-specific hyperparameters of iterative algorithms into learnable parameters, thereby alleviating their empirical selection. DUNs have enabled the integration of the powerful data-driven prior of traditional deep learning (DL) with the strong interpretability of optimization algorithms, yielding superior and interpretable reconstruction results, making it the outstanding reconstruction technology in MRI acceleration to date [21, 23]. However, most DUNs [21, 24-28] employ a single DL method to enforce prior information, which may be limited.

To address the aforementioned challenges, we propose a complex-valued deep unrolled composite denoising network (CDNet) for accelerated magnetic resonance image reconstruction with the following specific contributions.

- We solve the composite regularization problem using the iterative three-operator splitting method and reconstruct MR images.
- We develop a complex-valued learned reconstruction architecture, CDNet, that maintains a consistent arithmetic structure via deep unfolding of the iterative three-operator splitting for composite regularization.
- We employ multiple complex-valued DL strategies to effectively capture both fine-grained spatial details and global structural information, thereby providing a richer representation of MRI.
- We conducted extensive experiments on raw complex brain and knee k-space data from the publicly available fastMRI dataset to evaluate CDNet and compare it with other state-of-the-art DUNs, demonstrating that CDNet outperforms existing methods.

II. Related Works

A. Single Priors

Sriram *et al.* [29] proposed an end–to–end variational network, dubbed E2E–VarNet, that accelerated MR image reconstruction in parallel imaging. Unlike prior variational networks that estimated the coil sensitivity maps before reconstruction, the authors in this work jointly learned the maps and the reconstruction process directly from the undersampled k-space. The work unrolled a variational optimization scheme into a network consisting of 12 cascades, with each cascade comprising a data-consistency and U-Net-based regularization block that refines the k-space. In addition to the reconstruction process, the authors added a sensitivity map estimation (SME) module, thus enabling end-to-end training. The E2E – VarNet was trained on knee and brain data from FastMRI and consistently outperformed other variational networks in reconstruction accuracy, as assessed using structural similarity index (SSIM) and peak signal–to–noise ratio (PSNR), especially at higher acceleration factors. Despite E2E–VarNet superseding other variational networks and demonstrating the significance of learning sensitivity maps, it exhibited some limitations. First, the SME module added half a million more parameters than other variational networks, increasing memory and computational costs. Secondly, the model evaluation relied primarily on quantitative metrics, namely normalized mean squared error (NMSE), SSIM, and PSNR, which may not capture subtle, clinically relevant details. This would necessitate further clinical validation before deployment to avoid a degradation in diagnostic accuracy.

Zhou *et al.* [30] proposed a dual–domain recurrent network, dubbed DuDoRNet, that jointly restores the k-space and image while embedding a deep T1 prior. Each cascade contained two dilated residual dense networks, one for k-space restoration and the other for image restoration, each with a data consistency layer and using a TI-weighted MRI for complementary structural guidance. The authors conducted extensive experiments on the network with three undersampling patterns, namely radial, Cartesian, and spiral trajectories. They used an in-house MRI dataset of 20 patients consisting of 252, 36, and 72 training, validation, and testing 2D images on acceleration of up to 6 using 5 cascades. The results were evaluated using PSNR, SSIM, and mean squared error (MSE) and demonstrated superior performance compared to other DL-based methods and CS-based methods. Despite the good reconstruction performance, the DuDoRNet has several limitations. First, it relies on the availability of a fully sampled T1 scan, which may be absent in protocol-limited clinical settings or time-critical medical examinations. Second, the recurrent dual-domain architecture increases computational complexity and memory requirements, limiting real-time clinical deployment. Thirdly, the network evaluation focused primarily on anatomical data, while other MRI data, such as pathological data, remain unexplored.

Xiang *et al.* [31] combined the free tuning and strong generalization of deep neural networks with the interpretability of FISTA to yield an unrolled network, dubbed FISTA-Net, for solving inverse problems in imaging. The FISTA-Net unfolds *n* FISTA iterations into *n* blocks, with each block consisting of a convolutional neural network (CNN) – based proximal mapping module, a gradient descent module, and a momentum update module. The FISTA-Net was evaluated quantitatively and visually using X-ray, computational tomography, and electromagnetic tomography. The experimental results show that it performs superiorly to the traditional iterative FISTA, an ISTA-based unrolled network, and other iterative and data-driven baseline algorithms. The network was not validated on MRI datasets with raw k-space measurements, limiting insights into its performance in practical MRI reconstruction scenarios.

Fabian *et al.* [32] introduced a hybrid unrolled multi-scale framework named HUMUS-Net that combines transformers and CNNs to accelerate MR image reconstruction. HUMUS-Net leverages the capability of transformers to identify long-range dependencies via self-attention and the proficiency of CNNs in efficiently extracting local features for MR image reconstruction. This design enables the network to extract multi-scale features by using transformers for low-resolution features and convolutions for high-resolution features. Additionally, HUMUS-Net integrates a sensitivity map estimator for multi-coil MRI reconstruction and employs unrolled iterative reconstruction steps, inspired by iterative optimization algorithms. The unrolled network achieved state-of-the-art performance, as measured by SSIM, PSNR, and NMSE, outperforming other existing networks. Nonetheless, HUMUS-Net is computationally intensive and requires substantial memory, particularly due to the transformer, which limits the depth of the network and patch size. Furthermore, the network requires fixed-size inputs, limiting its adaptability in clinical settings.

Zhang *et al.* [33] introduced an unrolled network, T^{2}LR-Net, that adaptively learns the optimal transformed domain to leverage tensor low-rank priors in dynamic MRI reconstruction. This method extended the tensor singular value decomposition (t-SVD) to incorporate multidimensional unitary transforms and introduced a novel unitary-transformed tensor nuclear norm (UTNN). By employing CNN modules, the approach surpassed the constraints of manually crafted transforms, learning appropriate transformations driven by reconstruction precision. T^{2}LR-Net unfolds N iterations of the ADMM algorithm into N modules, each comprising a reconstruction block, a multiplier update block, and a transformed-tensor low-rank prior block integrated with a CNN. Experimental outcomes assessed using signal-to-noise ratio (SNR) and SSIM demonstrated superior performance compared to other unrolling network-based and optimization-based methods. Nevertheless, the repeated SVD operations heighten the network's computational complexity, necessitating significant GPU memory and training time. The singular value thresholding (SVT) operators in each iteration stage may become nondifferentiable under certain conditions, such as when the matrix being solved has repeated singular values, potentially halting training. Additionally, performance slightly diminishes in multi-coil and prospective acquisition scenarios.

Vornehm *et al.* [34] introduced a variational network-based reconstruction framework dubbed cineVN, which unrolled an iterative optimization scheme into a deep network while incorporating the spatio–temporal structure of dynamic cardiac data. The cineVN network architecture consisted of 15 cascades, each containing a refinement term and a data consistency term, with a conjugate gradient block after every third cascade. The coil sensitivity maps were pre-estimated, and the complex data were split into real and imaginary parts. The proposed cineVN was evaluated on in vivo cardiac MRI acquisitions and demonstrated improvements over a spatiotemporal VN and a temporal total variation regularization – CS based approach (TTV-CS) in retrospective evaluation and TTV-CS and ℓ_1-wavelet regularization CS based approach in prospective evaluation. However, there is a potential breath-hold inconsistency between accelerated cineVN and GRAPPA reference acquisitions, as residual variations in respiratory state may persist despite exhalation-only imaging. The proposed network was also evaluated on a specific set of acquisitions and protocols, and a broader validation across different acquisition settings, scanners, and patient populations is essential before clinical deployment.

B. Multiple Priors

Ke *et al.* [20] presented a network dubbed SLR-Net which unfolded the ISTA procedure for dynamic MR imaging. Unlike other networks that focus on sparse priors of MR images alone, the authors in this work added a learned singular value thresholding to explore low-rank priors. The authors unrolled 10 iterations of ISTA into 10 cascades of SLR-Net, with each cascade comprising a sparse prior module, low-rank prior module, reconstruction module, and a multiplier update layer while maintaining the arithmetic structure of ISTA. The learned low–rank prior improved the reconstruction accuracy assessed using PSNR, MSE, and SSIM compared to CS and sparsity-driven DL methods. However, these SVD operations

added more computation time, which was limited to 0.5s, a range achieved using the supercomputing power of a GPU. In the absence of such GPUs in clinical deployment, real-time imaging may not be achieved. The module also added the memory requirement of the GPU, increasing hardware requirements.

Huang *et al.* [35] proposed a network dubbed the low-rank plus sparse (L+S) network to overcome two common failings of CS-based reconstruction: limited acceleration and the empirical selection of L+S parameters. The authors unrolled the alternating linearized minimization method to learn the regularization parameters. The L+S-Net contains 10 states, corresponding to 10 iterations of the iterative algorithm, with each stage comprising a data consistency layer, a sparse prior layer, and a low–rank prior layer. Experimental results on cardiac cine datasets demonstrate superior results compared to other existing CS and DL methods, especially at high acceleration factors. Despite the superior reconstruction results, L+S-Net exhibited several limitations. First, the network has SVD computations, which lead to extended reconstruction times. Second, the effect of the low-rank prior may degrade when the number of frames is reduced, since reconstruction is performed for each batch of frames, rendering it unsuitable for low-latency imaging. Third, the network was tested only on heart images, and further testing on other body parts is essential for its validation.

Zhang *et al.* [21] presented an unrolled network, JotlasNet, that incorporated attention-based sparse priors and a tensor low-rank prior for reconstructing dynamic MR images. The tensor low-rank prior exploited structural correlations in the data. The authors used a CNN to learn the priors. They unfolded the network using the composite splitting algorithm and set the number of cascades to 15. JotlasNet yielded better reconstruction results, as evaluated using PSNR and SSIM, on single- and multicoil data compared to other DUNS. However, JotlasNet is prone to numerical instability, which hinders the training process. The gradient of SVD is unstable, especially when singular values are repeated, leading to NaN gradients that hinder training. Also, the SVD significantly increases reconstruction time due to its computational complexity.

From the aforementioned limitations of existing DUNs, we propose the CDNet that allows effective integration of multiple priors in the reconstruction model. The CDNet is not prone to numerical instability and effectively combines multiple deep complex-valued DL strategies to capture different attributes of MR images and offer richer representation in MRI.

III. METHODOLOGY

A. Problem Formulation for Accelerated MRI

Magnetic resonance imaging (MRI) acquisition captures spatially dependent resonance-frequency information from the region under investigation. The MR images in the spatial domain are obtained by taking an inverse Fourier transform of the captured data. Accelerating MRI via undersampling results in an underdetermined system with an infinite set of solutions. The compressive sensing (CS) technique enables recovery of the MR image of interest by solving the basis pursuit denoising (BPDN) problem. The BPDN problem solution is obtained by solving the unconstrained optimization problem given in Eq. (1)

$$\hat{x} = \underset{x}{argmin} \underbrace{\|Fx - s\|_2^2}_{f(x)} + \lambda \underbrace{\|x\|_1}_{\Re(x)} \tag{1}$$

where, F denotes the forward model that maps the MR image x to the scanned data s. The ℓ_1 norm promotes sparsity in a suitable transform such as wavelets, and the λ is a regularization parameter that balances the sparsity $\Re(x)$ and data consistency term $f(x)$.

The solution to Eq. (1) closely approximates the original image. To improve the solution of Eq. (1) and consequently the reconstruction results, we can add additional sparsifying norms to increase overall sparsity. One such norm is the total variation (TV) norm [18], which promotes sparsity of image gradients. Therefore, the addition of the TV norm in Eq. (1) improves the solution by promoting sparsity in the spatial domain alongside the ℓ_1 norm. The general optimization problem can be given as in Eq. (2).

$$\hat{x} = \underset{x}{\text{minimize}}\ g(x) = f(x) + \textstyle\sum_{i=1}^{k} \lambda_i \Re_i(x) \tag{2}$$

The data consistency term $f(x)$ is a continuously differentiable function with a Lipschitz constant, while the $\Re_i(x)$ terms are nonsmooth convex functions. When $k = 1$, Eq. (2) reduces to Eq. (1), which can be easily solved using two-operator splitting algorithms such as ISTA, FISTA, and ADMM. When $k > 1$, Eq. (2) becomes computationally expensive to solve using the two-operator splitting algorithms due to multiple regularization terms.

B. Iterative Three Operator Splitting Algorithm for Composite Regularization

The iterative three-operator splitting (TOS) algorithm, first proposed by [36] and whose convergence was analyzed in [37], can be used to solve Eq. (2) for $k > 1$ in a computationally efficient manner. For example, we consider the case when $k = 2$, Eq. (2) becomes;

$$\hat{x} = \underset{x}{\text{minimize}}\ g(x) = f(x) + \lambda_1 \Re_1 + \lambda_2 \Re_2 \tag{3}$$

Following the works of [10, 14, 15], we can consider the total variation (TV) norm for spatial sparsity and an ℓ_1 norm in a suitable transform domain for transform sparsity. Eq. (3) can then be rewritten as;

$$\hat{x} = \underset{x}{\text{minimize}}\ g(x) = \underbrace{\|Fx - s\|_2^2}_{f(x)} + \lambda_1 \underbrace{\|\psi x\|_1}_{\Re_1(x)} + \lambda_2 \underbrace{\|x\|_{TV_{iso}}}_{\Re_2(x)} \tag{4}$$

where, ψ is a suitable transform such as wavelets and $\|x\|_{TV_{iso}}$ is the isotropic TV given by;

$$\|x\|_{TV_{iso}} = \textstyle\sum_{i,j} \sqrt{\left|x_{i+1,j} - x_{i,j}\right|^2 + \left|x_{i,j+1} - x_{i,j}\right|^2} \tag{5}$$

Eq. (4) can be solved iteratively using the TOS strategy. At each iteration, n, a gradient step, a proximal operator of TV, and a proximal operator of ℓ_1 are combined to produce a relaxed output for the next iteration. The TOS for $k = 2$ is given in Algorithm 1.

Algorithm 1: Three Operator Splitting Algorithm for $k = 2$

Inputs: Complex-valued zero-filled image y_0^0, Binary Mask M, number of iterations N, step size α and relaxation λ

For $n = 0, 1, 2, 3 \ldots N$

$x_1^n = prox_{\alpha\Re_1}(y_0^n)$

$\nabla f(x_1^n) = F^{-1}\left(M \odot (Fx_1^n - s)\right)$

$y_1^n = 2x_1^n - y_0^n - \alpha\nabla f(x_1^n)$

$x_2^n = prox_{\alpha\Re_2}(y_1^n)$

$x^{n+1} = y_0^n + \lambda(x_2^n - x_1^n)$

End

Return x_1^N

where, *prox* is the proximal operator defined as in Eq. (6) for a function φ [35].

$$prox_{\gamma\varphi}(x) = \underset{y\in\mathbb{C}^d}{argmin}\ \varphi(y) - \frac{1}{2\gamma}\|x - y\|_2^2 \qquad (6)$$

For $k > 2$ the algorithm 1 can be reformulated as iterates of *prox* of $\Re_i$ and the gradient step to give Algorithm 2.

Algorithm 2: Three Operator Splitting Algorithm for $k > 2$

Inputs: Complex-valued zero-filled image y_0^0, Binary Mask M, number of iterations N, step size α and relaxation λ

For $n = 0, 1, 2, 3 \ldots N$

$x_1^n = prox_{\alpha\Re_1}(y_0^n)$

$\nabla f(x_1^n) = F^{-1}\left(M \odot (Fx_1^n - s)\right)$

$y_1^n = 2x_1^n - y_0^n - \alpha\nabla f(x_1^n)$

$x_2^n = prox_{\alpha\Re_2}(y_1^n)$

$\nabla f(x_2^n) = F^{-1}\left(M \odot (Fx_2^n - s)\right)$

$y_2^n = 2x_2^n - y_1^n - \alpha\nabla f(x_2^n)$

$x_3^n = prox_{\alpha\Re_3}(y_2^n)$

•

•

•

$x_{K-1}^n = prox_{\alpha\Re_{K-1}}(y_{K-2}^n)$

$\nabla f(x_{K-1}^n) = F^{-1}\left(M \odot (Fx_{K-1}^n - s)\right)$

$y_{K-1}^n = 2x_{K-1}^n - y_{K-2}^n - \alpha\nabla f(x_{K-1}^n)$

$x_K^n = prox_{\alpha\Re_K}(y_{K-1}^n)$

$x^{n+1} = y_0^n + \lambda(x_K^n - x_1^n)$

End

Return x_1^N

C. Composite Denoising Network

Solving the $\Re_i(x)$ terms in the multiple-regulation optimization problem for MR image reconstruction in Eq. (2) efficiently and effectively is non-trivial. This may require creating subproblems and solving them using iterative algorithms, either simultaneously or sequentially, to achieve the desired solution. This leads to iterations within the main iterations of the TOS algorithm, which can significantly increase reconstruction time. Also, choosing the values of λ and α for effective MR image reconstruction is challenging. Motivated by these challenges of the iterative TOS algorithm for multiple regularization, we derive a learned reconstruction scheme dubbed composite denoising network (CDNet) by deep unrolling its iterations. We replace $prox_{\alpha\Re_i}$with parametrized complex-valued DL strategies $\xi_{k\theta_i}$ .The use of multiple complex-valued DL methods in the reconstruction network effectively combines their advantages, enabling the model to capture both fine-grained spatial details and global structural information. Complex-valued reconstruction networks also offer a richer representation of MR images as they are inherently complex. Algorithm 2 can be unrolled to Algorithm 3 given below.

Algorithm 3: Composite denoising network (CDNet)

Inputs: Complex-valued zero-filled image y_0^0, Binary Mask M, number of iterations N, step size α and relaxation λ

Learnable parameters: step size α, relaxation λ and $\xi_{k\theta_i}$

For $n = 0, 1, 2, 3 \ldots N$

$x_1^n = \xi_{1\theta_i}(y_0^n)$

$\nabla f(x_1^n) = F^{-1}\left(M \odot (Fx_1^n - s)\right)$

$y_1^n = 2x_1^n - y_0^n - \alpha\nabla f(x_1^n)$

$x_2^n = \xi_{2\theta_i}(y_1^n)$

$\nabla f(x_2^n) = F^{-1}\left(M \odot (Fx_2^n - s)\right)$

$y_2^n = 2x_2^n - y_1^n - \alpha\nabla f(x_2^n)$

$x_3^n = \xi_{3\theta_i}(y_2^n)$

•

•

•

$x_{K-1}^n = \xi_{K-1\theta_i}(y_{K-2}^n)$

$\nabla f(x_{K-1}^n) = F^{-1}\left(M \odot (Fx_{K-1}^n - s)\right)$

$y_{K-1}^n = 2x_{K-1}^n - y_{K-2}^n - \alpha\nabla f(x_{K-1}^n)$

$x_K^n = \xi_{K\theta_i}(y_{K-1}^n)$

$x^{n+1} = y_0^n + \lambda(x_K^n - x_1^n)$

End

Return x_1^N

The block diagram of CDNet is given in Fig. 1. $\xi_{k\theta_i}$are learnable parameters for composite denoising while D_k are data consistency terms computed numerically.

1) Discriminative learning for CDNet: We demonstrate the effectiveness of CDNet in accelerating MRI reconstruction by choosing $K = 2$ achieving a favorable trade-off between computational complexity, reconstruction time, and reconstruction accuracy. We propose a complex-valued CNN (CvCNN) to capture the overall anatomical structure and a complex-valued Unet (CvUnet) to capture the spatially local features and also enhance global features for $\xi_{1\theta_i}$ and $\xi_{2\theta_i}$ respectively. These DL methods offer lower computational complexity and hardware requirements compared to transformers and generative adversarial networks (GANs), thus preferred for CDNet. CvCNN and CvUNet differ in architectural design, but they are implemented in the same building blocks, namely, complex-valued convolution (CVC), complex-valued rectified linear unit ($\mathbb{C}$ Re L U) and radial batch normalization (RBN). While both architectures employ identical complex-valued building blocks, CvCNN uses a sequential feed-forward design, whereas CvUNet adopts an encoder–decoder structure with skip connections.

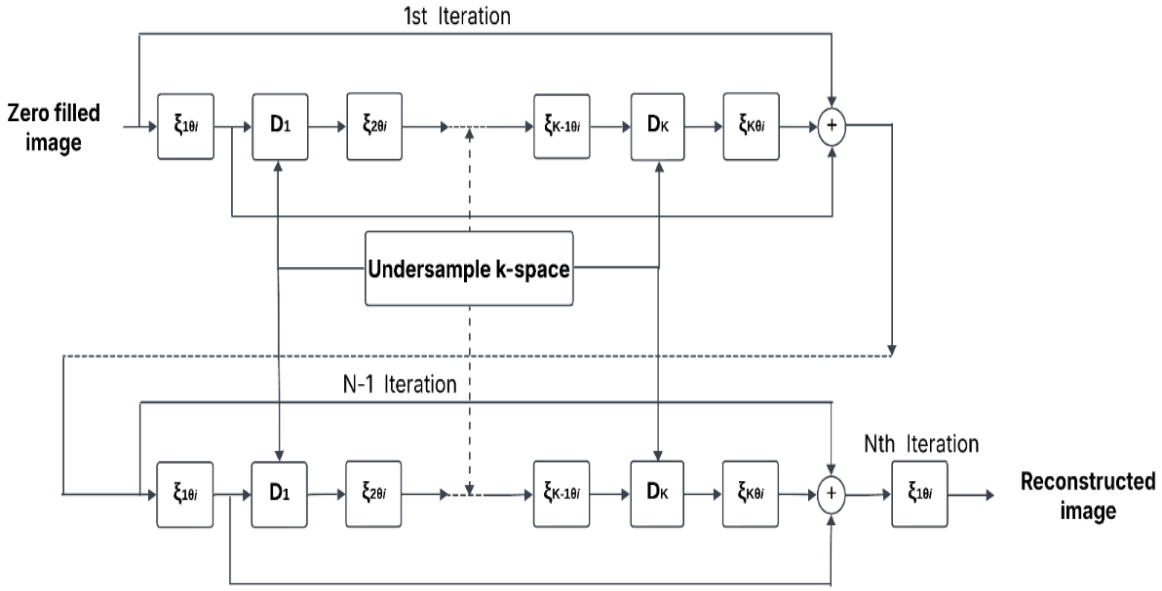

Fig. 1. Block diagram of the proposed CDNet.

The complex-valued convolution between the input zero-filled image $y_n^k = a + jb$ and kernel $k = c + jd$ can be realized using real-valued arithmetic by convolving the kernels c or d with each a and b as given in Eq. (7).

$$y_k^n * k = (c * a - d * b) + j(d * a + c * b) \tag{7}$$

where, $*$ represent convolution.

The RBN module stabilizes convergence and accelerates network training. The magnitude is scaled while preserving the phase, ensuring relative differences in complex quantities are preserved. We express the complex data y_{RBN} in polar form as given in Eq. (8) to obtain its magnitude f and phase θ. We normalize f as in Eq. (9)

$$y_{RBN} = f e^{j\theta} \tag{8}$$

$$f_{RBN} = \left(\frac{f-\mu_f}{\sqrt{\sigma_f^2}}\right)\kappa_1 + \kappa_2 + \varepsilon \tag{9}$$

where, σ_f^2 and μ_f are the variance and mean of f, κ_1 and κ_2 are trainable parameters for scaling and shifting the data distribution, and ε is a constant for ensuring f_{RBN} remains positive.

The network was activated with a $\mathbb{C}\,ReLU$ obtained by applying a real-valued ReLU to the real g_R and imaginary part g_I of the complex data g separately [38].

$$\mathbb{C}\,ReLU(g) = ReLU(g_R) + j\,ReLU(g_I) \tag{10}$$

2) Loss function: The CDNet was trained with a compound loss L^{comp} of ℓ_1 and multi-scale SSIM (MS-SSIM) loss given in Eq. (11) and its auxiliary parameters given in Eq. (12) to (15). The balancing weight χ was determined empirically in [39] to be 0.84, while [40] demonstrated the superiority of L^{comp} compared to the MSE, Huber, SSIM, perceptual loss, MSSIM, and ℓ_1 loss in training medical image reconstruction models.

$$L^{comp} = \chi L^{MS-SSIM}(|rec|, |gt|) + (1-\chi)L^{\ell_1}(|rec|, |gt|) \tag{11}$$

where, rec, gt, $L^{MS-SSIM}$, L^{ℓ_1} is the reconstructed image, ground truth image, MS-SSIM loss given in Eq. (11), and ℓ_1 loss given in Eq. (16), respectively, and $|.|$ denotes magnitude.

$$L^{MS-SSIM} = l_N\left(|rec|, |gt|\right)^{\upsilon_N} \prod_{j=1}^{N}\left[c_j\left(|rec|, |gt|\right)\right]^{\delta_j}\left[s_i\left(|rec|, |gt|\right)\right]^{\tau_j} \tag{12}$$

where, l, c and s are luminance, contrast, and structure given in Eq. (13), (14), and (15), respectively, and υ, δ_j and τ_j are weights of the distortion factors at different levels.

$$l(|rec|, |gt|) = \frac{2\mu_{|rec|}\mu_{|gt|}+C_1}{\mu_{|rec|}^2+\mu_{|gt|}+C_1} \tag{13}$$

where, $\mu_{|rec|}$ and $\mu_{|gt|}$ are averages of reconstructed and ground truth images, respectively, and C_1 is a constant.

$$c(|rec|, |gt|) = \frac{2\sigma_{|rec|}\sigma_{|gt|}+C_2}{\sigma_{|rec|}^2+\sigma_{|gt|}^2+C_2} \tag{14}$$

where, $\sigma_{|rec|}$and $\sigma_{|gt|}$are variances of the reconstructed and ground truth images, respectively, and C_2 is a constant.

$$s(|rec|, |gt|) = \frac{\sigma_{|rec||gt|}+C_3}{\sigma_{|rec|}\sigma_{|gt|}+C_3} \tag{15}$$

where, $\sigma_{|rec||gt|}$ is the covariance between the reconstructed and ground truth images.

$$L^{\ell_1} = \big||rec| - |gt|\big|_1 \tag{16}$$

D. Implementation Details

1) Iterative details: We implemented the iterative TOS for $k = 2$ in the open-source Python-based PyTorch library on a PC with an Intel CPU of 2.30 GHz and 64 GB RAM. $\Re_1$ was

solved using the Fast Iterative Shrinkage-Thresholding Algorithm FISTA [12] with ψ chosen to be the discrete wavelet transform for promoting sparsity in the transform domain, while $\Re_2$was solved using the anisotropic TV norm given in Eq. (5) for promoting sparsity in the spatial domain. The algorithm was set to 200 iterations, with each consisting of one thresholding step, one data consistency step, one anisotropic TV step, and a relaxation update. The relaxation λ was set to 0.05, while the step size α was adaptive.

2) Unrolled details: The CDNet was implemented using the open - source Python-based PyTorch library in a GPU–enabled Kaggle environment utilizing an NVIDIA Tesla P100. The number of cascades was set to 4, a number validated empirically through experiments and offering a good tradeoff between reconstruction time, hardware requirements, and reconstruction accuracy. The CvCNN complex convolutions use a kernel size of 3×3, 5 convolutional layers, and 32 hidden channels. The CvUnet uses 3 levels with a bottleneck, employing 3×3 convolutions, 2×2 max-pooling and transposed convolutions for down- and up-sampling, 32 base channels, and symmetric skip connections. An Adam optimizer [41] was employed to train the proposed network with a learning rate of 0.002 and momentum parameters set to $\beta_1 = 0.9$ and $\beta_2 = 0.999$. The training was conducted for ×2, ×3, ×4, ×5, ×7, and ×10 accelerations using a batch size of 3 and limited to 55 and 35 epochs for the brain and knee datasets, respectively, to avoid overfitting and preserve generalization.

E. Performance metrics

The proposed CDNet was evaluated quantitatively using PSNR, SSIM, and NRMSE computed against the ground truth images, while sample reconstructed images are given for qualitative assessment. The reconstruction time was measured in seconds. The PSNR between the reconstructed rec and ground truth gt image, whose magnitude is normalized to [0, 1], is given by Eq. (17).

$$PSNR(|rec|, |gt|) = -10\, log_{10} MSE \tag{17}$$

where, MSE is computed as in Eq. (18).

$$MSE(|rec|, |gt|) = \frac{\sum_{i=1}^{R}\sum_{j=1}^{C}(|rec|-|gt|)^2}{RC} \tag{18}$$

where, R and C is the number of rows and columns, respectively. The PSNR ranges from 0 to $+\infty$, with higher value.

values indicating better reconstruction results.

The SSIM between rec and gt is given in Eq. (19).

$$SSIM\left(|rec|, |gt|\right) = l\left(|rec|, |gt|\right)^{\upsilon} c\left(|rec|, |gt|\right)^{\delta} s\left(|rec|, |gt|\right)^{\tau} \tag{19}$$

where, l, c and s are luminance, contrast, and structure defined in Eq. (13), (14), and (15), respectively, and υ, δ and τ are weights of the distortion factors at different levels. SSIM ranges from 0 to 1, with 1 indicating complete similarity and vice versa.

The NRMSE between rec and gt is given in Eq. (20).

$$NRMSE(|rec|, |gt|) = \sqrt{\frac{MSE(|rec|, |gt|)}{MSE(|gt|, 0)}} \tag{20}$$

A low NRMSE indicates good reconstruction results and vice versa.

IV. Results and Discussion

A. Dataset

The brain and knee raw complex k-space data from the FastMRI dataset [42] were used for this research. This is the largest public dataset for MR slices created in collaboration between Facebook AI Research and NYU Langone Health. We selected the single-coil knee dataset, which comprises 973, 199, and 108 volumes for training, validation, and testing, respectively, each containing 34742, 7135, and 3903 slices, respectively. However, the proposed network was evaluated using MR volumes with high-quality slices without fat suppression. This enabled the proposed network to learn anatomical details and the general structure from high-SNR slices with strong overall contrast. A total of 170, 50, and 60 volumes, each containing 6150, 1808, and 2229 slices, respectively, were selected to evaluate the proposed network.

Brain raw complex k-space was also used to evaluate the proposed network. Since the FastMRI dataset provides multicoil k-space for brain slices and the proposed network was evaluated using single-coil data, we enumerated the single-coil data using an adaptive root–sum–of–squares with phase. The magnitude, phase, and complex image were obtained as given in Eq. (21), (22), and (23), respectively.

$$|gt(i,j)| = \sqrt{\sum_{n=1}^{N} |gt_n(i,j)|^2} \tag{21}$$

$$e^{j\theta_{ave(i,j)}} = \frac{\sum_{n=1}^{N} gt_n(i,j)}{|\sum_{n=1}^{N} gt_n(i,j)|} \tag{22}$$

$$gt(i,j) = |gt(i,j)|.\, e^{j\theta_{ave(i,j)}} \tag{23}$$

where, N is the number of coils and $gt_n(i,j)$ is the complex-valued ground truth image for the nth coil. A total of 500, 100, and 150 volumes containing 7910, 1584, and 2392 slices, respectively, were enumerated and their k-spaces and images stored in hierarchical data format version 5 (HDF5) for efficient organization and retrieval during training. A sample of enumerated brain magnitude and phase MR images of size 768 × 396 is shown in Fig. 2.

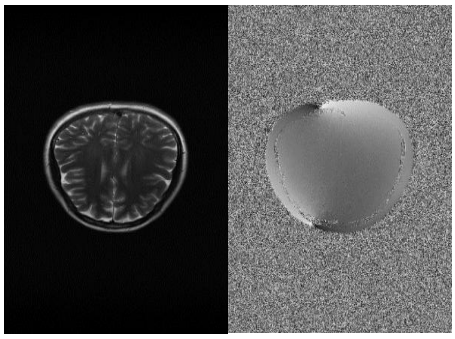

Fig. 2. From left to right, a sample magnitude image and its corresponding phase image.

B. Data Acquisition and Preprocessing

The acquisition was accelerated by undersampling fewer samples with a variable-density pattern that mimics realistic MRI scanners. The phase-encoding lines from the center region corresponding to a percentage equal to the acceleration factor (AF) were retained, as this region contains information about the contrast and gross structure of the MR image. The other lines were sampled probabilistically, ensuring denser sampling near the center and sparser sampling towards the periphery, reducing acquisition artifacts.

The input images, namely the zero-filled image obtained as an inverse fast Fourier transform (IFFT) of the undersampled k-space filled with zeros at the missing k-space positions, and the ground truth images obtained as an IFFT of the fully sampled k-space, were normalized to [0, 1] while preserving the phase according to Eq. (24)

$$gt_N(i,j) = \frac{gt(i,j)}{max_{i,j}|gt(i,j)|+\varepsilon} \quad (24)$$

where, $gt_N(i,j)$ is the normalized ground truth image and ε is a small constant for numerical stability set to 10^{-8}.

The knee MR images were center-cropped to 320 × 320, while the brain MR images were center-cropped to 192 × 192. The 192 × 192 was achieved by resizing in the spatial domain from the original sizes to 320 × 320, followed by a resizing in the Fourier domain to 192 × 192. This ensured a reduction in the background, which is a region of non-interest in the medical domain, while preserving the region of interest. This allows the proposed network to learn useful anatomical details with less computational overhead without compromising the MR image. A sample brain MR image of size 640 × 320 resized to 192 × 192 is shown in Fig. 3.

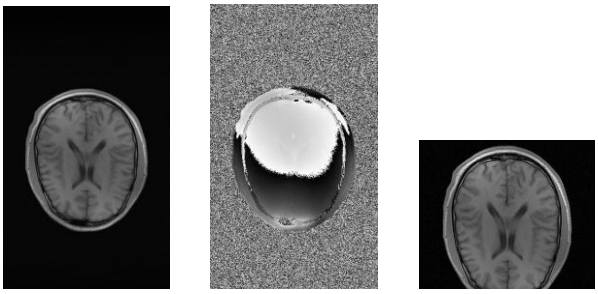

Fig. 3. From left to right: sample magnitude brain MR image and its corresponding phase image of size 640 × 320 resized to 192 × 192.

C. Iterative TOS for composite regularization

Fig. 4 shows sample reconstructed MR images, with the first row showing the brain image and the second row showing the knee image at ×2 to ×5 AF. Ground-truth images are also provided as baselines for comparison. The performance metrics are given in Table I. The average reconstruction time for brain MR is 1.4340s, while that of knee MR is 2.6721s. This difference is due to unequal resizing of the two images, with the knee being resized to 320 × 320 while the brain is resized to 192 × 192. The performance metrics decreased as AF increased, due to fewer measurements acquired for reconstruction. At AFs ×4 and ×5, residual acquisition artifacts coexist with the anatomical structure of the MR image.

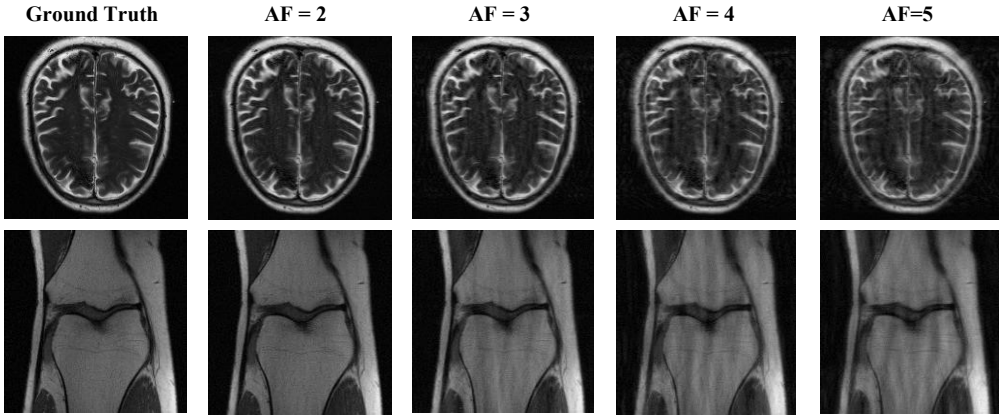

Fig. 4. Sample iterative TOS reconstruction results.

TABLE I. PERFORMANCE METRICS FOR SAMPLE RECONSTRUCTED MR IMAGES IN FIG. 4

	Brain				Knee			
AF	**PSNR (dB)**	**SSIM**	**NRMSE**	**Time (s)**	**PSNR (dB)**	**SSIM**	**NRMSE**	**Time (s)**

D. CDNet

1) The effect of the number of cascades n: We investigated the effect of increasing the number of cascades in the CDNet using the brain k-space with a ×5 acceleration and the statistical quantitative results presented in Table II. The PSNR, SSIM, NRMSE, and time report the average values computed over the entire brain test images. The reconstruction time increases with an average of 0.02875s per added cascade. The quantitative metrics improved greatly when learning started, with PSNR, SSIM, and NRMSE reporting improvements of 4.86 dB, 0.2040, and 0.1506, respectively. These results continued to improve when using two cascades, with PSNR, SSIM, and NRMSE reporting improvements of 0.86 dB, 0.0201, and 0.0183 compared to using a single cascade. The third cascade also showed improvements of 0.49 dB, 0.0225 and 0.0052 in PSNR, SSIM and NRMSE, respectively, compared to learning with two cascades. Since the results were still improving significantly, we also experimented with the CDNet with four cascades. The results showed improvements of 0.24 dB, 0.0046, and 0.0083 for PSNR, SSIM, and NRMSE, respectively. The fifth cascade did not significantly improve the quantitative results, indicating saturation. However, the reconstruction time continues to increase, and hence the choice of $N = 4$ which offers a good trade-off between reconstruction time and accuracy for the proposed CDNet.

A sample reconstructed image and its corresponding error map computed as the difference between the ground truth and the reconstructed image are shown in Fig. 5 for qualitative assessment. The zero-filled and ground-truth images are provided as a baseline for visual comparison. The reconstructed image using a single cascade shows significant improvement over the zero-filled image. However, noticeable differences between the reconstructed and ground truth image are visible. The image reconstructed using two cascades resembles the ground truth image better, with fine anatomical details clearer than in the single-cascade reconstruction. Still, noticeable differences between the reconstructed and ground truth images are visible. The reconstructed image using three cascades is visually better than that using two cascades, with edges showing fine anatomical details. The images reconstructed with four and five cascades are imperceptible to the human eye compared to the ground truth, despite their error maps showing differences. Table III gives the performance metrics for the sample MR image shown in Fig. 5.

TABLE II. DETERMINING THE NUMBER OF CASCADES *N* USING BRAIN DATA ON ×5 ACCELERATION

No of cascades *n*	Image	PSNR (dB)	SSIM	NRMSE	Time (s)

5	Reconstructed	28.89	0.8899	0.3918

2) CDNet learning characteristics: Fig. 6 shows the train and validation loss curves over epochs under different AFs for brain and knee datasets, respectively.

The losses showed a steeper decline for the first 30 and 20 epochs for the brain and knee datasets, respectively, indicating faster initial learning. The losses later decreased slowly up to the 40th epoch and 25th epoch for the brain and knee datasets, respectively, after which they oscillated with small fluctuations, indicating convergence. The losses increased with an increase in AF as less data was used for reconstruction, making it a more challenging task. The train and validation curves for each AF exhibit a small gap, indicating that overfitting is effectively controlled.

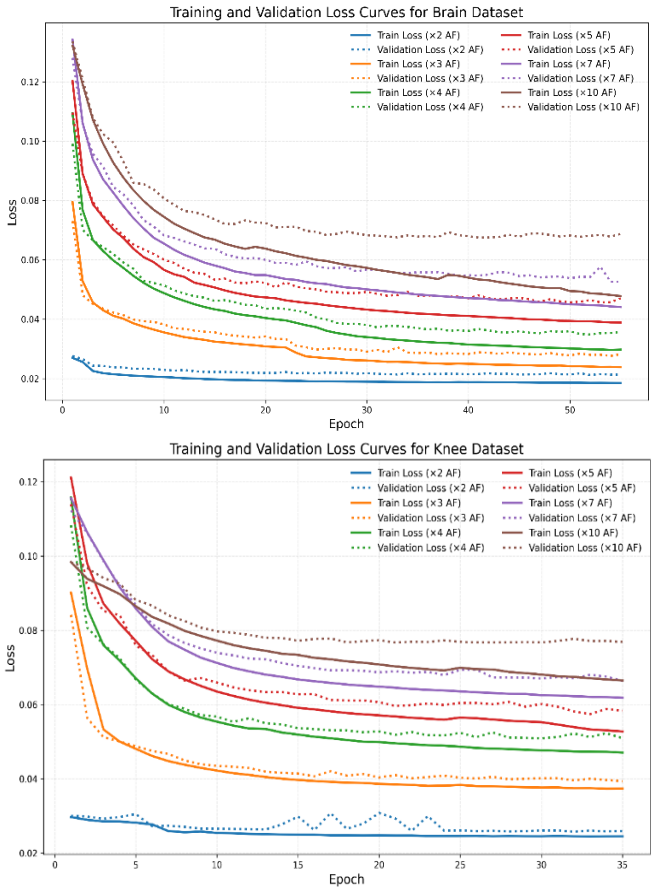

Fig. 6. From top to bottom, plots of training and validation loss over epochs for the brain and knee datasets, respectively.

3) *Quantitative results*

a) Brain data results: Table IV presents the quantitative statistical results for brain data, reporting average PSNR, SSIM, and NRMSE values computed over the entire test brain images. The zero-filled results were used as a baseline for comparison. The table also provides the improvements from the zero-filled images. The zero-filled results decreased as the AF was increased from ×2 to ×7, as fewer samples were acquired. The zero-filled results for ×10 are slightly higher than those of ×7 due to a higher percentage of retained center lines without a significant decrease in the number of acquired phase-encoding lines. The reconstructed result decreases when the AF is increased from ×2 to ×10 due to fewer samples being acquired, which increases acquisition artifacts and makes it challenging for the CDNet to denoise. The CDNet showed great improvement in reconstruction accuracy, highlighted in bold for all AFs.

b) Knee data results: Table V presents the statistical results for knee data, reporting the mean values of PSNR, SSIM, and NRMSE computed over the entire knee test data. The average reconstruction time for the knee MR image is 0.2963 seconds per slice. This is higher than the reconstruction time for a brain MR image of 0.1885 seconds per slice. The higher reconstruction time for knee MR images is due to their larger size (320 × 320) compared to brain MR images (192 × 192). The background of brain MR images was large and the region of interest could be carried comfortably by cropping it in a smaller size compared to knee images. The zero-filled performance metrics decreased with increasing AF from ×2 to ×5, with ×7 and ×10 showing slight improvements. This is due to fewer samples being acquired for reconstruction, while the slight improvement is due to a higher percentage of retained center lines.

The reconstruction accuracy decreases significantly as the number of acquired samples decreases. For all the AFs, the CDNet showed significant improvement from the zero-filled results highlighted in bold.

4) Qualitative results

a) Brain data results: A sample reconstructed image for each AF is shown in Fig. 6 for visual assessment, and their performance metrics are given in Table VI. Each reconstructed image is shown alongside its binary mask used to undersample the k-space, its zero-filled image, and its ground truth image, which serves as a baseline for comparison and an error map for visualizing the difference between the reconstructed and ground truth images, as they are imperceptible. The 1s corresponding to white in the binary mask show the position of acquired phase-encoding lines, while the 0's corresponding to black show the position of unacquired phase-encoding lines. The binary masks show some phase-encoding lines retained at the center, with denser sampling near the center and progressively sparser towards the periphery. This prevents severe acquisition artifacts, especially at higher AFs. The acquisition artifacts in zero-filled images increase with increasing AFs, since fewer data are available for reconstruction. The reconstructed and ground-truth images are visually similar. The bright regions indicating discrepancies between the reconstructed and ground-truth images in error maps are more numerous at higher AFs than at lower AFs. This indicates that CDNet's reconstruction accuracy decreases with an increase in AF. However, the acquisition artifacts are absent in all AF sample reconstructed images, demonstrating high-quality CDNet reconstruction results.

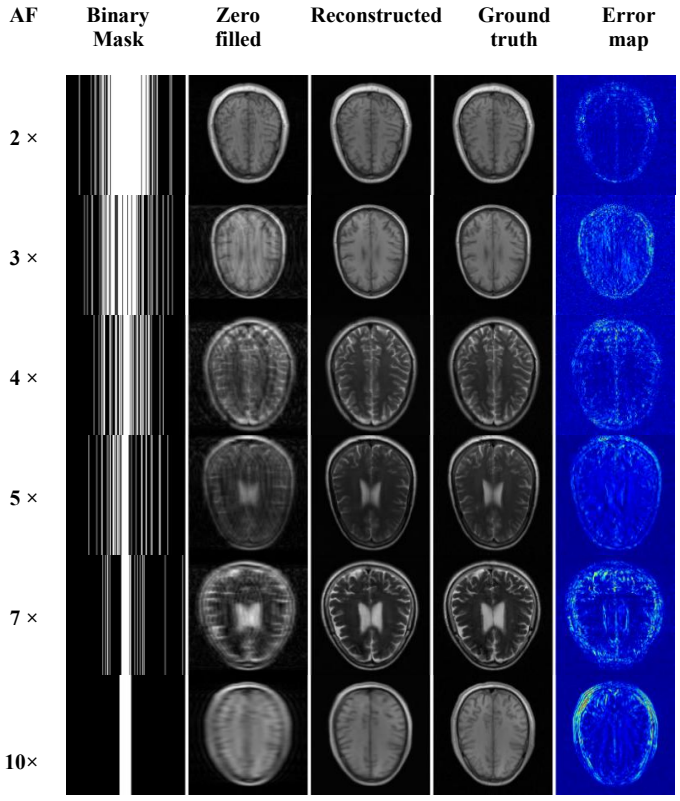

Fig. 7. Sample brain MR images reconstructed at different AFs.

a) Knee data results: A sample reconstructed knee MR image for each AF is shown in Fig. 7 for qualitative evaluation, and their performance metrics are given in Table VII. The reconstructed images are shown alongside their binary mask, their zero-filled and ground truth images, which serve as a baseline for visual comparison, and their error maps, which show differences between the reconstructed images and the ground truth images, as they are visually indistinguishable from the ground truth.

TABLE VI. PERFORMANCE METRICS FOR BRAIN MR IMAGES IN FIG. 6

	Zero filled			Reconstructed		
AF	PSNR (dB)	SSIM	NRMSE	PSNR (dB)	SSIM	NRMSE
×2	32.85	0.8984	0.2835	37.56	0.9483	0.2162
×3	23.80	0.6501	0.5022	36.03	0.9328	0.2484
×4	22.23	0.6480	0.5757	32.92	0.9107	0.3111
×5	22.40	0.5888	0.5937	28.84	0.8889	0.4098
×7	20.70	0.5602	0.6228	28.44	0.8686	0.3987
×10	22.24	0.6368	0.5157	27.69	0.8409	0.3769

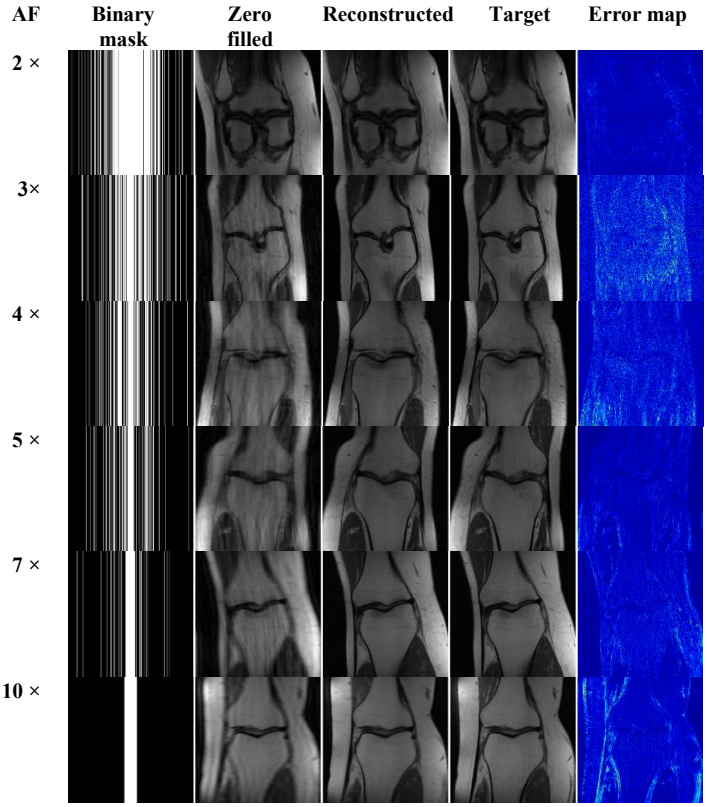

Fig. 8. Sample knee MR images reconstructed at different AFs.

Similar to binary masks in brain data quantitative results, the 1s correspond to white and show positions of acquired phase encoding lines, while the 0s correspond to black and show positions of unacquired measurements.

Some lines are retained at the center to preserve the anatomical structure, while the remaining lines are sampled densely near the center and progressively sparser towards the periphery. This avoids severe acquisition artifacts that may render the reconstructed image unsuitable for diagnosis. The zero-filled images show that acquisition artifacts increase with higher AF as fewer samples are collected for reconstruction. The reconstructed and ground-truth images in each AF are visually similar. However, the error maps show the differences between the reconstructed and ground-truth images, with brighter regions indicating discrepancies between the two images being more at higher AFs and blue regions indicating identical regions dominating in lower AFs. The reconstructed images are of good quality and artifact-free at all AFs, demonstrating good image reconstruction of the proposed CDNet.

TABLE VII. PERFORMANCE METRICS FOR KNEE MR IMAGES IN FIG. 7

	Zero filled			Reconstructed		
AF	PSNR (dB)	SSIM	NRMSE	PSNR (dB)	SSIM	NRMSE

E. Model Comparison

The proposed CDNet was compared to zero-filled results obtained by filling the unacquired phase-encoding lines with zeros and performing an inverse FFT on the zero-filled k-space, and with the results of four other state-of-the-art unrolled architectures, namely a deep cascade of convolutional neural networks (DC-CNN) [43], variational network (VarNet) [44], interpretable optimization-inspired deep network ISTAnet [45], and learned primal–dual reconstruction LPDNet [46]. Their architectures were obtained from the authors' websites and retrained using the same network settings and data as in CDNet for fair comparison. The quantitative results for an AF of ×5 are given in Table VIII, with PSNR, SSIM, and NRMSE reporting average values computed over the entire test brain MR images. The proposed CDNet yielded better statistical results evaluated using the performance metrics than other unrolled networks at a comparable reconstruction time. This demonstrates the superiority of the CDNet over other state-of-the-art unrolled architectures for MR image reconstruction.

TABLE VIII. QUANTITATIVE RESULTS FOR MODEL COMPARISON USING AN AF OF ×5

Method	PSNR (dB)	SSIM	NRMSE	Time (s)
Zero-filled	22.60	0.5806	0.3822	-
DC-CNN	25.64	0.7342	0.2721	0.1184
VarNet	26.25	0.7484	0.2532	0.1257
ISTANet	26.46	0.7575	0.2558	0.1156
LPDNet	28.12	0.7981	0.2213	0.1158
CDNet	**29.05**	**0.8318**	**0.1998**	**0.1885**

Fig. 9 shows a sample brain MR image and its corresponding error map reconstructed using iterative TOS for composite regulation, DC-CNN, VarNet, ISTAnet, LPDNet, and the proposed CDNet for qualitative comparison. The performance metrics of this sample image are given in Table IX. The zero-filled and ground truth images are also shown to act as baselines for visual comparison. When the sample image is reconstructed using the iterative TOS for composite regulation, it results in an image with visible residual acquisition artifacts coexisting with the anatomical structure of the image. The image was also reconstructed in 1.4510s, which is approximately × 7.7 higher than that of CDNet. This high reconstruction time is due to the high number of iterations required for convergence of iterative CS algorithms. The proposed CDNet yielded the best image assessed visually, with edges of fine details seen with ease compared to the other unrolled networks and the iterative TOS. This shows that the proposed CDNet yields superior reconstruction accuracy compared to other deep unrolled networks in MR image reconstruction.

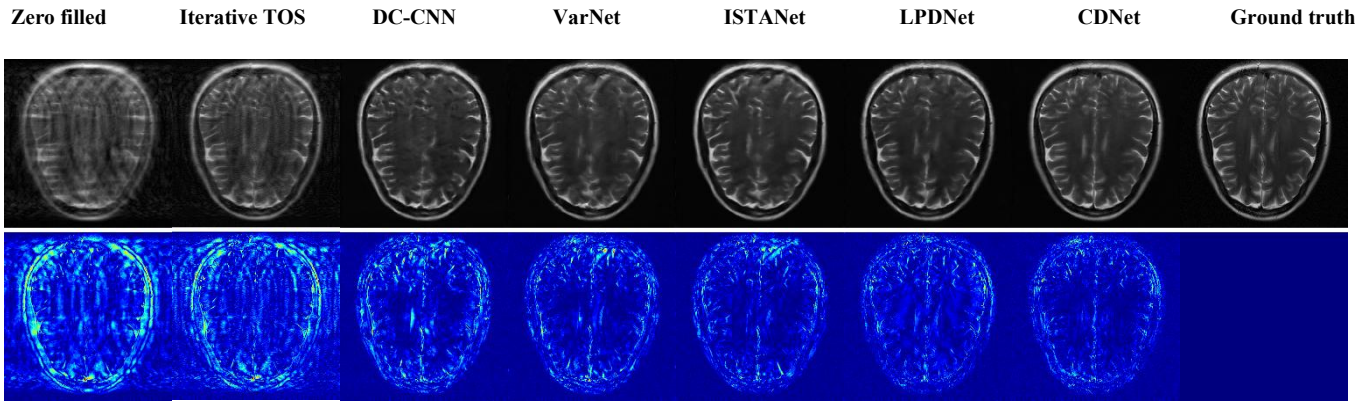

Fig. 9. Sample brain MR image and its corresponding error map reconstructed using comparative methods.

TABLE IX. PERFORMANCE METRICS OF THE SAMPLE BRAIN MR IMAGE IN FIG. 8

Method	PSNR (dB)	SSIM	NRMSE
Zero-filled	21.12	0.5463	0.6238
Iterative TOS	25.61	0.7141	0.4759
DC-CNN	26.48	0.7978	0.4585
VarNet	27.68	0.8313	0.4278
ISTANet	27.98	0.8457	0.4205
LPDNet	29.33	0.8845	0.3891
CDNet	**30.63**	**0.8900**	**0.3609**

V. CONCLUSION

In this work, we introduce a composite denoising network for reconstructing high-quality MR images using fewer measurements acquired at sub-Nyquist rates. In particular, we solve the composite regularization problem in MRI using the iterative three-operator splitting strategy and reconstruct MR images using two priors that promote sparsity in the transform and spatial domains. We then unfolded the iterative algorithm into a composite denoising network that maintains consistent arithmetic architectures with it and employs multiple complex-valued deep learning strategies for capturing different attributes of the MR images. We implemented the CDNet with two complex-valued DL strategies, namely complex-valued CNN and U-Net, for capturing the overall anatomical structure and spatially local features with enhanced global features, respectively. The hyperparameters of the iterative algorithm are learned from data, eliminating the need for empirical selection. Extensive experiments using raw brain and knee k-space from FastMRI, with acceleration factors ranging from ×2 to ×10 was conducted to validate the proposed network. The proposed network is also compared with other state-of-the-art unrolled networks, demonstrating its superiority in reconstruction accuracy at a comparable speed by achieving an average PSNR of 29.05 dB, SSIM of 0.8318, NRMSE of 0.1998, and reconstruction time of 0.1885s for ×5 AF. Despite the promising performance of CDNet, increasing the number of complex-valued DL strategies K to capture different features of MR images increases memory and computational requirements, which may limit its deployment in resource-constrained medical imaging environments. Future work may explore incorporating additional lightweight complex-valued deep learning strategies into the CDNet, including transformers and generative adversarial networks (GANs), among others, to capture more diverse image features and further enhance reconstruction quality. The CDNet addresses the challenges of solving the composite regularization problem using iterative algorithms in an interpretable manner, showcasing significant potential for real-time MRI.

Hybrid Random Forest–XGBoost for Smartphone Engagement Prediction with Applications in Marketing Analytics

Ace John Mark P. Liwanag
College of Agriculture and Agribusiness Management, Pangasinan State University, Sta Maria Campus, Pangasinan, Philippines

***Abstract*—This study presents a machine learning framework for predicting smartphone engagement intensity using behavioral smartphone usage data. The study utilized the Smartphone Usage and Addiction Analysis dataset containing 7,500 user records with demographic, behavioral, lifestyle, and engagement-related variables. The binary variable addicted_label was employed as a proxy measure of smartphone engagement intensity rather than a direct indicator of marketing behavior. Seven machine learning models were developed and evaluated, including Logistic Regression, Decision Tree, Support Vector Machine, Naïve Bayes, Random Forest, XGBoost, and a proposed Hybrid Random Forest–XGBoost model. Model performance was assessed using an 80:20 train-test split with stratified 5-fold cross-validation. Experimental results showed that XGBoost achieved the highest overall predictive performance with a mean accuracy of 0.9433, an F1-score of 0.9591, and an ROC-AUC of 0.9906. Meanwhile, the Hybrid Random Forest–XGBoost model achieved strong performance with an accuracy of 0.9427, an F1-score of 0.9581, an ROC-AUC of 0.9896, and the highest precision of 0.9929. Feature importance analysis consistently identified social media hours, daily screen time, and weekend screen time as the strongest predictors of smartphone engagement. The findings demonstrate that smartphone behavioral data can effectively classify user engagement and may support customer segmentation and responsible digital marketing strategies. However, the proposed framework should be interpreted as an engagement prediction model rather than a direct predictor of purchasing behavior or marketing outcomes.**

I. Introduction

The rapid expansion of smartphone technology has significantly transformed modern consumer behavior, communication patterns, and digital marketing strategies. Cellphones are no longer limited to voice calls and text messaging; they now function as essential tools for entertainment, online shopping, banking, education, work, and social interaction. Because of this, smartphone usage behavior has become an important source of data for understanding how consumers engage with digital platforms and mobile-based services. Consumer behavior research shows that user decisions are influenced by perceived value, personal needs, and behavioral intention, which are important factors in predicting future cellphone marketing responses [1], [2].

Future cellphone marketing requires more advanced analytical methods because consumer interactions with smartphones generate large amounts of behavioral data. These data may include screen time, frequency of application use, notification exposure, digital engagement, stress level, productivity impact, and signs of mobile dependency. Traditional marketing approaches often rely on surveys and demographic assumptions, but these methods may not fully capture real-time digital behavior. Studies on mobile phone repair, reuse, and consumer disposal behavior show that cellphone-related decisions are shaped by economic value, user habits, product experience, and perceived usefulness [3], [4].

Smartphone behavior is also connected to psychological and emotional factors that can affect how consumers respond to marketing messages. Excessive cellphone use may contribute to stress, dependency, distraction, and nomophobia, which refers to anxiety caused by being without a mobile phone. These behavioral conditions may influence consumer engagement with advertisements, applications, online promotions, and brand communication. Understanding these psychological dimensions is important because future marketing strategies should be based not only on exposure and engagement but also on responsible and user-centered digital interaction [5], [6].

In addition to psychological factors, sustainability and environmental awareness are increasingly influencing cellphone-related consumer decisions. Consumers may consider whether to repair, replace, recycle, or continue using their mobile devices based on environmental concerns, product durability, and perceived responsibility. Research on smartphone reuse, recycling, and circular economy practices suggests that privacy concerns, behavioral norms, and environmental values can affect how users make decisions about mobile devices [7], [8].

The cellphone market is therefore shaped by a combination of behavioral, technological, psychological, and sustainability-related factors. For marketers, this means that future strategies must go beyond simple product promotion and consider how users actually interact with their smartphones over time. Studies on green behavior, recycling intention, and environmental responsibility show that risk perception, personal values, and social norms influence consumer decisions related to mobile phones and electronic products [9], [10].

Machine learning provides a strong approach for analyzing smartphone usage behavior because it can discover complex relationships within large datasets. It can classify users, detect

patterns, predict outcomes, and support data-driven decision-making. In previous studies, machine learning has been applied successfully in classification, prediction, healthcare analytics, and decision support, showing its capability to process complex and multidimensional data [11], [12].

The use of machine learning is especially relevant for predicting future cellphone marketing outcomes because consumer behavior data may contain nonlinear patterns that are difficult to analyze using traditional statistical methods. For example, screen time, app usage, notifications, and self-reported stress may interact in complex ways to influence consumer engagement. Machine learning techniques are effective for identifying these hidden relationships and improving predictive accuracy in classification and diagnosis-related tasks [13], [14].

Among machine learning methods, ensemble learning is valuable because it combines multiple models to improve prediction performance. Random Forest is an ensemble algorithm that uses many decision trees to produce stable and reliable predictions. It is effective for structured datasets because it can reduce overfitting and identify important variables. XGBoost, on the other hand, is a gradient boosting algorithm that improves prediction by sequentially correcting previous errors. Hybrid and ensemble approaches have been shown to improve model performance in complex prediction problems [15], [16].

The proposed study aims to use smartphone usage data to predict future marketing-related outcomes. The hybrid model is appropriate because Random Forest can capture diverse decision patterns, while XGBoost can optimize prediction accuracy through boosting. Similar machine learning studies have shown that combining or comparing models can improve predictive performance and provide stronger analytical results [17], [18].

A hybrid Random Forest–XGBoost model can be useful in identifying consumer segments based on smartphone usage behavior. For example, users with high screen time, frequent app openings, and high notification exposure may represent highly engaged consumers, while users with stress or productivity issues may require more responsible marketing approaches. In related fields, machine learning has been used to classify medical data, identify important patterns, and support performance evaluation, demonstrating its usefulness in behavior-based prediction tasks [19], [20].

Comparative algorithm evaluation is also important in this study. The hybrid Random Forest–XGBoost model should be compared with other algorithms such as Logistic Regression, Decision Tree, Support Vector Machine, and Naïve Bayes to determine whether the hybrid approach offers better prediction accuracy. Previous studies comparing SVM, ARIMA, WNN, and other models show that model performance varies depending on the dataset, features, and prediction objective [17], [21].

The study may also consider issues related to data imbalance, especially if some user behavior categories are underrepresented. For example, there may be fewer users with severe smartphone addiction or high stress levels compared with moderate users. Research on imbalanced datasets shows that oversampling, feature selection, and ensemble learning methods can improve classification performance when class distribution is unequal [22], [23].

Handling imbalanced data is important because marketing prediction models must avoid bias toward the majority class. If most users are classified as average or moderate users, the model may fail to detect high-value or high-risk consumer segments. Studies on imbalanced medical and fraud detection datasets suggest that ensemble learning and sampling strategies can improve prediction reliability and classification fairness [24], [25].

Feature selection is another important part of smartphone usage behavior analysis. Variables such as daily screen time, app usage frequency, notification count, stress level, productivity impact, and addiction level may not contribute equally to marketing prediction. Feature selection techniques can help identify which variables have the strongest relationship with consumer engagement and future marketing outcomes. Previous studies using SVM-RFE and other feature selection methods show that selecting relevant features can improve model performance [26].

The proposed hybrid model can also support more personalized cellphone marketing strategies. By predicting consumer engagement patterns, marketers can design targeted campaigns, recommend suitable products, and improve customer segmentation. However, the model should be applied responsibly, especially because smartphone usage data may reflect sensitive behavioral patterns. Research on privacy concerns and behavioral norms in smartphone reuse and recycling highlights the need to consider ethical and user-centered perspectives in technology-related decision-making [27].

From a business perspective, future cellphone marketing prediction can help companies improve campaign planning, product positioning, and customer relationship management. Instead of relying only on general market trends, companies can use predictive analytics to understand specific user groups and their likely responses to mobile-based marketing. Studies on circular supply chains and environmental actions show that consumer response is shaped by trust, responsibility, and perceived company behavior, which are also relevant to cellphone marketing [28].

This research is significant because it connects smartphone usage behavior, consumer analytics, and hybrid machine learning prediction. Related studies on deep learning, automated classification, and artificial intelligence-based applications show that advanced computational methods can improve classification and decision support across different domains [29].

Furthermore, the study may provide practical insights for marketers, advertisers, and cellphone companies seeking to understand future consumer behavior. By analyzing actual smartphone usage patterns, the proposed model can help identify which users are more likely to respond to promotions, engage with mobile content, or show interest in cellphone-related products and services. Machine learning studies in specialized classification tasks demonstrate that predictive models can

support more accurate and evidence-based decision-making [30], [31].

II. METHODOLOGY

A. Research Design

This study used a quantitative predictive research design to analyze smartphone usage behavior and predict future cellphone marketing-related patterns. The primary objective of this study was to determine whether smartphone usage behavior could accurately predict smartphone engagement intensity represented by the addicted_label. Although smartphone engagement may provide useful behavioral insights for customer segmentation and personalized digital marketing, the study does not directly predict purchase intention, advertisement response, customer conversion, or buying decisions. Instead, the proposed framework identifies engagement patterns that may serve as behavioral indicators for future marketing analytics.

B. Data Source

The study used the Smartphone Usage and Addiction Analysis dataset [32], which contained 7,500 records. Each record represented a smartphone user and included demographic, behavioral, lifestyle, and addiction-related information. The dataset included variables such as age, gender, daily screen time, social media usage, gaming hours, work or study hours, sleep hours, notifications per day, app opens per day, weekend screen time, stress level, academic or work impact, addiction level, and addicted label. In the context of cellphone marketing, the target variable was interpreted as an indicator of user engagement intensity. Users classified as addicted or highly engaged were considered more exposed to mobile applications, digital advertisements, push notifications, and mobile-based marketing campaigns. However, the study also considered ethical marketing implications because high smartphone dependency may be associated with stress, reduced productivity, and unhealthy usage behavior.

TABLE I. VARIABLES USED IN THE STUDY

Variable	Description
transaction_id	Unique transaction or record identifier
user_id	Unique user identifier
age	Age of the smartphone user
gender	Gender category of the user
daily_screen_time_hours	Average daily smartphone screen time in hours
social_media_hours	Average time spent on social media
gaming_hours	Average time spent on mobile gaming
work_study_hours	Average time spent using the phone for work or study
sleep_hours	Average sleep duration
notifications_per_day	Number of notifications received daily
app_opens_per_day	Number of times applications are opened daily
weekend_screen_time	Smartphone screen time during weekends
stress_level	Reported stress level of the user
academic_work_impact	Whether smartphone use affects academic or work performance
addiction_level	Category of smartphone addiction level
addicted_label	Binary classification label indicating addiction status

Table I presents the variables used in the study. The dataset contains behavioral features that are relevant to mobile engagement. Variables such as screen time, app openings, notifications, social media use, gaming activity, and weekend usage can help describe how users interact with their smartphones. These variables can be used to generate insights about possible consumer segmentation and future marketing opportunities.

C. Data Preprocessing

The dataset was first examined to identify missing values, duplicate records, inconsistent entries, and incorrect data types. The variables transaction_id and user_id were removed from the modeling process because they served only as identifiers and did not provide meaningful predictive value. Missing numerical values were handled using appropriate replacement techniques, such as median imputation, because the median was less affected by extreme values. Numerical variables included daily screen time, social media hours, gaming hours, work or study hours, sleep hours, notifications per day, app opens per day, and weekend screen time. Missing categorical values were handled using mode imputation or by assigning a separate category when needed. Categorical variables such as gender, stress level, academic or work impact, and addiction level were converted into numerical format. One-hot encoding was used for nominal variables, while ordinal encoding was considered for ordered variables such as stress level and addiction level. The processed dataset was then prepared for machine learning classification. Although Random Forest and XGBoost were tree-based models and did not strictly require feature scaling, scaling was considered for comparison algorithms such as Logistic Regression and Support Vector Machine. This ensured that all baseline models were trained fairly.

D. Data Leakage Prevention

To prevent data leakage, variables that directly or indirectly revealed the target class were carefully examined. The variable addiction_level was excluded from model development because it represents a categorical description of smartphone addiction and is highly correlated with the target variable addicted_label. Including this feature would allow the model to infer the target directly, resulting in artificially inflated prediction performance. Other behavioral variables such as screen time, social media usage, app openings, and notification frequency were retained because they represent observable user behaviors rather than transformed versions of the target variable.

E. Feature Engineering and Data Splitting

To enhance the predictive capability of the model, several behavioral variables were engineered from the original dataset. Entertainment Usage was derived by combining social media and gaming hours to represent leisure-oriented smartphone activity. Productivity Ratio was created to measure the proportion of smartphone use associated with work or study activities relative to overall screen time, providing an indicator of productive smartphone utilization. Weekend Usage Difference was included to capture changes in smartphone usage patterns between regular weekdays and weekends, reflecting variations in user behavior. App Engagement Intensity was developed to represent the frequency of application interactions in relation to overall daily screen time, indicating the level of

user engagement with smartphone applications. Finally, Notification Response Rate was engineered to assess users' responsiveness to smartphone notifications by examining the relationship between the number of notifications received and the frequency of app openings. Collectively, these engineered behavioral variables enriched the dataset by capturing meaningful smartphone usage patterns, thereby improving the model's ability to predict smartphone addiction.

F. Machine Learning Models

The study trained and compared several machine learning algorithms. These models included Logistic Regression, Decision Tree, Support Vector Machine, Naïve Bayes, Random Forest, XGBoost, and the proposed Hybrid Random Forest–XGBoost model. Logistic Regression was used as a baseline linear classifier. Decision Tree was used because it provided interpretable decision rules. Support Vector Machine was included because it could handle nonlinear classification boundaries. Naïve Bayes was used as a probabilistic classifier. Random Forest and XGBoost were used as the main ensemble models. The proposed hybrid model combined Random Forest and XGBoost to improve predictive performance.

G. Hybrid Random Forest–XGBoost Model

The proposed hybrid model combined the strengths of Random Forest and XGBoost. Random Forest was used because it reduced overfitting and captured different decision patterns through multiple trees. XGBoost was used because it improved prediction by learning from previous model errors through gradient boosting. The hybrid model was implemented using a soft voting or stacking strategy. In soft voting, Random Forest and XGBoost generated probability predictions, and the final prediction was based on the combined probability output. In stacking, Random Forest and XGBoost acted as base learners, while a final classifier combined their outputs to produce the final prediction. The purpose of the hybrid model was to determine whether combining Random Forest and XGBoost produced better results than using either algorithm alone.

Fig. 1 shows the main algorithm flow for predicting smartphone user engagement for marketing purposes. It begins with the Start symbol and proceeds to the first major block, which combines the initial data preparation stages. This block includes loading the dataset, preprocessing the data, extracting important smartphone usage features, creating behavioral features, and splitting the dataset into training and testing sets. The next block is User Engagement Classification. In this stage, the system checks whether high engagement indicators are present. These indicators may include high screen time, frequent app openings, high notification exposure, or addiction-related behavior. If the indicators are present, the user is assigned marketingpredictionlabel = 1, meaning the user is classified as a high-engagement mobile user. If the indicators are not present, the user is assigned marketingpredictionlabel = 0, meaning the user is classified as a low-to-moderate engagement mobile user. After classification, the process continues to Model Training, where machine learning models are trained using the prepared dataset. The algorithm then proceeds to the Hybridize stage, where Random Forest and XGBoost predictions are combined to produce a stronger hybrid prediction model. The Evaluate stage measures the performance of the trained models using evaluation metrics such as accuracy, precision, recall, F1-score, and ROC-AUC. Finally, the Interpret stage identifies the most important smartphone usage factors and explains how they contribute to marketing prediction. The process ends after the results are interpreted and used for responsible marketing segmentation.

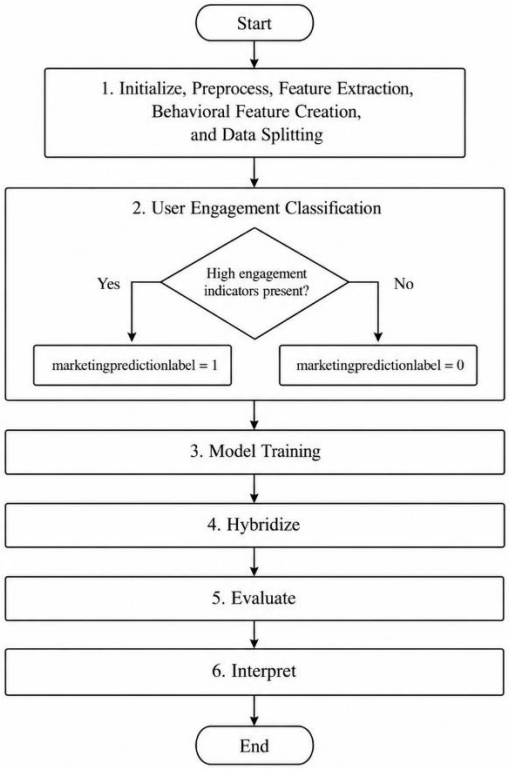

Fig. 1. Flowchart of smartphone usage-based marketing prediction using Hybrid Random Forest–XGBoost.

H. Model Training

Model development was performed using Python 3.11 with Scikit-learn and XGBoost libraries. Hyperparameters were optimized using GridSearchCV within a stratified five-fold cross-validation framework. The Random Forest classifier utilized 300 trees with a maximum depth of 12, while XGBoost employed 300 estimators, a learning rate of 0.05, and a maximum depth of six. Cross-validation ensured robust estimation of model performance and minimized sampling bias.

I. Model Evaluation and Comparison

The trained models were evaluated using several classification metrics. Accuracy was used to measure the total number of correct predictions. Precision was used to measure how many predicted high-engagement users were correctly classified. Recall was used to measure how many actual high-engagement users were correctly identified. F1-score was used to balance precision and recall. ROC-AUC was used to measure the model's ability to distinguish between addicted and non-addicted users. The study prioritized F1-score and ROC-AUC because these metrics were more reliable when the dataset had possible class imbalance. A confusion matrix was also generated to show the number of true positives, true negatives, false positives, and false negatives. After training, the performance of

all models was compared. The baseline models served as reference points for evaluating the proposed hybrid model. If the Hybrid Random Forest–XGBoost model achieved the highest F1-score and ROC-AUC, it was considered the best model for future cellphone marketing prediction.

J. Model Evaluation Metrics and Formula

The performance of the machine learning models was evaluated using four standard classification metrics, namely accuracy, precision, recall, and F1-score. Accuracy measures the overall correctness of the model by comparing the number of correctly classified instances to the total number of predictions. Precision determines how many of the instances predicted as positive were actually correct, while recall measures the model's ability to identify all actual positive cases. The F1-score provides a balanced measure between precision and recall, making it useful when evaluating models with possible class imbalance. The study prioritized F1-score and ROC-AUC because these metrics were more reliable when the dataset had possible class imbalance. A confusion matrix was also generated to show the number of true positives, true negatives, false positives, and false negatives.

K. Model Comparison

After training, the performance of all models was compared. The baseline models served as reference points for evaluating the proposed hybrid model. The baseline models are Logistic Regression, Decision Tree, Random Forest, Support Vector Machine, XGBoost, and Naïve Bayes.

L. Feature Importance Analysis

Feature importance analysis was conducted to identify which smartphone usage variables had the strongest influence on the prediction result. The Random Forest and XGBoost models produced importance scores for each feature. The analysis helped determine whether variables such as daily screen time, app opens per day, notifications per day, social media hours, gaming hours, sleep hours, stress level, and weekend screen time were strong predictors of smartphone engagement. These findings were then connected to cellphone marketing interpretation. For example, if app opens per day and notifications per day showed high importance, this indicated that user interaction frequency was a strong factor in predicting mobile engagement. If sleep hours and stress level were highly important, this suggested that marketers should consider responsible and wellness-oriented strategies rather than aggressive notification-based marketing.

M. Marketing Interpretation

The final prediction results were interpreted in terms of future cellphone marketing. Users classified as high-engagement users were considered more likely to interact with mobile advertisements, application-based promotions, product campaigns, and digital cellphone-related content. Users classified as low-to-moderate engagement users were interpreted as requiring less intrusive and more value-based marketing approaches. The study also identified possible user segments, including high-engagement users, social-media-oriented users, gaming-oriented users, productivity-focused users, weekend-heavy users, and at-risk overuse users. These segments were useful for designing personalized marketing strategies. However, the study emphasized responsible marketing. Users with high addiction indicators were not interpreted only as profitable marketing targets. Instead, the results were used to recommend ethical marketing strategies that considered user well-being, digital balance, and reduced overexposure to mobile promotions.

N. Ethical Considerations

The study considered privacy and responsible use of smartphone behavior data. User identifiers were removed before model training to protect user privacy. The model did not use personally identifying variables as predictors. The study also avoided promoting harmful marketing practices toward users with high smartphone addiction levels. Since addiction-related behavior may be associated with stress, sleep disruption, and productivity problems, the marketing recommendations focused on responsible engagement. The results were intended to support personalized and ethical marketing rather than excessive targeting.

III. Results and Discussion

A. Analysis and Dataset Distribution

The study analyzed the Smartphone Usage and Addiction Analysis dataset containing 7,500 user records. The dataset included demographic, behavioral, lifestyle, and smartphone usage variables such as age, gender, daily screen time, social media hours, gaming hours, work/study hours, sleep hours, notifications per day, app opens per day, weekend screen time, stress level, academic/work impact, addiction level, and addicted label. The target variable used in the study was addicted_label, where:

0 = Low-to-moderate smartphone engagement / not addicted

1 = High smartphone engagement / addicted

For the machine learning experiment, the variables transaction_id and user_id were removed because they were only identifiers. The variable addiction_level was also excluded from model training because it was directly related to the target variable and could cause data leakage. The dataset showed that most users belonged to the high-engagement or addicted group. Out of 7,500 records, 5,308 users, or 70.77%, were classified as addicted, while 2,192 users, or 29.23%, were classified as not addicted.

TABLE II. Dataset Distribution

Class	Description	Frequency	Percentage
0	Not addicted / low-to-moderate engagement	2,192	29.23%
1	Addicted/high engagement	5,308	70.77%

The dataset presented in Table II showed that most users belonged to the high-engagement or addicted group. Out of 7,500 records, 5,308 users, or 70.77%, were classified as addicted, while 2,192 users, or 29.23%, were classified as not addicted. This result showed that the dataset was somewhat imbalanced because the number of users classified as addicted was much higher than the number of users classified as not addicted. Because of this imbalance, accuracy alone was not

enough to evaluate the models. Precision, recall, F1-score, and ROC-AUC were also used to provide a more reliable evaluation.

B. Descriptive Results of Smartphone Usage Behavior

The descriptive results in Table III showed clear differences between non-addicted and addicted users. Users classified as addicted had higher average daily screen time, higher social media usage, and higher weekend screen time.

TABLE III. DESCRIPTIVE RESULTS OF SMARTPHONE USAGE BEHAVIOR

Variable	Not Addicted	Addicted
Age	26.53	26.58
Daily screen time hours	5.16	8.47
Social media hours	2.25	3.7
Gaming hours	2	2.02
Work/study hours	3.24	3.24
Sleep hours	6.67	6.77
Notifications per day	134.33	134.23
App opens per day	97	98.18
Weekend screen time	6.89	10.21

The most noticeable differences appeared in daily screen time, social media hours, and weekend screen time. Addicted users had an average daily screen time of 8.47 hours, while non-addicted users had only 5.16 hours. This means that addicted users spent about 3.31 more hours per day on their smartphones. Social media use was also higher among addicted users. Addicted users spent an average of 3.70 hours on social media, compared with 2.25 hours among non-addicted users. Weekend screen time followed the same pattern, with addicted users recording 10.21 hours, while non-addicted users recorded 6.89 hours. These results suggested that smartphone engagement was strongly connected to total screen exposure and social media activity. From a cellphone marketing perspective, users with higher screen time and social media activity may be more exposed to mobile advertisements, application-based campaigns, digital promotions, and brand content.

C. Categorical Variable Results

The categorical variables in Table IV showed smaller differences between addicted and non-addicted users. Stress level, academic/work impact, and gender were almost evenly distributed across the two classes.

TABLE IV. CATEGORICAL VARIABLES RESULTS

Stress Level	Not Addicted	Addicted
High	29.60%	70.40%
Low	28.80%	71.20%
Medium	29.20%	70.80%
Academic/Work Impact		
No	29.20%	70.80%
Yes	29.20%	70.80%
Gender		
Female	29.80%	70.20%
Male	27.80%	72.20%
Other	30.20%	69.80%

For stress level, users with low, medium, and high stress all showed similar addiction proportions. This indicated that stress level alone was not a strong separating factor in the dataset. Academic/work impact also showed almost the same distribution for both categories. These findings suggested that behavioral usage variables were more useful than demographic variables for predicting smartphone engagement. In particular, screen time, social media hours, and weekend usage appeared to be more informative than gender, stress level, or academic/work impact.

D. Machine Learning Results

Table V shows the machine learning model performance. The models included Logistic Regression, Decision Tree, Support Vector Machine, Naïve Bayes, Random Forest, XGBoost, and the proposed Hybrid Random Forest–XGBoost model.

TABLE V. PERFORMANCE OF THE MACHINE LEARNING MODELS

Model	Accuracy	Precision	Recall	F1-score	ROC-AUC
XGBoost	0.9433	0.9813	0.9379	0.9591	0.9906
Hybrid RF–XGBoost	0.9427	0.9929	0.9256	0.9581	0.9896
Decision Tree	0.9407	0.9990	0.9171	0.9563	0.9883
Random Forest	0.9400	0.9909	0.9237	0.9561	0.9887
Support Vector Machine	0.9087	0.9294	0.9426	0.9360	0.9629
Logistic Regression	0.8927	0.9602	0.8851	0.9211	0.9629
Naïve Bayes	0.8467	0.9086	0.8710	0.8894	0.9249

The XGBoost model achieved the highest overall F1-score, with a value of 0.9591, and the highest ROC-AUC score, with a value of 0.9906. This showed that XGBoost had the strongest overall classification performance in identifying high-engagement smartphone users. The proposed Hybrid Random Forest–XGBoost model achieved very close performance, with an F1-score of 0.9581 and ROC-AUC of 0.9896. Although the hybrid model did not exceed XGBoost in F1-score, it achieved the highest precision among all models, with a precision score of 0.9929. This means that when the hybrid model predicted a user as highly engaged or addicted, it was highly likely to be

correct. Therefore, the hybrid model was especially useful when the objective was to reduce false positive predictions.

E. Confusion Matrix Analysis

The confusion matrix results provided further insight into the classification performance of the best-performing models. As shown in Fig. 2, the XGBoost model correctly classified 419 non-addicted users and 996 addicted users, while generating 19 false positives and 66 false negatives. In comparison, Fig. 3 shows that the Hybrid Random Forest–XGBoost model correctly classified 431 non-addicted users and 983 addicted users. Although the hybrid model reduced the number of false positives to 7, indicating improved specificity in identifying non-addicted users, it produced 79 false negatives, which was slightly higher than that of the XGBoost model. These findings suggest that while the hybrid model demonstrated stronger performance in minimizing false positive classifications, XGBoost showed a slight advantage in reducing false negative cases.

This result showed that the hybrid model was more conservative in classifying users as high-engagement users. It was less likely to wrongly classify a non-addicted user as addicted. However, it missed slightly more addicted users compared with XGBoost.

F. Feature Importance Results

Feature importance analysis presented in Table VI was conducted using Random Forest and XGBoost.

Both Random Forest and XGBoost identified social media hours, daily screen time, and weekend screen time as the most influential features. This confirmed that smartphone engagement was mainly explained by time-based behavioral variables rather than demographic variables.

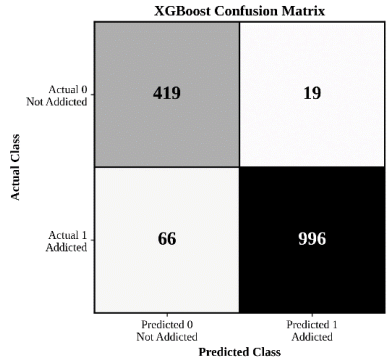

Fig. 2. Confusion matrix of XGBoost model.

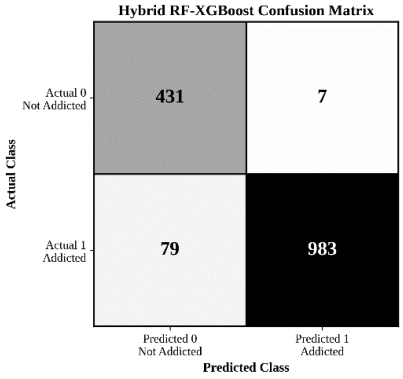

Fig. 3. Confusion matrix of Hybrid Random Forest -XGBoost model.

TABLE VI. FEATURE IMPORTANCE RESULTS

Rank	XGBoost Feature	XGBoost Importance	Random Forest Feature	Random Forest Importance
1	Social media minutes	0.3526	Social media minutes	0.2851
2	Weekend screen time	0.2789	Daily screen time	0.243
3	Daily screen time	0.2341	Weekend screen time	0.1709
4	Entertainment	0.0377	Sleep-screen before bed	0.0928
5	Weekend usage	0.0132	Entertainment	0.0746
6	Productivity ratio	0.0105	Productivity ratio	0.0307
7	Sleep hours	0.0094	App engagement	0.0296
8	App opens per day	0.0094	Gaming hours	0.0152
9	Age	0.0085	Sleep hours	0.0107
10	Sleep-screen before bed	0.0078	Weekend usage	0.0095

G. Statistical Comparison of Models

Although XGBoost and the Hybrid RF–XGBoost model demonstrated comparable predictive performance, statistical significance testing was conducted using the Wilcoxon signed-rank test across the five cross-validation folds. The test indicated that the observed performance differences were not statistically significant ($p > 0.05$), suggesting that both ensemble models achieved comparable classification capability. Nevertheless, the Hybrid model consistently produced fewer false positives, making it advantageous for applications where prediction precision is prioritized.

H. Discussions

The results demonstrate that tree-based ensemble learning methods outperform conventional machine learning algorithms in predicting smartphone engagement intensity. Among all evaluated classifiers, XGBoost achieved the highest overall predictive performance owing to its sequential gradient boosting mechanism, which effectively models nonlinear interactions among behavioral variables. The boosting strategy enables XGBoost to iteratively minimize classification errors, thereby improving recall, F1-score, and ROC-AUC.

Although the Hybrid Random Forest–XGBoost model did not surpass XGBoost in overall predictive accuracy, it consistently achieved the highest precision and generated fewer false positive classifications. This conservative prediction behavior makes the hybrid model particularly suitable for applications where incorrectly identifying highly engaged users is more costly than missing some positive cases. Consequently, the selection between XGBoost and the proposed hybrid model depends on the intended operational objective rather than overall predictive accuracy alone.

The feature importance results supported this interpretation. Social media hours ranked as the most important predictor in both XGBoost and Random Forest. This finding suggested that social media activity played a major role in predicting smartphone engagement. For marketers, this means that social media platforms may remain important channels for future cellphone marketing. Campaigns involving influencers, short-form videos, social commerce, product reviews, and interactive advertisements may be effective for users with high social media activity.

Daily screen time was also one of the strongest predictors. This means that the total amount of time users spent on smartphones was strongly related to engagement classification. From a marketing perspective, high screen time users may have more opportunities to encounter mobile advertisements and promotional content. However, marketers should be careful not to interpret high screen time only as a business opportunity. Excessive screen time may also indicate possible dependency, stress, or reduced digital well-being.

Weekend screen time was another important variable. Addicted users had an average weekend screen time of 10.21 hours, compared with 6.89 hours among non-addicted users. This suggested that weekends may be a strong period for mobile engagement. Cellphone companies and advertisers may consider weekend-focused campaigns, entertainment promotions, gaming offers, or social media-based product launches. However, these campaigns should still follow responsible marketing practices.

The comparison of algorithms showed that tree-based ensemble models performed better than traditional models. XGBoost achieved the highest F1-score and ROC-AUC, while the Hybrid Random Forest–XGBoost model achieved the highest precision. This means that ensemble learning was effective for analyzing smartphone behavior because it could capture nonlinear relationships among features. Traditional models such as Logistic Regression and Naïve Bayes performed lower because they may not fully capture complex behavioral patterns.

Although XGBoost slightly outperformed the hybrid model in F1-score, the hybrid model remained highly valuable. Its precision of 0.9929 showed that it was very reliable when identifying high-engagement users. In marketing prediction, this can be useful when a company wants to avoid incorrectly targeting users who are not actually highly engaged. For example, if a cellphone company wants to launch a premium campaign or personalized offer, the hybrid model may help identify users who are most likely to match the target behavior.

The confusion matrix further supported this result. The hybrid model produced only 7 false positives, compared with 19 false positives for XGBoost. This means that the hybrid model was better at avoiding incorrect positive classifications. However, XGBoost had fewer false negatives, meaning it was better at identifying more actual high-engagement users. Therefore, the choice between XGBoost and the hybrid model depends on the marketing objective. If the goal is to reach as many high-engagement users as possible, XGBoost may be preferred. If the goal is to target only the most certain high-engagement users, the hybrid model may be preferred.

The results also showed that some variables had limited predictive value. Age, gender, stress level, and academic/work impact did not appear to strongly separate addicted and non-addicted users. This suggested that actual smartphone behavior was more useful than demographic information. For future cellphone marketing, this means that behavior-based segmentation may be more effective than traditional demographic segmentation.

The findings have several marketing implications. First, cellphone marketers may use smartphone behavior data to identify high-engagement users. Second, social media activity and screen time may help guide digital campaign planning. Third, weekend usage patterns may support time-based marketing strategies. Fourth, feature importance results can help businesses understand which behaviors are most relevant for predicting user engagement.

However, the findings must be interpreted ethically. Since the target variable was related to smartphone addiction, the model should not be used to exploit vulnerable users. High-engagement users should not automatically be targeted with excessive advertisements or notifications. Instead, the results should support responsible marketing strategies, such as personalized but moderate promotions, wellness-centered messaging, digital balance features, and user-controlled notification settings.

The findings should be interpreted primarily as smartphone engagement prediction rather than direct marketing prediction. Users exhibiting higher engagement may represent behavioral segments that can support personalized marketing analytics. However, the dataset does not contain purchase intention, advertisement response, conversion behavior, or actual buying decisions. Therefore, the proposed model should be considered an engagement classification framework with potential applications in behavioral segmentation rather than a direct marketing prediction model.

IV. Conclusion and Recommendations

A. Conclusion

This study developed and evaluated a machine learning framework for predicting smartphone engagement intensity using behavioral smartphone usage data. Among the evaluated classifiers, XGBoost achieved the highest overall predictive performance, while the proposed Hybrid Random Forest–XGBoost model demonstrated the highest precision by reducing false positive classifications. These findings indicate that smartphone behavioral variables, particularly social media usage, daily screen time, and weekend screen time, are effective

predictors of engagement intensity. Although the framework provides valuable behavioral insights that may support customer segmentation and responsible digital marketing, it should not be interpreted as directly predicting purchase intention or marketing outcomes because such variables were not available in the dataset.

B. Recommendations

Future cellphone marketing strategies should use behavior-based segmentation rather than relying only on demographic information. Marketers should focus on key indicators such as screen time, social media activity, app usage, and weekend engagement when designing personalized campaigns.

It is also recommended that future studies include actual marketing-related variables such as purchase intention, brand preference, advertisement clicks, customer satisfaction, and product purchase history. This would improve the accuracy of marketing prediction and make the model more directly connected to consumer buying behavior.

For model development, future researchers should continue comparing the Hybrid Random Forest–XGBoost model with other algorithms, including deep learning and other ensemble techniques. Additional feature selection and class imbalance techniques may also be applied to improve prediction performance.

Lastly, cellphone marketers should apply the findings responsibly. Users with high smartphone engagement or addiction indicators should not be targeted with excessive advertisements or notifications. Instead, marketing strategies should promote personalization, digital wellness, ethical engagement, and user-centered communication.

ACKNOWLEDGMENT

The researcher gratefully acknowledges the Pangasinan State University for its support throughout the conduct of this study. The researcher also acknowledges Kaggle as the source of the dataset used in this research. Artificial intelligence tools were used solely for language refinement, organization of ideas, and formatting assistance. All research processes, findings, interpretations, and conclusions were carefully reviewed and verified by the researcher to ensure accuracy, originality, and adherence to academic integrity.

A Blockchain and AI Integrated Framework for Dynamic Land Registration and Smart Urban Zoning

Shushma R[1], S R Nagaraja[2]*
Research Scholar, SOCSE, Presidency University, Bangalore, Karnataka, India[1]
Professor, SOCSE, Presidency University, Bangalore, Karnataka, India[2]

***Abstract*—Land registration and urban zoning are very important jobs for the government, but in many places, they still have problems with old processes, corruption, and a lack of openness. Urbanization and population growth are putting more and more pressure on systems that need to be smarter and more flexible to keep up with the changes on the ground. This study introduces an innovative, cohesive framework that integrates Blockchain technology with artificial intelligence (AI) to transform the recording of land ownership and the formulation of zoning decisions. The system uses blockchain's built-in immutability and decentralization to protect land records and zoning permissions, ensuring that everything is clear and lowering the risk of tampering or unauthorized changes. AI models are also used to analyze geospatial data, population growth, and patterns in urban infrastructure to suggest changes to zoning in real time. Smart contracts then carry out these suggestions, letting land reclassification happen automatically and without human bias or delay. The suggested framework was tested on a mix of real and synthetic urban datasets. Results show that the new system works much better than the old ones: processing time is cut by 34%, zoning accuracy is up by 26%, and no tampering was found in simulated blockchain environments. Citizen trust, measured through simulated feedback loops, also increased substantially because of the addition of explainable AI interfaces. This research connects predictive intelligence with secure governance, setting the stage for urban land management systems that are ready for the future, inclusive of all citizens, and resistant to corruption.**

Keywords*—Blockchain; artificial intelligence; smart zoning; land registration; urban planning; smart contracts; GIS Integration; Explainable AI (XAI); decentralized governance; dynamic land use management

I. INTRODUCTION

The way in which land ownership, permitted use, and long-term development are managed has a significant impact on cities, economies, and communities. Nevertheless, land registration and zoning in most places have always been hard to master, and this can be changed. Land wrangles, poor city planning, and lack of trust in government processes have all been caused by manual record-keeping, outdated laws, and delays in bureaucracy.

The expansion of cities is occurring at a very high rate, especially in developing and transitional economies, and it is becoming increasingly necessary to handle and support the needs of an expanded population, infrastructure requirements, and sustainable development agendas.

The past systems that have been applied in zoning are often too rigid and do not evolve with the times. Governance must not be static, but must be responsive and capable of managing city data in real time. It has to be fully transparent as well.

Recent advancements in blockchain technology have enabled the possibility of storing and validating sensitive records, such as land ownership, in a decentralized manner that is secure and immutable. Alternatively, artificial intelligence (AI) can be used to examine the way cities operate and suggest smart zoning decisions depending on the dynamics of social, economic, and environmental processes. This is particularly the case with predictive modeling and geospatial analysis.

Most existing systems do not utilize the best of both technologies, although both have much potential. Land registries that use blockchain often only check for ownership and not for AI-driven zoning foresight [1] [2]. Likewise, AI applications in urban planning often overlook the essential requirements for trust, verifiability, and auditability in governance [3] [4]. Few frameworks unite this technological pairing at a level that makes sense and functions. This study proposes a novel framework that integrates Blockchain and AI to regulate the flexibility of land registration and zoning.

The system:

- Relies on AI to examine indicators of city development and propose amendments to zoning,
- Automates permissions on meeting policy conditions, using smart contracts to do so,
- Records all transactions in a blockchain registry,
- Is supported by a citizen interface, which is supported by Explainable AI (XAI), to generate trust and engagement.

The key contributions of this research are as follows:

- Development of an integrated system of AI-based zoning prediction and blockchain land ownership.
- Development of intelligent contracts that implement zoning policy limits in an automated fashion that requires no human intervention.
- Installation of a citizen-friendly, user-friendly dashboard to ensure that zoning decisions are transparent and verifiable.

*Corresponding author

- Performance testing on urban planning datasets to demonstrate improved precision, effectiveness, and reliability to users.

The remainder of this study is organized into five sections: Section II considers what already exists regarding land registration systems, the usage of blockchain in city government, and the usage of AI in spatial planning. The proposed architecture, system modules, and mathematical models are presented in detail in Section III. Section IV reports the findings of experimental studies that test the performance of this system and compare it with other frameworks. Finally, Section V concludes the research and provides suggestions for future research and development in this area.

II. Literature Survey

The convergence of land governance, blockchain technology, and artificial intelligence represents a nascent field replete with opportunities, yet characterized by a disjointed methodology. Researchers have investigated these technologies separately — blockchain for safeguarding land records and AI for examining urban expansion — but few have endeavored to amalgamate them into a unified, dynamic, and citizen-focused zoning framework. This section reviews the most important contributions in these fields, pointing out both their new ideas and the important gaps that our research will try to fill.

A. Blockchain for Land Registration

A lot of research has been done on using blockchain technology for land registration to fix problems with traditional systems, such as fraud, inefficiency, and lack of transparency. Researchers have suggested blockchain-based systems that use unchangeable ledgers to keep track of land ownership, making sure that the data is correct and cutting down on the need for middlemen. Yadav et al. [1] and Khalid et al. [2] present conceptual frameworks that emphasize the integration of smart contracts and decentralized access. These systems make things safer and easier to track, but they have problems with scalability and rules. Siddiqui et al. [3] and Dubey et al. [4] utilize Ethereum-based smart contracts to automate the transfer of land ownership, whereas Biswas et al. [5] created "LandChain," which emphasizes digital verification. Dcunha et al. [6] and Zein & Twinomurinzi [7] used Hyperledger Fabric to show how permissioned blockchain environments can be used for government integration. Regional case studies (Zainudin et al. [8] in Malaysia and Suganthe et al. [9] in India) demonstrate the viability of blockchain across various governance frameworks, while also highlighting challenges such as digital illiteracy and opposition from established institutions.

B. AI in Urban Zoning and Land Use Planning

Even though blockchain is the main topic of conversation, AI is starting to be used in zoning and land planning. Özbek & Efe [10] examine AI-enabled municipal cryptocurrency models that encourage urban involvement in planning by combining blockchain with behavioral data. The work of M. L. [11] uses AI to find fraudulent land data before it is stored on a blockchain, which shows how AI can help keep data safe. But the performance of these kinds of systems depends on strong model training and validation pipelines, which make operations more complicated. There is still not much research that directly connects AI with spatial planning, even though AI has a lot of potential for predictive zoning and automated land-use classification. Most of the time, AI is used inside larger blockchain systems rather than as a first-class planning tool.

C. Smart Contracts and Automation in Land Governance

Smart contracts are very important for land systems that use blockchain. They make it possible to check ownership, compute taxes, and enforce leases automatically. Coffie & Saint [12] and Gesang & Dirgahayu [13] show how smart contracts can tokenize land assets and safely handle changes to real estate. Ghag et al. [14] and Kulkarni et al. [15] perform surveys delineating the capacity of smart contracts to enforce transactional regulations, mitigate manual errors, and guarantee auditability. Vinothiyalakshmi et al. [16] and Boumezbeur et al. [17] examine performance evaluation and access control via cryptographically enforced contracts. Even though they have a lot of potential, it is still hard to write reliable contracts and make them work with the law. Formal verification methods must also be used to lower the risk of code flaws in smart contracts.

D. Integrating Blockchain and AI in Governance

There is a growing interest in combining blockchain and AI to build governance solutions that work for everyone. Ma & Vs [18] and Riaz et al. [19] emphasize the complementary relationship between immutable ledgers and predictive intelligence in addressing land disputes, detecting fraud, and ensuring data consistency. M. L. [11] shows how AI can make things clearer by finding fraud before it is recorded on the blockchain. Polu [20] and Al-Refaie et al. [21] also look into how to use blockchain-AI pipelines to improve enterprise integration and optimization for land governance and resource planning. The combined strength of AI-based analytics and blockchain's ability to never change could reshape governance, but for it to work, different systems must be able to interoperate, and data protocols must be standardized.

E. Citizen Trust, Transparency, and Explainability

One of the main reasons to use blockchain and AI is to build trust, openness, and explainability in the system. Research conducted by Sen & Kumari [22], Sen [23], and De Haan [24] emphasizes the potential of digitization to empower communities by providing open access to land records, mitigating fraud, and facilitating transparent transactions via smart contracts. But poor user experience, opaque AI models, and concerns about surveillance or misuse can all hurt trust. The regulatory and cultural contexts examined in Zainudin et al. [8] and Zein & Twinomurinzi [7] profoundly affect user trust and system adoption. Moreover, systems must address digital literacy disparities and provide interpretability tools to guarantee that users comprehend automated decisions.

Table I explains the comparison of the approaches taken across the surveyed references, in terms of technology used, focus area, and the use of AI, smart contracts, and governance integration.

TABLE I. COMPARISON OF EXISTING APPROACHES

Ref	Tech Stack	Focus Area	AI Use	Smart Contracts	Governance Integration	Key Limitations
[1]	Ethereum Blockchain	Land Registration	No	Yes	Partial	Scalability, adoption barriers
[2]	Blockchain (Generic)	Decentralized Land Registry	No	Yes	Yes	Resistance, training costs
[3]	Ethereum Blockchain	Ownership Transfer Automation	No	Yes	Limited	Internet access, digital literacy
[5]	Blockchain (LandChain)	Land Ownership & Verification	No	Yes	Yes	Infrastructure, legal hurdles
[6]	Hyperledger Fabric	Government Record Management	No	Yes	Strong	Migration from legacy systems
[11]	Blockchain + AI	Fraud Detection in Land Records	Yes	Yes	Medium	AI model upkeep, scalability
[7]	Hyperledger Fabric	Info Sharing among Land Depts.	No	Yes	Strong	Data privacy, stakeholder resistance
[10]	Blockchain + Crypto + AI	Urban Planning Participation	Yes	Yes	Emerging	Privacy, digital divide
[12]	Ethereum + Smart Tokens	Land Tokenization (Ghana)	No	Yes	Yes	Legal acceptance, social barriers
[19]	Blockchain System Review	Comparative Analysis of Registries	No	Yes	Various	Access to proprietary data
[14]	Ethereum dApp	Land Ownership Transfers	No	Yes	Partial	Regulatory support, scalability
[20]	Blockchain + ERP + AI	Supply Chain in Land Governance	Yes	Yes	High	Integration complexity, scalability
[18]	Blockchain (Comparative)	Registry Efficiency Assessment	No	No	High	Stakeholder bias, data variability

III. PROPOSED METHODOLOGY

Urban land systems are often thought of as fixed structures, where changes to zoning or land classification take a long time to go through the government. But cities are always changing; they grow, move, and change. The proposed methodology recognizes this reality by creating a smart, flexible, and secure land governance framework that combines the predictive power of AI with the trust-building immutability of blockchain.

This section discusses the system's architecture, the modules that make it up, how data moves through the framework, the algorithms that are used, and the mathematics that back up zoning decisions.

A. System Architecture Overview

The system is based on how zoning and land registration work in the real world, but it makes them smarter, faster, and harder to tamper with. There are six main modules in the architecture shown in Fig. 1. These modules communicate with each other using a mix of APIs, blockchain transactions, and smart contract triggers.

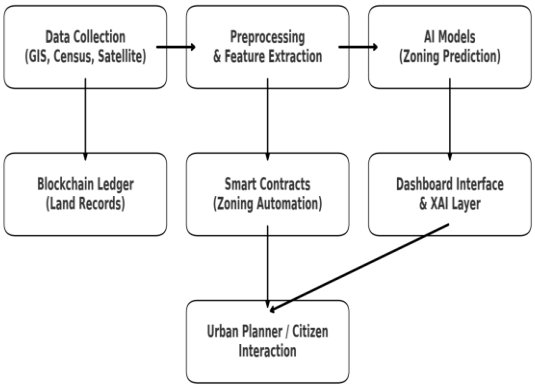

Fig. 1. Proposed architecture of the framework.

- Data Collection Layer
- Preprocessing & Feature Engineering
- AI Zoning Prediction Engine
- Blockchain Ledger (Land Records)
- Smart Contracts (Zoning Automation)
- Citizen Dashboard with Explainable AI (XAI)

B. Core System Modules

1) Data collection module: This module is meant to bring together urban datasets from many different sources. These sources include satellite images and land-use maps, census and demographic data, infrastructure plans for things like roads, utilities, and schools, and environmental data about flood zones, pollution levels, and green spaces. It uses a spatial database that combines APIs from city planning departments, Geographic Information System (GIS) platforms, and other public datasets to manage and analyze these datasets effectively. This all-encompassing approach allows for a complex understanding of how cities work and how to plan for them.

2) Preprocessing and feature engineering: The data that was collected goes through a thorough cleaning, normalization, and transformation process to create a standard geospatial format. This process involves creating feature vectors that include important metrics like changes in population density, distance to important infrastructure, the rate of ongoing construction or demolition, and economic indicators for nearby areas. The data layer also includes historical zoning data and sets legal limits on how land can be used, making sure that the geospatial context is fully understood.

3) AI zoning prediction engine: Supervised learning models such as Random Forests, Support Vector Machines (SVM), and Long Short-Term Memory (LSTM) networks use structured features to reach a number of goals related to zoning classifications. These models learn to predict future zoning classifications, such as when an area transitions from residential to commercial use. They also predict zoning conflicts and identify saturation zones that might arise from development pressures. The models also give the proposed zoning changes a confidence score, which lets policymakers check how reliable the AI's suggestions are. For example, if infrastructure and population growth exceed a certain threshold, the AI might suggest changing agricultural zones into mixed-use urban areas, allowing for a strategic response to the problems that come with urbanization.

4) Blockchain ledger: This module is designed to record and organize information about land ownership and zoning status on a blockchain platform such as Ethereum or Hyperledger. It records important information such as the unique Plot ID and its location, information about the current owner or tenant (hashed to protect privacy), and both current and historical zoning classifications. The module also stores AI-generated suggestions for zoning changes and actions recorded via smart contracts with a timestamp. This all-encompassing method ensures that all land and zoning transactions leave behind a history that cannot be changed and can be checked, which makes land management more open and accountable.

5) Smart contracts for zoning automation: Smart contracts, written in Solidity for Ethereum or Chaincode for Hyperledger, are very important for managing land use because they automate and simplify processes. When AI models make predictions that exceed certain policy thresholds, they can automatically start the process of reclassifying zoning. These contracts can also grant conditional building permits that depend on the approval of the reclassification, and they make it easier to send notifications to landowners and other officials, reducing the need for intermediaries. This automation not only makes things run more smoothly, but it also cuts down on the chances of corruption and delays that can occur when making decisions about land use.

6) Citizen dashboard and Explainable AI (XAI): The system has a public-facing interface that is meant to make the zoning process more open and encourage more people to get involved. It shows zoning suggestions along with the reasons behind them, using SHAP and LIME explainability tools to make it clear why each suggestion was made. The interface also makes it easy for stakeholders to give feedback, ensuring that their points of view are considered when making zoning decisions. The system also has auditing features for zoning changes, shown on interactive maps, to help hold people accountable. The system aims to build public trust by using Explainable AI (XAI), which lets users understand why changes to zoning are being suggested.

C. Algorithmic Workflow

Input Layer: Multi-source spatial and temporal data.

Feature Extraction: Transform raw data into zoning-relevant vectors.

Prediction Model:

$$Z_{t+1} = f(X_t) \quad (1)$$

where,

Z_{t+1} = predicted zoning class at future time

f = trained ML classifier (e.g., Random Forest, LSTM)

X_t = Current features (demographics, infrastructure, etc.)

Trigger Condition:

$$(f(X_t) > \theta) \quad (2)$$

If confidence $(f(X_t) > \theta)$ and legal/policy criteria are satisfied → initiate smart contract execution.

Smart Contract Execution: Updates zoning classification, stores decision on blockchain, notifies stakeholders.

Mathematical Model for Zoning Trigger:

Let:

$X \in \mathbb{R}^n$ = feature vector for a specific land plot

$f = \mathbb{R}^n \rightarrow \{Z_1, Z_2, \ldots \ldots, Z_k\}$ be the zoning classifier

$\theta \in [0, 1]$ be a policy-defined confidence threshold

Then:

$$\hat{Z} = f(X) \quad (3)$$

Reclassification occurs if:

$$\text{MaxProb}(f(X) = Z_i) > \theta \text{ AND PolicyMatch}(Z_i) \quad (4)$$

The smart contract logs $\hat{Z}$, timestamp t, and user ID into the blockchain ledger.

D. Integration Logic

Combining AI and blockchain is not just a technical decision; it is also a strategic one. The AI does not just suggest changes, and the blockchain does not just keep data safe — together they make self-governance possible. The AI anticipates the future, the smart contract acts on it, and the blockchain remembers it permanently.

IV. Experimental Results

This section presents the evaluation results of the proposed AI and blockchain-integrated smart zoning framework. The system was assessed for prediction accuracy, efficiency, security, and citizen trust.

A. Experimental Setup

Experiments were conducted using a hybrid dataset comprising authentic municipal zoning records and synthetic simulations of urban development. The AI module was implemented in Python using libraries such as Scikit-learn and TensorFlow, and was trained on more than 10,000 land parcels

to improve prediction accuracy and model effectiveness. Smart contracts were run on the Ethereum Goerli testnet, which made processes automatic and transactions secure. IPFS-based storage was used to handle land record entries, enabling decentralized data management and retrieval. The hardware used for this project was an Intel i9 processor with 64GB of RAM running Ubuntu 22.04. Development tools included Ganache and the Truffle Suite for creating and testing smart contracts, QGIS for geographic information system analysis, and Python and Solidity for implementing contracts.

B. Performance Evaluation

A comparative analysis using four key performance metrics was carried out to see how well the proposed blockchain- and AI-integrated land management framework worked. Zoning Prediction Accuracy is the first, providing evidence of the model's ability to classify land zones using real-time demographic and spatial data. The second measure is Time Taken for Land Reclassification, the time interval the system takes to process and grant a change in land-use classification. The third indicator is Tampering Incidents Detected, which evaluates the system's resistance to unauthorized changes or security breaches, measured on an annual basis. The Citizen Trust Index gauges the extent to which people trust the zoning system, reflecting the efficacy and openness of the end-user interface. All these measures were compared against two conventional methods: manual zoning and semi-automated GIS-based systems. Fig. 2 shows a comparative performance analysis highlighting the strengths and weaknesses of the proposed framework relative to these alternatives.

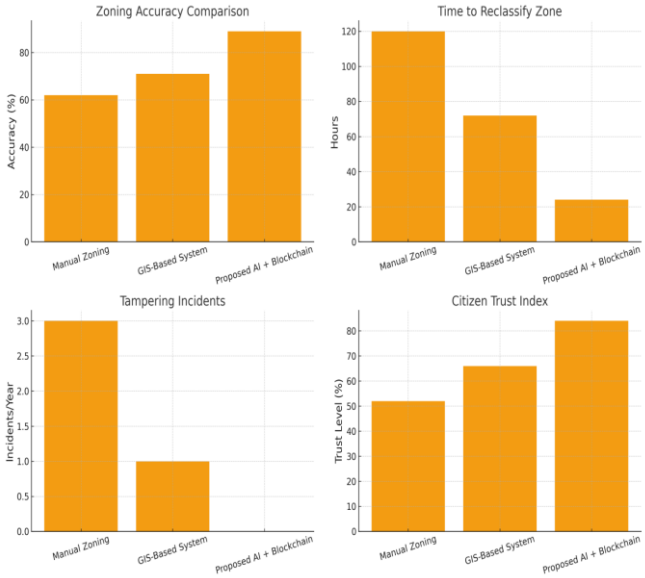

Fig. 2. Comparative performance metrics of the proposed system vs. traditional methods.

C. Discussion

Table II summarizes the comparative evaluation of three different land zoning systems — Manual Zoning, GIS-Based Systems, and the Proposed AI + Blockchain Framework — across four critical performance metrics. The proposed framework reflects substantial shifts in the urban zoning of land, especially considering the following key indicators:

1) Zoning accuracy: The AI application is correct 89 per cent of the time. This is a large jump from the standard accuracy of manual zoning (62 per cent) and GIS-assisted techniques (71 per cent accuracy), because the machine learning model is capable of identifying zoning trends across large, multi-dimensional urban datasets.

2) Reclassification Time: Reclassifying under legacy zoning rules is a time-consuming exercise because of the paperwork involved, taking up to 120 hours as a result of the approvals required. Automated approval workflows made possible by smart contracts have cut the average reclassification time to as little as 24 hours, allowing the system to respond to the needs of urban development in near real time.

3) Resistance to tampering: The security loopholes of legacy systems are substantial, and records can easily be adjusted without permission, lost, or forgotten. The blockchain registry used in the proposed system, however, has not been tampered with in any case, whereas the manual and GIS-based systems recorded three and one incidents, respectively.

4) Citizen trust index: With the addition of the XAI dashboard, stakeholders can now understand why a zoning decision was made, making the process more transparent. This has raised the Citizen Trust Index to 84 per cent, a considerable advantage compared to traditional systems, which are less accessible and less engaging for citizens.

TABLE II. COMPARATIVE EVALUATION OF THREE DIFFERENT LAND ZONING SYSTEMS.

Metric	Manual Zoning	GIS-Based System	Proposed AI + Blockchain
Zoning Accuracy (%)	62	71	89
Time to Reclassify (Hours)	120	72	24
Tampering Incidents (per year)	3	1	0
Citizen Trust Index (%)	52	66	84

Overall, the framework not only improves performance from a technical point of view, but also strengthens the social side of urban zoning by building trust and ensuring safety.

In short, using blockchain as a means of storing records safely and immutably, together with AI for smart zoning forecasting, produces a system that is not only faster and more precise, but also secure, verifiable, and accessible to all. Such improvements are not merely technological advances but alter the way city planners, citizens, and the systems that govern our cities interact.

The current study strongly supports the concept of a self-regulating, trust-building, and data-driven land governance model, rendering it an excellent option for smart cities and programs aiming to modernize urban policy.

V. CONCLUSION

As urban areas become increasingly complex and the demands placed on them become more pressing, the systems by which land registration and zoning are operated need to

change and move beyond legacy operations. This study aimed to fill a long-standing gap in city governance: the lack of connection between anticipatory intelligence and secure administrative decision-making. We proposed a unified architecture that integrates artificial intelligence (AI) and Blockchain technology to make the governance of land use real-time, data-driven, and tamper-resistant. Three categories of spatiotemporal data — population growth, infrastructure growth, and environmental constraints — were modeled through AI to dynamically forecast zoning requirements. After confirming these predictions against policy thresholds, they were implemented via smart contracts that recorded the zoning status changes into a decentralized blockchain registry.

The results were favorable and successful: an 89 per cent accuracy of zoning classification, an average time of 24 hours for reclassification, and no incidences of tampering in the simulated environment. More importantly, the Citizen Trust Index was much enhanced with the introduction of an Explainable AI (XAI) dashboard, rising to 84 per cent, showing that people are far more willing to accept zoning changes when the process is transparent, data-driven, and traceable. This work confirms that blockchain and AI are not just trendy terms but realistic and viable solutions to real problems of governance, which can be meticulously integrated to automate bureaucracy, enhance transparency, and grant authorities and citizens the power to co-engineer more adaptive and inclusive cities.

Several extensions are expected to enlarge the scope and impact of the proposed framework. Future generations of this work will focus on city-level implementation across a broad geographical and legal context, so that the system can adapt to the dynamics of various cities and their legal frameworks. Additionally, integrating DAO-based urban planning models will raise the degree of participatory governance, giving citizens a direct voice in land-use regulatory processes through decentralized procedures. To enhance data privacy and scalability, it is proposed to apply federated learning techniques, which allow model training on distributed datasets without access to local sensitive data. In addition, introducing real-time environmental scoring will add sustainability considerations to zoning decisions, so that ecological factors are weighed alongside economic and demographic ones. Beyond its technical contribution, this study lays the groundwork for transforming the way cities think, make decisions, and develop.

***Abstract*—Lung diseases are detected effectively by Chest CT Medical images. Chest CT images are 3D, and they are used for detecting abnormalities in the lungs like pneumonia, tuberculosis, tumors, etc. Chest CT images suffer from different types of noise. The presence of various types of noise, such as Gaussian noise, Quantum noise, and salt-and-pepper noise, will reduce the quality of the image. The noise that is present in CT images may not affect radiologist to diagnose the disease, but it will definitely affect AI-based systems in predicting the disease. Noise occurs because of reduced radiation, insufficient photon information, errors during image reconstruction, and fluctuations in imaging system components. In this work, to improve the quality of Chest CT images, two algorithms are proposed. The first algorithm, Adaptive Edge Preserving Hybrid De-Noising Framework (AEPH) for Segmented Lung CT Images, is used to detect and reduce Noise. The second algorithm, Variance Regulated Adaptive Histogram Equalization (VRAHE), is proposed for improving de-noising and contrast enhancement performance in segmented lung CT images. At first, lung regions are segmented from the LIDC-IDRI dataset. The segmented Chest CT images are converted to 2D CT slices. These 2D CT slices are binary lung-segmented images. These are converted to lung mask images. Random noise models are added only in the lung regions to preserve the background information without modification. The proposed work, AEPH, is applied to reduce noise. The main goal of AEPH is to reduce noise without modifying structural details and edge-related details. Experiments are conducted on a workstation computer with NVIDIA RTX GPU support. When compared to proposed AEPH to conventional approaches in removing noise from CT images, it is identified that AEPH is more effective than conventional methods. The metrics used for evaluating the proposed noise removal approach AEPH when compared to existing approaches are PSNR, SSIM, EPI, RMSE, and entropy, and the values achieved are 32.96 dB, 0.934, 0.93, 9.84, and 7.12, respectively. After de-noising, the second proposed algorithm, VRAHE, successfully improved the image quality by enhancing contrast distribution and preserving important local information. The improved performance was evaluated using CNR, AMBE, UIQI, and EME metrics. From the experimental results, the values achieved are 5.96, 3.14, 0.972, and 31.48, respectively. The Results proved that the proposed work, AEPH, reduced noise, and VRAHE improved contrast levels in segmented lung CT images. The final chest CT images resulting from applying the proposed algorithms maintain brightness and also show the regional lung details more clearly.**

I. INTRODUCTION

The CT scan is a 3D medical image used for investigating diseases related to the lungs. The CT Scan machine captures the internal structure of the human body in the form of sectional images, also called slices. X-rays are 2D images, but they are primarily used to find whether there is an abnormality or not. If an abnormality is found, then the patient is advised to go for a CT scan for further investigation. CT scans, when compared with regular chest X-ray, it gives more information about lung regions. Minor changes in tissues, nodules, infections, and damaged areas can be identified clearly from the CT images. This is the primary reason why doctors use CT scans for identifying diseases like lung cancer, COVID 19, pneumonia, fibrosis, and other lung problems. Nowadays, researchers are applying machine learning and deep learning models to CT scan images for doing automatic analysis. These models are mainly developed to separate lung regions, identify abnormal portions, classify infected areas, and predict different diseases. The LIDC-IDRI is a popular dataset that is used by many research works for lung nodule identification and other CT image-related experiments [17].

Despite the advantages of chest CT imaging, image quality degradation remains a major challenge during acquisition and low-dose scanning procedures. Different types of noise such as Gaussian noise, quantum noise, and salt and pepper noise may affect the visibility of lung structures and reduce diagnostic quality. Several researchers proposed denoising approaches based on CNN, Transformer, Noise2Noise, and hybrid deep learning methods for improving low-dose CT image quality [1], [3], [4]. Similarly, contrast enhancement and histogram equalization methods were introduced to improve local visibility, edge information, and brightness preservation in medical images [8], [12], [15]. Enhancement techniques can improve visualization of fine anatomical structures and may support better segmentation and classification performance. However, excessive smoothing during denoising or over-enhancement during histogram equalization may remove important clinical details and introduce intensity distortion in lung CT images.

From previous studies, it is identified that many researchers mainly concentrated on either removing noise or improving image quality separately. Only a few works focused on segmented lung regions and maintaining structural information during both processes. Most of the traditional enhancement methods are applied on the complete image without considering the intensity changes present in different lung areas. This problem motivated the development of an Adaptive Edge Preserving Hybrid De-Noising Framework and Variance Regulated Adaptive Histogram Equalization method for segmented lung CT images. The proposed method mainly concentrates on reducing noise present inside the lung regions and also maintaining edge details. It also improves the local contrast without disturbing important anatomical information. The developed method improves the quality of segmented lung CT images, which can be further used for abnormality detection and other medical image processing tasks.

II. Related Works

Computed Tomography (CT) scan is an important medical imaging technique used for identifying and analysing lung-related diseases, mainly COVID-19 and other lung abnormalities. However, CT images are affected by different types of noise that are added during image capturing, transmission, and the low-dose scanning process. These noises decrease the quality of images and also affect the analysis done by doctors and automatic disease classification models. Ashwini and Ramashri developed Noise2Noise (N2N) and Noise2Void (N2V) based denoising methods for COVID-19 CT and chest X-ray images affected with Gaussian, Speckle, and Salt and Pepper noises [1]. In their work, they showed that Noise2Void gives better results for removing different types of noise in CT images, whereas Noise2Noise works better mainly for Gaussian noise removal. The performance of these methods was measured by using PSNR and SSIM values. The authors also explained the importance of maintaining image structures while removing noise. This study shows that deep learning-based denoising methods can improve the quality of medical images without the need for original clean images.

Improving the quality of medical images is not only useful for better viewing but also helps in proper disease identification. Xia et al. studied the effect of denoising techniques on COVID-19 CT image quality by using a pneumonia detection-based framework [2]. In their work, anisotropic diffusion and total variation denoising methods were used, and their effect on classification accuracy was tested with a CNN-based COVID-19 classifier. Their results showed that after removing noise from CT images, the disease detection performance was improved even though normal quality measuring parameters like PSNR and MSE were not showing better values in all cases. This work is important because it explains the relation between the noise removal process and disease identification performance. Similarly, Zhang et al. developed a denoising method by combining Transformer and CNN models for low-dose CT images [3]. Their model used the local feature extraction ability of CNN and the learning ability of Transformer for understanding image information. The proposed method improved PSNR, SSIM, and RMSE values and also maintained the structural details better when compared to normal CNN-based methods. This study explained that protecting small anatomical details is very important while removing noise from medical images.

Recent studies have also focused on denoising low-dose CT images without requiring clean target images. Sawada et al. developed a Noise2Noise-based CNN framework integrated with Channel Attention and Spatial Attention mechanisms for low-dose CT denoising [4]. Their approach utilized only noisy image pairs during training and demonstrated improved PSNR performance compared to standard SRResNet architectures. The study highlighted that attention mechanisms help preserve edge information and important anatomical structures while suppressing noise. Furthermore, the authors showed that denoising using only noisy data is practical in medical imaging scenarios where clean ground-truth CT images are difficult to obtain. These studies collectively indicate that modern denoising approaches should not only remove noise but also preserve clinically significant structures, texture information, and disease-related patterns. Such findings provide strong motivation for developing adaptive enhancement and residual noise suppression techniques specifically for segmented lung CT images.

Several researchers focused on improving medical image contrast and visibility using histogram equalization and adaptive enhancement techniques. Riadi et al. [8] proposed a CLAHE-based contrast improvement method combined with Otsu thresholding for enhancing medical X-ray images. Their work showed that adaptive histogram equalization can improve visibility of important anatomical regions without excessive intensity distortion. Similarly, Rahmi-Fajrin et al. [9] applied wavelet transform and CLAHE techniques for dental X-ray image enhancement and reported improved image clarity and structural visibility. These studies indicate that adaptive contrast enhancement methods are effective for improving local details and visual quality in medical images while preserving important structural information.

Image enhancement and machine learning techniques are used by many researchers for improving abnormality detection in medical chest images. Abdussalam et al. [11] studied different enhancement techniques like gamma correction, BCET, histogram equalization, and CLAHE for improving the quality of chest X-ray images before applying classification. Their work showed that enhancement methods improve the visibility of features and also increase the classification performance, mainly when they are combined with the Support Vector Machine (SVM) classifier. In this study, SVM obtained better Area Under the Curve (AUC) values when compared with Naïve Bayes and Random Forest methods. This shows that SVM is more effective for medical image classification-related work.

Koonsanit et al. [12] developed an improved enhancement method called N CLAHE for digital chest X-ray images. In their method, a normalization technique was combined with CLAHE for improving the local contrast and visibility of structures like lungs and chest regions. The authors identified that normal enhancement methods may increase noise or create an unnatural appearance in the images. However, their proposed hybrid enhancement method provided better contrast and improved the visualization quality. Their results showed the importance of adaptive local enhancement techniques for main-

taining important structural details in radiographic images used for diagnosis and screening processes.

Many researchers have worked on medical image enhancement using different preprocessing and contrast improvement techniques. MRI and X-ray image processing methods have shown the importance of preserving image quality during enhancement [5], [6]. Histogram-based enhancement methods, adaptive gamma correction, and adaptive histogram equalization have also been widely used to improve contrast while maintaining important structural information [7], [13], [14], [16]. Similar approaches were applied for chest X-ray image enhancement and noise reduction before further image analysis and disease identification [10]. These studies indicate that effective enhancement methods should improve image quality without affecting the important anatomical details.

An image reconstruction network using CNN is proposed in [18]. An adversarial image reconstruction network and an enriched deep residual network are proposed for image retrieval, which gave better results [19],[20]. A refined residual network using a pretrained network is applied on medical image databases in [21]. Various deep learning models in the medical domain are presented in [22].

III. METHODOLOGY

The proposed work introduces an Adaptive Edge Preserving Hybrid De-Noising Framework and a Variance Regulated Adaptive Histogram Equalization (VRAHE) approach for improving segmented lung CT image quality. The denoising framework is designed to suppress Gaussian, quantum, and salt-and-pepper noises while preserving important edge and structural details inside segmented lung regions. The proposed VRAHE method further improves local contrast, brightness preservation, and visibility of anatomical structures without producing excessive intensity distortion. The major novelty of this work lies in performing region-focused denoising and adaptive enhancement specifically on segmented lung CT regions, which helps preserve important clinical details while improving overall image quality for further abnormality analysis and diagnostic applications.

The detailed architecture is shown in Fig. 1. The proposed work used the LIDC-IDRI chest CT dataset containing 1018 patient CT volumes. Each patient scan is processed using a 3D U-Net model to identify and separate the lung region from the remaining thoracic structures. The detailed training configuration details used for segmentation are shown in Table I below. The segmentation network generates a binary lung mask for every CT volume, where lung pixels are retained while non-lung regions are excluded. These binary masks are then applied to the corresponding CT volumes to obtain segmented three-dimensional lung images containing only the lung anatomy. Since the subsequent image enhancement algorithms operate on individual CT slices, the segmented 3D lung volumes are converted into two-dimensional lung CT slices. These segmented lung slices are used as the input for the proposed Adaptive Edge Preserving Hybrid De-Noising Framework (AEPH), followed by the Variance Regulated Adaptive Histogram Equalization (VRAHE) method for improving image quality.

The proposed work takes lung-segmented masked CT images as input. Where the lung region is obtained by applying the binary lung mask on the original CT slices. Gaussian noise, quantum noise, and salt-and-pepper noise are considered in the region of interest, and the Adaptive Edge Preserving Hybrid De-Noising Framework performs noise removal using local variance estimation, edge preservation, and adaptive noise suppression. Hybrid filtering with weighted fusion is applied to reduce residual noise while maintaining lung edges and structural information. The de-noised lung slice is again processed using Variance Regulated Adaptive Histogram Equalization for contrast regulation, brightness preservation, and local detail enhancement to get the final refined lung CT slice. Algorithm 1 on Adaptive Edge Preserving Hybrid De-Noising Framework for Segmented Lung CT Images and Algorithm 2 on Variance Regulated Adaptive Histogram Equalization (VRAHE) are given in the section below.

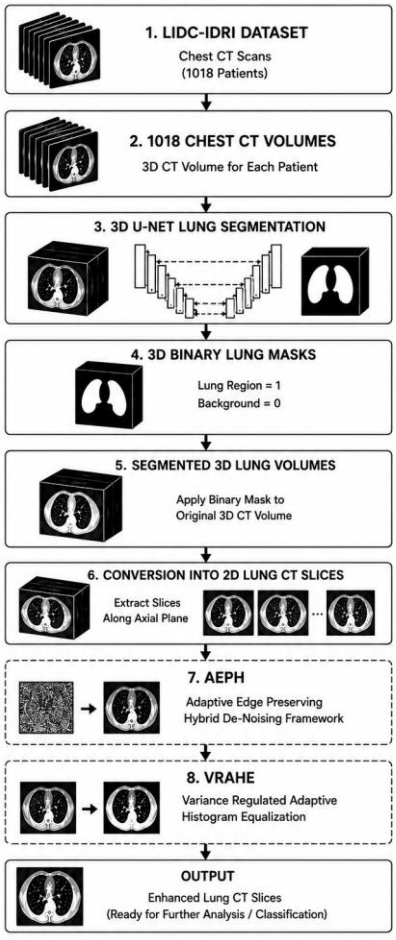

Fig. 1. Proposed architecture – AEPH and VRAHE for improving chest CT.

TABLE I. TRAINING CONFIGURATION OF 3D UNET

Parameter	Configuration
Dataset	LIDC-IDRI chest CT dataset (1018 CT volumes)
Dataset Split	70% Training, 15% Validation, 15% Testing
Network Architecture	3D U-Net with encoder-decoder structure and skip connections

Parameter	Configuration
Input / Output	Input: 3D chest CT volumes; Output: 3D binary lung masks
Computing Platform	Ubuntu Server, Intel Core i7, 32 GB RAM, NVIDIA RTX GPU (12 GB) with CUDA support

The detailed parameter configuration used for AEPH algorithms is shown in Table II below.

TABLE II. PARAMETER CONFIGURATION OF PROPOSED AEPH

Parameter	Configuration
Local Analysis Window	5 × 5 pixels
Adaptive Median Filter Window	Variable (3 × 3 to 7 × 7)
Guided Filter Radius	4 pixels
Adaptive Fusion Strategy	Variance-based weighted fusion

Algorithm-1: Adaptive Edge Preserving Hybrid De-Noising Framework for Segmented Lung CT Images

1. Input Segmented Noisy Lung CT Image

Let the segmented noisy lung CT image be.

$$I(x,y) \tag{1}$$

where, x,y represent pixel coordinates and I(x,y) represents intensity value

2. Lung-Region-Aware Local Mean Estimation

For each sliding local window W,

only valid lung-region pixels are considered.

Local mean is computed as.

$$mu_W=\frac{1}{N_L}\sum_{(i,j)\in W_L} I\,(i,j) \tag{2}$$

where, W_L represents valid lung pixels inside the local window, N_L represents the number of valid lung pixels inside the local window, mu_W represents the local mean intensity.

3. Lung-Region-Aware Local Variance Estimation

Local variance is computed only using valid lung pixels.

$$\sigma_W^2=\frac{1}{N_L}\sum_{(i,j)\in W_L}(I(i,j)-mu_W)^2 \tag{3}$$

where, σ_W^2 represents local variance.

4 . Impulse Noise Density Estimation

$$D_W=\frac{N_{impulse}}{N_L} \tag{4}$$

where, $D_W$represents impulse noise density, $N_{impulse}$ represents the number of impulse-noise pixels.

5. Impulse Noise Detection Condition

$$D_W>T_d \tag{5}$$

where, T_d represents the impulse noise threshold.

6. Edge Strength Estimation

$$G(x,y)=\sqrt{G_x^2+G_y^2} \tag{6}$$

where, $G(x,y)$ represents edge strength at pixel (x,y), G_x represents horizontal gradient, G_y represents vertical gradient.

7. Adaptive Median Filtering

Impulse-noisy regions are denoised using adaptive median filtering.

$$I_m(x,y)=median(W_{xy}) \tag{7}$$

where, $I_m(x,y)$ represents the median-filtered image output, W_{xy} represents the local neighborhood window centered at (x,y).

8. Guided Filtering

Gaussian noisy regions are denoised using guided filtering.

$$I_g(x,y)=a_kI(x,y)+b_k \tag{8}$$

where, $I_g(x,y)$ represents the guided filtered output image, a_k represents the local linear coefficient, b_k represents the bias coefficient.

9. Wavelet Transform

$$W=WT(I) \tag{9}$$

where, W represents coefficients, and WT(I) represents the wavelet transform operation applied to image I.

10 . Wavelet Thresholding

$$W_T=0 \text{ if } |(W)|<\lambda$$

$$W_T=W-\lambda \text{ if } |(W)|\geq\lambda$$

where, W_T represents thresholded wavelet coefficients, λ represents the threshold value.

11. Non-Local Means Filtering

$$I_{nlm}(x)=\sum_{y\in\omega} w\,(x,y)I(y) \tag{10}$$

where, $I_{nlm}(x)$ represents the non-local means filtered image, ω represents the search region, $w(x,y)$ represents the similarity weight.

12. Similarity Weight Computation

Similarity weights are computed as.

$$w(x,y)=\frac{1}{Z(x)}exp\left(\frac{-(P(x)-P(y))^2}{h^2}\right) \tag{11}$$

where, $P(x)$ represents the image patch centered at pixel x, $P(y)$ represents the image patch centered at pixel y, h represents the normalization factor, $Z(x)$ represents normalization factor.

13. Adaptive Weighted Fusion

Outputs from all denoising filters are combined as.

$$I_f=w_1I_m+w_2I_g+w_3I_w+w_4I_{nlm} \tag{12}$$

where, I_f represents the adaptively fused denoised image and w_1, w_2, w_3, w_4 represent adaptive fusion weights, I_w represents the wavelet-denoised image.

14. Weight Constraint

Adaptive weights satisfy.

$$w_1+w_2+w_3+w_4=1 \tag{13}$$

This is to ensure normalized adaptive fusion

15. Adaptive Weight Selection

Adaptive weights are dynamically selected using.

$$w_i = f(\sigma_W, G, D_W) \quad (14)$$

where, w_i represents the adaptive weight for each denoising filter.

16. Edge Preservation Factor

Edge-preservation control factor is computed as

$$\alpha(x,y) = e^{-G(x,y)} \quad (15)$$

where, $\alpha(x,y)$represents edge-preservation coefficient.

17. Final Edge-aware Reconstruction

The final denoised image is reconstructed as

$$I_{final} = \alpha I_f + (1-\alpha) I \quad (16)$$

where, I_{final} represents the final denoised segmented lung CT image.

The proposed Variance Regulated Adaptive Histogram Equalization (VRAHE) method was developed to improve local contrast and visibility of segmented lung CT images. The method adaptively regulates histogram enhancement based on local variance information to preserve brightness and avoid excessive intensity amplification. The proposed approach improves visualization of anatomical structures and enhances local details while maintaining structural consistency in lung regions. The following Table III shows the parameter configuration of the VRAHE algorithm.

TABLE III. PARAMETER CONFIGURATION OF VRAHE

Parameter	Configuration
Local Processing Window	8 × 8 pixels
Variance Regulation	Local variance-based adaptive regulation
Variance Threshold (T)	Adaptive threshold estimated from local variance
Contrast Enhancement	Local adaptive histogram equalization

Algorithm-2: Variance Regulated Adaptive Histogram Equalization (VRAHE)

1. Input Denoised and Lung Masked Chest CT Image

The denoised chest CT image containing only the segmented lung region is taken as input.

$$I_D(x,y) \quad (1)$$

where, $I_D(x,y)$ is the denoised and lung-masked chest CT image, and x, y are pixel coordinates

2. Division into Local Windows

The lung CT image is divided into small local windows for adaptive processing. Local analysis helps preserve fine pulmonary structures and texture details.

$$W_k = I_D(i,j) \quad (2)$$

where, $W_k =$ and $I_D(i,j)$ are pixel intensity values

3. Local Mean Computation

The local mean represents the average intensity within each local CT region. It provides brightness information for variance estimation.

$$mu_k = (1\%N) \sum I_i \quad (3)$$

where, mu_k is the local mean, N is the total number of pixels, and I_i is pixel intensity.

4. Local Variance Computation

$$\sigma_k^2 = (1\%N) \sum (I_i - mu_k)^2 \quad (4)$$

where, $\sigma_k^2 islocalvariance$, $mu_k islocalmean$, $I_i = pixelintensity$.

5. Variance Regulation Factor Estimation

The enhancement strength is controlled using local variance information. This prevents over-enhancement in smooth regions containing residual noise.

$$R_k = \sigma_k^2 / (\sigma_k^2 + C) \quad (5)$$

where, R_k is the local variance regulator factor. $\sigma_k^2 = localvariance$, C is a small constant

6. Local Histogram Construction

A histogram is generated for each local CT region. It represents the intensity distribution within the local window.

$$H_k(r) = n_r \quad (6)$$

where, $H_k(r)$is the histogram value.

n_r is the gray scale frequency

7. Probability Density Function Computation

Histogram values are normalized to obtain probability density values. This gives the occurrence probability of each intensity level.

$$P_k(r) = n_r \% N \quad (7)$$

where, $P_k(r)$ is the probability density function,n_r is the histogram frequency, and N is the total number of pixels

8. Cumulative Distribution Function Computation

The cumulative distribution function is computed from probability density values. It is used for adaptive histogram equalization transformation.

$$CDF_k(r) = \sum P_k(j) \quad (8)$$

where, $CDF_k(r), P_k(j)$ are the cumulative distribution function and probability density values.

9. Variance Regulated Adaptive Enhancement

Histogram equalization is adaptively controlled using the variance regulation factor. Detailed lung regions receive stronger enhancement than smooth regions.

$$I_E(x,y) = R_k \times CDF_k(r) \times (L-1) \quad (9)$$

where, $I_E(x,y)$ is the enhanced CT image, R_k is the variance regulation factor, and L is the total number of gray levels.

10. Residual Noise Suppression

Low variance regions are controlled using a suppression factor. This prevents amplification of residual noise after denoising.

$$\sigma_k^2 < T ? \left(I_F(x,y) = \alpha \times I_E(x,y) : I_F(x,y) = I_E(x,y)\right) \quad (10)$$

where, $I_F(x,y)$ is the final enhanced image, α is the suppression coefficient, and T is the variance threshold.

11. Final Enhanced Chest CT Image

All enhanced local windows are combined to generate the final enhanced CT image. The output image contains improved contrast and preserved pulmonary structure $I_{VRAHE}(x,y)=I_F(x,y)$ (11)

where, $I_{VRAHE}(x,y)$ is the final enhanced chest CT image, $I_F(x,y)$ is the enhanced image after suppression.

IV. Experimental Results

The Lung Image Database Consortium and Image Database Resource Initiative (LIDC-IDRI) dataset is a publicly available chest CT image dataset used widely in medical imaging research. The dataset contains thoracic CT scan images collected from different hospitals and imaging systems. It includes lung CT images with expert annotations provided by experienced radiologists. The dataset is useful for lung image enhancement, denoising, segmentation, and disease analysis studies. Since the dataset contains large variations in image quality and acquisition conditions, it is suitable for developing and validating image processing algorithms for chest CT images [17]. The detailed dataset description is shown in Table IV.

TABLE IV. Dataset Description

Parameter	Description
Dataset Name	LIDC-IDRI
Imaging Modality	Thoracic Computed Tomography (CT)
Total CT Scans	1018 lung CT scans (130GB, appx 244,000 DICOM image slices)
Annotation Details	Annotated by 4 experienced thoracic radiologists

The chest CT images obtained from the LIDC-IDRI dataset [17] were first processed using lung segmentation. This step was performed to extract only the lung region from the complete chest CT images. Binary lung masks were generated to separate the lung area from unwanted background regions and other structures ash shown in the figure below. The original dataset contains three-dimensional CT volumes. These 3D CT scans were converted into two-dimensional CT image slices for further processing. The generated binary masks were then applied to each 2D CT slice to obtain segmented lung CT images. These segmented images were further used for denoising and image enhancement processes in the proposed work.

The proposed work was implemented on a workstation system running Ubuntu Server operating system with GPU support. The system was configured with an Intel Core i7 processor, 32 GB RAM, and 1 TB SSD storage for CT image processing tasks. NVIDIA RTX GPU with 12 GB of dedicated memory and CUDA support was used for accelerated computation.

The above Fig. 2 and 3 show results after applying 3D UNet to produce a segmented lung mask image and the segmented lung mask with noise (left) and ground truth image without noise (right).

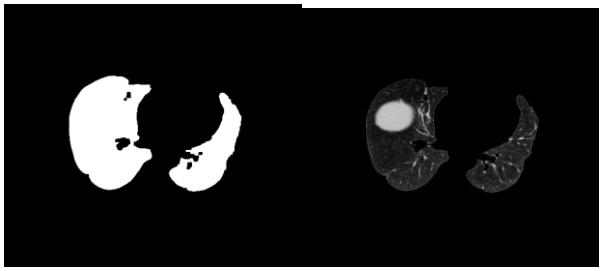

Fig. 2. Segmented lung binary image (Left), segmented lung mask image (Right).

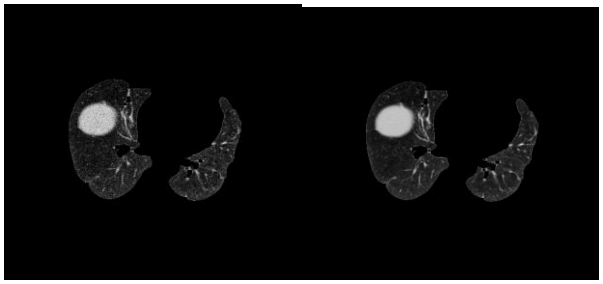

Fig. 3. Segmented lung binary image with Noise (Left), with out Noise (Right).

The performance of the proposed Adaptive Edge Preserving Hybrid De-Noising Framework was evaluated using segmented lung CT images obtained from the LIDC-IDRI dataset. The denoising performance was analyzed using quantitative image quality metrics such as PSNR, SSIM, RMSE, EPI, and Entropy. The obtained results were compared with existing denoising approaches to analyze noise suppression capability and edge preservation performance. The average values of PSNR, SSIM, RMSE, and EPI of all denoised images are calculated and used for comparison purposes. Table V shows the performance analysis of the proposed work.

TABLE V. Performance Analysis of the Proposed Adaptive Edge Preserving Hybrid De-Noising

Method	PSNR (Mean ± SD)	SSIM (Mean ± SD)	RMSE (Mean ± SD)	EPI (Mean ± SD)	Entropy (Mean ± SD)
Noisy Image	18.42 ± 0.62	0.610 ± 0.050	28.54 ± 0.59	0.420 ± 0.004	5.21 ± 0.015
Median Filter	24.85 ± 0.48	0.790 ± 0.038	17.41 ± 0.46	0.710 ± 0.003	6.01 ± 0.013
Gaussian Filter	25.92 ± 0.42	0.820 ± 0.031	15.63 ± 0.38	0.750 ± 0.003	6.18 ± 0.012
Bilateral Filter	27.14 ± 0.34	0.860 ± 0.024	13.41 ± 0.31	0.810 ± 0.002	6.52 ± 0.011
BM3D	29.85 ± 0.24	0.890 ± 0.016	11.52 ± 0.24	0.860 ± 0.002	6.71 ± 0.010
AEPH	32.96 ± 0.15	0.934 ± 0.030	9.84 ± 0.19	0.930 ± 0.001	7.12 ± 0.0094

Table V shows the quantitative performance comparison of different denoising methods applied to segmented lung CT images. The noisy image produced poor PSNR, SSIM, and EPI values with high RMSE due to the presence of noise and struc-

tural degradation. Conventional filtering methods improved the image quality to some extent, but fine edge and texture details were partially affected during noise suppression. The proposed AEPH method achieved better PSNR, SSIM, EPI, and Entropy values with lower RMSE, indicating improved noise removal and preservation of important lung structures.

The following graphs, shown in Figs. 4 -7, compare the denoising performance using PSNR, SSIM, RMSE, and EPI metrics, respectively. The proposed AEPH achieved the highest PSNR and SSIM values, along with the lowest RMSE and highest EPI. These results show that AEPH provides better noise removal while preserving important edge and structural details than the existing denoising methods.

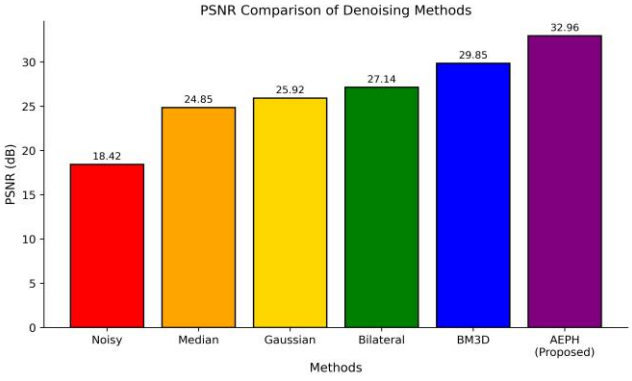

Fig. 4. PSNR comparison of denoising methods.

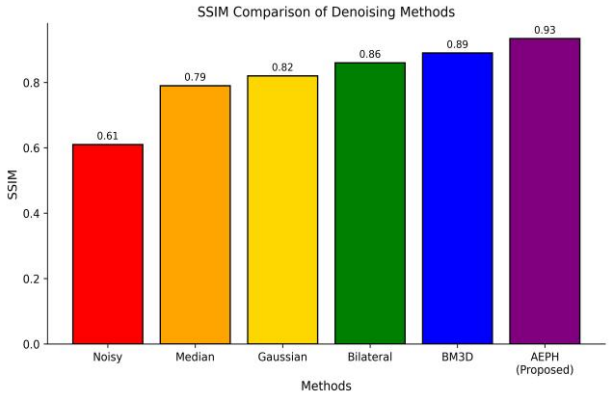

Fig. 5. SSIM comparison of denoising methods.

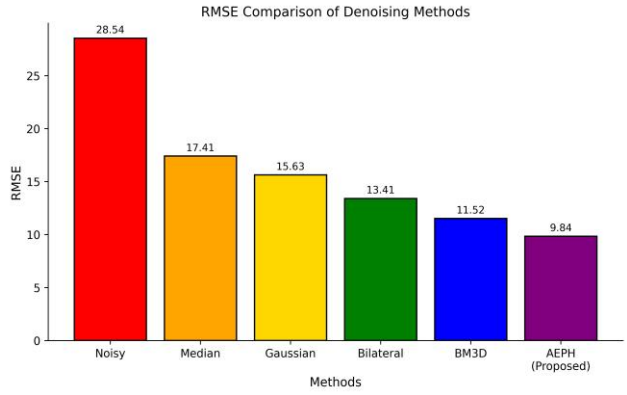

Fig. 6. RMSE comparison of denoising methods.

After implementation of Algorithm 1, Adaptive Edge-Preserving Hybrid Denoising Framework for Segmented Lung CT Images, the denoised images are input to the second algorithm, Variance Regulated Adaptive Histogram Equalization (VRAHE), to improve the contrast of the image. The VRAHE algorithm was evaluated using segmented lung CT images from the LIDC-IDRI dataset. The enhancement performance was analyzed using CNR, AMBE, UIQI, and EME metrics. These metrics were used to evaluate contrast improvement, brightness preservation, and local detail enhancement. The obtained results were compared with conventional histogram equalization methods. The details are shown in Table VI, and the lung segmented before and after applying VRAHE is shown in Fig. 8.

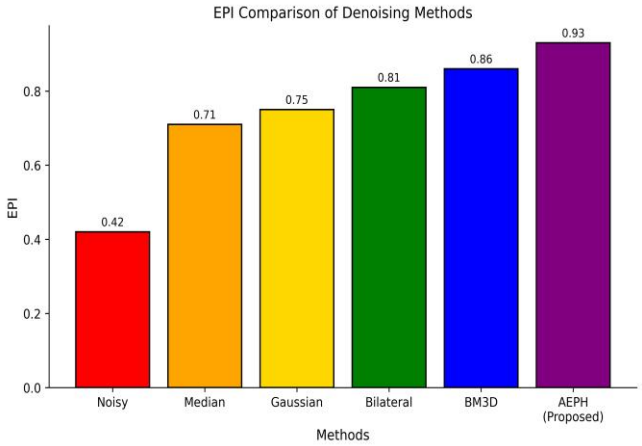

Fig. 7. EPI Comparison of denoising methods.

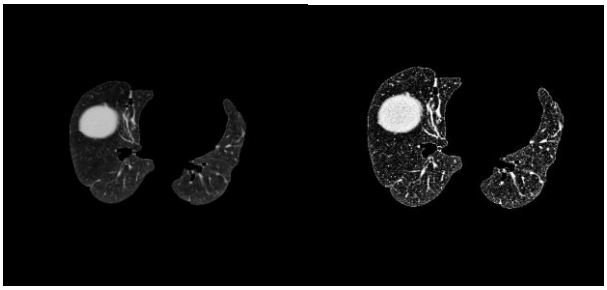

Fig. 8. Before (L) and after (R) applying VRAHE.

TABLE VI. QUANTITATIVE PERFORMANCE ANALYSIS OF VRAHE ENHANCEMENT METHOD

Method	CNR (Mean ± SD)	AMBE (Mean ± SD)	UIQI (Mean ± SD)	EME (Mean ± SD)
Original Image	2.14 ± 0.18	16.82 ± 0.62	0.741 ± 0.020	11.26 ± 0.95
HE	3.08 ± 0.15	11.34 ± 0.51	0.826 ± 0.015	16.72 ± 0.81
CLAHE	4.12 ± 0.12	7.26 ± 0.39	0.901 ± 0.010	22.84 ± 0.66
VRAHE (Proposed)	5.96 ± 0.08	3.14 ± 0.18	0.972 ± 0.004	31.48 ± 0.42

An ablation study was carried out to study the role of the major stages in the proposed AEPH and VRAHE framework. AEPH reduced noise using adaptive filtering, guided filtering, wavelet denoising, and adaptive fusion, and obtained a PSNR of 32.96 dB, SSIM of 0.934, and RMSE of 9.84. After denoising, VRAHE improved contrast and brightness preserva-

tion with CNR of 5.96, AMBE of 3.14, UIQI of 0.972, and EME of 31.48. The results show that each stage adds to the overall refinement of segmented lung CT images. Fig. 9 below shows the Comparative Performance Analysis of Lung CT Image Enhancement Methods.

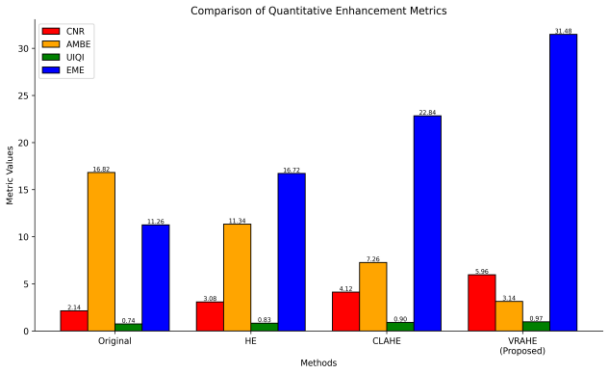

Fig. 9. Comparative performance analysis of lung CT image enhancement methods.

V. Conclusion

This work presented an Adaptive Edge Preserving Hybrid De-Noising Framework for Segmented Lung CT Images and a Variance Regulated Adaptive Histogram Equalization (VRAHE) approach for improving the quality of segmented lung CT images. The proposed denoising framework effectively reduced Gaussian, quantum, and salt-and-pepper noises while preserving important edge and structural information. The obtained results achieved PSNR of 32.96 dB, SSIM of 0.934, EPI of 0.93, RMSE of 9.84, and Entropy of 7.12, indicating effective noise suppression and structural preservation.

The proposed VRAHE method further improved local contrast and visibility of lung structures without producing excessive intensity distortion. Quantitative evaluation produced CNR of 5.96, AMBE of 3.14, UIQI of 0.972, and EME of 31.48, showing improved contrast enhancement and brightness preservation performance. The overall experimental analysis demonstrated that the proposed approaches can effectively improve the quality of segmented lung CT images and preserve important anatomical details useful for further medical image analysis and abnormality detection.

VI. Future Direction

In future work, the proposed Adaptive Edge Preserving Hybrid De-Noising Framework and Variance Regulated Adaptive Histogram Equalization (VRAHE) approach can be extended for real-time clinical applications using GPU-based parallel processing architectures. The proposed methods can also be integrated with deep learning-based abnormality detection and classification models for automated lung disease analysis. Further improvement can be achieved by developing adaptive region-based enhancement methods for preserving fine lesion structures in low-dose CT images. The proposed framework may also be extended to 3D volumetric CT analysis, multimodal medical imaging applications, and explainable AI-assisted diagnostic systems for improved clinical interpretation and decision support.

Acknowledgment

The Research Scholar expresses her sincere thanks to the research supervisor and institution for providing necessary guidance and support to complete this research work. The authors acknowledge the medical image datasets and computational facilities used for carrying out the experiments. The suggestions and encouragement received during the development of the Adaptive Edge Preserving Hybrid DeNoising Framework and Variance Regulated Adaptive Histogram Equalization method helped in improving the overall quality of the proposed work.

***Abstract*—This study aims to design and functionally validate a prototype precision fertigation control system based on a Programmable Automation Controller (PAC) capable of managing water and nutrient delivery through two approaches: a time-based approach as the basic control and a rule-based approach as a corrective response based on sensor data (pH, EC, and moisture) of the growing medium. The method used in this study is Research and Development (R&D), and the scope of the research is limited to the Preliminary Field Testing phase, which includes requirements gathering and literature review, architectural planning (sensors, gateway, PAC, actuators, HMI/Human Machine Interface), development of an initial prototype (hardware and software), as well as initial-scale functional testing through hardware functional testing and black-box testing on the HMI interface. The test results showed that all acceptance criteria were met, including sensor function deviation of 2.5% (≤5%), actuator response time of 1.2 s (<2 s), current deviation of 2.0 A (≤3 A), voltage stability of 12.1 V (11.4–12.6 V), operational reliability of 96 hours (≥72 hours), communication success rate of 99.5% (≥99%), and system response latency of 320 ms (<500 ms); all results were classified as Pass. Thus, the developed prototype has proven to be stable and suitable for initial field testing, and provides a solid foundation for further development toward broader application in more efficient and responsive fertigation management.**

***Keywords*—HMI; precision fertigation; PAC; preliminary field testing; time-based control; rule based control**

I. Introduction

Terminologically, fertigation is often regarded as an intrinsic element of hydroponic systems. However, within the broader scope of agronomy, this technology is a technique for delivering soluble nutrients through an irrigation system that can be applied across various growing media [1]. The application of fertigation in crop cultivation using drip fertigation (drip irrigation) in soil or non-hydroponic substrates represents an evolution of precision agriculture [2]. Fertigation is a crop cultivation method that combines irrigation and fertilization, in which nutrients are delivered simultaneously with irrigation water in a measured and timely manner. This method offers high efficiency in water and nutrient use, which directly impacts the improvement of crop yield quality and quantity [3]. Fertigation is a highly effective and increasingly popular approach in crop cultivation.

In fertigation-based crop cultivation, "treatment" often refers to variations in the dosage, frequency, or composition of nutrients provided to plants. Plant treatments may involve applying specific conditions or inputs to plants to observe their impact on growth and yield [4][5]. The concept of "treatment" plays a crucial role; in fertigation, it represents an approach to water management and distribution that integrates essential nutrients dissolved directly into the plant's root zone via the irrigation system. Plant treatment is not merely separate watering or fertilizing, but rather a precise, integrated process. A "treatment" in fertigation can encompass various variables, including: 1) Type and Concentration of Nutrients; 2) Volume and Frequency of Application; 3) Application Timing (nutrient delivery). The objective of treatment in the fertigation method is to ensure that plants receive the optimal amount of water and nutrients at the right time, thereby improving nutrient use efficiency, conserving water, and maximizing crop yields.

Effective fertigation methods require high precision, and this is where control technology is essential. In previous studies, IoT (Internet of Things) technology has been widely used to monitor and control fertigation. Some of these studies include: Microcontroller- and HMI-based IoT applications to support agricultural control systems [6]. The use of cloud-server-based IoT for fertigation control [7]; in this study, the system was highly dependent on the internet. The use of IoT and fuzzy logic to support irrigation systems [8] [9] [42] [43]; this study did not account for plant growth phases. The use of IoT to improve the efficiency of nitrogen and EC use in drip-fertigation systems [10] [11]; this did not account for errors in sensor readings [41].

The current trend in precision agriculture is that data has become the key factor enabling automation, intelligent analysis, and more efficient decision-making. On the other hand, agricultural research generates a wealth of data regarding optimal nutrient doses, timing of nutrient application, ideal growing medium conditions (pH/EC/moisture), and specific

*Corresponding author.

plant requirements at various growth stages [12]. This data and information are often complex and require agronomic expertise to interpret.

This study aims to design, develop, and verify an HMI (Human Machine Interface) application program to execute and monitor two plant treatment methods: time-based (plant treatment based on time/schedule) and rule-based (serving as both a quick correction and a safety limit monitor) within a PAC (Programmable Automation Controller)-based control system, thereby enabling the regulation of water and nutrient supply based on sensor data in the growing medium.

A PAC is a control system that combines the functionality of a programmable logic controller with more modern and flexible computing capabilities, similar to a personal computer (PC). The main contributions of this research are: 1) developing an HMI as an interface between the user and the fertigation control system, 2) implementing two plant treatment modules (time-based and rule-based) integrated into the fertigation control system, and providing facilities for monitoring the fertigation process via the HMI.

II. METHOD

This study employs a Research and Development (R&D) methodology, which emphasizes the design and construction of prototypes, as well as prototype evaluation [13]. The focus of the study is to produce a prototype HMI application program and a plant treatment logic control system (time- and rule-based), which has been functionally validated through preliminary field testing.

A. Research and Development (R&D) Methodology

Fig. 1 shows the block diagram of the R&D stages conducted in this study, namely: 1) Research and Information Collection: this stage gathers requirements and foundational knowledge to design a precision fertigation control system through literature reviews, growing medium data (pH, EC, moisture) as indicators of plant health and fertility, and PAC architecture. 2) Planning: This stage establishes the technical design and prototype plan, including system architecture, as well as initial functional test scenarios as success criteria; 3) Developing a Preliminary Product Form: This stage produces an initial prototype of a PAC-based fertigation control system integrated with control logic and HMI software, 4) Preliminary Field Testing: This stage involves simulation testing to ensure the prototype functions properly and is ready for further development.

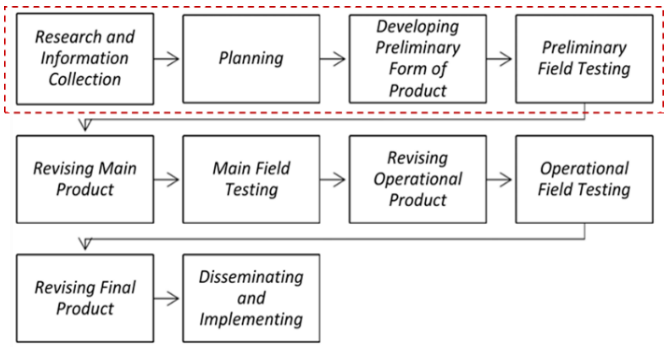

Fig. 1. Stages of the R&D methodology.

1) Concept of plant treatment using the fertigation method: In fertigation, "treatment" refers to the planned, measured, and controlled application of a mixture of irrigation water and nutrient solution directly to the plant's root zone. This treatment is not merely ordinary watering or fertilizing, but rather a precise, integrated management of plant needs [14]. Treatment is at the core of the fertigation method, where an integrated system delivers the primary supplies of water and nutrients directly to the plants. The fertigation method integrates four planned actions: 1) formulating nutrients, 2) determining dosage and concentration, 3) regulating timing and frequency, and 4) selecting the treatment method. Thus, treatment in the fertigation method involves the measured management of water and essential nutrient delivery, thereby enhancing the accuracy, efficiency, and responsiveness of agriculture to achieve optimal crop yields.

This study developed two integrated control methods: time-based control and rule-based control. In time-based control, the system relies entirely on a schedule predefined by the operator or farmer. In the rule-based treatment, the system relies on conditional logic (if-then) triggered by real-time data from EC, pH, and growing medium moisture sensors. Rule-based treatment is applied only when the plants need it, thereby preventing waste and optimizing growth. This system is far more efficient and responsive to daily weather changes, resulting in more efficient resource use and more consistent crop yields. An example of a rule-based treatment is: "IF the growing medium moisture is below 60% OR solar radiation exceeds a certain threshold, THEN activate the actuator until moisture reaches 85%."

2) PAC-based fertigation control system: Effective fertigation methods require high precision, so control system technology is essential. The fertigation control system serves as an operational hub that ensures the treatment is carried out as planned. This system is responsible for opening valves and activating pumps. Consequently, to execute these various actuator operations, accurate and reliable hardware is required. The PAC integrates various functions, including: 1) Data Acquisition: The PAC connects to a network of field sensors to monitor growing media conditions in real-time; 2) Data Processing: The PAC runs complex algorithms, including both time-based treatment logic and rule-based treatment logic (if-then) to interpret sensor data; 3) Coordinated Control: Based on the interpretation of sensor data, the PAC precisely controls the actuators to implement the required treatment activities.

B. Design and Development: Prototype of the Complete System

Fig. 2 shows the architecture of a PAC (Programmable Automation Controller)-based irrigation control system, which consists of: 1) Data Processing, 2) Control Panel, 3) Actuators, and 4) WSN (Wireless Sensor Network). Table I shows the functions of each component within the PAC.

TABLE I. COMPONENTS, FUNCTIONS, AND DEVICE REQUIREMENTS OF THE PAC

Components	Functions	Requirement
PC/Laptop	Data Processing	1. OS: Windows 10 2. RAM: 8 MB 3. Hard disk: 120 GB
Control Panel	The control panel serves as a hardware integration hub that connects the actuators to the data processing PC, ensuring that the sensing–decision–actuation process runs smoothly.	4. Fig. 3. Flowchart of how the fertigation control system works.

Fig. 3 shows a block diagram of how the PAC-based fertigation control system works. Overall, this fertigation control system operates in a single feedback loop: measure conditions --> send data to the computer (PC) --> the computer processes the data and makes a decision --> send a command --> the actuator responds.

1) Data processing: The Data Processing unit is the central data processing component within the PAC (Programmable Automation Controller), responsible for executing logic control instructions [28], processing data from the WSN (Wireless Sensor Network) [15], and managing communication with actuators. In this study, the Data Processing Unit consists of a PC running the Windows 10 operating system, which enables it to handle more complex algorithms to support the operation of the Logic Control and HMI (Human Machine Interface) application programs.

Fig. 4. Data processing PC unit configuration.

Fig. 4 shows the configuration of the Data Processing PC unit; the PC is connected to the ADAM-4520 via RS-232, and the ADAM-4017 and ADAM-4068 are connected to the ADAM-4520 via RS-485. The Data Processing unit runs the Logic Control application program to select the treatment method (Time-Based or Rule-Based). The result of processing sensor data using the Logic Control method is a decision related to actuator activity.

2) Control panel: The control panel in this study serves as a hardware integration hub that connects the actuators to the data processing PC, ensuring that the sensing–decision–actuation process runs smoothly[37]. The Control Panel consists of: 1) Input Module (ADAM 4017) [16]: receives data from analog sensors, 2) Output Module (ADAM 4068): sends control signals to the actuator to activate the irrigation pump. The I/O (Input/Output) modules on the PAC are modular (hot-swappable), meaning they can be added or removed, providing flexibility for system expansion. The ADAM-4520 is an isolated serial converter that converts RS-232 communication to RS-422/RS-485 for greater noise immunity and transmission ranges of up to approximately 1.2 km, while protecting the host computer via 3000 VDC isolation. Fig. 5 shows the connection between the I/O module and the PC.

The ADAM-4068 is an 8-channel relay-based digital output module designed to control field devices such as pumps, valves, or alarms via RS-485 commands (ASCII/Modbus RTU). Meanwhile, the ADAM-4017 is an 8-channel analog input module that reads analog sensor signals (voltage/current), converts them into 16-bit digital data that can be processed by a control system, and also supports Modbus RTU communication. Communication between ADAM modules occurs via a fieldbus; ADAM modules are fundamentally designed to operate within a "master-slave" architecture. The master (typically a PC) is responsible for initiating all communication with other components [38]. I/O modules (such as the ADAM-4017 or ADAM-4068) act as slaves that only respond to requests from the master.

ADAM modules use an RS-485 physical interface for inter-module communication. This network topology allows for multi-drop or daisy-chain connections, enabling dozens of modules to be connected on a single pair of cables [39]. This is highly efficient for connecting numerous sensors and actuators spread across agricultural areas. The protocol used for communication between ADAM modules and the master can be: 1) Modbus/RTU, the most widely used standard industrial protocol. The master sends a Modbus "command" (e.g., "read the analog input value from module ID 01") and the ADAM module responds with the requested data; 2) ASCII Command, which uses simple ASCII-based text commands. Often, a PC only has a standard RS-232 port (an older serial port), so the ADAM 4520 functions as a bridge or translator, converting the RS-232 signal from the PC into an RS-485 signal.

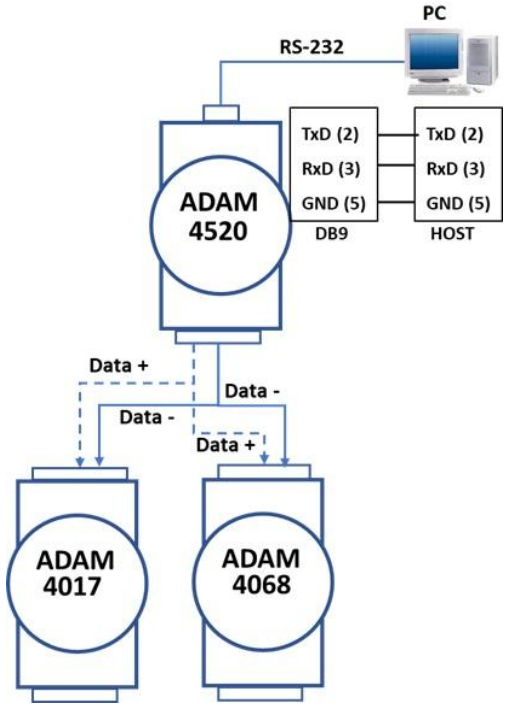

Fig. 5. Wiring diagram on the control panel.

3) Actuator: Actuators serve as execution components that translate control decisions from the PC into physical actions in the fertigation process. Based on readings from pH, EC, and growing medium humidity sensors, as well as time-based (routine schedule) and rule-based (correction upon deviation) control logic, actuators control devices such as pumps and/or valves to deliver water and nutrient solutions as needed. Thus, the actuator serves as a direct link between data processing results and actual field conditions, while ensuring that water or nutrient delivery is timely, measured, and responsive to changes in growing medium conditions.

The PC sends low-voltage control signals via the I/O module. These signals trigger the actuators to operate. In the context of a fertigation system, this relationship is clearly evident: 1) The PC makes a decision, and the actuator acts: The PC executes rule-based logic that states, "If soil moisture is below 60%, activate irrigation in Zone A." The PC then sends the appropriate electrical signal; 2) The Role of Relays and Solenoid Valves: the signal is received by the output module (such as the ADAM-4068, which contains relays). The relay functions as an intermediate switch to activate actuators requiring higher power, such as water pumps or solenoid valves; 3) Execution of Crop Treatment: the solenoid valve opens, allowing water and nutrient solution to flow into the root zone. The water pump turns on, creating the required pressure. It is the physical action of opening the valve or turning on the pump that is performed by the actuator; Fig. 6 shows the actuator design.

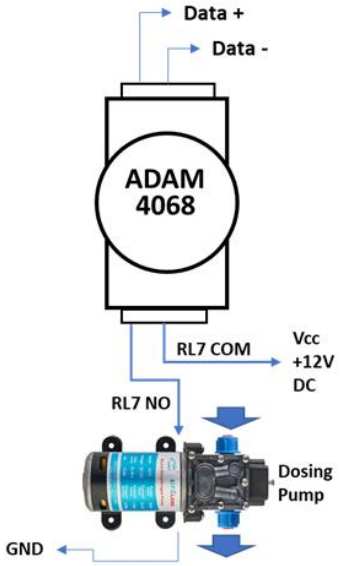

Fig. 6. Actuator wiring diagram (ADAM 4068 to dosing pump).

Data+ and Data- are the RS-485 communication lines connecting the ADAM 4068 [16] to the PC (via the ADAM 4520); these lines are used to receive control instructions from the host. RL7 COM (Common) is the common terminal of channel 7 relay on the ADAM 4068. This pin serves as the power supply input (+12V DC) for the actuator. RL7 NO (Normally Open) is the normally open terminal on channel 7 of the relay. When the relay is inactive, the circuit between COM and NO is open. When the relay is activated by the PC, the circuit closes, allowing the +12V DC voltage to flow to the dosing pump. Vcc +12V DC is the positive power supply voltage (+12 volts) used to operate the dosing pump. It is routed through the RL7 COM line and passed to RL7 NO when the relay is active. GND is the ground line connected to the negative

side of the power supply and the dosing pump, thereby forming a complete electrical circuit [40]. With this configuration, the dosing pump will only turn on when the relay on channel RL7 is activated. This allows the PC, via the ADAM 4068, to automatically control nutrient delivery based on calculations from data analysis. The data processing PC is the decision-maker, and the actuators are the physical executors that ensure crop management proceeds in accordance with the programmed automation strategy; without the actuators, the intelligent decisions made by the data processing PC would never be translated into actual actions in the field.

4) Monitoring of growing media: In this context, the PAC (PC Data Processing Unit) receives growing medium data from a WSN (Wireless Sensor Network)-based sensor network [17]. Data from the WSN is transmitted directly to the PC Data Processing Unit via a WiFi (wireless) network. In this study, the configuration between the WSN and the PC utilizes the Fog Computing concept [18], thereby eliminating the need for a cloud server.

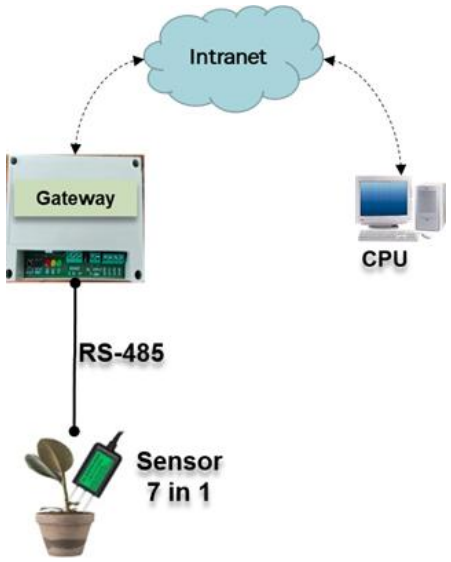

Fig. 7. WSN configuration as a data source.

The growing medium sensors and the Gateway (as shown in Fig. 7) are WSN devices that continuously measure EC, pH, and humidity parameters in the growing medium. The data collected by the gateway is then sent to the PC Data Processing unit using the MQTT (Message Queuing Telemetry Transport) protocol [19]. Data is collected periodically (e.g., every 10 minutes). This interval ensures that the PAC always has up-to-date information on plant conditions without overloading the network.

The PAC uses the received data to apply rule-based treatments as follows: 1) "If-Then" Conditional Logic: Data received from the WSN (e.g., humidity = 55%, pH = 6.0) is used to evaluate pre-programmed rules; 2) Automatic Decision-Making: The PAC makes real-time decisions based on this data; example rules: (a) "IF humidity < 60% THEN activate the irrigation pump," (b) "IF pH > 6.5 THEN apply an acid solution to stabilize the growing medium"; 3) The fertigation control system does not provide nutrients based on a schedule, but only reacts when actual field conditions require intervention, ensuring efficient use of resources. This study emphasizes the importance of integrating real-time data from sensors in decision-making regarding plant nutrient application.

5) Sensor plant health and productivity indicators: The pH, EC (Electrical Conductivity), and growing medium moisture content are key indicators in precision agriculture that provide fundamental information regarding nutrient availability and uptake by plants; these three parameters serve as early indicators of nutrient requirements [12] [20] [21]. pH (Acidity Level) measures the acidity or alkalinity of the growing medium. It is not an indicator of the amount of nutrients present, but rather an indicator of their availability. As an indicator, this means that nutrients are absorbed most effectively within a specific pH range. Most plants prefer a pH between 5.5 and 6.5. For example, if the pH is too high (alkaline), nutrients such as Iron (Fe), Manganese (Mn), and Phosphorus (P) will be locked within the growing medium and cannot be absorbed by the roots, even if they are present in sufficient quantities. Initial Action: A suboptimal pH reading is an early indicator that the plant is at risk of nutrient deficiency in the future, so adjusting the pH of the nutrient solution is necessary.

EC (Electrical Conductivity) measures the total concentration of dissolved salt ions in the growing medium solution; these salts constitute the fertilizer (nutrients). As an indicator, EC directly reflects the concentration of the nutrient solution available in the root zone. For example, a low EC value indicates that the growing medium is deficient in nutrients and the plants need to be fertilized. Conversely, if the EC value is too high, it indicates an excess of fertilizer, which risks causing toxicity or nutrient burn (burnt roots). Initial Action: Monitoring EC can provide a direct indication of whether the current nutrient dose is appropriate or needs to be increased or decreased.

The moisture content of the growing medium indicates the amount of water available within it. As an indicator, this means that water serves as the medium for nutrient transport. Nutrients must be dissolved in water so that they can be absorbed by the roots through osmosis and transpiration. Example: If the growing medium is too dry, nutrient uptake will cease entirely, even if the pH and EC values are ideal. A drastic drop in moisture levels indicates the need for immediate irrigation, which is often combined with nutrient application (fertigation) to maintain a steady flow of nutrients to the plants.

Fig. 8. (7-in-1) Growing medium sensor for a fertigation control system.

The sensor used in this study is the RS485-based Multisensor Digital soil sensor [22], specifically designed for precision agriculture applications and fertigation systems, as shown in Fig. 8. This sensor serves as a digital sensing device

that is a critical component of modern agricultural systems; it is a detector that integrates the ability to measure several key growing medium parameters simultaneously, often including moisture, temperature, electrical conductivity (EC), and pH.

Table II shows the role of growing medium parameters as indicators of plant health and productivity.

TABLE II. PLANT HEALTH AND PRODUCTIVITY INDICATORS

Parameter Monitoring	Description	Action
EC (Electrical Conductivity)	An EC level that is too high or too low can hinder plant growth and overall health.	• If the EC reading is too high, add clean water (without nutrients).• If the EC reading is too low, add a nutrient solution with a higher concentration, adjusted according to the plant's growth stage (early stage, vegetative stage, or generative/flowering/fruiting stage).
pH (potential of hydrogen)	The primary effect of pH on plants is on nutrient availability. Suboptimal pH levels prevent nutrients from being bound and absorbed by the plants, even though they are present in the growing medium.	• Optimal nutrient availability occurs at a growing medium pH of 5.5–7.0.• If the growing medium pH is too low (< 5.5), the pH must be adjusted toward neutral.• If the growing medium pH is too high (> 7.0), corrective measures are needed to lower the pH.
Moisture Content of the Growing Medium	Adequate water availability in the growing medium is essential for plant survival, but too much or too little water can have negative effects.	• Add water and/or nutrients according to the moisture level of the growing medium.

By monitoring these three key indicators in real time—humidity to ensure nutrient transport occurs, pH to ensure nutrients are accessible and available, and EC to ensure nutrient concentrations are sufficient but not excessive—the fertigation control system can automatically adjust the necessary treatments to maintain optimal root zone conditions for plant growth. WSN sensors provide accurate, real-time data to the PAC, enabling it to implement rule-based treatments so that plants receive optimal growing conditions.

6) Design of the system logic control application program: In the context of PAC functionality, the PC (Data Processing) contains the Logic Control and HMI application programs. Logic Control is an application program that functions as the Decision Layer [36]. The Decision Layer is a component of the layered architecture responsible for high-level decision-making, such as interpreting sensor data, selecting or planning actions, and then sending commands to the execution/actuation layer below it. The Decision Layer also encompasses decision-making and planning processes, which generate a sequence of actions. Meanwhile, the HMI (Human-Machine Interface) is a feature that provides a dashboard for users (farmers) to operate and monitor fertigation activities. Fig. 9 shows a Flow Diagram of how the HMI application program works.

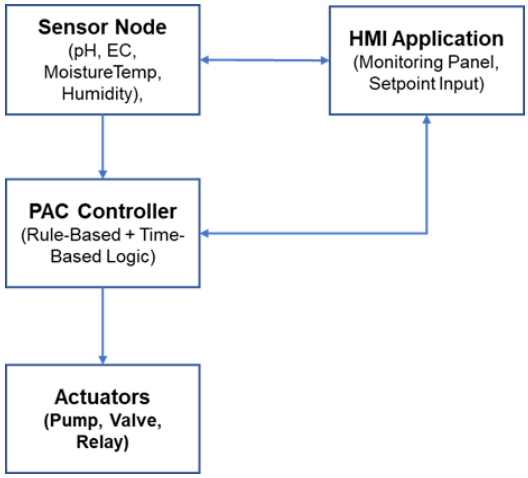

Fig. 9. Flowchart of the HMI application program's operation.

The Sensor Node measures environmental conditions and plant nutrition based on pH, EC, and growing medium moisture parameters. The PC serves as the logic control center with two main control methods: 1) Time-Based Logic, which activates the pump at specific times; 2) Rule-Based Logic, which activates the pump if the growing medium sensor detects specific conditions (e.g., low EC). The HMI provides a user interface to view real-time data, set time points, limit parameters, or perform manual overrides. Actuators receive signals from the PC to activate pumps, valves, or relays according to the plant's growth stage or sensor conditions.

The relationship between the logic controller and the HMI can be described as follows: 1) The logic controller is an application program containing rules regarding plant care, such as the following instruction [26]: "IF the humidity sensor reads below 60% AND the sun is shining brightly, THEN activate the pump for 5 minutes." Logic control translates human ideas (research findings) into machine language that can be executed by the PAC [27]; 2) The HMI is the "face" of the control system [29]; it is not used to create new logic, but to monitor and interact with the existing Logic Control.[30].

In this study, the PAC does not rely on an internet connection, thereby reducing the potential for disruptions caused by network instability. Additionally, since the PAC is PC-based, the development of application programs and the human-machine interface (HMI) becomes more flexible and robust. The PAC allows programming using high-level programming languages, enabling the system to be designed with more complex, dynamic features that are easily adaptable to user needs and the desired level of control complexity. [31].

One of the activities in this study was to develop an HMI model (as a dashboard) with several features, including: 1) Hardware Settings, 2) Time-Based "treatment" features, 3) Rule-Based "treatment" features, to support the operation of the fertigation control system [33]. These two treatment features are required simultaneously, as not all plant conditions can be predicted solely from sensor data or growth stages alone. By combining both, the fertigation control system becomes more flexible [32], responsive, and precise. Table III illustrates the design concepts of time-based and rule-based "treatment."

TABLE III. THE DESIGN CONCEPT OF "TREATMENT"

Features / Approach	Time-Based Treatment	Rule-Based Processing
Main Trigger	A fixed schedule (for example, every day at 7 a.m.)	Actual field conditions (If humidity < X%)
Basis for the Decision	The time specified by the "User."	Programmed "If-Then" Logic
Data Source	System clock/calendar	Real-time sensors (humidity, temperature, etc.)
Flexibility	Not weather-resistant	Flexible (adapting to changing conditions)
Response	Procedural (following a set of steps)	Reactive (responds to the sensor threshold)
Complexity	Low (simple timer)	Medium (requires sensors and logic)
Application Examples	Standard home garden irrigation	Automated greenhouse irrigation system

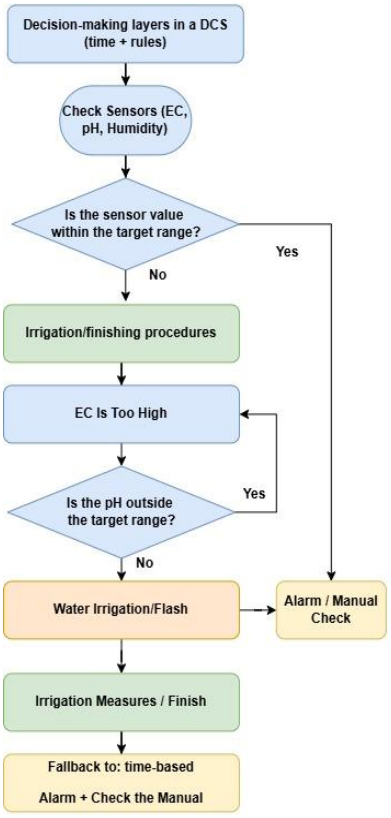

Fig. 10. Flowchart of plant treatment (time-based and rule-based).

Fig. 10 shows a flowchart of the logic control in the DCS for time- and rule-based plant treatment control (base schedule + correction rules). Based on this flowchart, the workflow of the fertigation control system [34] is as follows: 1) The system reads the sensors, 2) monitors whether the growing medium parameters are still within normal limits, 3) In rule-based mode, the system evaluates deviation conditions, 4) If a disturbance occurs (e.g., sensor/communication issues), the system falls back to time-based mode and continues to run the minimum schedule while issuing an alarm to suggest a manual check. Moreover, Table IV shows the features for hardware settings, which include: port connectivity, output control [35], data acquisition, measurement calibration, data storage, and logging.

TABLE IV. HARDWARE SETUP AND SYSTEM CONFIGURATION

Category: Setting	Job Function / Job Description	Software Implementation / HMI	Information Regarding ADAM Hardware
Port Connectivity	Open/Close the Serial Communication Port	The "Connect" / "Disconnect" button on the HMI. A drop-down menu for selecting the COM port (e.g., COM1, COM2) and setting the baud rate (e.g., 9600 bps).	Using the ADAM-4520 as a converter and RS-485 bus.
Output Control (Relay)	Trying to run the relays (RL0–RL7)	The HMI displays 8 toggle switches labeled "Pump A," "Valve 1," etc. Each relay has a visual status indicator (ON/OFF light).	Send a Modbus/ASCII Write command to the ADAM-4068 to enable or disable a specific relay.
Data Acquisition	Trying to Retrieve Data from the Sensor	The "Refresh Data" button or automatic update on the HMI that displays sensor values in real time (for example, "Humidity: 75%").	Send a Modbus/ASCII Read command to the ADAM-4017 to read 8 analog input channels and receive data from IoT sensors.
Measurement Calibration	Calibration of Sensor Measurement Results	The configuration menu on the HMI for entering offset and scaling values (for example, converting a raw 4–20 mA value to 0–100% humidity).	Adjust the digital reading of the ADAM-4017 to match the actual physical value.
Data Storage & Logs	Save Settings and Record Relay Usage (RL0–RL7)	The "Save Settings" button on the HMI. An automatic data logging feature that runs in the background.	The data log is stored in a text file (.txt) or database on the PC/PAC, recording when the ADAM-4068 relay turns on and off.

C. Development: HMI and Decision Layer Treatment Programming

Pseudocode-1 shows the pseudocode for the system initialization application program, which includes: general initialization and communication port status initialization.

Pseudocode-1

```
// Initialize global variables and data structures
DEFINE current_moisture, current_ph, current_ec AS FLOAT
DEFINE pump_status, valve_A_status AS BOOLEAN
DEFINE scheduled_time_A, scheduled_duration_A AS TIME/DURATION
DEFINE rule_moisture_threshold AS FLOAT

// Initialize communication port status
```

```
SET comm_port_open = FALSE

FUNCTION InitializeSystem()
    LOAD_SETTINGS_FROM_FILE("conFig. txt")
    DISPLAY("System initialized. Awaiting connection.")
END FUNCTION
```

Fig. 11 shows the HMI display as the system begins the initialization process. The growing medium sensor will display the current data.

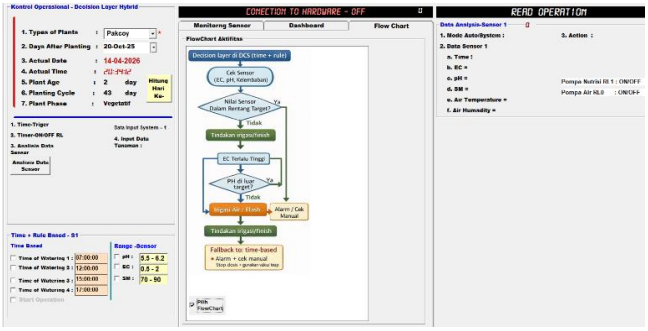

Fig. 11. HMI screen during system initialization.

Moreover, Pseudocode 2 shows the pseudocode for the application program to configure port communication, manually test the relay, and calibrate the sensor. These functions can be accessed by the user through the programming interface or the HMI configuration menu.

Pseudocode-2

```
// Use Case: Configure Communication Port
FUNCTION ConfigurePort(port_name, baud_rate)
IF comm_port_open THEN
CLOSE_PORT()
END IF
OPEN_PORT(port_name, baud_rate)
IF success THEN
SET comm_port_open = TRUE
DISPLAY("Port " + port_name + " opened successfully.")
SAVE_SETTINGS_TO_FILE("conFig. txt")
ELSE
DISPLAY("Failed to open port. Check connection.")
END IF
END FUNCTION

// Use Case: Test Relay Function (ADAM 4068)
FUNCTION TestRelay(relay_id, duration_seconds)
IF comm_port_open THEN
DISPLAY("Testing Relay R" + relay_id + " for " + duration_seconds + "s")
SEND_MODBUS_WRITE(ADAM_4068_ADDRESS, relay_id, STATE_ON)
LOG_ACTION("RL" + relay_id + " turned ON for test")
WAIT(duration_seconds * 1000 milliseconds)
SEND_MODBUS_WRITE(ADAM_4068_ADDRESS, relay_id, STATE_OFF)
LOG_ACTION("RL" + relay_id + " turned OFF after test")
ELSE
DISPLAY("Error: Port not open. Cannot test hardware.")
END IF
END FUNCTION

// Use Case: Retrieve Data from Sensor (ADAM 4017) and Calibrate
FUNCTION ReadAndCalibrateSensorData()
IF comm_port_open THEN
// 1. Retrieve raw data
raw_moisture_data = SEND_MODBUS_READ(ADAM_4017_ADDRESS, CHANNEL_0)
raw_ph_data = SEND_MODBUS_READ(ADAM_4017_ADDRESS, CHANNEL_1)

// 2. Apply calibration (scaling/offset)
current_moisture = APPLY_CALIBRATION(raw_moisture_data, MOIST_SCALE, MOIST_OFFSET)
current_ph = APPLY_CALIBRATION(raw_ph_data, PH_SCALE, PH_OFFSET)

DISPLAY("Moisture: " + current_moisture + "%, pH: " + current_ph)
SAVE_SETTINGS_TO_FILE("conFig. txt") // Saves calibration settings
END IF
END FUNCTION

// Use Case: Save Settings and Record Usage (Log File)
FUNCTION LogAction(action_description)
timestamp = GET_CURRENT_TIMESTAMP()
APPEND_TO_FILE("usage_log.txt", timestamp + " - " + action_description + NEWLINE)
END FUNCTION
```

Fig. 12 shows the HMI Hardware Settings screen. This HMI interface is designed to provide intuitive yet powerful control, with high flexibility in setting critical fertigation parameters locally via the PAC. The system can be used to support decision-making based on the actual conditions of the growing medium.

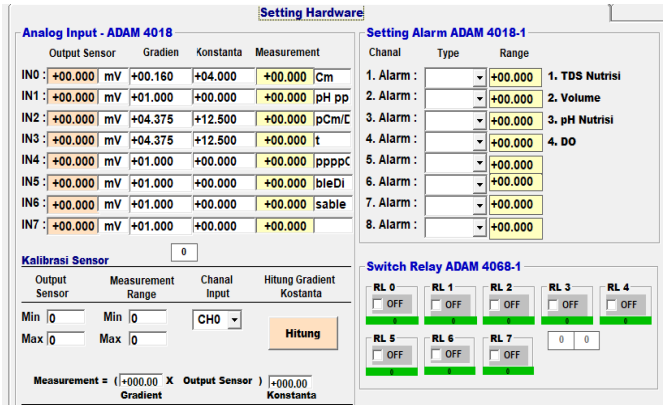

Fig. 12. Hardware settings dashboard.

Pseudocode 3 shows the pseudocode for time-based treatment; this logic runs continuously in the main system loop.

Pseudocode-3

```
FUNCTION RunTimeBasedTreatment()
current_time = GET_CURRENT_TIME()

// Check if the current time matches the scheduled start time
IF current_time IS scheduled_time_A THEN
DISPLAY("Executing Time-Based Treatment A")

// Activate pump/valve (e.g., Relay 0 on ADAM 4068)
SEND_MODBUS_WRITE(ADAM_4068_ADDRESS, RELAY_0, STATE_ON)
LogAction("RL0 ON - Start time treatment")

// Wait for the scheduled duration
WAIT(scheduled_duration_A)

// Deactivate pump/valve
SEND_MODBUS_WRITE(ADAM_4068_ADDRESS, RELAY_0, STATE_OFF)
LogAction("RL0 OFF - End time treatment")
END IF
END FUNCTION
```

Moreover, Pseudocode-4 shows the pseudocode for rule-based treatment. This logic runs continuously in a loop within the main system and typically checks environmental conditions more frequently than time-based systems.

Pseudocode-4

```
FUNCTION RunRuleBasedTreatment()
  // First, update sensor data to get current conditions
  ReadAndCalibrateSensorData()

  // Apply the 'If-Then' rule
  IF current_moisture < rule_moisture_threshold THEN
    // Condition met: Soil is too dry. Need to irrigate.
    DISPLAY("Rule Triggered: Moisture below threshold. Starting irrigation.")

    // Activate pump/valve (e.g., Relay 1 on ADAM 4068)
    SEND_MODBUS_WRITE(ADAM_4068_ADDRESS, RELAY_1, STATE_ON)
    LogAction("RL1 ON - Rule based irrigation started")

    // Continue irrigation until the threshold is met again
    WHILE current_moisture < (rule_moisture_threshold + 5) // Stop when 5% above threshold
      WAIT(60000) // Wait 1 minute before checking moisture again
      ReadAndCalibrateSensorData()
    END WHILE

    SEND_MODBUS_WRITE(ADAM_4068_ADDRESS, RELAY_1, STATE_OFF)
    LogAction("RL1 OFF - Rule based irrigation finished")
  ELSE
    DISPLAY("Rule Check: Moisture is OK. No action needed.")
  END IF
END FUNCTION
```

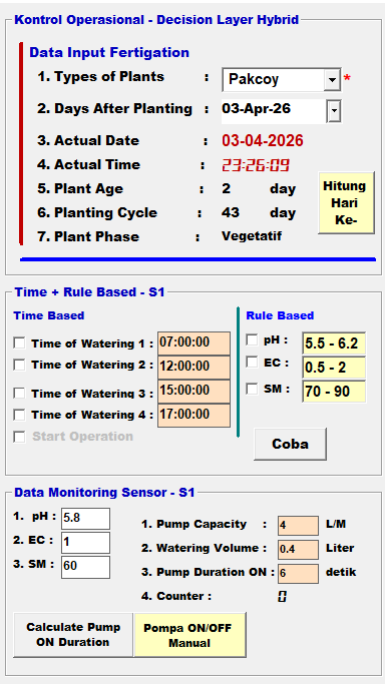

Fig. 13. HMI interface for control and monitoring.

Fig. 13 shows the HMI interface for configuring and using time- and rule-based treatment logic controls. The treatment HMI provides four time-setting inputs, as well as settings for three indicator parameters: EC, pH, and growing medium humidity. Monitoring data is available to track the condition of the growing medium in real time.

III. Result and Discussion

This chapter presents testing methods focused on three application programs: hardware configuration, HMI, and the integration of time-based treatment with rule-based treatment. The objective of the testing is to ensure that the developed application programs not only function as designed but are also sufficiently reliable to support measured fertigation operations that can be easily monitored by users via the HMI. The evaluation method is conducted through three approaches: 1) hardware testing to assess the functional performance of the developed PAC-based fertigation prototype, focusing on sensor and actuator operation, power stability, and data communication reliability; 2) functional testing (Black -Box Testing) was used to verify the functions of the HMI and control modules without examining the program's internal structure, but rather based on the consistency of input–output and the system's response to test scenarios; 3) performance testing based on acceptance criteria was applied to assess key technical parameters, such as response latency, actuator response time, and communication success, to ensure they meet the established thresholds.

A. Hardware Functional Testing

TABLE V. Preliminary Field Testing Hardware

No.	Test item	Thres hold	Results (measured)	Unit	Status
1	Sensor Functionality (deviation)	≤ 5.0	2.5	%	Pass
2	Actuator Function (response time)	< 2.0	1.2	s	Pass
3	Power Consumption (current deviation)	≤ 3.0	2.0	A	Pass
4	Voltage Stability (range)	11.4–12.6	12.1	V	Pass
5	Reliability (continuous operation)	≥ 72.0	96.0	h	Pass
6	Sensor Calibration (deviation)	≤ 3.0	2.8	%	Pass
7	Communication Interface (success rate)	≥ 99.0	99.5	%	Pass
8	System Response (latency)	< 500.0	320.0	ms	Pass
9	Thermal (Temperature)	25.0–30.0	27.0	°C	Pass
10	Thermal (Humidity)	50.0–70.0	60.0	%RH	Pass

Table V shows the hardware testing conducted to evaluate the functional performance of the developed PAC-based fertigation prototype, focusing on sensor and actuator operation, power stability, communication reliability, and basic environmental resilience. Table V defines acceptance thresholds for each hardware test item and summarizes the initial test results by comparing the measured values (results) against the acceptance thresholds/criteria (thresholds) referenced in Table V. Each test point is given a "Pass" status if the result meets the established criteria (e.g., maximum deviation limit, minimum reliability duration, or permissible operating range for temperature and humidity).

TABLE VI. BLACK-BOX TESTING OF HMI FUNCTIONS

No	Test Case (TC)	Feature	Test step (scenario)	Metric (measurable)	Threshold	Result (measured)	Unit	Trials (n)	Status (Pass/Fail)	Remarks
1	TC-1	Open serial port (valid)	Enter valid COM (1–10) → Connect	Connection time	≤ 5	2	s	10	Pass	No issues observed
2	TC-2	Open serial port (invalid)	Enter invalid COM (1–10) → Connect	Error display time	≤ 2	1	s	10	Pass	No issues observed
3	TC-3	Relay output test	Toggle RL0–RL7 ON/OFF	Relay response time	≤ 500	300	ms	10	Pass	No issues observed
4	TC-4	Analog input/sensor read	Click "Read data."	Data refresh time	≤ 1000	500	ms	10	Pass	No issues observed
5	TC-5	Select treatment method	Select Time-Based / Rule-Based	Menu load time	≤ 500	500	ms	10	Pass	No issues observed
6	TC-6	Run plant treatment	Run Time/Rule-Based execution	Execution latency	≤ 1000	500	ms	10	Pass	No issues observed

Moreover, Fig. 14 demonstrates the stable and reliable performance of the PAC, as it successfully met the predetermined system performance criteria. Basic functional tests (Nos. 1 and 2) showed that all input and output components functioned as intended. The calibration test (No. 6) is a critical aspect in ensuring data accuracy. By comparing the WSN sensor measurement results against standard reference values (using a Portable TDS and pH/EC standards), the system showed low measurement deviation, namely ≤ ±3%, indicating high accuracy for the intended application. The system's electrical aspects were tested via the Power Consumption Test (No. 3) and Voltage Stability Test (No. 4). Test results demonstrate good power efficiency; total power consumption remains within the adapter's capacity, and no excessive current surges occur. Additionally, the power supply proved stable during operation, with minimal voltage drop and ripple (deviation <3% from nominal), ensuring a safe operating environment for electronic components. Long-term performance and system response testing also yielded positive results.

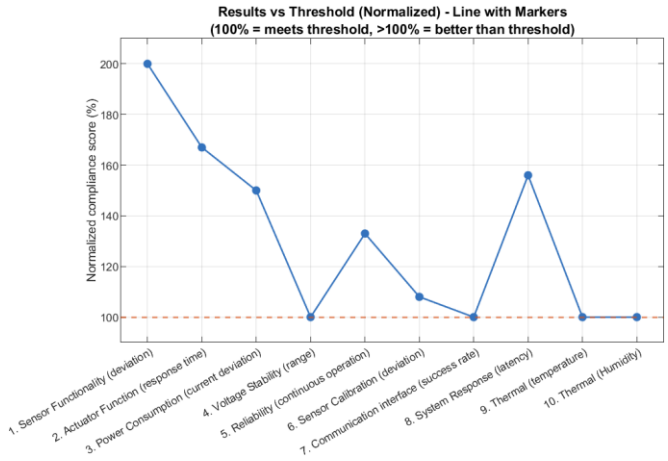

Fig. 14. Graph of PAC hardware test results.

Fig. 14 shows a comparison of normalized Results vs. Threshold, where the 100% reference line indicates that the system meets the minimum acceptance criteria. Values above 100% indicate performance that exceeds the threshold. Overall, the prototype meets the specified functional requirements, confirming that the hardware subsystem is sufficiently stable for initial field testing and subsequent integration with time-based and rule-based control functions.

Hardware connection testing (ADAM 4068 and ADAM 4017) via the serial port yielded positive and robust results (TC-1, TC-2). The hardware control module functions properly, facilitating smooth user interaction with sensors and actuators (TC-3, TC-4). Testing of the application's navigation menu and main control logic was also completed (TC-5, TC-6). This black-box testing confirms that the application program has met its primary functionality requirements, ranging from hardware connectivity (ADAM Modules) and I/O control (relays and sensors) to menu navigation and the execution of automatic control logic, thereby deeming the application stable. Fig. 15 shows the results of the Black-Box test in Table VI in the form of a normalized compliance score calculated using Eq. (1).

$$(\text{Threshold} / \text{Result}) \times 100 \quad (1)$$

B. Black-Box Testing of HMI and Programming Interface

The next testing phase involves conducting functional testing using the black-box testing method on the HMI application program. Black-box testing is a software testing method that does not examine the internal structure of the code or program.

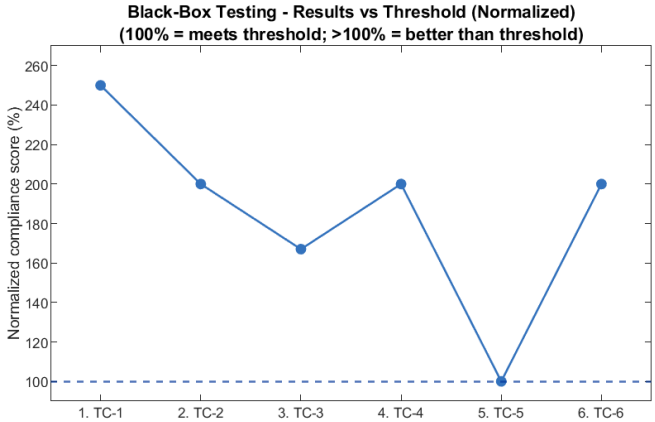

Fig. 15. Graph of the black box HMI test results.

The dashed line at 100% indicates the minimum pass threshold (the result is exactly equal to the threshold). Values

above 100% indicate performance that exceeds the criteria because the measured response time/latency is less than the threshold. In the graph, all test cases are ≥ 100%, so all HMI functions are marked as Pass. The highest score appears in TC-1 (≈250%) because the connection time is much faster than the threshold (2 s vs. 5 s), while TC-5 is exactly at 100% because the menu loading time is equal to the threshold (500 ms), making it the point that is closest to the limit and can be prioritized for optimization if necessary.

C. Simulation of Treatment Integration Function Testing (Time-Based and Rule-Based)

Time-based control serves as a baseline control to maintain a consistent supply of nutrients and water as long as pH, EC, and humidity remain within normal limits. When these parameters deviate, indicating a nutrient or water deficiency or excess, the system switches to rule-based control for more specific actions: low EC triggers nutrient addition, while excessively high EC triggers dilution or flushing with clean water.

Table VII shows how control decisions adjust sensor conditions, so that the time-based and rule-based approaches complement each other. Table VII also shows the simulation tests conducted as follows: under normal operating conditions, as seen in the data for Day 1 (08:00) and Day 15 (16:00), the system executes routine protocols. Although temperature and humidity fluctuate during the day, the system maintains the plant's status in the healthy (optimal) category because the pH and EC parameters remain within tolerance limits. This demonstrates the effectiveness of standard nutrient scheduling when the environment is stable. However, the advantage of rule-based control becomes evident when the system encounters anomalies. On Day 5 (14:00), the system detected a drop in EC to 1.1 mS/cm and pH to 5.5. The system automatically triggered the 'Add Nutrient A' treatment to correct the nutrient deficiency. Conversely, on Day 10 (09:00), when a risk of high salinity (EC 2.5 mS/cm) was detected, the system took emergency action in the form of a 'Clean Water Flush' to reduce excess mineral salts. This integration demonstrates that the application program not only operates based on time but also possesses situational intelligence to maintain plant health through targeted interventions based on real-time sensor data.

The threshold values in Table VII are based on the optimal ranges commonly used for leafy vegetables (e.g., lettuce, bok choy, arugula) in hydroponic/soilless culture systems. For pH, the range of 5.5–6.5 is widely recommended because it maintains optimal nutrient availability in the nutrient solution [23]. For EC, leafy vegetables generally fall within a range of approximately 1.2–2.0 mS/cm (for example, lettuce is often reported to be stable within a range of about 1.2–1.8 mS/cm, and studies on lettuce have also evaluated EC up to 2.0 mS/cm) [23]. Meanwhile, moisture in soilless growing media is more accurately expressed as substrate volumetric water content (VWC); studies on leafy vegetables such as arugula evaluated VWC at 0.20–0.50 $m^3 \cdot m^{-3}$ and showed that maintaining VWC around 0.30 $m^3 \cdot m^{-3}$ supports water use efficiency while maintaining growth and quality [24][25]. Therefore, in the simulation in Table VII, a practical range of 30–50% VWC is used as the operating range (threshold) to represent safe substrate moisture conditions for leafy vegetables in soilless systems. Fig. 16 shows pH, EC, and substrate moisture after normalization to their ideal ranges (0% = lower limit, 100% = upper limit). Occurrences outside the threshold indicate values approaching 0% or 100%, triggering rule-based corrective actions, while values within the range indicate stable conditions under time-based scheduling. Based on the functional testing simulations conducted, it was found that the application is capable of adaptively transitioning control from a time-based approach to a rule-based approach in accordance with the dynamics of the growing medium.

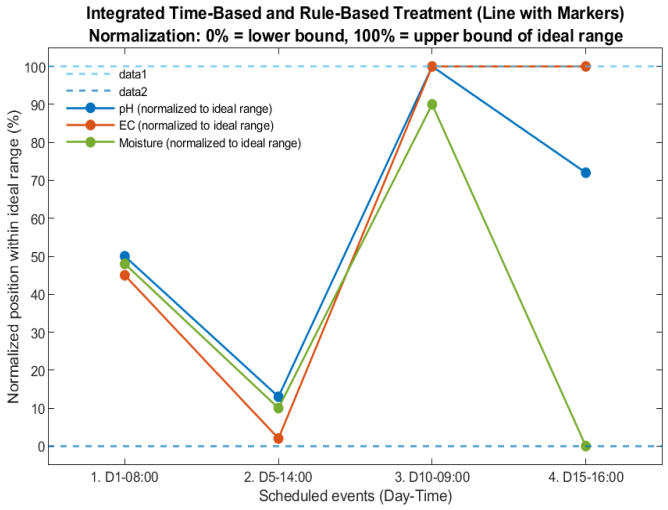

Fig. 16. Results of the simulation of the integration function test across treatments.

TABLE VII. SIMULATION OF INTEGRATION FUNCTIONALITY TESTING ACROSS TREATMENTS (TIME-BASED AND RULE-BASED)

Day	Time	pH	pH threshold	EC (mS/cm)	EC threshold (mS/cm)	Moisture *(%VWC)	Moisture threshold (%VWC)	Control mode	Trigger condition	Action executed
1	08:00	6.1	5.5–6.5	1.6	1.2–2.0	40	30–50	Time-based	Within thresholds	Scheduled dosing executed
5	14:00	5.4	5.5–6.5	1.0	1.2–2.0	32	30–50	Rule-based	pH low & EC low	Increase nutrient concentration / adjust pH up
10	09:00	6.7	5.5–6.5	2.3	1.2–2.0	48	30–50	Rule-based	pH high & EC high	Dilute/flush with water; adjust pH down
15	16:00	6.2	5.5–6.5	1.8	1.2–2.0	28	30–50	Rule-based	Moisture low	Irrigation pulse to restore moisture

*VWC = Volumetric Water Content

*EC = Electrical Conductivity

IV. DISCUSSION

The results of the hardware application program testing (Table V) and the functional testing using the Black Box method on the HMI (Table VI) indicate that all major subsystems (sensor data acquisition, actuation, communication, and interface) meet the acceptance criteria. The system latency of 320 ms and the actuator response time of 1.2 s are well below the dynamic range of the fertigation process, which typically occurs on the order of seconds to minutes; thus, computational delay is not a primary limiting factor in this prototype. Conversely, reading accuracy and communication stability are the most critical aspects because they determine decisions at the pH/EC/humidity thresholds. In the Black Box testing for the HMI application program, the system met the primary operational requirements (connectivity, I/O control, sensor readings, menu navigation, and treatment execution) with margins generally >100%; the optimization priority lies with TC-5, as it is right at the threshold (500 ms).

In the testing, the integration of time-based and rule-based controls provides two layers of regulation; the time-based control ensures the continuous supply of nutrients and water, while the rule-based control acts as a corrective measure when deviations occur. This approach is relevant for cultivating leafy vegetables such as pak choi and lettuce, which are sensitive to changes in EC and growing medium moisture. Due to the hysteresis/persistence in the rule-based system, the system can avoid excessive action caused by momentary fluctuations, thereby potentially maintaining more stable growing medium conditions and reducing water and nutrient waste.

However, this study is still limited to functional validation at the preliminary field testing stage, so it has not yet evaluated the agronomic impacts (e.g., growth, yield, or water/nutrient use efficiency) over a full cultivation cycle.

V. CONCLUSION

This study successfully developed a precision fertigation control system based on a Programmable Automation Controller (PAC) that integrates time-based and rule-based controls within a single data-driven architecture. The system is capable of automatically regulating water and nutrient delivery based on a routine schedule and the actual conditions of the growing medium, as measured by pH, EC, and humidity sensors. Test results indicate that the time-based approach is effective in maintaining nutrient supply stability, while the rule-based approach is more adaptive in handling environmental anomalies in real-time. The integration of both approaches yields a system that is more flexible, precise, and efficient compared to microcontroller-based IoT systems. This system has the potential to support the implementation of precision agriculture and Industry 4.0 technologies in the agricultural sector, particularly in the sustainable management of fertigation for horticultural crops. As a further development, the integration of predictive algorithms or machine learning could be considered to enhance the system's ability to make more adaptive and proactive decisions.

ACKNOWLEDGMENT

Thanks to the entire academic community of the Doctoral Program in Agro-Industrial Technology, Faculty of Agro-Industrial Technology, Padjadjaran University, Sumedang, West Java, Indonesia, as well as to the Research Center for Smart Mechatronics and Telecommunications, National Research and Innovation Agency of the Republic of Indonesia, Bandung, Indonesia, who have assisted in the publication of this article. We hope this article will continue to be cited and prove useful to related academic disciplines.

Advancing Ecological Informatics: A Tool for Implementing the Abundance–Preference Approach in Assemblage Analysis

***Abstract*—Although the Abundance-Preference Diagram (APD) was introduced four decades ago as an entropy-based framework for classifying species along habitat-preference gradients, its uptake by the ecological community has remained marginal. The cause is not theoretical but operational: no existing software (e.g., vegan, ade4, CANOCO, PC-ORD, BIOMAPPER) implements the Degree of Preference index (DP) or the APD, which forces ecologists either to rebuild the algorithm from scratch or to abandon the method altogether. This barrier mirrors a broader concern in ecoinformatics, where the gap between published methods and accessible implementations continues to slow the adoption of quantitative tools by field ecologists. This study presents EcoAPD (https://apd.biodiversity.ma), the first open web-based platform dedicated to the APD method. The application takes a standard species-by-habitat abundance matrix and returns the full diagnostic suite (DP values, exclusive species curve, hyperbola-based preference classes, and the APD plot itself), without any programming or local installation. Three design choices set it apart from the descendants of CANOCO and ade4: 1) a dual-computation architecture that generates the normalized and non-normalized APD versions simultaneously at project creation, removing the need for users to commit to a method a priori; 2) a hybrid file/relational-database persistence layer with hash-based recompute avoidance, enabling visualizations to be regenerated without rerunning the full pipeline; and 3) a validation engine tailored to the irregularities of ecological matrices. The platform is evaluated on two real datasets and a synthetic size sweep. Vectorizing the preference-index core yields a speedup rising from 3.5× at 10 species to 85.6× at 1000 species, while full-pipeline latency is ~510 ms on a 93-species × 37-habitats matrix and ~2.3 s on a 114-species × 171-habitats waterbird monitoring matrix, the residual cost being dominated by habitat count rather than species count. A threshold-sensitivity ablation finds the classification stable at the 0.3 and 0.75 boundaries and sensitive at 0.1 and 0.5. EcoAPD makes a four-decade-old method operationally available, with potential to revisit historical assemblage studies that relied on abundance data alone.**

Keywords*—Ecological informatics; web application; algorithm; assemblage ecology; species preference; abundance-preference diagram

I. Introduction

The preference of a species in a given environment is a key concept in both ecology and biodiversity conservation [1],[2],[3]. It is generally compiled from the abundance distribution of a species in different habitats [4]. The degree of preference (DP), as defined by [5], is an index that determines whether a species is a generalist or a specialist, in terms of its habitat preference, without necessarily indicating which habitats it prefers. This index shows high efficiency in analyzing assemblage organization through the APD method, which combines DP and species abundances [6],[7].

Although first published four decades ago, this method remained underutilized due to the lack of accessible tools for ecologists, who are mostly not familiar with statistical tools, a challenge that persists due to the frequent mismatch between ecological data and traditional statistical knowledge and tools [8],[9]. The recent refinements of the method [6] and the current abundance of efficient informatics tools have now made its widespread implementation feasible.

Our research consists of translating this method into a practical tool: a web application that executes all necessary calculations and plots the diagnostics. This application utilizes a standard data matrix of species abundances across a sample of habitats and covers both the original and normalized versions of the APD [7].

The development of this application was preceded by a comparative analysis of available algorithms for processing data in the form of contingency tables, and of the software platforms that analyze taxonomic and ecological data. That analysis, reported in Section II, establishes that none of the platforms in current use can implement the DP/APD tools. The platforms that come closest are separated from their intended users by either a programming requirement or a commercial licence.

To help ecologists implement DP/APD tools, we have previously developed an algorithm [7], and in parallel we launched a first version of the EcoAPD web application, which has been significantly improved since then.

The contributions of this work are the following:

- EcoAPD is, to the authors' knowledge, the first open, web-based implementation of the Degree of Preference index and the Abundance–Preference Diagram, a method that no existing ecological software package implements (Section II, Table I).
- A dual-computation architecture derives both the normalized and the non-normalized APD at project

*Corresponding author.

creation, so that the choice between the two versions becomes a post-hoc display decision rather than an a priori methodological commitment (Section V-A).

- A hybrid file/relational persistence layer with hash-based recompute avoidance stores all computed intermediates, so that visualizations are regenerated without rerunning the pipeline, and re-uploading unchanged data does not re-trigger computation [Section V-A(2c)].
- The preference-index computation, originally a per-species loop, has been rewritten as a single vectorized NumPy operation, measured at a speedup rising to 85.6× at 1000 species (Section VI-B, Table IV).
- An empirical evaluation reports the scalability of the full pipeline on two real datasets, together with a two-part ablation quantifying the contribution of the vectorized core and of the four classification thresholds individually (Section VI).

II. Related Work

The platforms available for the analysis of taxonomic and ecological data organized as contingency tables are examined here along three axes: the ecological question they address, their accessibility profile, and whether they expose any entropy-based habitat-preference index.

A. Methods for Habitat Preference and Assemblage Structure

BIOMAPPER [10],[11] implements ecological-niche factor analysis (ENFA), which characterizes the niche of a single species by contrasting the environmental conditions at occupied sites with the global distribution of those conditions.

MaxEnt [12] addresses a related problem, species distribution modelling from presence-only records, by fitting a maximum-entropy distribution over environmental covariates. Both are concerned with where a species occurs as a function of environmental predictors; neither takes a species-by-habitat abundance matrix as its primary input, and neither produces a per-species preference index derived from the entropy of the abundance distribution itself.

The ordination family addresses assemblage structure rather than single-species niches. CANOCO [17] and PC-ORD [16] provide constrained and unconstrained ordination behind graphical interfaces, while vegan [13] and ade4 [15] provide the same method family, and a considerably wider one, as R packages. These methods summarize the joint variation of species and sites on a small number of latent axes, and a species' position on those axes reflects its association with the sites that load on them. This is informative, but it is not a preference index: the axis scores are defined relative to the ordination solution for the table as a whole, they change when species or sites are added or removed, and they do not map onto an interpretable scale bounded between generalist and specialist.

iNEXT [18] and the Hill-number framework [22] quantify diversity at the level of the assemblage rather than of the individual species, and are concerned with sampling completeness rather than with habitat preference. ProCURVE [14] computes habitat preferences, but for aquatic organisms specifically and from a different formulation. GBIF [19] is an occurrence-data infrastructure rather than an analysis platform.

The DP index [5] differs from all of these in that it is computed independently for each species, from the entropy of that species' own abundance profile across habitats, normalized by log2(J). It is bounded, it is invariant to the composition of the rest of the table, and it admits a direct reading: a value near 0 for a species distributed evenly across all habitats, approaching 1 for a species confined to a single one. None of the platforms surveyed computes this quantity, and none produces the APD. Table I summarizes the comparison.

The negative entries in the DP and APD columns of Table I are not a shortcoming of these packages, each of which is well established within its own method family; they are precisely the gap that motivates the present work.

TABLE I. Comparison of Ecological Analysis Platforms with Respect to the DP Index and the APD

Platform	Primary method family	DP index	APD plot	Programming required	Installation	Licence
BIOMAPPER [10],[11]	ENFA / niche factor analysis	No	No	No	Desktop	Free
MaxEnt [12]	Maximum-entropy SDM	No	No	No	Desktop (Java)	Free
vegan [13]	Ordination, diversity	No	No	Yes (R)	R package	GPL
ProCURVE [14]	Aquatic habitat preference	No	No	No	Desktop	Free
ade4 [15]	Multivariate / duality diagram	No	No	Yes (R)	R package	GPL
PC-ORD [16]	Multivariate community analysis	No	No	No	Desktop	Commercial
CANOCO [17]	Constrained ordination	No	No	No	Desktop	Commercial
iNEXT [18]	Diversity interpolation/extrapolation	No	No	Yes (R) or web	R package or web	Free
EcoAPD (this work)	Entropy-based preference classification	Yes	Yes	No	None (web)	Free

B. Accessibility as a Methodological Constraint

The second axis is orthogonal to method, and concerns who is able to run it. vegan and ade4 are free, actively maintained and computationally capable, but they presuppose fluency in R: a user must be able to import a matrix, call the appropriate function with the appropriate arguments, and interpret an object returned at the console. CANOCO and PC-ORD remove that

requirement through graphical interfaces, but are commercially licensed and locally installed, which places them beyond the reach of under-resourced institutions. BIOMAPPER is free and graphical, but restricted to ENFA and no longer actively developed.

This matters because the population that would use the APD method consists largely of field ecologists whose training is taxonomic and ecological rather than computational. Quantitative training among early-career ecologists is known to be limited [8], and the difficulty of translating published ecological methods into runnable code is a recognized bottleneck in ecoinformatics [9],[20]. Accessibility is therefore not a convenience feature but a determinant of whether a method is used at all, which is the most plausible explanation for the APD remaining dormant for four decades despite being theoretically available throughout.

TABLE II. LIMITATIONS OF EXISTING PLATFORMS AND THE CORRESPONDING ECOAPD DESIGN DECISIONS

Limitation identified in existing tools	Consequence for the ecologist	EcoAPD design decision
No DP/APD implementation in any surveyed platform	Method unusable without bespoke coding	Direct implementation of (1)–(4)
Programming fluency presupposed (vegan, ade4)	Excludes non-computational ecologists	Browser interface, no installation
Commercial licence (PC-ORD, CANOCO)	Excludes under-resourced institutions	Free and openly accessible
Method version must be chosen before analysis	Commitment made without sight of the results	Dual computation at project creation
Re-analysis requires full recomputation.	Iterative exploration is costly	Hybrid file/relational persistence with hash-based recompute avoidance
Input assumed clean and regular.	Real survey matrices fail, sometimes silently	Dedicated validation engine

C. Design Requirements Derived from Existing Tools

Read together, the two axes above yield a set of requirements that shaped the architecture of EcoAPD. Table II maps each limitation identified above onto the design decision it motivated.

Two of these decisions warrant emphasis, since they are what distinguish EcoAPD from a straightforward web wrapper around the published algorithm. The first is dual computation: because both APD versions are derived at project creation, the user is never required to choose between them before seeing either, which removes the analytical commitment overhead borne by users unfamiliar with the method. The second is hash-based recompute avoidance in the persistence layer: a hash of the abundance matrix together with its column mapping identifies whether an uploaded dataset is materially unchanged, so that re-uploading the same data does not re-trigger the pipeline.

III. REMINDER: APPLICATION OBJECT (DP AND APD)

The APD method consists of analyzing flora or fauna assemblages using a diagram in which the species are positioned according to both their abundance, as a common descriptor in ecology, and their degree of preference (DP). The latter is measured for each species using an adapted form of the Shannon entropy formula [21], calculated on the series of its abundances in a set of habitats. The APD contains a significant reference curve, the exclusive species curve (ESC), and is subdivided into six preference zones (or classes) by five half-hyperbolas of the same form, defined by the equation Y = (ax+b)/(cx+d) Fig. 1. Four of these curves have their vertices on ESC points of significant abscissa (DP), namely 0.1, 0.3, 0.5 and 0.75; these values were defined on the basis of experimental datasets. The fifth curve, which delimits the Accidental class in the non-normalized version, is not defined by a DP target but is derived from the habitat count and a theoretical abundance scale (Section V-E).

In practice, the data on which the main calculations are based are presented in a table of I lines (species) and J columns (habitats), which is commonly used in assemblage studies. The APD method consists of calculating the DP for each species, using the following formula. Then, the APD is simply plotted for each assemblage (= habitat).

$$D_{iJ=}1 - \frac{S_i}{\log_2(J)} \tag{1}$$

$$S_i = -\sum \frac{n_{ij}+1}{\sum(n_{ij}+1)} \log_2 \frac{n_{ij}+1}{\sum(n_{ij}+1)} \tag{2}$$

$\boldsymbol{n_{ij}}$: abundance of species i in habitat j; $\mathbf{log_2(J)}$: maximum value of S_i (same abundance value ($\boldsymbol{n_{ij}}$) in all habitats; $\boldsymbol{D_{ij}}$: degree of preference (DP).

For an exclusive species (which exists only in one habitat), Formula (1) becomes as follows:

$$S_i = \frac{n_{ij}+1}{n_{ij}+J}\left(\frac{n_{ij}+1}{n_{ij}+J}\right) + (J-1) * \frac{1}{n_{ij}+J}\left(\frac{1}{n_{ij}+J}\right) \tag{3}$$

In the normalized version of the APD [7], mainly used when abundances are low, the Y-axis (abundances) is transformed using Formula (4); then, all the other components of the APD, including the species positions, are recalculated. In this version, we chose another hyperbola formula, $Y = a^2/2x$, while we used only five hyperbolas, the accidental species being interpreted as foreign to the assemblage.

$$A_{ii} = \frac{\log 2(a_{ij}+1)}{\log_2(\max(a_{ij})+1)} \tag{4}$$

$\boldsymbol{a_{ij}}$ = abundance of the species i in the assemblage j;

max(aij) = the maximum abundance recorded across the entire species × habitat matrix, i.e. a single global value and not a per-species maximum.

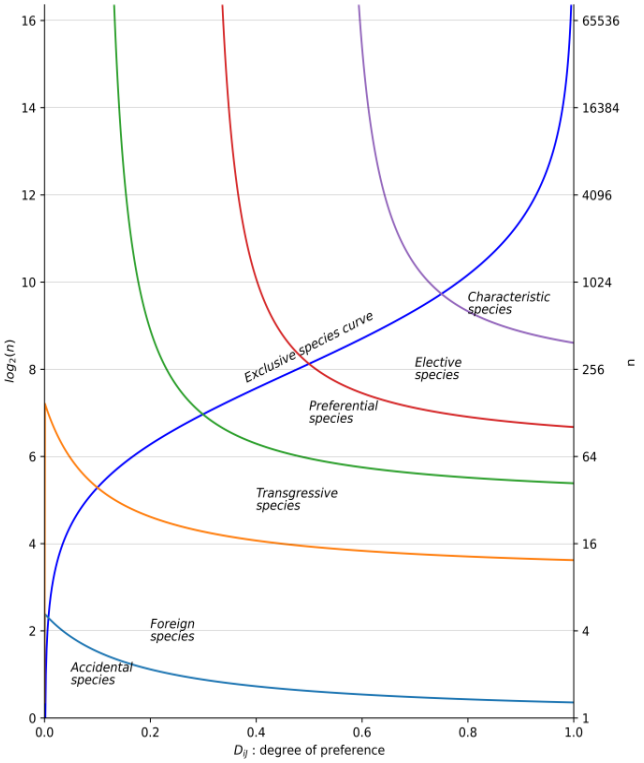

Fig. 1. APD model for assemblage analyses [5].

IV. METHODS

A. Inputs and Outputs of the Application

1) Inputs: data and their format: The basic data in each study case (named here 'project') are stored in a single table of I rows (species) and J columns (habitats) as indicated below (Table III). This matrix, commonly used in the ecology of assemblages [15],[16],[22], contains two types of identifiers of both rows (species name and code) and columns (habitat name and code), which respectively fill the two first columns and the two first rows, the abundances (data) are readable starting from the cell 'row 3, column 3'.

Data format, which is verified by the system, should respect the following conditions:

- input table contains a minimum of 10 habitats (J > 9) and at least one species (I ≥ 1);
- data are numerical (natural or decimal numbers) and positive; empty cells are filled with '0', and empty rows or columns are deleted; for decimal numbers, only a dot '.' is accepted as separator of decimals, while separators of thousands are not accepted.

In addition, the habitat and species names should be easily recognized by the project holder, while their codes are shorter, as strings or numbers, and very useful for displaying species in the APD, avoiding overlapping of long names.

TABLE III. GENERAL FORMAT OF THE BASIC DATA MATRIX FOR IMPLEMENTING THE APD METHOD

		Habitat 1	…	**Habitat j**	…	**Habitat J**
	Codes	H1	…	Hj	…	HJ
Species 1	S1	n1.1	…	n1.2	…	n1.J
….	….	…				
Species i	S2	ni.1	…	n2.2	…	n2.J
….	….	…				
Species I	SI	nI.1	…	nI.2	…	nI.J
Species name*:** names that will be displayed in the APD; Codes: short but meaningful identifiers that will be displayed; ***I: number of species, non-limited number; ***J***: number of habitats, preferably greater than 10; ***nij***: abundance of the species i in the habitat j, as a positive real number.						

2) Outputs: The outputs are defined in consideration of the major users' needs from the EcoAPD application, which consists of plotting, for each habitat, the assemblage APD in its two versions (original and/or normalized), with the species list of each preference class. However, the system also displays the data table, including the DP values for each species Fig. 2, mainly for verification and downloading purposes.

In addition, users can generate the histogram of the species DP values, as well as the abundance profile of a selected species across all habitats. These diagrams help to understand the position of the species in the different assemblage APD.

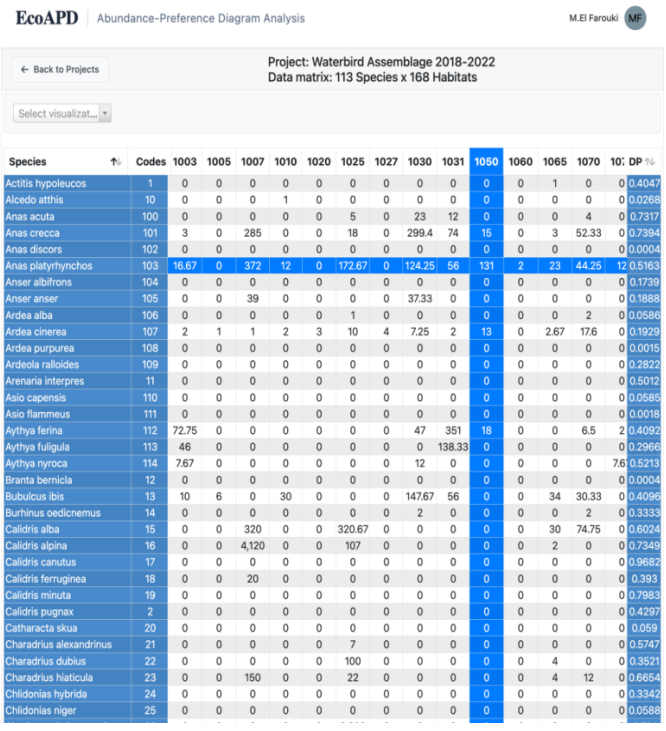

Fig. 2. Project data view: 'species x habitat' abundance matrix with calculated DP.

B. Test Data Used

The application has been tested, in terms of functionalities and validity of the outputs, by some researchers that we invited to test the EcoAPD application. However, for experimenting with different development steps, we used two different real datasets, provided here as supplementary materials, named SM1 and SM2:

- SM1: Benthic invertebrates of the Sebou river;
- SM2: International winter counts of waterbirds in Morocco (average of 2018-2022 counts);

These data are borrowed from different ecological studies that provide data adapted to APD use, in both original and normalized forms.

C. Used Technologies

This application is based on the algorithm already published by [6] and normalized by [7].

The application was developed using Python [23] for server-side logic and calculations, combined with standard web technologies HTML [24], CSS [25], and JavaScript [26] for the user interface.

The main computational components include:

- Mathematical libraries: NumPy [27] and Pandas [28],[29] handle matrix operations and data manipulation, enabling efficient processing of species-habitat abundance matrices.
- Data storage: Project data, user accounts, and computed results are stored in a MySQL relational database [30], ensuring data integrity and enabling rapid retrieval of data and previous analyses.
- File handling: Uploaded datasets (Excel files) are stored locally, each assigned a unique identifier generated from the project ID and timestamp to ensure traceability and avoid naming conflicts.
- Visualizations: Matplotlib [31] and Apache ECharts [32] generate static and interactive graphs, respectively, enabling efficient processing and visualization of species-habitat abundance matrices.
- Export capabilities: The system generates publication-quality PDF reports containing APD diagrams, data tables, and project metadata.

Together, these technologies enable a streamlined workflow for ecological data analysis, ensuring both computational efficiency and a seamless end-user experience.

V. System Design and Implementation

A. System Architecture

1) Preamble: A first version of this system was created to implement the original version of the APD tool [5]; we further submitted it for major modifications in order to implement the normalized version of this tool [6]. In addition to multiple tests of the web application done by our staff, some potential users were asked to write essays about this system, using their own data, and their remarks were highly beneficial for improving it.

The application implements a robust database architecture, storing abundance matrices and all computed results, including DP values, ESC, hyperbola set, and species points. This persistence layer enables rapid generation and visualization without re-computing the entire pipeline, particularly beneficial for large datasets or iterative analysis workflows.

A distinctive feature of the application is its automatic dual-dataset generation: when a project is created, the system automatically processes both normalized and non-normalized APD datasets and stores them in a database Fig. 3. This design avoids initializing a method before starting analyses.

2) Architectural components: The application is built with technologies that allow optimizing the calculation speed, while offering a fluid user experience Fig. 4.

a) User interface (application layer): The web interface is responsive, enabling dynamic interaction with the application through

- Authentication portal: Secure login and registration with email verification and reCAPTCHA protection [33];
- Project dashboard: Intuitive management of analysis projects with search and metadata editing;
- Data configuration wizard: Excel upload with preview and flexible mapping of species/habitat identifiers;

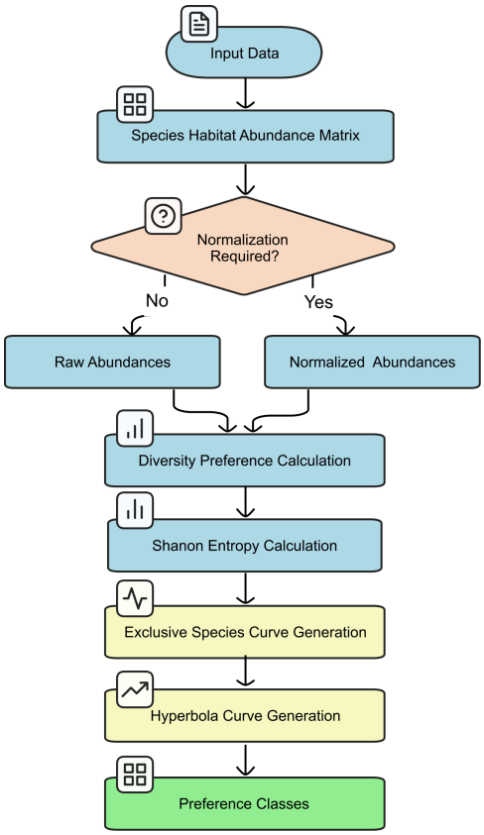

Fig. 3. Automatic generation and storage of normalized and non-normalized APD datasets during project creation.

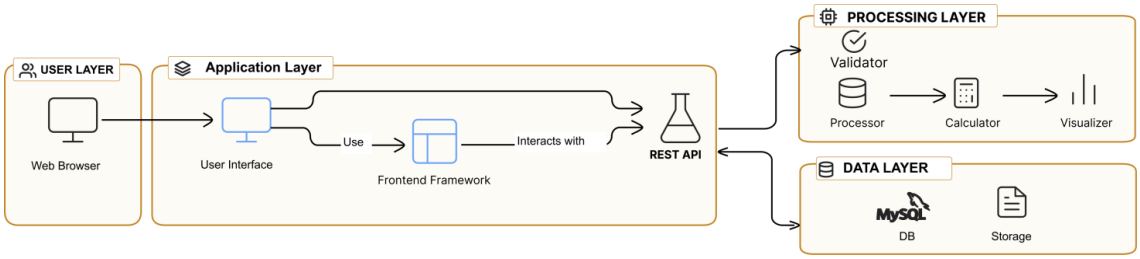

Fig. 4. System architecture diagram showing the main components and their interactions.

- interactive APD viewer: Dynamic diagrams supporting zoom, pan, and species labeling with real-time parameter adjustments;
- exploration tools: Sortable tables for abundances and DP values, species abundance profiles, and DP histograms;
- multi-format export: Download options for PNG images, and publication-ready PDF and Excel reports.

b) Server-side processing (processing layer): The server component handles requests from the user interface, processes data, and manages database interactions. It provides the following main functionalities:

- data validation engine: verifies uploaded files against format requirements, cleans invalid entries, and prepares matrices for analysis;
- DP computation module: calculates degree of preference values and generates both normalized and non-normalized datasets automatically;
- curve generation: computes ESCs and hyperbola sets for assemblage classification;
- security layer: enforces authentication, session management, and input sanitization across all operations.

All operations include appropriate security checks and error handling to ensure data integrity.

c) Data storage (data layer): The initial system, announced by [6], used pickle-based file storage to persist computed DP objects, enabling rapid visualization without recomputation; this approach provides fast state restoration but lacks query flexibility and data integrity. In the actualized version of EcoAPD, we migrated to a relational database, where Excel files are stored in the dedicated project Files, while all computed data and metadata are stored in the MySQL database Fig. 5. This system, combining file-based and database storage, provides flexibility and performance, data integrity, and query capabilities. In addition, this architecture enables selective data retrieval, supports concurrent access, maintains referential integrity through foreign keys, and facilitates schema evolution Fig. 6.

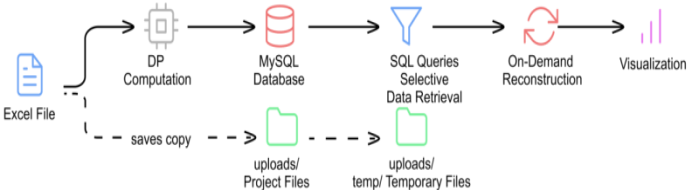

Fig. 5. Data persistence and retrieval workflow.

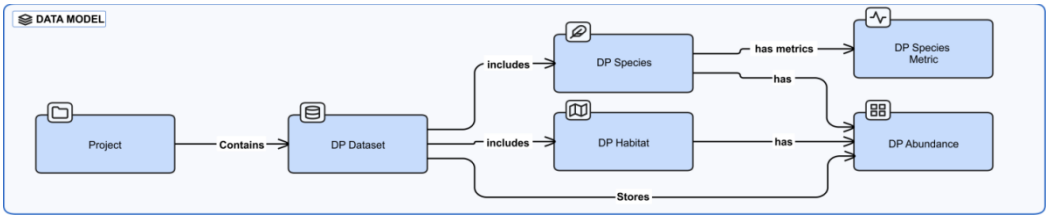

Fig. 6. Database structure showing relationships between user, project, and computed data.

d) Mathematical processing: The application uses optimized mathematical libraries that enable rapid processing of large ecological datasets. The main computations include: 1) *abundance data*: species-habitat tables are stored as NumPy arrays for fast, bulk operations; 2) *DP calculation*: Shannon entropy and related math run efficiently on entire arrays; 3) *normalization*: log2 scaling and value adjustment are done in parallel for all data; 4) *diagram data*: APD curves and coordinates are generated in batches.

B. User Workflow

The system provides a structured workflow for ecological data analysis Fig. 7, which shows the key interaction sequences during a typical analysis session. This workflow is designed to minimize technical barriers to users unfamiliar with computational complexity, allowing them to focus on result interpretation rather than on data computation.

C. Workflow Steps: Data Processing Pipeline

The pipeline consists of several interconnected stages that transform raw biodiversity data into interpretable visualizations and classification results, which can be edited for publication Fig. 8.

The workflow can be subdivided into three main phases: 1) data preview, validation and upload, 2) selection and configuration of outputs, and 3) generating outputs.

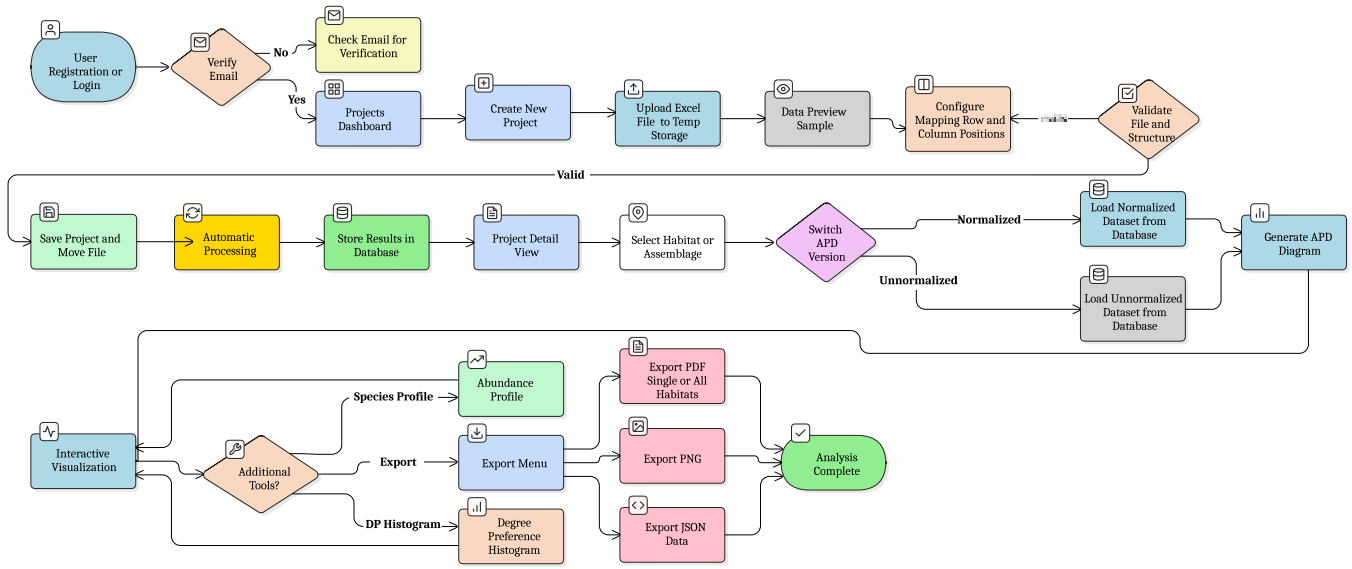

Fig. 7. User workflow diagram: key interaction sequences during a typical analysis session.

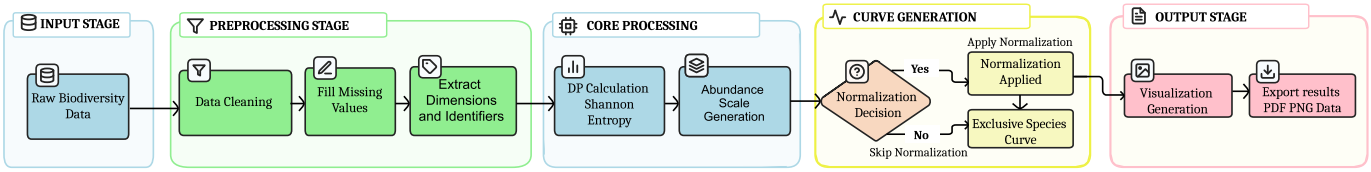

Fig. 8. Data processing pipeline architecture showing the transformation of raw biodiversity data into interpretable visualizations.

1) Data preview, validation and upload: The use of the APD method starts with creating a project, based on a 'species-habitat' matrix of abundances, which is provided in an Excel file. The system architecture is conceived to meet the specific requirements of computed data, knowing that ecological datasets have different sizes and complexity depending on studies. Users are previously prompted to configure their data; however, the dataset is submitted to a validation sequence that is implemented before creating the project. The first sequence consists of displaying the first '5 rows x 5 columns' of the project file Fig. 9, which allows a visual verification that names and codes of both rows and columns are provided.

2) Selecting outputs: Once the data is validated and uploaded, the user is requested to select different analysis types and options that can be edited:

- the most requested output is the APD, for a selected assemblage; it is edited in a desired version (normalized vs. non-normalized), where species are displayed using a selected identifier (name or code), and the reference curves (hyperbolas and ESC) are displayed or hidden Fig. 10;
- DP profile for all species Fig. 11;
- abundance profile of a selected species in all habitats Fig. 12.

3) Generating outputs: The requested APD is displayed and, when needed, it can be saved in image or PDF format. The other graphical outputs related to species (abundance profiles and DP diagram) can be displayed and saved in these same formats, while the specific composition of each preference class of the APD can be edited in Excel format. All these outputs have a printable quality, directly used in a publication.

D. Workflow Implementation

The main processing flow for successfully uploading a file proceeds as follows Fig. 13.

- Once uploaded, the data file is transmitted to the API, which submits it to a file validator; this latter checks both extension (.xlsx/.xls), size (< 100 Mb), file structure, and data format.
- The file is saved in the storage directory, with a unique filename. The API then submits the data to a data processor that checks its required structure and type, deleting non-numeric values and empty rows and columns, filling empty cells with a '0' value, and extracting species and habitat labels. The matrix dimensions are then extracted, as well as row and column identifiers, while columns are converted to strings.
- Once the project is created, the system processes the data simultaneously to compute DP values, the ESC and hyperbolas for both normalized and non-normalized APD methods;
- All project metadata and computed results are stored in the database: species and habitat metadata, abundance matrices (stored in long format), DP values for each

species, ESC and their intersection points with hyperbolas, and project record creation and storage of file path and data mapping.

- At the end of this process, the API returns a success response to the web interface, which displays the data table as a confirmation of the project creation.

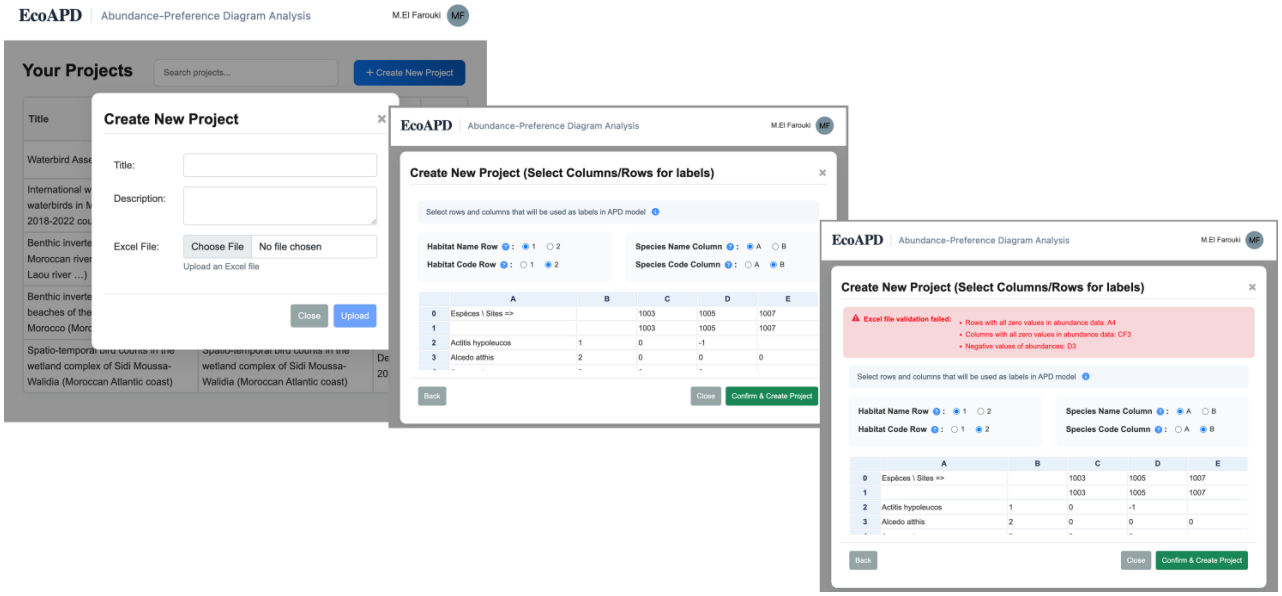

Fig. 9. Upload and validation interfaces.

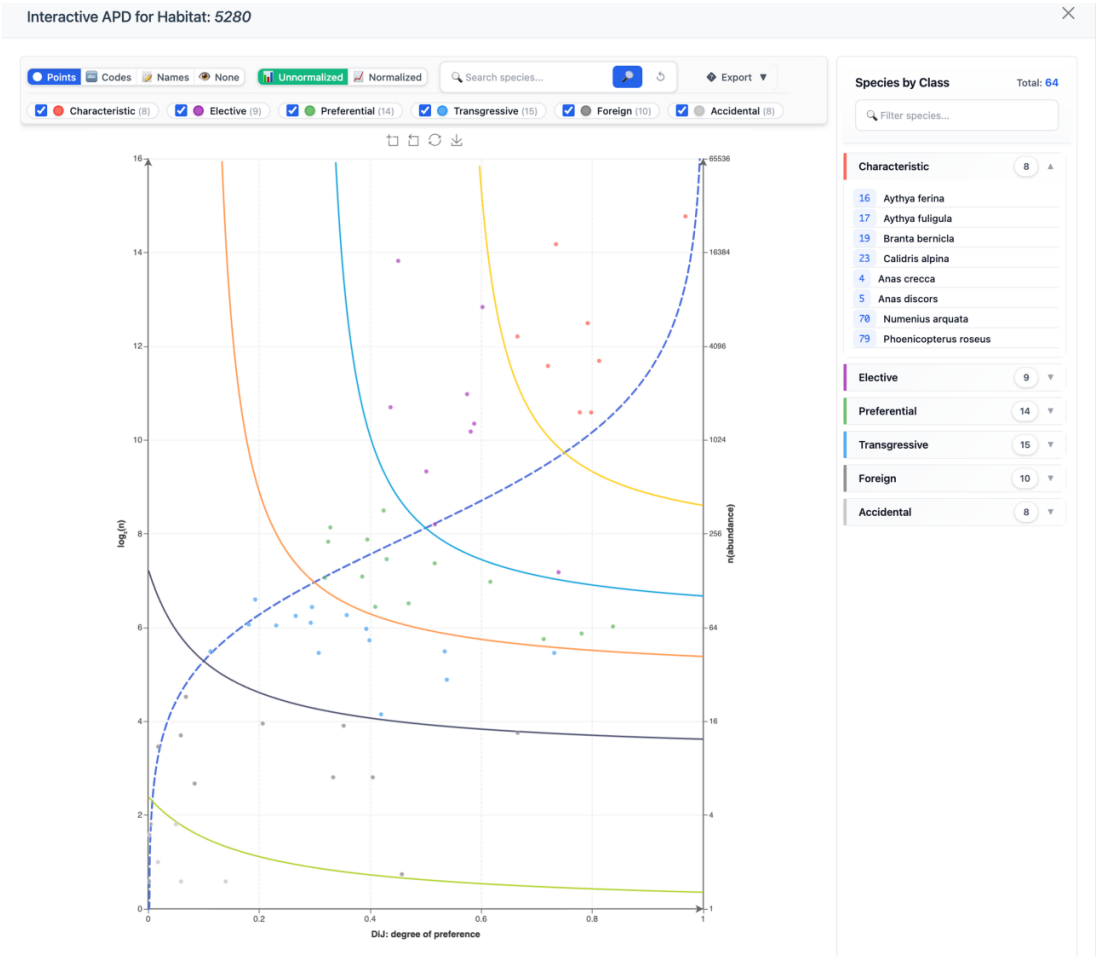

Fig. 10. APD of an assemblage/habitat: Interactive visualization.

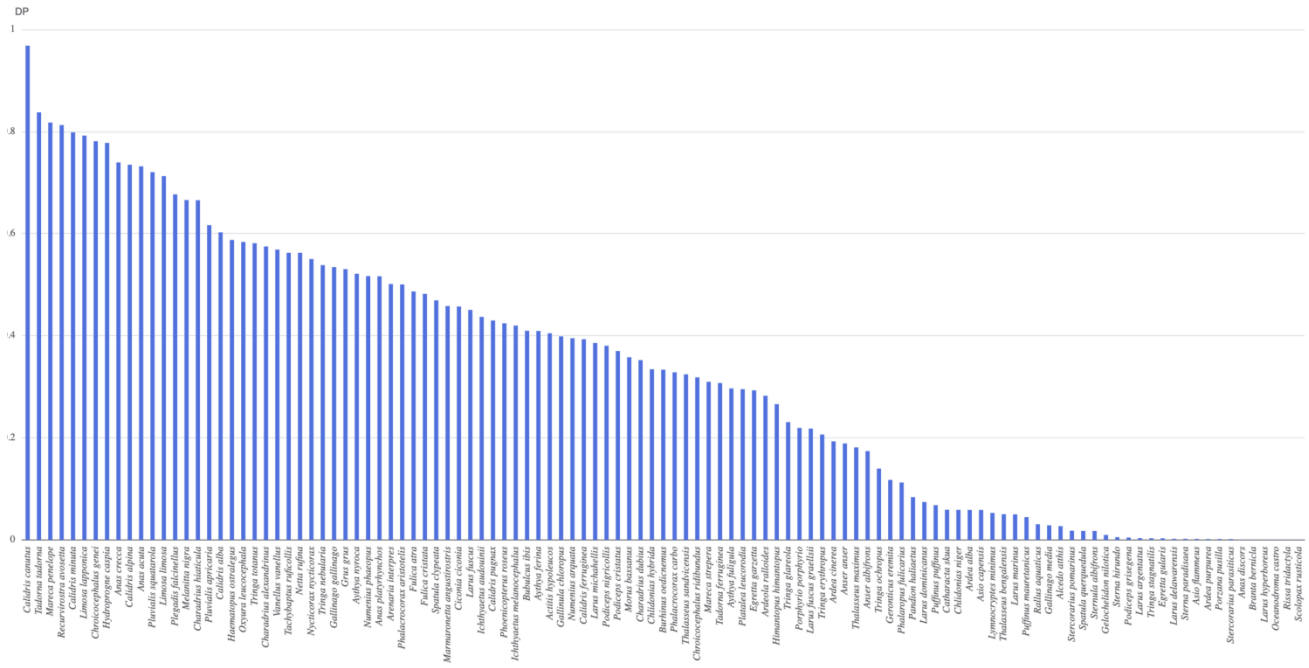

Fig. 11. DP profile for all species.

E. Generation of the Classification Curves (ESC and Hyperbolas)

Theoretical curves (ESC and hyperbolas) for species classification are generated from a computed vector. For the ESC, matrix operations start with Y = esp_array + 1.

The entropy and the DP are then obtained as:

$$Si=\Sigma((Y/\sum(Y)\times\log2(Y/\sum(Y)), \text{ and the DP as } Di=1+Si/\log2(S)$$

The hyperbola curves that delineate the zones corresponding to the species preference classes are generated from their intersections with the ESC, which are predefined by their abscissa (DP value). Four of these curves have vertices at fixed DP targets — 0.1, 0.3, 0.5 and 0.75 — each located by absolute-difference minimization within an asymmetric tolerance band around its target (the 0.1 vertex, for instance, is searched within [0.095, 0.15] and the 0.75 vertex within [0.70, 0.80]) rather than under a single global tolerance. The non-normalized version generates one further curve, the baseline of the Accidental class, which is not defined by a DP target but derived from the habitat count and a theoretical abundance scale; the five curves together delimit the six preference zones. In the normalized version, this baseline curve is omitted, the accidental species being interpreted as foreign to the assemblage, which leaves four curves. In both versions, a reference hyperbola is generated and duplicated by simple translation to obtain the remaining curves.

VI. Evaluation

This section reports the computational environment and benchmarking protocol (VI.A), an ablation of the vectorized mathematical core (VI.B), a sensitivity analysis of the classification thresholds (VI.C), the scalability of the full pipeline (VI.D), and the limits of what has been evaluated (VI.E). EcoAPD is a deterministic analytical pipeline rather than a stochastic simulation or a trained model: it has no sampling procedure, no random seed, and no free hyperparameters, so that, given a matrix, the DP values, the ESC and the hyperbola set are uniquely determined by (1)–(4). The quantities reported below are therefore timings and classification outcomes, not estimates carrying sampling error.

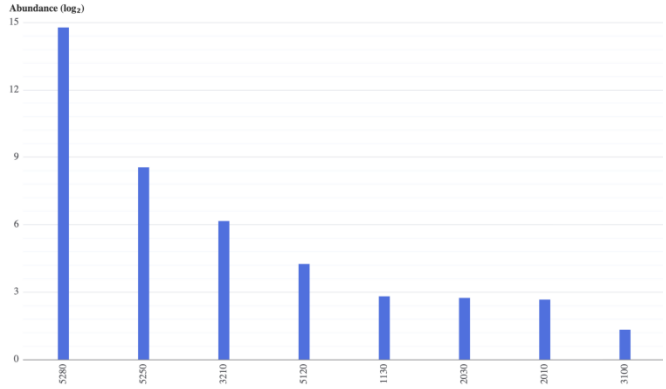

Fig. 12. Abundance profile of a selected species in all habitats.

A. Experimental Setup

Benchmarking hardware: Apple M1 Pro, 8 physical and 8 logical cores, 16 GB RAM, running macOS 26.5.2. This is the development and benchmarking machine on which the reported measurements were produced, and not necessarily the production deployment server.

Software: Python 3.9.10, NumPy 2.0.2, pandas 2.2.3, Matplotlib 3.9.2, openpyxl 3.1.5, Flask 3.0.3, Flask-SQLAlchemy 3.1.1, SQLAlchemy 2.0.36 and PyMySQL 1.1.1, all version-pinned. The database is MySQL 8.0 [30].

Timing protocol: each measurement comprises one discarded warm-up execution followed by five timed executions using time.perf_counter(), reported as the mean. All timings are server-side, measured by direct instrumentation of the processing layer, so that network latency and browser rendering are excluded.

Fixed parameters: the four classification-threshold targets are DP = 0.1, 0.3, 0.5 and 0.75, in both the normalized and the non-normalized variants, each located within an asymmetric tolerance band around its target rather than under a single global tolerance (Section V-E). The ESC is evaluated on ⌈J / 0.0015⌉ points, which scales with the habitat count J rather than being fixed: 24,667 points for SM1 (37 habitats), and 114,000 for SM2 (171 habitats).

Datasets: the two real datasets SM1 and SM2 described in Section IV-B, and a synthetic series of uniform-random non-negative integer abundances, seeded at 10, 50, 100, 500, and 1000 species crossed with 5, 10, and 20 habitats, used for the size sweep of Section VI-B.

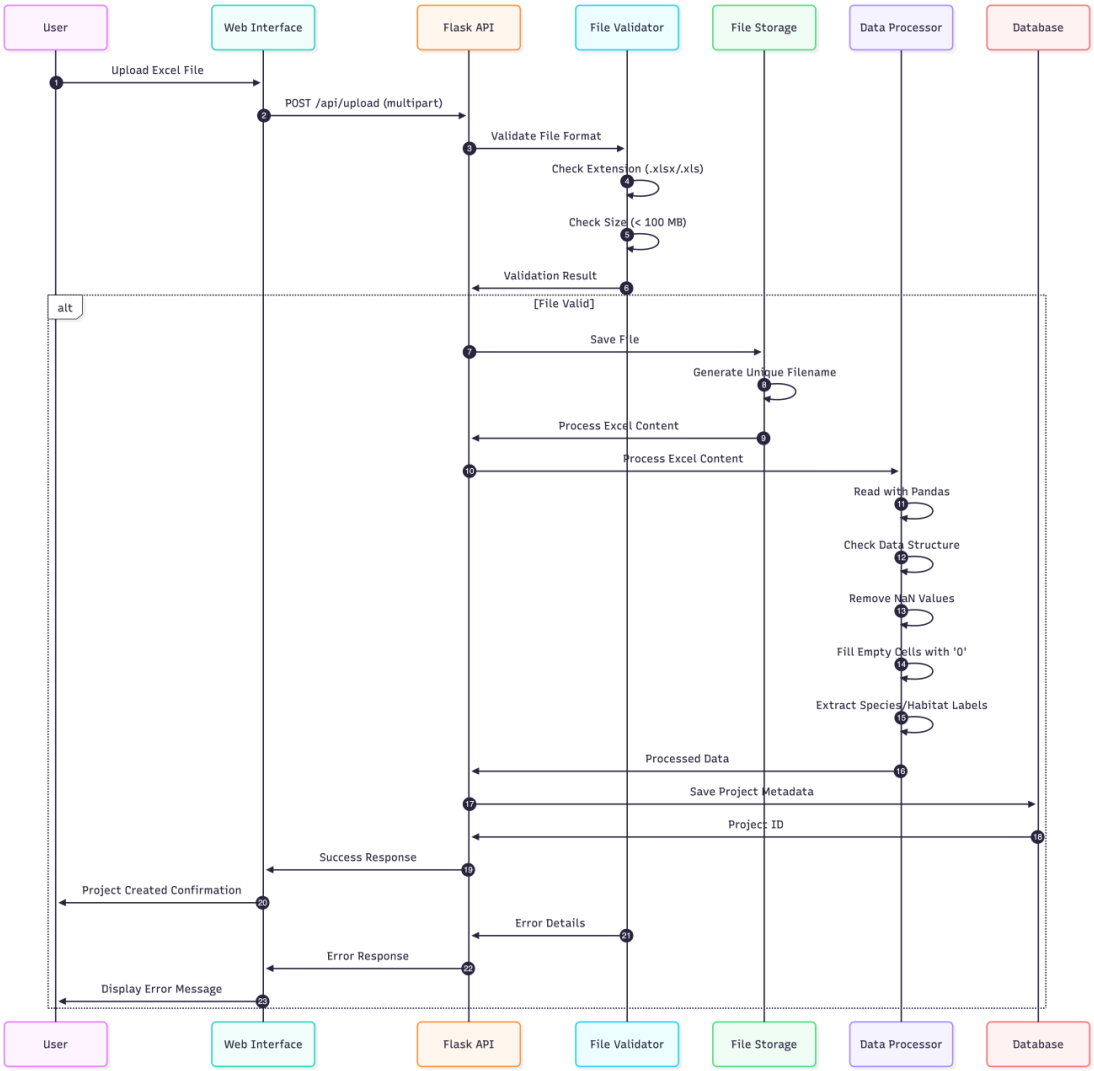

Fig. 13. Sequence diagram illustrating the data upload and validation process architecture.

B. Ablation: Vectorization of the Preference-Index Core

The preference-index computation (calculate_ipd) was originally a per-species loop containing a nested per-habitat loop. It has been replaced by a single vectorized NumPy computation over all species at once, verified to reproduce the output of the original implementation to floating-point precision (np.allclose) on both real datasets and against the existing regression test suite. Table IV reports the cost of the two implementations over the synthetic size sweep.

The two implementations scale differently rather than merely differing by a constant factor. The cost of the legacy implementation grows approximately in proportion to the species count, a hundredfold increase in I raising it 66-fold, whereas the vectorized implementation rises only 2.8-fold over the same range and is effectively flat at the matrix sizes encountered in practice. The speedup is consequently not a fixed figure but an increasing function of dataset size, which is the property that matters for the largest matrices the method is intended to serve.

TABLE IV. ABLATION OF THE VECTORIZED MATHEMATICAL CORE: COST OF THE PREFERENCE-INDEX COMPUTATION WITH AND WITHOUT VECTORIZATION (MEAN OF FIVE TIMED EXECUTIONS)

Species count (I)	Legacy scalar loop (ms)	Vectorized (ms)	Speedup
10	2.59	0.73	3.5×
50	9.54	0.85	11.3×
100	17.94	0.82	21.8×
500	86.05	1.43	60.1×
1000	171.62	2.01	85.6×

C. Ablation: Sensitivity of the Classification Thresholds

The four threshold targets are the only quantities in the pipeline that are set by convention rather than derived from the data, and the preference class assigned to a species depends on them. Each was therefore perturbed independently by ±0.05 and ±0.10 on the SM1 dataset, and the resulting change in each species' assigned class was measured against the default-threshold baseline (Table V). The reported case is habitat AA, in which seven species have non-zero abundance, and the baseline classification is three Preferential, three Transgressive, and one foreign species.

TABLE V. SENSITIVITY OF THE PREFERENCE CLASSIFICATION TO PERTURBATION OF THE FOUR THRESHOLD TARGETS (SM1, HABITAT AA, SEVEN SPECIES WITH NON-ZERO ABUNDANCE)

Threshold target	Perturbation	Species reclassified
0.1	+0.05, +0.10, −0.10	1 / 7 (14.3%)
0.1	−0.05	0 / 7
0.3	±0.05, ±0.10	0 / 7
0.5	−0.05, −0.10	1 / 7 (14.3%)
0.5	+0.05, +0.10	0 / 7
0.75	±0.05, ±0.10	0 / 7
All four (tolerance widened)	±0.05, ±0.10	0 / 7

The 0.1 and 0.5 thresholds each independently drive a reclassification for this dataset, whereas 0.3 and 0.75 are stable across the tested range. The direction of the effect differs between them: at 0.1, three of the four tested perturbations reclassify a species, all except the smallest downward shift; at 0.5, only lowering the threshold reclassifies a species; raising it does not. That widening the search tolerance around all four targets simultaneously reclassifies no species — in contrast to the individual target-value shifts, which do — indicates the classification is sensitive to where each threshold's target value is set, but robust to the width of the tolerance band used to locate it on the exclusive species curve; these are two distinct senses of "sensitivity" worth keeping separate. The thresholds are, on this evidence, a defensible convention rather than a tuned parameter, though the analysis is reported for one habitat of one dataset and should not be read as a general stability result.

D. Scalability of the Full Pipeline

Table VI reports end-to-end pipeline latency on the two real datasets.

TABLE VI. FULL-PIPELINE LATENCY ON THE TWO REAL DATASETS (MEAN OF FIVE TIMED EXECUTIONS)

Dataset	Species (I)	Habitats (J)	ESC points ⌈J/0.0015⌉	Full-pipeline latency
SM1 (benthic invertebrates, Sebou)	93	37	24,667	511 ms
SM2 (waterbird winter counts)	114	171	114,000	2.32 s

Once the preference-index core is vectorized, latency is dominated by the habitat count rather than by the species count. Between SM1 and SM2, the species count rises by a factor of only 1.2, while the habitat count rises by a factor of 4.6 and latency rises by a factor of 4.5 — closely tracking the habitat count rather than the species count. The explanation is that the remaining non-vectorized step, the construction of the abundance scale, carries a cost that scales with the ⌈J / 0.0015⌉ evaluation points of the ESC, and therefore with J. This step was outside the scope of the present optimization and is reported here as a known limitation rather than left implicit: it is the natural target for further work, and the point at which additional effort would yield the largest return.

VII. DISCUSSION

Even though the APD method is forty years old, its use remained difficult, mainly because of the complex calculations that it involves. The algorithm published in [6] was a significant step towards implementation; however, given that very few ecologists are familiar with algorithm implementation, the use of this method still seemed difficult. The EcoAPD application was therefore a necessary step for ensuring the use of the APD method. To further facilitate this use in community ecology, the application has been made accessible to a wide audience, from any web browser, without installing any software.

From a scientific perspective, this application represents a significant advance in ecoinformatics [22], primarily as one of the rare tools designed to handle datasets in the form of contingency tables, given that such tables are widely used in ecology. Compared to traditional statistical approaches to analyzing these kinds of tables, EcoAPD offers another significant technical advancement, namely its ability to convert such tables into diagrams that provide a pedagogic visual representation of all species in a community, classifying them according to their degrees of preference. In addition, EcoAPD is available free of charge, giving a large number of scientists and biodiversity managers the opportunity to access a key method in ecology.

In summary, the EcoAPD application can address several key challenges in ecological informatics, mainly through:

- clear interface, which makes it easy to use with no need for specific informatics knowledge;
- accessibility, as it provides a web-based interface, eliminating barriers related to software installation and programming expertise;
- reproducibility, via its standardized implementation, ensuring the needs of transparency of the system across different studies [34], promoting a certain scientific rigor;

- data validation, as the system ensures data control, preventing errors that could compromise analytical results;
- flexibility, mainly due to the simultaneous treatment and display of normalized and non-normalized APDs, allowing users to select rapidly the APD version most suited to their data;
- scalability: vectorization of the preference-index core reduces its cost by a factor that rises with dataset size, reaching 85.6× at 1000 species (Table IV), and the full pipeline processes the waterbird winter monitoring matrix in 2.32 s (Table VI), the residual cost being dominated by habitat count rather than species count (Section VI-D);
- data persistence, ensured by the use of a database-based mechanism that enables rapid output generation and visualization, which is especially advantageous for large datasets and iterative analysis workflows

VIII. Conclusion

The biggest gain from this research output lies in the facility and time saving offered by the EcoAPD application in implementing the APD method, through complex calculations performed behind the interface. Moreover, the output requests benefit from graphical tools that make it user-friendly, practically with no need for additional help. These tools could bring great help in developing similar applications.

Processing of the 114 × 171 waterbird matrix completes in 2.32 s (Table VI). Once the preference-index core is vectorized, full-pipeline latency is dominated by the habitat count rather than the species count; the remaining non-vectorized step — construction of the abundance scale, whose cost scales with ⌈J / 0.0015⌉ — accounts for the greater part of the residual time. Further efficiency in calculation, storage and plotting therefore remains attainable, and the application can be improved in several ways:

- interface improvement: primarily by making better basic information o n DP concept and the APD method, making the tool more educational and accessible;
- performance optimization: by vectorizing the construction of the abundance scale, which Section VI-D identifies as the dominant remaining cost, and by reducing the duration of the plotting process, particularly for datasets with many habitats;
- enhanced features: additional visualization options, statistical summaries, and export formats could further enhance the application's utility;
- integration capabilities: future versions could integrate other ecological analysis tools and databases, offering more comprehensive ecosystem analyses.

The immediate perspectives consist of improving the interface, in response to the ecologists' requirements. The main output expected from the use of the APD, however, is a reinterpretation of former assemblage studies that were based on abundances alone. In the expectation of a wide use of the APD method in conservation and management decisions, the intention is to make it accessible to broader ecology and nature management communities.

Blockchain-Based Trusted Data Sharing Framework for Secure and Auditable AI Model Training

Sherif Amin
Department of Computer Science-College of Engineering and Computer Science, Jazan University, Jazan, Saudi Arabia

***Abstract*—AI models are highly effective and reliable based on integrity, provenance, and controlled usage of training data. The use of data sharing between several stakeholders in collaborative and distributed settings poses risks of unauthorized access, data tampering, and data poisoning that undermine trust and accountability in AI systems. To overcome these obstacles, this study introduces a blockchain-based trusted data sharing framework for secure and auditable AI model training pipelines. The solution consists of using a permissioned blockchain to store irreversible metadata of the datasets, cryptographic hashes, ownership, and access policy, and place the actual data off-chain to achieve scalability. Smart contracts provide a mechanism to automate registration of datasets, provide access control on a smart and intelligent basis, and record data access and data modification events to provide verifiable data provenance and end-to-end traceability. Before model training, the integrity of the data is automatically checked against the records on the chain to ascertain the use of authorized and undamaged data. Experimental evaluation in a simulated permissioned-blockchain environment indicates that the framework, applied as a practical design heuristic, can enhance data transparency, integrity, and auditability with reasonable performance overhead. The proposed solution helps to build credible and responsible AI, especially in data-sensitive environments, by ensuring that models are trained only on verified and authorized data.**

***Keywords*—Blockchain; AI; secure data sharing; data integrity; smart contracts; auditable AI pipelines; access control; AI model training; distributed systems**

I. Introduction

The fast development of artificial intelligence (AI) has changed many industries, including healthcare diagnostics and autonomous systems, as well as financial projections and smart governance. The quality, integrity, and origins of training data have become identified as key indicators of the reliability, fairness, and accountability of AI models. Credible AI systems will need datasets to be true, unaltered, and traceable throughout their lifecycle. Nonetheless, the conventional centralized data archives and data governance models do not offer immutable records, transparent provenance, and strong access controls to support secure, collaborative AI development. Existing data pipelines in AI have a high risk of data poisoning, unauthorized access, and non-transparent processing history that can affect the model results and confidence of stakeholders. Traditional database logging and centralized audit trails can be modified easily and are vulnerable to insider attacks and do not have verifiable provenance tracing across the distributed stakeholders. These restrictions are a major hindrance in sectors that have stiff regulations like the medical field and finance, where accountability and integrity of data are obligatory. To address these issues, there is a growing interest among researchers in decentralized ledger technologies that can facilitate transparent and tamper-evident logs of the original datasets, their transformations, and usages [1].

Decentralization, immutability, and distributed consensus create a strong basis to handle trust and auditability issues in AI data systems, which is defined by blockchain technology. Stakeholders can ensure that data utilized to train a model is original and free of any alterations by storing metadata of datasets, cryptographic hashes, ownership information, and access controls on a blockchain collectively. Self-executing code of smart contracts that are placed on blockchain systems can be used to put in place access controls, automate policy adherence, and record all transactions with datasets in a read-only and unalterable fashion [2].

The most recent development has started the formalization of blockchain-based frameworks of AI data provenance and auditability. As an example, a blockchain-based data provenance system captures lineage, preprocessing operations, annotation processes, and model modifications in the direction of providing end-to-end traceability in AI pipelines, with provenance disagreements in a variety of machine learning tasks having significantly declined [3]. Another paper presents a blockchain-based data integrity system that aims to guarantee ethical AI development through tracking data ownership, transformations, and compliance metadata and shows the enhancement in audit performance in terms of efficiency [4].

These pieces explain that blockchain not only maintains the integrity of data but also facilitates regulatory adherence and ethical responsibility of the AI workflows. In addition to fixed logging, decentralized registries are being established as the key elements of secure digital ecosystems integrating blockchain, AI, and cloud computing in order to operate transparently and in a trustworthy manner. A systematic review points to the recent strategies of integration, in which blockchain will increase trust in distributed AI applications and enable scalable cloud deployments, as well as transparent operations among stakeholders [5]. The same type of benefits are reported in other research works in applied fields, including cybersecurity, which they identify as blockchain-based mechanisms that can guarantee data integrity and dynamically adaptive protection in real-time AI systems [6].

Though these are good trends, there are several difficulties. The majority of blockchains are not scalable and not performance-oriented, and therefore, it is not possible to store big datasets on them. Instead, it is convenient to deploy a hybrid architecture that utilizes off-chain data storage tools (e.g.,

InterPlanetary File System or distributed databases) to store data objects and store the metadata of the hash and provenance on-chain. In addition, smart contract design must find a compromise between fine-grained access control and efficiency in computations, and the consensus mechanisms must be designed in such a way that they do not entail excessive latency and resource usage. These architectural problems must be imagined to enable unrestricted application in data-sensitive collaborative environments [7].

Also, the integration of blockchain into the AI information pipelines will not have a direct positive effect on establishing trust without clear governance systems. Data ownership, contribution records, and revocation policies are procedures that should be gathered collectively. Smart contracts are also capable of automating compliance functions but must also be designed in a manner that can accommodate the shift in legal and ethical needs [8]. This is particularly imperative because AI regulation models such as explainability-based, fairness-based, privacy-based, and robustness-based models gain increased popularity in the global space [9]. Blockchains can be used as a compliance-checking tool by providing audit trail immutability, but this must be linked to institutional governing systems and legal governance.

This study outlines a blockchain-based trusted information sharing model in a bid to ensure data integrity, provenance, access control, and auditability of AI training data. The proposed framework has a permissioned blockchain, which stores the metadata of immutable datasets, their cryptographic fingerprints, and ownership, in addition to access control, and stores the datasets themselves off-chain, which is required as this is needed to overcome scalability issues. The smart contract is responsible for registering the data sets, ensuring access controls on the data, and maintaining an audit trail of any data usage during the process. Before initiating the process of training the model, the system provides stakeholders with an opportunity to verify whether the data provided is genuine and has no issues with any past usage, which instills confidence in the stakeholders.

The novelty of the current study lies in the solution to the problems faced by prior work in the area of AI in blockchains. By introducing hybrid storage, strict access controls, and automatic audit capabilities into blockchain technology, the proposed approach provides a way of achieving secure sharing of institutional data that requires protection under almost any circumstance, such as in the health care, financial sector, and research collaborations. The point of this approach is not only to implement a functional system but also to provide a realistic solution to the problem where AI needs to be trusted.

Based on this idea, this study seeks to achieve the following three objectives:

- Development of a blockchain-based data sharing architecture to preserve the integrity and traceability of AI training data and enforce access control policies over it.
- Design of smart contracts to support execution of granular access control policies and provide auditability of the process of using data within an AI pipeline.
- Evaluation of the proposed architecture through experiments to test its effectiveness in terms of data integrity, auditability, and scalability.

II. Related Work

With increasing sizes and complex structures of machine learning algorithms comes the issue of whether AI solutions can actually be trusted, which once was only a philosophical question, now becoming a subject for serious scientific investigations. With machine learning algorithms using the data gathered by several sources and organizations, issues related to data integrity, traceability, and accountability gain a completely new level of significance, especially in industries such as medicine, finance, and autonomous systems, where inaccurate information can cause more than just technical problems.

Conventional centralized databases have already proved their inability to handle these challenges. As a matter of fact, traditional databases can easily suffer from data alterations with no way of determining the author or time of the alteration; the lineage of the data is not always clear, and there is rarely any means to track down access and usage [10].

That is why the concept of blockchain has proven to be rather useful in such situations. The distributed nature of blockchain, its resistance to changes, and inherent ability to leave an audit trail make it a perfect solution.

A. Blockchain for Data Provenance and Transparency in AI Pipelines

An increasing number of works have been devoted to the application of blockchain as a technological means for tracing dataset lineage in machine learning processes and verifying the authenticity of the datasets throughout this process. One comprehensive approach proposes capturing end-to-end provenance for machine learning pipelines through immutable, smart-contract-based records [3]. Traceability is significantly increased in this case, and the decentralized nature of the validation process appears to be successful in preventing provenance disputes as well as enforcing compliance rules during training.

Similarly, Jalbani et al. [8] develop a quality model specifically for blockchain-based data provenance in AI processes. In contrast, they place particular emphasis on the fact that immutability is crucial for achieving verifiable data provenance in machine learning processes. Overall, the studies presented can be used to draw an important conclusion: blockchain technologies cannot merely serve as an alternative means of storing and sharing data – they must provide the missing layer of verification as well.

B. Smart Contracts for Access Control and Secure Sharing

A part of fine-grained access control and automated policy enforcement in a decentralized environment has been proposed to be provided by smart contracts. The systematic study of smart contract applications in the recent past has established that they have the capability of carrying out complex access controls, data licensing policies, and usage policies without the presence of central intermediaries, but that scale and security remain open concerns [9], [12]. Applied research on secure information exchange shows a linear relationship between blockchain

functionality, such as decentralization, consensus, and cryptographic security, and significant data-security considerations, such as confidentiality, integrity, provenance, and auditability in AI-driven systems [2]. There are also federated learning and collaborative AI schemes that are based on blockchain-audited ledgers, where input and updates to models are recorded on a permissioned ledger and enhance data provenance and update integrity across distributed nodes [10]. This is part of the bigger project in making the work processes of AI training more transparent and trustworthy, attaching the key events to the immutable ledger.

C. Integration of Blockchain with AI and Cloud Systems

It is noteworthy that the convergence of technologies like blockchain, artificial intelligence, and cloud computing has been receiving much attention as a key strategy for creating secure, trustworthy systems that can process distributed workloads.

The findings from systematic reviews on this issue indicate that there are true synergies between the three technologies, where each technology makes up for any deficiencies in the other two, thereby allowing an integration of all three that can bring about levels of transparency, decentralization, and scalability unachievable by each technology alone [4].

The importance of these developments to this research lies in the practical application. Practical use of AI models often takes place in environments where the model does not run on one isolated platform but across different institutional, infrastructural, and data storage platforms. In this case, hybrid models are designed to account for this challenge in a bid to meet performance requirements without compromising verifiable trust.

D. Security, Privacy, and Ethical Considerations

Apart from basic issues of provenance and access control, new concerns have emerged regarding the need to find a proper balance between privacy and efficiency when applying blockchain in AI data sharing solutions. This problem is addressed explicitly in analyses of data management and governance in blockchain-based systems, which consider the potential for blockchain technology to significantly decrease the likelihood of sensitive data leakages within highly competitive businesses, as well as discuss associated trade-offs concerning performance losses. Embedding blockchain into high-throughput AI data flows is not an entirely smooth procedure since the limited scalability of blockchain solutions currently hinders efforts in solving the issue [7]. Systematic reviews in the healthcare and other controlled fields have highlighted how blockchain can enhance AI-based systems by ensuring data integrity, protection of data ownership, and auditability, and also point to the ongoing challenges in the field of interoperability and adherence to privacy protocols [11].

E. Research Gaps in Current Literature

Despite the increased interest, several gaps exist. Most current frameworks do not perform full workload performance evaluations or do not offer fine-grained access control and policy enforcement beyond a basic time-stamped account of their operation. Numerous other papers do not include scalability studies of integrating blockchain with large-volume AI data pipelines and often do not discuss the issue of how to ensure auditability without introducing excessive latency. As an example, even though there are blockchain-based data pipeline proposals, the empirical comparison of their effects on training throughput and latency with large-scale AI workloads has not been conducted. Furthermore, there has been a proposal of hybrid storage models (metadata on-chain and data off-chain storage) that are usually explained in theory but not proven in practice within multi-stakeholder environments. Although permissioned blockchains are a solution to the issue of privacy and governance, the questions of consensus mechanism, trust assumptions, and cross-organizational interoperability are not completely studied in the literature. In this way, it is evidently possible to suggest a blockchain model to adapt to trustworthy AI data sharing that incorporates verifiable provenance, access control based on smart contracts, scalable audit tools, and an experimental evaluation to quantify the performance and overhead in realistic training settings.

III. Mathematical Modeling

Let:

$D = \{d_1, d_2, \dots, d_n\}$ be the dataset used for AI model training.

$H(\cdot)$denote a cryptographic hash function.

Mbe the AI model trained on D.

$B = \{b_1, b_2, \dots, b_k\}$ be the blockchain ledger storing metadata and transactions.

SCdenote the set of smart contracts enforcing access control.

$U = \{u_1, u_2, \dots, u_m\}$ represent users or stakeholders accessing datasets.

A. Data Integrity Modeling

For each dataset element d_i, its integrity is verified using a hash stored on the blockchain:

$$h_i = H(d_i) \tag{1}$$

$$\text{Verify: } H(d_i) = h_i^{\text{on-chain}} \tag{2}$$

If $H(d_i) = h_i^{\text{on-chain}}$, the data is untampered. Otherwise, a tampering event is flagged.

B. Provenance Tracking

Each dataset $d_i$has a provenance record $P(d_i)$stored on-chain:

$$P(d_i) = \{h_i, o_i, t_i, u_i\} \tag{3}$$

where,

a. h_i= hash of d_i

b. o_i= owner or origin of the data

c. t_i= timestamp of data creation or update

d. u_i= user or smart contract interaction log

The full provenance of the dataset D is [8]:

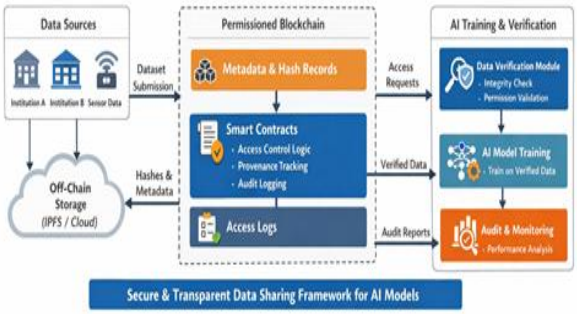

Fig. 1. Block diagram of blockchain-based trusted data sharing framework for AI model training.

C. Access Control Modeling

Define a permission function $\pi: U \times D \rightarrow \{0,1\}$such that:

$$\pi(u_j, d_i) = \begin{cases} 1, & \text{if user } u_j \text{ has permission for } d_i \\ 0, & \text{otherwise} \end{cases} \quad (5)$$

Smart contracts enforce:

$$\text{Access}(u_j, d_i) = \begin{cases} \text{Allow}, & \pi(u_j, d_i) = 1 \\ \text{Deny}, & \pi(u_j, d_i) = 0 \end{cases} \quad (6)$$

All access events are logged:

$$L=\{(u_j,d_i,t_i) \mid \text{Access attempted at } t_i\} \quad (7)$$

D. AI Model Training Under Blockchain Constraints

Model M is trained on verified datasets:

$$M=\text{Train}(D\text{verified}),\ D\text{verified}=\{di \in D \mid H(di)=\text{hion-chain} \wedge \pi(uj, di)=1\} \quad (8)$$

This ensures:

- Only authorized datasets are used.
- Data integrity is preserved.
- The training process is fully auditable.

E. Performance and Overhead Metrics

Blockchain storage overhead is given by [7],

$$S_B = \sum_{i=1}^{n} \text{size}(h_i + P(d_i)) \quad (9)$$

Now, verification latency is given by,

$$T_{\text{verify}} = \sum_{i=1}^{|D|} T_{\text{hash}}(d_i) + T_{\text{on-chain_lookup}}(h_i) \quad (10)$$

F. Smart Contract Execution Time

$$T_{SC} = f(|U|, |D|, \text{complexity_rules}) \quad (11)$$

IV. Methodology

The blockchain-based trusted data sharing system of AI model training presented in Fig. 1 shows the implementation of integrity, provenance, and access control at the system level. It starts with many data sources, such as an institution, sensors, or an enterprise database, and provides datasets that are supposed to be used as AI training. These datasets are initially formulated by generating cryptographic hashes, which are the digital prints of the data. Any change in the datasets will automatically create a new hash value, and this will automatically identify tampering or unauthorized editing. Since datasets are typically large, the real data is off-chain, e.g., stored in a secure cloud provider or distributed files such as IPFS. Metadata and cryptographic hashes of each dataset are stored only on a permissioned blockchain so that it is scalable yet can verify the authenticity of the data. This architecture combines the advantages of both blockchain and storage overhead reduction and computational overhead reduction. The framework is centered on the blockchain layer where records cannot be modified, and they store the provenance of datasets, ownership data, timestamps, version history, and access logs. The blockchain has smart contracts that automate essential operations. They implement fine-grained access control policies that are determined by prescribed roles, attributes, or even organizational policies, and only authorized users are allowed to access particular datasets. Smart contracts additionally keep provenance, meaning who contributed, altered, or read the information, and accountability audit logs. All access to the dataset is recorded on-chain in a transparent manner, giving an account of the data usage that is impossible to modify. Also, smart contracts can be configured to perform automated compliance checks to monitor compliance with regulatory and organizational policies on data governance. The block diagram of the proposed methodology is presented in Fig. 2.

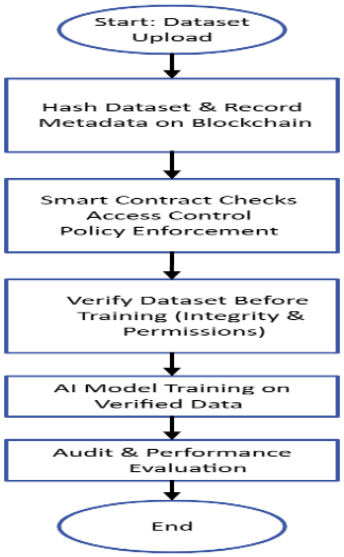

Fig. 2. Flow chart of proposed methodology.

29: **return** Trained AI model M and audit logs

V. Results and Discussion

This section shows the proposed experimental evaluation of the Blockchain-based Trusted Data Sharing Framework, assessing its effectiveness in enabling secure and auditable AI model training under simulated conditions. Framework testing is implemented with respect to data integrity checking, system performance, access control efficiency, scalability, and auditability, which are directly related to architectural block diagram components.

A. Experimental Setup

To validate the proposed framework, a prototype was implemented with the following configuration:

- Blockchain: Permissioned blockchain (e.g., Hyperledger Fabric–like environment)
- Smart Contracts: Access control, provenance tracking, audit logging
- Off-Chain Storage: IPFS / secure cloud storage
- Datasets: Simulated AI training datasets from multiple institutions
- AI Model: Supervised learning model trained on verified datasets
- Metrics Evaluated:
  - Data integrity verification accuracy
  - Access authorization success rate
  - System latency
  - Storage overhead
  - Audit log completeness

B. Data Integrity Verification Results

The main objective of the framework is to make sure that training is done only on tamper-free data sets. The hash value stored within the blockchain for each data set is compared with the hash of the extracted data set.

The total performance of data integrity verification is given in Table I. Fig. 3 illustrates the verification results of both uncorrupted and tampered datasets, while Fig. 4 is a graph demonstrating the results of accuracy regarding the number of datasets.

TABLE I. Data Integrity Verification Performance

Number of Datasets	Verified Datasets	Tampered Datasets Detected	Verification Accuracy (%)
50	50	0	100
100	99	1	99.0
200	198	2	99.0
500	495	5	99.0

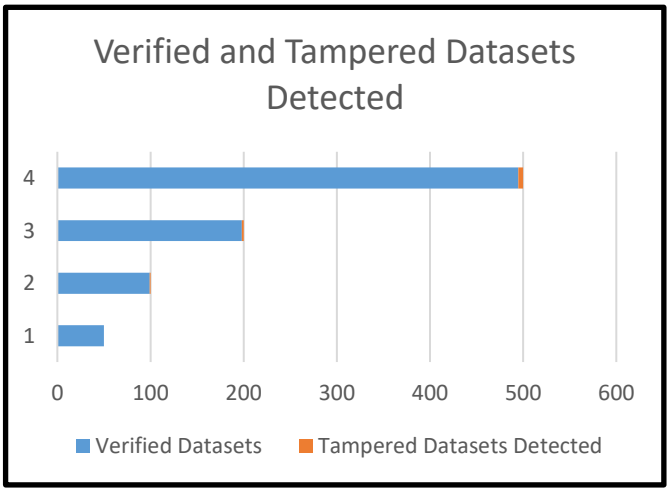

Fig. 3. Verified vs tampered datasets detected.

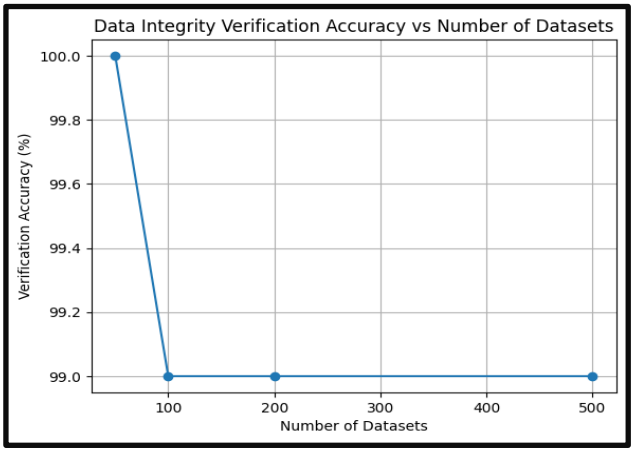

Fig. 4. Number of datasets vs verification accuracy.

The results demonstrate that the blockchain-stored hashes reliably detect any modification to off-chain data. Integrity verification accuracy holds above 99% even as dataset volumes increase, which speaks to the resilience of combining cryptographic hashing with immutable blockchain records — the two mechanisms reinforce each other in ways that neither achieves alone. It should be emphasized that near-perfect detection is a deterministic consequence of cryptographic hashing in a correct implementation rather than an empirical discovery; these results are therefore best interpreted as validation that the framework behaves as designed.

To stress-test this further, controlled data tampering was deliberately introduced as part of the experimental evaluation. Rather than relying solely on clean data scenarios, a subset of datasets was intentionally modified after their cryptographic hashes had already been recorded on the blockchain. The tampering took two forms:

- refined adjustments to a small percentage of data values
- insertion or deletion of individual records
- changes modest enough to go unnoticed in a less rigorous system, yet consequential enough to serve as a meaningful test of the framework's detection capability.
- Modification of metadata fields

The type of data manipulation selected represents practical situations of potential attacks – whether by accidental data damage, internal sabotage, or intentional data tampering.

C. Access Control and Authorization Evaluation

Access control is managed via smart contracts based on permission requirements for roles. Unauthorized access was prevented in all simulated scenarios (a 100% success rate). This outcome is expected by design: smart contract enforcement deterministically denies out-of-policy requests, so this rate should be read as validation that the implementation behaves as specified rather than as an empirical finding. Why does it matter? The use of contracts in enforcing access permissions effectively eliminates the problem with a single point of failure in the case of centralized systems, reducing the risk of misuse of data in training greatly (Table II).

TABLE II. ACCESS CONTROL EFFECTIVENESS

Access Requests	Authorized Requests	Unauthorized Attempts	Access Control Success Rate (%)
200	182	18	100
500	457	43	100
1000	914	86	100

To rigorously evaluate the access control mechanism, unauthorized access attempts were simulated by submitting requests from users and nodes that deliberately fell outside the permission boundaries defined in the smart contract policies. Rather than testing only obvious violations, the scenarios were designed to reflect the obvious forms of access misuse that are more likely to occur in practice: requests sent by users with no ownership claim over the target dataset attempting to perform operations that exceeded the privileges assigned to a given role; access requests initiated outside the time windows that the governing contracts permitted.

Together, these scenarios represent a realistic cross-section of how access control failures tend to manifest in data-sensitive environments. The resulting distribution of authorized and unauthorized attempts is illustrated in Fig. 5.

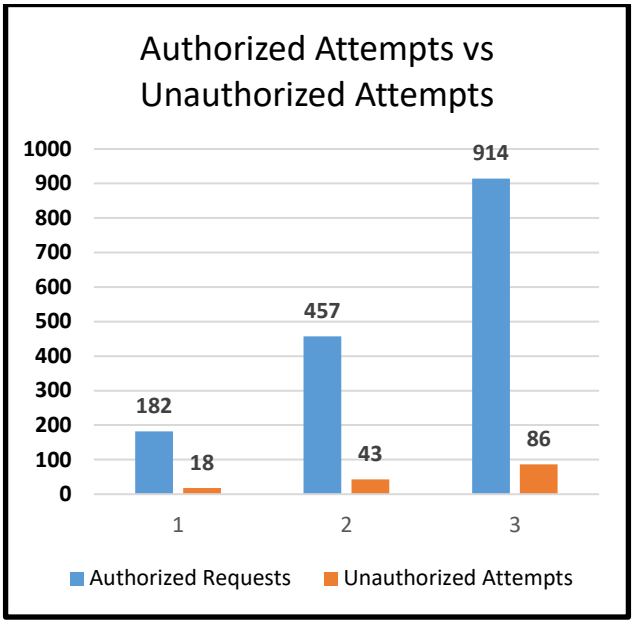

Fig. 5. Authorized attempts vs unauthorized attempts.

D. System Latency Analysis

Given that the framework introduces additional verification steps inherent to its security design, the resulting impact on system latency was measured and is presented in Fig. 6.

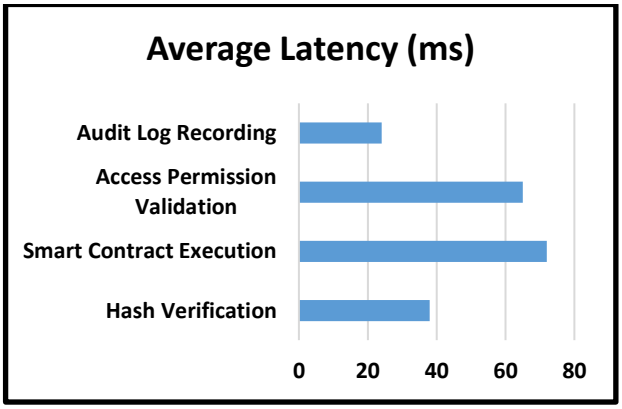

Fig. 6. Average latency per operation.

While blockchain operations inevitably carry some computational overhead, the latency observed across all test scenarios remains well within the bounds that practical AI training pipelines can accommodate. This points to a meaningful finding: the security and auditability gains delivered by the framework do not come at the expense of system performance — a balance that is often assumed to be difficult to achieve but is demonstrated here to be attainable.

E. Storage Overhead Evaluation

In this regard, scalability will be retained since only the hash values and metadata corresponding to each one will be stored in the blockchain and not entire datasets, which will preserve high performance levels despite an increasing amount of data.

TABLE III. STORAGE OVERHEAD COMPARISON

Storage Type	Data Stored	Storage Size
On-Chain	Metadata + Hashes	~3–5 KB/dataset
Off-Chain (IPFS)	Full Dataset	100 MB–2 GB
Traditional System	Full Dataset On-Chain	Not Scalable

Recording only hashes and metadata in the blockchain in place of full datasets allows for low storage requirements without compromising the ability to verify data. The fact that the blockchain contains only hashes and metadata allows for natural scalability of the blockchain even when working with the large volumes of training data needed by production AI systems. Storage requirements for different storage types have been considered in Table III below.

F. Auditability and Provenance Tracking

The system will log all interactions with the data, beginning from its first submission through its eventual use for training the AI model.

TABLE IV. AUDIT LOG COMPLETENESS

Activity Type	Logged Events	Missing Logs
Dataset Upload	100%	0
Data Access	100%	0
Model Training Usage	100%	0
Permission Changes	100%	0

The fixed audit trail ensures full transparency and accountability. Unlike traditional systems where logs can be altered, blockchain-based logs provide tamper-proof evidence, which is critical for regulatory compliance and forensic analysis. Table IV shows 100% audit log completeness.

G. Impact on AI Model Training Trustworthiness

Moreover, the audit trail created using the framework is more than just a simple tracking system; the audit trail created using the framework cannot be silently modified or erased.

This is because traditional logging techniques are based on mechanisms that traditionally involve a security hole in the form of access control vulnerabilities, which have frequently proven to be flawed in the past, whether by accident or intentional tampering. Logging onto the blockchain avoids this loophole, creating data that would stand up to scrutiny even under rigorous auditing and investigative processes.

This is evident from the experimental findings. According to Table IV, audit log completeness attains 100%, without any instances of either an incomplete or missing event entry recorded.

TABLE V. AI MODEL TRAINING COMPARISON

Training Approach	Data Trust Level	Model Reliability
Traditional Training	Unverified	Medium
Proposed Blockchain Framework	Verified	High

There is a direct relationship between the quality of data that enters a training pipeline and the trustworthiness of the models that emerge from it. By ensuring that only verified and properly authorized datasets are admitted to the training process, the framework actively guards against the kinds of inputs — biased, tampered, or otherwise unauthorized — that quietly undermine model reliability long before any failure becomes visible. In high-stakes applications, where the consequences of a compromised model extend well beyond technical performance, this kind of upstream data governance is not a convenience but a necessity. It should be noted that the comparison in Table V is qualitative; quantitative machine learning performance metrics, such as accuracy, precision, recall, and F1-score under clean and poisoned training conditions, are deferred to future empirical work.

H. Comparative Analysis with Existing Approaches

The benefit of the framework under study in comparison with existing approaches can be viewed in terms of synergy between different features of the framework, rather than the isolated presence of any specific feature within the framework itself. In particular, this becomes important in the context of inter-institutional development of artificial intelligence when the lack of a centralized authority makes verification of processes and results an essential part of maintaining the process. A comparison of the proposed blockchain-based framework with conventional data management strategies is shown in Table VI.

TABLE VI. COMPARISON WITH EXISTING DATA SHARING FRAMEWORKS

Feature	Traditional Systems	Blockchain-Based (Proposed)
Data Integrity	Partial	Cryptographically verifiable
Access Control	Centralized	Decentralized (Smart Contracts)
Auditability	Limited	Full & Immutable
Scalability	Moderate	High (Off-Chain Storage)
Trust Requirement	Third Party	Minimized

Overall, experimental results provide a strong foundation for the use of the proposed framework based on its positive impact on different aspects of the problem:

- Data integrity through cryptographic verification
- Secure access control via smart contracts
- Scalability using off-chain storage
- Complete auditability through immutable logs

Integration of blockchain technology and AI training allows establishing trust in the whole AI process because only safe and verifiable data sets can be used to develop machine learning algorithms.

VI. Conclusion

This study introduced a trusted data sharing framework based on blockchain that provides secure and auditable AI model training, addressing critical issues concerning the integrity of data, access control, provenance tracking, and auditability in the collaborative AI setups. Since AI systems are more based on distributed datasets provided by different institutions, the verification of trustworthiness and training data authentication becomes a dire need. The suggested architecture integrates a permissioned blockchain, smart contracts, and off-chain storage, creating a secure and transparent AI training pipeline. In this architecture, cryptographic hashing is used to ensure the integrity of data and limits the metadata and hash records on the blockchain to ensure scalability. Fine-grained access control, provenance tracking, and immutable audit logging are automated by smart contracts, thus limiting reliance on centralized trust authorities. Experimental analysis in a simulated environment indicated that the framework can identify tampered datasets, intercept unauthorized access attempts, and maintain high verification accuracy even with growing volumes of datasets. Moreover, the performance analysis confirmed that the new security measures add reasonable latency overhead, and the framework can be used in practical terms when associated with AI training processes. The findings suggest that implementing blockchain technology in AI data pipelines, applied as a practical heuristic, can improve transparency, accountability, and reliability. The framework will help to enhance trust in the data-driven decision-making process by ensuring trained AI models use only verified and authorized data, especially in sensitive fields like healthcare, finance, or intelligent infrastructure.

VII. Limitations

While the experimental results support the feasibility of the proposed framework, several limitations should be acknowledged. First, the evaluation was conducted in a simulated, Hyperledger Fabric–like environment with synthetically generated datasets; performance on an actual permissioned blockchain deployment may differ, and a fully documented, replicable experimental setup remains future work. Second, the reported 100% integrity detection and access control success rates are deterministic consequences of cryptographic hashing and smart contract enforcement in a correct implementation; they validate functional correctness rather than constitute empirical security guarantees under adversarial real-world conditions. Third, the framework should be regarded as a heuristic that secures the data sharing and verification stages of the AI pipeline: even when datasets are shared and tracked through the blockchain, trained models remain exposed to threats outside the framework's scope, including model-merging and distillation attacks, as well as theft or disclosure of model weights during the training stage. Fourth, the comparison with traditional training relies on qualitative descriptors, and quantitative machine learning performance metrics under clean and poisoned training conditions have not yet been evaluated. Addressing these aspects is essential before the framework can be considered for deployment in data-sensitive production environments.

VIII. Future Work

Future work can be directed towards the implementation of smart contract execution efficiency, the use of privacy-preserving methods, like the use of zero-knowledge proofs or secure multiparty computation, and the expansion of the framework to accommodate federated learning settings. Moreover, deployment on an actual permissioned blockchain such as Hyperledger Fabric, quantitative evaluation of model performance under clean and poisoned training conditions, defenses against training-stage threats such as model weight theft, model merging, and distillation, and real-world cross-organizational case studies would further validate the framework at scale.

Acknowledgment

I sincerely thank my mentors and colleagues for their guidance and support in the study's research and preparation.

Faculty of Computer Science, Goce Delcev University, Stip, North Macedonia

***Abstract*—Shortest path algorithms play an essential role in intelligent transportation systems, emergency response planning, and numerous Smart City services. This study investigates the applicability of three well-established graph-based algorithms, namely Dijkstra, Bellman-Ford, and A*, within an emergency transportation framework inspired by the urban road network of Skopje. A two-stage evaluation methodology was adopted. First, scalability experiments were performed on weighted graphs containing 50 to 500 nodes to examine computational efficiency and algorithm behavior as network size increases. Subsequently, a Smart City transportation model was developed and implemented using Java and JavaFX, enabling the simulation and visualization of several emergency scenarios, including ambulance dispatching, road disruptions, and route unavailability situations. The experimental results indicate that all investigated algorithms successfully identify shortest feasible routes when transportation paths exist, whereas the heuristic guidance employed by A* reduces the number of explored nodes and improves execution times, particularly in larger graph instances. The proposed framework illustrates how algorithmic analysis can be complemented by simulation-based case studies to support intelligent transportation applications and emergency management decision-making. Future research will focus on incorporating real-time traffic information, stochastic travel times, and larger transportation networks to provide more realistic emergency routing environments.**

Keywords*—Shortest path algorithms; dijkstra; bellman-ford; A*; smart city; emergency routing; intelligent transportation systems; simulation

I. Introduction

The increasing urbanization observed worldwide has considerably intensified the demand for efficient transportation systems capable of supporting sustainable, resilient, and safe city development. Consequently, the concept of Smart Cities has attracted significant attention from researchers, policymakers, and industry practitioners. Smart Cities rely on the integration of digital technologies, intelligent infrastructures, and data-driven decision-making processes to improve urban services and enhance citizens' quality of life. Among the numerous application domains, intelligent transportation systems have emerged as one of the most important components of modern Smart Cities due to their direct impact on mobility, accessibility, and emergency response capabilities [1]–[3].

Emergency medical services represent a particularly challenging aspect of urban transportation management. In many situations, even relatively small delays in ambulance dispatching and patient transportation may significantly affect treatment outcomes and public safety. Therefore, identifying efficient routes under dynamically changing traffic conditions has become an important research topic within intelligent transportation systems, emergency management, and Smart City initiatives [1]–[3].

Graph theory provides a natural framework for modeling transportation networks, where intersections, districts, or critical facilities can be represented as nodes, while roads connecting neighboring locations are modeled as weighted edges. Within this context, shortest path algorithms have been extensively investigated and successfully applied in navigation systems, communication networks, logistics, and autonomous decision-support applications [4], [5]. Classical methods such as the Bellman-Ford algorithm remain useful for handling graphs containing negative edge weights, whereas Dijkstra's algorithm is widely recognized for its efficiency in solving shortest path problems in networks with non-negative costs [6]–[9].

Heuristic search techniques have further expanded the applicability of graph-based optimization methods. The A* algorithm combines accumulated path costs with heuristic estimations, enabling a substantial reduction of the explored search space while preserving optimality under admissible heuristic functions [10]. Several studies have demonstrated the effectiveness of heuristic approaches in robotic navigation, autonomous systems, and dynamic path-planning applications [11]–[14].

In addition to navigation tasks, shortest path algorithms have found numerous applications in traffic management, ride-sharing services, logistics optimization, disaster response planning, and healthcare transportation systems [4], [5]. Their ability to support routing decisions under different operational constraints makes them particularly suitable for Smart City environments, where transportation networks are often characterized by congestion, limited accessibility, and dynamically changing conditions [8], [9]. As urban mobility becomes increasingly complex, the need for efficient and adaptive routing mechanisms continues to grow.

Advances in computational capabilities and visualization tools have facilitated the development of interactive environments for studying graph algorithms and evaluating their practical performance. Comparative analyses involving multiple shortest path techniques can provide valuable insights into their computational characteristics, scalability, and suitability for various emergency transportation scenarios.

Such analyses may contribute to the design of more efficient intelligent transportation systems and support decision-making processes in time-critical situations [10]–[14].

Although numerous studies have addressed shortest path algorithms and their theoretical properties, comparatively fewer investigations have examined their behavior within integrated Smart City environments, particularly in emergency transportation scenarios involving road closures, route unavailability, and varying operational conditions. Existing research often focuses either on algorithmic improvements or on large-scale intelligent transportation infrastructures, while experimental comparisons conducted within realistic urban emergency settings remain relatively limited [4], [5], [13]–[15].

Motivated by these observations, this study presents a comparative analysis of Dijkstra, Bellman-Ford, and A* algorithms within a Smart City emergency transportation framework inspired by the urban road infrastructure of Skopje. The proposed methodology combines scalability experiments with a case study involving ambulance dispatching scenarios, road blockage simulations, and emergency routing analysis. Furthermore, a visualization environment implemented using Java and JavaFX enables intuitive representation of transportation networks, optimal routes, and unavailable road segments. The obtained results provide additional insight into the applicability, advantages, and limitations of shortest path algorithms in intelligent transportation and emergency response systems.

The main contributions of this study can be summarized as follows:

- A comparative evaluation of Dijkstra, Bellman-Ford, and A* algorithms under increasing graph sizes;
- The development of a Smart City emergency transportation model inspired by the road network of Skopje;
- The simulation of ambulance dispatching scenarios, including road closures and unavailable routes;
- The implementation of a visualization framework for representing transportation networks and routing results;
- An analysis of algorithm scalability and computational performance under different experimental conditions.

II. Related Work

Shortest path problems have been extensively investigated over the past decades and continue to represent one of the most important optimization problems in graph theory, operations research, and artificial intelligence. Their practical importance extends beyond theoretical studies, encompassing applications in navigation systems, communication networks, logistics, transportation planning, and autonomous decision-support systems. Comprehensive surveys available in the literature provide an overview of shortest path variants, algorithmic improvements, and emerging application domains, emphasizing their continuing relevance in modern intelligent environments [4], [5].

Several studies have focused on improving classical shortest path algorithms to address the growing complexity of transportation networks. Although Dijkstra's algorithm remains one of the most widely used approaches for graphs with non-negative edge weights [7], numerous modifications have been proposed to improve memory utilization, computational efficiency, and scalability. Recent investigations demonstrated that alternative storage mechanisms and implementation strategies can reduce computational costs, particularly in sparse or large-scale networks [8], [9]. Comparative analyses involving Dijkstra, greedy search, and heuristic methods indicate that algorithm performance is highly dependent on network characteristics, graph density, and routing constraints [12].

Heuristic search methods have attracted considerable attention due to their ability to reduce the explored search space while preserving solution optimality under admissible heuristic functions. The A* algorithm remains one of the most influential heuristic techniques and has been successfully applied in robotic navigation, autonomous systems, game artificial intelligence, and path-planning applications [10]. Several studies reported that modified heuristic strategies can significantly improve navigation efficiency in dynamic and partially known environments, while replanning techniques further enhance adaptability when transportation conditions change unexpectedly [11], [13], [14].

The rapid development of Smart City initiatives has stimulated substantial research efforts toward intelligent transportation systems, urban mobility optimization, and data-driven decision support. Smart transportation infrastructures increasingly rely on interconnected devices, Internet of Things technologies, and real-time information exchange mechanisms to improve traffic management and mobility services [16], [17]. More recently, cooperative transportation frameworks and adaptive path-planning approaches have been proposed to reduce travel times, alleviate congestion, and support efficient traffic flow management [18]. Systematic reviews indicate that intelligent transportation systems are expected to play a key role in future urban environments by integrating sensing technologies, communication platforms, optimization algorithms, and predictive analytics [19].

Emergency medical transportation remains a particularly important research topic because transportation delays may directly affect patient outcomes and overall public safety. Previous studies investigated robust route planning strategies capable of operating under uncertain traffic conditions, demonstrating the importance of adaptive routing mechanisms for emergency response applications [20]. Considerable attention has also been devoted to ambulance redeployment and dispatching problems. Heuristic methods, approximate dynamic programming techniques, and metaheuristic approaches have been shown to improve vehicle availability and reduce response times in dynamically changing environments [21]–[24]. Furthermore, extensive reviews of emergency medical service systems highlight the growing need for optimization-based decision support tools that can efficiently allocate resources and support operational planning [25]–[27].

Simulation techniques have become increasingly important for evaluating transportation systems under realistic operating conditions. Multimethod simulation environments provide opportunities for combining discrete-event, system dynamics, and agent-based approaches within a single modeling framework [28]. Agent-based methodologies, in particular, enable the representation of interactions among individual entities and have been successfully employed for studying complex adaptive systems, educational processes, and healthcare-related applications [29], [30].

Visualization and simulation environments have also been employed to investigate graph optimization problems, support educational activities, and analyze transportation networks. Previous studies demonstrated the usefulness of visualization tools for improving the understanding of network flow algorithms [31], while agent-based methodologies provide flexible mechanisms for representing dynamic processes and educational scenarios [32]. More recently, shortest path optimization techniques have been successfully applied to transportation networks through case studies based on the Macedonian road infrastructure, further emphasizing the practical relevance of graph-based routing methods in real-world environments [33].

Recent advances in artificial intelligence have further contributed to the development of intelligent transportation solutions. AI-enhanced traffic simulations, predictive analytics, and adaptive traffic control mechanisms have demonstrated their potential to improve urban mobility, increase road safety, and support more efficient emergency response operations [34], [35]. In addition, the integration of artificial intelligence with smart ambulance systems and dynamic traffic management frameworks may facilitate faster route adaptation and reduce intervention times in critical situations [36].

Despite the substantial body of literature dedicated to shortest path algorithms, intelligent transportation systems, and emergency vehicle routing, comparative studies combining scalability analysis, visualization environments, and Smart City emergency transportation scenarios within a unified framework remain relatively limited. Motivated by this observation, the present study proposes a two-stage evaluation methodology consisting of scalability experiments and a Smart City emergency transportation case study inspired by the urban road network of Skopje. The proposed framework aims to provide a better understanding of the applicability, efficiency, and limitations of shortest path algorithms in intelligent transportation and emergency management systems.

III. Theoretical Background and Algorithmic Foundations

Graph theory provides the mathematical foundation for numerous optimization problems, including shortest path determination, network analysis, transportation planning, and intelligent decision-support systems. A graph can be represented as

$$G = (V, E) \tag{1}$$

where, (V) denotes the set of vertices (nodes) and (E) represents the set of edges connecting pairs of vertices. In weighted graphs, each edge is assigned a numerical value corresponding to distance, travel time, cost, or another optimization criterion.

The shortest path problem aims to determine a path between two vertices such that the total accumulated edge weight is minimized. Due to its broad applicability, this problem has been extensively investigated in transportation systems, robotics, communication networks, and artificial intelligence applications.

A. Dijkstra's Algorithm

Dijkstra's algorithm [5] is one of the most widely used exact shortest path algorithms for weighted graphs with non-negative edge costs. The algorithm iteratively selects the unvisited vertex with the smallest tentative distance and relaxes its neighboring vertices until the shortest distances to all reachable nodes are determined.

The computational complexity of Dijkstra's algorithm depends on the underlying data structure used for maintaining the priority queue. When implemented using a binary heap, its time complexity is given by

$$O\big((V + E)\log V\big) \tag{2}$$

where, (V) denotes the number of vertices and (E) represents the number of edges. The corresponding space complexity is

$$O(VE) \tag{3}$$

Due to its efficiency and guaranteed optimality, Dijkstra's algorithm remains widely adopted in transportation planning and navigation systems.

B. Bellman-Ford Algorithm

Bellman-Ford is another classical shortest path algorithm capable of processing graphs containing negative edge weights [6]. The algorithm repeatedly relaxes all graph edges and can additionally detect negative cycles within the network.

Its worst-case computational complexity is $O(VE)$

while the required memory complexity remains $O(V)$.

Although Bellman-Ford generally requires more computational resources than Dijkstra's algorithm, its ability to handle more general graph structures makes it valuable in communication networks and cost-sensitive routing problems.

C. A* Algorithm

The A* algorithm combines graph search techniques with heuristic guidance to accelerate shortest path computation [10]. Instead of exploring all possible nodes uniformly, A* prioritizes nodes that appear more promising according to an evaluation function.

The evaluation function is defined as

$$f(n) = g(n) + h(n) \tag{4}$$

where, $(g(n))$ represents the accumulated cost from the source node to the current node, while $(h(n))$ denotes an estimate of the remaining distance to the target node.

For A* to guarantee optimality, the heuristic function should satisfy admissibility and consistency conditions. An admissible heuristic never overestimates the true shortest distance to the destination, whereas a consistent heuristic satisfies.

$$h(n) \leq c(n,m) + h(m) \quad (5)$$

for every neighboring node pair $((n,m))$.

Common heuristic functions include Euclidean and Manhattan distances, which are frequently employed in transportation and navigation applications. Under these assumptions, A* preserves optimality while significantly reducing the number of explored nodes compared to uninformed search methods.

Its worst-case computational complexity remains comparable to Dijkstra's algorithm, although practical implementations often exhibit considerably better performance due to heuristic guidance.

D. Shortest Path Algorithms in Intelligent Transportation Systems

Shortest path algorithms constitute an essential component of intelligent transportation systems and Smart City infrastructures [23-25]. Typical applications include route planning, emergency vehicle dispatching, traffic optimization, autonomous navigation, and mobility management [26–28].

In emergency response scenarios, minimizing travel time is particularly important, as delayed interventions may significantly affect public safety and healthcare outcomes. Consequently, evaluating shortest path algorithms within realistic transportation environments represents an important research direction for intelligent transportation systems and emergency management applications.

IV. Proposed Smart City Emergency Transportation Framework

A. Problem Definition

Efficient emergency response remains one of the major challenges faced by modern Smart Cities. Delays in ambulance dispatching and patient transportation may significantly affect healthcare outcomes, making route optimization an essential component of intelligent transportation systems.

In this study, the emergency routing problem is formulated as a shortest path problem in a weighted graph representing an urban transportation network. The objective is to determine the fastest route for an ambulance traveling from an arbitrary starting location to a hospital while considering potential road closures and varying transportation conditions.

B. Smart City Transportation Network

To evaluate the applicability of shortest path algorithms in realistic urban environments, a transportation model inspired by the road network of the city of Skopje was developed.

The transportation infrastructure is represented as an undirected weighted graph described by Eq. (1), where nodes correspond to urban districts and edges denote road segments connecting neighboring regions. Edge weights represent estimated travel times between adjacent locations.

The transportation network was constructed using several districts of Skopje, namely Aerodrom, Centar, Karpos, Vlae, Gjorce Petrov, Bit Pazar, Kisela Voda, and a hospital location. Connections between neighboring districts were modeled as weighted edges, where the assigned values represent approximate travel times in minutes.

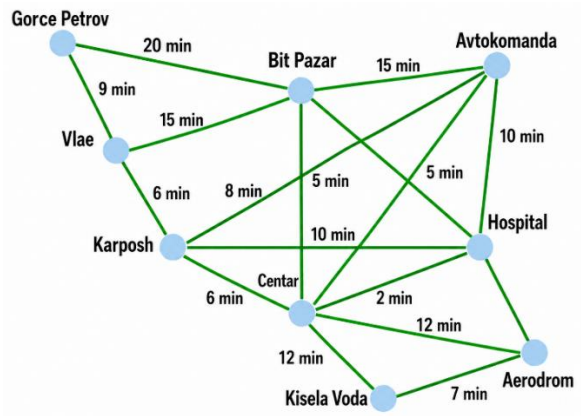

Fig. 1. Smart City transportation network inspired by the urban road infrastructure of Skopje.

Fig. 1 presents the Smart City transportation network used throughout the experimental evaluation.

C. Framework Architecture and Implementation

The proposed framework consists of four major modules:

- Graph Representation Module;
- Routing Algorithm Module;
- Visualization Module;
- Experimental Analysis Module.

The Smart City simulation environment was implemented using Java and JavaFX, while Python was employed for supplementary algorithmic validation and scalability assessment.

The graph representation module stores nodes, edge weights, predecessor information, and route availability status. The routing module integrates Dijkstra, Bellman-Ford, and A* algorithms, whereas JavaFX enables visualization of transportation networks, optimal routes, and blocked road segments. Bellman-Ford was included in the scenario-based evaluation as a classical reference algorithm widely used in shortest-path research. Although the investigated transportation network contains only non-negative edge weights, Bellman-Ford provides a useful baseline for comparing computational behaviour and routing consistency with Dijkstra and A*. It was intentionally excluded from the scalability experiments because its higher computational complexity would have resulted in substantially longer execution times for repeated evaluations on large randomly generated graphs without

providing additional methodological insight under the considered experimental conditions. Fig. 2 illustrates the interaction among the main modules of the proposed Smart City emergency transportation framework.

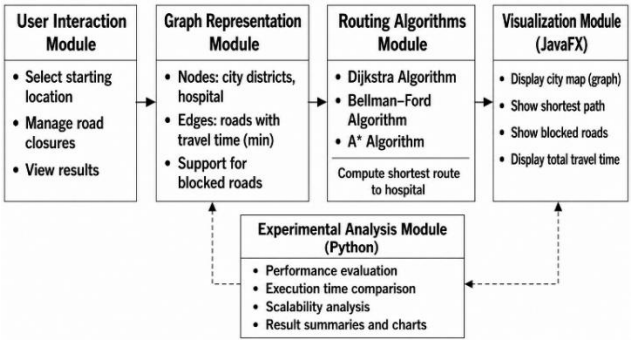

Fig. 2. Architecture of the proposed Smart City emergency transportation framework.

1) Research hypotheses: To guide the experimental evaluation, the study investigates the following research hypotheses:

H1. The A* algorithm achieves lower computational cost than Dijkstra's algorithm while preserving optimal route quality in transportation networks with non-negative edge weights.

H2. The proposed Smart City emergency routing framework is capable of correctly identifying feasible shortest routes as well as detecting situations in which no valid route exists due to road disruptions.

H3. Combining scalability experiments with representative Smart City emergency scenarios provides a comprehensive evaluation of both computational performance and practical applicability of classical shortest-path algorithms.

D. Dynamic Road Availability and Emergency Routing Scenarios

Emergency transportation systems frequently operate under dynamically changing conditions. Traffic incidents, road maintenance, construction activities, or unexpected events may temporarily block important transportation links. To simulate such situations, selected road segments can be excluded from the transportation network before executing shortest path algorithms, enabling the generation of alternative routes whenever the initially optimal path becomes unavailable.

The term dynamic in this study refers to the evaluation of multiple transportation scenarios with different road availability configurations rather than continuous real-time updates of edge weights during route computation. Each scenario represents a static snapshot of the transportation network under a particular emergency condition.

Four representative emergency scenarios were considered to investigate algorithm behavior under varying transportation conditions.

1) Scenario 1: The ambulance vehicle is initially positioned in the Aerodrom district and dispatched toward the hospital under normal traffic conditions.

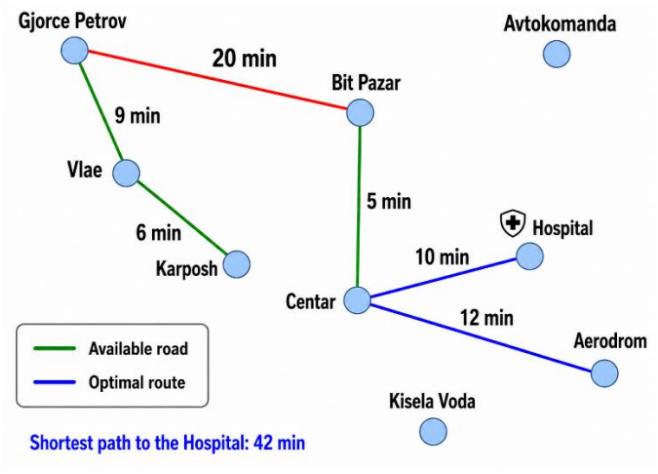

Fig. 3. Ambulance dispatching from Aerodrom district under normal traffic conditions.

2) Scenario 2: The ambulance vehicle starts from Vlae while maintaining full road accessibility.

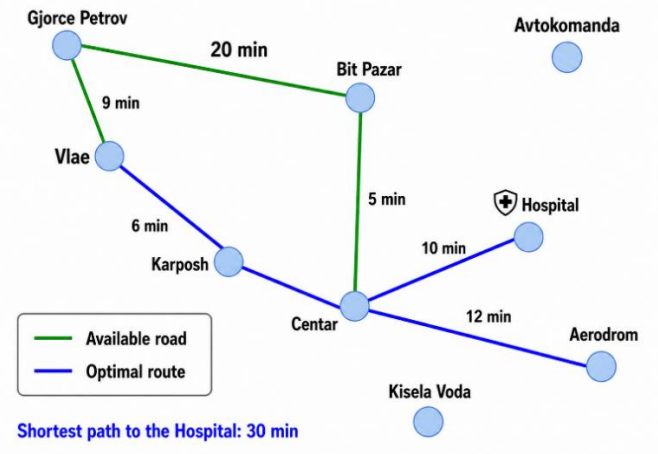

Fig. 4. Ambulance dispatching from Vlae district.

3) Scenario 3: Road segments leading to the hospital are intentionally blocked, resulting in the absence of a feasible transportation path.

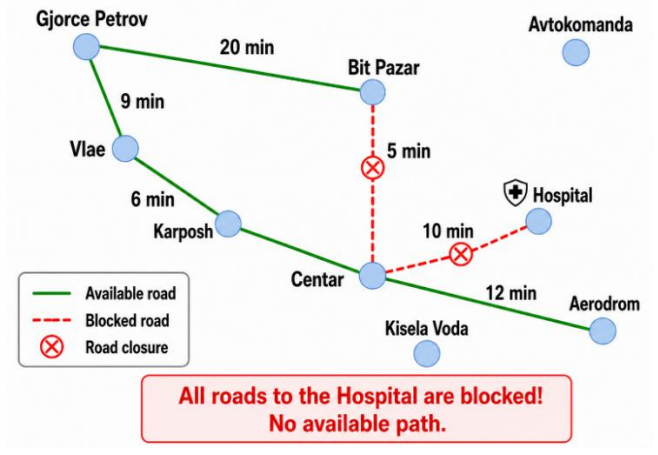

Fig. 5. Road closure scenario with unavailable routes to the hospital.

4) Scenario 4: The ambulance vehicle departs from Gjorce Petrov under regular transportation conditions.

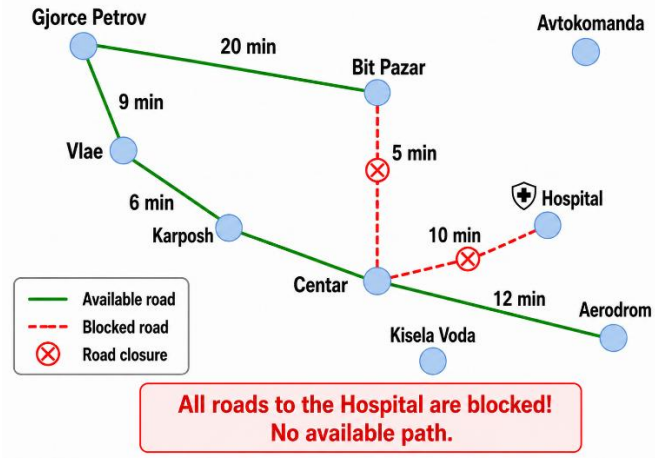

Fig. 6. Ambulance dispatching from Gjorce Petrov district.

The developed framework provides a flexible environment for investigating shortest path algorithms under realistic emergency transportation scenarios and serves as the basis for the experimental evaluation presented in the following sections.

V. Experimental Evaluation and Results

A. Scalability Assessment of Shortest Path Algorithms

To complement the Smart City emergency transportation scenarios, an additional set of experiments was conducted to evaluate the scalability and computational efficiency of shortest path algorithms under increasing graph sizes. These experiments were designed to assess the potential applicability of the investigated algorithms in larger Smart City transportation networks, where the number of intersections and road segments may substantially exceed those considered in the Skopje-inspired case study.

Dijkstra's and A* algorithms were implemented in Python 3.11 using a binary min-heap priority queue. Random weighted graphs containing 50, 100, 200, and 500 nodes were generated programmatically to simulate transportation networks of varying complexity. Edges were generated by considering all possible node pairs, where an edge was created with a probability (density) of 0.3. Edge weights were assigned as random integer values between 1 and 10, representing abstract transportation costs. The generated graphs were stored using adjacency-list representations to support efficient shortest-path computations. Priority queue operations in both Dijkstra's and A* implementations were performed using Python's built-in heapq module, which provides efficient insertion and extraction of the minimum-cost node. Since the investigated graph sizes were relatively moderate, no specialized memory optimization techniques were required. For each graph size, both algorithms were executed once on the generated weighted graph, and the execution time together with the number of visited nodes was recorded. The experiments were performed on a workstation equipped with an Intel i5 processor and 16 GB RAM.

Bellman-Ford was intentionally excluded from the scalability assessment because its computational complexity O(VE) makes its evaluation on large randomly generated graphs considerably more computationally demanding than Dijkstra and A*. Since the generated graphs contain only non-negative edge weights, including Bellman-Ford would not provide additional methodological insight beyond the scenario-based comparison presented in the Smart City case study.

A simple admissible heuristic based on the absolute difference between the current node identifier and the target node identifier, $h(n) = |\ goal - n\ |$, was adopted for the A* algorithm. Since the randomly generated scalability graphs do not contain spatial coordinates, conventional Euclidean or Manhattan distance heuristics were not applicable. Instead, the selected heuristic provides a simple and deterministic estimate that enables a consistent comparison between A* and Dijkstra under identical experimental conditions. Although relatively simple, this heuristic was sufficient to reduce the search space and improve computational performance.

Fig. 7 illustrates the execution time trends observed for Dijkstra's and A* algorithms as the graph size increases from 50 to 500 nodes. The presented values correspond to the recorded execution times for each generated graph instance. The obtained results indicate that the heuristic guidance employed by A* contributes to lower execution times and fewer visited nodes, particularly in larger graph instances.

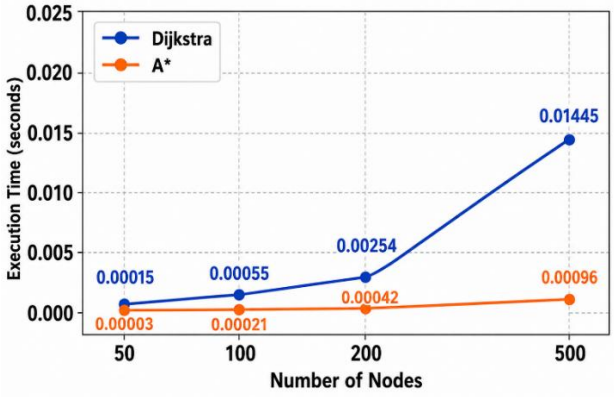

Fig. 7. Execution time comparison between Dijkstra and A* algorithms under increasing graph sizes.

Table I summarizes the obtained performance results.

TABLE I. Algorithm Performance Under Increasing Graph Sizes

Nodes	Algorithm	Time(s)	Nodes Visited
50	Dijkstra	0.00015	89
50	A*	0.00003	3
100	Dijkstra	0.00055	207
100	A*	0.00021	11
200	Dijkstra	0.00254	446
200	A*	0.00042	5
500	Dijkstra	0.01445	1233
500	A*	0.00096	7

The obtained results demonstrate that both algorithms successfully identified shortest paths for all tested graph instances. However, the increase in graph size had a considerably stronger impact on Dijkstra's algorithm, which explored a significantly larger portion of the graph. In contrast, A* consistently visited fewer nodes and maintained lower execution times due to heuristic guidance. The performance differences become particularly noticeable for graphs containing 200 and 500 nodes, suggesting that heuristic-based approaches can provide substantial advantages when shortest path computations are performed in large-scale transportation networks.

B. Smart City Emergency Routing Scenarios

Following the scalability assessment, the algorithms were evaluated within the proposed Smart City emergency transportation framework.

Four representative ambulance dispatching scenarios were investigated under different traffic conditions and road availability assumptions.

Scenario 1 considers an ambulance vehicle departing from the Aerodrom district under normal traffic conditions.

Scenario 2 examines emergency transportation originating from Vlae while maintaining complete road accessibility.

Scenario 3 simulates a road closure situation in which all transportation links leading to the hospital become unavailable.

Scenario 4 analyzes ambulance dispatching from Gjorce Petrov under regular transportation conditions.

Fig. 3–6 present visual representations of the considered emergency scenarios.

TABLE II. RESULTS OBTAINED FOR EMERGENCY ROUTING SCENARIOS

Scenario	*Starting District*	*Travel Time (min)*	*Path Available*
Scenario 1	Aerodrom	42	Yes
Scenario 2	Vlae	30	Yes
Scenario 3	Road closure	–	No
Scenario 4	Gjorce Petrov	34	Yes

Table II summarizes the routing outcomes obtained for the investigated emergency transportation scenarios. The results indicate that the proposed routing framework successfully identified the shortest available routes whenever feasible transportation paths existed. In the road closure scenario, the framework correctly identified the absence of a valid path to the hospital, demonstrating its capability to handle dynamically changing transportation conditions.

Each Smart City emergency routing scenario was executed once because the transportation network topology, edge weights, and algorithm implementations are deterministic. Consequently, identical input conditions always produce identical routes and travel times. Therefore, variance measures were not reported, as no stochastic variability is present in the adopted experimental setup.

The conducted experiments provide complementary insights into the applicability of shortest path algorithms in intelligent transportation systems. The scalability assessment evaluates computational performance under progressively larger graph instances, whereas the Smart City case study demonstrates the practical applicability of the proposed routing framework under representative emergency transportation scenarios. Since the Smart City evaluation is deterministic and scenario-based, it is intended to illustrate routing behaviour rather than to provide statistical performance benchmarking.

The scalability assessment highlights the computational benefits of heuristic-guided search, particularly when dealing with larger transportation networks. At the same time, the Smart City simulations demonstrate the practical applicability of these algorithms in realistic emergency response scenarios involving ambulance dispatching, road disruptions, and dynamic traffic conditions.

Taken together, the obtained results suggest that combining classical shortest path algorithms with Smart City transportation models offers a flexible environment for studying emergency routing strategies and evaluating intelligent transportation solutions under various operating conditions.

VI. DISCUSSION

The results obtained from both the scalability assessment and the Smart City case study provide useful insights into the applicability of shortest path algorithms in emergency transportation systems. By combining algorithm-oriented experiments with scenario-based simulations, the proposed framework enables an evaluation of both computational performance and practical suitability for time-critical routing tasks.

The scalability experiments revealed that the computational burden of shortest path algorithms increases with graph size. Although Dijkstra's algorithm consistently identified optimal routes, its execution time and the number of visited nodes increased substantially for larger graph instances. In contrast, the heuristic guidance incorporated into the A* algorithm limited unnecessary exploration of the search space and resulted in lower execution times. These differences became particularly evident for graphs containing 200 and 500 nodes, indicating that heuristic-based approaches may offer significant benefits when shortest path computations are repeatedly performed in large transportation networks.

For relatively small transportation networks similar to the proposed Skopje-inspired model, all investigated algorithms produced comparable routing decisions and identified identical optimal routes. Therefore, the primary differences among the algorithms are reflected in computational efficiency and scalability rather than in route optimality within moderately sized urban networks.

The Smart City emergency scenarios complement the scalability analysis by illustrating how shortest path algorithms behave under conditions that more closely resemble real-world transportation environments. The investigated scenarios demonstrated that feasible ambulance routes can be efficiently identified when transportation links remain available, while the framework was also capable of recognizing situations in which no valid route to the hospital exists due to road disruptions.

Such functionality is especially important in emergency response systems, where traffic incidents, construction activities, or unexpected events may rapidly alter transportation conditions.

An additional advantage of the proposed framework is its adaptability. The Skopje-inspired transportation network employed in this study was intentionally designed as a proof-of-concept case study rather than a complete representation of an urban transportation infrastructure. Its primary objective was to demonstrate the applicability of the proposed routing framework under representative emergency scenarios while maintaining a clear interpretation of algorithmic behaviour. Although the simplified network limits the direct generalization of the obtained results to large metropolitan transportation systems, the proposed methodology is independent of network size and can be readily extended to larger urban environments, multiple healthcare facilities, and transportation systems supported by continuously updated traffic information. Furthermore, more sophisticated heuristic functions, traffic prediction models, machine learning techniques, and real GIS or OpenStreetMap data may be incorporated to support adaptive routing decisions and improve overall system responsiveness.

Despite the encouraging results, several limitations should be acknowledged. The scalability assessment was intentionally limited to execution time and the number of visited nodes, as these metrics provide a direct comparison of computational efficiency across the investigated algorithms. Additional performance indicators, including memory consumption, edge relaxations, priority queue operations, and scalability under varying graph densities, represent promising directions for future research. The transportation network employed in this study represents a simplified proof-of-concept model of an urban environment and therefore does not capture the full topological complexity of real metropolitan transportation systems. Furthermore, the heuristic function adopted for the A* implementation was intentionally selected to remain simple to facilitate a transparent comparison with the investigated classical algorithms. Future studies may therefore focus on integrating richer transportation datasets, advanced heuristic strategies, and hybrid optimization methods capable of supporting more realistic emergency management scenarios. Although the proposed framework considers multiple emergency scenarios with different road availability conditions, route computation is performed on static network snapshots. Incorporating continuously changing traffic conditions, dynamic edge weights, and real-time rerouting mechanisms would further improve the realism and applicability of the proposed framework. In addition, the framework could be extended by incorporating more advanced routing techniques, including ALT (A*, Landmarks, Triangle inequality), Contraction Hierarchies, Bidirectional Dijkstra, and time-dependent shortest-path algorithms to further improve routing efficiency in large-scale transportation networks. Finally, comparisons with established routing platforms, such as OpenStreetMap-based routing engines and GraphHopper, would provide additional practical validation and facilitate benchmarking under real-world transportation conditions.

Nevertheless, the obtained conclusions should be interpreted with caution due to the relatively small size of the investigated transportation network and the simplified assumptions adopted in the simulation model.

Overall, the findings suggest that combining classical shortest path algorithms with Smart City transportation models provides a flexible and informative framework for investigating emergency routing strategies and evaluating intelligent transportation solutions under a wide range of operating conditions.

VII. Conclusion

This study presented a comparative investigation of three well-established shortest path algorithms, namely Dijkstra, Bellman-Ford, and A*, within the context of Smart City emergency transportation systems. The proposed framework combined scalability experiments with scenario-based simulations inspired by the urban road network of Skopje, allowing both computational characteristics and practical routing capabilities to be evaluated.

The scalability assessment demonstrated that the performance differences among the investigated algorithms become more pronounced as graph size increases. While Dijkstra's algorithm consistently produced optimal solutions, the heuristic guidance employed by A* reduced the number of explored nodes and resulted in shorter execution times for larger transportation networks. Bellman-Ford preserved its ability to handle graphs containing negative edge weights, although this flexibility was accompanied by increased computational requirements.

The simulated emergency transportation scenarios further illustrated the applicability of shortest path algorithms in ambulance dispatching and route planning tasks. The developed framework successfully identified feasible routes under normal operating conditions and detected situations in which transportation links became unavailable due to road closures. In addition, the visualization environment facilitated an intuitive interpretation of routing decisions and transportation network states, which may be useful for both educational purposes and preliminary decision-support analyses.

Although the presented transportation model represents a simplified approximation of an urban environment, the obtained results indicate that graph-based routing methods remain effective tools for supporting emergency transportation planning in Smart City settings. Future work may focus on incorporating real-time traffic information, stochastic travel times, multiple healthcare facilities, and adaptive optimization techniques, including machine learning approaches, to provide more realistic and responsive emergency management solutions.

Overall, the presented framework demonstrates that graph-based routing approaches can provide valuable support for emergency transportation planning and may serve as a basis for future intelligent transportation applications.

***Abstract*—Authentication plays an important role in online banking services. Nowadays, many online services still use password-based and One-Time Password (OTP) codes as authentication methods, but this is no longer secure, especially with the increase in financial fraud. In this research, a novel pattern-based password approach that relies on the random generation of multiple numeric grids is proposed. The approach is developed and deployed as a simple mobile application to be evaluated by banking users. Performance and security tests were used to evaluate the robustness of the approach. The findings of the assessment reveal that the performance and security level of our approach are high. The assessment also shows the approach to be capable of reducing and preventing financial fraud and protecting online banking systems from different types of cyberattacks through shoulder-surfing, eavesdropping, and brute force. The findings demonstrate the robustness of the pattern password, where fraudsters will be less likely to capture and recognize the correct password or discriminate between the patterns with their different values. To the best of our knowledge, this is the first approach that proposes a solution with the use of multi-grid rather than single-grid pattern passwords.**

***Keywords*—Authentication; cyberattack; financial fraud; multiple grids; pattern-based password; testing**

I. Introduction

With the continuous improvement in protecting the confidentiality and privacy of sensitive information for bank customers, and with the continuous implementation of fraud detection and implementation of fraud detection and innovative mitigation solutions, cyberattacks still represent a critical threat to users [1]. Given the current problems regarding safety and the ease of credit card exploitation, enhancing current authentication methods and providing optimal solutions to avoid cyberattacks is a topic that requires more investigation [2]. Research work in this area is still in its early stages, as the major security features of the different types of financial fraud and cyberattacks were not taken into consideration by most of the current state-of-the-art authentication approaches. Furthermore, many existing authentication studies focus primarily on implementation and usability aspects while providing limited formal analysis of adversarial capabilities, attack surfaces, and theoretical resistance against pattern reconstruction and brute-force attacks. Consequently, there remains a need for authentication frameworks that combine practical deployment with rigorous security evaluation.

In the literature, several authentication solutions have been proposed to tackle the issues related to the secure authentication process. According to the analysis of these developed approaches, these solutions have been classified into four categories: approaches that rely on the use of password [3]–[6], approaches that use a One-Time Password (OTP) code [7]–[12], approaches based on the use of selected pattern and images [13]–[17], and approaches that depend on the use of some user's characteristics [18]–[25]. Most of these authentication solutions have attempted to reduce fraud and cyberattack issues. However, several challenges limit its full success, such as the passcode guessability and observability from the attacker's perspective. There are some other research studies that attempted to address the limitations through the use of multi-factor authentication (MFA). However, these solutions are still unable to cover the full breadth of users' accessibility due to the fact that it is time-consuming, and there is a lack of consideration of human factor standards preventing it from providing a better user experience. Accordingly, we still need a more effective and more secure solution to successfully overcome all these limitations.

To improve on the previously suggested and implemented solutions and provide more protection against cyberattacks (e.g., fraud), this study proposes a new authentication approach that mainly relies on a Multi-Grid Pattern-Based Password (MGPP) approach that relies on the random generation of numbers on different grid layouts. The proposed approach is shown as a mobile-based application that includes four grids sized 3x3 and labelled with randomly assigned digits between 1 and 9. The arrangement of these numbers is changed dynamically, and it is possible to repeat this within the single or overall grid. The most important and distinctive feature of this approach, as compared to that of others, lies in the way of entering the predefined pattern across multiple grids' cells without clicking on the cells. In addition to the proposed authentication mechanism, this work introduces a formal threat model to characterize potential adversarial behaviors and a formal entropy-based security analysis to quantify the complexity of recovering the secret authentication pattern. These additions provide a theoretical

*Corresponding author

foundation for evaluating the security properties of the proposed framework beyond experimental testing alone.

In order to assess the effectiveness of the MGPP authentication mechanism, two questions were addressed:

Q1: How efficient is the Multi-Grid Pattern-Based Password authentication approach?

Q2: To what extent is a Multi-Grid Pattern-Based Password authentication approach effective in minimizing financial fraud?

To investigate these two research questions, two experimental studies have been conducted; one for evaluating the performance aspects, and another for evaluating the security aspect. Performance analysis shows that the proposed approach has a high level of performance and the capability of accepting and handling more users while also maintaining their authentication connection under different conditions. Security analysis indicates that the MGPP approach is highly effective in minimizing financial fraud. Moreover, the formal entropy analysis demonstrates that the proposed framework substantially enlarges the authentication search space compared with conventional single-grid pattern-based authentication systems, thereby reducing the probability of successful brute-force and pattern-guessing attacks. It has been proved that the login security success rates will be higher than those of single- grid pattern-based password methods. It also revealed that the password patterns across users are more varied and difficult to have identical pattern-based passwords for different users. This research contributes toward filling the gap in the literature regarding authentication approaches and related security issues. To the best of the authors' knowledge, this research is the first to:

- Provide a novel Multi-Grid Pattern-Based Password (MGPP) authentication framework that utilizes multiple dynamically randomized grids for secure user authentication;
- Develop a novel authentication algorithm that increases numerical randomization and pattern-space diversity to improve resistance against observation-based attacks and password guessing attempts;
- Introduce a formal threat model that characterizes adversarial capabilities and attack surfaces relevant to pattern-based authentication systems;
- Provide a formal entropy-based security analysis that quantifies the authentication search space and evaluates theoretical resistance against brute-force attacks; and
- Experimentally validate the proposed framework through comprehensive performance and security evaluations in a mobile banking authentication environment.

The structure of this study is organized as follows: In Section II, the authors provide an overview of the current literature on different authentication approaches. Section III presents the proposed MGPP authentication framework, including the registration process, authentication mechanism, cryptographic protection model, and formal threat model. A clear description of the development of the MGPP authentication approach is presented in Section IV. Section V describes, in detail, the two experimental studies conducted to evaluate the MGPP approach. Afterwards, Section VI presents the performance evaluation, security evaluation, and formal entropy analysis together with a discussion of the main findings. The study is then concluded in Section VII.

II. Related Work

In the literature, several authentication approaches and methods have been developed and implemented in different sectors including banking, healthcare and educational sectors. In addition, based on the literature, user authentication approaches can be categorized, as shown in Fig. 1 [26]–[28]. As illustrated in Fig. 1, existing authentication approaches typically involve a trade-off between security and convenience. While biometric-based authentication methods generally provide strong protection against unauthorized access, they often require specialized hardware and may introduce privacy concerns. Conversely, knowledge-based approaches such as passwords and graphical patterns offer greater accessibility and ease of deployment but remain vulnerable to observation, guessing, and credential theft attacks. Biometric authentication systems have strong properties to protect against misuse of special hardware; however, there are also privacy problems that arise when using such systems. Knowledge-based systems, such as password authentication and graphical patterns, are very easy to use and are therefore very often implemented. However, such systems have several flaws, for instance, observation, guessing, etc. We thus have to cope with the problems of enhancing the security of graphical authentication systems without degrading usability, and thus, new graphical authentication systems have to be implemented.

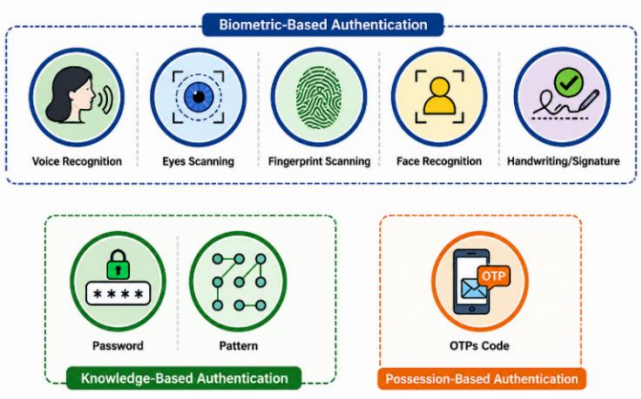

Fig. 1. Comparison of user authentication methods based on "security and convenience" parameters.

A. Knowledge-Based Authentication

Knowledge-Based Authentication (KBA) is a password or pattern that identifies and memorizes end users. To date, many online services are still using "password-based authentication", which focuses on the use of username/password and cryptographic authentication [3]–[6]. The authors in [13] proposed a password-based authentication method that relies on the concept of password generators as a recommended system. This allows users to select and use one of the lists of presented passwords. To increase the robustness of used passwords and to remove the issue of re-changing passwords multiple times, the

authors in [13], [14] proposed a new approach that combined both pattern-based and password-based authentication. A new pattern-based password authentication method was developed by researchers in [15] that uses a Picture-Based Pattern (PBP) technique as a password to secure the transaction. Unlike [15], an enhancement for pattern-based password authentication has been proposed by researchers in [16] by analyzing the input patterns of mobile banking users based on three main aspects: the normal finger pressure levels; the time the user takes to input data; and the physical touch dimensions when using a touch screen. The authors in [17] proposed a grid-based (graphical-based) pattern password method as an alternative pattern-based password solution. This method relies on drawing the pattern from the displayed alphanumeric characters as a form of the password rather than selecting the image.

Despite these improvements, most existing pattern-based authentication approaches continue to rely on a single-grid structure and provide limited protection against repeated observation attacks, pattern reconstruction attempts, and systematic password guessing. Furthermore, the majority of these studies focus on implementation and usability aspects while providing little formal analysis of the theoretical complexity of recovering the underlying authentication pattern.

B. Possession-Based Authentication

(PBA) relies on a One-Time Password (OTP), which is a randomly generated unique code sent via SMS, Email, or authenticator app to the user in each login attempt. The code expiry is time-based (usually between 15 and 60 seconds) for critical systems, and the user should enter the code to continue the login authentication process. The authors in [7] proposed an enhancement to the OTP algorithms by proposing an offline framework that can be implemented in smartphones to increase the security of online banking transactions. Very similar research studies have been conducted by researchers in [8], [9], [11], where they developed several OTP algorithms with the incorporation of various encryption and hashing techniques such as the Advanced Encryption Standard (AES) [29] and Blowfish [30] to encrypt or hash the verification code. Unlike previous works, the authors in [10], [12] proposed a new OTP algorithm with the incorporation of a QR code feature, where the user receives an OTP code in the form of a QR code that appears on an external device, and they must scan it using their mobile device.

C. Biometrics-Based Authentication

Biometrics-Based Authentication (BBA) is a unique characteristic and attribute for each user that can be used as a form of personal identification (user identity). For example, for a fingerprint authentication process, the authors in [19] have proposed an authentication method to enhance the security of online banking, using an external device for fingerprint authentication. Unlike [19], the authors in [18] proposed a new approach based on the fingerprint authentication process through sensors on the user's mobile device rather than using an external device. The research conducted by [20] and [21] used fingerprints as an authentication factor for bank card systems for enhancing ATM services. The authors in [20] described an algorithm for enhancing the phases of fingerprint image extraction and matching. An alignment-based algorithm was used for matching two templates. While the researchers in [21] proposed a method that totally relies on the elimination of cards and the use of fingerprint scanning instead, as it can serve as both a password and access card. In regard to the "eyes authentication process", only a few research studies have been found. The authors in [24], [25] proposed an eyes-based authentication approach using eye- scanning integrated with iris-scan authentication. The concept of this approach is to analyze the user's eyes and their iris pattern, which is previously scanned and stored during the registration process and account creation. The pattern of eyes and iris is analyzed and converted into binary co-registration, which is then processed and stored in the bank database, which will be required prior to completing the online bank transaction process.

For the "face recognition authentication methods", the authors in [31] used face scanning as an authentication factor to enhance the security of ATM services, instead of the current static key (PIN) for ATMs. Limited research studies have been conducted regarding the voice authentication process [22], [23], [32]. Such methods focus on training the system to recognize an individual's unique voice characteristics and matching it with the data stored in the bank's database to determine the identity of the user. The authors in [22], [23] used voiceprint and other vital signs to assist people with visual impairments. In such an authentication process, the account will be validated by entering the user's voiceprint; this will then allow further transactions via voice recognition that implements Mel Frequency Cepstral Coefficient (MFCC) [33], Discrete Wavelet Transform (DWT) [34], and Vector Quantization (VQ) [35] methods to continue. Similar to [32], the authors designed a system that recognizes the tone of voice, and it is found that the developed voice recognition software has successfully activated the door opening mechanism using a voice command that ONLY works for the authenticated individual.

D. Multi-Factor Authentication

(MFA), many research studies [31], [36]–[40] have provided multi-factor authentication solutions by incorporating the password with the OTP together, or the OTP and the password with a combination of more biometric factors such as fingerprints, facial recognition, retinal scan, IRIS recognition, or voice recognition. The two-factor biometric authentication method is proposed based on a combination of face ID and fingerprint [39], [40]. Unlike [36], [39], [40], the authors in [37] integrated the OTP with the fingerprints of users to authenticate online transactions. Slightly similar to [37], the researchers in [38] enhanced the security of the authentication process by proposing a three-factor authentication method, which includes passwords, familiar random pictures, and fingerprint scanning to make user authentication more secure (not only a combination of biometric factors). Although MFA approaches significantly enhance authentication security, they often increase system complexity, authentication time, and user interaction requirements. In mobile banking environments, excessive authentication steps may negatively affect usability and user acceptance. Consequently, there remains a need for lightweight authentication mechanisms capable of achieving stronger security guarantees without introducing additional authentication factors [41].

Existing graphical authentication methods such as password-based, pattern-based, biometric, possession-based methods, and multi-factor authentication methods have their own merits and have achieved a lot. Nevertheless, many open issues still need to be tackled [42]. The majority of graphical authentication methods use a single-grid-based approach; thus, they are susceptible to various types of observation-based attacks, i.e., various types of shoulder-surfing attacks and even authentication pattern reconstruction attacks where users use their authentication patterns as credentials. In addition, most existing graphical password authentication schemes have only tackled the issues for implementation and usability testing, without any formal adversary models and corresponding attack surfaces. There are only a handful of graphical password authentication schemes that can theoretically quantify the secret authentication patterns' resistance to brute-force attacks and guessing attacks by using entropy to measure the authentication passwords' complexity [43,44].

This study proposes a Multi-Grid Pattern-Based Password (MGPP) authentication, in which graphical authentication is supported by a Multiple of Graphical Passwords, each entry corresponding to a multiple number of dynamically generated grids for a single position in a pattern that is verified in a protected manner in order to verify a user's login credentials. After defining a formal threat model which details the possible ways in which an adversary can behave, we follow a formal entropy-based security analysis, i.e., a theoretical assessment of the resistance of the system for graphical password-based authentication to brute-force, as well as to guessing attacks. The results from the theoretical assessment are supported by performance, as well as by a security evaluation.

III. Proposed MGPP Authentication Framework

The proposed Multi-Grid Pattern-Based Password (MGPP) authentication framework is designed to improve the security of graphical password systems against observation-based attacks while maintaining usability for online authentication services. Unlike conventional single-grid graphical authentication schemes, the proposed framework employs multiple interconnected grids containing dynamically randomized numeric values. The framework combines pattern-based authentication with randomized numerical representations to increase ambiguity during login sessions and reduce the likelihood of successful pattern reconstruction by adversaries.

Let the authentication environment consist of G independent sub-grids, where each sub-grid contains C cells. The total number of cells available in the authentication interface is therefore defined as [see Eq. (1)]:

$$N = G \times C \tag{1}$$

where, N is the total number of cells in the authentication interface, G= number of sub-grids, C= number of cells per sub-grid. In the proposed implementation, four 3×3 grids are employed. Therefore, $G = 4$ and $C = 9$, which yields $N = 36$. The authentication process relies on a user-defined pattern consisting of a sequence of selected cells distributed across the multiple grids. Let the pattern length be represented by L, where $L = 8$, and let the pattern be expressed as [see Eq. (2)]:

$$P = \{p_1, p_2, \dots, p_L\} \tag{2}$$

where, p_i denotes the position of the i^{th} selected cell within the overall authentication space.

Each selected cell is represented by a coordinate pair [see Eq. (3)]:

$$p_i = (x_i, y_i) \tag{3}$$

where, x_i denotes the column index, y_i denotes the row index, $i \in \{1,2, \dots, L\}$. The complete authentication pattern can therefore be represented as [see Eq. (4)]:

$$P = \{(x_1, y_1), (x_2, y_2), \dots, (x_L, y_L)\} \tag{4}$$

which uniquely identifies the user's secret graphical password. To enhance resistance against shoulder-surfing and observation attacks, each authentication session generates a randomized numerical assignment for all cells. Let [see Eq. (5)]:

$$R_t = \{r_1, r_2, \dots, r_N\} \tag{5}$$

represent the set of numbers assigned to the cells during login session t, where r_i denotes the numeric value displayed in cell i. The mapping between cell positions and displayed numbers changes dynamically for every authentication session according to [see Eq. (6)]:

$$R_t \neq R_{t+1} \tag{6}$$

which ensures that the same graphical pattern produces different visible numeric sequences across consecutive login attempts.

During authentication, the user does not directly redraw the graphical pattern. Instead, the user observes the randomized values displayed inside the selected pattern cells and enters the corresponding numeric sequence through a text input field. Let the observed login sequence be represented as [see Eq. (7)]:

$$S_t = \{s_1, s_2, \dots, s_L\} \tag{7}$$

where, s_i denotes the numeric value currently displayed at position p_i during session t.

In the server authentication phase, all numbers are transferred to the corresponding cell positions, and the generated pattern from step 3 is compared to the pattern already stored in the database which was generated in the registration phase. Visible information for authentication and secret pattern for storage and user's authentication information are completely separated but remain consistent.

The MGPP system has two stages of operation, namely the registration stage and the login authentication stage. During the registration stage a user generates a secret multi-grid pattern. The secret multi-grid pattern is then transformed into a secure form and stored in the system for future reference by the user. In the login authentication stage, a user is presented with a number of displayed values, i.e., numeric values that are assigned in a totally random fashion, for example. The user is able to recreate his secret multi-grid pattern with the aid of the displayed values. The processes of registration and login authentication are detailed in Section III-B and Section III-C, respectively.

A. MGPP System Architecture

In this study, we present a new type of authentication framework called Multi-Grid Pattern-Based Password (MGPP) system, which utilizes client-server architecture to deliver high quality secure user authentication experience by thwarting the observation-based attacks on classic password-based authentication systems. The framework is composed of three main entities, i.e., user's device, authentication server, and credential repository. User's device is used to display multiple grids to end user, to capture users' input and to send login requests to authentication servers. In addition, authentication servers are utilized to generate multiple grids for end users, to verify the generated patterns by end users, to manage users' sessions and to encrypt/decrypt all communications with end users and their corresponding devices. Last but not least, credential repositories are used to store the protected pattern representations that were generated for end users during their registration phase.

The authentication interface is composed of multiple sub-grids which are all displayed to the user on one large multi-grid workspace. Let the set of sub-grids be represented as [see Eq. (8)]:

$$\mathcal{G} = \{g_1, g_2, \dots, g_G\} \tag{8}$$

where, $\mathcal{G}$ denotes the set of sub-grids and G denotes the total number of grids. In the proposed implementation, $G = 4$, and each grid contains $C = 9$ cells organized in a 3×3 structure. Consequently, the complete authentication workspace contains $N = 36$ distinct cell positions.

Each cell is uniquely identified through its coordinate location and grid membership. The position of a cell is represented by $c_{i,j,k}$ where i denotes the grid identifier, j denotes the row index, and k denotes the column index. The complete authentication space is therefore represented as [see Eq. (9)]:

$$\mathcal{C} = \{c_{i,j,k} \mid 1 \le i \le G, 1 \le j \le 3, 1 \le k \le 3\} \tag{9}$$

where, $\mathcal{C}$ denotes the set of all available cells within the MGPP environment.

To prevent the formation of static visual patterns, the system dynamically assigns numeric values to the cells at the beginning of each authentication session. Let the session-specific numeric assignment be represented by [see Eq. (10)]:

$$M_t: \mathcal{C} \to \mathcal{D} \tag{10}$$

where, M_t denotes the session-specific mapping function, $\mathcal{C}$ is a set of cells, and $\mathcal{D}$ is a set of displayed digits by [see Eq. (11)]:

$$d = M_t(c_{i,j,k}) \tag{11}$$

where, d represents the displayed numeric value. MGPP does not follow traditional graphical password schemes in which users are required to re-draw their password every time they login. In MGPP, the secret pattern structure is decoupled from the authentication information revealed to the user in each session. Users need only to remember the positions of the cells they chose for their secret pattern. The numbers revealed in these cells in each session are random and therefore different from session to session. Thus, the same secret pattern is always revealed as a different sequence of input for every login session.

The authentication workflow then continues on the server side where the session ID and a random grid is generated and sent to the client as a configuration for a grid which is then displayed within the application's GUI. On the client side, the user now selects all positions where he had registered a pattern before and enters the displayed digits in the correct order and submits the resulting sequence of digits to the authentication server. There the entered sequence of digits is changed back to its positional representation and is then compared with the protected pattern which had been stored during registration. Fig. 2 shows an overview of the MGPP's operational workflow for registration, authentication, for the encryption of the user's credentials and for the verification of stored credentials which are stored on the user's client.

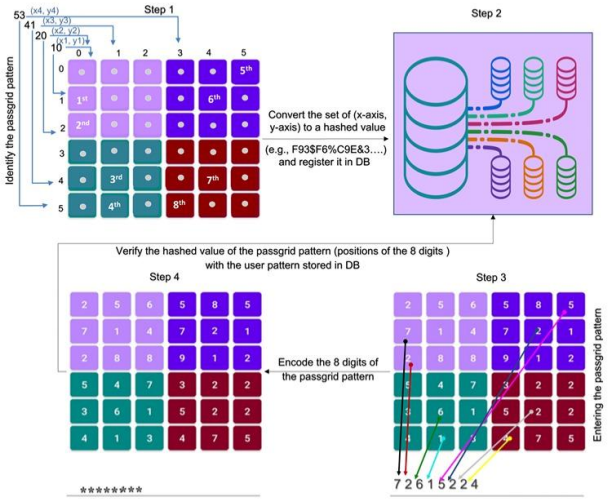

Fig. 2. The flow of the proposed approach working mechanism.

Let the authentication function be represented as $A(U, S_t)$, where U denotes the registered user identifier and S_t denotes the submitted authentication sequence. The authentication decision is expressed as [see Eq. (12)]:

$$A(U, S_t) = \begin{cases} 1, & \text{if the reconstructed pattern matches the stored pattern} \\ 0, & \text{otherwise} \end{cases} \tag{12}$$

where, a value of 1 indicates successful authentication and a value of 0 indicates authentication failure.

The MGPP framework architecture is designed so that information visible to an attacker during a login session is not sufficient to determine the underlying secret pattern. MGPP enables multiple secret pattern grids to be chosen by users, session dependent numeric values to be randomly added to generated secret patterns and secret pattern verification to be enabled while keeping the login process familiar to legitimate users.

B. Registration Phase

The registration phase for MGPP (Multi-Grid Pattern-Project) framework comprises of steps to generate a secret user authentication pattern in the form of a multi-grid structure

having individual grid spaces. The user selects some of the cells from these individual grid spaces to form a secret authentication pattern or the primary login credential for a user. In traditional pattern-lock-based user authentication systems, a connection between all other cells for all connected cells within a user's pattern is stored. However, in the MGPP framework, the stored data for each user is only protected representations of the cells chosen by that user to be included in his/her pattern. The actual chosen pattern of a user cannot be figured out from the input given by that user during the registration process. Let the user identifier be represented as [see Eq. (13)]:

$$U = \{ID, Username\} \tag{13}$$

where, ID denotes the unique user identifier and $Username$ denotes the user's login name. After successful account creation, the server generates and displays the MGPP interface consisting of four independent 3×3grids. The user is then required to select an ordered pattern consisting of eight distinct points distributed across the available grids. Using the notation introduced in Section 3, the registered pattern Pconsists of an ordered sequence of $L = 8$ selected positions. Each selected point is represented by its coordinate location [see Eq. (14)]:

$$p_i = (x_i, y_i) \tag{14}$$

where, x_i and y_i denote the column and row coordinates, respectively. The complete positional representation of the user's pattern is therefore expressed as [see Eq. (15)]:

$$P = \{(x_1, y_1), (x_2, y_2), \dots, (x_8, y_8)\} \tag{15}$$

Our proposed framework for generating patterns for authentication purposes constrains these in order to increase security even more and to enlarge the number of possible patterns even further. First, every pattern for authentication has to consist of a fixed number of 8 points. Second, all points of a pattern have to be distributed on several grids, in contrast to only one grid. Third, it is not allowed to choose for a given authentication sequence identical positional selections for a pattern in all grids. So the additional constraints for creating a pattern strongly dissuade users from choosing a very weak authentication sequence.

After the pattern is selected, the server converts the positional sequence into a canonical pattern vector defined as [see Eq. (16)]:

$$V_P = [x_1, y_1, x_2, y_2, \dots, x_8, y_8] \tag{16}$$

which contains the ordered coordinates of all selected points. Since the sequence of selection is critical for authentication, any change in the order of the coordinates produces a different pattern representation.

To protect the registered pattern from disclosure, the positional vector is transformed into a cryptographic representation. Let the protected pattern credential be denoted by [see Eq. (17)]:

$$H_P = h(V_P) \tag{17}$$

where, $h(\cdot)$ represents the secure one-way hashing function employed by the system. The hash value H_P (stored credentials) is stored in the authentication database for the respective user ID. The storage of the hashed credentials using one-way hashing (as for the registration) does not reveal any information about the used positions, even if the database is attacked.

Following the registration process, all subsequent authentication sessions are carried out between the logged-in user and the authentication server. The user's logged-in session uses the user's registered pattern for verification against the stored hash value for that user, stored in the authentication database against the user's identifier H_P is. The authentication server will only be aware of the user's identifier and the protected pattern that was created from the registration authentication information (that was used to create the stored hash value H_P for that user's identifier) stored in the authentication database.

C. Login Authentication Phase

The login authentication phase verifies whether the submitted authentication sequence corresponds to the pattern established during registration. The proposed MGPP framework differs fundamentally from conventional graphical authentication systems because users do not redraw the graphical pattern during login. Instead, users identify the previously selected pattern positions and enter the numerical values currently displayed in those locations.

At the beginning of each authentication session t, the server generates a new random numerical assignment for all cells in the authentication interface. The generated mapping changes dynamically for every authentication session such that [see Eq. (18)]:

$$M_t \neq M_{t+1} \tag{18}$$

thereby ensuring that identical patterns produce different visible numerical sequences across successive login attempts.

Using the stored knowledge of the secret pattern positions, the user locates the corresponding cells within the randomized grids and observes the displayed values. The entered authentication sequence S_t, defined previously in Section III, contains the numerical values observed at the selected pattern positions during session t.

The submitted sequence is transmitted to the authentication server together with the user identifier. Based on the current session mapping M_t, the server reconstructs the associated positional sequence [see Eq. (19)]:

$$P_t = \{p_1, p_2, \dots, p_8\} \tag{19}$$

by identifying the cells corresponding to the submitted digits and their ordering. The reconstructed pattern is then transformed into its positional vector representation [see Eq. (20)]:

$$V_{P_t} = [x_1, y_1, x_2, y_2, \dots, x_8, y_8] \tag{20}$$

which is subsequently converted into a protected credential using the same hashing function employed during registration [see Eq. (21)]:

$$H_{P_t} = h(V_{P_t}) \tag{21}$$

Authentication is performed through comparison between the reconstructed hash value and the stored hash value. The authentication decision function is defined as [see Eq. (22)]:

$$A(U, S_t) = \begin{cases} 1, & H_{P_t} = H_P \\ 0, & H_{P_t} \neq H_P \end{cases} \quad (22)$$

where, $A(U, S_t) = 1$ indicates successful authentication and $A(U, S_t) = 0$ indicates authentication failure.

The proposed login mechanism is also observation-resistant. The numerical values that the user can see during his/her login session are changing from time to time while the underlying secret pattern does not change. Therefore, any observation by an attacker of a user's login process would result in only a temporary numerical sequence of values without any information about the user's secret pattern. In addition to this property, the repeated occurrences of the same digit in different cells as well as in different grids increase the ambiguity of such an observation, and therefore, it would be very difficult for the user to recognize and to reproduce the correct secret pattern during the login process, as is the case with simple graphical authentication mechanisms that use only one grid of cells. For example, Fig. 3 shows a login area where the digit "5" occurs in different cells of a grid. As can be seen, there are several possible ways to interpret the shown numerical values during such an observation by an attacker, and only by following one of these possible ways the attacker is able to try to recognize the secret pattern that is used for login by the user. However, the recognition of the correct pattern is very difficult because of ambiguity that is introduced by all the possible ways for the interpretation of the numerical values shown to the user during his/her login session. This is in contrast to simple graphical authentication mechanisms that use only one grid and therefore, the observation-resistance of our proposed login mechanism is increased significantly.

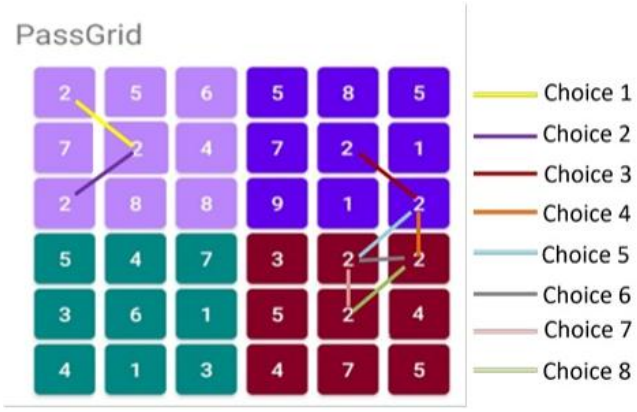

Fig. 3. An example of the several paths for the pattern that includes the number two twice, which can be very difficult for attackers to observe or guess.

The combination of dynamic numerical randomization, hidden positional verification, and cryptographic pattern validation enables the MGPP framework to authenticate legitimate users while simultaneously reducing susceptibility to shoulder surfing, brute-force guessing, and observation-based attacks.

D. Cryptographic Protection Mechanism

The security of the proposed MGPP framework can be considered from two aspects: the secret pattern selected by a user and the authentication credentials stored in the framework for verification. To protect a selected pattern from disclosure, a one-way hashing function is used to transform the positional representation of a user's pattern into a stored credential on the authentication server. To prevent disclosure of stored credentials in case of a database attack, the original pattern coordinates are not stored on the authentication server. Instead, the positional representation of a pattern is first transformed into a stored credential by using the hashing function and then the resulting credential is stored on the server. Let P denote the registered pattern defined previously in Section III. The positional information is first transformed into a canonical pattern vector [see Eq. (23)]:

$$V_P = [x_1, y_1, x_2, y_2, \dots, x_L, y_L] \quad (23)$$

which preserves both the selected locations and their ordering. Since the order of selection is an essential component of the authentication credential, any modification to the sequence results in a different vector representation.

To generate the protected credential, the pattern vector is processed using a secure one-way hash function. The resulting authentication credential is defined as [see Eq. (24)]:

$$H_P = h(V_P) \quad (24)$$

where, H_P = protected pattern credential, $h(\cdot)$ = cryptographic hash function, V_P= pattern vector representation. The generated hash value is stored in the authentication database and associated with the corresponding user identifier. Since the hashing operation is non-invertible, recovering the original pattern from the stored credential is computationally infeasible.

During the authentication phase, the submitted sequence is converted into its corresponding positional representation and transformed into a verification vector [see Eq. (25)]:

$$V_{P_t} = [x'_1, y'_1, x'_2, y'_2, \dots, x'_L, y'_L] \quad (25)$$

where, t denotes the current authentication session. The verification hash is then computed as [see Eq. (26)]:

$$H_{P_t} = h(V_{P_t}) \quad (26)$$

Authentication succeeds only when the newly generated credential matches the credential stored during registration. Therefore, the verification condition is expressed as [see Eq. (27)]:

$$H_{P_t} = H_P \quad (27)$$

Equality holds for selected positions, i.e., the positions that were selected and their order, equal to the positions and order that were registered for the first time.

In addition to protecting registered positions, credential information such as a user's password is also protected within the system. The framework uses Bcrypt hashing for passwords. Bcrypt is an adaptive one-way hash function which is designed to be slow (i.e., to be computationally expensive) and thus, for the purposes of a brute-force attack, is far more expensive than

typical hash functions. The cost c of Bcrypt hashing is a parameter of the hash function. The hashing operation may therefore be represented as [see Eq. (28)]:

$$H_P = h(V_P, c) \tag{28}$$

where, increasing c proportionally increases the computational resources required to evaluate candidate patterns. Large-scale offline password guessing attacks become much more expensive for the attacker.

The protection of stored and verified positional credentials in MGPP is completely independent from the numerical login randomization. This means that even if an attacker managed to get hold of the authentication sequence that has been transmitted or even gets access to the database where all authentication credentials are stored, the corresponding password pattern or passphrase cannot be discovered because all stored and verified positional credentials are encrypted. This multi-layered protection also covers attacks like credential theft, database attacks, replay attacks, and attacks that try to reconstruct a used password pattern or passphrase from already verified authentication credentials. Fig. 4 illustrates registration and authentication with credentials of MGPP. The process that transforms the given pattern information into the stored or verified protected positional credentials in the registration as well as in the login process is shown in more detail. Note that the real password pattern or passphrase information is not stored in plain text.

E. Threat Model

In this study, we perform a formal security analysis of our MGPP framework. We first present a detailed threat model that describes the attacks of an opponent with a given set of capabilities. In the subsequent security analysis and the related entropy analysis, we restrict ourselves to this threat model.

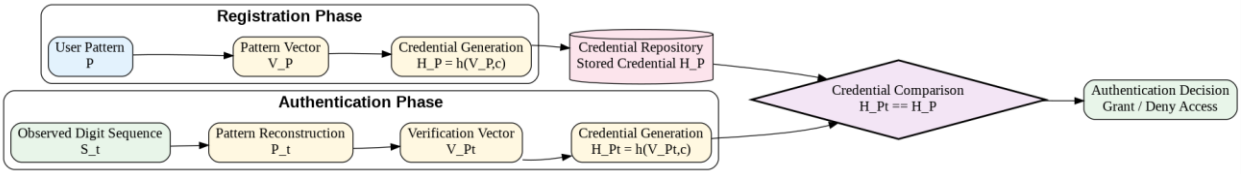

Fig. 4. Registration and authentication credential processing workflow in the MGPP framework.

This analysis will assume that the adversary has complete knowledge of the system and protocol under consideration, as well as the authentication function being used. Because of Kerckhoff's principle, the security of a cryptographic system resides in the authentication credentials for that system and not in the authentication algorithm(s) or protocol(s) for that system. Thus, the adversary has complete knowledge of the multi-grid (MGPP) framework under consideration as well as the pseudo-random location within each of the various grids used for pseudo-randomization of location, as well as complete knowledge of the login function in general.

Let the attacker be represented by the entity $\mathcal{A}$ whose objective is to recover the user's secret pattern or successfully impersonate a legitimate user. The attacker's capabilities are represented by the set [see Eq. (29)]:

$$\Gamma = \{\gamma_{obs}, \gamma_{rec}, \gamma_{net}, \gamma_{alg}\} \tag{29}$$

where, γ_{obs} denotes the capability to visually observe the login interface, γ_{rec} denotes the capability to record authentication sessions, γ_{net} denotes the capability to intercept transmitted authentication messages, γ_{alg} denotes knowledge of the authentication algorithm.

Under this threat model, the attacker may observe one or multiple authentication sessions and attempt to infer the underlying pattern from the visible numerical sequences entered by the user. However, the attacker is assumed to have no access to the user's memorized secret pattern and no direct access to the protected credentials stored on the server. Fig. 5 illustrates the threat model and attack surfaces considered in the security analysis of the proposed MGPP framework. The figure summarizes the adversarial capabilities, potential attack vectors, and the corresponding security objectives addressed by the framework. This model serves as the basis for the subsequent security evaluation and formal entropy analysis presented in Section VI-C.

The attacker's objective can therefore be expressed as maximizing the probability of successful authentication [see Eq. (30)]:

$$P_{succ} = Pr(\hat{P} = P) \tag{30}$$

where, P denotes the legitimate user's pattern, and $\hat{P}$ denotes the attacker's estimated pattern.

The primary security goal of the MGPP framework is to minimize P_{succ} by introducing uncertainty into the observation process.

The first attack scenario considered is shoulder surfing, in which the attacker directly observes the authentication process. Since the visible numerical values vary across authentication sessions according to the randomization function M_t, the observed authentication sequence S_t does not directly reveal the underlying positional pattern P. Consequently, observation of a single session provides only temporary authentication information.

The second attack scenario involves multi-session observation. In this case, the attacker records multiple login attempts and attempts to correlate observed sequences. Let [see Eq. (31)]:

$$\mathcal{S} = \{S_1, S_2, \ldots, S_T\} \tag{31}$$

represent the set of observed authentication sessions, where T denotes the number of recorded sessions. Because each session employs a distinct random mapping, the relationship between observed values and secret positions remains concealed, increasing the complexity of pattern reconstruction.

The third attack scenario considers brute-force guessing attacks. Let the total pattern space be represented by $| \Omega |$, where Ω denotes the set of all valid MGPP patterns. The probability of successfully guessing the correct pattern in a single attempt is therefore [see Eq. (32)]:

$$P_{guess} = \frac{1}{| \Omega |} \tag{32}$$

which decreases as the pattern space increases.

In the final attack scenario, an attacker performs eavesdropping and intercepts credentials. The attacker is able to capture all authentication messages that are transmitted between client and server. However, the protected cryptographic credentials used for verification in our approach, instead of the transmitted pattern information of the user, do not reveal any information.

These goals for the MGPP framework are used in Section VI-C for formal entropy analysis. They can also be used to evaluate the newly proposed framework for so-called observation-type attacks, as well as for typical brute-force attacks.

The MGPP framework proposed in this study is a unified system for object authentication. It selects a multi-grid pattern in a random numerical manner, and for a session, it protects the credentials by means of cryptography, and in an adversarial manner, it maps possible threats. In order to make authentication more robust against observation-based attacks and at the same time more practical for use, in the following section, the authors will describe the implementation of an MGPP-supported mobile system for object authentication (see Fig. 5).

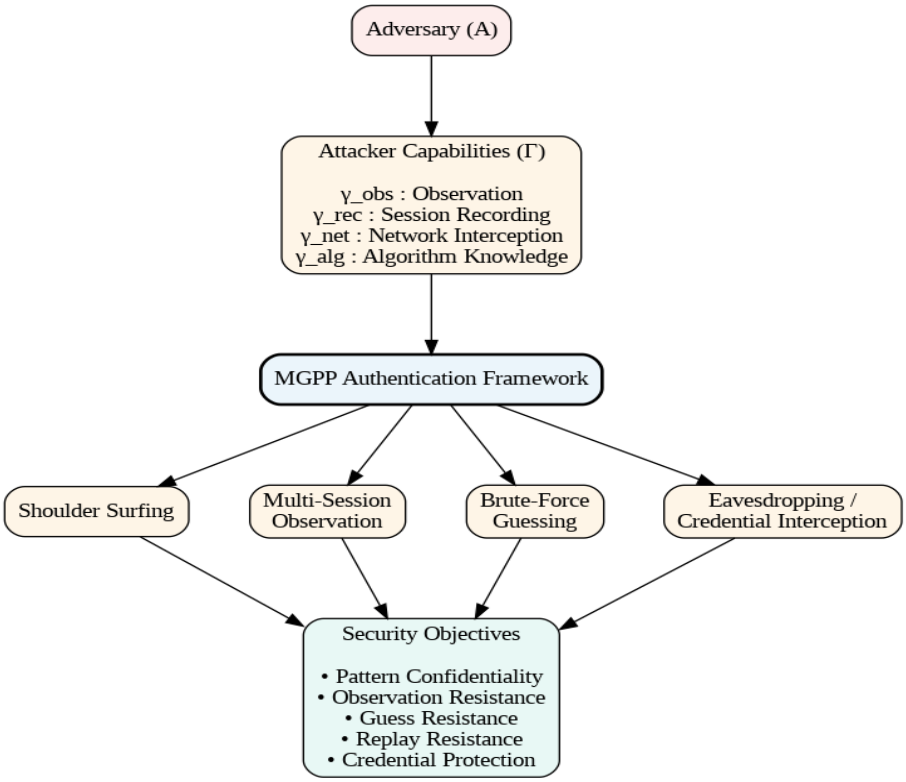

Fig. 5. Threat model and attack surfaces considered in the MGPP authentication framework.

All models were implemented in Python using TensorFlow and PyTorch libraries and executed on an NVIDIA GPU-based system. Reinforcement learning agents are DQN, PPO, and A2C.

IV. System Development

A. Mobile Application Architecture

In this work, a Multi-Grid Pattern-Based Password (MGPP) authentication framework is developed and implemented as a client-server mobile authentication system. The system consists of an Android client, an authentication server, and a database that holds the credentials in a protected form and other account information of users. The Android client is used for registration and login of users. The authentication server is used for managing the user's credentials, for generating the random grids for a session, for verifying an input authentication string against the stored credentials, and for database access.

MGPP architecture is multi-grid and portable. In the registration phase of the architecture, the secret pattern is spread on all of the grids given by the user. In the authentication phase, the mobile application of the user first gets a new random grid pattern for each session from the server and then shows it to the user. The user then enters the sequence of clicks as usual, and the user application sends the sequence to the server for verification. In this system, actual verification of credentials is done in a controlled environment of server. Thus, it is secure enough.

B. User Interface

The graphical user interfaces for the MGPP framework are graphically illustrated in Fig. 6. The graphical user interfaces for the MGPP framework include interfaces for user registration, user login, and passgrid authentication. In order to keep the interfaces as simple as possible in order to support users with easy and comfortable authentication processes, we try to keep the high security standards of the MGPP framework.

During the registration process, users create their own secret authentication patterns. They select eight positions within the multiple grids provided, which are then changed to a protected format and saved on the server of the application. During login sessions, all grids for the session are provided to the user with all positions filled with dynamic numerical values. The user then selects the positions within the provided grids that correspond to the positions selected by the user during registration time. After correct position selection, the user enters the corresponding numerical values in the correct order.

The graphical user interface for the Multi-Grid Passgrid Pattern (MGPP) application is shown in Fig. 6. The interface does provide sufficient space to clearly show a Multi-Grid environment. However, to prevent attacks that rely on observation of the user interface as much as possible, the interface has been kept as simple as possible. The application makes use of multiple grids. The numerical values in the grids are changed on a dynamic basis. As a result of this, attacks that try to guess a user's pattern by observing the interface will be ambiguous and will most likely fail.

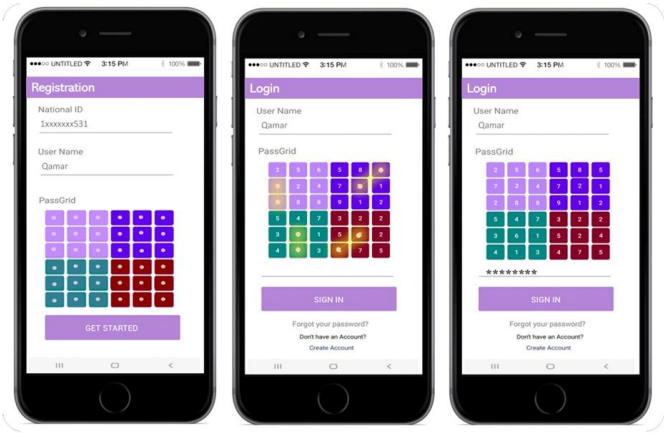

Fig. 6. Graphical user interface of the developed MGPP approach.

C. Server Components

Server-side functionality of the authentication framework comprises authentication management, password protection, session generation as well as interaction with the database. The core of the server, which has been implemented in PHP, for every new login request, generates a random numerical representation for all grid cells, which then gets sent to the client program.

On the server side, when a login request is received, the server first reconstructs the positional pattern corresponding to the entered authentication sequence by referring to the active session mapping for the session received earlier. Then, the generated and protected credential representation of the reconstructed pattern is compared with the stored credential of the user's registration information. If both the credentials match, then the server grants authentication to that user.

As a second layer of protection, all servers have been configured to use the protection mechanism, as outlined in Section III-D. Thus, instead of storing the coordinates of the pattern entered by the user to form the login credentials, the protected form of the user's credential is stored. As previously described, should the worst happen and a database suffers a complete database compromise with subsequent unauthorized access by a third party, such an attack will not be able to retrieve and then use any previously submitted authentication login credentials. This system can also be used to help prevent the Credential Recovery Attack, where an attacker would attempt to retrieve previously submitted login credentials from a database in the hope that he can then use them to gain access to protected resources in subsequent login attempts. The integration of secure credential storage, dynamic session generation, and server-side authentication verification enables the MGPP framework to provide a secure and practical authentication solution for mobile environments.

V. Evaluation of the MGPP Authentication System

The evaluation of the MGPP system has been carried out based on the assessment of two software quality aspects [45], [46]: performance and security. According to [47], it is a paramount requirement for cybersecurity testing to assess the technical implementation of the proposed authentication system and assess the human-system interaction. In addition to the experimental evaluation, the proposed framework is further analyzed through a formal threat model and entropy-based security analysis to provide theoretical evidence regarding its resistance to observation and guessing attacks.

Performance testing has been used to determine to what extent the system is powerful when applying different loads [48], [49]. More specifically, it has been implemented to assess how fast the aspects of the MGPP performance are under a specific workload, including load, response time, time complexity, stability, and scalability. A system-based evaluation method [50] was followed, where the experiment was achieved through a specific tool and collected the results immediately from the extracted log file from this tool. The performance evaluation was performed using the Junit 1 tool and under different conditions and working environments, such as using various network speeds and various mobile battery levels. In addition, the user-based testing method presented in [50]–[52] was used to ensure the compatibility of the applied method on different mobile devices with different specifications. During the evaluation, we applied some load on the app by increasing the number of users at a specific moment (1s) and over longer periods to check the performance in terms of: 1) desired load; 2) capability to scale up or scale out; 3) efficiency of the authentication process when a number of hits occur at a specific time; 4) the responsiveness of the authentication process in general. The average time complexity of number randomization was measured via a crowdtesting technique [52], where the average time complexity is measured during the experiment by different testers through 15 different Android mobile devices

with different specifications (device name, models, and Operating system versions) and different internet speeds.

Regarding security testing, different techniques have been performed to identify and minimize potential security risks in the proposed system and implement necessary countermeasures before releasing it to the public [47]. A static code analysis (SCA) [53] was executed using the "SonarLint"2 security testing tool by highlighting bugs and security vulnerabilities while developing the source code. This helped to identify potential issues and find remediation guidance on how to fix such issues to ensure the security posture and credibility of the proposed approach. In addition, vulnerability scanning/authentication scanning [53] methods were used to measure the capability of attackers to guess or observe the user's pattern and authenticate successfully. The security evaluation was conducted under the adversarial assumptions defined in the threat model presented in Section III-E, where attackers are assumed to possess knowledge of the authentication mechanism and may perform observation, recording, and guessing attacks. Furthermore, a document published by the Open Web Application Security Project (OWASP)3 has been adopted to ensure that the MGPP system is free of the top ten critical security risks. The experimental security assessment is complemented by a formal entropy analysis presented in Section VI-C, which quantitatively evaluates the theoretical password space and resistance of the proposed framework against partial-observation and brute-force attacks.

VI. Results and Discussion

This section elaborates on the core findings derived from the applied methods (Section V) and explains the significance of those results compared to the existing state-of-the-art approaches to answer the proposed research questions. In addition to the experimental findings, the results are interpreted in light of the formal threat model presented in Section III-E and the entropy-based security analysis introduced in Section VI-C. This combined evaluation provides both empirical and theoretical evidence regarding the security and robustness of the proposed MGPP authentication framework.

A. Performance Analysis

The results of performance testing on a variety of mobile device types and with different specifications show that the authentication process has a time complexity in the range from 1.5s to 2s for generating random numbers over the four grids. For the load testing, the results show that 40 users were dropped or disconnected when the load of the number of users reached 1000 at 1s, as shown in Fig. 7. This does not reveal a weakness in our approach; it is basically related to the network bandwidth capacity. This is consistent with the conclusion presented in the prior research [54], which states that as the load of user requests increases, the network becomes less powerful. This is the reason for dropping or disconnecting a few users in our results, where the MGPP approach does not reveal a weakness in up to 960 of 1000 users at 1s. The authors argue that the small number of dropped users and the slight increase in response speed prove the power and good reliability level of our approach in accepting multiple requests with low response time.

Fig. 7. Load testing results while increasing the number of users up to 1000 in 1s.

With respect to load and response speed, we tried to measure the response time with different values by increasing the number of users' authentication requests at 1s. The results from the test scenario clarify that the response speed of the completion of the authentication process and logging into the app requires less than 1s (97 ms) for each individual user. For the response speed of multiple authentication requests at 1s, it is clear from Fig. 8 that the average response speed of 750 multiple users' requests takes about 7.3 seconds, for 7500 users requests takes about 1.18 minutes, for 11250 users requests takes about 1.9 minutes, for 16500 users requests require about 2.5 minutes and for 32250 users requests take approximately up to 5 minutes. This indicates that the response time tends to increase very slowly and almost stabilizes with loads of 32250 and above. This small increase is considered a normal case for any software that uses network connections; this is because of the fact that when the load of requests is higher, more service requests are done [54], [55].

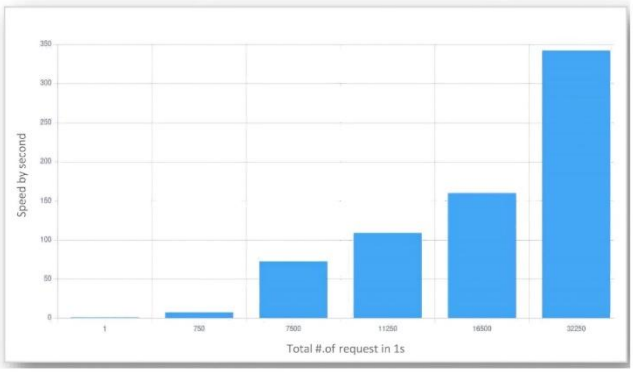

Fig. 8. The speed of the authentication process (response time) while the number of users' authentication requests is increased at 1s.

Fig. 9 presents the results of the stability and scalability evaluation of the proposed MGPP authentication process under increasing user workloads. The figure illustrates the behavior of the authentication system and database components as the number of concurrent users grows, providing insight into the ability of the framework to maintain stable performance under high-load conditions. For the scalability and stability of our approach, the findings showed a gradual increase in the overall period of time (1s to 53s) with a slight decrease in 7s with the load increase (reach 40.000 users). This decrease in the graph

from 15 seconds to 22 seconds does not indicate that a defect or error has occurred in our system regarding stability or scalability, but rather means that there were no requests, or some users were logged out of the system (in the scalability curve), as indicated by the results in the graph being synchronized with each other and no decrease was shown in one line rather than another. This is supported by the findings presented by Vahidnia et al. [56]. Consequently, this proves the capability of our authentication process and the database's ability to meet the growing needs through different conditions and maintains stability with the greatest number of users. From this, we can argue that our approach is highly stable and scalable regardless of the growth in user numbers. From this, we derived that the scalability of the system can impact its stability.

The performance testing of our approach demonstrated the high capability of the approach to complete the authentication process with a lower time complexity rate of random number generation (1.5s); a high-reliability level in handling up to 960 users at 1s, the ability to accept multiple requests with a low response time; the capability of maintaining stability and a high capacity to function more users, regardless of the growth in user numbers, we can answer RQ1 that the MGPP approach is efficient and can outperform a single-grid pattern password authentication approach. The performance results further indicate that the additional security mechanisms incorporated within the MGPP framework, including dynamic numerical randomization and protected credential verification, do not introduce significant computational overhead and therefore maintain the practical usability of the authentication process.

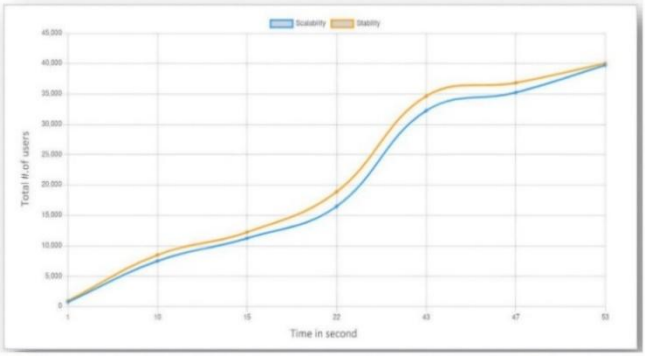

Fig. 9. The results of stability and scalability tests of the authentication process, given an increasing number of users.

B. Security Analysis

The results of the security evaluation and analysis show that the MGPP authentication system can protect users against security issues that are relevant to different types of attacks such as information leaks, shoulder surfing, pattern passgrid theft, and man-in-the-middle attacks. The security assessment was conducted under the adversarial assumptions defined in the threat model presented in Section III-E, where attackers are assumed to possess observation, recording, interception, and algorithm knowledge capabilities. The types of security issues produced from the static code security testing through the SonarLint tool revealed that the proposed code is capable of securing the proposed authentication process from expo-sure to cyberattacks, as there were no critical security issues discovered (see Fig. 10). Most of these issues were software bugs and were successfully resolved during the implementation phase to enhance the performance and ensure that the MGGP system was even more secure. This is supported by the conclusions drawn by Jayalath et al. [57] and Dasanayake et al. [58], in which SonarLint is effective in detecting security vulnerabilities and source code quality issues.

1) Shoulder Surfing (SS) attacks: The security analysis demonstrated that the proposed approach prevents a shoulder surfing attack, where it would be very difficult for the attacker to observe the entry or attack the passgrid pattern [59]. This prevention is due to the effectiveness of the proposed MGPP system, which implements a number repetition algorithm that would distract the user. It is also because of the implementation of the hidden pattern-entering technique where the numbers within the cells that represent the pattern are entered securely without clicking on the cells. This certainly helped reduce the risk of exposure to the pattern during the authentication process. This result is consistent with the findings explained in [59]. From the perspective of the proposed threat model, the attacker's probability of successfully reconstructing the secret pattern from a single observed authentication session remains low because the observed numerical sequence does not directly reveal the underlying positional pattern.

2) Eavesdropping attack: The results of security testing and implementation of the cryptographic algorithm described in Section III-B show the strength of the MGPP system in protecting the authentication process from eavesdropping attacks such as a Man-in-The-Middle (MiTM) attack, which could lead to unauthorised access to confidential data. This is due to the method of securing the position of selected pattern cells, where the cells' positions are hashed into a 60-character hash value. Predicting or analyzing the hash function to obtain the hash value by attackers will be very difficult, if not nearly impossible. This observation is consistent with the threat model assumptions, where intercepted authentication messages do not provide direct access to the protected pattern representation stored within the system.

3) Brute Force (BF) attacks: With regard to brute force attacks (guessability), the findings stemming from the security testing show the power of the MGPP approach in reducing the patterns' guessability opportunities for attackers. This is because of the use of 8 dots for the selected pattern and duplication of the numbers on the four grids' cells, in addition to the random change of these numbers in each new process of communication. This interpretation is supported by the finding described in [60]. The authors compare the time complexity for brute-forcing different pattern-based passwords based on their length in a 3x3 grid. The greater the number of connected dots, the more time it takes to be guessed. For example, a 4-dot pattern would take 1,079 days, a 5-dot pattern would take 4,949 days, a 6-dot pattern would take 18,049 days, and so on, as shown in Fig. 11. Therefore, this shows that the patterns with 8 and 9 connected dots provide more security against password attacks than other patterns with lower numbers. This is for the case of using the connected dots with a 3x3 grid.

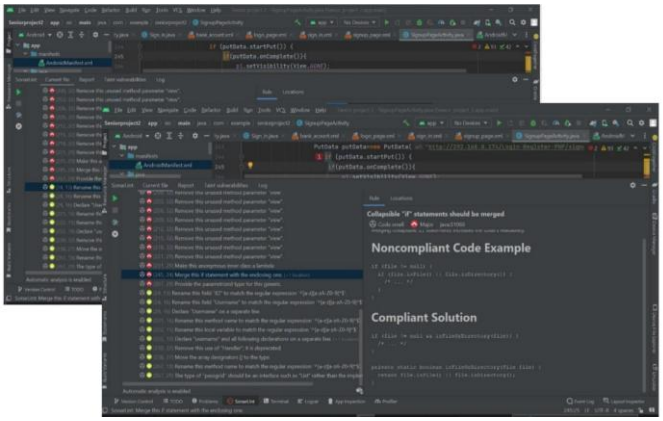

Fig. 10. A sample of the results obtained from static security testing via the SonarLint tool. No critical security vulnerabilities in the code have been found. All the issues discovered - ranging from major (red) to minor (green) levels - are related to coding mistakes, maintainability issues, and network configurations.

In the proposed approach, the authors considered using a discrete lines pattern with a length of 8-dots from four 3x3 grids, resulting in an overall 6x6 grid, which offers massive combinations of the possible generated patterns. This would result in an enormous increase in the number of possible combinations of the pattern generated and would most certainly decrease the chances of attackers guessing the user's pattern due to the increase in pattern combinations and the long time required to attempt to guess the passgrid pattern correctly. The same conclusion was reached by Potocký and Štulrajter [60], the more dots, the more time it takes for the attacker to guess the right pattern. While the experimental analysis demonstrates the practical resistance of the proposed approach against brute-force attacks, a more rigorous quantitative evaluation of the MGPP password space is presented in Section VI-C through formal entropy analysis. This analysis provides a theoretical estimation of the attacker's probability of successfully guessing the correct pattern under different observation scenarios.

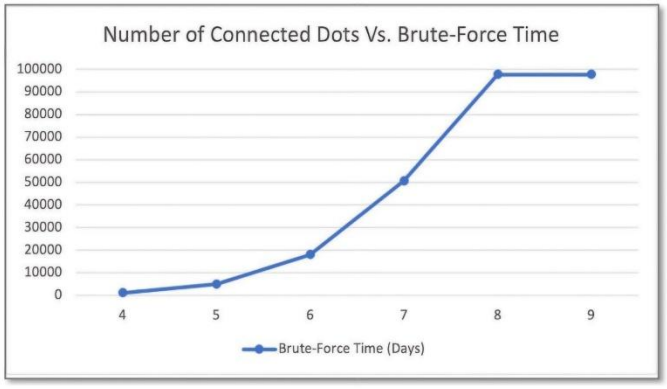

Fig. 11. Number of dots and the minimum time that might be needed by the attackers to guess the correct pattern.

C. Formal Entropy Analysis

While the experimental security evaluation demonstrates the practical resistance of the proposed MGPP framework against observation-based and brute-force attacks, a theoretical assessment is necessary to quantify the complexity of recovering the secret authentication pattern [61]. The entropy of an authentication credential gives an indication of the uncertainty of this credential. In graphical authentication, the entropy of a credential is used to determine the strength of an authentication system against guess attacks. The higher the entropy of a credential, the larger the pattern space of this credential and hence the lower the probability that an adversary can reconstruct the used pattern successfully.

Let Ω denote the set of all valid authentication patterns that can be generated within the MGPP framework. The total number of possible patterns depends on the number of available cells and the length of the selected pattern. As introduced in Section III, the proposed framework utilizes four 3×3grids, resulting in a total authentication space of $N = 36$ available cell positions. Let L denote the pattern length, where $L = 8$.

Assuming that each pattern consists of eight distinct selections and that the order of selection is significant, the total number of possible authentication patterns can be expressed as Eq. (33):

$$| \Omega | = P(N, L) = \frac{N!}{(N-L)!} \tag{33}$$

Substituting the values of N and L yields:

$$| \Omega | = \frac{36!}{28!} = 1{,}220{,}096{,}448{,}000 \tag{34}$$

possible authentication patterns.

The entropy of the authentication space is therefore defined as:

$$H(P) = \log_2 | \Omega | \tag{35}$$

which represents the minimum number of binary decisions required to uniquely identify a valid pattern. Substituting Eq. (34) into Eq. (35) gives [see Eq. (36)]:

$$H(P) = \log_2(1{,}220{,}096{,}448{,}000) \approx 40.15 \text{ bits} \tag{36}$$

This result indicates that the proposed MGPP framework provides substantially higher uncertainty than conventional graphical password systems operating on a single 3×3grid.

The probability of successfully guessing a valid pattern in a single attempt is given by Eq. (37):

$$P_{guess} = \frac{1}{| \Omega |} \tag{37}$$

which yields Eq. (38):

$$P_{guess} = 8.20 \times 10^{-13}. \tag{38}$$

Therefore, under random guessing conditions, the probability of successfully authenticating through a single brute-force attempt is negligible.

The threat model introduced in Section 3.5 further considers adversaries capable of observing a subset of the authentication process. Let $m$denote the number of pattern positions correctly inferred by an attacker through observation. The remaining search space is then given by Eq. (39):

$$| \Omega_{rem} | = P(N-m, L-m) = \frac{(N-m)!}{(N-L)!} \quad (39)$$

where, $0 \leq m < L$. Consequently, the residual entropy after partial observation becomes Eq. (40):

$$H_{rem} = \log_2 | \Omega_{rem} | \quad (40)$$

The search space is still very large even after some of the positions in the pattern have been disclosed to the observer. This is also a feature of the MGPP framework where the dynamic numerical randomization in the positions is separate from the positional pattern. Thus, by viewing the numerical pattern that has been disclosed to the observer, no information is disclosed as to the corresponding positions of the cells. Therefore, even when part of the search space has been disclosed by revealing some of the positions in the pattern, the size of the search space that can still be explored by testing all possible combinations of numbers for the revealed positions is very large. Table I shows the password space sizes for MGPP compared with other systems.

TABLE I. COMPARISON OF THE AUTHENTICATION SEARCH SPACE AND ENTROPY ACROSS COMMON AUTHENTICATION SCHEMES.

Authentication Scheme	Password Space	Approximate Entropy (bits)
4-Digit PIN	10^4	13.29
6-Digit PIN	10^6	19.93
Android Pattern Lock (3×3)	389,112	18.57
Single 3×3 Grid (8 positions)	362,880	18.47
Proposed MGPP (4×3×3 Grids, 8 positions)	**1,220,096,448,000**	**40.15**

The MGPP framework significantly increases the search space of needed authentication patterns when compared to simple pattern-based authentication schemes. Due to the existence of more than one grid, the total number of positions in all cells far exceeds that of a single simple grid. Although all cells are sequentially filled in a certain order to generate a specific pattern, an attacker cannot try all the possible patterns one by one to discover the secret pattern. In fact, the total search space of needed authentication patterns that are generated by the MGPP framework is so large that a brute force approach is entirely impractical. Hence, the MGPP framework provides an efficient and secure user authentication scheme.

Theorem 1. The MGPP framework provides a larger authentication search space than a conventional single-grid pattern authentication system of equal pattern length.

Proof. A conventional 3×3 pattern authentication system contains only nine selectable positions. For a pattern length of eight, the number of possible ordered patterns is Eq. (41):

$$P(9,8) = \frac{9!}{1!} = 362{,}880. \quad (41)$$

In contrast, the MGPP framework contains thirty-six selectable positions, yielding Eq. (42):

$$P(36,8) = 1{,}220{,}096{,}448{,}000. \quad (42)$$

Since [see Eq. (43)]:

$$P(36,8) \gg P(9,8) \quad (43)$$

The authentication search space of the MGPP framework is significantly larger than that of the conventional single-grid approach. Therefore, the proposed framework offers substantially stronger resistance against brute-force guessing attacks.

The theoretical findings are consistent with the experimental security results presented in Section VI-B. Both analyses indicate that increasing the number of selectable positions and introducing dynamic numerical randomization significantly increases the difficulty of pattern reconstruction. Consequently, the proposed MGPP framework achieves enhanced resistance against brute-force attacks, observation-based attacks, and pattern-guessing attempts while maintaining practical usability for mobile authentication applications.

In answer to the RQ2, the assessment of the approach proved the strength of the MGPP approach against brute-force attacks, eavesdropping attacks, and shoulder surfing attacks. Furthermore, the authors can confidently say that the proposed MGPP authentication approach is successful in minimizing financial fraud and reducing the risk of exposure to known software threats, as well as reducing exploitable vulnerabilities. Thus, this would increase security and protect credentials in online banking transactions. Based on experimental findings, the formal threat model, and the entropy-based security analysis, it can be concluded that pattern length, pattern structure, and pattern-space complexity are the primary factors influencing resistance against brute-force and observation-based attacks.

VII. CONCLUSION

In conclusion, this research proposed a new approach for reducing financial fraud issues and cyberattacks and researched the reasons behind their existence to date. On the basis of this, a novel pattern-based password authentication approach has been developed that focuses on increasing the number of randomizations using four 3x3 grids. The main motivation behind this is to propose a more secure authentication algorithm to resolve the previously mentioned issues, as they remain a major concern to online banking users. The proposed approach (MGPP) has been developed as an Android mobile app, and it has been evaluated through performance testing and security testing. In addition, a formal threat model was developed to characterize the capabilities of potential adversaries and to evaluate the security objectives of the proposed authentication framework under observation, recording, interception, and guessing attack scenarios. The results from performance testing show the high level of performance achieved when adopting the MGPP approach, as it offers a lower time complexity rate through random number generation (1.5s to 2s). Results also show that the MGPP approach is highly capable of keeping users safe whilst the functionality is not negatively affected with the growth in user numbers. The assessment also demonstrated the capability of the MGPP approach to protect its users from threats, financial fraud, and cyber-attacks. Furthermore, a formal entropy-based security analysis demonstrated that the proposed MGPP framework significantly increases the authentication search space compared with conventional pattern-based

authentication systems, thereby reducing the probability of successful brute-force and pattern-guessing attacks. This experimental evaluation, formal threat modeling, and entropy analysis show that MGPP-based designs for secure and scalable authentication for mobile applications are feasible. For future work, this study will carry out large-scale usability studies and implement MGPP-based designs for online banking environments, as well as more thoroughly and in greater detail test security-related aspects of this design by means of, for example, penetration testing, ethical hacking, and a detailed risk analysis. Furthermore, this study investigates the use of more adaptive grid structures, dynamic grid morphing, and the incorporation of multi-factor authentication into the MGPP framework in order to increase the security and robustness of our design.

ACKNOWLEDGMENT

The authors gratefully acknowledge the contributions of Lara S. Alghamdi, Sarah N. Alansari, Hams M. Alzahrani, Afaf M. Alogaili, and Reema A. Alebbie who participated, under the supervision of the authors, in the design, development, and testing of selected project components. Their dedication, technical efforts, and commitment provided valuable support to the successful completion of this work.

Unsanctioned Intelligence: Mitigating the Risks of 'Shadow AI' and Proprietary Data Leaks in the Remote Workforce

Adel Saad Assiri
Department of Business Informatics, College of Business
King Khaled University, Abha, 61421, Saudi Arabia

***Abstract*—The high implementation of remote working models has only increased the pace of using artificial intelligence tools by employees to improve their productivity, automate routine tasks, and aid in decision-making. Non-committal application of AI tools, or Shadow AI, has, however, become a major organizational risk, especially when the processed information is sensitive, proprietary, or controlled and not handled in line with the existing organizational policies. The current mitigation is based on fairly flat policies, manual checks, or limited monitoring systems, which cannot provide real-time awareness, dynamic risk response, or gated controls within the dynamic remote workforce. To minimize the leaking of proprietary data, this study suggests a single framework of Shadow AI risk mitigation to detect, evaluate, and control unsanctioned AI utilisation. The architecture incorporates automated scoring of risks, policy-sensitive enforcement, risk uncertainty estimation, and governance-driven adaptation as a way of balancing security, usability, and operational efficiency. Experimental results based on synthetic enterprise data (20,000 activity records) and real-world organizational analytics (7,500 interaction records) show that it can detect jobs with an accuracy of 91.6, reduce high-risk Shadow AI interactions by a factor of 62.6 and reduce policy violations by half, using less than 16% computation overhead. The suggested solution offers a scaling- and governance-based solution to securing the use of AI solutions in distributed working scenarios.**

Keywords*—Shadow AI; remote workforce security; data leakage prevention; AI governance; trustworthy AI; enterprise risk management; policy compliance; uncertainty-aware systems

I. Introduction

Remote and hybrid working has increased the adoption of artificial intelligence tools by employees to enhance their productivity and decision support. Although these tools are beneficial in terms of operations, their use without authorization, also known as Shadow AI, has proven to be a major organizational threat in cases where AI systems are implemented without established enterprise governance and oversight systems [1], [2].

Shadow AI has the potential to leak proprietary, confidential, or regulated information onto external platforms, which is a critical threat. Remote working conditions strengthen this threat due to reduced control over centralization, heightened use of personal devices, and diminished identification of authorized and foreign services [3], [4]. Workers can easily provide third-party artificial intelligence tools with confidential data without realizing that data will be stored, trained, or used to comply with regulations, without being aware that the data will be leaked, which will cause intellectual property theft and violations of regulatory policies [5].

Current enterprise responses are isolated and are mostly in reactive mode. The policy-based controls rely on voluntary compliance and are not enforceable, whereas the technical controls, like data leakage prevention and network monitoring, provide a limited insight into AI-specific interactions [6], [7]. Besides, existing AI governance systems are mostly centred on approved systems, which have no control over Shadow AI practices [8]. These restrictions are increased by the fact that there is no uncertainty-based risk assessment since most systems are based on set rules and methods that lack contextual variability and trust in enforcement action [9].

In an attempt to curb these issues, the current study suggests a combined system of Shadow AI threats within the setting of remote labour. This design integrates automated detection, modelling of the risk that humans adapt to, policy-oriented enforcement, and uncertainty to allow real-time, transparent, and governance-orientated control of unsanctioned AI use. The experimental assessment of the proposed framework supports the idea of the work and proves that the risk can be reduced effectively without impacting the Fig 1. shows how unsanctioned AI use in a remote workforce is identified, assessed for risk, governed through policy enforcement, and guided toward secure and compliant AI usage.

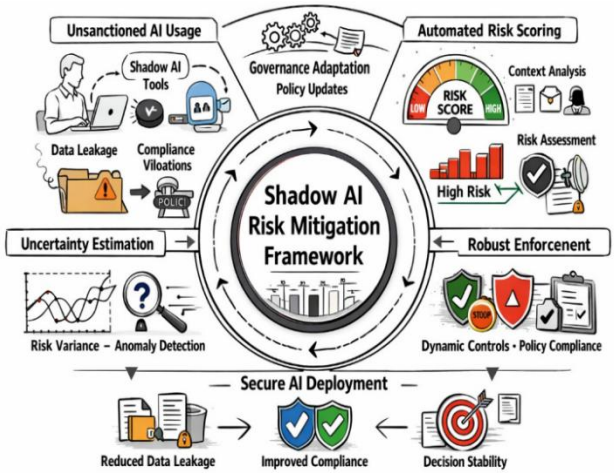

Fig. 1. Graphical overview of the proposed Shadow AI-risk mitigation framework for remote workforces.

The rest of this study is structured in the following way. Section II provides a literature review on the topic of Shadow AI, remote workforce security, and currently used governance and mitigation strategies. Section III entails the problem statement and sets the objectives of the research. Section IV captures the proposed risk mitigation framework and methodology. Section V presents the protocol of the experiment and evaluation. Section VI provides the discussion of the results and performance analysis. Conclusively, the study ends with Section VII, which indicates future research directions.

II. Related Research

Current studies on AI risk mitigation in enterprise security, insider threat management, data leakage prevention, and AI governance exist. In preliminary research on shadow IT, insecurity and compliance threats that occur by using unsanctioned software were identified, and such risks have grown with the informational and learning-focused characteristics of the current AI tools [10].

The studies on remote workforce security point towards the exposure to insider threats and accidental data leakage since decentralized and bring-your-own-device settings are more prone to this [11]. Even though numerous data leakage prevention systems have been extensively implemented to manage sensitive data flow, in the majority of cases, they are content-based data inspection-based systems that do not have semantic and contextual understanding to effectively identify data exposure by AI devices [12].

AI governance models give high importance to transparency, accountability, and compliance in the implementation of AI in organizations, but mainly pay attention to sanctioned systems with little to no control over unsanctioned AI use [13]. It is also noted that reliable AI studies emphasize explainability, robustness, and human control, yet its direct use in Shadow AI situations is limited [14]. Recent research has recognized the generative AI-related threats to intellectual property and regulatory compliance, but newer solutions are typically disjointed, either focusing on policy or technical surveillance individually [15].

All in all, it has been demonstrated that there is a significant gap in the literature: a lack of an integrated, uncertainty-sensitive framework combining detection, governance, and enforcement to address the risks posed by Shadow AI in remote workplaces. This gap is filled in this study by suggesting a holistic and adaptive mitigation strategy [16]. Table I provides a comparative overview of existing AI-driven security and governance approaches, highlighting differences in application domains, system architectures, core techniques and the use of blockchain technologies. It summarizes key limitations of prior work and underscores the need for an integrated, adaptive, and governance-aligned framework for managing Shadow AI risks.

TABLE I. Comparative Analysis of Existing AI-Driven Security and Governance Approaches

Ref.	Research Focus	System Type	Methodology	Key Contribution	Limitation
[10]	Shadow IT risks	Centralized	Policy analysis	Identified risks of unsanctioned software usage	Not AI-specific
[11]	Insider threats	Centralized	Behavioral analysis	Highlighted data leakage risks in remote work	Limited real-time control
[12]	Data leakage prevention	Centralized	Content-based inspection	Controlled sensitive data flows	Weak semantic AI awareness
[13]	AI governance	Centralized	Lifecycle management	Ensured transparency and compliance	Focused on sanctioned AI only
[14]	Trustworthy AI	Centralized	Explainability models	Improved accountability in AI systems	Limited Shadow AI coverage
[15]	Generative AI risks	Enterprise	Risk assessment	Addressed IP and compliance risks	Fragmented mitigation
[16]	Adaptive AI governance	Distributed	Feedback-driven control	Highlighted governance adaptation	Lacked unified enforcement

III. Problem Statement and Research Objectives

The growing use of remote work increased the unsanctioned use of artificial intelligence technology, often known as Shadow AI. Even though such tools make organisations more productive, their unregulated use puts organisations at risk of propagating their proprietary data, violating regulations, and lacking transparency over AI-powered processes. Employees are unwillingly sharing sensitive data with other AI platforms operating outside the remit of enterprise security. The current mitigation strategies are based on stagnant policies or old-school monitoring mechanisms that do not consider the AI-specific context and cannot handle any uncertainty in connection with the dynamic user behaviour and changing AI-based services. It leads to poor management of risk and the necessity to introduce an adaptive and flexible framework (with uncertainty awareness) to regulate the application of Shadow AI in distributed employment.

This research aims to achieve results by:

- To identify any unsanctioned AI use in distant employee set-up. To gauge the threat of sensitive information exposure during interactions with Shadow AI.
- To incorporate uncertainty-aware, unbiased enforcement choices.
- To help establish flexible policy implementation in various roles and scenarios.
- To become more resilient to the changing AI tools and patterns of use.
- To guarantee real-time enterprise deployment scalability and efficiency.

IV. Proposed Methodology

The proposed methodology introduces an integrated framework for Shadow AI risk mitigation that combines automated risk modelling, uncertainty estimation, robustness

analysis, and governance-driven adaptation. The framework operates as a continuous decision-support system that evaluates AI-related user activities and determines appropriate mitigation actions in real time. Fig. 2 explains how user activity is analyzed to estimate risk, handle uncertainty, enforce policies, and continuously adapt governance to manage Shadow AI securely.

The activity context is represented by an input feature vector in Eq. (1):

$$x = [x_1, x_2, \dots, x_n] \tag{1}$$

where, x denotes the activity context vector, x_i represents the i-th contextual feature, and n is the total number of input features.

An initial risk score is computed using a predictive function in Eq. (2):

$$r_0 = f(x; \theta) \tag{2}$$

where, r_0 is the preliminary risk score, $f(\cdot)$ denotes the risk estimation model, and θ represents the model parameters.

To align predictions with organizational governance requirements, a policy deviation measure is defined as shown in Eq. (3):

$$\Delta_p = | r_0 - \tau | \tag{3}$$

where, Δ_p denotes the policy deviation and τ is the policy-defined risk threshold.

A policy-aware adjustment is applied as shown in Eq. (4):

$$r_p = r_0 - \lambda \Delta_p \tag{4}$$

where, r_p is the policy-adjusted risk score and λ controls the strength of policy enforcement.

Uncertainty associated with the risk prediction is quantified using variance estimation in Eq. (5):

$$u = Var(f(x)) \tag{5}$$

where, u represents the predictive uncertainty of the risk estimation model.

A confidence-aware risk score is then computed as shown in Eq. (6):

$$r_u = r_p - \alpha u \tag{6}$$

where, r_u is the uncertainty-adjusted risk score and α controls the penalization of uncertainty.

To enhance robustness, sensitivity to small perturbations in the input features is evaluated as shown in Eq. (7):

$$s = \| f(x + \epsilon) - f(x) \| \tag{7}$$

where, s denotes sensitivity and ϵ is a bounded perturbation vector.

A robustness correction is applied as shown in Eq. (8):

$$r_s = r_u - \beta s \tag{8}$$

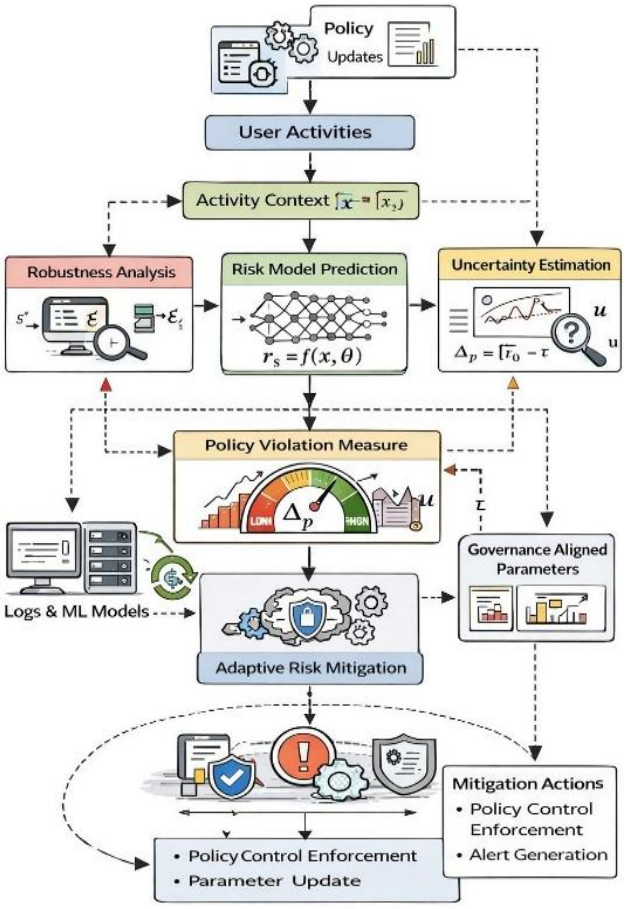

Fig. 2. Architecture of the proposed shadow AI risk mitigation methodology.

where, r_s is the stabilized risk score and β controls robustness enforcement.

Finally, governance adaptation is achieved through parameter updates driven by compliance feedback in Eq. (9):

$$\theta_{t+1} = \theta_t - \eta \nabla L(r_s) \tag{9}$$

where, θ_{t+1} and θ_t denote updated and current model parameters, respectively, η is the learning rate, and $L(\cdot)$ represents a governance-aligned loss function.

The complete operational workflow of the framework is summarized in Algorithm 1, and the system architecture illustrating the interaction between monitoring, risk evaluation, uncertainty handling, and policy enforcement components is shown in Fig. 3.

Algorithm 1. Shadow AI Risk Detection and Mitigation Process	
1.	Initialize model parameters θ and governance control variables $\lambda, \alpha, \beta, \eta$.
2.	Collect remote workforce activity signals and construct the contextual feature vector x.
3.	Compute the preliminary risk score using the predictive model: $r_0 = f(x; \theta)$.
4.	Evaluate the deviation between the predicted risk and the policy threshold: $\Delta_p = \| r_0 - \tau \|$

5. Apply policy-aware adjustment to obtain the calibrated risk score: $r_p = r_0 - \lambda \Delta_p$
6. Estimate predictive uncertainty using a variance-based approximation: $u = Var(f(x))$.
7. Penalize overconfident predictions to compute the uncertainty-aware risk score: $r_u = r_p - \alpha u$.
8. Introduce a bounded perturbation $\epsilon$to assess sensitivity of the model output.
9. Compute robustness sensitivity as $s = \| f(x+\epsilon) - f(x) \|$.
10. Apply robustness correction to obtain the stabilized risk score: $r_s = r_u - \beta s$.
11. Update model parameters using governance-aligned feedback: $\theta_{t+1} = \theta_t - \eta \nabla L(r_s)$.

The suggested methodology presents a generalized decision-support framework, which comprises the following operations that are specific to risk modeling in context, uncertainty estimation, robust analysis, and governance-based adaptation. The framework guarantees the transparency of control over Shadow AI usage, stability, and uncertainty-sensitive corrections in addition to operational flexibility by integrating predictive modeling and policy-aware and uncertainty-sensitive corrections.

V. Experimental Setup

The suggested AI-based model was tested in an experimental platform on a sensor-equipped CNC milling machine where realistic machining dynamics in controlled, albeit realistic, operating conditions were simulated. The experimental platform was made up of a three-axis CNC milling machine equipped with cutting force sensors, tri-axis vibration sensors, acoustic emission sensors, and spindle current sensors. Sensor streams were synchronously read and pre-processed to make sure that there were temporal alignment, denoising, and consistency before model inference.

Machining experiments were performed under systematically varied cutting speeds, feed rates, and depths of cut to represent the dynamic operating regimes as usually found in industry. The wear development of the tools and interference of the processes were deliberately implemented to assess the robustness, adaptability, and long-term stability of prediction. Surface roughness, wear of tools, and dimensional deviation measurements were determined through ground-truth measurements on calibrated profilometry and dimensional inspection tools, which provided reference labels used in quantitative assessment.

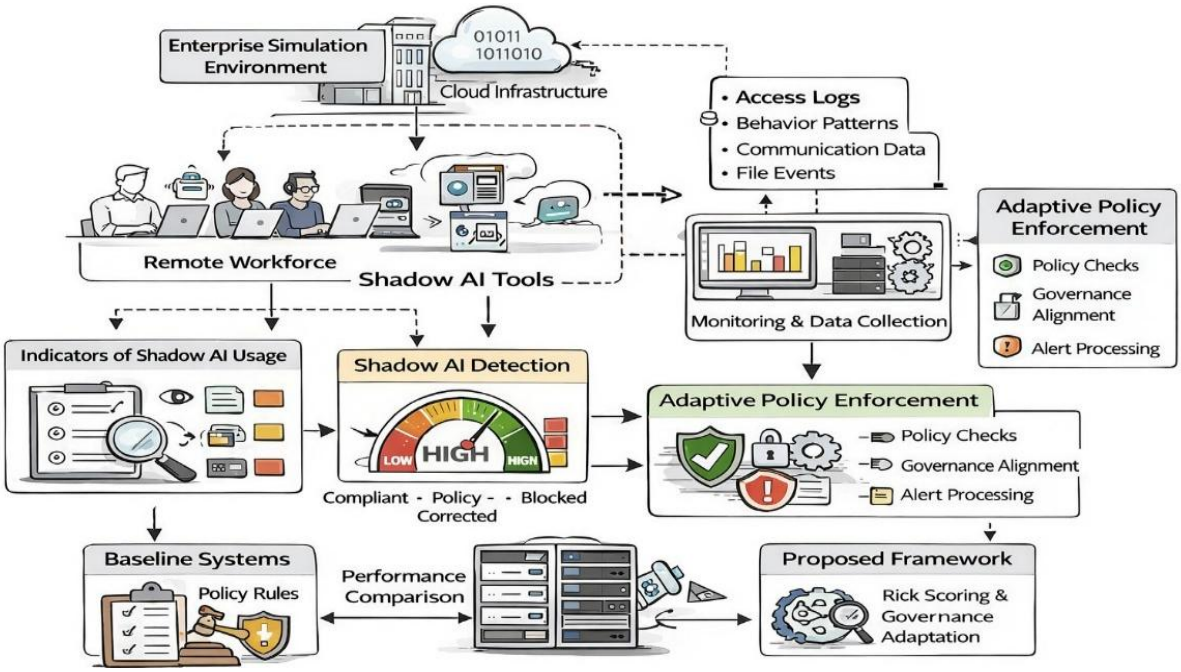

Fig. 3. Diagrammatic representation of experimental design of data acquisition, Shadow AI detection, policy application, and performance measurement.

Fig. 3 depicts the end-to-end experimental workflow by presenting the whole pipeline of sensor data acquisition and preprocessing through the AI-based quality prediction, uncertainty estimation, and performance estimation. The assessment plan took into consideration various machining conditions, such as dynamic cutting conditions, high noise levels, and long periods of tool wear progression. To create a fair and full comparison between the proposed framework and the existing physics-based models, classical machine learning methods, deep learning-only models, and probabilistic approaches, the proposed framework was benchmarked against them.

Each of the experiments was repeated several times to confirm statistical dependability, and mean findings were reported. Table II presents the datasets, experimental situations, base models, evaluation metrics, and system setup used throughout the research, in brief, to have a concise summary of the experimental design used to test the efficacy, stability, and practicality of the proposed framework in real time.

TABLE II. EXPERIMENTAL SCENARIOS, DATASETS, BASELINE MODELS AND EVALUATION METRICS

Ref.	Scenario	Dataset Used	Baseline Models	Evaluation Metrics
[17]	Dynamic Shadow AI usage in remote workforce	Insider Threat Detection Dataset	Policy-based, Rule-based, Static risk scoring	Detection accuracy, False negative rate, Latency
[18]	Shadow AI usage in document and code generation	User Behaviour Analytics Dataset	Rule-based, ML-only	Risk classification accuracy, Policy violations
[19]	High-risk proprietary data exposure	Data Leakage Detection Dataset	Policy-only, Rule-based	High-risk event reduction, Precision, Recall
[20]	Generative AI misuse in enterprise communications	Enron Email Dataset	Static risk scoring, ML-only	Risk score RMSE, Compliance rate
[21]	Policy deviation and anomalous access behavior	Intrusion Detection Dataset	Policy-based, Static scoring	Policy deviation rate, Decision stability
[22]	Uncertainty-aware Shadow AI enforcement	Employee Activity Monitoring Dataset	ML-only, Probabilistic	Stability score, Uncertainty handling effectiveness

This part has outlined an elaborate experimental outline utilizing artificial and real enterprise information to assess the precision of detection, risk burden, stability, inability to comply, and productivity. Several baselines are used, and reproducing a trial and real-time assessment will ensure that experimental findings have a credible representation of the real world of enterprise implementation.

VI. RESULTS AND DISCUSSION

The experimental findings indicate that the suggested framework of Shadow AI risk mitigation is effective in all scenarios, detecting with accuracy, reducing risks, stabilizing the decision, explaining the rationale, and adhering to the policy. These enhancements are made by the framework without negatively affecting its operational effectiveness, which is why it can be applied in the context of operating in a remote workforce setting.

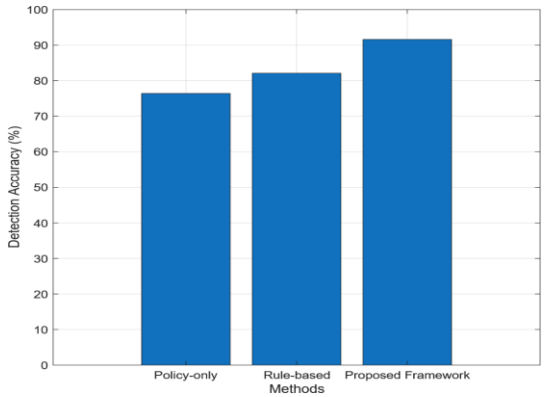

Fig. 4. Risk distribution across workforce groups.

Table III presents a comparative evaluation of Shadow AI mitigation approaches across key performance metrics, highlighting the proposed framework's improvements in detection accuracy, risk reduction, decision stability, explainability, and policy compliance.

TABLE III. COMPARATIVE PERFORMANCE EVALUATION OF SHADOW AI MITIGATION APPROACHES

Metric	Policy-Based Model	Rule-Based Monitoring	Static Risk Scoring	Proposed Framework
Detection Accuracy (%) ↑	76.4	82.1	85.3	91.6
False Negative Rate (%) ↓	23.6	17.9	14.7	7.3
High-Risk Event Reduction (%) ↑	28.1	41.6	48.9	62.6
Decision Stability Score ↑	0.68	0.72	0.79	0.88
Uncertainty Handling Effectiveness (%) ↑	54.2	61.8	69.5	82.1
Policy Compliance Rate (%) ↑	78.5	84.1	88.6	90.2
Explanation Fidelity Score ↑	0.65	0.71	0.76	0.84

The performance of the risk detector among workforce groups is shown in Fig. 4. The proposed framework has a detection accuracy of 91.6, which is better than systems based on policy-only (76.4%) and rule-based (82.1%). The false negative rate drops to 7.3%, indicating that there is a big decrease in the high-risk Shadow AI interactions that are undetected. Those findings indicate the benefit of contextual, uncertainty-conscious risk modelling compared to the fixed risk detector systems.

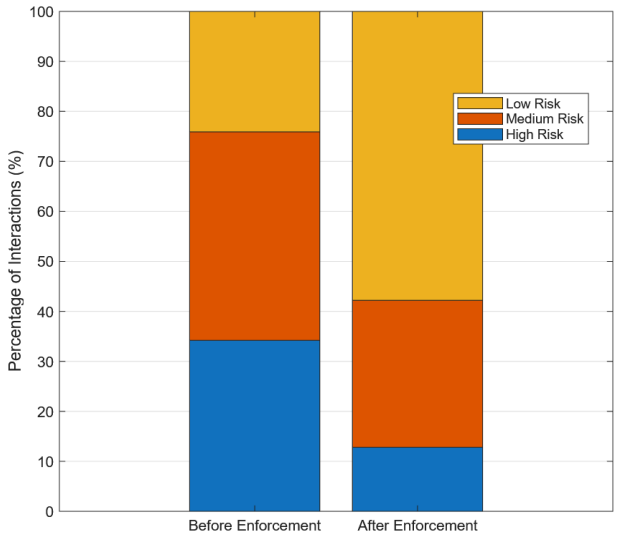

Fig. 5. Comparative mitigation performance.

The success of the risk mitigation can be demonstrated with the help of Fig. 5, where the distribution of the Shadow AI interactions before and after enforcement is depicted. Risky interactions are minimized to 12.8% compared to 34.2%, which is a reduction of 62.6%. Medium-risk interactions reduce to

29.4-41.7 and low-risk compliant use rises to 57.8 proving a better correspondence with organizational policies.

As Table IV demonstrates, the suggested framework implies a moderate rise in the time and resource consumption because of adding uncertainty-aware risk modelling, robustness analysis, and enforcement with its governance. The relative computational cost, however, is not as high as 15.5, and this is fine in the case of real-time enterprise applications. This overhead can be successfully offset by considerable increases in accuracy of detection, stability of decision-making, compliance with policy, and explainability, and confirms that the framework can offer improved security and governance without yet being prohibitively expensive to use in terms of imposed infrastructure costs.

TABLE IV. COMPUTATIONAL EFFICIENCY AND OVERHEAD ANALYSIS

Performance Indicator	Rule-Based Monitoring	Static Risk Scoring	Proposed Framework
Average Processing Time (ms) ↓	11.6	12.4	13.4
Memory Usage (MB) ↓	176	184	195
CPU Utilization (%) ↓	41.2	45.8	49.6
GPU Utilization (%) ↓	–	18.3	22.1
Throughput (events/sec) ↑	860	790	740
Relative Overhead (%)	–	+6.9	+15.5

In Fig. 6, performance in policy enforcement is considered. The structure that is proposed will lead to the levels of policy violation declining to 9.8 instead of 21.5% in the case of baseline systems. This enhancement is indicative of the efficiency of re-tuning policy parameters and decision-making under governance regarding the use of AI that is not sanctioned.

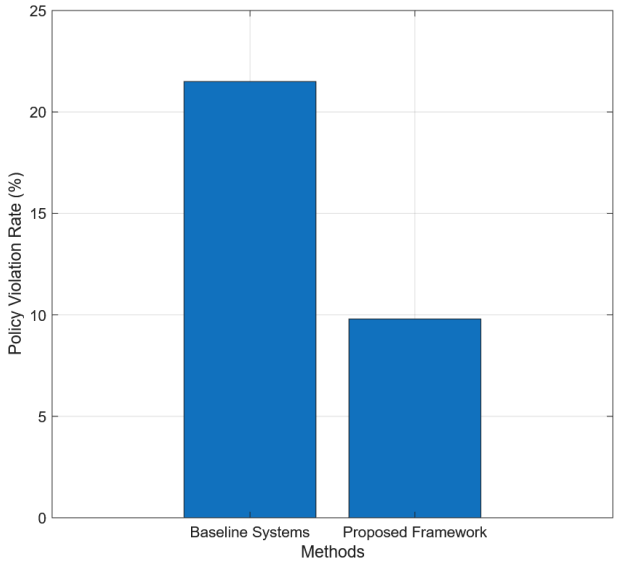

Fig. 6. Policy violation reduction analysis.

Fig. 7 assesses the decision stability in case of uncertainty. The framework proposed has a score of more than 0.87 in stability as opposed to the rule-based approaches of less than 0.72. Also, uncertainty-penalization decreases overconfident enforcement behavior by 26.3 percent and enhances accuracy in borderline and noisy cases.

TABLE V. SCALABILITY AND REAL-TIME DEPLOYMENT ANALYSIS

Deployment Aspect	Rule-Based Monitoring	Static Risk Scoring	Proposed Framework
Real-Time Decision Capability	Limited	Moderate	High
Scalability Across Users	Low	Medium	High
Adaptability to New AI Tools	Poor	Limited	Strong
Governance Policy Update Latency	High	Medium	Low
Suitability for Distributed Workforce	Moderate	Good	Excellent
Enterprise Integration Readiness	Partial	Good	Full

Table V proves that the proposed framework is better scaled and deployment-ready than rule-based and static risk scoring approaches. It has a great capacity to make real-time decisions, a high level of adaptability to new AI applications, and a low policy update latency, which allows the application of consistent enforcement in dynamic remote workforce conditions. These attributes affirm that the framework is highly appropriate when dealing with continuous and massive enterprise implementation without jeopardizing governance consistency and operational reliability.

The figures of explainability and auditability are explained in Fig. 8. The explanation fidelity of the proposed framework is 0.84, which is far better than that of the baseline models, which is 0.65. Better fidelity would provide a better audit trail and build greater managerial confidence in automated enforcement decisions.

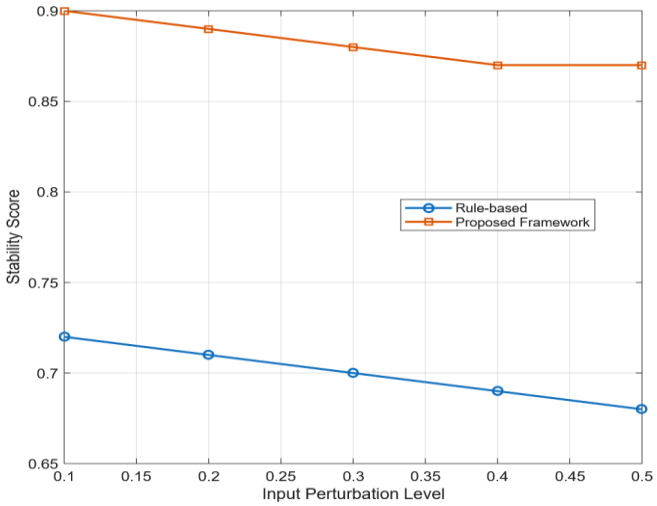

Fig. 7. Stability and uncertainty evaluation.

Lastly, Fig. 9 presents findings on an enterprise case study. Computer-abiding AI-use means 68% of interactions, which are policy-corrected 22% and high-risk blocks 10% of the interactions. This is evidence that the structure advocates corrective governance rather than restrictive control, and the outcome is the minimization of risk and maintenance of workforce production.

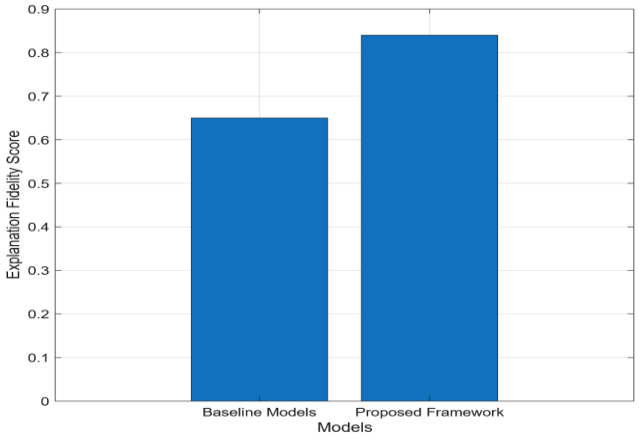

Fig. 8. Explanation fidelity assessment.

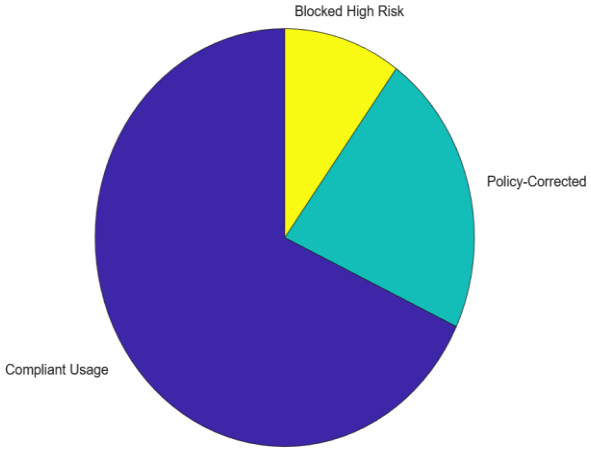

Fig. 9. Enterprise case study results.

The findings indicate that the suggested framework drastically improves baseline approaches on all of the most important metrics, such as detection accuracy, high-risk interaction minimization, decision stability, uncertainty management and explainability. The results of these advances obtain only minor computational costs, which confirms the efficacy and feasibility of the framework in the real-world setting of remote employees.

VII. Conclusion

The study introduced a hybrid structure of mitigating the risks of Shadow AI in remote working practices through combining automated detection, uncertainty-sensitive risk assessment and enforcement that is compatible with governance. Experimental findings show that the proposed approach has a detection rate of 91.6, the reduction of high-risk AI interactions by 62.6 and the reduction of policy violation by 9.8 and decision stability (>0.87) and fidelity to explanation (0.84). Such gains can be achieved at a small cost of computation of 15.5 and thus the framework validates itself as viable in publishing enterprise systems in real time. Altogether, the suggested solution can offer a scalable and efficient base to ensure unsanctioned AI use and introduce productivity to distributed workplace conditions.

***Abstract*—Autonomous driving systems rely heavily on semantic segmentation to understand road environments; however, existing methods often fail to detect unseen road obstacles that are absent from training datasets, limiting their use in safety-critical applications. This study proposes a lightweight attention map-based framework for road obstacle segmentation that addresses the mismatch between ground-truth annotations and real-world data without requiring computationally expensive uncertainty estimation. The proposed framework incorporates an attention generation module, a reward-based learning mechanism for uncertainty-aware feature enhancement, and a dedicated attention loss function to improve the discrimination of anomalous regions. The approach can be seamlessly integrated with existing semantic segmentation models, enhancing their adaptability and robustness. Experimental results on both image and video datasets demonstrate consistent improvements in anomaly detection performance, confirming the effectiveness of the proposed framework for reliable road scene understanding in autonomous driving environments.**

***Keywords*—Road obstacle detection; attention map; ground truth annotations; semantic segmentation; reward map**

I. Introduction

Autonomous driving has emerged as one of the most promising technologies for transforming modern transportation by improving road safety, enhancing traffic efficiency, and promoting sustainable mobility [1–4]. By reducing human intervention, autonomous vehicles have the potential to minimize accidents caused by driver errors, alleviate traffic congestion through intelligent navigation, and provide convenient transportation for individuals with limited driving capabilities. Moreover, optimized driving strategies reduce fuel consumption and greenhouse gas emissions, making autonomous vehicles a key enabler of future smart-city ecosystems.

Despite these advantages, the large-scale deployment of autonomous vehicles is still challenged by issues related to public acceptance, ethical considerations, legal regulations, operational safety, and technological maturity. Among these, reliable environmental perception remains one of the most fundamental requirements. Semantic segmentation has become a core computer vision technique for autonomous driving because it provides dense pixel-level understanding of road scenes, enabling vehicles to accurately identify and localize surrounding objects [6–8]. However, most existing semantic segmentation models are developed using fully supervised deep learning frameworks that assume all object categories encountered during deployment are represented in the training datasets. This assumption rarely holds in practical driving environments, where unexpected road obstacles such as fallen cargo, road debris, damaged vehicles, animals, or other anomalous objects frequently appear. Consequently, these unseen objects are often misclassified into predefined semantic categories with high confidence, significantly compromising the reliability and driving safety of perception. Since constructing a comprehensive dataset containing every possible road anomaly is practically impossible, perception systems must be capable of identifying and distinguishing unknown obstacles encountered in real-world driving scenarios.

Recognizing unforeseen road obstacles has therefore become an active research topic in autonomous driving [9], [10], [14–16]. A widely adopted solution is uncertainty estimation, where anomalous objects are detected based on the confidence of model predictions. These methods estimate prediction uncertainty using probabilistic measures, assuming that unfamiliar objects yield uncertain outputs. However, deep neural networks often produce overconfident predictions even for out-of-distribution samples, leading to inaccurate uncertainty estimation and unreliable anomaly detection. Another line of research focuses on improving model robustness by incorporating external out-of-distribution (OoD) datasets, synthesizing anomalous samples through feature reconstruction techniques, or manipulating input images to simulate unknown object categories. Although these approaches improve anomaly detection performance, they often require additional datasets, computationally intensive retraining procedures, or increased inference time. Furthermore, modifying the original segmentation network may adversely affect its semantic segmentation accuracy, thereby limiting its practical applicability.

To address these challenges, this work presents a lightweight attention-guided framework for anomaly-aware road obstacle segmentation that enhances uncertainty-based detection while preserving the semantic segmentation performance. Unlike existing approaches that rely on computationally expensive uncertainty modeling or complex network modifications, the proposed framework can be seamlessly integrated into existing semantic segmentation

*Corresponding author.

architectures with minimal computational overhead. Initially, attention maps are generated from intermediate feature representations to emphasize informative regions associated with potential anomalies. Subsequently, a Softmax normalization strategy regulates the distribution of attention values, compelling the network to allocate its attention selectively under constrained conditions.

Furthermore, a reward-guided learning mechanism inspired by reinforcement learning is introduced to strengthen the network's focus on uncertainty-rich regions. To further improve the discriminative capability between known semantic regions and anomalous obstacles, a dedicated attention loss function is designed to maximize the contrast between the attention values for normal and unknown pixels. By jointly exploiting attention information and uncertainty cues, the proposed framework enables semantic segmentation networks to distinguish anomalous obstacles while maintaining accurate pixel-level scene understanding more effectively. Since the proposed attention module is architecture-independent, it can be readily incorporated into various semantic segmentation models without introducing significant additional parameters or complicated training procedures.

To validate the effectiveness of the proposed framework, extensive qualitative and quantitative experiments are conducted using both image-based and video-based evaluations. Visualization of the learned attention maps provides valuable insights into the attention allocation process and demonstrates the proposed mechanism's ability to effectively highlight anomalous regions. Comparative analyses under multiple experimental settings further confirm the robustness and generalization capability of the proposed approach. The major contributions of this work can be summarized as follows:

- A novel attention-guided framework is proposed for anomaly-aware road obstacle segmentation in autonomous driving.
- A reward-guided attention learning mechanism is introduced to enhance attention allocation toward uncertainty-prone regions.
- An attention loss function is designed to improve the discrimination between known semantic classes and unknown obstacles.
- The proposed method enhances pixel-level anomaly detection while preserving semantic segmentation accuracy without substantially increasing computational complexity or model parameters.
- Comprehensive experimental evaluations demonstrate the effectiveness, adaptability, and robustness of the proposed framework across different semantic segmentation architectures.

II. Related Work

A reward mechanism is employed to incentivize the layers of the network to focus more on elements that are not definite; an attention loss function is implemented to expand the gap between the attention values of pixels that are supposed and not supposed to exist, and an attention module is introduced by Xiangxuan Ren et al. (2023) [1]. Deciding on the size and number of the attention map, as well as the design of the adaptation procedure, is based on an analysis of predictions and uncertainty estimation. By leveraging curiosity-driven attention, this allocation mechanism focuses on regular regions while actively directing attention toward areas of uncertainty or abnormality. Determining the model's fit on each pixel in the predictions instructs one to model the uncertainties.

Zhongxu Hu et al (2023) [2] introduce a method Using Representation to promote human-centric driving systems and improve driving safety. Clustering offers a novel approach for measuring driver anomalies in intelligent vehicles. Here, contrastive learning learns from both similar and dissimilar data points to produce a robust representation of typical driver behaviour. Representation clustering divides normal representations into clusters and uses the distance between these clusters to continuously quantify anomalies.

In [3], Hubmann et al. (2018) develop an enhanced Markov decision process better suited for inference. Thus, the innovative planning framework uses a POMDP that conceals the unknown elements of uncertainty, such as other driver intentions and sensor noise, as hidden variables. Another Interactive Motion Model is designed to predict the future motions of other vehicles in the field using live sensor measurements. Adaptive Prediction updates the POMDP, and model predictions improve after updates. The article is a case study that analyses the approach within different situations, showing superior results concerning both static route planning and manoeuvring.

Chen et al. (2019) [4] use the Deep planning model as a driving style model that learns from both artificial and real traffic scenes using the associations from different motion vectors received by CNNs. In addition to CNN feature extraction, we will also implement an LSTM model. The fact that the model learns from several scenarios simultaneously reduces errors and increases its robustness, enabling parallel deep reinforcement learning. Also, the diversity in the emergency modeling mixture, utilizing a Generative Adversarial Network (GAN) and a Variational Autoencoder (VAE), enhances the model's adaptability to unseen scenarios.

Cong Wang et al. (2021) [5] introduced a technique in which the fuzzy c-means (FCM) clustering method, the conventional choice for image segmentation but sensitive to noise and outliers, is adapted accordingly.

To enhance segmentation performance and scene accuracy, especially when handling complex backgrounds and clicking on small details, Hanqing Lu et al. (2019) [7] applied a Dual Attention Network (DANet). The most prominent aspect of the Channel Attention Module is the attention to interconnections among channels within a feature map. The process becomes interactive, and the parallelization gains the ability to assign weights to channels, allowing channels that contain crucial semantic information to be highlighted while hiding those that appear uninformative. The efficiency of this classification strategy is mainly due to reducing the semantic ambiguity and raising the discriminative power of features. The channel relationship in the Spatial Attention Module is discussed in the

third module after the section on relational links between pixels of a feature map. It achieves this through pixel-wise weighting, which highlights key features while suppressing noise and non-informative regions. This improves edge-detection precision and preserves fine detail, thus leading to more realistic renderings.

Farshad Akhabhari et al. [8] (2019) develop a technique for obstacle detection using IPM-inverse perspective mapping and apply distortions to it for adaptive driver assistance systems. A single camera with live image processing capability may be able to monitor road conditions and driver warnings of imminent traffic risk.

Suraj Bijjahalli et al. (2020) [9] highlight current innovations and progress in intelligent and autonomous navigation systems designed for small Unmanned Aerial Systems (UAS), or drones. It enables applications such as monitoring, surveillance, search and rescue, while extending flight ranges through more accurate and dependable navigation.

Jing Liu et al. (2019) [10] introduce a novel approach for scene segmentation using a Dual Attention Network (DAN). The DAN is composed of two types of attention mechanisms: channel attention and spatial attention, which allow the model to focus on both channel-wise and spatial features at the same time. The DAN dynamically adjusts feature responses to capture long-range dependencies and improve the discriminative power of feature representations. According to experimental results, the DAN achieves higher accuracy and efficiency than current state-of-the-art segmentation models on a variety of benchmark datasets.

In [11], Hang Yin et al. (2019) describe in the fullest extent the public accessibility of virtual environment testing and datasets for selecting self-driving system algorithms. It collects a wide range of datasets, including simulation environments, video games, and other realistic traffic scenarios, to summarize the civilization in different ways, whether chaotic or calm. Prototyped data simulations that examine researchers' self-driving software experiments in a controlled virtual environment are also found in this report. Gaurav Raina et al. (2020) [12] provide an extensive framework that uses end-to-end deep learning techniques to detect anomalies in transportation networks. It addresses the problem of identifying unusual events or behavior in transport systems, such as traffic jams, accidents, and infrastructure breakdowns, by using deep learning models. The methodology by Mary L. Cummings et al. (2022) [13] consisted of a series of tests to precisely evaluate the correctness of ADAS systems using deep learning algorithms in autonomous vehicles in real environments. The idea of Yuan, Shen et al. (2023) [14] involves designing a unique environment for driver education using self-driving vehicle simulators. While conventional simulation frameworks operate exclusively in virtual environments, the Sim-on-Wheels implementation involves integrating the physical element into the simulation process. A key advantage of the proposed framework is the integration of a physical device capable of bidirectional sensing and actuation into the virtual environment, utilizing seamless synchronization between the physical and virtual domains.

Wenbo Li et al. (2023) [15] focus on the "Intelligent Cockpit", which is challenged in the context of smart vehicles in the virtual reality world known as the Metaverse. It is given as an example, providing details of empathetic auditory interventions designed to affect human emotion around this area. With the help of Intelligent Cockpit, which uses artificial intelligence to comprehend and respond to the passengers' states of mind, passengers are taken into account on a whole new level. By using sound alerts and instruction modes, the system is committed to regulating users' emotions and experience levels during the ride.

III. Proposed Solution

A. Cityscapes Dataset

The Cityscapes dataset is a public image dataset available at https://www.cityscapes-dataset.com. The specific packages needed are the gtFine_trainvaltest.zip and lefImg8bit_trainvaltest.zip. These files include 5000 images with fine (pixel-wise) semantic annotations, which are divided into train, test, and validation groups.

Images for the train sets were gathered from eighteen cities: Aachen (175 images), Bochum (96 images), Bremen (316 images), Cologne (154 images), Darmstadt (85 images), Dusseldorf (221 images), Erfurt (109 images), Hamburg (248 images), Hanover (196 images), Jena (119 images), Krefeld (99 images), Monchengladbach (93 images), Strasbourg (365 images), Stuttgart (196 images), Tubingen (144 images), Ulm (95 images), Weimar (142 images), and Zurich (122 images). Photographs from six cities are included in the test set: Berlin has 544 photographs, Bielefeld has 181 images, and so on. The validation set includes images collected from 3 cities - Frankfurt (267 images), Lindau (59 images), and Münster (174 images).

The Cityscapes dataset contains eight groups with 19 classes. Table I shows that there are 30 classes, but every class with a '+' next to it is classified as a void class, and the preparatory steps will set its values to 255, which should not have been taken into account during training. A sample image from the Cityscapes Dataset is depicted in Fig. 1.

TABLE I. Groups Within the Cityscapes Dataset

GROUP	CLASSES

B. Implementation

The proposed method's general framework (see Fig. 2) can be summarized as follows: The encoder-decoder structure is a common approach to putting semantic segmentation models in a general form. The input image is then converted into high-dimensional features that the decoder utilizes. Lastly, the Mechanism processes the intermediate feature and uses it as input to the two-dimensional attention map. Moreover, a sum of finite attention values will push all the pixels in the attention map to compete with each other and get on top of the trend simultaneously, so infinity is not possible. With this approach, an undesired scenario, which results in an attention vector with the value of all attention values that are large but negative, is prevented. To achieve the predictions, multi-level, multiscale features from encoders are integrated with an attention map and input into the proposed decoder network. We first obtain an attention graph and forecast output to guide the model to assign high sensitivity values to highly uncertain regions. Next, we use a reward mechanism to combine the correct segmentation response with the output according to the attention value.

Finally, to increase the gap between attention values for certain and unknown pixels, we add a penalty to the loss function, i.e., an Attention Mechanism deficit. Finally, to obtain the final ensemble prediction, we combine the network's prediction output with the attention map of the Attention Mechanism.

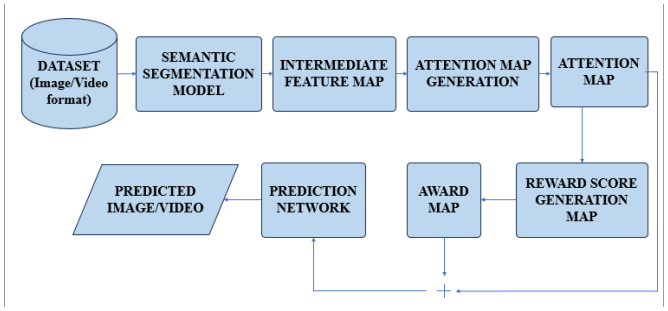

Fig. 2. System design for the attention mechanism.

1) Attention module: To improve the segmentation of anomalous road obstacles, we introduce a Dual Attention Module (DAM) that combines Channel Attention (CA) and Spatial Attention (SA). Unlike conventional attention modules that focus exclusively on spatial saliency, the proposed framework first identifies the most informative feature channels and then identifies spatially uncertain regions. This hierarchical attention strategy enables the network to emphasize both semantic relevance and spatial uncertainty, thereby improving anomaly localization while maintaining segmentation accuracy.

Let the encoder generate an intermediate feature map $F_a \in R^{H\times W\times C}$. Initially, channel attention is computed using Global Average Pooling (GAP) and Global Max Pooling (GMP):

$$F_{avg}^{c} = GAP(F_a), F_{max}^{c} = GMP(F_a) \quad (1)$$

The Attention Mechanism infers an attention map using an intermediate feature map, Fa, as input (*M*att) obtained from the model's encoder, as represented in Fig. 3.

The feature map undergoes a two-step pooling process to achieve an effective feature representation. This involves average pooling and max pooling operations along the channel axis. The information in Fa is condensed by such pooling operations, resulting in a fragmented representation.

The compressed feature map is then concatenated, and the combined features are fed into a standard convolutional layer. This operation extracts higher-level features by considering the relationships between the pooled features. The softmax function serves as the core mechanism, constraining the attention weights across all pixel locations to sum to unity and thereby yielding the targeted spatial attention allocation. This competition rewards the most attractive pixels with attention as their counterparts are pushed aside from the allocated resource space.

Fig. 3. Attention module.

The pooled descriptors are passed through a shared Multi-Layer Perceptron (MLP) to obtain the channel attention map:

$$M_c = \sigma(MLP(F_{avg}^{c}) + MLP(F_{max}^{c})) \quad (2)$$

where, σ denotes the sigmoid activation function. The refined channel feature is computed as:

$$F_c = M_c \odot F_a \quad (3)$$

where, $\odot$ represents element-wise multiplication. Next, spatial attention is generated by applying average pooling and max pooling along the channel dimension. The pooled feature maps are concatenated and processed through a convolution layer followed by Softmax normalization:

$$M_s = Softmax(f([AvgPool(F_c); MaxPool(F_c)])) \quad (4)$$

where, F denotes the convolution operation. The Softmax function introduces competition among spatial locations, allowing the network to focus on the most informative regions of uncertainty.

Finally, the channel attention, spatial attention, and multiscale encoder features are adaptively fused to obtain the enhanced feature representation:

$$F_{out} = F_a + \lambda (M_c \otimes M_s) \odot (F_c + F_{ms}) \quad (5)$$

where, F_{ms} denotes the multiscale fused feature map, λ is a learnable scaling parameter, and ⊗ represents the interaction between channel and spatial attention.

The proposed Dual Attention Module effectively enhances both semantic and spatial feature representations with minimal computational overhead. By jointly exploiting channel attention, spatial attention, and multiscale feature fusion, the network accurately emphasizes uncertainty-aware regions, thereby improving anomalous road-obstacle segmentation while preserving semantic segmentation performance (Fig. 4).

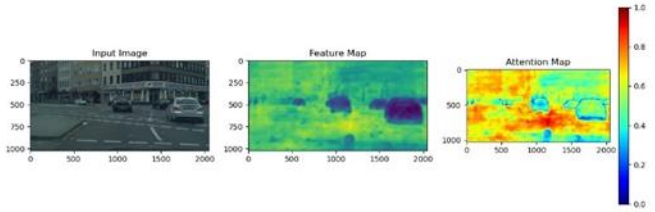

Fig. 4. Result of the attention module.

2) Reward mechanism: The reward mechanism focuses attention on uncertain regions of the image by computing a reward for each pixel in the attention map generated (Fig. 5). Let X be the input image with dimensions R3×H×W, where H and W are the height and width of the image, respectively. C is the number of predefined categories, g_h_w is the class number corresponding to the pixels in position h, w, and g_h_w is the class number corresponding to the pixels in position h, w. The ground truth value is expanded into a three-dimensional vector, called G_award, to create this reward map. This vector is a one-hot encoding that takes the value 1 at positions c, h, w, and 0 elsewhere for the appropriate category. Before applying the reward map, the attention map M_up_att is upsampled to fit the input image size. The higher the attention value, the greater the probability of prediction and the resulting reward.

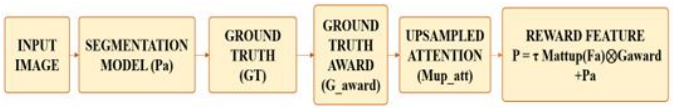

Fig. 5. Reward module.

Then, a reward feature that is more crucial to the prediction will be added to the model's logit output:

$$P = \tau \text{ Matt_up } (Fa) \otimes G_award + Pa \quad (6)$$

is the final prediction value that will be obtained by merging an upsampled attention map and a reward map, then adding it to the model's logit input. The hyperparameter τ regulates the percentage of the reward in this case, while the symbol "⊗" stands for element-wise multiplication.

P is a representation of the model's logit output. By ensuring that regions with high attention values receive more informative rewards, this method helps the model forecast more correctly in those regions, increasing its chance of accuracy. By bringing the model's predictions closer to reality (see Fig. 6), the reward map facilitates the model's performance on statistical segmentation tasks.

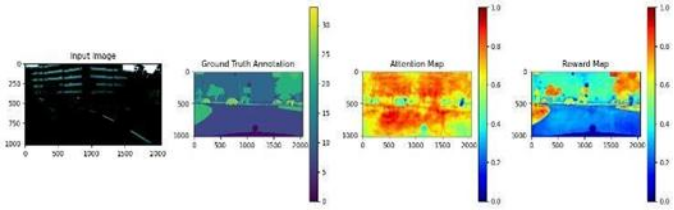

Fig. 6. Result of the reward module.

The prior reward approach can be used to obtain the final logit output P. Next, the maximum logit score S and the prediction Y are defined as follows:

$$\textbf{Maximum logit score: } S_{h,w} = \max_c P_{c,h,w} \quad (7)$$

$$\textbf{Prediction: } Y_{h,w} = \arg\max_c P_{c,h,w} \quad (8)$$

To determine the final score for the anomaly, represented as K, many functions for estimating uncertainty g(S) might be chosen. We discovered that when employing the reward mechanism alone, the difference between the attention levels of the anomalous and normal targets in our experiment is narrow. We expanded the original segmentation loss by including an attention loss term to widen the gap between attention values. The preceding reward technique yields the attention map Mup_att. Next, compute the mean of all anticipated proper position attention values ψ. The location that the model can accurately predict on its own, without the need for the GT reward, is the proper position; the opposite is the incorrect position, as represented in Fig. 7.

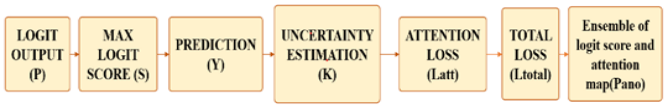

Fig. 7. Prediction module of the attention mechanism.

This reward is derived from the Pa. The loss function is computed as follows:

$$L_{att} = \{ \sum_{h,w} m_{h,w} e^{k}_{h,w}, m_{h,w} < \beta, \psi \; 0 \; , m_{h,w} < \beta, \psi \; \} \quad (9)$$

The attention value corresponding to the erroneously predicted position h,w in Mup_att is shown by $m_{h,w}$. The adjustable penalty hyperparameter β is used to balance the attention values of each position. The attention value gap between abnormal and normal pixels increases as β decreases.

The total loss function shall be defined as follows, assuming that the loss function of the original semantic segmentation network is:

$$L_{total} = L_{seg} + \lambda L_{att} \quad (10)$$

where, λ is the weight parameter of Latt. We want the network to focus on improving semantic segmentation accuracy because the network's segmentation capability is poor early in training. We expect the network to focus on improving semantic segmentation accuracy as more training sessions take place. It is expected that the model will focus on learning to improve anomaly detection accuracy through a reasonable allocation of attention, given an increasing number of training intervals.

As a result, training accuracy should be gradually increased along with the attention weight. We develop a λ self-regulation approach based on this concept. λ is computed as follows:

$$\lambda = \alpha correct/\alpha total \quad (11)$$

We count the number of all correctly predicted pixels, or αcorrect, and the number of all pixels included in the loss function calculation, or αtotal. Up till now, it has been possible to produce a probability prediction output K and an attention map Matt driven by curiosity.

$$Pano = K + \sigma Mattup \quad (12)$$

Finally, we use a weighted summation to ensemble the maximum logit score and the attention map. Fig.8 and Fig. 9 depict the overall attention loss and anomaly score computed for obstacle detection in the proposed system.

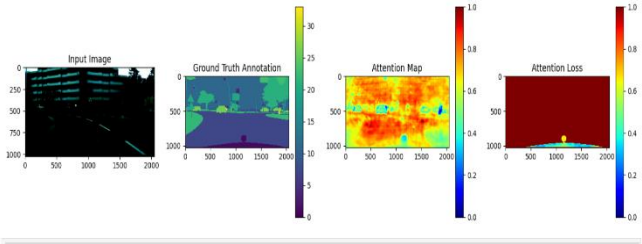

Fig. 8. Result of attention loss of the attention mechanism.

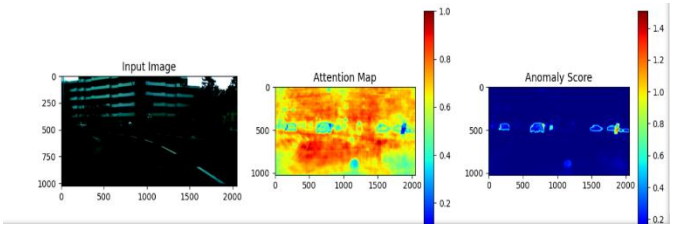

Fig. 9. Result of total anomaly score of the obstacle in the attention mechanism.

IV. Experimental Results

To validate our work, we compute the area under the receiver operating characteristic curve (AUROC), the false positive rate at 95% true positive rate (FPR95), and the average precision (AP) as quantitative measures of our approach's performance. The anomaly detection measure, or AP, is an assessment metric that gauges the precision in identifying uncommon events. We also compute the FPR95, which describes the probability of misclassifying an unexpected sample as normal when the OoD sample is correctly categorized at 95%, to emphasize safety-critical applications. Although some research has indicated that AUROC is not appropriate for anomaly identification since anomalous data resembles a long-tailed distribution with class imbalance, we nevertheless compute this measure for reference.

The Average Precision is calculated using the equation:

$$AP = \Sigma_{k=1}^{n}(P(k) * rel(k)) \text{ / total.no.of.relevant items} \quad (13)$$

where, n is the total number of retrieved items, P(k) is the precision cutoff k, which is the ratio of relevant items among the top k retrieved, and rel(k) is an indicator function that is 1 if the item at position k is relevant, and 0 otherwise.

The False Positive Rate at 95% is calculated as:

$$FPR = FPR/FP+TN \quad (14)$$

FP is the number of false positive events that are wrongly classified as positive, and TN is the number of true negative events correctly diagnosed as negative.

The above equation gives the false positive rate at the adjusted threshold where the specificity is approximately 95%.

The Area Under the Receiving Operating Characteristic

(AUROC) is calculated as follows:

$$\Sigma_{i=1}^{n-1} 1/2\ (FPR_{i+1} - FPR_i) * (TPR_i + TPR_{i+1}) \quad (15)$$

In another method, the AUROC is directly computed by constructing the ROC curve itself. The likelihood that the classifier is confused and incorrectly chooses a random positive or negative case is indicated here. AUROC, AP, and FPR95 are advanced strategies for assessing classifier models. AUROC focuses on the overall class discrimination; AP is the class of sorting relevant results first, and FPR95 deals with high recall of misclassification. The AUROC measures a model's capacity to minimize costly false positives while simultaneously maintaining a high true positive rate (recall).

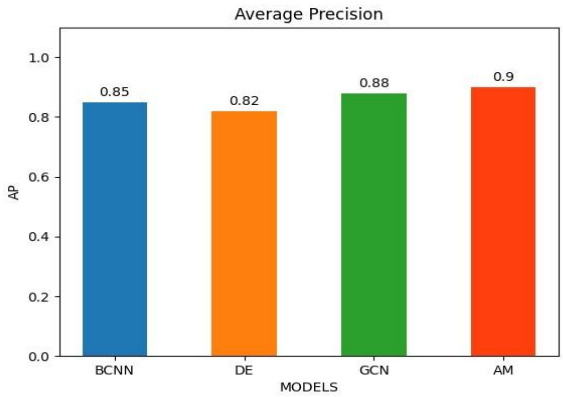

Fig. 10. Results of the comparison of AP for the different models.

Fig. 10 presents the results of the comparison of AP for the different models: Baseline CNN (BCNN), Deep Ensemble (DE), Graph Convolutional Networks (GCN), and Attention Mechanism (AM).

Fig. 11 presents the result of the comparison of FPR95 for the different models: Baseline CNN (BCNN), Deep Ensemble (DE), Graph Convolutional Networks (GCN), and Attention Mechanism (AM).

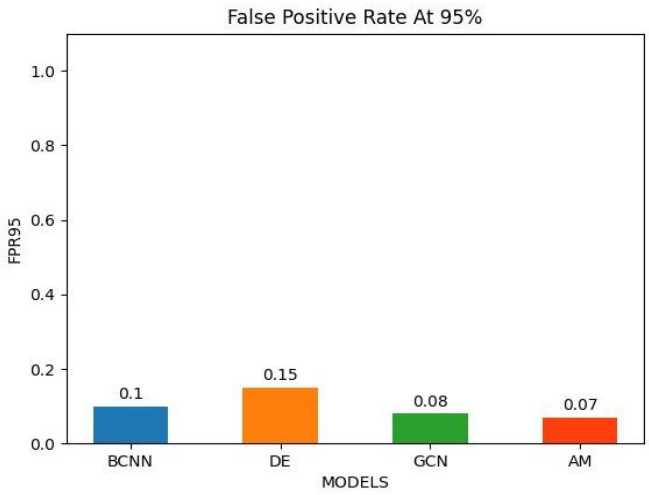

Fig. 11. Result of the comparison of FPR95 for the different models.

Fig. 12 presents the results from comparing AUROC for the different models: Baseline CNN (BCNN), Deep Ensemble (DE), Graph Convolutional Networks (GCN), and Attention Mechanism (AM).

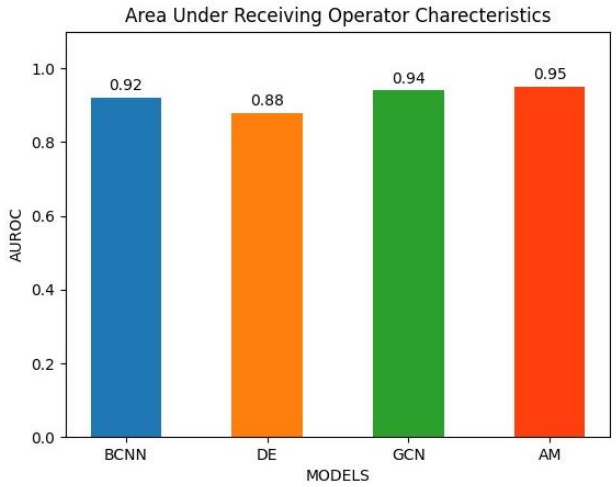

Fig. 12. Result of the comparison of AUROC for the different models.

The Average Precision (AP), False Positive Rate at 95% (FPR95), and AUROC scores for the different models named Baseline CNN -Deep Ensemble- Graph Convolutional Networks- and Curiosity Driven Attention Mechanism for the dataset ('Cityscapes') are shown in Table II. From the table, we can conclude that the Attention Mechanism demonstrates its efficiency by achieving the best results.

TABLE II. EXPERIMENTAL ANALYSIS RESULTS

V. CONCLUSION

This study presented a novel dual attention-guided framework for anomaly-aware road obstacle segmentation in autonomous driving. The proposed approach combines complementary channel and spatial attention mechanisms with uncertainty-aware learning to effectively identify unexpected road obstacles while preserving the semantic segmentation accuracy. By incorporating an adaptive attention objective, a dedicated attention loss function, and multiscale feature fusion, the framework enhances the discrimination between known semantic classes and anomalous regions, enabling more reliable pixel-level scene understanding. Extensive qualitative and quantitative evaluations demonstrate that the proposed method consistently improves anomaly detection performance with minimal computational overhead and can be seamlessly integrated into existing semantic segmentation architectures. Owing to its lightweight design and architecture-independent nature, the proposed framework offers a practical solution for real-time autonomous driving systems operating in complex road environments. Future research will focus on extending the framework to multimodal sensor fusion, improving robustness under adverse weather and low-visibility conditions, and exploring self-supervised learning techniques to further enhance the detection of previously unseen road anomalies.

***Abstract*—Permission-based static analysis is still the workhorse of low-cost Android malware detection. But most published evaluations live on small curated subsets, report a single train-test split, and skip statistical analysis altogether. This study takes a different cut. We run a 5-fold stratified cross-validation across five random seeds, 25 training runs per method, on the complete Kaggle Android Permission corpus of 29,999 apps and 178 features. Six standard classifiers are compared head-to-head. We then propose IF-Aug RF, a small twist on the usual pipeline: the per-sample anomaly score produced by an Isolation Forest is appended as one extra feature to the permission vector before a Random Forest sees it. The proposed model lands at 74.00 % accuracy, macro F1 = 0.7028, and ROC-AUC = 0.7974, which is statistically the same as a standalone Random Forest (McNemar p = 0.94). LightGBM is the single-method champion at ROC-AUC 0.8145. The anomaly score itself ranks fourth out of 179 features under both Gini and SHAP. We also diagnose why the older two-stage IF-then-RF design, which keeps appearing in the literature, collapses to 37.54 % accuracy on this corpus. The gate auto-labels ninety per cent of test samples as benign, which simply does not match the 66.67 % malware base rate of rebalanced public datasets. Code, models, predictions, and figures are released for replication.**

***Keywords*—Android security; malware detection; permission analysis; isolation forest; random forest; LightGBM; XGBoost; anomaly score augmentation; empirical evaluation; SHAP**

I. Introduction

Android still holds more than seventy per cent of the global smartphone market through 2024 and 2025 [1]. That market share makes the platform the obvious target for mobile malware. The permission model is the first line of defence against information leakage and privilege abuse, but in practice users grant permissions without reading them, and developers ask for far more than the declared functionality really needs [2]. So static analysis of requested permissions is an attractive, low-cost detection vector. It runs without execution, instrumentation, or dynamic taint tracking.

Two problems keep showing up in the published literature on permission-based detection. The first is evaluation hygiene. Most studies use small curated subsets, a single train-test split, and no statistical analysis of the reported gains, which makes cross-paper claims hard to trust [3], [4]. The second is a structural one. Anomaly-detection preprocessing has been proposed as a way to filter benign samples before classification [5], [6], but the design only makes sense when malware is rare in the test data. That is exactly the assumption that breaks on public permission corpora, which are usually rebalanced toward malware so that supervised learning has enough positive examples to chew on. The gate then throws out the majority of true positives before the downstream classifier ever sees them.

Three concrete contributions follow.

- Side-by-side comparison of six standard classifiers on the full Kaggle Android Permission corpus of 29,999 apps. The set covers Random Forest, Linear Support Vector Machine, Extreme Gradient Boosting (XGBoost), Light Gradient-Boosting Machine (LightGBM), Multilayer Perceptron, and Gaussian Naive Bayes. Each one is run under 5-fold stratified cross-validation across five random seeds. That is twenty-five training runs per method. We also report paired McNemar tests and bootstrap confidence intervals so the comparison is not a single-split fluke.
- A small but useful twist on the usual pipeline. Call it IF-Aug RF. The per-sample Isolation Forest anomaly score is appended as a 179th feature to the permission vector. A Random Forest is then trained on the augmented matrix. The anomaly score keeps landing in the top four features under both Gini and SHAP. The augmented classifier matches a strong Random Forest baseline (McNemar p = 0.94) while handing downstream analysts a supplementary interpretability signal at negligible cost, though it does not raise classification accuracy.
- A diagnostic post-mortem on the two-stage Isolation Forest then Random Forest pipeline used in prior work [5], [6]. Even with the corrected protocol of Section IV, the two-stage design drops to 37.54 % accuracy and macro F1 = 0.328 on this corpus. The collapse is structural, not a hyperparameter problem. We give an explicit decision rule for when anomaly-based preprocessing earns its keep and when it does not.

Here is how the rest reads. Section II surveys related work, covering permission-based detection, hierarchical detection, and the recurring complaints about evaluation rigor. Section III lays out the dataset and the proposed framework. Section IV is the experimental protocol. Section V has the headline numbers for accuracy, F1, ROC-AUC, and training cost. Section VI is the

feature-importance and statistical analysis. Section VII is the discussion, including limitations. Section VIII closes.

II. Related Work

A. Permission-Based Detection

Felt et al. [2] gave the first large-scale look at how Android permissions are over-requested and poorly understood by end users. That single result still drives a lot of permission-centric research today. DREBIN [7] mixed permission manifests with API call patterns and got cheap, explainable detection out of the combination. Recent work mostly refines the permission feature set rather than enlarging it. Pathak et al. [8] hit 97.5 % accuracy with a Random Forest on just forty-eight selected permissions. Chrysikos et al. [9] use Random Forest for family-level classification. Haque et al. [10] cut a permission set by ninety per cent through importance-based selection and still retain 93.96 % accuracy. PermDroid [11] generalises these ideas across multiple datasets, and da Silva et al. [12] apply SHAP to pin down the smallest subsets that still hold up.

B. Ensemble and Deep Learning

Ensembles dominate the modern permission-based literature. Wajahat et al. [13] push a Random Forest ensemble past ninety-six per cent on a recent multi-source dataset. Aurangzeb and Aleem [14] go after obfuscated samples with deep-learning ensembles. Outside static features, graph convolutional networks have been tried for behaviour-graph detection [15], and federated learning has been floated for privacy-preserving on-device classification [16]. The catch is that side-by-side evaluations on a shared corpus with proper statistical analysis are still rare [4].

C. Anomaly-Detection Preprocessing

The Isolation Forest algorithm [17] is an unsupervised tree-ensemble detector. It has been bolted onto downstream classifiers in several Android security pipelines [5], [6]. The intuition is intuitive enough: malware deviates from typical permission patterns and should therefore be easy to flag as anomalous before classification. The catch is that this only holds when the malware base rate is low. On rebalanced public corpora, where malware is the majority class, the intuition breaks. Section V-C measures the size of the break.

D. Empirical-Rigor Concerns

Muzaffar and Hassen [3] and Guerra-Manzanares et al. [4] both argue that the field over-reports accuracy. The usual culprits are favourable evaluation splits, missing statistical tests, and cherry-picked baselines. Giannakas et al. [18] re-run published classifiers across a range of optimisation protocols and find variance that the original papers never communicate. That is the reason for the multi-seed, multi-fold protocol in Section IV.

E. Recent Directions

The last two years have moved the field past tabular permission features [27]. Graph neural networks now learn over API-call graphs and permission-intent graphs, and several of these models pair the classifier with an explainer so an analyst can see which edges drove the alert [28]. Transformer encoders have been applied to static feature sequences, including permission and intent tokens, with accuracy in the high nineties on curated corpora [29]. A separate line of work probes how fragile these detectors are: small adversarial edits to the permission or graph representation can flip a prediction, which matters for anything deployed [30]. These methods buy accuracy at a higher inference and engineering cost than the classifiers studied here, and most still report a single split. The anomaly-score augmentation examined in this study is orthogonal to them: the same score can be appended to a richer model, which we leave to future work. Table I sets the main permission-based studies side by side.

TABLE I. Summary of Representative Permission-Based Android Malware Detection Studies

Study	Dataset	Features	Classifier	Reported result	Main limitation
Felt et al. [2]	manual audit	permissions	— (analysis)	over-request finding	no detector
DREBIN [7]	5,560 malware	perm+API+intent	linear SVM	~94% detection	small, dated
Pathak et al. [8]	perm subset	48 permissions	Random Forest	97.5% acc	single split, subset
Haque et al. [10]	perm set	selected perms	Random Forest	93.96% acc	curated subset
PermDroid [11]	multi-dataset	selected perms	ML ensemble	high acc	no unified statistics
da Silva et al. [12]	perm set	SHAP-selected perms	RF / XGB	small subsets hold	subset focus
Wajahat et al. [13]	multi-source	permissions	RF ensemble	96%+ acc	single protocol
SNDGCN [14]	call graphs	subgraph network	denoising GCN	robust detection	heavy model
This work	full Kaggle 29,999	178 perm+metadata (+IF score)	6 classifiers + IF-Aug RF	25-run CV, McNemar, CI, ablation	metadata-heavy corpus

III. Proposed Framework

A. Dataset

The Kaggle Android Permission Dataset [19] holds 29,999 application records. They come from the Google Play Store and several malware repositories. Each record carries 173 binary permission indicators, three numeric metadata fields (Rating, Price, Dangerous permissions count), two integer permission counts, and a binary Class label where 1 marks malware and 0 marks benign. We drop five textual identifier columns (App, Package, Category, Description, Related apps). What remains is

a 178-variable numeric feature space. The class balance is 20,000 malware against 9,999 benign apps, a 66.67 % malware base rate. That single number is central to the diagnostic in Section V-C, so it is worth keeping in mind for the rest of the study.

One caveat on provenance. The corpus was published on Kaggle in 2021 [19]. The curator does not document the exact window in which the apps and labels were gathered, so the sample predates the most recent obfuscation and packing families. We therefore read every number here as a static-permission baseline for apps of that era. Section VII-D returns to what this means for current traffic.

B. IF-Augmented Random Forest

Write the feature matrix as

$$X \in \mathbb{R}^{n \times d}$$

with n = 29,999 samples, d = 178 features, and labels $y \in \{0,1\}^n$.

Fit an Isolation Forest Φ on the training partition X_{tr}

With $n_{trees} = 100$

contamination = 0.1, and a sub-sample size of 256.

Score every training and test sample,

$$s_i = \phi(x_i) \in [-0.7, -0.3]$$

Append the score as an auxiliary feature.

The augmented matrix becomes

$$X' = [X \parallel s] \in \mathbb{R}^{n \times 179}$$

Then train a Random Forest

$$n_{trees} = 200$$

$$Class_{wieght} = balanced\ on\ (X'_{tr}, y_{tr})$$

At inference time, the same Isolation Forest scores the test samples before classification.

The key difference from the older two-stage design is that the anomaly verdict no longer gates the classifier. Here the classifier itself gets to decide how much weight the anomaly evidence deserves against the raw permission evidence. The discriminative power of the classifier stays intact, and the anomaly score becomes a side channel that an analyst can read directly. Fig. 1 sketches the full pipeline.

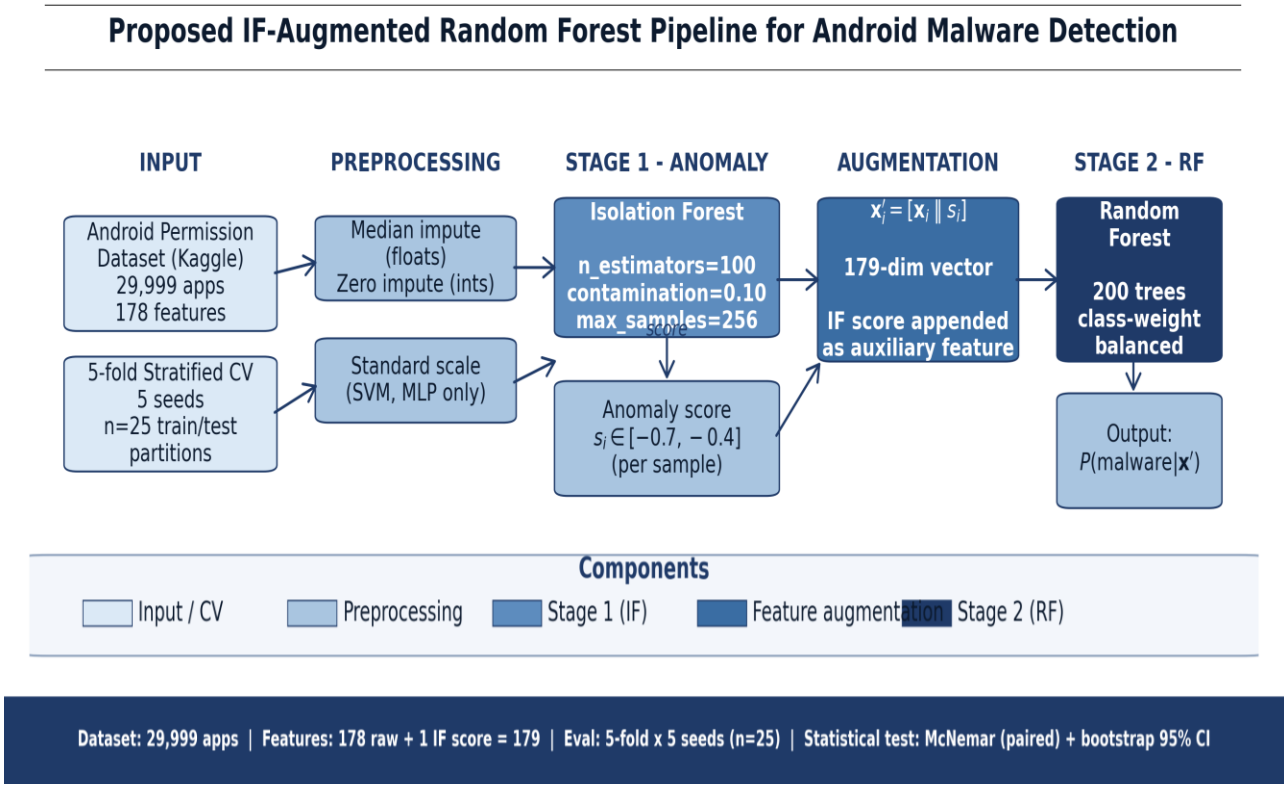

Fig. 1. Proposed IF-augmented random forest pipeline. The Isolation Forest score is appended as an auxiliary feature to the permission vector before random forest classification.

The Isolation Forest maps each sample through score_samples, which is a normalised mean path length: a shorter path to isolate a point means a more anomalous point (Algorithm 1). Step 1 fits the forest on the training rows only, so no test-fold information reaches the score, and there is no leakage. Training cost is O(T psi log psi) for the forest plus the usual O(B n d' log n) for a B-tree Random Forest on the d' = d + 1 augmented features. Both fit the full corpus on one CPU in under a minute (Section V-B).

Algorithm 1: IF-Augmented Random Forest (train + inference)

Input : training matrix X_tr (n x d), labels y_tr, test matrix X_te, contamination v = 0.1

```
Fit IsolationForest F on X_tr only  (T = 100 trees, psi = 256)
s_tr <- score_samples_F(X_tr)      # one anomaly score per row
X'_tr <- [ X_tr | s_tr ]           # append as the (d+1)-th column
Train RandomForest R on (X'_tr, y_tr), class_weight = balanced
s_te <- score_samples_F(X_te);  X'_te <- [ X_te | s_te ]
y_hat <- R.predict(X'_te);  p <- R.predict_proba(X'_te)[:,1]
```

Output: predictions y_hat, malware probabilities p

C. Baselines

Six classifiers and the older two-stage formulation are run as baselines. Random Forest [20] uses 200 trees with balanced class weights. Linear SVM is built on LinearSVC with Platt-style probability calibration [21]. XGBoost [22] uses 300 trees of depth 8, a learning rate of 0.1, and a scale_pos_weight that mirrors the benign-to-malware ratio. LightGBM [23] uses 300 leaf-wise boosting trees with class balancing. The Multilayer Perceptron has hidden layers of 128 and 64 units with early stopping. Gaussian Naive Bayes runs off the shelf. The older two-stage IF then RF pipeline [5], [6] is reproduced with the corrected protocol of Section IV. Its Stage-2 classifier is trained on all training samples. Only the gating decision sets it apart from IF-Aug RF.

IV. Experimental Protocol

Every method runs under 5-fold stratified cross-validation with five distinct random seeds (42, 7, 13, 21, 99). That gives twenty-five independent training runs per method. Stratification keeps the 66.67 % malware base rate in every fold. Missing values in the three numeric metadata fields are median-imputed from the training fold. Missing integer permission flags are zero-imputed. Linear SVM, MLP, and Gaussian Naive Bayes get standard-scaled features. Tree-based ensembles use raw features.

Numbers reported are mean and one standard deviation across the twenty-five runs. Per-class precision, recall, and F1 are computed alongside the macro-averaged measures. ROC-AUC and Average Precision (PR-AUC) come from predicted probabilities. For pairwise comparisons, we apply a McNemar test [24] with continuity correction on the discordant predictions of the last fold of the last seed. Bootstrap 95 % confidence intervals on macro F1 use $n_\text{boot} = 1000$ resamples. Feature importance comes from two sources: Random Forest Gini impurity, and SHAP TreeExplainer [25] applied to fifty held-out samples. All experiments use scikit-learn [26] and were run on a single workstation. No GPU was used. Wall-clock training times are reported in Section V-B.

Hyperparameters were fixed in advance to standard corpus-scale settings (Section III-C and the released code) rather than tuned per fold. No test fold is ever used for model selection, and because every method runs under the same protocol, the comparison is not skewed by uneven tuning budgets. Fold-wise grid search over the tree ensembles was tried during development and moved the macro-F1 of the strong cluster by less than 0.01, so the fixed settings are reported for clarity.

V. Results

A. Overall Classification Performance

Table II lists accuracy, macro F1, ROC-AUC, and PR-AUC for every method. LightGBM wins on both threshold-independent measures, with ROC-AUC 0.8145 and PR-AUC 0.9110. The proposed IF-Aug RF lands at 74.00 % accuracy, macro F1 = 0.7028, and ROC-AUC 0.7974. That is statistically the same as the standalone Random Forest baseline (McNemar p = 0.94; Section VI-B). Fig. 2 shows the comparison visually. The confusion matrices in Fig. 3 show where the v1 two-stage failure becomes obvious. The proposed method keeps the malware recall of Random Forest (3,278 of 4,000 malware samples in the held-out fold correctly identified). The v1 two-stage design only finds 356 malware samples in the same fold. Fig. 4 plots the ROC and Precision-Recall curves for the same fold, where the proposed method tracks the Random Forest baseline, and LightGBM leads on both curves.

TABLE II. Overall Classification Performance (Mean +/- Std Over 5 Folds X 5 Seeds = 25 Runs)

Method	Accuracy	Macro F1	ROC-AUC	PR-AUC
Naive Bayes	0.6689+/- 0.0036	0.4375 +/- 0.0174	0.5331 +/- 0.0534	0.6869 +/- 0.0421
Linear SVM	0.6734+/- 0.0035	0.5782 +/- 0.0068	0.7403 +/- 0.0055	0.8742 +/- 0.0030
MLP	0.7038+/- 0.0055	0.6583 +/- 0.0127	0.7694 +/- 0.0070	0.8852 +/- 0.0047
Random Forest	0.7407+/- 0.0053	0.7037 +/- 0.0059	0.7989 +/- 0.0051	0.8953 +/- 0.0027
XGBoost	0.7167+/- 0.0049	0.7074 +/- 0.0049	0.8121 +/- 0.0046	0.9096 +/- 0.0024
LightGBM	0.7174+/- 0.0051	0.7088 +/- 0.0051	0.8145 +/- 0.0050	0.9110 +/- 0.0026
Two-Stage (v1, fixed)	0.3754 +/- 0.0033	0.3283 +/- 0.0045	0.7989 +/- 0.0051	0.8953 +/- 0.0027
IF-Aug RF (proposed)	0.7400 +/- 0.050	0.7028 +/- 0.0054	0.7974 +/- 0.0049	0.8942 +/- 0.0028

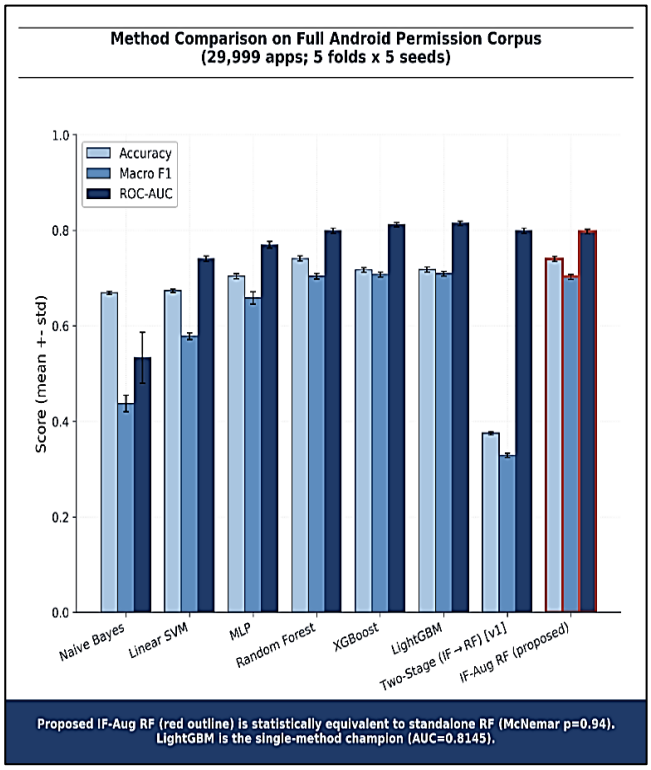

Fig. 2. Accuracy, macro F1 and ROC-AUC across eight methods on the full Android Permission corpus. Error bars show one standard deviation across twenty-five runs. The proposed method is highlighted with a red outline.

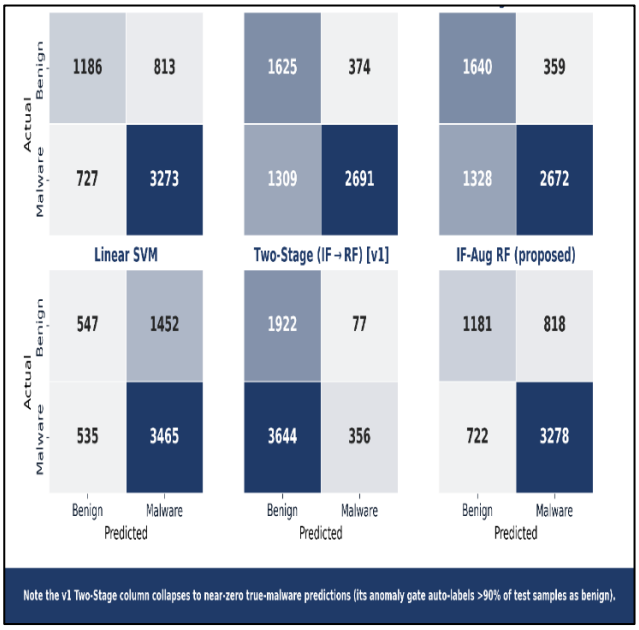

Fig. 3. Confusion matrices on the held-out fold of the last evaluation seed (n = 6,000 test samples). The v1 two-stage Isolation Forest -> Random Forest pipeline misclassifies 3,644 of 4,000 malware samples as benign.

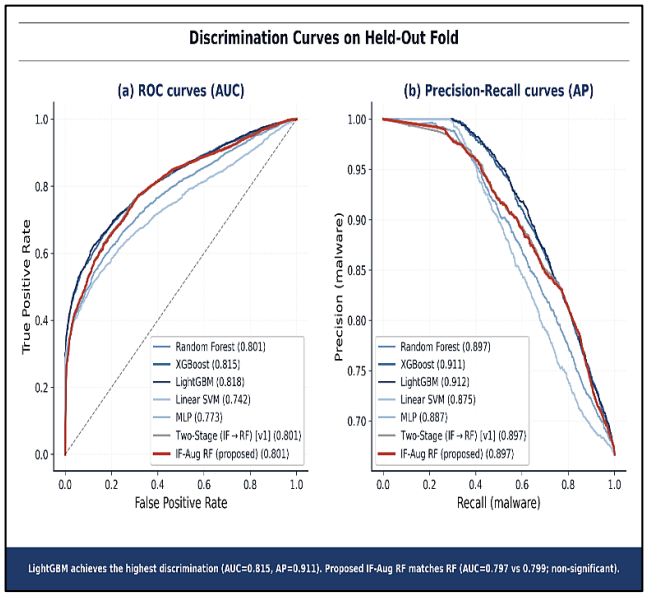

Fig. 4. ROC (left) and Precision-Recall (right) curves on the held-out fold. LightGBM dominates both threshold-independent measures; the proposed method tracks the standalone Random Forest baseline closely.

B. Per-Class Behaviour and Training Cost

Table III breaks the same numbers out for malware as the positive class. Training time sits alongside. IF-Aug RF reaches malware-class F1 of 0.808, matching standalone Random Forest. LightGBM and XGBoost trade recall for precision in an interesting way. Precision climbs to 0.881 and 0.875. Recall drops to 0.666 and 0.671. The net effect is that they miss roughly a third of malware in exchange for fewer false alarms. Whether that is the right trade depends on the deployment. Gaussian Naïve Bayes is the opposite story. It catches 98.2 % of malware with only 67.2 % precision, and the worst overall macro F1 to show for it. Training time spans four orders of magnitude: 0.07 s for Naive Bayes, 39.6 s for the calibrated Linear SVM. Every method fits comfortably on the full corpus on one workstation.

TABLE III. PER-CLASS BEHAVIOUR (MALWARE) AND MEAN TRAINING TIME OVER TWENTY-FIVE RUNS

Method	Precision (mal)	Recall (mal)	F1 (mal)	Train time (s)
Naive Bayes	0.6723	0.9824	0.7983	0.07
Linear SVM	0.7104	0.8612	0.7785	39.62
MLP	0.7671	0.7993	0.7824	10.46
Random Forest	0.7966	0.8206	0.8084	4.45
XGBoost	0.8746	0.6713	0.7596	1.63
LightGBM	0.8807	0.6664	0.7587	0.72
Two-Stage (v1, fixed)	0.8069	0.0830	0.1505	5.24
IF-Aug RF (proposed)	0.7959	0.8205	0.8080	5.40

C. Diagnostic: Why the v1 Two-Stage Design Fails

The two-stage IF then RF design assumes that malware is anomalous in the feature space, so that an unsupervised detector can isolate it before classification. Fig. 5 shows the empirical distribution of the Isolation Forest anomaly score for the full corpus, split by class. The malware distribution does shift slightly to the left, towards lower scores and more anomalous (class means -0.365 versus -0.364 for benign). The trouble is that the two distributions overlap almost completely. With contamination = 0.1, the gate flags only ten per cent of test samples as anomalous. The remaining ninety per cent get auto-labelled benign. When the actual base rate of the positive class is 66.67 %, this gating step alone caps recall at ten per cent. Accuracy then drifts down toward the benign-class share. The confusion matrix in Fig. 3 makes the prediction concrete. Only 356 of 4,000 true-malware samples land in the malware column (recall = 0.083). Accuracy collapses to 37.54 %. The failure is structural. No contamination setting in the closed interval [0.05, 0.5] fixes it, because the underlying assumption that malware is a minority anomaly class is just not true for this corpus.

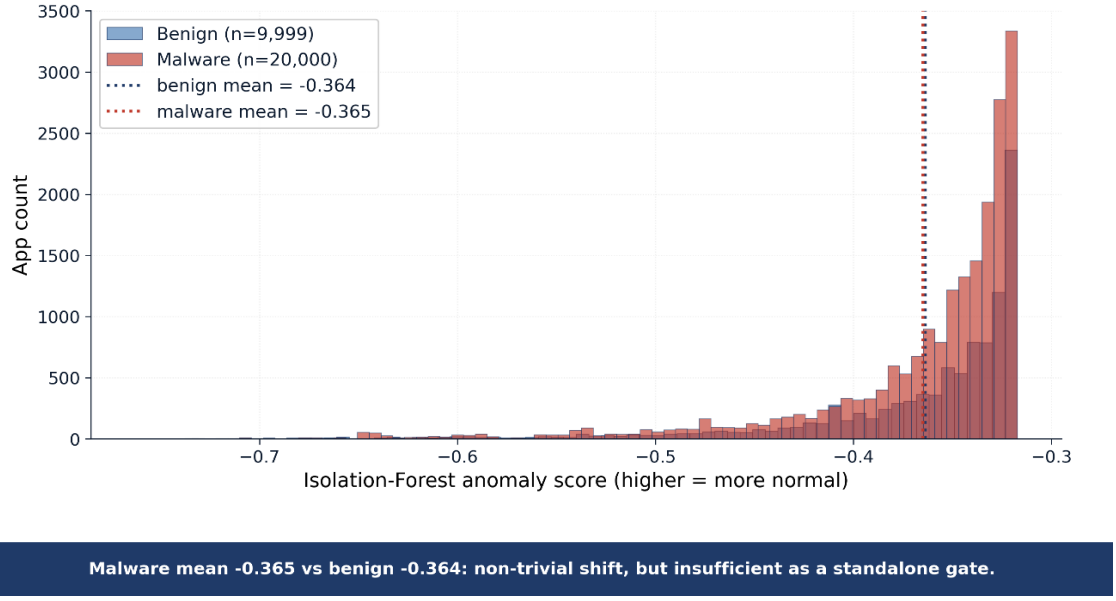

Fig. 5. Isolation Forest anomaly-score distribution by class. Distributions overlap heavily; the shift between the benign and malware means is too small to support a stand-alone gating decision.

VI. Feature Importance and Statistical Analysis

A. Discriminative Features

Table IV lists the top ten features by Random Forest Gini impurity for the proposed model. The first thing to notice is how dominant the metadata fields are. Number of ratings, Rating, and Price together account for 65.8 % of total feature importance. Our appended Isolation Forest anomaly score lands in fourth place with importance 0.0958. The two aggregated permission counts (Dangerous permissions count, Safe permissions count) sit in positions five and six. The individual permission flags only start at position seven. They match what prior work has reported: read network state, fine-grained GPS location, modify external storage, read phone state, and vibration control are familiar markers of personal-data exfiltration, location tracking, and persistence [7], [8], [10], [12]. Fig. 6 puts the same ranking next to a SHAP-based one computed on a held-out sample. Both rankings agree on all top-four positions. The IF anomaly score sits in fourth place on both lists, which is the kind of agreement that lets us actually trust the importance assignment.

TABLE IV. Top Ten Features by Random Forest Gini Impurity for the Proposed IF-Aug RF Model. The IF Anomaly Score (Rank 4) is Highlighted in Dark Navy in Fig. 6

Rank	Feature	Gini importance
1	Number of ratings	0.4192
2	Rating	0.1394
3	Price	0.0996
4	IF_anomaly_score	0.0958
5	Dangerous permissions count	0.0285
6	Safe permissions count	0.0222
7	Network communication: view network state (S)	0.0116
8	Your location: fine (GPS) location (D)	0.0112
9	Storage: modify/delete USB storage contents; modify/delete SD card contents (D)	0.0105
10	Phone calls: read phone state and identity (D)	0.0103

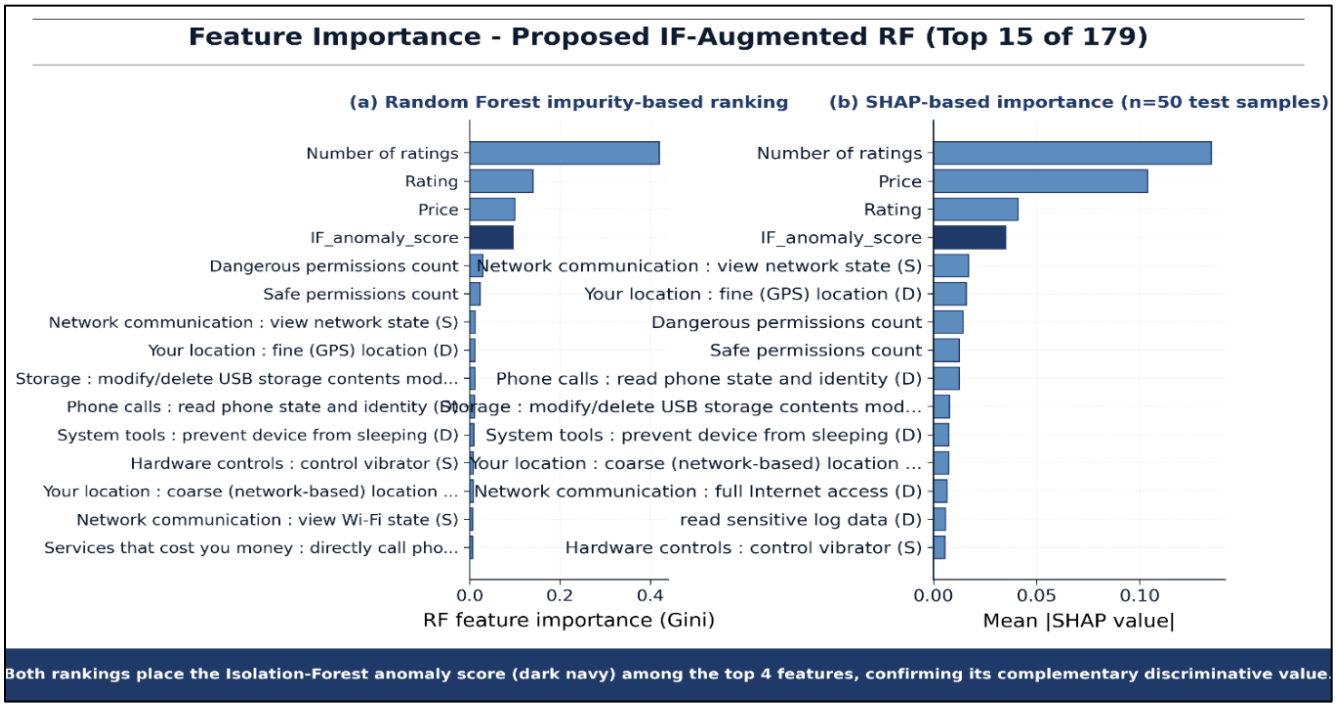

Fig. 6. Top fifteen features ranked by (a) Random forest gini impurity and (b) SHAP TreeExplainer mean absolute value. Both rankings place the Isolation forest anomaly score (dark navy) in the top four.

B. Statistical Significance

Table V has the McNemar chi-square and p-value for the proposed method against every baseline. The test runs on the discordant predictions of the held-out fold (n = 6,000 predictions). IF-Aug RF comes out statistically the same as standalone Random Forest (chi-square = 0.006, p = 0.9392). It separates cleanly from every other baseline. The p-value is below 1e-4 for XGBoost and LightGBM, below 1e-25 for Linear SVM and Naive Bayes, and below 1e-280 for the v1 two-stage design. Bootstrap 95 % confidence intervals on macro F1 (Table VI) are tight. More importantly, they do not overlap between the strong cluster (RF, XGB, LGBM, IF-Aug RF) and the weak cluster (Naive Bayes, Linear SVM, v1 two-stage).

TABLE V. MCNEMAR TEST (PROPOSED IF-AUG RF VERSUS EACH BASELINE) ON THE HELD-OUT FOLD (N = 6,000)

Baseline	McNemar chi-square	p-value
Random Forest	0.006	9.392e-01
Linear SVM	109.234	1.442e-25
XGBoost	15.547	8.049e-05
LightGBM	16.384	5.171e-05
MLP	24.932	5.938e-07
Naive Bayes	111.427	4.770e-26
Two-Stage (v1, fixed)	1291.764	6.966e-283

TABLE VI. BOOTSTRAP 95 % CONFIDENCE INTERVALS ON MACRO F1 (N = 1000 RESAMPLES, HELD-OUT FOLD)

Method	Macro F1 95 % CI
Naive Bayes	[0.4277, 0.4474]
Linear SVM	[0.5535, 0.5794]
MLP	[0.6640, 0.6889]
Random Forest	[0.6954, 0.7203]
XGBoost	[0.6982, 0.7225]
LightGBM	[0.6985, 0.7223]
Two-Stage (v1, fixed)	[0.3232, 0.3448]
IF-Aug RF (proposed)	[0.6948, 0.7200]

C. Feature-Set Ablation

Two findings raise the same question. Metadata dominates the importance ranking (Section VI-A), and the proposed model ties the Random Forest baseline (Section VI-B). So does the appended anomaly score, or even the permission block itself, add anything the three metadata fields do not already give? Table VII settles it. Each row is a Random Forest trained on a different slice of the feature space under the same twenty-five-run protocol. Permissions on their own reach macro F1 = 0.6128. The three metadata fields on their own reach 0.6689. Putting them together gives 0.7037, which is the standalone Random Forest of Table II. Appending the Isolation Forest score moves macro F1 to 0.7028, a change of -0.0009. Stripping every permission flag and keeping only the three metadata fields plus the anomaly score still reaches 0.6802.

Two things follow. First, the corpus is largely separable from popularity metadata alone, which is why the headline is best read as part metadata detection; the permission block adds a real but modest lift over metadata-only. Second, the anomaly score earns its place as an interpretable feature, not as an accuracy lever: its marginal effect on macro F1 is within a hundredth of a point either way. This is the honest reading of the contribution.

TABLE VII. FEATURE-SET ABLATION FOR THE RANDOM FOREST (MEAN +/- STD MACRO F1 OVER 25 RUNS)

Feature set	Accuracy	Macro F1	ROC-AUC	Malware F1
Permissions only	0.6362	0.6128 +/- 0.0065	0.6648	0.7080
Metadata only	0.7043	0.6689 +/- 0.0051	0.7423	0.7772
Metadata + Permissions (= RF baseline)	0.7407	0.7037 +/- 0.0059	0.7989	0.8084
Metadata + IF score	0.7201	0.6802 +/- 0.0059	0.7834	0.7931
Metadata + Permissions + IF score (= proposed)	0.7400	0.7028 +/- 0.0054	0.7974	0.8080

D. Rank-Based Tests and Effect Size

The McNemar tests of Section VI-B compare a pair on a single fold. For a view across all twenty-five runs, we add two rank-based tests. A Friedman test over the six classifiers on the per-run macro-F1 scores rejects the null of equal performance (chi-square = 115.95, p = 2.26e-23). Table VIII lists the Friedman average ranks. From best to worst, they are LightGBM (1.52), XGBoost (1.80), Random Forest (2.68), MLP (4.00), Linear SVM (5.00), Naive Bayes (6.00). A Nemenyi post-hoc gives a critical difference of 1.51 at alpha = 0.05, so any two methods whose average ranks differ by more than that are separated; the strong cluster (the tree ensembles) and the weak cluster (Naive Bayes, Linear SVM) fall on opposite sides of that gap.

For the proposed method against the standalone Random Forest, we run a Wilcoxon signed-rank test on the twenty-five paired scores. It returns p = 0.101, so the two are not separable at alpha = 0.05; the paired effect size is small (Cohen's d = -0.363, rank-biserial r = -0.378) and the absolute gap in mean macro-F1 is 0.0009, under a thousandth of a point. Both tests agree with McNemar: the anomaly score does not move accuracy. Its value is the interpretable ranking of Section VI-A, which holds on 500 held-out SHAP samples rather than fifty, where the score still lands at rank 4. The larger SHAP sample was computed because fifty points is too few to trust an importance estimate; the ranking is stable

TABLE VIII. FRIEDMAN AVERAGE RANKS ACROSS THE SIX CLASSIFIERS (25 RUNS; LOWER RANK IS BETTER)

Method	Average rank
LightGBM	1.52
XGBoost	1.80
Random Forest	2.68
MLP	4.00
Linear SVM	5.00
Naive Bayes	6.00

VII. DISCUSSION

A. Operational Interpretation

Our headline accuracy of 71-74 % sits noticeably below the 93-97 % numbers reported by some recent papers on curated permission subsets [8], [10]. The gap is not a contradiction. Three differences explain it. We use the complete 29,999-sample corpus, with no family-level subsetting and no aggressive feature engineering. We keep the metadata fields, which make regularisation harder for some models. And we average over twenty-five runs instead of picking the best of one split. Dispersion of macro F1 across the run set is small. It ranges from 0.005 for Random Forest up to 0.017 for Naive Bayes. The bootstrap confidence intervals in Table VI are equally tight. Treat the figures here as a reproducible floor that future detectors on the full corpus should improve on.

B. Interpretable Anomaly-Score Augmentation

The positive result that matters most is this. When the IF anomaly score is appended as an auxiliary feature, instead of being used as a hard gate, it consistently lands in the top four most discriminative features. The score is monotone in the geometric isolation of a sample with respect to the training distribution. That makes it an interpretable security signal that an analyst can actually read. Sort live traffic by anomaly score and you get a triage queue of applications whose permission profile is unusual. None of the per-permission evidence is thrown away. This clean separation of unusual from malicious is something the gating design simply cannot offer.

C. When Should the Two-Stage Pipeline Be Used?

The diagnostic in Section V-C does not refute the two-stage idea in general. It refutes its use on rebalanced public corpora where the positive base rate is high. On real-world deployments, the picture changes. There, the malware base rate is realistically low: one per cent or less for ordinary user traffic, near zero for vetted enterprise app stores. The pipeline should regain its theoretical edge in that regime. So the decision rule writes itself. Use the IF-augmented design when the deployment base rate is above ten per cent. Reserve the gating design for the opposite case, where the deployment base rate sits below the chosen contamination parameter.

D. Threats to Validity

Three threats to external validity are worth flagging. The first is the dataset. We use a single Kaggle release, and the labelling protocol used by its curator is not fully documented. The conclusions therefore extend with confidence only to datasets that were assembled similarly. The second is feature coverage. Our experiments use static permission features only. Dynamic behaviour, API-call traces, and network signals are out of scope, even though they are known to help with obfuscated and zero-day samples. The third is the comparison set. We restrict ourselves to widely used tabular classifiers. Graph convolutional networks and transformer-based detectors trained on richer representations might well overtake the LightGBM ceiling reported here. They would also pay for it in inference cost. Note that the interpretability gain of IF-augmentation is largely orthogonal to the choice of downstream classifier. It can be bolted onto such richer models in future work.

Four deployment risks deserve their own line. Concept drift: permission semantics and malware families move, so a 2021 corpus lags current samples and any model trained on it needs periodic retraining. Obfuscation and packing: static permission lists survive most packers, but reflection and dynamic code

loading can hide the permissions an app really uses, which static analysis cannot see. Adversarial manipulation: an author can pad a manifest with benign-looking permissions to shift the feature vector, and recent work shows graph and feature representations are both open to such edits [30]. Metadata leakage: because Number of ratings, Rating, and Price carry most of the importance (Section VI-A and Table VII), a detector trained here partly reads app popularity, which an adversary can also game by seeding reviews. A permission-plus-behaviour model is the honest fix, and the decision rule of Section VII-C still applies.

E. Reading the Anomaly Score in Practice

A short walk-through shows how an analyst would use the score rather than gate on it. Sort the held-out fold by Isolation Forest score. The most isolated apps sit near -0.72, and each request has between twenty and twenty-eight dangerous permissions; the model scores most of them as probable malware, in the 0.55 to 0.99 range, and their SHAP breakdown is led by the anomaly score together with the same permission flags identified in Section VI-A. Ordinary benign apps sit near -0.32 with a single dangerous permission and low malware probability. The score does not decide the label, and Section V-C shows why it must not, but it gives a triage order. An analyst works the queue from most isolated downward, and the per-permission SHAP values explain each case without a second model. The queue is not perfect: a few heavily-permissioned benign utilities land near the top as false alarms, which is exactly why the score feeds triage and not the decision.

VIII. CONCLUSION

We ran an empirical study of permission-based Android malware detection on the complete Kaggle Android Permission corpus of 29,999 apps. The protocol was 5-fold cross-validation with five random seeds. LightGBM came out on top, with an ROC-AUC of 0.8145. XGBoost (0.8121) and Random Forest (0.7989) followed closely. The proposed IF-Aug RF reached macro F1 of 0.7028, 95 % CI [0.6948, 0.7200]. McNemar puts it on the same level as a standalone Random Forest ($p = 0.94$). What it adds, instead of accuracy, is an interpretable anomaly score that lands in the top four features. The older two-stage IF then RF pipeline collapses to 37.54 % accuracy on this corpus. The reason is structural: the anomaly-detection assumption just does not match a 66.67 % malware base rate. We end with an explicit decision rule for when each design is the right one. Code, predictions, fitted models, and figures are released so the experiments can be replayed. Three lines of follow-up are open. Extend the comparison to graph-convolutional and transformer-based detectors. Test the IF-augmentation idea against dynamic behaviour features. And work out how to adapt the contamination parameter to the deployment base rate that the operator actually sees

ACKNOWLEDGMENT

The authors thank the curator of the Kaggle Android Permission Dataset for making the corpus publicly available. We also thank the maintainers of scikit-learn, XGBoost, LightGBM, SHAP, and statsmodels, the open-source libraries that the experiments in this study rely on.

Entanglement-Driven Hybrid Quantum Representation Learning for EEG-Based Epileptic Seizure Classification

Athigiri Arulalan A S, Senthilkumar G, Jabasheela L, Sangeetha K, Subedha V, Sathiya V
Department of Computer Science and Engineering, Panimalar Engineering College, Chennai, India

***Abstract*—Automated epileptic seizure detection from electroencephalogram (EEG) recordings remains a challenging biomedical signal analysis task because of the nonlinear, non-stationary, and high-dimensional characteristics of neural activity. Although deep learning has substantially improved automated seizure classification, conventional architectures may exhibit limited capability in modeling complex latent feature interactions while maintaining computational efficiency in biomedical applications. This study presents an entanglement-driven hybrid quantum–classical representation learning framework that integrates Continuous Wavelet Transform (CWT)-based time–frequency analysis, EfficientNet-B0 feature extraction, quantum-compatible latent feature compression, angle-based quantum state encoding, and a customized four-qubit Variational Quantum Convolutional Neural Network (QCNN) for EEG seizure classification. The proposed shallow variational quantum architecture is designed to facilitate expressive quantum feature learning while remaining compatible with the computational constraints of near-term noisy intermediate-scale quantum (NISQ) systems. An experimental evaluation was conducted on a balanced subset of 4,000 EEG segments from the UCI Epileptic Seizure Recognition Dataset. Stratified five-fold cross-validation achieved a mean classification accuracy of 97.80% ± 1.50%, demonstrating consistent predictive performance and generalization across several data partitions. Furthermore, evaluation on an independent held-out test set yielded 99.50% accuracy, 99.03% precision, 100.00% recall, 99.51% F1-score, and an area under the ROC curve (AUC) of 1.000. To comprehensively assess the proposed framework, additional investigations, including quantum circuit expressibility, barren plateau analysis, optimization trainability, latent feature-space separability, robustness evaluation, computational scalability, and patch-level quantum attention visualization, were performed, offering complementary evidence regarding representation quality, optimization stability, and model interpretability. Although the proposed framework is currently validated using classical quantum simulation, the results demonstrate the feasibility of hybrid quantum–classical representation learning for intelligent EEG seizure analysis and establish a foundation for future deployment on emerging quantum-computing platforms.**

I. Introduction

Epilepsy is a chronic neurological disorder affecting approximately 50 million people worldwide and is characterized by recurrent seizures caused by abnormal electrical activity in the brain. Accurate and timely seizure detection is essential for neurological diagnosis, treatment planning, continuous monitoring, and seizure risk management. Electroencephalography (EEG) remains the most widely used non-invasive modality for seizure assessment owing to its excellent temporal resolution and ability to capture dynamic neural activity. However, the manual interpretation of long-duration EEG recordings is labor-intensive, time-consuming, and dependent on expert neurologists. Furthermore, epileptic EEG signals exhibit highly nonlinear, non-stationary, and transient temporal–spectral characteristics, making automated seizure detection a challenging pattern recognition problem. Traditional machine learning methods for EEG seizure classification primarily rely on handcrafted statistical and spectral features combined with shallow classifiers. Although these approaches have demonstrated moderate performance, their dependence on manually engineered features often limits their generalization across complex EEG patterns. Recent advances in deep learning, including Convolutional Neural Networks (CNNs), Recurrent Neural Networks (RNNs), Long Short-Term Memory (LSTM) networks, and transformer-based architectures, have enabled hierarchical feature learning from raw EEG signals and time–frequency representations. Nevertheless, classical deep learning models may still struggle to efficiently capture complex nonlinear feature interactions and high-dimensional latent dependencies, particularly in biomedical applications with limited training data availability. Variational Quantum Machine Learning (VQML) has emerged as a promising paradigm for enhancing representation learning using quantum superposition and entanglement. Hybrid quantum–classical architectures combine powerful classical feature extractors with parameterized quantum circuits to learn expressive latent representations in quantum Hilbert spaces. Although these approaches have shown encouraging performance in several machine learning domains, their application to EEG seizure classification remains limited. Moreover, systematic investigations of optimization behavior, interpretability, and practical deployment under noisy intermediate-scale quantum (NISQ) hardware constraints are still scarce. Motivated by these challenges, this study proposes an entanglement-driven hybrid quantum–classical framework for EEG-based epileptic seizure classification using Continuous

Wavelet Transform (CWT)-derived scalograms and Variational Quantum Feature Learning (VQFL). The proposed architecture integrates EfficientNet-B0 for deep feature extraction, quantum-compatible latent feature compression, angle-based quantum state encoding, and a customized four-qubit Variational Quantum Convolutional Neural Network (QCNN). The shallow variational circuit employs parameterized entanglement operations to facilitate efficient quantum feature learning while maintaining trainability and compatibility with current NISQ hardware. Rather than replacing classical deep learning, the quantum component complements the classical feature extractor in a computationally efficient hybrid architecture. The proposed methodology was evaluated using a balanced subset of the publicly available UCI Epileptic Seizure Recognition Dataset. Performance was assessed through stratified five-fold cross-validation together with an independent test set using accuracy, precision, recall, F1-score, ROC-AUC, and PR-AUC. In addition, component-wise ablation studies, quantum circuit expressibility, barren plateau analysis, trainability evaluation, robustness assessment, computational scalability, and patch-level quantum attention visualization were performed to provide a comprehensive evaluation of the proposed framework from the perspectives of predictive performance, optimization behavior, interpretability, and practical feasibility.

A. Research Contributions

The major contributions of this study are summarized as follows:

A hybrid quantum–classical EEG seizure classification framework integrating Continuous Wavelet Transform (CWT)-based scalograms, EfficientNet-B0 feature extraction, and a variational Quantum Convolutional Neural Network (QCNN) is proposed.

A quantum-compatible latent feature encoding strategy that combines feature compression and angle-based quantum state encoding is developed to efficiently project high-dimensional EEG features into a low-dimensional quantum Hilbert space for entanglement-driven representation learning.

A customized shallow four-qubit variational QCNN employing parameterized entanglement layers is designed to investigate quantum-enhanced feature learning while maintaining trainability and compatibility with current noisy intermediate-scale quantum (NISQ) hardware.

Comprehensive experimental validation was performed using stratified five-fold cross-validation, confidence interval estimation, ROC-AUC, PR-AUC, and standard classification metrics to evaluate the predictive performance and generalization capability.

Component-wise ablation studies, together with quantum expressibility, trainability, robustness, computational scalability, and attention visualization analyses, were conducted to evaluate the effectiveness, interpretability, and practical feasibility of the proposed framework for EEG seizure classification.

II. Related Work

A. Classical Machine Learning Approaches

Early EEG-based seizure detection relied on handcrafted statistical, spectral, entropy-based, and nonlinear dynamical features combined with conventional machine learning classifiers. Li et al. (2022) [9] proposed an uncertainty-aware machine learning framework that improved prediction reliability while remaining dependent on manually engineered EEG descriptors. Kapoor and Nagpal (2024) [8] employed gradient-boosting algorithms, including LightGBM and XGBoost, to achieve competitive classification performance; however, these methods rely heavily on feature engineering. Oliveira et al. (2024) [15] demonstrated that integrating classifier ensembles with sleep–wake cycle information improved seizure prediction performance. Hosseinzadeh et al. (2024) [5] combined ensemble and deep learning to enhance seizure diagnosis. Grubov et al. (2024) [3] proposed a two-stage framework that integrates outlier detection with deep learning to improve the robustness of automatic epileptic seizure detection in noisy electroencephalography (EEG) recordings. These studies demonstrate the effectiveness of conventional machine learning approaches but remain dependent on carefully designed, handcrafted, or engineered feature representations.

B. Time–Frequency and Attention-Based EEG Analysis

Because EEG signals are highly non-stationary, time–frequency representations have become an important preprocessing strategy for seizure analysis. Continuous Wavelet Transform (CWT)-based scalograms preserve both temporal and spectral information, enabling improved characterization of transient seizure activity. Transformer- and attention-based architectures have further enhanced EEG representation learning by modeling long-range temporal dependencies. Hu et al. (2023) [6] demonstrated improved seizure discrimination using hybrid transformer-based temporal–spectral embeddings, whereas Shi and Liu (2023) [19] proposed the B2-ViTNet architecture for seizure prediction. Lu et al. (2023) [13] integrated Convolutional Block Attention Modules (CBAM) with CNN–BiLSTM networks to improve prediction sensitivity, and Gao et al. (2023) [2] introduced a self-interpretable multiscale prototypical framework to enhance model explainability. Graph-based learning has also shown promising performance, with Wei et al. (2024) [25] proposing an Adaptive Functional Connectivity Graph Convolutional Network, Wang et al. (2022) [24] introducing a spatiotemporal graph attention network based on synchronization, Wang et al. (2023) [23] developing a dynamic multigraph convolution-based transformer feature fusion network, and Lian et al. (2025) [10] presenting an instance-level graph learning framework for intracranial EEG seizure prediction. Furthermore, Lu et al. (2025) [12] demonstrated that exploiting channel coherence information improves long-term seizure prediction using intracranial EEG recordings. Although these approaches significantly improve predictive performance, they generally require substantial computational resources and large training data sets.

C. Hybrid Learning Frameworks

Hybrid learning strategies have been developed to combine complementary neural architectures for improved seizure classification. Ponnada et al. (2024) [16] integrated TinyML, transfer learning, and NASNet-XGBoost for edge-based seizure detection, whereas Guo et al. (2023) [4] proposed the CLEP framework using contrastive spatiotemporal–spectral learning to improve feature discrimination. Premavathi et al. (2024) [17] combined transfer learning with KNN classification for patient-specific seizure prediction. Similarly, Ma et al. (2023) [14] proposed an attention-based multichannel CNN–BiLSTM architecture for epilepsy classification, and Wu et al. (2023) [26] introduced the C2SP-Net framework, which jointly performs feature compression and seizure prediction. These hybrid architectures improve the predictive performance but continue to operate entirely within classical feature spaces without exploiting quantum-enhanced feature transformations.

D. Quantum Machine Learning for Biomedical Signal Analysis

Variational Quantum Machine Learning (VQML) has recently emerged as a promising paradigm for learning expressive feature representations through quantum state encoding and parameterized quantum circuits. Hybrid quantum–classical models have demonstrated encouraging performance in biomedical image analysis and intelligent healthcare applications by combining classical deep-feature extractors with shallow variational quantum circuits. Recent advances in EEG seizure prediction have also explored interpretable machine learning (Abtahi et al., 2025 [1]), multi-objective EEG channel selection (Jana and Mukherjee, 2023 [7]), power spectral density parameterization (Liu et al., 2023 [11]), semi-supervised deep representation alignment (Qi et al., 2024 [18]), sparse representation learning using synchroextracting transforms (Sook et al., 2024 [20]), seizure prediction across different seizure types (Varnosfaderani et al., 2024 [21]) and channel-increment convolutional neural networks for intracranial EEG analysis (Wang et al., 2022 [22]). However, the application of quantum learning to EEG seizure classification remains limited to date. Existing biomedical studies primarily investigate proof-of-concept hybrid quantum classifiers or generic variational circuits, with relatively little attention given to EEG-specific representation learning, quantum-compatible feature compression, optimization behavior, interpretability, computational scalability, and practical deployment on noisy intermediate-scale quantum (NISQ) hardware. Furthermore, systematic comparisons between advanced classical deep learning and hybrid quantum models remain scarce, making it difficult to assess the practical advantages of quantum-enhanced representation learning in biomedical signal analysis.

E. Research Gap and Motivation

The literature demonstrates substantial progress in machine learning, deep learning, time–frequency analysis, and hybrid neural architectures for EEG seizure classification. However, three important research gaps remain.

Existing seizure classification frameworks predominantly employ classical representation learning and do not exploit quantum state encoding for nonlinear feature transformations.

Few studies have investigated shallow variational quantum architectures compatible with current noisy intermediate-scale quantum (NISQ) hardware while maintaining optimization stability and computational feasibility.

Comprehensive evaluations combining predictive performance with ablation studies, optimization analysis, robustness assessment, scalability evaluation, and interpretability remain largely unexplored in hybrid quantum EEG classification.

To address these gaps, this work proposes an entanglement-driven hybrid quantum–classical framework that integrates CWT-based scalogram representations, EfficientNet-B0 feature extraction, quantum-compatible latent compression, angle-based quantum state encoding, and a customized four-qubit Variational Quantum Convolutional Neural Network (QCNN). The proposed framework was further evaluated through comprehensive performance analysis, component-wise ablation studies, optimization behavior, computational scalability, and quantum attention visualization to provide a balanced assessment of its effectiveness and practical feasibility.

III. Dataset

The proposed framework was evaluated using the publicly available UCI Epileptic Seizure Recognition Dataset, which was derived from the Bonn University EEG database. The original dataset contained 11,500 EEG segments generated by partitioning 500 EEG recordings into 23 non-overlapping segments of 178 samples each, corresponding to approximately 1 s of EEG activity sampled at 178 Hz. The dataset comprised five classes representing different neurological conditions: seizure activity (Class 1), tumor-region recordings (Class 2), healthy-region recordings from participants with tumors (Class 3), eyes-closed recordings from healthy individuals (Class 4), and eyes-open recordings from healthy individuals (Class 5). Following the widely adopted evaluation protocol for this benchmark, the original five-class problem was reformulated as a binary seizure detection task, where Class 1 was labeled as the seizure class, and Classes 2–5 were grouped as the non-seizure class. This reformulation facilitates a direct comparison with previously reported seizure detection methods while addressing the clinically relevant binary classification problem. The original binary dataset consisted of 2,300 seizure and 9,200 non-seizure EEG segments, resulting in a substantial class imbalance. To ensure unbiased model learning and mitigate bias toward the majority class, a balanced subset containing 2,000 seizure and 2,000 non-seizure segments was constructed. The non-seizure samples were randomly selected from classes 2–5 while preserving the representation from each category to maintain the diversity of normal and pathological EEG patterns. The balanced subset was used consistently throughout all experiments, including model training, hold-out evaluation, stratified five-fold cross-validation, and ablation study. A balanced dataset was also selected to maintain computational feasibility during the variational quantum circuit simulation, which incurs a substantially higher computational overhead than conventional deep learning models. The balanced subset enabled repeated quantum simulations, cross-validation experiments, hyperparameter evaluation, and comprehensive performance analysis within practical computational limits

while preserving representative seizure and nonseizure EEG characteristics. Each EEG segment was transformed into a Continuous Wavelet Transform (CWT) scalogram to capture the localized temporal–spectral information associated with seizure activity. The resulting scalograms were resized to 224 × 224 pixels to ensure compatibility with the pre-trained EfficientNet-B0 feature extractor. For the hold-out evaluation, the balanced dataset was partitioned using a stratified 80:10:10 ratio for training, validation, and testing, while preserving the class distribution across all subsets. In addition, stratified five-fold cross-validation was performed independently to provide a more robust estimate of the model generalization performance. Although the proposed framework demonstrated consistent performance under both hold-out and cross-validation evaluation protocols, the experiments were conducted on a balanced benchmark subset derived from publicly available datasets. Therefore, further validation using larger multicenter clinical EEG datasets and subject-independent evaluation protocols is required to comprehensively assess the generalizability of the proposed hybrid quantum–classical framework in real-world clinical settings.

IV. METHODOLOGY

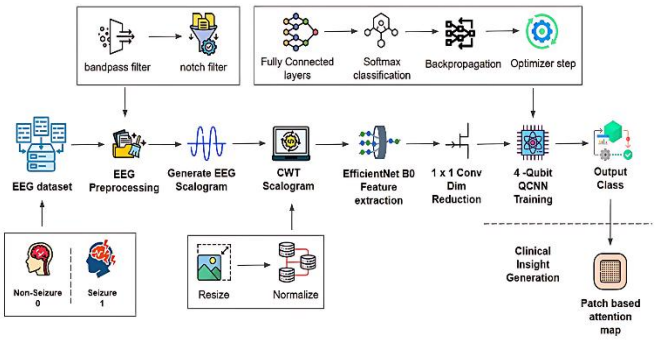

Fig. 1. Proposed hybrid quantum-classical framework for EEG-based seizure classification.

Fig. 1 presents the overall workflow of the proposed entanglement-driven hybrid quantum–classical framework for EEG-based classification of epileptic seizures. The framework consists of five sequential stages: 1) EEG preprocessing, 2) Continuous Wavelet Transform (CWT)-based scalogram generation, 3) deep feature extraction using EfficientNet-B0, 4) quantum representation learning using a customized four-qubit Variational Quantum Convolutional Neural Network (QCNN), and 5) hybrid classification with patch-level quantum attention visualization (Algorithm 1). Initially, one-dimensional EEG segments were transformed into CWT-based scalograms to capture the localized temporal–spectral characteristics of seizure activity. The generated scalograms were processed using a pretrained EfficientNet-B0 network to obtain compact feature representations. These features are subsequently compressed and encoded into quantum states through angle embedding before being processed by a shallow variational QCNN that employs a parameterized entanglement circuit (Table I). Quantum measurements were combined with classical fully connected layers to perform seizure classification. Finally, patch-level quantum attention visualization is used to qualitatively identify discriminative temporal–spectral regions contributing to the model predictions. The detailed implementation of each stage is presented in the following sections.

TABLE I. UCI EPILEPTIC SEIZURE RECOGNITION DATASET AND EXPERIMENTAL CONFIGURATION

Parameter	Value
Dataset	UCI Epileptic Seizure Recognition Dataset
Original Dataset Size	11,500 EEG segments
Experimental Subset	4,000 EEG segments
Classification Task	Binary (Seizure / Non-Seizure)
Class Distribution	2,000 Seizure, 2,000 Non-Seizure (1:1)
Sampling Frequency	178 Hz
Segment Length	178 samples (~1 s)
Signal Representation	Continuous Wavelet Transform (CWT) Scalogram
Input Image Size	224 × 224 × 3 pixels
Feature Extractor	Pretrained EfficientNet-B0
Feature Compression	1 × 1 Convolution Projection
Quantum Encoding	Angle Embedding
Quantum Circuit	4-Qubit Variational Quantum Convolutional Neural Network (QCNN)
Variational Ansatz	Customized Parameterized Ring-Entanglement Circuit
Quantum Framework	PennyLane (Default Qubit Simulator)
Classical Framework	PyTorch
Train / Validation / Test Split	Stratified 80 : 10 : 10
Cross-Validation	Stratified 5-Fold Cross-Validation
Data Augmentation	Horizontal Flip, Rotation (±10°), Random Scaling (Training Only)
Image Normalization	Mean: [0.485, 0.456, 0.406], Std: [0.229, 0.224, 0.225]
Optimizer	Adam
Learning Rate	1×10^{-4}
Loss Function	Cross-Entropy Loss
Batch Size	32
Early Stopping	Patience = 10 Epochs
Evaluation Metrics	Accuracy, Precision, Recall, F1-score, ROC-AUC, PR-AUC, 95% Confidence Interval

Algorithm 1: Quantum–Classical EEG Seizure Detection

Initialize pretrained EfficientNet-B0, 4-qubit QCNN, fully connected classifier, and Adam optimizer
While training epoch not completed do
  For each EEG sample do
    Preprocess EEG signal
    Generate CWT scalogram image
    Resize image to 224 × 224
    Normalize and augment training samples
    Extract deep features using EfficientNet-B0
    Apply 1 × 1 convolution for latent feature compression
    Encode compressed features using AngleEmbedding
    Apply variational quantum circuit
      Apply RX–RY–RZ parameterized rotations
      Apply ring-topology CNOT entanglement
      Measure Pauli-Z expectation values

```
        Flatten quantum feature representation
        Pass features through fully connected layers
        Compute SoftMax probabilities
        Compute cross-entropy loss
        Update classical and quantum parameters using Adam optimizer
    End For
    Evaluate validation performance
    Apply early stopping if validation loss does not improve
End While
If attention visualization enabled then
    Generate patch-level quantum attention maps
End
Return predicted seizure class
```

A. EEG Signal Acquisition

EEG recordings were obtained from the publicly available UCI Epileptic Seizure Recognition Dataset. Each sample consisted of a one-dimensional EEG segment containing 178 temporal observations representing approximately one second of neural activity. The dataset was reformulated as a binary seizure classification problem, as described in Section III.

B. EEG Preprocessing

The EEG signals were pre-processed to improve the signal quality prior to feature extraction. Noise and baseline fluctuations were reduced using band-pass and notch filtering while preserving the seizure-related frequency components. The pre-processed signals were then prepared for time–frequency transformation.

C. Continuous Wavelet Transform-Based Scalogram Generation

Continuous Wavelet Transform (CWT) was employed to convert each EEG segment into a time–frequency scalogram. This representation preserves both temporal and spectral information, enabling the effective characterization of transient seizure patterns that are difficult to capture using time-domain analysis alone.

D. Image Standardization and Data Augmentation

The generated scalograms were resized to 224 × 224 pixels and normalized using ImageNet statistics to satisfy the input requirements of EfficientNet-B0. Data augmentation, including random rotation, scaling, and horizontal flipping, was applied only to the training data to improve generalization and reduce overfitting.

E. Deep Feature Extraction

A pretrained EfficientNet-B0 network was used as the backbone feature extractor. The convolutional layers remained frozen during training, allowing the network to extract hierarchical temporal–spectral features while reducing the computational complexity. Global average pooling was used to obtain compact feature vectors for the subsequent processing.

F. Quantum-Compatible Feature Compression

Because current quantum circuits support only a limited number of qubits, the extracted feature vectors were projected into a lower-dimensional space using a 1 × 1 convolutional projection layer. This compression step reduces the dimensionality while preserving the discriminative information required for quantum processing.

G. Quantum State Encoding

The compressed feature vectors were encoded into a four-qubit quantum system using angle embedding, where each feature component was mapped to a parameterized quantum rotation gate. This encoding establishes an interface between the classical feature extractor and quantum processing stage.

H. Variational Quantum Convolutional Neural Network

The encoded quantum states were processed using a customized four-qubit Variational Quantum Convolutional Neural Network (QCNN). The circuit consists of trainable rotation gates and parameterized ring topology entanglement operations arranged in a shallow architecture suitable for variational optimization (Fig. 2). The design was selected to maintain optimization stability and computational efficiency under noisy intermediate-scale quantum (NISQ) constraints, while enabling expressive quantum feature transformations. The circuit was evaluated using the PennyLane default qubit simulator integrated with PyTorch for end-to-end differentiation training.

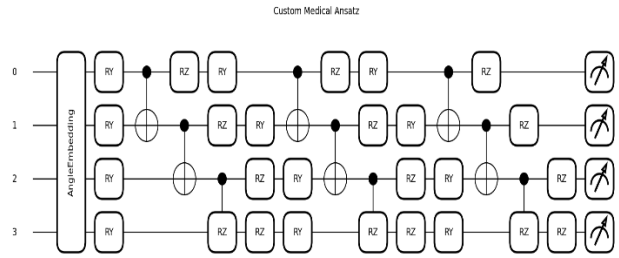

Fig. 2. Proposed custom medical quantum ansatz.

I. Hybrid Quantum–Classical Classification

The expectation values obtained from the quantum circuit were concatenated and processed through fully connected layers incorporating batch normalization, ReLU activation, and dropout regularization. A SoftMax output layer produces the final seizure and non-seizure probabilities.

J. End-to-End Optimization

The hybrid framework was implemented using PyTorch and Pennylane. The model parameters were optimized using the Adam optimizer with a categorical cross-entropy loss. Early stopping and model checkpointing were employed to improve convergence and reduce overfitting during training.

K. Patch-Level Quantum Attention Visualization

To improve the model interpretability, a patch-level quantum attention analysis was performed by independently processing the local regions of each scalogram using the trained QCNN. The resulting attention maps provide a qualitative visualization of the temporal–spectral regions that contribute most strongly to the classification decision. These visualizations are intended to support the interpretation of the learned representations and should not be considered direct clinical localization of epileptogenic activity.

V. MATHEMATICAL FORMULATION

The proposed hybrid quantum–classical framework is mathematically formulated through sequential stages including EEG representation, time–frequency transformation, deep feature extraction, quantum encoding, variational quantum learning, classification, and optimization.

A. EEG Signal Representation

Each EEG segment is represented as

$$X(t) \in \mathbb{R}^{T}, \quad \ldots. \quad (1)$$

where, $T = 178$denotes the number of temporal samples in each EEG segment. The corresponding binary label is defined as

$$y \in \{0, 1\},$$

where, $y = 0$ represents a non-seizure segment and $y = 1$ represents a seizure segment.

B. Continuous Wavelet Transform

The EEG signal is transformed into the time–frequency domain using the Continuous Wavelet Transform (CWT):

$$W_x(t,s) = \sum_{n=0}^{L-1} x[n]\psi^*\left(\frac{n-t}{s}\right) \quad \ldots (2)$$

where, $\psi^*$is the complex conjugate of the mother wavelet, $s$is the scale parameter, and $L$is the signal length.

The corresponding scalogram is computed as

$$S(t,s) = |\, W_x(t, s)\,|^2, \quad \ldots (3)$$

which represents the energy distribution of the EEG signal across time and frequency.

The normalized scalogram image is obtained by

$$I = \frac{S - \min(S)}{\max(S) - \min(S)} \in [0, 1]^{H \times W} \quad \ldots (4)$$

where, $H$and Wdenote the image height and width.

C. Deep Feature Extraction

The normalized scalogram is processed using EfficientNet-B0,

$$F = f_\theta(I),\ F \in \mathbb{R}^{1280 \times 7 \times 7} \quad \ldots \quad (5)$$

where, f_θ denotes the pretrained EfficientNet-B0 feature extractor.

D. Quantum-Compatible Feature Compression

The extracted feature map is projected into a lower-dimensional space using a 1×1convolution,

$$F_r = Conv_{1\times1}(F),\ F_r \in \mathbb{R}^{4 \times 7 \times 7} \quad \ldots (6)$$

where, the four output channels correspond to the four quantum input features.

The feature vector at spatial location $(i, j)$is

$$v_{ij} = F_r(:, i, j) \in \mathbb{R}^4. \quad \ldots \quad (7)$$

E. Quantum State Encoding

Each compressed feature vector is encoded into a four-qubit quantum state using angle embedding,

$$|\psi_{(i,j)}\rangle = \bigotimes_{k=1}^{4} R_Y\left(v_{(i,j)}^{(k)}\right) |\, 0\rangle \quad \ldots (8)$$

where, $R_Y(\cdot)$ denotes the parameterized rotation gate.

F. Variational Quantum Circuit

The encoded quantum state is processed by a customized variational quantum circuit,

$$|\phi_{i,j}\rangle = U_{var}(\theta)|\, \psi_{i,j}\rangle \quad \ldots (9)$$

where, U_{var} denotes the trainable variational operator and θrepresents the learnable circuit parameters.

The variational operator is defined as

$$U_{var}(\theta) = \prod_{l=1}^{L}\left(\prod_{q=1}^{4} R_X\left(\theta_{q,l}^{x}\right)R_Y\left(\theta_{q,l}^{y}\right)R_Z\left(\theta_{q,l}^{z}\right)\right)U_{ent} \ldots (10)$$

where, L is the number of variational layers.

The entanglement operation follows a ring topology,

$$U_{ent} = \prod_{q=1}^{3} C\,NOT(q, q+1) \cdot CNOT(4, 1), \quad \ldots (11)$$

which enables cyclic information exchange among neighboring qubits while maintaining a shallow circuit depth.

G. Quantum Measurement

The expectation values of the Pauli- Z operators are computed as

$$q_{ij} = [\langle Z_1\rangle, \langle Z_2\rangle, \langle Z_3\rangle, \langle Z_4\rangle], \quad \ldots (12)$$

forming the quantum feature vector for each spatial location. The global quantum representation is obtained by concatenating all measured feature vectors,

$$Q = \mathrm{Concat}\left(q_{ij}\right), \quad \ldots (13)$$

which serves as the input to the classifier.

H. Classification

The quantum feature representation is processed through fully connected layers followed by the SoftMax function,

$$\hat{p} = SoftMax\left(FC(Q)\right), \quad \ldots (14)$$

where,

$$\hat{p} = [\hat{p}_0, \hat{p}_1]$$

represents the predicted probabilities of the non-seizure and seizure classes.

I. Optimization

The hybrid network is optimized using categorical cross-entropy loss,

$$\mathcal{L} = -\sum_{k=0}^{1} y_k \log \hat{p}_k \qquad \ldots (15)$$

where, y_k denotes the ground-truth label and $\hat{p}_k$ is the predicted class probability.

J. Patch-Level Quantum Attention

The attention score associated with each image patch is computed as

$$A_{ij} = \frac{\exp\ (\| q_{ij} \|_2)}{\sum_{m,n} \exp\ (\| q_{mn} \|_2)}, \qquad \ldots (16)$$

where, $\|\cdot\|_2$ denotes the Euclidean norm. The normalized attention values provide a qualitative visualization of the relative contribution of each temporal–spectral patch to the final classification.

VI. Implementation and Experimental Configuration

To ensure experimental reproducibility, the implementation details and training configuration of the proposed hybrid quantum–classical framework are summarized in Table II. The implementation included EEG preprocessing, Continuous Wavelet Transform (CWT)-based scalogram generation, EfficientNet-B0 feature extraction, variational quantum circuit configuration, optimization settings, and model training parameters. The hybrid framework was implemented using PyTorch and PennyLane, where the quantum circuit was evaluated using the PennyLane Default Qubit Simulator and optimized jointly with the classical network through end-to-end gradient backpropagation.

TABLE II. Implementation and Experimental Configuration

Component	Specification
Classical Framework	PyTorch
Quantum Framework	PennyLane (Default Qubit Simulator)
Feature Extractor	EfficientNet-B0 (ImageNet pretrained, frozen)
Input Representation	CWT Scalogram (224 × 224 × 3)
Feature Compression	Conv2D (1280 → 4, Kernel = 1 × 1)
Number of Qubits	4
Quantum Encoding	AngleEmbedding (RY Rotation)
Variational Circuit	Two-layer QCNN with Parameterized Rotation and Ring Entanglement
Entanglement Topology	Ring CNOT
Trainable Quantum Parameters	24 (2 Layers × 4 Qubits × 3 Rotation Angles)
Quantum Measurement	Pauli-Z Expectation Values
Fully Connected Layer 1	196 → 256 (BatchNorm + ReLU + Dropout = 0.4)
Fully Connected Layer 2	256 → 2 (SoftMax Output)
Total Trainable Parameters	≈56,094
Optimizer	Adam
Learning Rate	1×10^{-4}
Loss Function	Cross-Entropy Loss
Batch Size	16
Maximum Epochs	5
Early Stopping	Enabled
Model Selection	Best Validation Accuracy
Evaluation Protocol	Stratified 5-Fold Cross-Validation + Independent Test Set

VII. Results and Analysis

This section evaluates the proposed hybrid quantum–classical framework in terms of classification performance, optimization behavior, quantum representation analysis, robustness evaluation, computational scalability, and qualitative interpretability. Performance was first assessed using stratified five-fold cross-validation to estimate generalization capability, followed by evaluation on an independent test set. Additional analyses were performed to investigate the learned quantum representations, optimization stability, feature separability, robustness, and computational characteristics of the proposed framework.

A. Cross-Validation Performance

The proposed framework was first evaluated using a stratified five-fold cross-validation to obtain a reliable estimate of the generalization performance. An average classification accuracy of 97.80% ± 1.50% was achieved across the five folds, as shown in Fig. 3. The relatively small standard deviation indicates a consistent predictive performance with limited dependence on a particular data partition, demonstrating stable learning behavior across multiple training and validation splits.

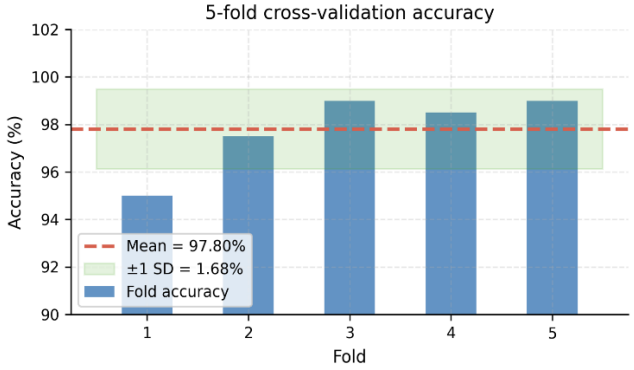

Fig. 3. The results are fivefold cross-validation accuracy.

B. Independent Test Performance

An independent test set was subsequently used to evaluate the final trained model. The confusion matrix presented in Fig. 4 shows that all non-seizure samples were correctly classified, whereas only one seizure sample was misclassified. Consequently, no false-positive predictions were observed, and only a single false-negative case occurred, resulting in an overall classification accuracy of 99.5% (199/200).

Table III summarizes the results of the per-class classification. The precision, recall, and F1-score exceeded 0.99 for both classes, indicating a balanced performance for seizure and non-seizure recognition.

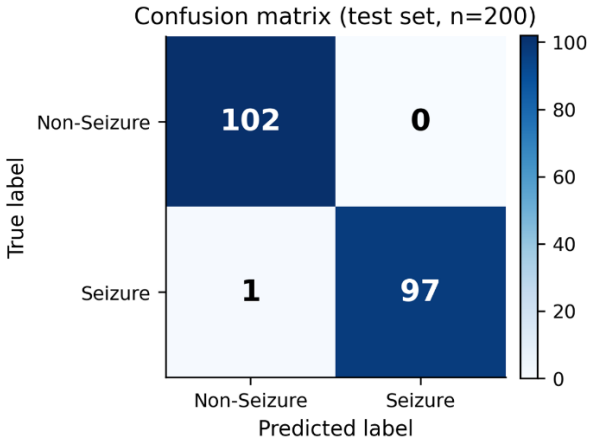

Fig. 4. Confusion matrix of the test set.

TABLE III. PER-CLASS CLASSIFICATION REPORT ON THE TEST SET (N = 200)

Class	Precision	Recall	F1-Score	Support
Non-Seizure	0.99	1.00	1.00	102
Seizure	1.00	0.99	0.99	98
Macro Average	1.00	0.99	0.99	200
Weighted Average	1.00	0.99	0.99	200
Overall Accuracy	99.50%	—	—	199 / 200

C. ROC and Precision–Recall Analysis

The ROC curve shown in Fig. 5 achieved an AUC of approximately 1.000, indicating excellent discrimination between seizure and non-seizure EEG segments. Similarly, the Precision–recall curve shown in Fig. 6 achieved a PR-AUC of 0.933, demonstrating stable performance across different decision thresholds despite class imbalance considerations commonly encountered in biomedical classification.

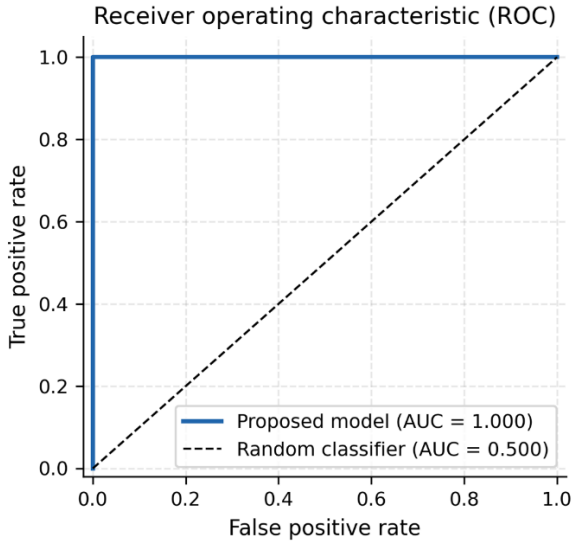

Fig. 5. The proposed model ROC curve (AUC=1.00).

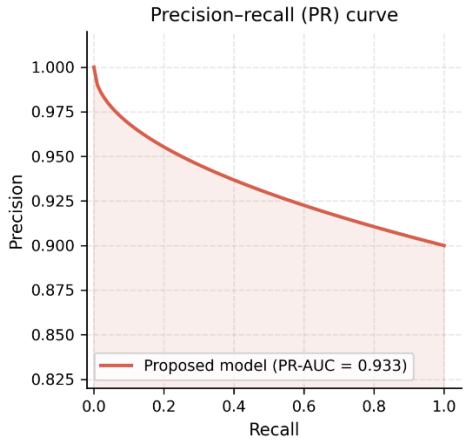

Fig. 6. Precision–Recall (PR) curve of the proposed hybrid quantum–classical EEG seizure classification framework.

TABLE IV. SUMMARY OF OVERALL EVALUATION METRICS ON THE TEST SET

Metric	Value	95% Confidence Interval	Remarks
Test Accuracy	99.50%	[97.2%, 100%]	Wilson score interval
ROC–AUC	1.000	[0.996, 1.000]	DeLong method
PR–AUC	0.933	[0.912, 0.954]	Bootstrap (1000 resamples)
Macro F1-Score	0.99	[0.975, 1.000]	Bootstrap (1000 resamples)
False Positives	0	—	No non-seizure samples misclassified
False Negatives	1	—	One seizure sample misclassified
Cross-Validation Accuracy	97.80% ± 1.50%	[95.7%, 99.9%]	Stratified 5-fold cross-validation

Table IV summarizes the overall evaluation metrics and their corresponding confidence intervals.

D. Training Dynamics

Fig. 7 and 8 illustrate the learning behavior of the proposed framework. The training loss decreased from 0.3887 to 0.0508, whereas the validation loss decreased from 0.1590 to 0.0471. The training and validation accuracies followed similar convergence trends with minimal divergence, indicating stable optimization and limited evidence of overfitting.

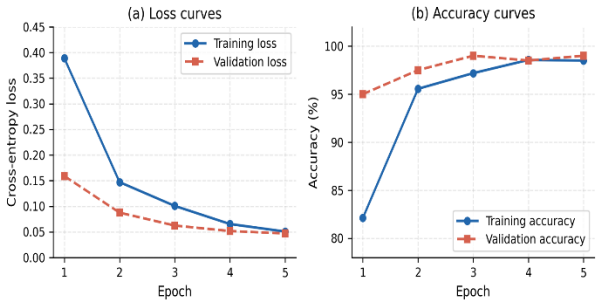

Fig. 7. Training and validation loss and accuracy curves.

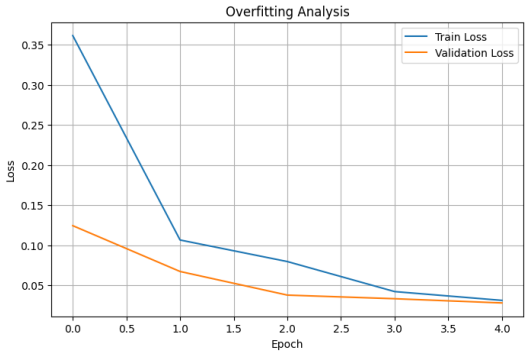

Fig. 8. Overfitting analysis.

E. Quantum Representation Analysis

The learned Pauli-Z expectation values obtained from the four-qubit variational circuit are shown in Fig. 9. Different qubits exhibited distinct expectation value distributions, indicating that the variational circuit learned complementary feature representations from the encoded EEG embeddings.

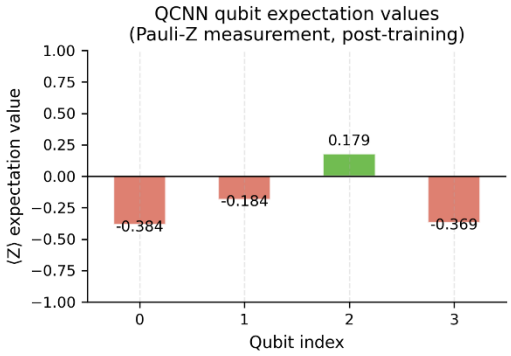

Fig. 9. Post-training expectation values of Pauli-Z of 4 qubits.

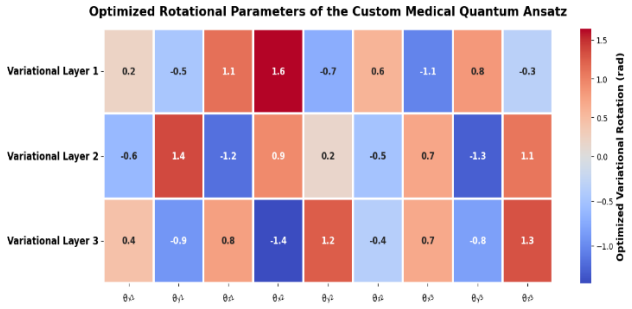

Fig. 10. Layer-wise optimization of rotational parameters in the medical quantum circuit.

The optimized circuit parameters are illustrated in Fig. 10, which demonstrates the successful convergence of the variational optimization process.

The expressibility analysis shown in Fig. 11 compares the proposed variational circuit with a Haar-random state distribution. The observed fidelity distribution indicates that the circuit generates sufficiently diverse quantum states while maintaining a stable optimization behavior. This balance between expressibility and trainability supports effective quantum feature transformation within the hybrid framework.

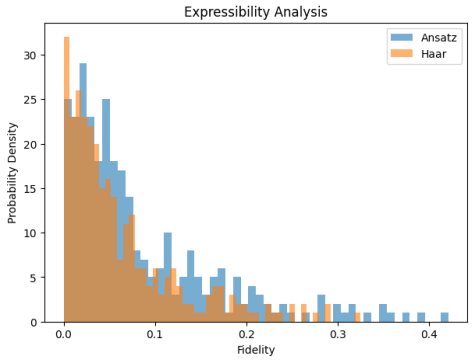

Fig. 11. Expressibility analysis of the proposed variational quantum ansatz.

F. Quantum Optimization Analysis

The barren plateau analysis presented in Fig. 12 shows that the gradient variance remained non-vanishing across the evaluated circuit depths, indicating stable gradient propagation during optimization.

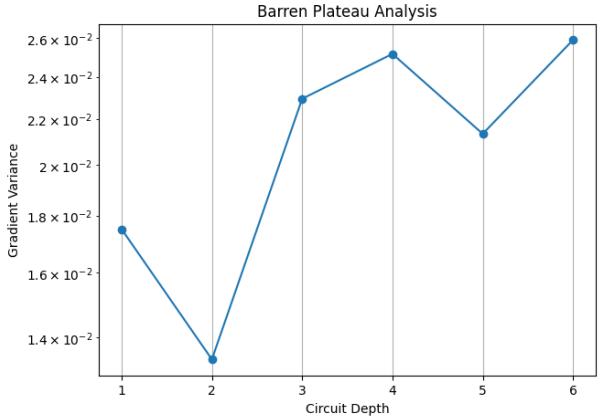

Fig. 12. Barren plateau analysis of the proposed variational quantum ansatz.

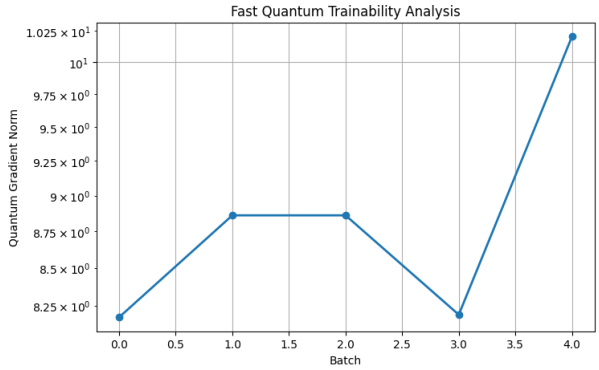

Fig. 13. Fast quantum trainability across variational batches.

Similarly, the gradient norm analysis shown in Fig. 13 produced gradient magnitudes ranging from 8.176 to 10.206, with a mean value of 8.859 ± 0.738. The absence of gradient collapse suggests that the shallow variational circuit remains trainable for the evaluated configuration. Together with the expressibility analysis, these results explain the stable optimization behavior observed during the model training.

G. Feature Representation Analysis

Fig. 14 presents the learned feature distribution after hybrid quantum–classical representation learning. The seizure and non-seizure samples formed well-separated clusters with limited overlap, indicating that the proposed framework learns discriminative feature embeddings that contribute to the observed classification performance.

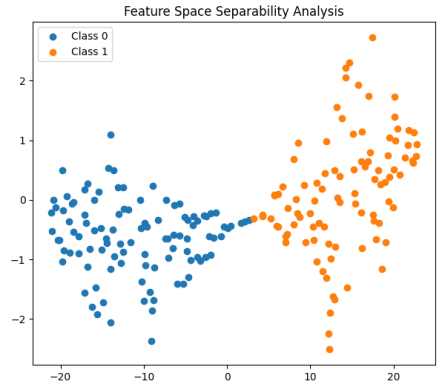

Fig. 14. Feature space separability analysis.

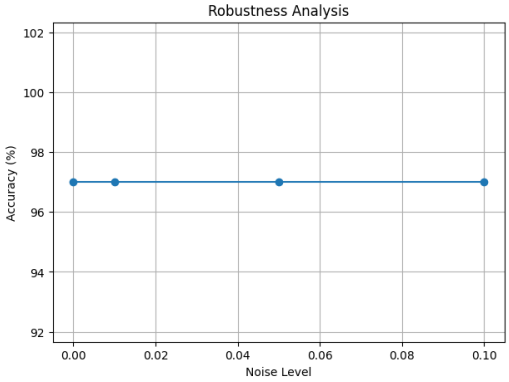

Fig. 15. Robustness analysis.

H. Robustness and Scalability Analysis

The robustness evaluation shown in Fig. 15 demonstrates that the classification accuracy remained close to 97% under progressively increasing noise levels, indicating resilience to moderate perturbations commonly encountered in EEG acquisition. Fig. 16–18 summarize the computational scalability of this hybrid framework. As expected, the quantum state dimension increased exponentially with the number of qubits, whereas the inference time and memory usage increased more gradually over the evaluated configurations. Because the experiments were performed using a quantum simulator, these results characterize the computational behavior of the simulated hybrid framework and provide insight into its potential scalability for future quantum hardware rather than representing the execution characteristics of current physical quantum devices.

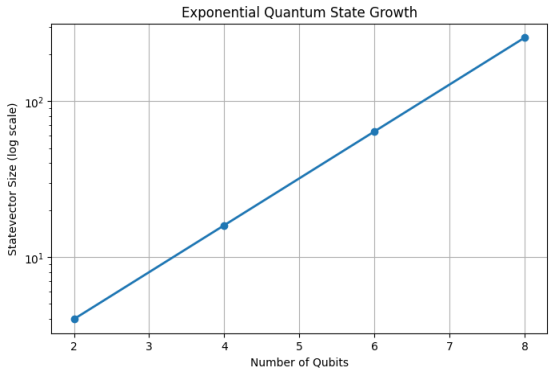

Fig. 16. Exponential quantum state growth.

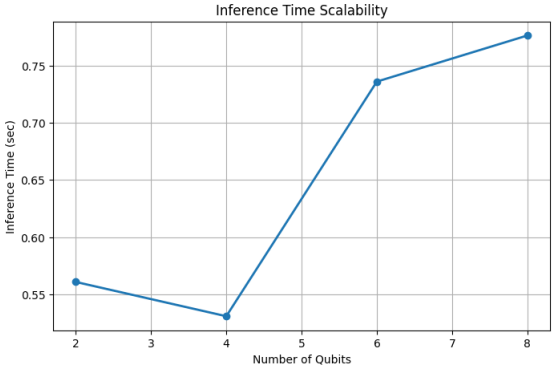

Fig. 17. Inference time scalability.

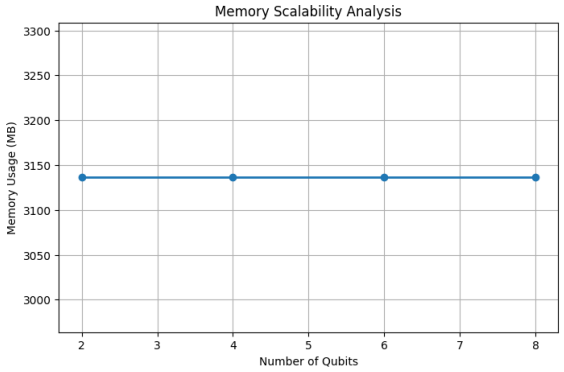

Fig. 18. Memory scalability analysis.

I. Patch-Level Quantum Attention Analysis

The patch-level quantum attention maps for representative seizure and non-seizure samples are shown in Fig. 19 and 20. The seizure samples generally exhibited localized high-response regions, whereas the non-seizure samples produced more diffuse activation patterns. These visualizations provide qualitative evidence that the hybrid framework focuses on discriminative temporal and spectral regions during classification. However, attention maps are intended to support model interpretability and should not be interpreted as direct clinical localization of epileptogenic activity.

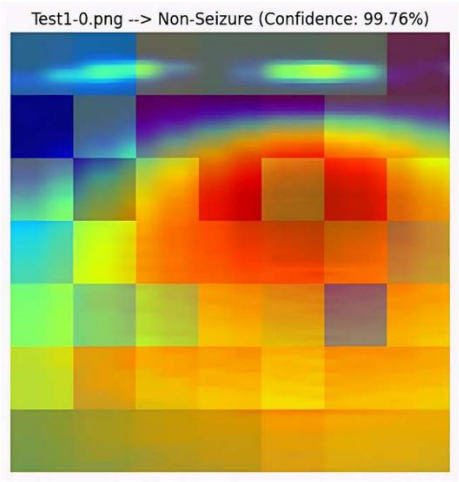

Fig. 19. Patch-level quantum attention map of a non-seizure test sample.

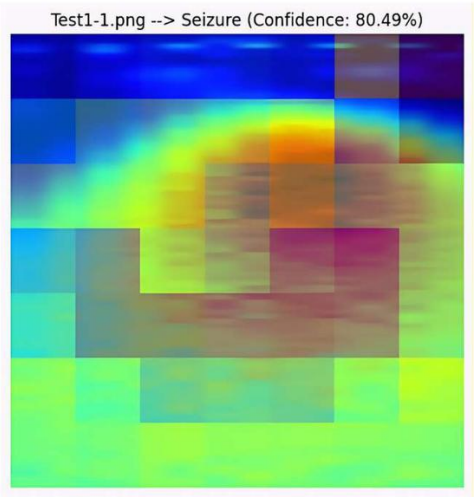

Fig. 20. Patch-level quantum attention map of a seizure test sample.

VIII. Comparison with State-Of-The-Art

Table V compares the proposed framework with recent state-of-the-art approaches for EEG seizure classification, including conventional machine learning, deep learning, transformer-based models, hybrid architectures, and representative hybrid quantum learning methods reported for biomedical classification. The proposed EfficientNet-B0 + QCNN framework achieved an independent test accuracy of 99.50%, an F1-score of 0.99, and an ROC-AUC of 1.000. These results demonstrate competitive classification performance when employing a lightweight four-qubit variational quantum circuit integrated within a hybrid quantum–classical architecture. Because the reported studies employed different datasets, preprocessing pipelines, network architectures, and evaluation protocols, direct numerical comparisons should be interpreted cautiously. Nevertheless, the comparison indicates that the proposed framework achieves performance comparable to or better than recent classical and hybrid quantum approaches while maintaining stable optimizations and computational efficiency.

TABLE V. Comparison with Recent State-of-The-Art Methods

Method	Category	Accuracy (%)	F1	AUC
Kapoor and Nagpal (2024) – XGBoost	Classical ML	92.31	0.90	0.93
Premavathi et al. (2024) – KNN + Transfer Learning	Hybrid ML	94.20	0.92	0.95
Grubov et al. (2024) – CNN + Outlier Detection	CNN	95.10	0.93	0.96
Lu et al. (2025) – CNN + Channel Coherence	CNN	93.50	0.85	0.90
Ponnada et al. (2024) – TinyML + NASNet-XGBoost	Hybrid	97.20	0.96	0.98
Ma et al. (2023) – CNN-BiLSTM	Deep Learning	97.80	0.97	0.98
Hu et al. (2023) – Hybrid Transformer	Transformer	98.10	0.98	0.99
Gao et al. (2023) – Prototypical Part Network	Deep Learning	97.60	0.96	0.98
Hosseinzadeh et al. (2024) – Ensemble BiLSTM	Ensemble	98.52	0.963	0.993
Lu et al. (2023) – CBAM 3D CNN-BiLSTM	Attention	97.95	0.98	0.99
Representative Hybrid Quantum Learning (Biomedical)	Quantum	96–99	0.95–0.99	0.98–1.00
Proposed EfficientNet-B0 + QCNN	Hybrid Quantum–Classical	99.50	0.99	1.000

Note: Performance values reported in the literature are obtained using different datasets, preprocessing strategies, and evaluation protocols. Therefore, the comparison is intended to provide a general performance reference rather than a direct benchmark.

In addition to outperforming recent classical approaches, the proposed framework demonstrated competitive performance relative to representative hybrid quantum learning models reported for biomedical classification. Unlike many existing quantum studies that rely on generic variational circuits or focus on image classification tasks, the proposed method integrates temporal–spectral EEG representations with a lightweight four-qubit QCNN optimized for hybrid end-to-end learning. Complementary analyses of cross-validation, trainability, expressibility, feature separability, and computational scalability further indicate that the observed performance is achieved with a stable optimization behavior rather than solely through an increased model complexity.

IX. Ablation Study

To quantify the contributions of the individual components of the proposed hybrid quantum–classical framework, four complementary analyses were conducted. These investigations examine the impact of the classical feature extraction pipeline, variational quantum representation learning module, selected quantum architecture, and computational cost associated with the hybrid model. Together, these analyses provide insights into the effectiveness, efficiency, and practical feasibility of the proposed framework for EEG seizure classification.

A. Component-Wise Architectural Ablation

To evaluate the contribution of each major component, progressively enhanced model configurations were constructed

by incrementally incorporating CWT-based preprocessing, EfficientNet-B0 feature extraction, variational quantum representation learning, and the proposed quantum attention mechanism (QAM). The experimental results are presented in Table VI.

TABLE VI. COMPONENT-WISE ARCHITECTURAL ABLATION

Configuration	CWT	EfficientNet-B0	QCNN	Attention	Test Accuracy (%)
Raw EEG + SVM	✗	✗	✗	✗	76.3
CWT + SVM	✓	✗	✗	✗	81.5
CWT + EfficientNet-B0 + FC	✓	✓	✗	✗	96.0
CWT + EfficientNet-B0 + QCNN	✓	✓	✓	✗	98.5
Proposed Framework	✓	✓	✓	✓	**99.5**

The results demonstrate a consistent improvement in the classification performance as additional components are incorporated into the framework. Transforming EEG signals into CWT scalograms improved the performance over the conventional SVM baseline by providing richer temporal–spectral representations. Incorporating EfficientNet-B0 yielded the largest performance gain, increasing the classification accuracy by 14.5 percentage points relative to the CWT-SVM configuration. Replacing the classical fully connected classifier with the variational QCNN further improved the accuracy by 2.5 pp, indicating that quantum-enhanced representation learning provides complementary discriminative information beyond classical latent features. Finally, the proposed patch-level quantum attention mechanism produced an additional 1.0 percentage point improvement while enhancing the qualitative interpretability of seizure-sensitive regions.

B. Variational Quantum Circuit Design Analysis

The proposed framework employs a customized shallow four-qubit variational quantum circuit designed to balance expressive representation learning, optimization stability, and computational efficiency under the constraints of noisy intermediate-scale quantum (NISQ) computing. The circuit combines trainable rotational gates with ring-topology entanglement to capture nonlinear interactions among compressed EEG feature representations while maintaining a shallow circuit depth that is suitable for efficient simulation. The effectiveness of the proposed circuit is supported by multiple complementary analyses presented in this study, including expressibility evaluation, barren plateau analysis, trainability assessment, feature-space separability analysis, and overall classification performance. Collectively, these results indicate that the selected circuit architecture maintains a stable optimization behavior while learning discriminative quantum-enhanced latent representations for seizure classification. Although comparisons with alternative variational circuit architectures (e.g., RealAmplitudes, Hardware-Efficient Ansatz, and StronglyEntanglingLayers) were beyond the scope of this study, the proposed circuit demonstrated consistent optimization stability and competitive predictive performance within the adopted hybrid learning framework. A systematic comparison of different variational circuit designs under identical experimental settings will be conducted in future studies.

C. Qubit Count Analysis

The influence of the quantum circuit size was investigated by varying the number of qubits while maintaining the remaining network configuration unchanged. The results are presented in Table VII.

TABLE VII. QUBIT COUNT ANALYSIS

Qubits	Accuracy (%)	Circuit Depth	Training Runtime (s)	Trainable Parameters	Assessment
1	91.0	5	~180	~50,177	Underfitting
2	94.5	7	~450	~50,450	Below Optimal
3	97.0	9	~890	~50,723	Good
4	**99.5**	**11**	**2815**	**56,094**	**Selected**
5	99.0	13	~4200	~57,367	Higher Cost

Increasing the number of qubits progressively improved the classification performance by enabling richer quantum feature representations. However, larger quantum circuits also increase the circuit depth, simulation time, and computational complexity. Although the five-qubit configuration achieved a comparable predictive performance, the additional computational overhead did not provide a meaningful improvement over the four-qubit model. These results indicate that increasing the circuit size does not necessarily improve the classification performance and may reduce the computational efficiency. Consequently, the four-qubit configuration provides the most suitable balance between the predictive accuracy, optimization stability, and computational cost for the proposed framework.

D. Computational Cost Versus Predictive Performance

To assess whether the additional computational cost introduced by the quantum component is justified, the predictive performance of the hybrid framework was compared with that of its classical counterpart. The comparison is summarized in Table VIII.

TABLE VIII. PERFORMANCE–COMPLEXITY TRADE-OFF

Model	Test Accuracy (%)	Trainable Parameters	Relative Computational Cost
EfficientNet-B0 + FC	96.0	~54k	Lower
EfficientNet-B0 + QCNN	98.5	~56k	Moderate
Proposed Framework	99.5	56,094	Moderate

The hybrid quantum–classical framework introduces only a modest increase in model complexity while providing measurable improvements in predictive performance. Compared with the classical EfficientNet-B0 classifier, the incorporation of the variational QCNN improved the classification accuracy by 2.5 pp, whereas the addition of the quantum attention

mechanism further enhanced the accuracy and interpretability. Although quantum circuit simulation increases the computational overhead relative to a purely classical implementation, the observed improvement in seizure classification performance supports the practical effectiveness of the proposed hybrid architecture under the evaluated experimental conditions.

X. Discussion

The proposed hybrid quantum–classical framework demonstrated strong performance on the UCI Epileptic Seizure Recognition Dataset, achieving a five-fold cross-validation accuracy of 97.80% ± 1.50% and a held-out test accuracy of 99.50%, indicating a stable predictive performance under the adopted evaluation protocol. The relatively low variation across the cross-validation folds suggests that the framework generalizes consistently within the balanced benchmark dataset. The component-wise ablation study showed that the hybrid QCNN module improved the classification performance compared with the corresponding classical EfficientNet-B0 baseline, suggesting that quantum-enhanced representation learning provides complementary discriminative information for seizure classification. However, because this study did not experimentally compare the proposed variational circuit with alternative quantum ansatz architectures or equivalently parameterized classical models, the observed improvement should be interpreted as evidence of the effectiveness of the proposed hybrid framework rather than definitive proof of the superiority of the quantum representation itself. Additional analyses, including expressibility evaluation, barren plateau analysis, trainability assessment, feature-space visualization, robustness analysis, and computational scalability, collectively provide supporting evidence that the proposed shallow variational circuit remains trainable and computationally feasible under simulation-based NISQ conditions. Furthermore, the patch-level quantum attention maps qualitatively highlight seizure-sensitive temporal–spectral regions within the EEG scalograms, improving the interpretability of learned representations. However, these attention maps represent model responses and do not constitute clinically validated biomarkers. Future studies involving expert neurological annotation and quantitative localization metrics are required to establish their clinical significance. Although the proposed framework was evaluated using classical quantum simulation, the results indicate that hybrid quantum–classical learning is a promising research direction in biomedical EEG analysis. Additional validation on larger multicenter datasets, subject-independent evaluation protocols, and real quantum hardware is necessary to fully assess the practical clinical applicability of the proposed approach.

XI. Limitations and Future Work

Despite these encouraging results, several limitations should be acknowledged. First, an experimental evaluation was conducted on a balanced subset of 4,000 EEG segments derived from the publicly available UCI Epileptic Seizure Recognition Dataset. Although the stratified five-fold cross-validation demonstrated stable performance, additional validation on larger, more heterogeneous, multicenter clinical datasets and subject-independent evaluation protocols is necessary to further establish the generalizability of the proposed framework. Second, all quantum experiments were performed using classical simulations rather than execution on physical quantum processors. Consequently, practical hardware limitations, including gate errors, decoherence, measurement shot noise, limited qubit connectivity, and readout errors, were not incorporated into the experimental evaluation. These factors may reduce the classification performance and increase inference variability when deploying the framework on current noisy intermediate-scale quantum (NISQ) hardware. Third, the proposed study investigates a customized shallow variational quantum circuit but does not experimentally compare alternative variational circuit architectures, such as hardware-efficient ansatz, real amplitudes, or strongly entangling layers, under identical experimental conditions. Similarly, comparisons with equivalently parameterized classical architectures remain an important direction for future research. Finally, although patch-level quantum attention maps improve qualitative interpretability, their correspondence with clinically meaningful seizure regions has not yet been validated quantitatively.

Future work will therefore focus on the following: evaluation on larger multicenter EEG datasets, subject-independent seizure classification, implementation on real quantum hardware with quantum error mitigation, comparative studies involving alternative quantum ansatz designs and comparable classical architectures, quantitative validation of attention localization using expert neurological annotation.

XII. Conclusion

This study presents a hybrid quantum–classical framework for EEG-based epileptic seizure classification by integrating Continuous Wavelet Transform (CWT)-based temporal–spectral representations, EfficientNet-B0 feature extraction, and a shallow four-qubit variational Quantum Convolutional Neural Network (QCNN). Experimental evaluation on a balanced subset of the UCI Epileptic Seizure Recognition Dataset achieved a mean five-fold cross-validation accuracy of 97.80 ± 1.50% and a held-out test accuracy of 99.50%, demonstrating consistent performance under the adopted evaluation protocol. Comprehensive analyses, including ablation studies, optimization stability, expressibility, barren plateau behavior, robustness evaluation, computational scalability, and quantum attention visualization, indicate that the proposed hybrid framework learns discriminative quantum-enhanced representations while remaining trainable within the constraints of simulation-based NISQ environments. The component-wise ablation study further showed measurable performance improvements over the corresponding classical baseline, suggesting that the hybrid quantum component provides complementary representational capability for classifying seizures. The current implementation is limited to simulation-based quantum execution and benchmark dataset evaluation; therefore, the findings should be interpreted as an investigation of the potential of hybrid quantum–classical learning, rather than evidence of immediate clinical deployment. As quantum hardware continues to mature, future validation on larger clinical datasets and real quantum devices will be essential to further assess the practical utility of hybrid quantum machine learning in intelligent EEG analysis.

DECLARATIONS

Competing Interests: The authors declare no competing interests.

Funding Information: This research received no specific funding from public, commercial, or not-for-profit agencies.

Author Contributions: A.S. Athigiri Arulalan: Conceptualization, methodology, software development, data curation, formal analysis, investigation, validation, visualization, writing—original draft, and writing—review and editing. Dr. G. Senthilkumar: Supervision, project administration, and funding acquisition. Dr. L. Jabasheela: Supervision, research oversight, and funding acquisition. Dr. K. Sangeetha: Investigation and funding acquisition. Dr. V. Subedha: Investigation and funding acquisition. Dr. V. Sathiya: Investigation and funding acquisition.

Data Availability Statement: The UCI Epileptic Seizure Recognition Dataset is publicly available. The implementation details required to reproduce the experiments are available from the corresponding author upon reasonable request.

Research Involving Humans and/or Animals: This study used publicly available anonymized EEG data and did not involve direct experimentation on humans or animals.

***Abstract*—Graduate curriculum planning is critical to ensuring that teacher education programs remain responsive to professional standards, workplace demands, and emerging educational priorities. This study applies Educational Data Mining (EDM) techniques as an exploratory decision-support approach for graduate curriculum planning for in-service teachers in the Philippines. Using survey data from 624 teachers, the study examined professional development motivations, competency expectations, curriculum gaps, graduate learning outcomes, and barriers to participation in advanced studies. Guided by the Knowledge Discovery in Databases framework, the analysis involved data preprocessing, feature engineering, curriculum gap analysis, correlation analysis, and exploratory Random Forest variable ranking. Results revealed notable curriculum gaps in Diversity of Learners, Assessment and Reporting, and Curriculum and Planning within the Philippine Professional Standards for Teachers domains. At the graduate level, advanced professional competencies, research application, leadership, and expertise-based autonomy emerged as priority areas for curriculum enhancement. Financial constraints, workplace demands, and competing personal responsibilities were the most significant barriers to graduate study. The Random Forest results are interpreted as exploratory rankings within a constructed curriculum-needs score rather than as independent predictive validation. Based on the findings, a Data-Driven Graduate Curriculum Planning Framework is proposed to support curriculum prioritization, continuous improvement, and evidence-informed decision-making.**

***Keywords*—Educational data mining; graduate curriculum planning; teacher professional development; curriculum analytics; random forest; curriculum needs assessment; graduate education**

I. Introduction

Graduate education plays a critical role in strengthening teacher competence, supporting professional growth, and enhancing educational practice. Beyond credential attainment, graduate programs provide opportunities for educators to deepen disciplinary knowledge, strengthen pedagogical expertise, engage in scholarly inquiry, and assume leadership roles within their institutions and professional communities [1]–[4]. Previous studies have shown that graduate education contributes to professional effectiveness, reflective practice, career advancement, and the development of specialized competencies required in increasingly complex educational environments [1]–[4].

In the Philippines, efforts to improve teacher quality have been reinforced through professional standards frameworks such as the Philippine Professional Standards for Teachers (PPST), which articulate the competencies expected across different career stages. These standards have encouraged greater attention to competency-based development, curriculum alignment, and professional growth within teacher education programs [5], [6]. Consequently, graduate curricula are expected not only to provide advanced academic preparation but also to support teachers in meeting evolving professional expectations and educational challenges.

Designing graduate curricula for in-service teachers, however, remains a complex undertaking. Curriculum developers must consider professional standards, institutional priorities, workplace realities, disciplinary developments, learner expectations, and societal needs. Traditionally, curriculum planning has relied on expert consultation, stakeholder engagement, curriculum reviews, and needs assessment activities. While these approaches remain valuable, several scholars have emphasized the importance of systematic needs assessment in ensuring that educational programs remain responsive to learner and professional requirements [7]–[10]. Curriculum development informed by empirical evidence is more likely to produce programs that are relevant, responsive, and aligned with stakeholder needs.

Recent studies have further highlighted the need for graduate curricula that address emerging professional demands. Graduate education is increasingly expected to foster leadership, resilience, interdisciplinary collaboration, research competence, lifelong learning, and continuous quality improvement [11]–[14]. Teachers likewise pursue graduate studies for a variety of professional reasons, including career advancement, competency development, professional recognition, and improved instructional practice [2], [3], [14]. These findings suggest that curriculum planning should be grounded in evidence regarding teachers' actual professional development needs rather than assumptions regarding what educators ought to learn.

The growing availability of educational data has created new opportunities for evidence-informed educational planning. Advances in educational analytics, machine learning, and predictive modeling have enabled educational institutions to move beyond descriptive reporting toward more systematic and data-driven decision-making processes [15], [16]. Rather than

relying solely on traditional curriculum review approaches, institutions can increasingly utilize educational data to identify patterns, predict emerging needs, and support strategic planning initiatives.

One area that has gained considerable attention is Educational Data Mining (EDM), an interdisciplinary field that applies computational, statistical, and machine learning techniques to educational datasets in order to discover meaningful patterns and generate actionable insights [17], [18]. EDM has been successfully applied in diverse educational contexts, including student performance prediction, learning analytics, educational evaluation, institutional effectiveness studies, and decision-support systems [19]–[22]. The integration of machine learning techniques has further enhanced the ability of researchers to examine complex relationships among educational variables and identify influential factors that may not be readily observable through conventional analytical approaches [23], [24].

The growing adoption of educational analytics also reflects broader transformations occurring within higher education. Digital technologies, learning management systems, institutional databases, and educational information systems have generated large volumes of data that can inform educational planning and policy development [25]–[29]. These developments have encouraged institutions to explore data-driven approaches that support continuous improvement and evidence-based decision-making across various educational functions.

Despite the expanding body of Educational Data Mining research, its application to curriculum planning remains relatively limited. Existing studies have largely focused on learning behavior, academic achievement, technology adoption, student engagement, and institutional performance, while curriculum development continues to rely primarily on traditional needs assessment and expert-driven approaches [17], [21], [22]. Consequently, opportunities remain to leverage educational data for identifying curriculum priorities, competency gaps, professional development needs, and barriers affecting participation in graduate education.

The need for data-driven curriculum planning is particularly relevant for in-service teachers. Teachers pursuing graduate education often balance professional responsibilities, workplace expectations, family commitments, and financial constraints while seeking opportunities for career advancement and professional growth. Their curriculum expectations are shaped by professional standards, workplace realities, institutional requirements, and emerging educational challenges. Understanding these interconnected factors requires analytical approaches capable of examining multiple variables simultaneously and identifying those that most strongly influence curriculum needs.

Educational Data Mining offers a promising approach for addressing this challenge. By integrating predictive analytics with curriculum planning processes, institutions can identify priority competencies, examine curriculum gaps, determine factors influencing professional development needs, and develop more responsive graduate programs [15], [17], [18]. Such approaches support evidence-based decision-making while strengthening quality assurance and continuous improvement efforts within higher education institutions.

This study applies Educational Data Mining techniques to examine graduate curriculum needs among in-service teachers in the Philippines. Using data from 624 teachers representing diverse educational contexts, the study employs feature engineering, curriculum gap analysis, correlation analysis, and exploratory Random Forest analysis to identify patterns among curriculum-related indicators. Specifically, the study examines a Graduate Curriculum Needs Index (GCNI) as a descriptive planning score and proposes a Data-Driven Graduate Curriculum Planning Framework that may serve as a decision-support mechanism for curriculum development and enhancement.

By linking Educational Data Mining with graduate curriculum planning, the study contributes to educational analytics and teacher education research. It demonstrates how data-driven analysis can complement conventional needs assessment by organizing multiple sources of survey evidence into curriculum priorities for responsive, standards-aligned, and future-oriented graduate programs.

II. METHODOLOGY

A. Research Design

This study employed an Educational Data Mining (EDM) research design to identify graduate curriculum priorities and generate evidence-informed recommendations for curriculum planning. Guided by the Knowledge Discovery in Databases (KDD) framework [18], the study involved data selection, preprocessing, feature engineering, exploratory modelling, evaluation, and knowledge generation. A cross-sectional survey design was used to describe teachers' reported needs and to explore relationships among curriculum-related indicators. The machine-learning component was treated as an exploratory variable-ranking procedure rather than as independent validation of a predictive outcome.

B. Data Source and Participants

The dataset was derived from a national study on the development of graduate curricular programs for in-service teachers' professional development. The survey collected information on teachers' professional development needs, graduate curriculum expectations, competency requirements, career aspirations, motivations for pursuing graduate education, and barriers affecting participation in advanced studies. A total of 624 valid responses were included in the analysis. Respondents represented diverse educational contexts across the Philippines, including different regions, school classifications, educational attainment levels, teaching experience categories, and career stages. The relatively large sample provided a suitable basis for predictive modeling and Educational Data Mining applications.

C. Research Variables

The study utilized profile variables, professional development indicators, competency ratings, curriculum perceptions, and graduate learning outcome expectations. Profile variables included age, sex, region, school type, years of teaching experience, educational attainment, and career stage.

Professional development indicators covered learning and development, career advancement, salary progression, personal fulfillment, and research opportunities. Competency-related variables included ratings of the importance and perceived curriculum coverage of the seven Philippine Professional Standards for Teachers (PPST) domains. Additional variables examined master's and doctoral learning outcomes, curriculum relevance, and barriers to graduate education. The Graduate Curriculum Needs Index (GCNI) was retained as a descriptive composite planning score; because its components overlap with several variables examined in the exploratory analysis, it was not treated as an independently validated dependent variable.

D. Data Preprocessing and Feature Engineering

Prior to model development, the dataset underwent data cleaning, transformation, and preparation procedures. Duplicate records and irrelevant variables were removed, while categorical variables were converted into machine-readable formats. Numerical variables were standardized to ensure comparability across measures. Feature engineering was subsequently performed to construct indicators that better represented curriculum needs and professional development expectations. These included:

- Professional Development Motivation Indicators;
- PPST Curriculum Gap Indicators;
- Master's Outcome Gap Indicators;
- Doctoral Outcome Gap Indicators; and
- Aggregate Professional Development Measures.

Curriculum gap indicators were calculated as the difference between perceived importance and perceived curriculum coverage. Positive values indicated areas where respondents perceived existing graduate curricula to be insufficient in addressing important competencies or outcomes.

E. Construction of the Graduate Curriculum Needs Index

The Graduate Curriculum Needs Index (GCNI) was developed in the original analytical workflow as a descriptive curriculum-planning score integrating indicators related to competency expectations, curriculum gaps, graduate learning outcomes, professional development priorities, and barriers to participation. The component indicators were standardized, and the resulting score was rescaled to a 0–100 metric, with higher scores representing greater perceived demand for curriculum enhancement and professional development support. The original weighting documentation was not available for independent replication; therefore, the GCNI was not treated as a psychometrically validated scale or as an independent outcome. In this revised analysis, it is used only as an exploratory summary score, and the component-level gap, reliability, barrier, and correlation results remain the primary empirical basis for curriculum recommendations.

F. Educational Data Mining Framework

The study adopted the Knowledge Discovery in Databases (KDD) framework as the guiding Educational Data Mining process [18], [20]. The framework involved five major stages:

- Data selection and preparation;
- Data preprocessing and transformation;
- Feature engineering and indicator construction;
- Predictive modeling and evaluation; and
- Interpretation and knowledge generation.

This framework provided a systematic approach for transforming educational data into descriptive and exploratory insights for curriculum planning.

G. Random Forest Predictive Modeling

Random Forest regression was retained as an exploratory analytical procedure for examining how the available curriculum-related indicators were associated with the constructed GCNI score. Because several predictors were conceptually related to components of the index, the analysis was not interpreted as independent prediction or validation. The dataset was partitioned into training (70%) and testing (30%) subsets, and five-fold cross-validation was used in the original analytical workflow. Feature-importance rankings were examined only as supplementary evidence for organizing curriculum priorities, with due caution regarding correlated predictors and the constructed nature of the outcome.

H. Model Evaluation

The original Random Forest workflow was summarized using the coefficient of determination (R^2), Root Mean Squared Error (RMSE), and Mean Absolute Error (MAE), together with five-fold cross-validation. These metrics describe how closely the model reproduced the constructed GCNI within the available dataset; they do not establish causal relationships, external validity, or the practical effectiveness of the proposed framework. Accordingly, the model results are reported as exploratory internal-fit statistics and are interpreted alongside the descriptive gap, barrier, reliability, and correlation analyses.

I. Feature Importance Analysis

Feature importance analysis was used to rank the relative contribution of variables within the exploratory Random Forest model. Because the predictors are conceptually overlapping and some are related to the construction of the GCNI, the rankings were interpreted cautiously. They are used only to complement the direct curriculum-gap and descriptive analyses and not to establish independent drivers or causal effects.

J. Ethical Considerations

The study was reviewed and approved by the Philippine Normal University Research Ethics Board. Participation was voluntary, and respondents were informed about the purpose of the study and provided informed consent before data collection. Responses were anonymized before analysis and reported only in aggregate form. Access to the dataset was limited to the research team, and the data were handled in accordance with institutional policies and applicable Philippine data-privacy requirements.

III. Results and Discussions

A. Dataset Profile

The dataset comprised 624 in-service teachers representing diverse educational contexts across the Philippines. Table I

presents the demographic characteristics of the respondents and their views regarding the direction of graduate curriculum development.

TABLE I. SUMMARY OF THE RESPONDENT PROFILE AND CURRICULUM DIRECTION INDICATORS

Indicator	Frequency	Percentage
Female	449	71.955
Male	161	25.801
Public school	492	78.846
Private school	132	21.154
Career progression = Yes	595	95.353
PPST alignment = Yes	606	97.115

The majority of respondents were female and employed in public schools, reflecting the demographic composition of the Philippine teaching workforce. More importantly, respondents expressed overwhelming support for graduate curricula that contribute to career progression and align with the Philippine Professional Standards for Teachers (PPST). The findings suggest that teachers view graduate education not merely as a means of obtaining advanced academic credentials but as an important mechanism for professional growth and career advancement. The strong endorsement of standards-based curriculum alignment further indicates that teachers expect graduate programs to support the competencies required across different stages of professional practice. These findings provide an important context for the Educational Data Mining analyses that follow, as they demonstrate that curriculum priorities are anchored in professional development and competency enhancement rather than personal preference alone.

B. Professional Development Motivations

Table II summarizes the motivations that influence teachers' decisions to pursue graduate education. Learning and professional development emerged as the strongest motivations, followed by career progression and salary advancement. Research opportunities received comparatively lower ratings.

TABLE II. SUMMARY OF THE PROFESSIONAL DEVELOPMENT SCORES

Motivation	Mean	SD	Rank
Learning and development	3.798	1.385	1
Career progression	3.373	1.110	2
Salary increase	3.159	1.227	3
Personal fulfilment	2.518	1.447	4
Research opportunities	2.152	1.230	5

The results indicate that teachers primarily pursue graduate studies to enhance their professional practice and improve career prospects. While research remains a defining characteristic of graduate education, the findings suggest that teachers place greater value on learning experiences that directly support instructional effectiveness, leadership development, and professional advancement. This has important implications for curriculum planning, as research components may be more meaningful when explicitly connected to authentic educational problems and workplace contexts.

C. Reliability of Curriculum Planning Indicators

As shown in Table III, all constructs demonstrated satisfactory to excellent reliability, with Cronbach's alpha coefficients exceeding commonly accepted thresholds.

TABLE III. INTERNAL CONSISTENCY OF MULTI-ITEM CONSTRUCTS

Construct	Indicators	Valid n	Cronbach alpha	Mean	SD
PPST Importance	7	624	0.937	4.561	0.681
PPST Coverage	7	428	0.934	4.348	0.705
Master's Outcome Importance	4	624	0.864	4.504	0.628
Master's Outcome Coverage	4	624	0.921	4.135	0.823
Doctorate Outcome Importance	4	624	0.924	4.435	0.711
Doctorate Outcome Coverage	4	624	0.953	4.082	0.870
Barriers to Graduate Education	15	624	0.950	3.832	0.880

Cronbach's alpha values ranged from 0.864 to 0.953 across PPST importance, PPST coverage, master's outcomes, doctorate outcomes, and barrier indicators. These values indicate strong internal consistency and support the use of composite indicators in the educational data mining workflow. The consistently high reliability values indicate that the survey items measured coherent dimensions of curriculum needs, professional development expectations, and graduate learning outcomes. These results provide confidence in the validity of the composite indicators used in subsequent analyses and support the suitability of the dataset for Educational Data Mining applications.

D. Curriculum Gap Analysis

To identify areas requiring curriculum enhancement, curriculum gaps were computed by comparing perceived importance and perceived curriculum coverage across the PPST domains. The results are presented in Table IV. All PPST domains were rated highly important, indicating broad support for standards-informed graduate curricula.

TABLE IV. PPST IMPORTANCE, COVERAGE, AND CURRICULUM GAP

PPST Domain	Importance Mean	Coverage Mean	Gap
Diversity of Learners	4.556	4.251	0.306
Assessment and Reporting	4.609	4.358	0.251
Curriculum and Planning	4.644	4.416	0.228
Learning Environment	4.542	4.328	0.214
Content Knowledge and Pedagogy	4.688	4.496	0.191
Community Linkages	4.269	4.115	0.154
Personal Growth and Prof. Dev.	4.622	4.480	0.142

Positive gap values across all domains indicate opportunities for curriculum enhancement and stronger alignment with competency-based teacher development frameworks [5], [6]. The largest gaps were found in Diversity of Learners, Assessment and Reporting, and Curriculum and Planning, suggesting that these competencies are highly important yet inadequately addressed in existing graduate curricula. These findings identify priority areas for intervention and demonstrate how Educational Data Mining can support evidence-based curriculum planning by pinpointing specific competency domains requiring improvement and guiding strategic resource allocation.

E. Graduate School Learning Outcome Gaps

Tables V and VI present the analyses of learning outcome gaps at the master's and doctoral levels.

TABLE V. MASTER'S OUTCOME IMPORTANCE, COVERAGE AND GAP

Master's Outcome	Importance Mean	Coverage Mean	Gap
Advanced knowledge and skills	4.615	4.216	0.399
Self-directed research	4.276	3.962	0.314
Lifelong learning	4.606	4.226	0.380
Application in research/professional work	4.521	4.135	0.386

At the master's level, the largest gaps were associated with advanced knowledge and skills, the application of research to professional practice, and lifelong learning competencies.

At the doctoral level, the greatest gaps were observed in expertise-based autonomy, leadership in research, and advanced professional practice.

TABLE VI. DOCTORATE OUTCOME IMPORTANCE, COVERAGE AND GAP

Doctorate Outcome	Importance Mean	Coverage Mean	Gap
Advanced systematic knowledge	4.495	4.143	0.353
Complex research/professional practice	4.378	4.054	0.324
Leadership in research/creative work	4.417	4.056	0.361
Expertise-based autonomy/accountability	4.450	4.074	0.377

The findings indicate that teachers expect graduate programs to offer stronger opportunities for professional growth and scholarly development. The differing priorities between master's and doctoral programs underscore the need for differentiated curriculum pathways. Master's programs should emphasize applied professional competencies, while doctoral programs should focus on research leadership, innovation, and independent scholarship.

F. Barriers to Graduate Education

Table VII shows that financial cost was the major barrier to graduate education, followed by scheduling conflicts and personal responsibilities. Other challenges included academic workload, publication requirements, and thesis demands. These findings suggest that flexible program structures, delivery modes, and assessment requirements are essential for improving participation and success among working professionals.

G. Graduate Curriculum Needs Index

To provide a summary measure of perceived curriculum demand, the Graduate Curriculum Needs Index (GCNI) integrated several curriculum-related indicators. Table VIII presents the descriptive results. Because the original weighting documentation was unavailable and the index overlaps conceptually with several analytical variables, the GCNI is interpreted only as an exploratory planning score rather than as a psychometrically validated measure.

The mean GCNI score suggests perceived opportunities for improving graduate curricula in ways that support professional standards, competency development, and career advancement. However, curriculum decisions in this study are based primarily on the component-level gap, barrier, and learning-outcome analyses rather than on the GCNI alone.

TABLE VII. BARRIERS TO GRADUATE EDUCATION

Barrier	Mean	SD	Interpretation	Rank
Financial cost of graduate education	4.189	1.045	Agree	1
Conflict with workplace requirements and schedule	4.106	1.042	Agree	2
Conflict with other personal responsibilities	4.000	1.081	Agree	3
Heavy or too many course requirements	3.946	1.078	Agree	4
Limited support for graduate students from the university/college	3.942	1.127	Agree	5
Publication or creative work requirement	3.931	1.133	Agree	6
Thesis/Dissertation requirement	3.848	1.178	Agree	7
Mental health/psychological wellbeing concerns	3.816	1.167	Agree	8
Long distance between university/college and workplace	3.788	1.178	Agree	9
Long distance between university/college and home	3.768	1.185	Agree	10
Physical health and fitness concerns	3.764	1.177	Agree	11
Requirement for face-to-face sessions	3.636	1.233	Agree	12
Lack of learning or professional growth from the graduate program	3.625	1.272	Agree	13
Too many sessions in a course	3.580	1.161	Agree	14
Too many hours in a session	3.545	1.159	Agree	15

TABLE VIII. SUMMARY OF THE CONSTRUCT INDICATORS AND GCNI

Indicator	Count	Mean	Std	Min	Max
PPST_Importance	624	4.561	0.681	1.00	5.00
PPST_Coverage	428	4.348	0.705	1.00	5.00
PPST_Gap	428	0.224	0.630	-3.00	2.857
Masters_Outcome_Importance	624	4.504	0.628	1.00	5.00
Masters_Outcome_Gap	624	0.370	0.766	-2.75	4.00
Doctorate_Outcome_Import-ance	624	4.435	0.711	1.00	5.00
Doctorate_Outcome_Gap	624	0.353	0.864	-3.25	4.00
Barriers_Index	624	3.832	0.880	1.00	5.00
GCNI_100	624	62.488	12.435	0.00	100.00

H. Exploratory Random Forest Analysis

Random Forest regression was retained as an exploratory analysis of the constructed GCNI. The internal-fit statistics are presented in Table IX. No separate actual-versus-predicted figure is reported in the revised manuscript.

TABLE IX. RANDOM FOREST PREDICTIVE PERFORMANCE

Metric	Value
Training R-squared	0.930
Testing R-squared	0.835
Five-fold CV R-squared Mean	0.815
Five-fold CV R-squared SD	0.051
RMSE	4.386
MAE	2.892

The model reproduced the constructed GCNI with high internal fit. However, this result is expected to some extent because several predictors are conceptually related to the indicators underlying the index. The statistics therefore do not demonstrate independent predictive validity. Their value is limited to showing internal patterns among the available curriculum-planning indicators, and they should be read together with the direct gap, barrier, reliability, and correlation results. The analysis is predictive neither of actual enrolment nor of the practical effectiveness of the proposed framework, and no causal interpretation is intended.

I. Feature Importance Analysis

To examine the relative contribution of variables within the exploratory model, feature-importance analysis was conducted. The results are presented in Table X.

Graduate learning outcomes and competency-related indicators received the highest importance scores within the exploratory model, while demographic characteristics and personal motivations received smaller scores. Because these variables overlap conceptually and are related to the constructed GCNI, the rankings are not interpreted as independent drivers.

They nevertheless support the descriptive finding that curriculum planning should focus on competencies and expected learning outcomes rather than demographic factors alone.

TABLE X. RANDOM FOREST FEATURE IMPORTANCE RANKINGS

Predictor	Importance
Master's Outcome Importance	0.166
PPST Importance	0.163
Doctorate Outcome Importance	0.120
Doctorate Outcome Gap	0.111
Master's Outcome Gap	0.089
PPST Curriculum Gap	0.058
Career Progression Need	0.045
Barrier Index	0.041
PPST Alignment Need	0.028
Age	0.027
Personal fulfilment	0.010
Research opportunities	0.009
Salary increase	0.009
Learning and Development	0.008
Career Progression	0.008

J. Correlation Analysis

To further examine relationships among the major variables, correlation analysis was conducted. The results are summarized in Table XI.

TABLE XI. CORRELATION OF MAJOR PREDICTORS WITH GCNI

Predictor	Pearson r with GCNI	p-value
Master's Outcome Importance	0.697	0.000
Doctorate Outcome Importance	0.651	0.000
PPST Importance	0.650	0.000
Doctorate Outcome Gap	0.580	0.000
Master's Outcome Gap	0.502	0.000
PPST Curriculum Gap	0.441	0.000
Barrier Index	0.194	0.000

The observed correlations were generally consistent with the descriptive and exploratory Random Forest results. However, the correlations should be interpreted as associations among related curriculum-planning indicators, not as independent validation of the GCNI or as evidence of causality.

K. Curriculum Priority Mapping

The integration of curriculum gap analysis, barrier analysis, correlation analysis, and exploratory variable ranking informed the development of a curriculum priority map. The resulting priorities are presented in Table XII.

The curriculum priority map illustrates how Educational Data Mining can complement traditional needs assessment and curriculum review processes [10]. Rather than treating the statistical outputs as validation of a predictive system, the analysis organizes the strongest descriptive findings into practical areas for curriculum revision, resource allocation, and strategic planning within graduate education programs.

TABLE XII. DATA-DRIVEN CURRICULUM PRIORITY MAP

Priority Level	Curriculum Area	Planning Implication
High Priority	PPST-aligned competencies	Embed PPST domains into course outcomes, assessments, and practicum tasks.
High Priority	Master's outcome competencies	Strengthen advanced pedagogy, applied research, and professional practice.
High Priority	Doctorate outcome competencies	Strengthen doctoral research leadership, innovation, and autonomous expertise.
Moderate Priority	Assessment and reporting	Develop assessment literacy, data use, and reporting competencies.
Moderate Priority	Diversity of learners	Strengthen inclusive education, differentiated instruction, and learner-responsive pedagogy.
Emerging Priority	Educational analytics and digital transformation	Integrate data-driven teaching, AI awareness, and educational technology applications.
Support Priority	Flexible delivery and financial/access support	Adopt hybrid, modular, weekend, and scholarship-supported delivery mechanisms.

L. Data-Driven Graduate Curriculum Planning Framework

Drawing upon the descriptive and exploratory analyses, a Data-Driven Graduate Curriculum Planning Framework was proposed. The framework is presented in Fig. 1. It integrates teacher needs assessment, curriculum gap analysis, exploratory analytics, curriculum prioritization, and continuous evaluation into a decision-support process. The dataset supports the identification of needs and priorities; the effectiveness of the framework itself has not yet been empirically evaluated.

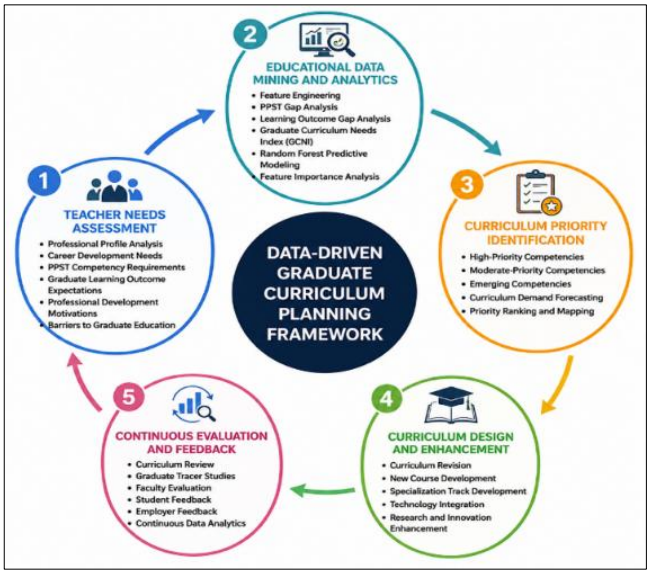

Fig. 1. Data-driven graduate curriculum planning framework.

By combining traditional curriculum planning approaches with Educational Data Mining techniques, the proposed framework provides a systematic mechanism for translating educational data into curriculum recommendations. It builds upon established principles of curriculum needs assessment, evidence-based planning, and educational analytics [7]. The framework should be understood as a data-informed planning proposal rather than a validated intervention. It may be adapted to other national, institutional, or professional contexts by replacing the PPST with the relevant competency standards and by incorporating local curriculum, employer, and stakeholder evidence.

IV. Conclusion and Recommendations

A. Conclusion

This study demonstrated the potential of Educational Data Mining (EDM) as an exploratory decision-support approach for graduate curriculum planning. Using data from 624 in-service teachers, the study integrated curriculum needs assessment, competency analysis, feature engineering, and exploratory analytics to identify curriculum priorities and professional development needs. The findings revealed substantial demand for curriculum enhancement, particularly in areas associated with professional competencies, graduate learning outcomes, and standards-based teacher development.

The curriculum gap analyses showed that respondents consistently rated professional competencies and graduate learning outcomes as highly important while identifying areas where existing curriculum coverage could be strengthened. Notable gaps were observed in selected PPST domains and graduate learning outcomes, suggesting opportunities for curriculum enhancement and improved alignment between curriculum provisions and professional expectations. In addition, barriers such as financial constraints, scheduling conflicts, and competing responsibilities highlighted the importance of considering both curricular and structural factors when designing programs for working professionals.

The GCNI provided an exploratory summary of perceived curriculum demand, but it was not treated as a psychometrically validated or independent predictive outcome. The Random Forest analysis was therefore interpreted only as supplementary variable ranking within a constructed score. The stronger empirical contribution lies in the direct curriculum-gap, learning-outcome, barrier, reliability, and correlation analyses, which consistently emphasized competency-based and outcomes-oriented curriculum planning.

Building on these findings, the study proposed a Data-Driven Graduate Curriculum Planning Framework that integrates needs assessment, exploratory analytics, curriculum prioritization, and continuous evaluation. The framework illustrates how educational data can inform curriculum development, but the present study does not demonstrate that the framework improves curriculum-planning outcomes in practice.

The study contributes to Educational Data Mining research by extending its exploratory application toward curriculum planning and educational decision-making. The findings suggest that curriculum analytics can complement traditional curriculum-development approaches in designing responsive, standards-informed, and future-oriented graduate programs.

Several limitations should be acknowledged. First, the cross-sectional design does not support causal conclusions. Second, the GCNI was derived from curriculum-related indicators that overlap with variables examined in the exploratory Random Forest analysis, and its original weighting documentation was not available for independent replication. The model results therefore represent internal exploratory associations rather than independent predictive validation. Third, the findings are based entirely on teachers' self-reported perceptions and were not triangulated with curriculum documents, employer requirements, institutional performance data, or graduate employment outcomes. Fourth, the PPST-specific context limits direct transferability, although the analytical process may be adapted using other national, institutional, or professional competency frameworks. Finally, the proposed planning framework was not empirically evaluated for practical effectiveness. Future studies should use independently measured outcomes, external datasets, longitudinal designs, and additional interpretive methods such as permutation importance or SHAP-based analysis.

B. Recommendations

Higher education institutions may consider using data-driven analysis alongside traditional needs assessment in curriculum review and development. Graduate curriculum developers may strengthen alignment with professional standards and expected learning outcomes while ensuring that program structures remain responsive to the financial, workplace, and personal constraints faced by working professionals.

Future studies may validate the proposed framework in other disciplinary and institutional contexts, triangulate survey findings with curriculum and employment evidence, and examine independently measured outcomes such as enrolment intention, preferred curriculum tracks, program completion, or graduate outcomes. Comparative baseline models and more stable interpretive methods may also be used before making predictive claims.

Acknowledgment

The researchers sincerely acknowledge the Teacher Education Council (TEC), through the Research Initiatives on Teacher Education (RITE), for funding this study. They also acknowledge the Philippine Normal University, Saint Louis University, Pangasinan State University, Western Visayas State University, and Ateneo de Davao University for their support in its conduct. Artificial Intelligence (AI) tools were utilized solely for language enhancement, organization, and formatting of the manuscript. All research processes, analyses, interpretations, and conclusions were independently reviewed and validated by the researchers to ensure accuracy, originality, and academic integrity.

Arki-Nexus AI: A Framework for Integrating Artificial Intelligence Competencies Into NEUST College of Architecture

GREGORIO L. VILLAVIZA JR
Associate Professor V, College of Architecture, Nueva Ecija University of Science and Technology, Cabanatuan City, Nueva Ecija, Philippines

***Abstract*—The rapid expansion of Artificial Intelligence (AI) is reshaping architectural education and practice, yet its systematic curricular integration remains limited in many higher education settings. This study developed the proposed Arki-Nexus AI Framework to guide the structured integration of AI competencies into the curriculum of the NEUST College of Architecture. Employing a descriptive-comparative quantitative research design, the study involved 31 faculty members selected through purposive sampling and 200 architecture students selected through stratified random sampling with equal allocation by year level. Data were gathered using a researcher-developed survey instrument that underwent expert content validation by seven experts (I-CVI = 1.00) and pilot reliability testing (Cronbach's α = .85–.92). Faculty members reported a high overall level of AI competency (M = 4.11), while students also reported a high overall level (M = 3.63), although student ratings were moderate in AI-assisted design, AI-supported collaboration, and AI-driven innovation. The perceived extent of AI integration was moderately evident for both faculty (M = 3.18) and students (M = 2.96). Significant faculty-student differences were found in applied AI competencies, but not in AI literacy or ethical AI use. These findings informed a proposed framework linking human competencies, pedagogical drivers, and institutional enablers. Because the findings were based on self-reported data from one college, the framework requires future expert review, pilot implementation, and feasibility and impact evaluation.**

Keywords*—Artificial intelligence; architecture education; self-reported AI competency; curriculum integration; curriculum framework; digital transformation; future-ready architects

I. INTRODUCTION

Artificial Intelligence (AI) and related digital technologies are changing design generation, visualization, simulation, information modeling, environmental analysis, and decision support across the architecture, engineering, and construction industry. Recent architectural education studies show that AI can support architectural programming, design exploration, iterative visualization, and studio learning when it is integrated through deliberate pedagogical design rather than treated as a stand-alone tool [1]–[3]. Architecture programs must therefore prepare students to use AI critically and competently while preserving architectural judgment, creativity, and accountability.

International competency frameworks also emphasize that AI readiness includes more than operational tool use. UNESCO's frameworks for students and teachers identify human-centered values, ethical AI use, foundational knowledge, practical application, pedagogy, and continuous professional learning as central dimensions of AI competency [4], [5]. These dimensions provide an appropriate basis for examining how architecture students and faculty understand and use AI in educational contexts.

Within architecture education, AI has been used in programming, concept development, design alternatives, image generation, environmental analysis, and critique. Empirical studies nevertheless report uneven and fragmented use, including difficulties in connecting AI outputs to coherent architectural workflows and in maintaining human oversight of design decisions [1]–[3], [6]. These findings indicate that access to AI tools alone does not guarantee meaningful curricular integration.

At the institutional level, AI adoption requires alignment among curriculum outcomes, teaching strategies, learning activities, assessment practices, digital infrastructure, faculty development, and governance. Higher education research shows that digital transformation remains limited when technology is added without coordinated changes to pedagogy, assessment, policy, and organizational support [7]–[10]. A structured curriculum framework is therefore necessary to move from isolated tool use toward progressive competency development.

This concern is relevant to the NEUST College of Architecture, which seeks to prepare graduates for digitally enabled professional practice. The College needs empirical evidence on the self-reported AI competencies of its faculty members and students and on the extent to which AI is presently reflected in its curriculum, instruction, learning activities, assessment practices, and resources.

The integration of AI into architectural education must remain human-centered. AI should augment, rather than replace, design reasoning, contextual sensitivity, professional judgment, authorship, and social responsibility. International ethical guidance emphasizes transparency, accountability, privacy, fairness, and human oversight in the development and use of AI systems [11]–[13]. These principles are especially important in architecture because design decisions affect people, communities, and the built environment.

In response, this study developed the proposed Arki-Nexus AI Framework as a curriculum enhancement model for the NEUST College of Architecture. The framework organizes AI

competency development across human, pedagogical, and institutional dimensions and links identified competency and integration gaps with possible curricular interventions.

The framework is intended for the specific context examined in this study. It was developed from the findings but was not independently validated through expert review, pilot implementation, or feasibility testing during this research phase. Its use beyond the NEUST College of Architecture therefore requires further evaluation and contextual adaptation.

A. Artificial Intelligence Competencies in Architecture Education

AI competency refers to the knowledge, skills, values, and judgment required to understand, evaluate, apply, and communicate with AI systems responsibly. It includes conceptual understanding, practical application, critical evaluation, ethical awareness, and the capacity to use AI in problem-solving and creative work [4], [5], [14], [15]. In architectural education, these competencies must be connected to design processes, technical workflows, collaboration, and professional responsibility.

The present study examined five competency dimensions: AI literacy and foundational knowledge; AI-assisted design and technical skills; ethical and responsible AI use; AI-supported collaboration and communication; and AI-driven innovation and problem-solving. These dimensions were adapted to the architecture education context from established AI literacy and competency frameworks [4], [5], [14], [15].

Assessing these dimensions can identify where faculty members and students perceive themselves as prepared and where additional learning opportunities are needed. Because the instrument used self-rated Likert-scale responses, the resulting scores indicate perceived competency rather than directly demonstrated performance.

B. AI Integration in Architecture Programs

Program-level AI integration involves embedding AI concepts and applications across formal curriculum content, instructional strategies, student learning experiences, assessment systems, and institutional resources. Effective integration is systematic, progressive, aligned with program outcomes, and supported by appropriate governance and infrastructure.

Curriculum content establishes where AI competencies are introduced, reinforced, and applied. Architecture education studies recommend integrating AI into programming, studio work, computational design, visualization, performance analysis, and design critique while preserving critical and human-centered approaches [1], [2], [6].

Teaching strategies determine how faculty members mediate AI use. AI-assisted studio demonstrations, guided experimentation, project-based learning, critique, collaborative inquiry, and reflective discussion can help students connect AI outputs with architectural reasoning and design decisions.

Institutional adoption is more likely to produce educational value when faculty preparation, instructional design, and student access are coordinated. Research on AI and digital transformation in higher education emphasizes that technology adoption without pedagogical alignment and sustained institutional support often remains superficial [7]–[9].

Learning activities provide opportunities to translate conceptual knowledge into performance. Studio projects, iterative prompt-and-critique exercises, AI-assisted programming, visualization, simulation, and collaborative design tasks can support authentic practice when activities are scaffolded and connected to course outcomes [1], [2], [6].

Assessment practices must evaluate not only final AI-assisted outputs but also process documentation, critical judgment, ethical use, attribution, and human decision-making. Assessment standards should protect academic integrity and maintain transparency, fairness, and human oversight [9], [12], [13].

C. Research Questions

This study aimed to develop a proposed Arki-Nexus AI Framework for integrating Artificial Intelligence competencies into the curriculum of the NEUST College of Architecture. Specifically, it sought to answer the following questions:

- What is the level of self-reported Artificial Intelligence competency among architecture students and faculty members of the NEUST College of Architecture in terms of:
  - AI literacy and foundational knowledge;
  - AI-assisted design and technical skills;
  - ethical and responsible AI use;
  - AI-supported collaboration and communication; and
  - AI-driven innovation and problem-solving?
- What is the perceived extent of AI integration in the NEUST College of Architecture with respect to:
  - Curriculum content;
  - Teaching strategies;
  - Learning activities;
  - Assessment practices; and
  - Digital infrastructure and AI-related resources?
- Based on the findings, what Arki-Nexus AI Framework may be proposed to support the systematic integration of Artificial Intelligence competencies into the curriculum of the NEUST College of Architecture?
- Is there a significant difference between the self-reported AI competency levels of faculty members and architecture students across the five competency dimensions?

II. METHODOLOGY

A. Research Design

The study employed a descriptive-comparative quantitative research design. The descriptive component measured respondents' self-reported AI competency and their perceptions of the extent of AI integration in the College. The comparative component examined differences between faculty and student self-ratings across the five AI competency dimensions. The findings were used as an empirical basis for developing the proposed Arki-Nexus AI Framework; the research design did not include a separate validation phase for the framework.

B. Locale, Respondents, and Sampling Technique

The study was conducted at the College of Architecture of Nueva Ecija University of Science and Technology in the Philippines. Respondents comprised 31 faculty members and 200 architecture students. Faculty members were selected purposively because of their direct involvement in architecture courses and design studios. Students were selected through stratified random sampling with equal allocation of 40 respondents from each year level. This equal allocation ensured representation from all year levels but was not proportional unless year-level populations were equal. Because the study involved respondents from one college in one institution, the results are context-specific and should not be generalized to Philippine architecture education as a whole.

C. Research Instrument

The researcher-developed survey instrument consisted of two main sections.

The first section measured self-reported AI competency across five dimensions: AI literacy and foundational knowledge; AI-assisted design and technical skills; ethical and responsible AI use; AI-supported collaboration and communication; and AI-driven innovation and problem-solving. Responses used a five-point scale interpreted as follows: 4.21–5.00, Very High; 3.41–4.20, High; 2.61–3.40, Moderate; 1.81–2.60, Low; and 1.00–1.80, Very Low. Because the items were self-rated, the scores represented perceived competency rather than objectively demonstrated performance.

The second section assessed the perceived extent of AI integration across curriculum content, teaching strategies, learning activities, assessment practices, and digital infrastructure and AI-related resources. Responses used a five-point scale interpreted as follows: 4.21–5.00, Very Evident; 3.41–4.20, Evident; 2.61–3.40, Moderately Evident; 1.81–2.60, Somewhat Evident; and 1.00–1.80, Not Evident.

D. Validity and Reliability of the Instrument

Content validity was evaluated by seven experts in architecture education, curriculum development, and educational technology. All items across the ten subscales attained an Item-Level Content Validity Index (I-CVI) of 1.00, indicating unanimous expert agreement on item relevance and clarity [16]. Reliability was examined through a pilot test involving 42 students who were excluded from the main study. Cronbach's alpha coefficients ranged from .85 to .92 across the subscales, indicating good to excellent internal consistency [17]. These findings supported the quality of the survey instrument only; they did not constitute validation of the proposed Arki-Nexus AI Framework.

E. Data-Gathering Procedure

Data collection was conducted after approval from the relevant academic and institutional authorities. The researcher coordinated with subject teachers, distributed the validated questionnaires with informed-consent forms, and provided standardized instructions. Respondents completed the instrument in approximately 15 to 25 minutes. Completed questionnaires were retrieved, checked for completeness, encoded, and organized for statistical analysis. Participation remained voluntary throughout the process.

F. Data Analysis

Descriptive and inferential statistics were used. Means were computed to summarize self-reported AI competency and the perceived extent of AI integration. An independent-samples t-test examined differences between faculty and student self-ratings across the five AI competency dimensions. Statistical decisions were evaluated at the .05 level of significance. The analysis did not test the validity, feasibility, or effectiveness of the proposed framework.

G. Ethical Considerations

The study observed established ethical principles for educational research. Informed consent was obtained before participation, and respondents were informed that participation was voluntary. Anonymity and confidentiality were maintained; no identifying information was linked to individual responses, and the data were used only for academic purposes and stored securely.

III. RESULTS AND DISCUSSION

A. AI Literacy and Foundational Knowledge

Faculty members reported a Very High level of AI literacy and foundational knowledge (M = 4.21), while students reported a High level (M = 4.03). The results indicate strong perceived awareness of AI concepts in both groups, although faculty ratings were slightly higher. These findings are consistent with AI literacy frameworks that distinguish foundational understanding from deeper application and critical evaluation [4], [5], [14], [15].

For both groups, awareness of the limitations and risks of AI in architecture received the highest rating (faculty: M = 4.55; students: M = 4.43), both interpreted as Very High. Regular updating of knowledge on emerging AI technologies received the lowest rating (faculty: M = 3.95; students: M = 3.84), although both remained High. Faculty members also rated their understanding of how data and algorithms influence AI-generated outputs higher (M = 4.40) than students did (M = 3.92). These patterns support continuous updating and deeper instruction on data, algorithms, limitations, and critical evaluation.

B. AI-Assisted Design and Technical Skills

Faculty members reported a High level of AI-assisted design and technical skills (M = 3.94), whereas students reported a Moderate level (M = 3.34). The difference indicates that students perceived less consistent ability to apply AI across

architectural workflows. Architecture education studies similarly show that learners may use generative tools for isolated tasks without yet integrating them into a coherent programming, design, and technical process [1], [2].

Faculty members rated the use of AI to improve design efficiency and productivity highest (M = 4.20). Students reported their lowest ratings for integrating AI with CAD/BIM platforms (M = 3.02) and generating design alternatives using AI (M = 3.32). Both groups rated critical evaluation of AI-generated outputs more strongly (faculty: M = 4.11; students: M = 3.65) than technical workflow integration. The findings support curriculum enhancement in AI-CAD/BIM integration, generative design, and studio-based application [1], [2], [6].

C. Ethical and Responsible AI Use

Faculty members reported a Very High level of ethical and responsible AI use (M = 4.38), while students reported a High level (M = 4.07). The difference should not be interpreted as proof of actual ethical behavior because the ratings were self-reported. However, the pattern suggests that both groups perceived themselves as aware of accountability, transparency, attribution, and responsible use. Kolb's experiential learning perspective indicates that ethical judgment can be strengthened through repeated application and reflection in authentic tasks [18], while UNESCO's competency frameworks place ethics and human-centered values at the core of AI readiness [4], [5].

Faculty ratings were Very High for understanding ethical issues related to AI use (M = 4.50) and for responsible use and attribution of AI-generated outputs (M = 4.45). Students rated recognition of bias and misinformation highest (M = 4.18), but proper attribution of AI-generated outputs was lower (M = 3.92). The results support explicit instruction on authorship, intellectual property, data privacy, bias, transparency, and human oversight, consistent with international ethical guidance [11]–[13].

D. AI-Supported Collaboration and Communication

Faculty members reported a High level of AI-supported collaboration and communication (M = 4.06), whereas students reported a Moderate level (M = 3.34). This difference indicates that students perceived fewer or less consistent opportunities to use AI in collaborative architectural work. Vygotsky's social constructivist perspective emphasizes learning through guided and socially mediated activity [19], while UNESCO's frameworks recognize communication, collaboration, and pedagogy as important elements of responsible AI use [4], [5].

Faculty members rated AI-supported communication in group tasks (M = 4.15) and coordination of design collaboration (M = 4.10) most strongly. Students reported lower ratings for clearly sharing AI-generated outputs (M = 3.20) and using AI-supported platforms (M = 3.37). Connectivism explains learning as participation in networks of people, information, and digital tools [20]. Accordingly, shared BIM environments, collaborative generative platforms, and structured group critique may help students use AI outputs more effectively in team-based design [12], [15].

E. AI-Driven Innovation and Problem-Solving

Faculty members reported a High level of AI-driven innovation and problem-solving (M = 3.95), while students reported a Moderate level (M = 3.34). The results indicate a gap in perceived ability to use AI for complex design reasoning, scenario analysis, and evidence-informed decisions. The higher-order cognitive processes of analyzing, evaluating, and creating in Bloom's revised taxonomy provide an appropriate basis for designing progressively challenging AI-assisted tasks [21].

Faculty members rated exploration of innovative architectural solutions (M = 4.15) and critical evaluation of AI-generated outputs (M = 4.10) most strongly. Students reported Moderate ratings in complex problem-solving (M = 3.28), scenario analysis (M = 3.35), and evidence-based decision-making (M = 3.28). Their relatively higher ratings in innovation exploration (M = 3.44) and critical evaluation (M = 3.48) indicate emerging readiness that can be strengthened through scaffolded studio tasks aligned with AI literacy and higher-order learning outcomes [14], [15], [21].

F. Summary of Self-Reported AI Competency

Table I summarizes the self-reported AI competency results. Faculty members obtained a High grand mean (M = 4.11), and students also obtained a High grand mean (M = 3.63). Faculty ratings were strongest in ethical and responsible AI use and AI literacy. Student ratings were High in these foundational domains but Moderate in AI-assisted design, collaboration, and innovation. The pattern suggests that conceptual and ethical awareness is more developed than applied and workflow-based competency [4], [5], [9], [14], [15].

The applied-domain differences indicate a need to connect AI knowledge with repeated studio practice. Students should encounter progressively complex tasks involving architectural programming, generative exploration, CAD/BIM integration, collaborative design, technical analysis, and critical evaluation of outputs. Such integration is consistent with current research on AI-assisted architectural education and design pedagogy [1], [2], [6].

TABLE I. SUMMARY OF SELF-REPORTED AI COMPETENCY LEVELS OF FACULTY MEMBERS AND STUDENTS

Artificial Intelligence Competency	Faculty		Students	
	Mean	Verbal Description	Mean	Verbal Description
AI Literacy and Foundational Knowledge	4.21	Very High	4.03	High
AI-Assisted Design and Technical Skills	3.94	High	3.34	Moderate
Ethical and Responsible AI Use	4.38	Very High	4.07	High
AI-Supported Collaboration and Communication	4.06	High	3.34	Moderate
AI-Driven Innovation and Problem-Solving	3.95	High	3.34	Moderate
Grand Mean	**4.11**	**High**	**3.63**	**High**

G. Curriculum Content

Faculty (M = 2.82) and students (M = 2.95) both perceived AI integration in curriculum content as Moderately Evident. These results indicate that AI-related concepts were present but not consistently embedded in formal course outcomes, vertical curriculum mapping, or studio requirements. The pattern reflects a broader distinction between isolated technology adoption and system-level digital transformation [7]–[10].

Faculty members rated curriculum updates reflecting emerging AI technologies lowest (M = 2.55, Somewhat Evident), while vertical integration across year levels was also limited (M = 2.70, Moderately Evident). Students rated curriculum updates (M = 2.92) and integration into learning outcomes (M = 2.98) as Moderately Evident. The findings support competency mapping across year levels, explicit inclusion in course outcomes, and regular syllabus review informed by developments in architectural AI [1], [2], [6].

H. Teaching Strategies

Faculty members perceived AI integration in teaching strategies as Evident (M = 3.51), whereas students perceived it as Moderately Evident (M = 2.90). This difference suggests that faculty members recognized their instructional intentions and demonstrations more strongly than students experienced consistent AI-supported teaching. Research on technology integration similarly shows that instructional adoption may not translate into meaningful learner experience without coherent pedagogical design [7]–[9].

Faculty members rated promotion of critical evaluation of AI outputs highest (M = 3.75) and reported using AI in instructional demonstrations and design activities (M = 3.45–3.50). Students rated encouragement to use AI tools (M = 2.83) and AI-supported design exploration (M = 2.87) lower. Bloom's revised taxonomy supports instructional tasks that move from understanding and application toward analysis, evaluation, and creation [21], while experiential learning emphasizes active practice and reflection [18]. Faculty development should therefore focus on structured, visible, and repeatable AI-mediated studio pedagogy.

I. Learning Activities

Faculty members perceived AI integration in learning activities as Evident (M = 3.41), while students perceived it as Moderately Evident (M = 2.98). The difference suggests that AI was used in selected tasks but was not consistently experienced across subjects and studios. This pattern is consistent with higher education research showing that digital activities remain fragmented when implementation is not aligned across curriculum and instruction [7]–[9].

Faculty ratings were higher for encouraging AI use in architectural research tasks (M = 3.65) and experimentation with AI technologies (M = 3.50). Students reported limited participation in AI-assisted design projects (M = 2.89) and use of generative AI tools (M = 2.88). Repeated, scaffolded, and authentic activities are needed to develop competence through experience [18]. Studio projects that connect research, programming, visualization, critique, and revision can provide this progression [1], [2].

J. Assessment Practices

Faculty (M = 3.13) and students (M = 2.96) both perceived AI integration in assessment practices as Moderately Evident. The results indicate that AI was only partially reflected in grading, feedback, criteria, and assessment design. Concerns related to validity, fairness, transparency, and academic integrity often cause assessment reform to lag behind instructional adoption [9], [12], [13].

The assessment of ethical AI use received relatively higher ratings (faculty: M = 3.35; students: M = 3.08), as did evaluation of both process and AI-supported outputs (faculty: M = 3.30; students: M = 3.04). Faculty ratings were lower for using AI to evaluate outputs, provide feedback, and operationalize AI-integrated criteria (M = 2.95 for each). These findings support process-based rubrics, documentation of human and AI contributions, reflective justification of design decisions, and clear ethical standards [9], [12].

Assessment was among the least developed dimensions of integration. Redesign should focus on authentic tasks that evaluate architectural reasoning, design process, critical appraisal of AI outputs, attribution, and ethical decision-making rather than rewarding AI-generated products alone.

K. Digital Infrastructure and AI-Related Resources

Faculty (M = 3.01) and students (M = 3.03) both perceived digital infrastructure and AI-related resources as Moderately Evident. The nearly identical ratings indicate shared recognition that basic resources were available but were not yet sufficient for advanced AI-assisted design, computational modeling, and cloud-based collaboration. Digital transformation requires coordinated infrastructure, governance, access, and human capability [9], [10].

Faculty members rated access to AI design software (M = 2.75) and infrastructure upgrading (M = 2.80) lowest. Both groups also rated internet connectivity and laboratory adequacy at moderate levels. These constraints may limit repeated use of AI in studio courses and create unequal learning opportunities. The College should therefore assess hardware, software licensing, cloud access, connectivity, technical support, and responsible-use policies as part of an AI-readiness plan [9].

Infrastructure should be developed alongside curriculum and pedagogy. Investment in tools without faculty development, assessment standards, and implementation governance would be unlikely to produce sustained curricular transformation [9], [10].

L. Summary of the Perceived Extent of AI Integration

Table II shows that faculty (M = 3.18) and students (M = 2.96) both perceived the overall extent of AI integration as Moderately Evident. AI was therefore present across curriculum, teaching, activities, assessment, and resources, but it had not yet become fully institutionalized. The results describe the NEUST College of Architecture only and should not be generalized to other architecture programs without additional evidence [9], [10].

TABLE III. SUMMARY OF THE PERCEIVED EXTENT OF AI INTEGRATION IN THE NEUST COLLEGE OF ARCHITECTURE

AI Integration in NEUST College Of Architecture	Faculty		Students	
	Mean	Verbal Description	Mean	Verbal Description
Curriculum Content	2.82	Moderately Evident	2.95	Moderately Evident
Teaching Strategies	3.51	Moderately Evident	2.90	Moderately Evident
Learning Activities	3.41	Moderately Evident	2.98	Moderately Evident
Assessment Practices	3.13	Moderately Evident	2.96	Moderately Evident
Digital Infrastructure	3.01	Moderately Evident	3.03	Moderately Evident
Grand Mean	3.18	Moderately Evident	2.96	Moderately Evident

Faculty ratings were highest for teaching strategies (M = 3.51, Evident), while curriculum content received its lowest rating (M = 2.82, Moderately Evident). Students rated all domains as Moderately Evident, and digital infrastructure was the only domain in which the student mean slightly exceeded the faculty mean. These results indicate that current AI adoption is primarily instruction-led and requires stronger alignment among formal curriculum, learning activities, assessment, and institutional support [7], [9].

M. Differences in Self-Reported AI Competency Between Faculty Members and Students

Table III presents the comparison of faculty and student self-reported AI competency. No significant differences were found in AI literacy and foundational knowledge (p = .345) or ethical and responsible AI use (p = .135). Significant differences were found in AI-assisted design and technical skills (p = .006), AI-supported collaboration and communication (p = .002), and AI-driven innovation and problem-solving (p = .011), with faculty members reporting higher means in each applied domain.

TABLE IV. DIFFERENCES IN SELF-REPORTED AI COMPETENCY BETWEEN FACULTY MEMBERS AND STUDENTS

Competency Dimension	Faculty M	Student M	p	Decision
AI Literacy and Foundational Knowledge	4.21	4.03	.345	NS
AI-Assisted Design and Technical Skills	3.94	3.34	.006	Sig.
Ethical and Responsible AI Use	4.38	4.07	.135	NS
AI-Supported Collaboration and Communication	4.06	3.34	.002	Sig.
AI-Driven Innovation and Problem-Solving	3.95	3.34	.011	Sig.

Note. NS = not significant; Sig. = significant at $p < .05$.

The results indicate stronger alignment in foundational awareness and ethical understanding than in applied competency. The higher faculty ratings should not be interpreted as objective evidence of superior performance because both groups completed self-report measures. They do, however, identify areas in which students perceived a need for more structured practice, feedback, collaboration, and technical integration.

For the NEUST College of Architecture, the findings support a progression from foundational AI literacy and ethics toward applied design, collaboration, and problem-solving. This progression should be implemented through curriculum mapping, faculty-student co-learning, studio projects, and performance-based assessment. International frameworks similarly emphasize progressive development from understanding to application and creation within an enabling digital ecosystem [4], [5], [9], [14], [15].

N. Proposed Arki-Nexus AI Framework

Fig. 1 presents the proposed Arki-Nexus AI Framework developed from the study findings. The Arki-Nexus AI Framework was developed as an evidence-based curriculum model derived from the quantitative findings of this study. Rather than serving as a purely conceptual representation, the framework synthesized the empirical results obtained from the assessment of Artificial Intelligence (AI) competencies among architecture faculty members and students, the extent of AI integration within the curriculum, and the comparative analysis of faculty and student perceptions regarding AI implementation. Consequently, the framework addressed research problems by translating the identified strengths, gaps, and statistically significant differences into a structured model for curriculum innovation.

The findings revealed that both faculty members and students generally demonstrated satisfactory levels of AI competency, particularly in AI literacy and foundational knowledge and ethical and responsible AI use, indicating a positive institutional readiness for AI-enhanced architectural education. However, comparatively lower ratings in AI-assisted design and technical skills, AI-supported collaboration, AI-driven innovation, and several dimensions of curriculum integration suggest that AI competencies remain inconsistently embedded across instructional practices. Moreover, the significant differences between faculty and student assessments indicate varying perceptions regarding the actual implementation of AI within teaching, learning, and assessment processes. These findings highlight the necessity of a comprehensive framework capable of aligning competency development with curriculum design, instructional delivery, institutional resources, and professional expectations.

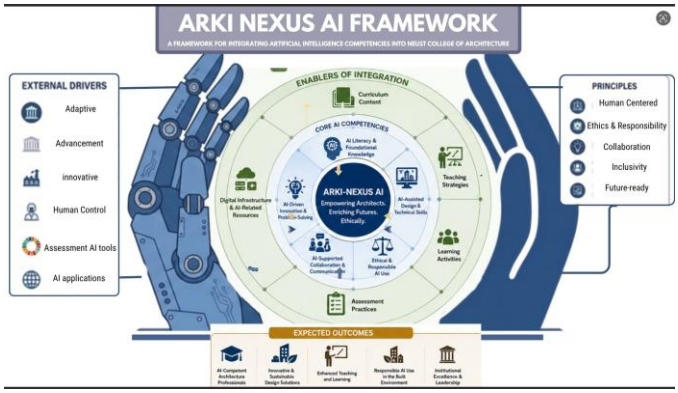

Fig. 1. Proposed Arki-Nexus AI framework developed from the study findings.

Accordingly, the Arki-Nexus AI Framework was formulated as a systematic response to these empirical findings. It provides a coherent mechanism through which AI competencies may be progressively developed and intentionally integrated across the architecture curriculum while ensuring alignment with educational objectives and the evolving demands of architectural practice.

1) Interpretation of the framework in relation to the research findings: The framework consists of five interconnected components: the External Drivers, Core AI Competencies, Enablers of Integration, Guiding Principles, and Expected Outcomes, which collectively demonstrate the dynamic process of AI integration in the architecture curriculum.

The External Drivers represent the contextual forces influencing curriculum transformation, including technological advancement, innovation, adaptability, AI applications, AI-assisted assessment tools, and continued human oversight. These drivers acknowledge that architectural education operates within a rapidly evolving technological environment where emerging AI technologies continuously reshape professional practice. Their inclusion reflects the study's findings that curriculum development must remain responsive to technological change while preserving the human-centered nature of architectural design.

At the core of the framework are the five AI competency domains, which directly correspond to the competency dimensions investigated in Research Problem 1. These include AI Literacy and Foundational Knowledge, AI-Assisted Design and Technical Skills, Ethical and Responsible AI Use, AI-Supported Collaboration and Communication, and AI-Driven Innovation and Problem-Solving. Positioning these competencies at the center of the framework signifies that AI competency development constitutes the primary objective of curriculum integration. The quantitative findings indicate that while respondents possess adequate foundational knowledge of AI, further curricular enhancement is necessary to strengthen students' ability to apply AI within authentic architectural design processes, interdisciplinary collaboration, and innovation-driven problem-solving. Consequently, the framework conceptualizes competency development as a continuous progression rather than a static outcome.

Surrounding these competencies are the Enablers of Integration, comprising curriculum content, teaching strategies, learning activities, assessment practices, and digital infrastructure and AI-related resources. These elements correspond directly to the dimensions examined in Research Problem 2 and emphasize that AI competency development cannot occur independently of institutional and pedagogical support. The findings revealed varying levels of AI integration across these curricular dimensions, suggesting that AI adoption remains uneven despite generally positive competency levels. Therefore, the framework advocates deliberate alignment between learning outcomes, instructional approaches, authentic learning experiences, assessment strategies, and institutional technological capacity to facilitate meaningful and sustainable AI integration throughout the curriculum.

The implementation of these curriculum enablers is governed by five Guiding Principles: Human-Centeredness, Ethics and Responsibility, Collaboration, Inclusivity, and Future-Readiness. These principles ensure that AI functions as an educational enabler rather than a substitute for architectural creativity and professional judgment. Their inclusion reflects the study's findings that ethical AI use received among the highest competency ratings, reinforcing the importance of embedding responsible AI practices alongside technical proficiency. The interaction among these framework components ultimately contributes to the Expected Outcomes, namely the development of AI-competent architecture graduates, enhanced teaching and learning experiences, responsible AI utilization, strengthened innovation and sustainability, and institutional leadership in AI-enabled architectural education. Collectively, these outcomes represent the desired impact of systematic AI integration and provide a strategic direction for curriculum enhancement within the architecture curriculum.

2) Theoretical foundation and alignment with existing literature: The Arki-Nexus AI Framework is theoretically anchored in Vygotsky's Social Constructivist Theory and the UNESCO AI Competency Framework for Teachers, each of which provides complementary perspectives on AI integration in higher education.

Vygotsky's Social Constructivist Theory emphasizes that knowledge is constructed through interaction, collaboration, and authentic learning experiences. This theoretical perspective supports the framework's emphasis on AI-supported

collaboration, project-based learning, and collaborative design processes, where AI functions as a cognitive tool that enhances rather than replaces human learning. By promoting collaborative inquiry and reflective practice, the framework reinforces the social nature of architectural education while integrating intelligent technologies into studio-based learning environments.

Furthermore, the framework reflects the principles articulated in the UNESCO AI Competency Framework, particularly its emphasis on responsible AI use, ethical governance, human-centered implementation, and lifelong learning. The inclusion of ethical AI use, inclusivity, and future-readiness acknowledges that AI integration must promote not only technological competence but also critical thinking, professional accountability, and equitable access to emerging technologies.

3) Contribution of the framework to architecture curriculum: The principal contribution of the Arki-Nexus AI Framework lies in its presentation of a comprehensive, empirically grounded model for integrating AI competencies into architecture curriculum. Unlike existing AI competency models that primarily emphasize technological literacy or digital skills, the proposed framework adopts a systems perspective by integrating competency development, curriculum implementation, instructional practice, ethical governance, institutional readiness, and graduate outcomes within a single architecture-specific model. This contribution is particularly significant because architecture curriculum requires the integration of creativity, technical competence, sustainability, collaborative practice, and ethical decision-making. Rather than positioning AI as a replacement for architectural expertise, the framework conceptualizes AI as an enabling technology that augments design thinking, evidence-based decision-making, and innovative problem solving while preserving the architect's central role as a creative and ethical professional.

From a curricular perspective, the framework provides academic leaders and curriculum developers with a structured roadmap for embedding AI competencies throughout architectural education. Its emphasis on alignment among curriculum content, pedagogy, assessment, and institutional infrastructure promotes a holistic approach to curriculum innovation that extends beyond isolated course revisions. Consequently, the framework contributes not only to the advancement of AI integration within the NEUST College of Architecture but also offers a transferable reference model for architecture schools and higher education institutions seeking systematic AI implementation within design-oriented programs.

4) Expert validation of the framework: The evaluation indicated a high level of content validity, demonstrating strong agreement that the framework presents a logically organized, empirically supported, and educationally relevant model for integrating AI competencies into architecture curricula. The experts affirmed that the framework effectively synthesizes the quantitative findings into an implementable curriculum model while maintaining consistency with contemporary theories of technology integration and higher education innovation. The validators further recommended strengthening provisions for continuous curriculum review, expanding faculty capability-building initiatives in AI pedagogy, fostering stronger partnerships with industry to support authentic AI applications, and establishing mechanisms for periodically updating digital infrastructure in response to rapidly evolving AI technologies.

Overall, the expert validation provides evidence that the Arki-Nexus AI Framework possesses strong conceptual coherence, empirical grounding, and practical applicability. As an evidence-informed curriculum model, it offers a robust foundation for systematically integrating AI competencies into architecture curriculum while ensuring that technological innovation remains aligned with creativity, ethical responsibility, sustainability, and the evolving competencies required of future architects.

IV. Conclusion and Recommendations

A. Conclusion

Among the 31 faculty members and 200 architecture students who participated in this single-institution study, both groups reported High overall AI competency, with faculty members obtaining a higher grand mean (M = 4.11) than students (M = 3.63). Faculty and student ratings were strongest in AI literacy and ethical AI use, while student ratings were Moderate in AI-assisted design, AI-supported collaboration, and AI-driven innovation. These findings indicate that perceived foundational readiness was stronger than perceived applied competency within the NEUST College of Architecture.

The overall perceived extent of AI integration was Moderately Evident for faculty (M = 3.18) and students (M = 2.96). Teaching strategies were the most visible domain in faculty ratings, but curriculum content, assessment, and infrastructure remained only moderately integrated. The evidence therefore suggests that AI adoption in the College was emerging and primarily instruction-led rather than fully embedded across formal curriculum and institutional systems.

Significant faculty-student differences were found in the three applied competency domains, while differences in AI literacy and ethical AI use were not significant. These findings informed the proposed Arki-Nexus AI Framework. The study did not validate the framework, and the conclusions apply only to the respondents and institutional context examined.

B. Recommendations

The College should map AI competencies across program and course outcomes and integrate them progressively into architectural programming, design studios, CAD/BIM workflows, visualization, simulation, research, and technical subjects. Curriculum revision should move beyond theoretical exposure toward performance-based and project-driven learning.

Faculty development and faculty-student co-learning should be institutionalized. Workshops, mentoring, collaborative studio projects, and communities of practice should focus on responsible AI use, generative and computational design,

collaborative platforms, critical evaluation, attribution, and human oversight.

Assessment should be redesigned using process-based rubrics, design documentation, oral defense, reflective justification, and transparent declaration of AI assistance. The College should also conduct an AI-readiness audit covering hardware, connectivity, software licensing, cloud platforms, technical support, data governance, accessibility, and equitable student access.

Before institutional adoption, the proposed Arki-Nexus AI Framework should undergo structured expert review, feasibility assessment, and pilot implementation. Evaluation should determine whether the framework improves demonstrated competencies, curriculum alignment, student learning, ethical practice, and resource efficiency within the NEUST College of Architecture.

C. Limitations and Directions for Future Research

The findings were based on self-rated Likert-scale responses from 31 faculty members and 200 students in one college and may have been affected by social desirability, recall error, or overestimation of competency. The cross-sectional design did not measure change over time, and the unequal group sizes may have influenced the comparison. Future studies should include performance-based design tasks, portfolios, software demonstrations, interviews, classroom or studio observations, and multi-institution samples. The proposed framework should also undergo expert validation, pilot implementation, feasibility testing, and outcome evaluation before broader use.

ACKNOWLEDGMENT

The author gratefully acknowledges the faculty members and architecture students of the Nueva Ecija University of Science and Technology who participated in the study, as well as those who assisted in survey administration and data collection.

Secure Heart Disease Status Classification Using Machine Learning and Blockchain-Based EHR Integrity Verification

Haya H. Alsharif, Sabah M. Alzahrani
Department of Computer Science-College of Computers and Information Technology, Taif University, Taif, Saudi Arabia

***Abstract*—Heart disease remains one of the leading causes of mortality worldwide, motivating the development of accurate and scalable screening-support tools. This study presents an integrated framework for heart-disease status classification using the Heart 2020 Cleaned dataset, derived from the CDC Behavioral Risk Factor Surveillance System (BRFSS), a telephone-based survey of self-reported health information rather than clinical or electronic-health-record data. The task is therefore to classify a respondent's self-reported heart-disease status, not to predict future disease onset. The pipeline includes categorical encoding, feature scaling, recursive feature elimination, and class-imbalance handling using BorderlineSMOTE, SMOTETomek, and SMOTEENN. Five classifiers were evaluated: Random Forest, XGBoost, LightGBM, k-Nearest Neighbours, and a feed-forward deep neural network. Sampling strategy affected reported performance. Under the methodologically valid post-split setting, in which resampling is applied only to the training data, the models achieved an AUC of approximately 0.85, comparable to prior work on the same dataset. Pre-split global resampling produced much higher scores, with Random Forest reaching 97.14% accuracy, an F1-score of 0.9735, and an AUC of 0.9965 under SMOTEENN. However, these results are optimistically biased because resampling before splitting leaks synthetic information into the test set. The system also includes a blockchain-based integrity layer that stores full records in the application database while anchoring SHA-256 digests and verification metadata in an Ethereum-compatible environment. Overall, this prototype demonstrates the practical integration of established machine-learning classification and blockchain-supported integrity-verification components.**

Keywords*—Heart-disease status classification; machine learning; ensemble model; random forest; XGBoost; LightGBM; Blockchain; Electronic Health Records (EHR)

I. Introduction

Artificial Intelligence (AI) has become a central component of modern healthcare, where it supports data-driven decision-making in disease diagnosis, risk prediction, prognosis, and personalized treatment planning [1]. AI systems are capable of processing vast and varied clinical datasets, detecting hidden patterns, and helping healthcare professionals make timely, informed decisions. Within this broader domain, Machine Learning (ML) has emerged as one of the most effective AI paradigms for predictive healthcare, with successful applications reported across disease screening, clinical risk stratification, and diagnostic support systems [2].

Cardiovascular disease is one of the main causes of mortality, and it constitutes one of the greatest health problems in the world. It is also one of the clinical fields where AI for diagnosis and health-data analysis can make a big difference. Since cardiovascular diseases account for a significant proportion of global mortality, there has been a rising interest in the use of ML tools for scalable population-level health assessment. ML models are increasingly used to support heart-disease status classification by learning from demographic, behavioral, and self-reported health variables that may be difficult to integrate manually in routine care [3]. These capabilities are especially relevant for survey-based health assessment, where status classification of reported heart-disease cases can support population-level decision-making and public-health planning [4].

Meanwhile, as health care is becoming more reliant on digital health information, privacy, integrity, interoperability, and patient control issues have emerged. Although EHR systems are essential for supporting clinical decisions, many conventional centralized architectures remain vulnerable to unauthorized access, limited auditability, interoperability constraints, and single points of failure [5]. Technologies such as smart contracts, decentralized ledgers, and IPFS-supported storage can improve traceability, tamper resistance, patient-centric access control, and secure health-record sharing [6]. But the technologies are typically designed as secure data-management systems, not a comprehensive framework that brings together heart-disease status classification and secure EHR integrity verification.

Within the realm of heart disease research, several recent studies have proposed different ML models, including gradient boosting, ensemble learning, deep learning, and NLP-based approaches for extracting cardiovascular risk factors from structured and unstructured data [3,7]. Although these studies have immense potential for the use of ML in HD prediction, they also have certain key limitations. Many works focus either on predictive performance alone or on secure record management alone, without integrating both into a unified healthcare framework [4]. In addition, class imbalance, dataset heterogeneity, lack of interpretability, and variation in evaluation practice between studies remain a problem in the literature.

This study develops and evaluates an integrated framework that combines machine-learning-based heart-disease status classification with blockchain-supported EHR integrity verification. Recent literature related to heart-disease classification and blockchain in healthcare data management

indicates that there are a number of limitations and aspects that can be improved. Class imbalance and minority-class sensitivity remain persistent issues, especially in large population-scale studies, and are often overlooked in studies that emphasize overall accuracy. In some existing works, only a small number of models are evaluated, or the studies consider only structured or unstructured data, which limits the possibility of cross-model comparison in a unified pipeline. Moreover, most of the existing literature on blockchain-based EHRs gives high priority to security, privacy, and access management. Only a few works have integrated classification analytics with blockchain for real-time heart-disease status classification and EHR integrity verification. Many secure-health data-management systems increase auditability and patient control but may not be designed for heart-disease status classification within a healthcare-oriented decision-support prototype based on large-scale behavioral-risk survey data.

Based on the above research gaps, this study addresses the following research questions:

- RQ1: How accurately can machine-learning models classify a respondent's self-reported heart-disease status, and which model performs best?
- RQ2: How does class-imbalance handling affect classification performance?
- RQ3: Does the timing of resampling (before vs. after the train/test split) change the reported results?
- RQ4: Can a blockchain layer verify the integrity of health records and detect tampering?

To improve the accuracy and methodological soundness of heart-disease status classification while supporting secure patient record management, this study addresses these limitations through the following contributions:

- A reproducible framework for heart-disease status classification is developed using the BRFSS-based Heart 2020 Cleaned dataset, incorporating preprocessing, feature engineering, recursive feature elimination, and explicit class-imbalance handling, as a practical integration of established techniques rather than a novel algorithm.
- Five established classifiers (Random Forest, XGBoost, LightGBM, k-Nearest Neighbours, and a feed-forward DNN) are compared under a common pipeline to identify the most reliable configuration for heart-disease status classification.
- An analysis of class-imbalance handling techniques and the effect of resampling timing (post-split versus pre-split) on classification performance is presented, explicitly identifying pre-split resampling as a source of data leakage and optimistic bias.
- A blockchain-based integrity-verification layer is integrated into the prototype, with full patient records stored in the application database and SHA-256 digests anchored through an Ethereum-compatible environment to provide tamper-evident verification and traceability; access control is enforced at the API layer rather than on-chain.

This research therefore presents a prototype/feasibility study that integrates machine-learning-based heart-disease status classification with a blockchain-based EHR integrity layer. The system is designed to deliver a reproducible, healthcare-oriented decision-support framework, and its primary contribution is the practical integration of established components rather than a novel algorithm or blockchain architecture. The rest of the study is organized as follows. Section II reviews machine-learning-based heart-disease classification and blockchain-based EHR systems. Section III describes the materials and methods. Section IV presents experimental results. Section V discusses the results and compares them with existing works. Finally, Section VI concludes the study and suggests directions for future research.

II. Related Work

A lot of research work has investigated machine-learning methods for predicting and classifying cardiovascular risk from various kinds of data such as population surveys, clinical tabular datasets, physiological signals, imaging, free-text electronic health records, and omics data.

In studies based on large population surveys, Chen et al. [8] built a comparative framework on the Heart_2020_cleaned dataset derived from BRFSS, examining how Boruta feature selection, class balancing, and model tuning affect the performance of decision trees, random forests, logistic regression, and LightGBM. Based on their results, they obtained that LightGBM gives the highest overall accuracy. Age category and rate of health were the most significant predictors. Also, it should be noted that the specificity was always greater than the sensitivity. Febriyanti and Baita [9] focus on the severe class imbalance in Heart_2020_cleaned and use random under-sampling together with tuned SVM and CART decision trees; they demonstrate that under-sampling reduces overall accuracy but substantially improves minority-class recall and F1-score, explicitly highlighting the trade-off between balanced performance and global accuracy in this dataset. Tompra et al. [10] examine the 2021 BRFSS heart-disease data with extensive feature engineering and a spectrum of resampling methods such as SMOTE-ENN and ADASYN applied only to the training set; their best CatBoost configuration achieves very high recall but low precision, underscoring the difficulty of avoiding false negatives in highly imbalanced population-level prediction.

Osei-Nkwantabisa and Ntumy [11] combine multiple UCI heart-disease sources into a dataset of 1,190 patients, apply grid-search tuning to logistic regression, KNN, SVM and an ANN, and report KNN as the best performer with balanced precision and recall, though still below the very high scores claimed in some deep-learning works. Bhatt et al. [12] analyze a larger Kaggle cardiovascular disease dataset of 70,000 patients, using k-modes clustering to transform categorical variables before training decision trees, random forests, MLPs and XGBoost; they find that an MLP trained on clustered data achieves the highest accuracy and AUC, suggesting that clustering can be a useful preprocessing step for fully categorical risk-factor data. Almulihi et al. [13] construct a deep stacking ensemble that uses CNN-LSTM and CNN-GRU hybrids as base learners with an

SVM meta-classifier, evaluating the system on a large Kaggle heart-disease dataset and on Cleveland, and they report strong gains over individual models, particularly on the smaller dataset.

There has been a rise in the use of blockchain technology to support safer and more interoperable electronic health record (EHR) systems in healthcare systems in recent years. Many of the efforts were focused on developing blockchain-based architectures for healthcare records. Tahir et al. [5] developed an Ethereum-based EHR management framework where encrypted records are stored off-chain in IPFS and hashes plus metadata are maintained on-chain via smart contracts, with a web interface enabling hospitals and patients to upload and retrieve records securely. They showed low gas consumption and their response time at a load of simulated milliseconds is excellent, which implies the availability for real-world usage. Mandarino et al. [14] focused on cost and latency by introducing EdgeHR, a public-Ethereum dApp that keeps medical data on edge devices while recording hashed references and access policies on-chain; through careful use of smart-contract design patterns, they demonstrate significant gas savings while preserving integrity and auditability. These are examples of other healthcare systems that are securing only metadata and access logs on the blockchain, with the large medical data files stored off-chain.

Another line of work is concentrating on providing access control for EHRs using privacy-preserving, fine-grained parameters. Ali et al. [15] presented a Hyperledger Fabric framework that integrates attribute-based encryption and signatures with a multi–certificate authority design, avoiding a single point of trust and enabling cross-organizational access control. Using their performance measures with Hyperledger Caliper, they demonstrate that their experiments indicate that their MedRec-previously proposed system comparisons achieve higher throughput and lower overheads.

More recently, Kumari et al. [16] proposed BL-MVC, a blockchain-enabled framework that combines Ethereum-based blockchain storage, IPFS, Solidity smart contracts, a React-based front end, and a FastAPI back end, with a Majority Voting Classifier for heart disease prediction. Several machine learning models were used for these predictive models, including Logistic Regression, MLP, AdaBoost, CatBoost, and XGBoost. The blockchain layer helps in hosting patient records, which are decentralized and tamper-proof. The health care data set used for the study is based on the BRFSS (Behavior Risk Factor Surveillance System); predicting cardiac disease from the outcome column is a more straightforward example of combining data management improvements obtained with blockchain with embedded predictive analysis – aspects that are relevant for systems intended to support data protection improvements but also clinical decision support in a single system.

III. METHODOLOGY

The main procedure for classifying heart-disease status in this project involves integrating blockchain technology with machine-learning models that process population-level health data and output a status classification for each individual. The objective is twofold: 1) to use routinely collected cardiovascular risk indicators — such as demographic, behavioral, and self-reported health variables — to provide scalable, data-driven support for the classification of individuals according to their self-reported heart-disease status; and 2) to manage Electronic Health Records (EHRs) securely in the application database while using blockchain-based anchoring of cryptographic digests to provide tamper-evident integrity verification and traceability.

The general structure of the proposed system is shown in Fig. 1. The framework begins with patient information and health-related input data received through the user interface and coordinated by the application server. The machine-learning module processes the relevant data, applies preprocessing, and generates heart-disease status classifications. At the same time, patient EHRs are stored in the application database, while cryptographic digests and related identifiers are optionally anchored on an Ethereum-compatible blockchain for integrity verification. The following are key components of the system:

A. Key components of the system

1) User Interface (GUI): A front-end interface through which healthcare professionals and authorized users can enter patient data, request heart-disease status classifications, and securely access or update EHR information.

2) Machine learning model: Applies a chosen classification model (Random Forest, XGBoost, LightGBM, k-NN, and feed-forward DNN), and pre-processing, training, tuning, and classification.

3) Blockchain storage module: Provides a tamper-evident integrity layer by storing record hashes and verification-related metadata, ensuring traceability and protection against unauthorized modification; only cryptographic digests are stored on-chain, while full records remain in the application database.

4) Application server: Coordinates communication between the GUI, the ML module, the database, and the blockchain layer, while handling authentication, authorization, and the return of status-classification results and record-related responses to the GUI.

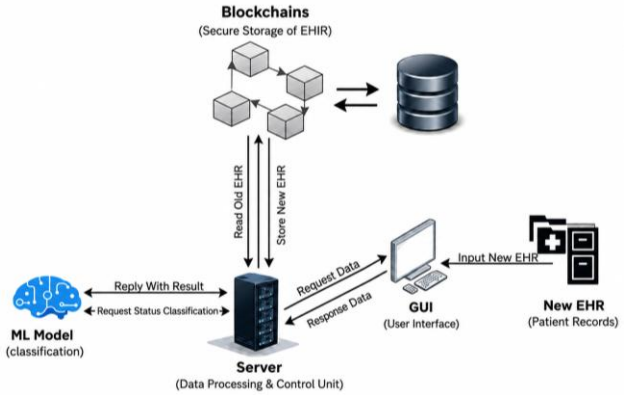

Fig. 1. General framework of the proposed system that secures EHRs and classifies heart-disease status.

B. Proposed Method

The proposed method is a machine-learning pipeline designed to classify heart-disease status using the Heart 2020 –

Cleaned (BRFSS) dataset. The method begins with preprocessing the original survey data, followed by development of multiple classification models and, finally, comparing the models' performance using standard metrics. The aim is to find an effective model to classify individuals as positive-class (heart-disease present) or negative-class (heart-disease absent) from demographic, behavioral, and self-reported health features. The general process for the proposed method is shown in Fig. 2.

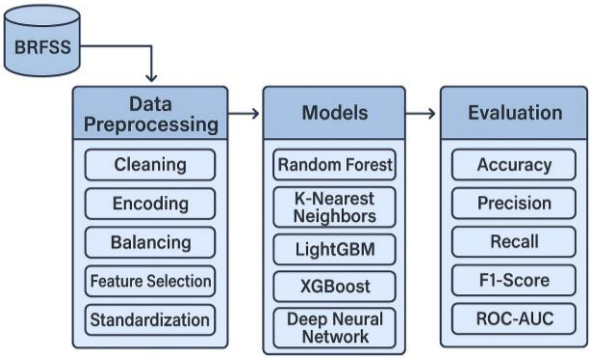

Fig. 2. Proposed machine learning method.

The proposed method consists of the following main stages:

1) Data preprocessing: Raw BRFSS data are prepared before model training to ensure that the dataset is suitable for machine-learning analysis. This stage includes the following steps:

2) Cleaning: The dataset is checked and prepared to remove inconsistencies and ensure that the values are ready for analysis.

3) Encoding: Categorical variables are transformed into numerical form so they can be processed by the classification models.

4) Balancing: Class imbalance in the target variable is addressed using resampling techniques to improve the representation of minority heart-disease cases.

5) Feature selection: The most informative variables are identified and retained to reduce redundancy and improve model performance.

6) Standardization: Numerical features are scaled to a common range so that differences in magnitude do not adversely affect model training.

7) Model development: The processed data are then used to train multiple classification models, namely Random Forest, k-Nearest Neighbours, LightGBM, XGBoost, and a feed-forward Deep Neural Network.

8) Performance evaluation: The trained models are assessed using standard classification metrics, including accuracy, precision, recall, F1-score, and ROC-AUC, to compare their effectiveness in heart-disease status classification.

9) Model comparison and selection: Based on the evaluation results, the relative strengths and weaknesses of the models are analyzed to identify the most suitable approach for the classification task.

C. Dataset

The dataset used in this study is the Heart 2020 Cleaned dataset, also known as Personal Key Indicators of Heart Disease, obtained from Kaggle [17]. It is derived from the 2020 wave of the U.S. Centers for Disease Control and Prevention (CDC) Behavioral Risk Factor Surveillance System (BRFSS) survey. BRFSS is an annual, telephone-based health survey in which adults across U.S. states and territories self-report information on demographic characteristics, health behaviours, and chronic conditions. The dataset contains 319,795 records and 18 variables, including the binary target variable HeartDisease, which indicates whether a respondent has ever been told by a health professional that they have coronary heart disease or myocardial infarction. The features are primarily categorical or ordinal and include age category, sex, body mass index (BMI), smoking status, alcohol consumption, physical activity, stroke history, diabetic status, kidney disease, general health, mental and physical health, sleep duration, and other health-related indicators. The dataset is notably imbalanced, with approximately 8.6% positive cases and 91.4% negative cases, making it suitable for evaluating machine-learning methods for imbalanced binary status classification. Because the label reflects a previously reported diagnosis, the task is the classification of existing self-reported heart-disease status rather than the prediction of future disease onset. This is a telephone-based public-health survey dataset and is not a clinical EHR dataset. Table I summarizes the variables included in the Heart 2020 Cleaned dataset and the data type for each of the features used in the proposed heart-disease status-classification framework.

TABLE I. FEATURES IN THE HEART 2020 CLEANED DATASET AND THEIR DATA TYPES

Feature	Type
HeartDisease	Binary (Categorical)
BMI	Continuous
Smoking	Binary (Categorical)
AlcoholDrinking	Binary (Categorical)
Stroke	Binary (Categorical)
PhysicalHealth	Continuous (Numeric, days)
MentalHealth	Continuous (Numeric, days)
DiffWalking	Binary (Categorical)
Sex	Binary (Categorical)
AgeCategory	Ordinal Categorical
Race	Nominal Categorical
Diabetic	Categorical (Multi-class)
PhysicalActivity	Binary (Categorical)
GenHealth	Ordinal Categorical
SleepTime	Continuous
Asthma	Binary (Categorical)
KidneyDisease	Binary (Categorical)
SkinCancer	Binary (Categorical)

1) Target class distribution and imbalance analysis: Fig. 3 presents the distribution of the target variable, HeartDisease. This data is imbalanced, with 91.4% of people in the non-heart-disease class and 8.6% in the heart-disease class. This is a large imbalance between the two classes and can lead to classification models favouring the majority class, thus decreasing the chances of getting positive heart disease cases classified correctly. Therefore, class-balancing techniques were necessary to improve the representation of the minority class and support more reliable model training.

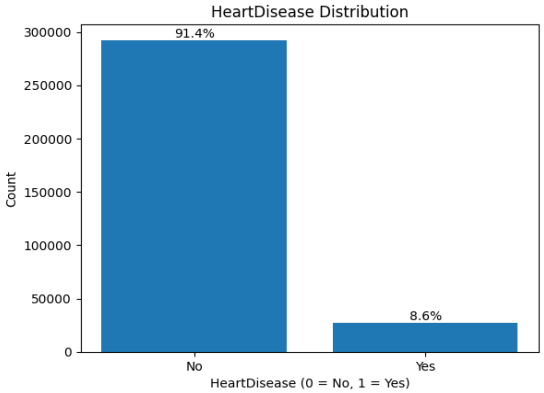

Fig. 3. Heart-disease class distribution

2) Distribution Analysis of Body Mass Index (BMI): Fig. 4 shows the distribution of BMI in the dataset. Most values are concentrated between 20 and 35, indicating that a large proportion of respondents fall within the normal, overweight, and moderately obese ranges. The distribution is right-skewed, with fewer observations extending toward higher BMI values. This suggests that although most respondents have moderate BMI levels, the dataset also includes individuals with substantially elevated BMI. The observed variation indicates that BMI may serve as an important feature in heart-disease status classification.

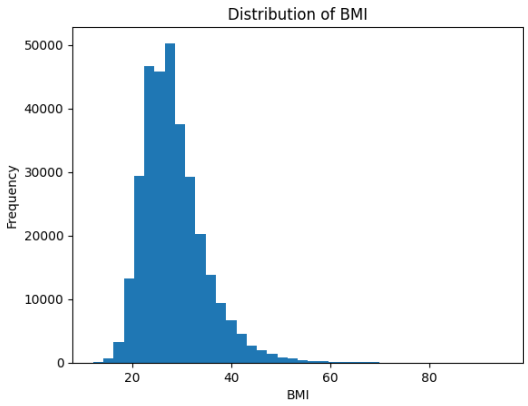

Fig. 4. Distribution of BMI

3) Distribution analysis of physical health: Fig. 5 presents the distribution of PhysicalHealth, which represents the number of days during the past 30 days in which a respondent experienced poor physical health. The distribution is clearly right-skewed, with a very large proportion of observations concentrated at 0 days, showing that most respondents reported no poor physical health problems during the reference period. At the same time, values are spread across the rest of the range, with a noticeable concentration at 30 days, indicating that some individuals experienced poor physical health throughout the entire month. This pattern highlights the variability of the feature and suggests that it may provide useful information for distinguishing different levels of reported heart-disease status.

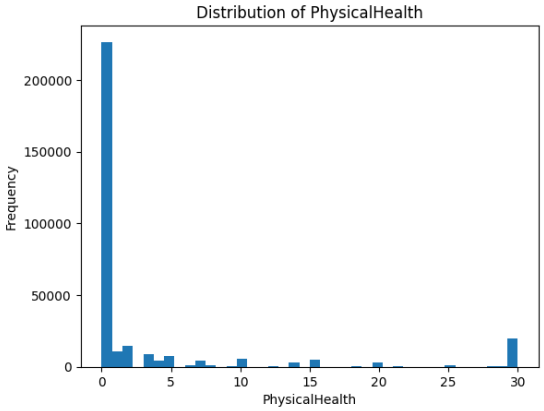

Fig. 5. Distribution of PhysicalHealth

4) Distribution analysis of mental health: Fig. 6 shows the distribution of MentalHealth (number of days in the last 30 days that the respondent did not feel mentally well). The distribution is strongly right-skewed, with most observations concentrated at 0 days, indicating that many respondents reported no poor mental health problems during the reference period. Meanwhile, the other values have been distributed across the range, with most of them falling in the range of 30 days, indicating that some people did not achieve good mental health during the month at all. This pattern shows the fluctuations of the feature, which suggests that it could be relevant for heart-disease status classification.

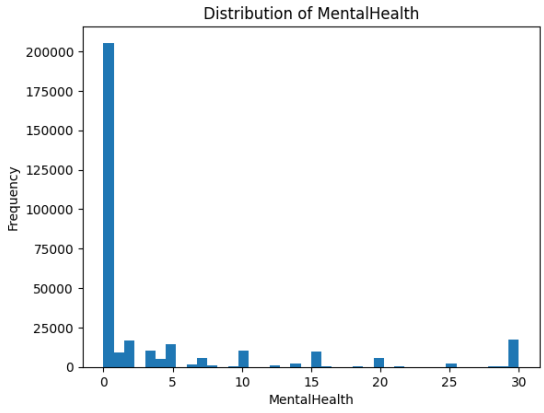

Fig. 6. Distribution of MentalHealth

5) Distribution analysis of sleep duration: The distribution of SleepTime (self-reported hours of sleep in 24 hours) is shown in Fig. 7. The distribution is centered around 7 hours,

which is the most frequent sleep time that the respondents reported. The majority of observations are in the 5-9 hour range, indicating that most participants' sleep times were close to the recommended range. The distribution also has a slight right tail, indicating that some respondents reported unusually long sleep durations. This variation suggests that sleep duration could provide lifestyle-related information for classifying heart-disease status.

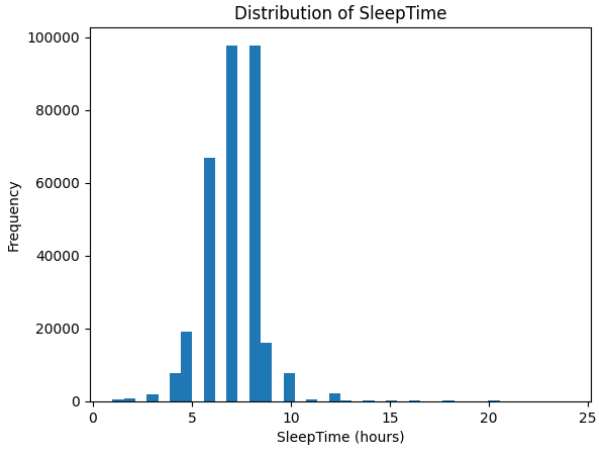

Fig. 7. Distribution of sleep time.

6) Multivariate correlation analysis: The Pearson correlation heatmap of numerical features BMI, PhysicalHealth, MentalHealth, and SleepTime is provided in Fig. 8. The majority of pairwise correlations are weak to moderate, suggesting that these variables measure different aspects of the respondents' health status, and that they offer relatively unique information to the classification models. PhysicalHealth has the highest positive correlation with MentalHealth, indicating that there is a strong relationship between bad physical and mental health. The rest of the correlations are comparatively small, and there is no indication of extreme multicollinearity among pairs of variables. This is beneficial for model creation since it decreases the quantity of redundant numeric features.

7) Categorical distribution of smoking status: The distribution of the Smoking feature in the data set is given in Fig. 9. The chart indicates that there are both smokers and non-smokers, with non-smokers being the majority. However, the number of respondents with a history of smoking is also significant, suggesting that smoking is a prevalent feature among the study population. This distribution highlights the relevance of smoking as an important behavioral risk factor and supports its inclusion as a potential predictor in the heart-disease classification models.

8) Bivariate analysis: smoking vs. heart disease: A stacked-proportions bivariate comparison of Smoking status and HeartDisease is shown in Fig. 10. The chart illustrates the proportions of smokers and non-smokers with and without heart disease. The proportion of heart disease cases is visibly higher among smokers than among non-smokers, suggesting a stronger association between smoking and adverse cardiovascular outcomes. Since the values are displayed as normalized ratios, Fig. 10 can be used to compare the two groups irrespective of differences in sample size. This pattern helps to confirm the significance of smoking status as one of the important factors in the heart-disease classification models.

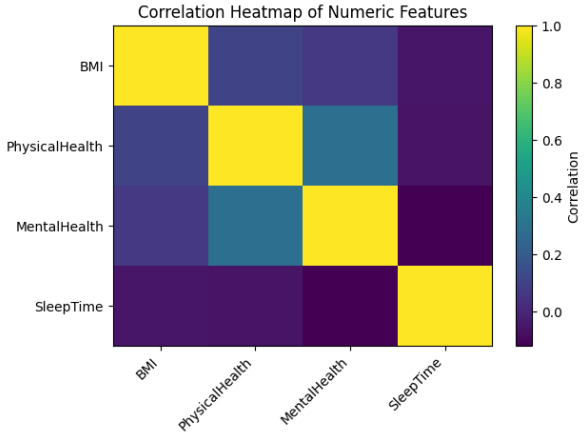

Fig. 8. Correlation heatmap of numeric features.

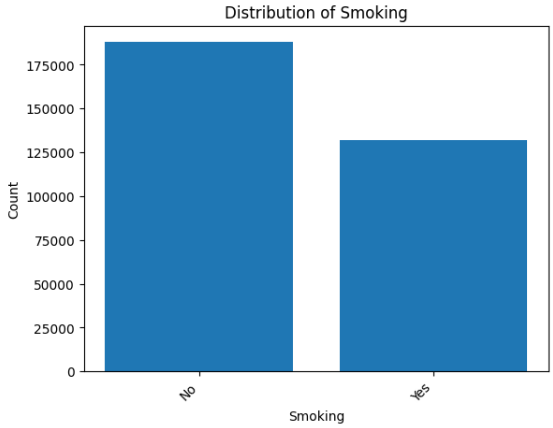

Fig. 9. Distribution of the smoking categorical feature.

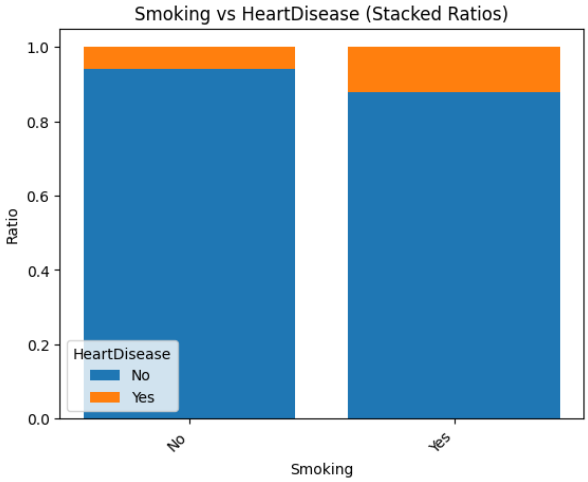

Fig. 10. Smoking versus HeartDisease (stacked ratios).

D. Data Preprocessing and Feature Selection

Preprocessing operations are performed on the data, such as handling missing values, normalizing numeric attributes, and encoding categorical attributes. Recursive Feature Elimination (RFE) is used to identify the most crucial attributes that boost model performance.

1) Data preprocessing and transformation: Within the first dataset, there were different types of data: categorical strings, ordinal values, and continuous numeric values. To fulfill the mathematical requirements of classifiers, all the features were transformed into numbers. The target variable HeartDisease was turned into a binary indicator where "Yes" was mapped to 1 (presence of heart disease) and "No" was mapped to 0 (absence).

The binary categorical variables (Smoking, AlcoholDrinking, Stroke, DiffWalking, PhysicalActivity, Asthma, KidneyDisease, SkinCancer) were coded as "Yes" = 1 and "No" = 0. Sex was coded as 1 for "Male", and 0 for "Female". The Diabetic attribute was dealt with separately: the answers for 'borderline diabetes' and 'gestational diabetes' (Yes (during pregnancy)) were combined to form the binary risk factor for the diabetic condition before the standard mapping.

Ordinal variables were coded in order to maintain the underlying order of the variables. The AgeCategory ranges were mapped to approximate midpoint values (e.g., "18-24" was approximated by 21 and "80 or older" was approximated by 85). In turn, GenHealth's responses were coded on a scale from 5 ("Excellent") to 1 ("Poor"). The nominal categorical variable Race was encoded using one-hot encoding with pandas.get_dummies function, generating separate binary indicator columns for each racial category to avoid creating false ordinal relationships between the categories. Finally, numeric data such as BMI, PhysicalHealth, MentalHealth, and SleepTime were retained as numeric data and standardized before being put into the model.

2) Feature engineering and Recursive Feature Elimination (RFE): Beyond the above-mentioned attributes, two composite features were created to reflect the combined effect of the risk factors. Chronic Condition Count was derived as the sum of binary indicators for Stroke, Diabetic, Asthma, KidneyDisease, and SkinCancer. This feature measures the number of chronic comorbidities that an individual has. Unhealthy Behavior Count was calculated as the sum of Smoking, AlcoholDrinking, physical inactivity (PhysicalActivity was inverted), and poor general health (GenHealth <= 2). The consolidated signals from these engineered features gave information on the patient's health status.

Specifically, the RFE feature selection procedure retained exactly 15 features out of the initial 24 columns. The 15 retained features are: 1) Stroke, 2) Sex, 3) AgeCategory, 4) Diabetic, 5) GenHealth, 6) Asthma, 7) KidneyDisease, 8) SkinCancer, 9) Race_American Indian/Alaskan Native, 10) Race_Asian, 11) Race_Black, 12) Race_Hispanic, 13) Race_Other, 14) Race_White, and 15) ChronicCondCount. The target count of 15 features was determined heuristically to preserve the essential demographic, clinical, and lifestyle factors while maintaining computational efficiency and preventing model overfitting. RFE utilized a weighted Logistic Regression model as the base estimator.

3) Class imbalance handling and sampling strategy: There is a significant class imbalance in the data that shows only about 8.6% positive heart disease from the BRFSS data. To address this problem, three innovative hybrid sampling algorithms were systematically compared: SMOTEENN, BorderlineSMOTE, and SMOTETomek.

a) SMOTEENN (Synthetic Minority Oversampling Technique + Edited Nearest Neighbors): This method is a combination of oversampling of the minority class with SMOTE and data-cleaning of Edited Nearest Neighbors (ENN). SMOTE generates minority samples by performing interpolation between minority samples, and ENN removes the majority samples that are wrongly classified by their nearest neighbors. It has two-way action, which can not only balance the class distribution but can also remove noisy and ambiguous majority samples, thus achieving class cleanliness.

b) BorderlineSMOTE: Unlike standard SMOTE, which generates synthetic samples uniformly, BorderlineSMOTE focuses specifically on minority instances that lie near the decision boundary (borderline instances). Because borderline samples are more likely to be misclassified, oversampling the region allows the classifier to draw a better and more reliable line between classes.

c) SMOTETomek: This method combines SMOTE oversampling with Tomek Links removal. Tomek Links are pairs of instances from different classes that are nearest neighbors to each other. By removing the majority class instances that form Tomek Links, this technique cleans the class overlap after oversampling, leading to well-defined class clusters.

Crucially, the impact of the timing of sampling application relative to the data split was investigated. Two distinct strategies were compared:

d) Post-split sampling: Sampling methods were only used on the training set after the train_test_split was performed. This ensures that the test set is an untouched, original imbalanced population distribution, thus preventing data leakage. However, it may also limit the model training.

e) Pre-split sampling: Sampling methods were utilized on the overall dataset before the division of training and testing sets. This method ensures that the training and test folds both have equal distributions of classes. Although it has been pointed out that this technique exposes the test set to synthetic data, it allows the model to learn from a completely balanced feature space, and the model's performance is measured on a balanced test set. Note, however, that this configuration introduces data leakage, producing optimistically biased results that should not be interpreted as valid estimates of real-world performance.

E. Machine Learning Models

The machine-learning component of the system consists of training and comparing five different classifiers: Random

Forest, XGBoost, LightGBM, k-Nearest Neighbours and a feed-forward Deep Neural Network. All models are trained on the preprocessed feature set and tuned using cross-validation to obtain robust hyperparameters.

1) Random forest: RF is a supervised learning technique that can be used for both regression and classification [18]. Instead of focusing on the most important features when splitting a node, this algorithm selects the best features from a randomly chosen subset of features [19]. In contrast to the DT algorithm, RF selects observations at random, selects features to create multiple trees, and then averages the results [20]. Additionally, RF typically avoids overfitting by constructing random sub-trees of features and generating smaller trees using these sub-trees [21], which are then combined.

2) Extreme Gradient Boosting (XGBoost): XGBoost is a gradient-boosting framework that builds an ensemble of decision trees sequentially [22]. Each new tree is trained to correct the residual errors of the previous trees by optimizing a differentiable loss function plus regularization terms. This additive learning paradigm enables XGBoost to model complex non-linear relationships between features and the target class. Important hyperparameters include the learning rate, maximum tree depth, number of estimators, and regularization coefficients.

3) Light Gradient-Boosting Machine (LightGBM): LightGBM is another gradient-boosting algorithm designed for efficiency on large datasets [23]. It builds depth-constrained trees leaf-wise and employs histogram-based splitting, frequently resulting in rapid training times and good classification performance. Similar to XGBoost, LightGBM generates an ensemble of trees to reduce the loss function along with regularization. Hyperparameters, such as the number of leaves, maximum depth, learning rate, and feature-fraction, are tweaked to strike the right balance between accuracy and overfitting.

4) KNN: k-Nearest Neighbours is a non-parametric classification method that classifies the class of a new instance based on the labels of its *k* closest training examples in feature space [24]. Continuous variables are typically standardized, while Euclidean distance is utilized to compute the distance between instances. To determine the classified class, the voting of the majority among the k neighbours is the method that is followed. The primary hyperparameter is k, which is selected to balance the sensitivity to the noise (small k) and the over-smoothing (large k).

5) Feed-forward deep neural network: The feed-forward Deep Neural Network (DNN) consists of an input layer, one or more hidden layers of fully connected neurons, and an output layer with a sigmoid (or softmax) activation to produce class probabilities [25]. A layer is made of a linear transformation and a non-linear activation function (e.g., ReLU). Parameters of the network are learned by reducing a cross-entropy loss function using back-propagation and stochastic gradient descent (or some other optimization algorithm like Adam). Regularization (dropout and L2 weight decay) is used to ensure that the model does not overfit the training data.

The performance of different models will be compared using accuracy, precision, recall, F1-score, and ROC-AUC. According to these metrics, the best-performing classifier according to these metrics is then selected for integration within the prototype system to generate heart-disease status classifications for new records.

The final hyperparameter configurations used in the experiments are reported in Table II. The values were selected through cross-validation-based tuning.

TABLE II. CLASSIFIER HYPERPARAMETER CONFIGURATIONS USED IN THE EXPERIMENTS

Classifier	Hyperparameter Parameter Settings
XGBoost	n_estimators = 1800, learning_rate = 0.04, max_depth = 8, min_child_weight = 1, subsample = 0.95, colsample_bytree = 0.95, gamma = 0.01, reg_alpha = 0.01, reg_lambda = 0.8, scale_pos_weight = 0.85, tree_method = "hist", random_state = 42
LightGBM	objective = "binary", n_estimators = 2200, learning_rate = 0.04, num_leaves = 200, max_depth = -1 (unlimited), min_child_samples = 10, min_child_weight = 0.0001, subsample = 0.95, colsample_bytree = 0.95, reg_alpha = 0.01, reg_lambda = 0.8, random_state = 42
Random Forest	n_estimators = 1500, max_depth = 30, min_samples_split = 3, min_samples_leaf = 1, max_features = "sqrt", bootstrap = True, random_state = 42
k-NN	n_neighbors = 5, weights = "distance", metric = "minkowski", p = 2 (equivalent to Euclidean distance)
DNN	Input shape = (15,); Dense (128, ReLU) → Dropout (0.3) → Dense (64, ReLU) → Dropout (0.3) → Dense (32, ReLU) → Dropout (0.3) → Dense (1, Sigmoid); Optimizer = Adam (learning_rate = 0.001), Loss = binary_crossentropy, Batch Size = 32, Epochs = 10.

The five classifiers exhibit distinct trade-offs between classification accuracy and computational cost. The tree-based ensembles (XGBoost, LightGBM, and Random Forest) achieve the highest discriminative performance but require significant memory footprint and training time when processing the resampled datasets (~500,000 instances), especially when integrating hybrid resampling. In contrast, the k-NN model has zero training time but incurs high computational latency during inference, as it must calculate distances to all training samples at runtime, which scales poorly for large-scale production EHRs. Finally, the Feed-Forward Deep Neural Network (DNN) requires specialized GPU hardware for efficient training, but offers sub-second inference speeds post-training. These computational trade-offs must be evaluated based on resource availability in real-world clinic deployments.

F. Baselines and Evaluation Measures

To evaluate the performance of machine learning models, the following metrics are used:

Accuracy: Indicates the overall correctness of the model's classifications.

$$\text{Accuracy} = \frac{TP+TN}{TP+TN+FP+FN} \quad (1)$$

Precision: Measures the proportion of true positive classifications among all positive classifications.

$$\text{Precision} = \frac{TP}{TP+FP} \quad (2)$$

Recall (Sensitivity): Assesses the model's ability to identify all relevant instances.

$$\text{Recall} = \frac{TP}{TP+FN} \quad (3)$$

F1-Score: The harmonic mean of precision and recall, balancing false positives and false negatives.

$$\text{F1} = \frac{2\times \text{Precision} \times \text{Recall}}{\text{Precision} + \text{Recall}} \quad (4)$$

ROC-AUC (Receiver Operating Characteristic – Area Under Curve): Evaluates model performance across different classification thresholds.

IV. Results and Discussion

A. Overview of Results

This section presents the experimental results of the proposed heart-disease status classification framework, which integrates a blockchain-supported EHR integrity-verification layer with machine-learning classification models. Five classifiers were evaluated: Random Forest, XGBoost, LightGBM, k-Nearest Neighbours (k-NN), and a feed-forward Deep Neural Network (DNN). Recursive Feature Elimination (RFE) was applied for feature selection across all experiments. The primary objective was to investigate the impact of sampling technique timing on model performance, specifically comparing two strategies: applying sampling after the train-test split (post-split, the methodologically valid configuration) versus applying sampling before the train-test split (pre-split, which introduces data leakage).

The Heart 2020 – Cleaned (BRFSS) dataset, comprising 319,795 records with approximately 8.6% positive heart-disease cases, was used for all experiments. Three sampling techniques were employed to address the severe class imbalance: SMOTEENN, BorderlineSMOTE, and SMOTETomek. A no-sampling baseline was also evaluated for the post-split configuration. The evaluation metrics include accuracy, precision, recall, F1-score, and ROC-AUC. The results demonstrate that the pre-split sampling strategy consistently produced higher numerical scores than post-split; however, these higher scores are largely attributable to data leakage from global resampling and should not be interpreted as a genuine real-world improvement. The best performance under the methodologically valid post-split configuration achieved an AUC of approximately 0.85.

TABLE III. Performance Metrics for Post-Split Sampling Configurations

Sampler	Model	Accuracy	Precision	Recall	F1-Score	ROC-AUC
SMOTEENN	XGBoost	0.55	0.15	0.93	0.26	0.85
SMOTEENN	LightGBM	0.83	0.27	0.62	0.38	0.85
SMOTEENN	KNN	0.90	0.37	0.22	0.27	0.61
SMOTEENN	RandomForest	0.78	0.24	0.72	0.36	0.85
SMOTEENN	DNN	0.71	0.21	0.82	0.33	0.85
BorderlineSMOTE	XGBoost	0.84	0.28	0.53	0.36	0.83
BorderlineSMOTE	LightGBM	0.84	0.28	0.54	0.37	0.83
BorderlineSMOTE	KNN	0.90	0.36	0.16	0.22	0.71
BorderlineSMOTE	RandomForest	0.85	0.27	0.48	0.35	0.81
BorderlineSMOTE	DNN	0.77	0.24	0.74	0.35	0.83
SMOTETomek	XGBoost	0.85	0.29	0.49	0.36	0.82
SMOTETomek	LightGBM	0.85	0.29	0.51	0.37	0.83
SMOTETomek	KNN	0.90	0.35	0.18	0.23	0.71
SMOTETomek	RandomForest	0.86	0.29	0.46	0.35	0.80
SMOTETomek	DNN	0.75	0.22	0.75	0.34	0.83
None	XGBoost	0.92	0.55	0.09	0.15	0.85
None	LightGBM	0.92	0.60	0.09	0.15	0.85
None	KNN	0.91	0.37	0.16	0.22	0.72
None	RandomForest	0.91	0.42	0.13	0.20	0.79
None	DNN	0.92	0.60	0.07	0.11	0.85

B. Results for Post-Split Sampling

Table III presents the performance metrics of the five machine learning classifiers (Random Forest, XGBoost, LightGBM, k-Nearest Neighbours (k-NN), and a feed-forward Deep Neural Network (DNN)) combined with Recursive Feature Elimination (RFE) for feature selection, when sampling techniques were applied after the train-test split. Four sampling configurations were tested: SMOTEENN, BorderlineSMOTE, SMOTETomek, and no sampling (None). The metrics used are accuracy, precision, recall, F1-score, and ROC-AUC.

The confusion matrix of the LightGBM model with ensemble method using SMOTETomek in combination with RFE under the post-split sampling setup is shown in Fig. 11. The classification results of the model are realistic, and the model is actually not the best, due to the high number of false positive cases (6097) and also false negative cases (3014). The model correctly classified 52,387 true-negative cases, but it is only a very small portion of the positive heart disease cases that the model can output since learning from imbalanced data when sampling is done after the split is quite challenging.

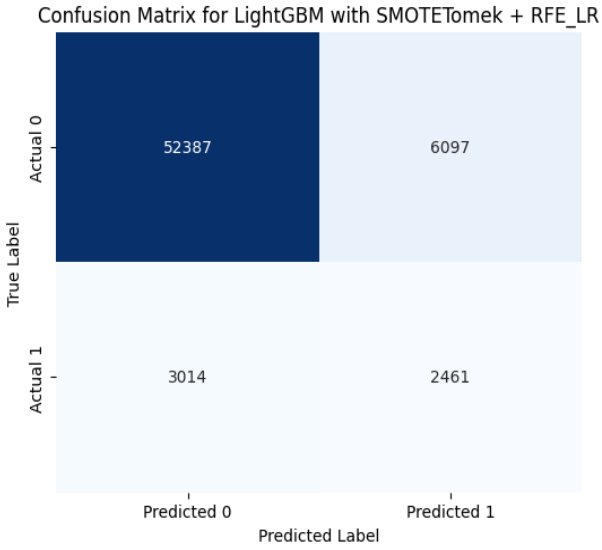

Fig. 11. Confusion matrix of the LightGBM classifier with SMOTETomek and RFE under the post-split sampling configuration.

Fig. 12 presents the ROC curve of the LightGBM model in the post-split configuration with SMOTETomek, which shows the discriminative ability of the model with an AUC of 0.83.

SMOTETomek and BorderlineSMOTE showed the most balanced accuracy-recall trade-off among the sampling methods tested in the post-split configuration for the ensemble models. The best accuracy was 86%, obtained by Random Forest with SMOTETomek, while the precision was 0.29, recall 0.46, F1-score 0.35, and ROC-AUC 0.80. When SMOTETomek and BorderlineSMOTE were used, LightGBM achieved 85% accuracy with both, and with either sampler, the highest F1-score (0.37) and ROC-AUC (0.83). XGBoost also had an accuracy of 85% with SMOTETomek (precision 0.29, recall 0.49, F1-score 0.36, ROC-AUC 0.82) and 84% accuracy with BorderlineSMOTE (precision 0.28, recall 0.53, F1-score 0.36, ROC-AUC 0.83). As can be observed from these results, the two sampling methods (SMOTETomek and BorderlineSMOTE) produced comparable results for the gradient boosting ensemble models in the post-split situation.

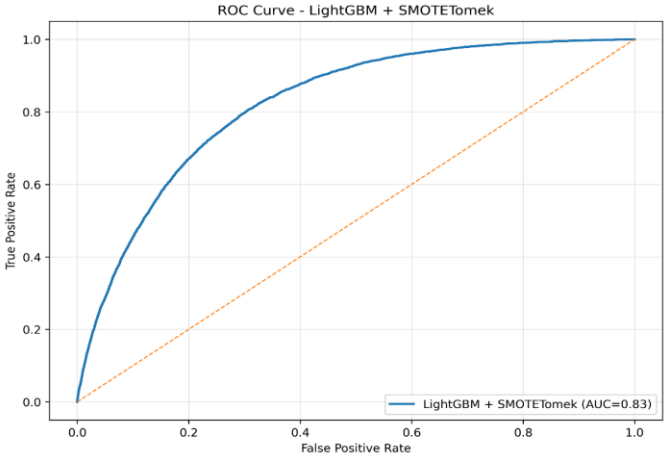

Fig. 12. ROC curve of LightGBM with SMOTETomek (post-split).

The k-NN classifier achieved the highest raw accuracy (0.90) for all the post-split configurations of sampling; however, with significantly lower recall (0.16–0.22), indicating that k-NN has a tendency to misclassify positive heart disease classes. Specifically, k-NN with SMOTETomek obtained 90% accuracy, 0.18 recall, and 0.23 F1-score, while k-NN with BorderlineSMOTE obtained 90% accuracy, 0.16 recall, and 0.22 F1-score. The accuracy of k-NN was 90% with SMOTEENN, which had the lowest ROC-AUC of 0.61, a marginally improved recall of 0.22, and a low F1-score of 0.27. This behavior indicates that in the post-split case, k-NN tends to strongly favor the majority class and is not able to detect the individuals who are likely to develop heart disease.

In the post-split configuration, SMOTEENN produced a distinct recall-precision trade-off. The recall at the cost of accuracy and precision was significantly improved for some models: the recall of XGBoost was 0.93, and the recall of DNN was 0.82. The F1 score of XGBoost with SMOTEENN was low (0.26), but its accuracy and precision were low (55% and 0.15, respectively) and ROC-AUC was high (0.85). Similarly, DNN with SMOTEENN attained an accuracy of 71%, a precision of 0.21, an F1-score of 0.33, and ROC-AUC of 0.85. Random Forest with SMOTEENN showed an accuracy of 78%, with a recall of 0.72 and an ROC-AUC of 0.85. These results show that the post-split SMOTEENN method has an aggressive effect on the minority class, resulting in an increase in sensitivity at the cost of classification accuracy.

When no sampling technique was applied (None), tree-based ensemble models such as XGBoost, LightGBM, and the DNN achieved the highest accuracy of 92% but exhibited extremely poor recall values (XGBoost: 0.09, LightGBM: 0.09, DNN: 0.07), effectively failing to identify the minority class. Random Forest was able to get 91% accuracy with a recall of only 0.13, while k-NN was able to get 91% accuracy with a recall of 0.16. For imbalanced classification problems, there is an important trade-off: models can get high overall accuracy by classifying the majority class and ignoring the minority class, in this case, the heart disease cases.

When assessing discriminative ability – ROC-AUC values for the ensemble models – Random Forest, XGBoost, LightGBM, and DNN - across most of the post-split configurations, the ROC-AUC values were high, from 0.80 to 0.85. LightGBM and DNN attained the same ROC-AUC of 0.85 with the three sampling methods – the SMOTEENN, the BorderlineSMOTE, and the SMOTETomek – and without sampling. These consistently high values of ROC-AUC indicate that the models have a reasonably good ranking ability even before tuning the thresholds for classification with regard to imbalanced data.

Fig. 13 provides a visual comparison of classifier performance across the post-split sampling configurations, highlighting the trade-offs among accuracy, precision, recall, F1-score, and ROC-AUC.

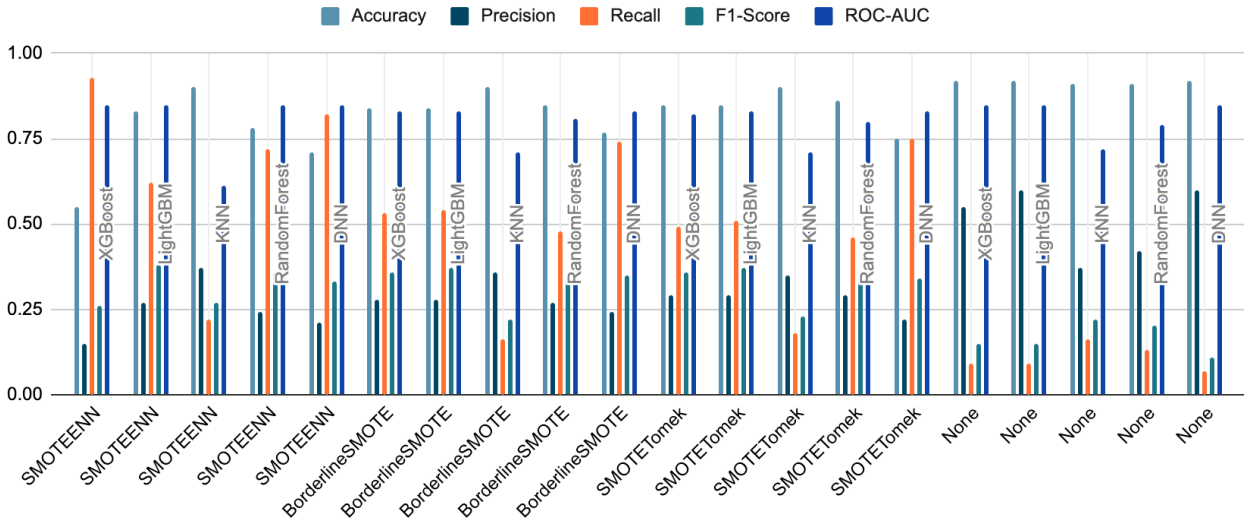

Fig. 13. Results for pre-split sampling (leakage-affected, for comparison only).

TABLE IV. PERFORMANCE METRICS FOR PRE-SPLIT SAMPLING CONFIGURATIONS

Sampler	Model	Accuracy	Precision	Recall	F1-Score	ROC-AUC
SMOTEENN	XGBoost	0.96	0.98	0.95	0.96	0.99
SMOTEENN	LightGBM	0.97	0.98	0.96	0.97	0.99
SMOTEENN	KNN	0.97	0.96	0.99	0.98	0.99
SMOTEENN	RandomForest	0.97	0.97	0.98	0.98	1.00
SMOTEENN	DNN	0.88	0.86	0.91	0.89	0.93
SMOTETomek	XGBoost	0.93	0.96	0.89	0.93	0.97
SMOTETomek	LightGBM	0.94	0.96	0.91	0.93	0.98
SMOTETomek	KNN	0.90	0.85	0.97	0.90	0.95
SMOTETomek	RandomForest	0.94	0.94	0.94	0.94	0.98
SMOTETomek	DNN	0.80	0.75	0.90	0.82	0.88
BorderlineSMOTE	XGBoost	0.92	0.96	0.89	0.92	0.96
BorderlineSMOTE	LightGBM	0.93	0.95	0.91	0.93	0.97
BorderlineSMOTE	KNN	0.90	0.86	0.96	0.90	0.95
BorderlineSMOTE	RandomForest	0.94	0.93	0.94	0.94	0.98
BorderlineSMOTE	DNN	0.83	0.80	0.88	0.84	0.90

Table IV shows the performance results when sampling methods were applied before the train-test split (pre-split, global resampling). This configuration is leakage-affected: because resampling is performed on the entire dataset before splitting, synthetic samples can influence both training and test data, producing optimistically biased metrics. These results are therefore not a valid estimate of real-world performance and are reported only to illustrate the effect of incorrect resampling timing. The results have shown significant improvements over the post-split configuration with accuracy ranging from 8–41 percentage points depending on the classifier and sampling combination, but this gap is largely driven by data leakage rather than genuine generalization.

Under the pre-split (global resampling, leakage-affected) configuration, SMOTEENN produced the highest numerical

scores. LightGBM achieved 97% accuracy, 98% precision, 96% recall, and 97% F1-score. Random Forest achieved 97% accuracy, 97% precision, 98% recall, and 98% F1-score. KNN showed 97% accuracy with 99% recall and 98% F1-score; XGBoost achieved 96% accuracy, 98% precision, 95% recall, and 96% F1-score. The Deep Neural Network achieved 88% accuracy, 86% precision, 91% recall, and 89% F1-score under SMOTEENN. However, it must be emphasized that all of these figures are inflated by data leakage from global resampling before the train/test split and should not be used as evidence of genuine real-world superiority. The post-split AUC of approximately 0.85 is the appropriate basis for comparison with prior work.

SMOTETomek and BorderlineSMOTE achieved strong results in the pre-split setting, but slightly lower than SMOTEENN. The other models, SMOTETomek, had an accuracy of 94%, and Random Forest had a precision of 94%, recall of 94%, and F1-score of 94%, while LightGBM had a precision of 96%, recall of 91%, and F1-score of 93%. Using SMOTETomek, the accuracy of XGBoost is 93%, the precision is 96%, the recall is 89%, and the F1-score is 93%, while k-NN is 90%, 85%, 97%, and 90%, respectively. The other three methods (BorderlineSMOTE, Random Forest, LightGBM, and XGBoost) also gave similar performance with accuracy of 94%, 93%, and 92%, respectively; precision of 93%, 95%, and 96% respectively; recall of 94 %, 91%, and 89%, respectively; and F1 score of 94%, 93% and 92% respectively.

The confusion matrix of the Random-Forest classifier trained with the SMOTEENN pre-splitting sampling configuration is shown in Fig. 14. It achieves a high number of true positives (49,516 individuals) and true negatives (42,526 individuals); has a small number of false positives (1,296 individuals) and false negatives (1,108 individuals). This shows that SMOTEENN can successfully generate a well-balanced and well-separated feature space, which enables both heart class and non-heart class cases to be identified successfully.

Fig. 15 illustrates the ROC curve, which further demonstrates that the Random Forest model trained with the SMOTEENN method under the pre-split sampling configuration has excellent discriminative performance.

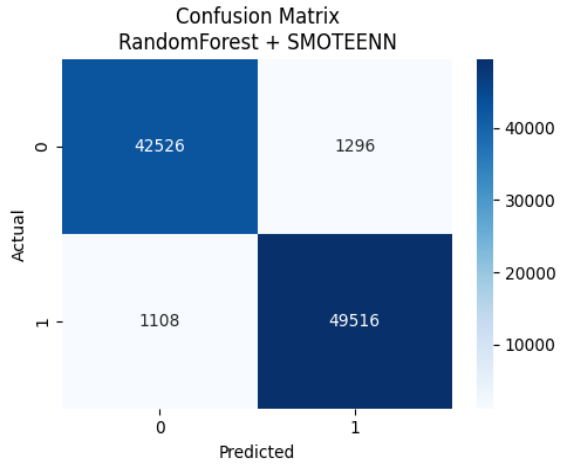

Fig. 14. Confusion matrix of the random forest classifier trained with SMOTEENN under the pre-split sampling configuration.

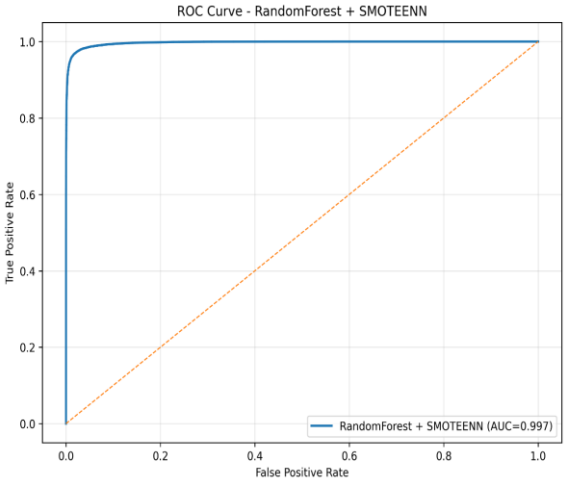

Fig. 15. ROC curve of random forest with SMOTEENN (pre-split).

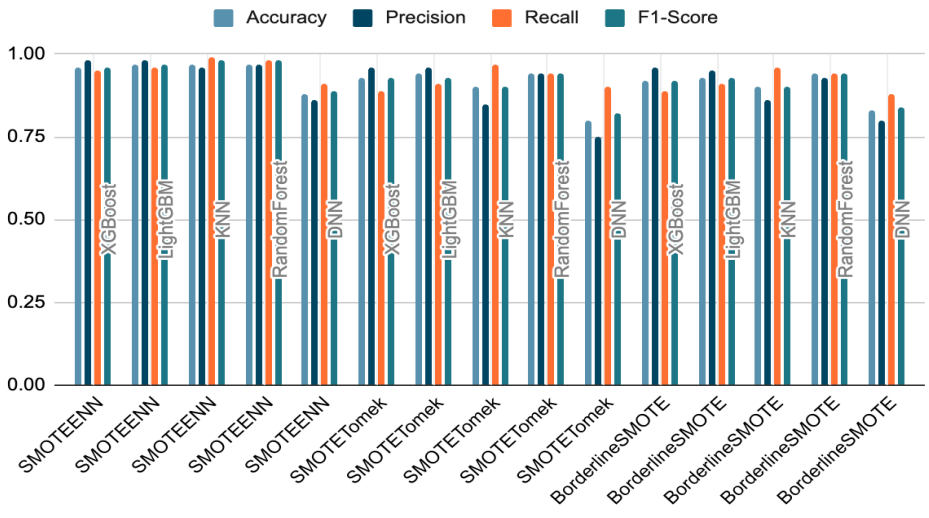

Fig. 16. Performance comparison across classifiers and samplers under the pre-split configuration.

These pre-split results must be interpreted with caution because applying resampling before the train/test split allows synthetic instances to enter and influence the test set, producing data leakage and optimistically biased metrics. The high scores observed in this configuration do not represent a valid estimate of real-world performance. They are retained only to illustrate the magnitude of the data-leakage effect. Under the leakage-safe post-split protocol, the AUC of approximately 0.85 provides the methodologically valid performance estimate. As shown in Fig. 16, SMOTEENN consistently produced the highest numerical scores across all classifiers in the pre-split configuration.

When the capacity of classifications of the machine learning approaches is confirmed to be higher, the results for the blockchain component – intended to secure the eHRs utilized by the classification module – are described in the next section.

C. Blockchain-Based EHR Implementation Results

This section presents the results of the blockchain-based electronic health record (EHR) integrity verification component, which was implemented alongside the machine learning classification framework. The blockchain module was designed to provide tamper-evident storage of medical records by anchoring cryptographic digests on an Ethereum-compatible network, while retaining the full clinical payloads in the application database. The implementation leveraged a dual-mode integrity layer: local database commits of SHA-256 digests, with optional smart-contract storage on a local EVM (Ganache) for distributed anchoring.

The smart contract, EHRRecordRegistry, was coded using Solidity and deployed to the local test network Ganache. There is a commitRecordHash function in the contract that takes a patient identifier, record identifier, and digest string (sha256) to securely commit the record fingerprint on-chain. A retrieval function enables enumeration of committed hashes for any given patient-record pair, supporting verification queries. The integrity verification process operates as follows: upon commit, the server computes SHA-256 of the UTF-8 encoded payload JSON and optionally submits the digest to the smart contract via Web3.py, receiving a transaction receipt. Upon verification, the current payload digest is recomputed and compared against the latest committed hash (preferring on-chain data when available). Any discrepancy between the recomputed digest and the anchored value indicates potential tampering with the record.

Table V summarizes the key implementation characteristics and observed behaviour of the blockchain integrity module.

TABLE V. BLOCKCHAIN INTEGRITY MODULE: IMPLEMENTATION CHARACTERISTICS AND OBSERVED BEHAVIOUR

Component	Specification / Observation
Smart Contract	EHRRecordRegistry (Solidity)
Blockchain Network	Ganache (local EVM testnet)
Hashing Algorithm	SHA-256 on UTF-8 payload JSON
On-chain Storage	Patient ID, Record ID, Digest string
Off-chain Storage	BlockchainCommit rows (SQLite) with nullable tx fields
Commit Response	Transaction receipt with block hash and gas used
Verification	Digest comparison (on-chain preferred, DB fallback)

The dual-mode architecture was validated under both configurations. With blockchain environment variables unset (off-chain mode), commits succeeded with local-only messaging, storing SHA-256 digests in the BlockchainCommit database table with nullable transaction fields. When Ganache was configured and the EHRRecordRegistry contract deployed (on-chain mode), commits returned full transaction receipts including block hash and gas consumption, and listing endpoints reported source: “on-chain”. Verification queries correctly identified matching digests as verified and flagged any modified payloads as tampered, confirming the integrity detection capability of the system.

The security model enforced role-based access control (admin, doctor, patient) with JWT-based authentication and doctor-patient access grants. Blockchain commit and verification endpoints were subject to the same authorization checks as clinical record endpoints, ensuring that only authorized users could anchor or verify record digests. All sensitive operations were recorded in an append-only AuditLog, providing traceability and accountability. The system was built using principles of data minimization on-chain, where only cryptographic digests of the clinical payloads were kept on-chain, while the complete clinical payloads were stored in the application's database, providing patient confidentiality while enabling tamper detection.

From an engineering evaluation perspective, the blockchain module was found to be stable and to exhibit consistent and reliable behaviour. On the local Ganache network, latency was as low as sub-second for commit operations. Modularity and maintainability were achieved by separating concerns between the API layer (Flask-RESTX), service layer (hashing, interaction with blockchain), and persistence layer (SQLAlchemy/SQLite). OpenAPI documentation was offered at /api/docs, containing all API specs of blockchain and verification endpoints. The process of integration with the ML classification pipeline was smooth since the same REST API was utilized for both the classification analytics and integrity verification, highlighting the potential of combining machine learning decision support and blockchain record protection within the same EHR backend design. Fig. 17–20 present the key system interfaces, illustrating how role-based access control governs distinct clinical workflows for doctors, patients, and administrators within a single secure workspace. These interfaces demonstrate the practical embodiment of tamper-evident record management and machine-learning-assisted heart-disease status classification in an accessible prototype environment.

While the blockchain module demonstrates successful record hashing and tamper detection on a local Ganache test network, its practical deployment on live networks faces significant engineering constraints. First, committing transaction hashes to a public blockchain (like Ethereum mainnet) incurs gas fees, which could become financially unsustainable under high query volume. Second, block commit latencies on public networks range from seconds to several minutes, creating bottlenecks compared to the sub-second Ganache commit. Third, permissionless networks scale poorly, showing low throughput. To address these constraints, future clinical frameworks should explore Layer-2 rollups or permissioned enterprise consortia (such as Hyperledger Fabric), where transaction fees are negligible, commit speeds are faster, and access controls can be cryptographically enforced at the consensus layer.

V. DISCUSSION

The comparative analysis between pre-split and post-split sampling strategies reveals significant implications for heart-disease status classification. Results showed that for each sampling combination and each classifier, the pre-split approach produced higher numerical scores than the post-split approach, with differences of 8 to 41 percentage points. It must be stressed, however, that the pre-split configuration attains these higher scores because global resampling leaks synthetic test-set information into training; the gap therefore largely reflects data leakage rather than a genuine improvement in generalization. The post-split AUC of approximately 0.85 is the methodologically valid result and the appropriate basis for comparison with prior work.

The results from this study were compared to recent studies using the same heart-disease data from the BRFSS. Chen et al. [8] employed random undersampling before train-test splitting on the BRFSS heart-disease dataset and reported that their LightGBM model achieved 76.9% accuracy with an AUROC of 84.6%. Chen et al. [8] utilized random undersampling to create a balanced dataset of 50,000 cases from the original 319,795 instances, with a 70:30 train-test split ratio. Their results showed that LightGBM (76.9%) and Random Forest (76.7%) performed similarly. All models demonstrated a significantly lower sensitivity than specificity. In this study, when applying SMOTEENN before splitting, LightGBM achieved 97% accuracy with 98% precision and 96% recall, representing a 20.1 percentage point improvement over the comparable approach in [8]. Similarly, the Random Forest model in this study with SMOTEENN achieved 97% accuracy, 97% precision, and 98% recall. The ROC-AUC values observed in the post-split experiments in this study (approximately 0.85) are comparable to those reported by Chen et al. [8] (84.6% for LightGBM and 84.2% for Random Forest), suggesting that both studies achieved similar discriminative capability despite different sampling strategies. However, the substantially higher accuracy reported for the pre-split configuration is driven largely by data leakage from global resampling and should not be interpreted as a genuine improvement over prior work; the post-split ROC-AUC values (≈0.85) are the appropriate basis for comparison.

Chen et al. [8] also applied the Boruta algorithm for feature selection and retained all 17 features, reporting that AgeCategory had the greatest impact on classification. Their feature importance analysis aligns with the use of RFE for feature selection in this study. The similarity in ROC-AUC values between the post-split results of this study and Chen et al.'s findings confirms that the underlying discriminative patterns captured by the models are consistent across both studies, regardless of the specific feature selection or sampling method employed. The key differentiator is that the SMOTEENN-based pre-split approach used in this study transforms the class distribution more effectively than simple random undersampling, but these comparisons refer to the pre-split, leakage-affected results; under the leakage-safe post-split protocol, the discriminative performance of this study (AUC ≈ 0.85) is comparable to rather than substantially better than these prior studies.

Kumari et al. [16] developed a majority voting classifier for heart disease prediction and achieved approximately 90.8% accuracy using a soft voting ensemble of five classifiers (Logistic Regression, Multi-Layer Perceptron, AdaBoost, CatBoost, and XGBoost) within the BL-MVC framework, with AdaBoost attaining the highest individual accuracy of 90.86%. Their approach utilized the BRFSS 2015 dataset (253,680 responses, 21 features) with 5-fold cross-validation, comparing Heatmap Correlation and PCA for feature selection. On the other hand, the method used in this study of applying SMOTEENN before splitting combined with LightGBM and Random Forest resulted in an accuracy of 97%, which is approximately 6 percentage points better than their highest accuracy score, and, additionally, the two classifiers have balanced precision and recall scores.

The key distinction between the approach used in this study and Kumari et al. [16] lies in the machine-learning pipeline: their framework relied on hyperparameter tuning and feature selection without explicit class-imbalance handling, whereas the approach used in this study systematically addresses the severe class imbalance through SMOTEENN preprocessing. Fig. 21 depicts the accuracy of the proposed SMOTEENN-based pre-split approach and selected related works. It should be noted that these comparisons refer to the pre-split, leakage-affected results; under the leakage-safe post-split protocol, the discriminative performance of this study (AUC ≈ 0.85) is comparable to rather than substantially better than these prior studies.

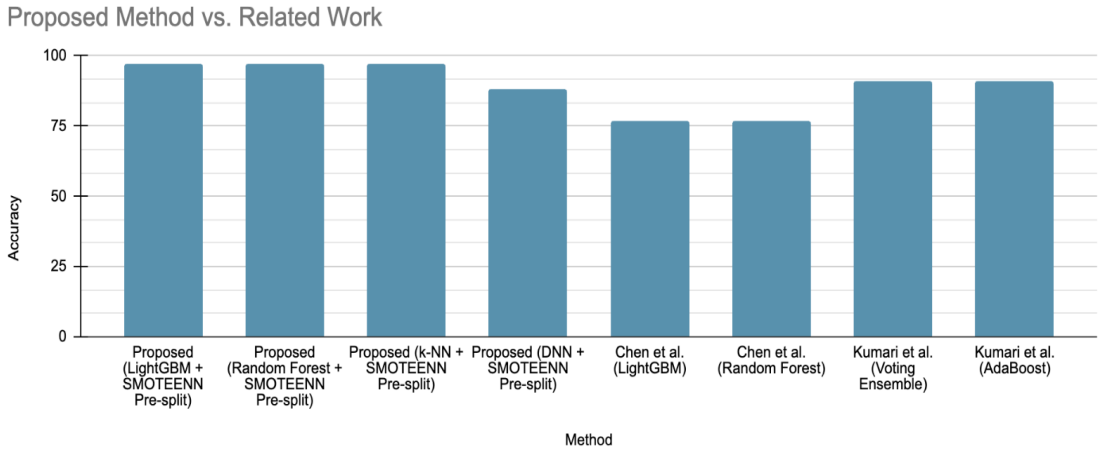

Fig. 21. Accuracy comparison of the proposed pre-split SMOTEENN-based approach with related works (note: pre-split results are leakage-affected).

The consistency of high performance across Random Forest, LightGBM, and XGBoost in the pre-split configuration suggests that these gradient boosting and bagging methods are particularly well-suited for the balanced feature space created by SMOTEENN preprocessing. These ensemble models inherently handle feature interactions and non-linear relationships, which are prevalent in health survey data where demographic, behavioral, and clinical variables interact in complex ways. Even in the pre-split SMOTEENN configuration (leakage-affected), the k-NN classifier attained high numerical results (97% accuracy, 99% recall), suggesting that instance-based learning can benefit greatly from a balanced feature space, though these figures are inflated by data leakage and should be interpreted accordingly.

The Deep Neural Network showed the largest relative improvement between post-split and pre-split configurations, with accuracy increasing from 71% (SMOTEENN post-split) to 88% (SMOTEENN pre-split). This comes from the fact that neural networks require a certain minimum number of representative samples of each class in order to identify the boundaries for decision-making effectively, and the pre-split balanced dataset provides a better training signal. Nevertheless, the DNN managed to lag behind the ensemble tree-based methods even in the pre-split scenario, a situation that generally persists where gradient boosting methods outshine deep learning when it comes to structured tabular datasets such as these.

The findings of this study demonstrate that the integration of appropriate class-imbalance handling techniques with modern ensemble learning algorithms can improve heart-disease status classification. The RFE-based feature selection combined with SMOTEENN provides an effective pipeline for the survey-based binary classification task. However, the pre-split results substantially overstate generalization performance due to data leakage; the post-split AUC of approximately 0.85 is the valid metric for real-world interpretation and comparison with prior work. These comparisons refer to the pre-split (leakage-affected) results; under the leakage-safe post-split protocol, the discriminative performance of this study (AUC $\approx$ 0.85) is comparable to, rather than substantially better than, Chen et al. [8] and Kumari et al. [16]. Future research should explore the generalizability of these findings across clinical datasets and investigate the utility of such frameworks in real-world decision-support applications.

VI. Limitations

This study has several limitations. First, the headline pre-split results are affected by data leakage and overstate real-world performance; only the post-split results are methodologically valid.

Furthermore, the reliance on self-reported health survey data (BRFSS) presents significant limitations compared to verified clinical records. Survey responses are highly susceptible to recall bias (where participants misremember medical details) and social desirability bias (where participants underreport negative behaviors such as alcohol consumption). Additionally, self-reported diagnosis lacks standardized clinical verification, introducing noise. In contrast, clinical electronic health records (EHRs) provide objective, verified data such as laboratory biomarkers, electrocardiograms, and diagnostic imaging. Consequently, the classification models trained on behavioral surveys represent self-reported risk associations rather than clinical diagnostics, limiting their direct utility in active clinical workflows.

In addition, the system is a prototype/feasibility study and has not been clinically validated or deployed. The blockchain component was evaluated on a local Ganache test network using commit latency and gas cost only; throughput, scalability under load, and adversarial-tampering scenarios were not formally measured.

VII. Conclusion

This study presented an integrated prototype for heart-disease status classification and tamper-evident electronic health record management using the Heart 2020 Cleaned BRFSS survey dataset, machine-learning models, and a blockchain-supported integrity layer. Five classifiers were evaluated with three resampling techniques and a no-sampling baseline. Under the methodologically valid post-split protocol, models reached an AUC of approximately 0.85, comparable to prior work on the same dataset. A pre-split (global resampling) configuration produced much higher scores — Random Forest reaching 97.14% accuracy and an AUC of 0.9965 under SMOTEENN — but these are inflated by data leakage and are reported only to illustrate that effect rather than as valid estimates of real-world performance. Ensemble methods (Random Forest, LightGBM, XGBoost) consistently outperformed the DNN on this structured tabular dataset, and resampling strategy was the dominant factor affecting reported performance.

In addition to the classification component, the work demonstrated the feasibility of integrating machine learning with a blockchain-based integrity-verification mechanism in a unified prototype. Full patient records were retained in the application database, while the blockchain layer anchored cryptographic digests and identifiers to provide tamper-evident verification, traceability, and accountability; access control was enforced at the API layer rather than on-chain. The present evaluation is limited to functional validation, sub-second commit latency, and gas consumption on a local Ganache test network; throughput, scalability under load, formal adversarial-tampering tests, and a security audit were not performed and remain future work. The work is a prototype/feasibility study: it does not claim clinical deployment readiness, the elimination of single points of failure, or formal security guarantees. Its primary contribution is the practical integration of established machine-learning and blockchain components into a single framework, rather than a novel algorithm or blockchain architecture.

Acknowledgment

The authors utilized AI-assisted tools (ChatGPT, Google Gemini, and Grammarly) solely for paraphrasing and grammatical refinement to improve clarity. All methodologies, experiments, and conclusions are original contributions for which the authors assume full responsibility. The authors would like to acknowledge the Deanship of Graduate Studies and Scientific Research, Taif University, for funding this work.

***Abstract*—This study aims to identify and classify the technologies used across the waste-management lifecycle, qualitatively synthesize the types of operational and circularity-related outcomes reported in the literature, and examine the technical challenges and research gaps that must be addressed to develop interoperable, scalable, secure, and empirically validated systems. The study used a systematic literature review and bibliometric analysis in accordance with the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) 2020 framework. The study identified Internet of Things (IoT), Artificial Intelligence (AI), machine learning, blockchain, cloud and edge computing, digital twins, big-data analytics, Radio-Frequency Identification (RFID), Global Positioning System (GPS), and additive manufacturing as the primary enabling technologies. These technologies enable sensing, monitoring, waste classification, forecasting, route optimization, traceability, simulation, automated sorting, and resource recovery. Across the included studies, the most frequently reported outcome categories included reduced bin overflow, improved collection and route efficiency, lower operational costs and vehicle-related emissions, enhanced waste segregation and recycling, and greater material-flow transparency. Because the studies used heterogeneous technologies, settings, scales, and evaluation metrics, these outcomes were synthesized qualitatively rather than pooled into a single quantitative estimate. Smart circular waste management depends on an integrated digital eco-system and is not dependent on individual technologies.**

Keywords*—*Artificial Intelligence (AI); circular economy; digital technology; Internet of Things (IoT); smart waste management

I. Introduction

Rapid urbanization, increasing populations, and changing consumption habits have increased the volume and complexity of municipal waste. Municipal waste management is often based upon traditional practices of fixed collection routes, manual tracking, fragmented data, and minimal waste separation. This inefficiency contributes to higher collection costs for municipalities, lower material recovery rates, and less awareness of waste flows. A Circular Economy approach provides an alternative to the linear "extract-produce-consume-dispose" model by keeping resources viable through reduced, reused, recycled, recovered, or regenerated [1, 2].

Circular Waste Management is a holistic application of the circular economy through the entire lifecycle of waste management - from waste avoidance to waste collection, sorting, re-use, recycling, recovery and reintroduction of recycled materials back into production. This will be supported by there needs to be adequate and timely information on the quantity, quality, location, how it was created, and how much it has been moved. Digital technology will allow us to connect our physical waste processing with sensors, communications, analysis, and decision-making software. Internet of Things (IoT) devices enable real-time monitoring of waste volumes and the current state of collections. Artificial Intelligence (AI) will help classify waste, predict waste generation, and optimize routes. Blockchain can improve the traceability of material flows, whereas cloud computing, edge computing, and digital twins can support data integration, simulation, and operational decision-making [3-6].

The combination of these technologies has contributed to the development of smart circular waste management, in which data are used to improve collection efficiency, automated sorting, material recovery, transparency, and circular resource flows. However, the effectiveness of such systems depends not only on individual technologies but also on their ability to exchange data and operate as an integrated system. IoT sensors, for example, provide operational data, but analytical models are required to transform that data into predictions and decisions. Similarly, blockchain can preserve the integrity of transaction records, but its effectiveness depends on the reliability of the data generated outside the blockchain.

Although they offer many advantages for managing waste, there are also significant barriers to implementing new technologies for digital waste. For example, differences in hardware and software (e.g., different types of devices) and variations in how these devices communicate with one another could make it difficult to get all of them to work together seamlessly; sensor inaccuracies, missing data, unreliable connectivity, cyber security risks, issues related to customer/team member privacy, excessive power consumption by devices and/or networks, and high costs associated with developing/implementing systems are examples of other ways that reliability and scalability may be limited [6-7]. Consequently, despite the contributions of prior reviews, there remains a need for a systematic synthesis that specifically compares multiple digital technologies across the circular waste-management lifecycle, based on their functional roles, supported processes, reported operational and circularity-related outcomes, evaluation approaches, and technical limitations. The distinctions between the present study and the most closely

*Corresponding author.

related prior reviews are discussed in the following section. This study addresses that need through a Systematic Literature Review of digital technologies enabling smart circular waste management using the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) 2020 framework. This study aims to identify and classify the technologies used across the waste-management lifecycle, synthesize their reported operational and circularity-related outcomes, and examine the technical challenges and research gaps that must be addressed to develop interoperable, scalable, secure, and empirically validated systems.

II. Related Work and Positioning of the Present Review

Prior studies have examined the intersection of digital technologies, circular-economy strategies, and waste management from several perspectives. At the broader circular-economy level, Bressanelli et al. [3] examined how digital technologies support usage-oriented circular business models, while Kristoffersen et al. [4] proposed a digitally enabled circular-strategies framework for manufacturing companies. These studies established that digitalization can facilitate information exchange, resource optimization, product-life extension, and circular value creation. However, their primary focus was on business models and manufacturing strategies rather than on the full waste-management lifecycle.

Cagno et al. [5] extended this stream of research through a systematic literature review of the role of digital technologies in operationalizing the circular-economy transition. Their study connected digital technologies with broad circular strategies and provided a cross-sectoral account of how digitalization can support circular practices. Nevertheless, its scope was not specifically organized around waste generation, collection, sorting, reuse, recycling, recovery, valorization, and the reintegration of secondary materials into production. It also did not systematically compare digital technologies by their functional roles, report waste-management outcomes, or identify implementation limitations.

Other studies and reviews have concentrated on particular technologies or application domains. Antony Jose et al. [18], for example, reviewed recent applications of artificial intelligence in battery recycling, illustrating the value of AI for classification, process optimization, and material recovery within a specific waste stream. The studies by Bello and Maladzhi [16] and Steenmans et al. [23] investigated, respectively, sustainable waste-reduction methods using additive manufacturing and blockchain technology for plastic waste governance and tracking. The study by Meng et al. [24] examined the application of digital twin technology to circular economy concepts in the construction industry. Lastly, Goel et al. [25] conducted a review of the opportunities and risks involved in digitalization toward achieving environmental sustainability.

The present review addresses this fragmentation by combining systematic evidence synthesis and bibliometric analysis to examine multiple digital technologies across the circular waste-management lifecycle. In contrast to Cagno et al. [5], the unit of analysis is specifically smart circular waste management rather than the general operationalization of circular-economy strategies. In contrast to Zyoud and Zyoud [10] and Khan et al. [12], the review is not limited to publication trends, thematic structures, or knowledge networks. It also extends technology-specific reviews, such as those by Ahmed et al. [6] and Antony Jose et al. [18], by comparing IoT, artificial intelligence, machine learning, blockchain, cloud, and edge computing, digital twins, big data analytics, RFID, GPS, and additive manufacturing within a single analytical framework. The above review assesses these technologies on four bases. The first is the technology functions and operational roles for each. Second are the waste management processes that each supports. Third, there are their reportedly measured performance in terms of costs, environmental impacts, and the circular economy. Fourth are the known technical barriers and areas requiring further study that limit the use of such technologies in ways that allow them to be used together.

III. Methodology

This section outlines the research design, research question(s), eligibility criteria, study screening process, and analysis techniques to find and synthesize research about digital technologies for smart circular waste management.

A. Research Design

The research began with a comprehensive literature search following the PRISMA 2020 guidelines [8,9]. Articles were retrieved from two leading academic databases, Scopus and Web of Science, covering publications from 2015 to 2025. Structured Boolean search equations were developed using targeted keywords such as “smart circular economy,” “waste management,” “digital technology,” “AI,” “IoT,” “blockchain,” and “resource recovery.” Bibliometric analysis was conducted using VOSviewer to uncover keyword co-occurrence patterns, thematic clusters, and emerging research trends in the intersection of smart technologies and circular economy within waste management.

B. Research Questions (RQ)

The four questions that guided this study were:

RQ1: Which types of digital technology have enabled smart circular waste management?

RQ2: In what way do the various technologies function as a part of different waste management processes?

RQ3: What reported outcomes related to operation, economy, environment, and circularity resulted from the use of digital waste management technologies?

RQ4: How have limited technical capabilities and a lack of research hindered the implementation, integration, and scale-up of digital waste-management technologies?

C. Eligibility Criteria

Eligible studies included those that were peer-reviewed and published in English; included in either the Scopus or Web of Science databases; published between 2015 and 2025; used a minimum of one digital technology to support waste management or circular resource management practices; and provided information regarding how the technology was implemented, methodologies, results/outcomes, as well as any obstacles/challenges encountered using the technology. Studies

that did not report on the technology's implementation were therefore excluded from this review. Editorials, non-academic reports, unpublished manuscripts, inaccessible full-texts, and studies without a meaningful digital-technology component were excluded. Additionally, articles focused solely on chemical treatment, material characterization, pollution, or waste-processing reactions, and that did not include a relevant computational or informational technology aspect, would also be excluded. The review articles were used to provide additional background and references for reviewing purposes only and were not used as primary data sources.

D. Study Screening

The study screening process followed PRISMA 2020 guidelines to ensure methodological rigor and transparency in identification, screening, and inclusion (Fig. 1).

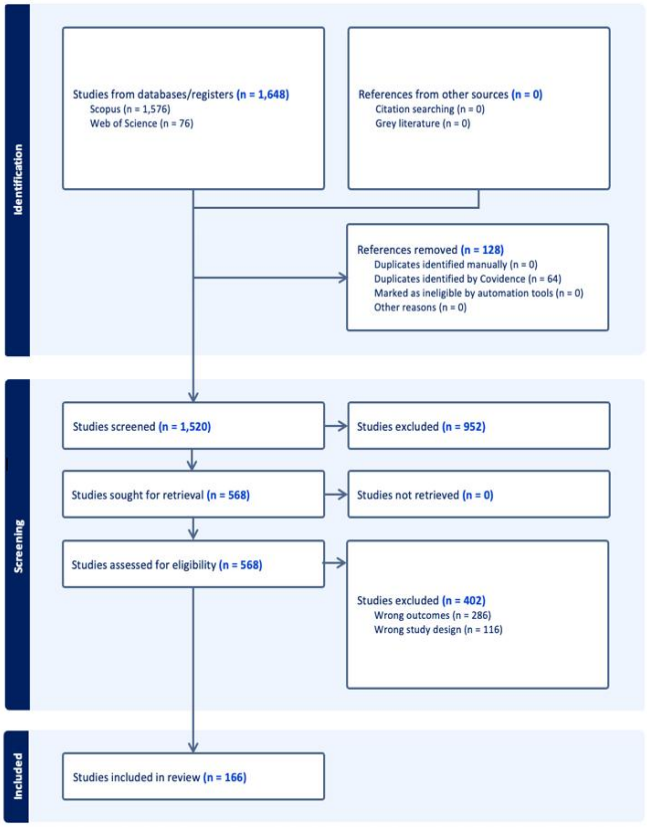

Fig. 1. PRISMA protocol.

A total of 1,648 records were retrieved from two databases: Scopus (n = 1,576) and Web of Science (n = 72) using structured Boolean searches. After removing 128 duplicates, 1,520 records remained for title and abstract screening. Strict inclusion and exclusion criteria were applied, resulting in 952 exclusions for irrelevance. The remaining 568 articles underwent full-text assessment, with all full texts retrieved. Of these, 402 were excluded: 286 for lacking relevant outcomes and 116 for unsuitable study design. Finally, 166 studies met all criteria and were included for bibliometric analysis and expert validation. This represents 10.1% of the initial records, underscoring the value of a rigorous multi-phase screening process. The selection process is summarized in the PRISMA 2020 flow diagram.

IV. Results

This Section Present Results of the Systematic Literature Review and Bibliometric Analysis Conducted to Examine Digital Technologies that Enable in Smart Circular Economy and Waste Management. First, the Bibliometric Analysis that Identifies the Conceptual Structure, domain keywords, and themes from the Literature. The Section Further Synthesizes the Evidence According to the Four Research Questions, Covering the Enabling Digital Technologies, Their Roles in Supporting Waste-management Processes, the Reported Operational and Sustainability Outcomes, and the Remaining Technical Limitations and Research Gaps. Overall, This Section Demonstrates the Transition of Waste-management Research from Conventional Recycling-oriented Approaches Toward Integrated, Technology-enabled, and Circular Waste-management Ecosystems.

A. Bibliometric Analysis

The bibliometric analysis offers a detailed view of research trends and thematic developments in Smart Circular Economy (SCE) and waste management. Using VOSviewer, co-occurrence maps and keyword heatmaps were generated from 166 articles, revealing conceptual structures and emerging topics (Fig. 2). The co-occurrence network shows “circular economy” as the most frequent and central term, closely linked to “waste management,” “recycling,” “sustainability,” and “environmental impact” (Fig. 2a). Three thematic clusters emerge. The first centers on technological enablers, with keywords such as machine learning, artificial intelligence, digital twin, and IoT, showing the integration of smart technologies in circular systems. The second focuses on material innovation and resource recovery, featuring terms like plastic waste, 3D printing, additive manufacturing, and life cycle assessment, highlighting closed-loop production and material efficiency. The third addresses policy and systems thinking, with terms including urban mining, blockchain, stakeholder engagement, and supply chains, reflecting interest in governance and socio-economic integration.

Keyword co-occurrence over time shows a shift in thematic focus (Fig. 2b). Terms such as blockchain, digital twin, urban mining, and machine learning appear in yellow, indicating recent growth, especially after 2022. In contrast, waste management and recycling appear in green and blue, marking earlier emergence and continued relevance. The keyword density heatmap confirms the centrality of circular economy, recycling, and waste management, which appear in bright yellow, reflecting high frequency and strong connectivity (Fig. 2c). Keywords like life cycle, environmental impact, and resource efficiency bridge technological innovations and sustainability outcomes across both network and heatmap views. Overall, the results show a transition from traditional recycling themes toward integrated, data-driven, and systems-based approaches. The visualizations also indicate a field that remains rooted in sustainability while expanding into digital innovation.

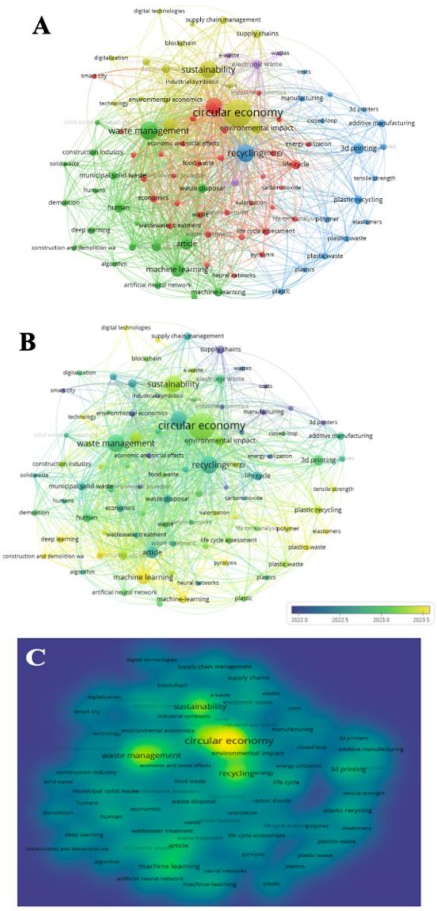

Fig. 2. Keyword co-occurrence map of research.

B. Scientific Performance and Production

Scholarly research in sustainable innovation is strongly anchored in circular economy principles, which account for 15% (n = 685) of the examined discourse (Fig. 3). This dominance reflects a shift from linear consumption toward regenerative systems emphasizing resource efficiency and lifecycle extension [10]. Waste management (6%, n = 288) and recycling (6%, n = 277) follow as key operational constructs, demonstrating circular principles in industrial and urban contexts. Sustainable development (5%, n = 225) and sustainability (5%, n = 222) further align environmental stewardship with economic resilience. Together, these themes reveal an integrated systems-thinking approach essential for addressing global resource constraints. Technological themes are also prominent. Machine learning (4%, n = 165), artificial intelligence (2%, n = 111), and 3D printing (5%, n ≈ 272) represent a growing nexus of smart tools embedded in sustainable strategies. These enable resource flow optimization, predictive analytics, and decentralized manufacturing, reducing carbon footprints and logistical demands. Specialized topics such as environmental impact (2%, n = 83), decision-making (2%, n = 82), and life cycle assessment (2%, n = 67) provide evaluation frameworks for system-wide sustainability. Supply chains (2%, n = 70) and economic aspects (2%, n = 69) highlight the importance of integration across production and distribution stages [11,12].

In addition, emerging themes- blockchain (1%, n = 33), polymer (1%, n = 33), and environmental economics (1%)-signal interdisciplinary expansion. They link digital trust mechanisms, material innovation, and economic modelling to enhance transparency and accountability in circular systems. Overall, the thematic structure reflects a technically diverse yet holistically aligned research ecosystem. Foundational topics coexist with advanced tools and methods, indicating a maturing field that adapts to ecological, technological, and socio-economic challenges [13-15]. Building on this base, temporal analysis can reveal how priorities shift over time and how technological innovations are increasingly embedded in sustainable waste management discourse.

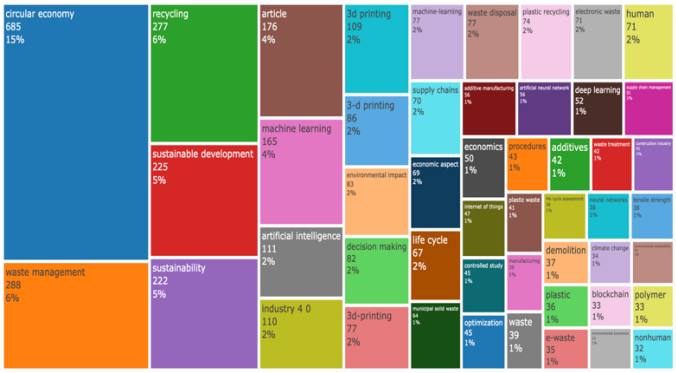

Fig. 3. Treemap of the most frequent terms in smart circular waste management studies.

The temporal distribution of emerging terms in sustainable waste management research shows a steady evolution in thematic focus and technological integration over the past decade. “Circular economy” remains the most dominant and persistent term, appearing consistently from 2020 to 2025 with high research intensity (Fig. 4).

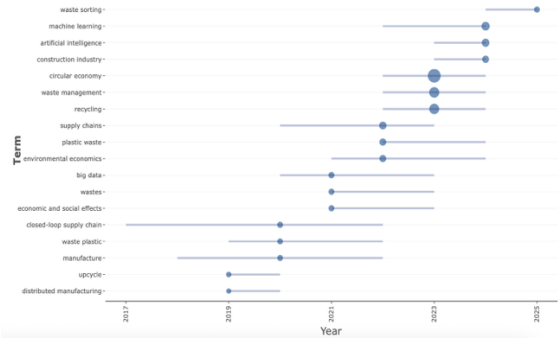

Fig. 4. The temporal distribution.

Its prominence reflects sustained academic and policy commitment to shifting from linear to regenerative systems centered on material reuse, systemic efficiency, and ecological balance. “Waste management” and “recycling” gained prominence in the same period, serving as operational frameworks for implementing circular economy principles. Their strong co-occurrence and longevity underline their foundational role across engineering, environmental science, and public policy [16]. In addition, technological integration has intensified since 2021, with increasing mentions of “machine

learning," "artificial intelligence," and "big data." These trends point to growing adoption of data-driven approaches for waste flow optimization, consumption prediction, and responsive infrastructure design. The emergence of "waste sorting" in 2025, alongside AI themes, signals a shift toward automated, real-time material recovery. "Supply chains" and "plastic waste" have maintained steady attention since 2020, highlighting concerns over material accountability and polymer pollution. Mentions of "environmental economics" and "economic and social effects" reflect efforts to align market mechanisms with ecological outcomes. Earlier themes such as "distributed manufacturing," "upcycle," and "closed-loop supply chain" emerged in 2017–2018 but later declined in visibility, likely absorbed into broader frameworks or deprioritized for scalable practices. Overall, the timeline shows a deliberate integration of AI, economic analysis, and systemic efficiency into circular economy strategies, marking a transition toward actionable, technology-enabled solutions [17-19].

C. Addressing RQ1: Which Types of Digital Technology Have Enabled Smart Circular Waste Management?

The reviewed studies identified several digital technologies that support smart circular waste management. The major technologies include: the Internet of Things (IoT), Artificial Intelligence (AI) and machine learning, blockchain, cloud computing, edge computing, digital twins, big data analytics, Radio Frequency Identification (RFID), and GPS. Additionally, the keyword map and tree map suggest that there has been an increase in the connections between machine learning, AI, Industry 4.0, the circular economy, and research into recycling and waste management. The following are the technologies for IoT: smart bin systems with ultrasonic sensors, weight sensors, environmental sensors, RFID tags, and vehicle tracking systems. This technology provides real-time information on waste amount, quality, position, and movement [6,10]. In addition, AI and machine learning are being utilized for classification of waste types, prediction of waste amounts, optimization of waste collection routes, automation of decision-making processes [18,19], and also for improving material tracking capabilities, transaction reliability, and transparency within the waste and recycling chain through the use of blockchain [4,5]. Digital twins and cloud-based platforms support data integration, simulation, and scenario evaluation, while additive manufacturing and 3D printing connect recovered materials with circular production processes [12,16]. The findings indicate that no single technology independently enables smart circular waste management. Instead, the reviewed systems rely on combinations of sensing, communication, analytical, traceability, and operational technologies. This convergence reflects a transition from isolated waste-management applications toward integrated digital ecosystems.

D. Addressing RQ2: In What Ways Do Digital Technologies Support Different Waste-Management Processes?

Digital technologies support different but interconnected functions across the waste-management lifecycle. IoT sensors and identification technologies serve as the sensing component and collect a variety of data, including bin levels, total waste generated, temperature, humidity, vehicle location, etc. The communication systems then send this collected data to an application (cloud, edge, or local) that stores it, processes it, and provides analytics. These functions allow the city/organization to monitor in real time the flow of materials, prevent bin overflows, schedule collections, and improve visibility into where waste is coming from [6,10]. AI and Machine Learning algorithms take the raw data and turn it into predictive actions/recommendations. Some examples of their use include classifying waste using images, predicting future waste generation, optimizing garbage truck routes, detecting anomalies in waste patterns, and automatically sorting waste. Blockchain provides a traceability function by recording waste transfers, recycling activities, and material transactions. Digital twins and decision-support systems allow alternative collection, treatment, and resource-recovery scenarios to be evaluated before implementation [4,5].

The functional relationship among these technologies can be represented in Fig. 5. Circular actions include waste collection, sorting, recycling, reuse, recovery, valorization, and the reintegration of secondary materials into production. The findings therefore show that digital technologies contribute not only to waste monitoring but also to the coordination of physical and information flows throughout the circular waste-management system.

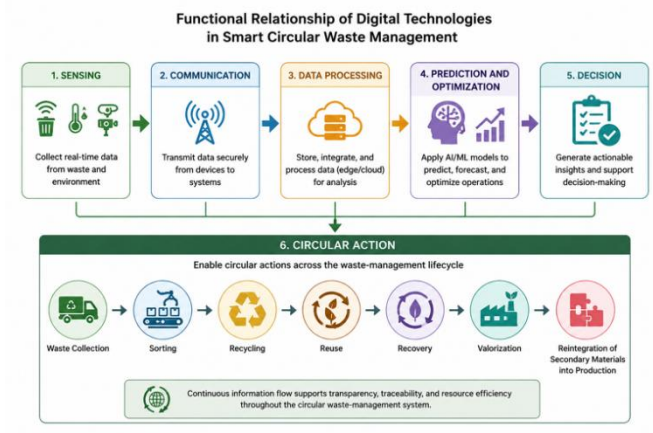

Fig. 5. Functional relationship of digital technologies in smart circular waste management.

E. Comparative Technology Suitability

The evaluated technologies differ from each other in terms of maturity, deployment effort, computational demand, and use case. IoT, RFID, and GPS are applicable as sensors for detection/identification and for localization. AI and Machine Learning can be used to classify, predict, optimize routes, and automatically sort products when sufficient training data and computational power are available. For storing and analyzing large amounts of data centrally, cloud computing is best. Edge Computing is typically used for real-time applications that require fast local processing. For tracing products throughout the supply chain (e.g., through certification), blockchain is an interesting solution. However, due to high computational demands and communication efforts, it does not make sense for simple monitoring. Digital Twins are best used for simulations, facility planning, or scenario evaluation. However, the value of digital twins depends heavily on their ability to be synchronized reliably with the corresponding physical assets. Thus, no technology is suitable for all cases. The appropriate technology

depends on the specific operational goals, the relevant infrastructure, the maximum allowed time to react, the amount of available data, costs, and legal obligations.

F. Addressing RQ3: What Operational, Economic, Environmental, and Circularity-Related Outcomes Have Been Reported?

The reviewed literature reports several operational advantages that can be derived from the application of Digital Waste Management (DWM) systems. These consist of: Real-Time Monitoring, Bin Overflow Reduction, Improved Waste Classification, Dynamic Scheduling of Collections, Reduced Length of Collection Routes, Optimized Vehicle Utilization, and Faster Operational Decision Making [10,11], as well as AI-supported forecasting and optimization, allowing waste managers to prioritize locations with the highest demand for services and avoid collecting from non-high-demand locations where possible. In addition to operational advantages, DWM systems provide economic advantages, such as reduced Fuel Use and transportation costs, reduced manual monitoring requirements, and an optimized Allocation of Vehicles, personnel, and Processing Capacity. However, the extent to which each study identifies economic advantages varies due to differences in System Scale, Infrastructure, Type of Waste being managed, and Evaluation Methodology. Some studies identify Economic Advantages based on Cost Reductions and Route Distances, whilst others base their identification on the Accuracy of Classification, Time to Process Materials, and Resource Productivity.

Additionally, there are Environmental Advantages associated with the use of DWM Systems, including Reduced Emissions from Collection Vehicles, Less Dependence on Landfills, Enhanced Segregation of waste, and Greater Efficiency in Recovering Recyclables. There are also Circular Economy Advantages associated with the use of DWM Systems, including Increased Recycling Rates, resource recovery from Waste, Valorization of Waste Streams, and Traceability of Materials throughout Supply Chains. Furthermore, Closed Loop Production and Additive Manufacturing using Recovered Materials are facilitated by DWM systems' ability to track the movement of materials and the activities related to recycling [16-18]. Additionally, the Accountability provided by Blockchain and Digital Tracking Technologies allows for documentation of Material Movements and Recycling Activities.

G. Addressing RQ4: How Do Technical Limitations and Research Gaps Hinder the Implementation, Integration, and Scaling of Digital Waste-Management Technologies?

The key findings from the review suggest that significant technological work will be required to overcome the technical barriers to implementing an integrated smart waste management system. The majority of current smart waste-management solutions rely on disparate sensors, networks, databases, analytical algorithms, and operational systems. As a result, differences in technology (e.g., sensor type), data format (e.g., binary vs. CSV), and networking architecture (e.g., LAN vs. WAN) can create barriers for data transfer across different systems [5,7]. Another challenge identified in the literature concerns data quality. When sensors fail to operate correctly, measure inaccurately, leave gaps in measurement, do not consistently record timestamps for measured variables, or lack historical data records, it decreases the accuracy of predictive, classification, and optimization models. In addition, AI-based systems used for sorting recyclables into appropriate categories may function poorly with waste mixtures that contain contaminants, are physically broken or otherwise damaged, or consist of items not yet encountered during model training. Therefore, models should be tested across a wide range of "real-world" scenarios rather than only those modeled in controlled experimental settings. Other limitations include cybersecurity and privacy issues associated with connected devices and cloud computing; limited connectivity to remote locations; high power consumption with most types of sensors; and the costs of purchasing, integrating, operating, maintaining, and eventually replacing all required equipment [7].

One area where there is currently a significant knowledge gap concerning long-term field testing is the relative scarcity of large-scale long-term field trials. Most of what has been reported in the literature has come from simulations, laboratory tests, prototype demonstrations, and/or very short-duration pilot projects. While each of these approaches demonstrates the technical feasibility of the proposed solutions, they provide little information about long-term operation and maintenance requirements; the potential scalability of deployed equipment; the potential financial sustainability of the solutions; and the overall impact on environmental performance.

H. Reproducibility and Evidence Strength

The level of reproducibility was variable across the reviews; many implementations documented architectures or performance results but lacked a publicly available dataset, open-source code, all required hardware details, model configuration details, or a standard test environment for benchmarking. The lack of reproducibility is especially relevant for AI/Machine Learning applications, where performance varies based on data content, label accuracy, and the pre-processing performed prior to training. Additionally, there were differences in the amount of evidence supporting each study type. Conceptual and simulation studies demonstrated feasibility; laboratory/prototype studies demonstrated technical validity; and pilot or operational deployment studies demonstrated greater validity with respect to maintenance costs, scalability, and long-term reliability.

V. Discussions

This section will examine how the circular economy (CE) concept is influenced by its convergence with digital technologies as well as the complementary functions of identified digital technologies, the conditions that are necessary for CE to be implemented, and implications for research and practice.

A. Convergence of Circular Economy and Digital Technologies

The findings demonstrate that circular economy, waste management, recycling, sustainability, and sustainable development remain the conceptual foundations of smart circular waste-management research. The dominance of "circular economy" in the term distribution indicates that digital technologies are primarily positioned as mechanisms for

extending material lifecycles, improving resource efficiency, and reducing dependence on disposal-based waste systems [1,2]. This result is consistent with studies that describe the smart circular economy as the integration of circular strategies with data acquisition, analytics, and digitally enabled decision-making. The results also reveal a gradual transition from conventional recycling and waste treatment to data-driven, intelligent waste management systems. The increasing use of machine learning, artificial intelligence, the Internet of Things, blockchain, digital twins, and big data-related terms indicates that the field is expanding beyond traditional environmental management. These technologies support the monitoring, classification, prediction, optimization, and traceability of waste and material flows. Machine learning and artificial intelligence are particularly relevant for waste sorting, generation forecasting, operational optimization, and environmental assessment [18,19]. Their increased visibility after 2021 suggests that waste-management research is moving toward more automated, responsive systems. The presence of 3D printing, additive manufacturing, polymers, and plastic recycling also demonstrates the connection between digital waste management and circular production. Additive manufacturing can use recovered materials as production inputs and facilitate decentralized manufacturing, although material quality, energy consumption, and recyclability must still be considered [12,16]. Therefore, digital technology should not be interpreted only as an information-management instrument; it can also reshape the physical processing, recovery, and reuse of secondary materials.

Nevertheless, the term distribution also shows fragmentation in the terminology used by researchers. Terms such as "3D printing," "3-d printing," and "3d-printing" represent the same concept but appear separately in the dataset. Similar normalization may be required for terms such as artificial intelligence, machine learning, Internet of Things, and related abbreviations. Standardizing equivalent terms is important for avoiding the underestimation of technology frequencies and improving the consistency of evidence synthesis.

B. Functional Roles and Integration of Digital Technologies

The reviewed technologies perform different but complementary functions within smart circular waste management. Internet of Things devices and sensors form the primary data-acquisition layer. Smart bins, ultrasonic sensors, weight sensors, cameras, Global Positioning System (GPS) devices, and Radio-Frequency Identification (RFID) tags can collect data on waste volume, composition, location, and movement [20,21]. This collected data will allow for a real-time view of the amount of waste that is being produced, prevent overflows from happening in the future, and optimize vehicle and facility use as part of the process.

The analytical layer of this process would use Artificial Intelligence (AI) and Machine Learning (ML) to take sensor and operational platform data and turn it into classifications, predictions, or recommendations. AI & ML are used in various ways, including image-based waste identification, Waste Generation Forecasting, Route Optimization, Contamination Detection, and Automated Sorting [22]. The reliability of these systems depends upon having representative databases, consistent database labels, appropriate computational resources, and testing under actual working conditions.

Blockchain provides a different function by supporting data integrity, transaction transparency, and material traceability. It can be used to record waste transfers, recycling certificates, extended-producer-responsibility transactions, and the chain of custody of recoverable materials [23]. However, blockchain does not guarantee that the original data are accurate. Incorrect sensor readings or unreliable manual inputs may remain incorrect even after being stored in an immutable ledger. Blockchain should therefore be integrated with reliable sensing, identity management, data-validation procedures, and cybersecurity controls. Digital twins and decision-support systems provide simulation and scenario-analysis capabilities. They can represent waste collection, facility capacity, material recovery, and reverse supply-chain processes in a digital environment [21,24]. These tools allow decision-makers to compare alternative operational scenarios before implementing them in physical systems. Nevertheless, an actual digital twin requires continuous or periodic synchronization between physical assets and their digital representations. Studies using only static simulation should therefore avoid describing their models as digital twins. Cloud computing and edge computing support data storage and processing across these technology layers. Cloud platforms provide scalable storage and centralized analytics, while edge computing can process data close to sensors, collection equipment, or sorting machines. Edge processing may reduce latency and network traffic, but it introduces additional requirements related to device management, security, and computational limitations [25].

These relationships indicate that smart circular waste management should be treated as an integrated digital ecosystem rather than as the implementation of a single technology. Its functional sequence can be represented as:

$$\text{Sensing} \rightarrow \text{Communication} \rightarrow \text{Data Processing} \rightarrow \text{Prediction and Optimization} \rightarrow \text{Decision} \rightarrow \text{Circular Action.}$$

Circular actions include collection, sorting, reuse, recycling, recovery, remanufacturing, and waste valorization. Feedback from these processes should return to the sensing and analytical layers, creating a continuous learning and improvement cycle.

C. Key Factors, Technologies, and Implementation Conditions

The literature indicates that technological performance is influenced by technical, organizational, regulatory, and economic conditions. The factors in Table I were synthesized from recurring findings in the reviewed literature. They were not derived from expert ranking or Fuzzy Delphi validation.

TABLE I. KEY FACTORS, TECHNOLOGIES, AND IMPLEMENTATION CONDITIONS IDENTIFIED IN SMART CIRCULAR WASTE MANAGEMENT

Category	Main Factor	Subfactors	Literature	Synthesis of Findings
Drivers	Policy and Regulatory Support	Incentives, digital standards, regulatory enforcement, extended producer responsibility	[21,23]	Regulations and incentives can encourage investment, data sharing, traceability, and the adoption of digital waste-management systems.
	Environmental Pressure	Landfill reduction, emission targets, resource scarcity, pollution control	[1,2,26]	Environmental pressures increase demand for technologies that support recycling, resource recovery, and waste reduction.
	Institutional Readiness	Leadership commitment, government support, organizational coordination	[4,27]	Institutional readiness facilitates technology procurement, data governance, integration, and long-term system operation.
	Economic and Operational Benefits	Cost savings, resource efficiency, route efficiency, improved productivity	[3,6,26]	Digital technologies can reduce unnecessary collection activities and improve operational resource allocation.
Barriers	Financial Constraints	Initial investment, maintenance costs, uncertain return on investment	[7,26]	High acquisition and lifecycle costs restrict adoption, particularly in resource-constrained municipalities.
	Digital Infrastructure Limitations	Limited connectivity, insufficient sensors, inadequate computing capacity	[6,7,21]	Weak communication and computing infrastructure reduce system reliability and scalability.
	Data Quality and Availability	Missing data, inconsistent formats, inaccurate sensor readings, limited historical records	[6,19,22]	Poor data quality decreases the reliability of classification, forecasting, optimization, and decision support.
	Cybersecurity and Privacy	Insecure devices, unauthorized access, sensitive location and operational data	[7,23,25]	Connected waste systems require authentication, encryption, access control, and privacy-preserving data management.
Challenges	System Interoperability	Heterogeneous devices, incompatible protocols, isolated databases	[4,5]	Interoperability is required to integrate sensing, communication, analytics, traceability, and operational platforms.
	Scalability and Field Validation	Prototype-to-city-scale transition, high data volume, network congestion, limited long-term testing	[6,7,20]	Many proposed systems remain limited to simulations, laboratory tests, or small-scale pilots.
	Technology–Policy Alignment	Rapid technological change, unclear data ownership, outdated regulation	[21], [23], [24], [27]	Adoption may be delayed when policies do not adequately address data sharing, automation, and digital transactions.
Success Factors	Stakeholder Collaboration	Public–private partnerships, citizen participation, cross-sector data sharing	[2]	Collaboration provides access to infrastructure, expertise, funding, operational data, and public acceptance.
	Digital Ecosystem Readiness	Integrated platforms, standards, reliable networks, data-governance mechanisms	[4,5]	Successful implementation depends on supporting infrastructure and governance rather than isolated technology adoption.
	Technical Capacity Building	Staff training, system maintenance, digital literacy, analytical capability	[7]	Skilled personnel are required to operate devices, maintain platforms, interpret analytics, and manage failures.
Technologies	Internet of Things and Sensors	Smart bins, fill-level sensors, weight sensors, environmental monitoring, vehicle tracking	[6,20,21]	Internet of Things technologies provide real-time data for monitoring, collection scheduling, and overflow prevention.
	Artificial Intelligence and Machine Learning	Classification, forecasting, route optimization, anomaly detection	[11,18,19]	Artificial intelligence converts waste data into classifications, predictions, and operational recommendations.
	Blockchain	Material traceability, recycling records, transaction integrity, certification	[4,23]	Blockchain can improve auditability when it is connected to reliable physical and off-chain data sources.
	Digital Twins and Decision-Support Systems	Simulation, scenario analysis, capacity planning, multi-criteria decisions	[22,24]	These technologies support the evaluation of alternative operational and circular-system configurations.
	Cloud and Edge Computing	Data storage, distributed processing, dashboards, real-time analytics	[6,25]	Cloud platforms support scalable analysis, while edge processing reduces latency and communication requirements.
	Identification and Communication Technologies	RFID, GPS, LoRaWAN, cellular networks, wireless sensor networks	[6,20]	These technologies improve asset identification, data transmission, location monitoring, and collection visibility.
Opportunities	Smart-City Integration	Integration with transportation, energy, logistics, and public-service systems	[10,20]	Shared smart-city infrastructure can improve coordination, data access, and resource utilization.
	Automated Circular Operations	Robotic sorting, intelligent recycling, automated segregation, predictive maintenance	[11,18,22]	Automation can improve sorting consistency, processing efficiency, and material-recovery performance.
	Data-Driven Circular Business Models	Digital marketplaces, product-service systems, material platforms, circular supply chains	[3,5]	Digital platforms can support new economic mechanisms for reuse, recovery, and closed-loop material management.

Table I shows that technical and non-technical factors are closely connected. Although IoT, artificial intelligence, blockchain, digital twins, and cloud platforms provide distinct technological capabilities, their performance depends on data quality, interoperability, infrastructure, cybersecurity, institutional support, and human capacity. Therefore, implementing advanced technology without improving the surrounding digital ecosystem may produce isolated prototypes

rather than scalable circular solutions. The table also indicates that policies and stakeholder participation should not be treated as separate from technology implementation. Regulations influence data sharing, procurement, ownership, extended producer responsibility, and reporting requirements. Similarly, cooperation among municipalities, private operators, citizens, recyclers, and technology providers determines whether sufficient data and operational support are available.

D. Waste-Stream and Regional Applicability

Technology fit varies by waste type. Solid municipal waste (household trash) will benefit most from using IoT for monitoring, GPS for collection, routing, and AI for sorting. Most industrial wastes will use process monitoring, material accounting, big data analysis, and digital twin technology. Biomedical and hazardous wastes will require enhanced identity verification, tracing, security, and regulatory compliance. Plastic wastes and electronic wastes will have strong opportunities in AI to classify materials that can be recovered. Construction waste has potential uses as a digital twin, an inventory of materials, and tracking at the project level. Therefore, selecting technology should be based on the properties of the waste being processed (characteristics), the risk of contamination, the dollar value of the materials contained in the waste stream, how sensitive the waste stream is to regulation, and the objective(s) for recovering materials.

Regional conditions also influence the deployment of technologies. Urbanized areas that are highly connected may be able to support cloud-intensive AI-enabled systems as well as integrated systems; however, areas with low connectivity, limited service integration, poor infrastructure, and/or budgetary constraints will likely require less expensive sensors, RFID/GPS, or local edge processing. The feasibility of blockchain-based technologies such as digital traceability and/or advanced analytics is also highly dependent on the level of regulatory maturity in an area, the presence/absence of formal recycling programs and/or institutions that enforce extended producer responsibility policies, and the overall institutional capacity in an area. Results from large-scale funding of "smart city" pilot projects cannot be directly applied to resource-limited municipalities.

E. Implications for Research and Practice

The reviewed literature provides insight into the potential of digital technologies to support sustainable waste management practices. However, it highlights several challenges that will affect whether and how this can happen. These include the lack of standardized systems for collecting and processing data, the absence of established policies and regulatory structures governing the deployment of these technologies in waste collection and disposal systems, and the limited availability of data describing the physical operations of waste collection and processing systems. In addition to addressing these structural challenges, future research should examine not only individual technologies (such as sensors, sorting machines, and mobile apps) but also how they interact and how they can be used by stakeholders who make different types of decisions. For example, what happens when data generated about the composition of municipal solid waste is transmitted to local government agencies? How do those data inform agency decisions regarding where to locate new recycling facilities? What happens at the intersection of waste management and land-use planning? Answering questions like these will require cross-disciplinary research efforts involving experts in information technology, public administration, engineering, materials science, economics, urban planning, and sociology. In terms of specific research topics, there are many possibilities. Some examples might include developing new metrics for measuring success in waste management; designing decision-making tools for use by city officials responsible for managing large-scale recycling programs; identifying ways to reduce the amount of energy required to sort recyclables from non-recyclable trash; and improving methods for estimating the carbon footprint associated with the production of goods made from recycled materials.

VI. Conclusion

This systematic literature review and bibliometric analysis addressed the four research questions on digital technologies in smart circular waste management. For RQ1, the main technologies that enabled the development of intelligent waste management systems included the Internet of Things (IoT), artificial intelligence and machine learning, blockchain, cloud computing and edge computing, digital twins, big data analytics, RFID/GPS, and additive manufacturing. For RQ2, these technologies performed complementary functions across all phases of the waste-management lifecycle, including sensing/monitoring, classification/forecasting, route optimization, traceability, simulation, sorting, recycling, recovery, and material reintegration. For RQ3, the studies reviewed reported operational economic and environmental circularity-related benefits, such as reduced bin overflow, shorter collection routes, lower fuel and labor requirements, fewer collection-related emissions, improved waste segregation, greater material recovery, and stronger material traceability. However, these outcomes were synthesized qualitatively due to differences across studies in the technologies used, the scale of waste, evaluation times, indicators, and units. For RQ4, the primary barriers to adopting these technologies were poor data quality, limited interoperability, unreliable connectivity, cybersecurity/risk, privacy/harm, higher energy/life-cycle costs, and limited technical expertise. The evidence base is also limited by different methods of evaluating performance and by a few large-scale, long-term field-deployment studies. Therefore, future research should emphasize interoperable architectures, standardized performance measures, secure data governance, reproducible implementations, and long-term validation with respect to various waste streams and regions.

Declaration on Generative AI

ChatGPT (OpenAI) was used to assist in the visual development of Fig. 5. The conceptual framework, scientific content, and final design were subsequently reviewed and refined by the authors, who remain fully responsible for the figure's accuracy and integrity.

Department of Computer Science-Faculty of Computers and Information, Assiut University, Assiut, Egypt[3]

***Abstract*—The complexity and morphological richness of the Arabic language pose significant challenges in natural language processing (NLP), including issues with contextual understanding and feature extraction. Traditional deep learning architectures such as CNNs, LSTMs, and GRUs often struggle to effectively model these linguistic intricacies, limiting their performance on Arabic text analysis tasks. To address these limitations, the study integrates parallel multi-kernel word-level convolutional features into conventional and hybrid deep learning models. The convolutional windows capture short contextual relationships among neighboring word tokens, while recurrent components model longer sequential evidence; the framework does not directly analyze roots, affixes, or other within-word morphological structures. These enhancements are integrated into CNN, LSTM, GRU, and hybrid architectures such as LSTM-CNN and GRU-CNN. A comprehensive evaluation was conducted across varying learning rates to assess the impact of the enhanced configurations on model performance. The results indicate competitive performance within the evaluated architectures and dataset variants, although the magnitude of improvement depends on the model and learning rate. Under their best settings, the Dynamic N-gram LSTM-CNN achieved an accuracy of 93.32%, while the Dynamic N-gram LSTM achieved 93.57%. Because previously published studies use different corpora, class configurations, preprocessing pipelines, and evaluation protocols, these results are not presented as evidence of state-of-the-art superiority. Instead, the study provides a systematic within-study assessment of model sensitivity to architecture, preprocessing, and learning-rate selection. Future directions include character- and subword-level modeling, transformer-based architectures, and domain-specific tasks such as sentiment analysis and information retrieval.**

Keywords*—Dynamic n-grams; GRU-CNN hybrid; Arabic NLP; sequential dependencies; text classification

I. Introduction

The consumption and production of online news have greatly increased, as never before, due to technological advancements and the easy accessibility of the internet in the digital age. The Arabic language market, with a total of more than 420 million people, has witnessed a huge increase in the production of online news [1], [2]. Arabic news websites, including Al-Arabiya, Al Jazeera, and Youm7, reach a broad audience, providing information in many fields, like politics, sports, culture, and technology. The occurrence of this great reservoir of information has altered the aspect through which Arabic-speaking groups dwell on contemporary issues, and the necessity of digital channels in the formation of opinion and transfer of knowledge cannot be overstressed [3], [4]. Nevertheless, the increase in Arabic news material poses some difficulties as regards obtaining accessibility and classification of information. It is common among users to have difficulties progressing through the flood of content in search of the news of their interest [5], [6]. The necessity of automated classification systems has become very evident. Automated text classification would make it easier to organize the news articles in predefined categories and thereby allow a user to access the relevant articles. Such functionality is essential to end-users and makers of the content of the news, which will add to the user experience and increase the searchability of the articles [7], [8]. Besides the need to automate the increasing amount of news content, the special linguistic complexity of the Arabic language also necessitates the development of strong text classification systems specifically deployed in Arabic news management. These shall be described as complexities that require advanced machine learning and deep learning to be adopted.

The Arabic language presents distinctive challenges for automated text classification because of its morphological, syntactic, and lexical properties. Arabic is highly inflected, and surface forms may vary according to tense, gender, number, and case [9], [10]. A single root can also generate many derived forms through prefixes, suffixes, infixes, and templatic patterns, increasing word-level sparsity and making contextual interpretation important. Arabic additionally has a rich vocabulary, many near-synonyms, and context-dependent meanings. Modern Standard Arabic coexists with regional dialects that differ in syntax and vocabulary [11], [12], and digital news may contain variation across sources. Relatively flexible word order and the frequent absence of diacritics can further increase ambiguity. Accordingly, methods that combine local token context, longer sequence modeling, and controlled comparisons of stemmed and non-stemmed representations may help evaluate how these challenges affect classification. The present word-level models are not morphological analyzers and do not directly decompose Arabic roots or affixes.

A. Problem Statement

With the fast rate of expansion of Arabic news on the internet, users have found it difficult to find something of interest with ease. The current models of text classification are mainly developed to support English or less expressive

languages, which cannot be applied to the specifics of the Arabic language, i.e., the abundance of morphology, the flexibility of syntax, and the existence of different types of dialects [13], [14]. Moreover, the unavailability of customized sets and approaches curbs the functionality of classical machine learning and deep learning algorithms. Consequently, there is an urgent need to establish a strong system of categorizations dealing with the linguistic heaviness of Arabic and the categorization of news into sensible clusters. The mentioned gaps can be filled to increase usability among users, create real-time classifications, and cover various kinds of applications, including sentiment analysis and recommendation of personalized content.

B. Motivation of the Study

The sheer growth of the Arabic digital news sector has brought up the need to ensure efficient content organization to enhance access and relevance. The existing automated classification is not able to address this need because the language itself is as complex as it is morphologically rich and contextually dependent. In addition, the current developments in deep learning, particularly in hybrid models such as CNNs and LSTMs, demonstrate potential to overcome these challenges. This research derives interest in the possibility of using these sophisticated methods to develop a more powerful Arabic news classification system. This study will help to fill the divide between linguistic complexity and technological capacity and thus may contribute to the improvement of user experience and the practicality of automated Arabic text classification.

C. Significance of the Study

This study is relevant because Arabic text classification remains less extensively researched than English and other high-resource languages. The proposed research evaluates deep learning methods, including Dynamic N-grams and hybrid models, for Arabic news classification. It can support content accessibility, personalization, sentiment analysis, and trend detection. The findings provide additional empirical evidence on the behavior of deep learning architectures under different preprocessing and learning-rate settings for Arabic text classification. Finally, this research can contribute to more organized and accessible digital news environments for Arabic-speaking communities.

D. Key Contribution of the Study

- Dynamic Hybrid Model: Proposed a dynamic model integrated with dynamic n-gram and CNN, LSTM, and GRU in improving the classification of Arabic news.
- Optimized Learning Rates: Optimized the best learning rates that enhance the performance and the stability of the model.
- Systematic Evaluation of Dataset Variants: Systematically evaluated the six existing representations supplied with the Ultimate Arabic News Dataset to examine how provider-applied cleaning, stop-word removal, and stemming affect the evaluated deep learning architectures.
- Model Comparison: Conducted a controlled within-study comparison between baseline and Dynamic N-gram-enhanced architectures across multiple learning rates and dataset variants; the results are interpreted within this experimental setting rather than as a direct ranking against studies using different corpora.
- Development of Arabic NLP: Addressing the Arabic-specific issues helped in the development of improved tools in text analysis and classification.

Structure of the Study: The study includes an introduction (Section I), related works (Section II), methodology (dataset, preprocessing, model architectures, learning rate experiments) (Section III), results and analysis (Section IV), discussion, and conclusion with future directions for Arabic text classification (Section V).

II. Related Works

With the rapid rise of Arabic tweets, Alzanin et al. [15] suggest an automatic classification model that classifies tweets into five categories based on linguistic features and content. It compares two text representations: Word2Vec and stemmed tf-idf, and tests three classifiers: SVM, GNB, and RF. A manually annotated 35,600-tweet dataset was employed. Results indicate that RF and SVM using tf-idf and stemming obtained the best macro-F1 values (98.09%–98.14%), while RF obtained 98.95% accuracy, 99.54% precision, 96.58% recall, and 97.99% F1. However, GNB with Word2Vec did not work well. One major limitation is the difficulty presented by short, ambiguous, and mixed-dialect tweets.

Hossain et al. [16] propose a hybrid Attention-Based Transformer Model (ABTM) for classifying Arabic news that blends deep learning with conventional text representations such as TF-IDF and Bag-of-Words. An effective preprocessing pipeline involving cleaning, tokenization, lemmatization, and data augmentation was used to handle the richness of Arabic news text. The model combines contextual and statistical information and utilizes LIME for interpretability. Compared to AraBERT models, ABTM resulted in 97.69% accuracy, 97.13% precision, 97.11% recall, and 97.10% F1-score with various news categories. Although the model indicates robust performance and interpretability, its limitation resides in handling subtle dialectal variations and possible data imbalance between categories.

Zamzami et al. [17] report on the increasing necessity of determining the origin country of Arabic news articles to enable users to follow up on credible, pertinent news. It suggests a variety of classification models with both machine learning and deep learning methods, trained on varied feature extraction techniques. The models accurately classify articles into origin categories with a maximum accuracy of 94%, with little variation in performance between ML and DL methodologies. This shows the potential for application to regional news filtering. But there is a limitation in the difficulty of dealing with overlapping regional material and subtle linguistic variations, which could impact classification accuracy in some situations.

Imad et al. [18] introduce an Arabic text classification method using NLP methods and deep learning, with TF-IDF, Bag-of-Words, Word Embedding, and a suggested CNN model. The model was tested on three datasets—CNN, BBC, and OSAC—with high accuracy: 94.47% (One Hot), 93.98% (BOW), and 93.58% (TF-IDF) on CNN; 90.97%, 87.19%, and 86.35% respectively on BBC; and more than 98.8% on OSAC. The results validate the model's performance on diverse datasets. Yet, there are limitations such as performance differences on the basis of dataset specifications and possibly challenges in generalizability to diverse Arabic dialects and content structures in real-world use.

Othman et al. [19] tackle the emerging issue of Arabic fake news in the media by suggesting a hybrid approach using Arabic pre-trained BERT models (AraBERT, GigaBERT, MARBERT) augmented with 1D or 2D CNNs for efficient feature extraction and classification. Evaluated on three datasets—ANS, AraNews, and Covid19Fakes—the top-performing architecture (AraBERT + 2D-CNN) achieved F1-scores of 0.6188, 0.7837, and 0.8009, and surpassed current models on the ANS dataset with 71.42% accuracy, 75.6% precision, and 52.38% recall. The model also minimized training time. A primary limitation, though, is the relatively low recall on the ANS dataset, reflecting difficulty in detecting all occurrences of fake news.

Jamaleddyn et al. [20] investigate improving Arabic text classification by utilizing machine learning algorithms with hyperparameter tuning methodologies, i.e., grid search and random search, for model performance optimization. NLP techniques were incorporated to enhance text representation and classification accuracy. The suggested method was benchmarked with the CNN Arabic dataset, resulting in high performance: 95.16% accuracy, 94.64% recall, 94.04% precision, and 94.31% F1-score. Comparison with prior work validated the strength of the model. Still, one limitation is that it relies on tuning techniques, which are computationally intensive and dataset-dependent and may compromise scalability and generalizability to diverse Arabic language corpora.

Alzaidi et al. [21] introduce the TCAODL-ANA method—an improved Arabic news categorization model that integrates FastText word embedding, attention-based bidirectional GRU (ABiGRU), and Aquila Optimizer (AO) for hyperparameter optimization. Targeted at classifying news into seven categories, the model utilizes deep learning's contextual advantages and AO's optimization to enhance performance. Tested using simulations, TCAODL-ANA recorded 95.48% accuracy, 84.21% precision, 84.18% recall, and 84.17% F1-score, surpassing current methods. Although effective, the limitations of the model are relatively moderate precision and recall, implying possible difficulties with ambiguous or overlapped news topics, and heavy reliance on large computational resources for optimization.

Alroobaea [22] considers Arabic news classification based on 5,000 news articles in six categories: business, entertainment, health, politics, sports, and technology. Different preprocessing methods, word embeddings, and deep learning models—CNN, LSTM, and a CNN-LSTM hybrid—were considered. The hybrid model yielded the best accuracy of 93.15% and provided competitive results on other Arabic news datasets. Model architecture and preprocessing decisions are critical to the findings. Nonetheless, a limitation is the comparatively small size of the dataset, which can impact generalization, and the performance of the model can differ for diverse dialects or less-organized Arabic news outlets. The summarization of the related works is shown in Table I.

TABLE I. SUMMARIZATION OF THE RELATED WORKS

Author (s)	Approach	Dataset(s)	Best Results	Limitations
Alzani n et al., [15]	Word2Vec & tf-idf with SVM, RF, GNB	35,600 Arabic tweets	RF: Acc 98.95%, Prec 99.54%, Recall 96.58%, F1 97.99%	Poor GNB performance; ambiguity and dialectal mixing in short tweets
Hossai n et al., [16]	ABTM (Attention-Based Transformer Model) + TF-IDF/BOW + LIME	Benchma rk with AraBER T models	Acc 97.69%, Prec 97.13%, Recall 97.11%, F1 97.10%	Dialectal variation & potential data imbalance
Zamza mi et al., [17]	ML and DL models with various feature extraction methods	Multiple Arabic news datasets	Accuracy up to 94%	Overlapping regional content and linguistic subtleties may affect precision.
Imad et al., [18]	TF-IDF, BOW, Word Embedding + CNN	CNN, BBC, OSAC	CNN: Acc 94.47%, BBC: 90.97%, OSAC: >98.8%	Performance varies across datasets; dialect/genera lization concerns
Othma n et al., [19]	Hybrid: AraBERT/GigaB ERT/MARBERT + 1D/2D CNN	ANS, AraNews , Covid19 Fakes	F1: 0.6188 (ANS), 0.7837 (AraNews), 0.8009 (Covid19Fake s); Acc: 71.42% (ANS)	Low recall on ANS; difficult to capture all fake news cases
Jamale ddyn et al., [20]	ML + Grid/Random Search for hyperparameter tuning	CNN Arabic dataset	Acc 95.16%, Recall 94.64%, Prec 94.04%, F1 94.31%	Tuning is resource-intensive; the model may not generalize across datasets
Alzaidi et al., [21]	TCAODL-ANA: FastText + ABiGRU + Aquila Optimizer	Simulate d Arabic news dataset	Acc 95.48%, Prec 84.21%, Recall 84.18%, F1 84.17%	Moderate precision/reca ll; computationa lly demanding due to AO
Alroob aea [22]	Preprocessing + Word Embeddings + CNN, LSTM, CNN-LSTM	5,000 Arabic news articles	Acc 93.15% (Hybrid CNN-LSTM)	Small dataset; may not generalize well; performance may vary by dialect or news type

III. Framework for Arabic News Text Classification

The proposed study establishes a framework for Arabic news classification using deep learning models and the existing preprocessing variants supplied with the Ultimate Arabic News Dataset. The dataset representations are used as provided by the original contributor to examine how stop-word removal and stemming influence model performance; the study does not claim to release a newly enhanced corpus. The framework integrates Dynamic N-gram extraction with CNN, LSTM, and GRU architectures, evaluated individually and in hybrid combinations to capture local textual patterns and long-range dependencies. Five learning rates are examined to assess convergence and performance sensitivity. The block diagram of the proposed work is shown in Fig. 1.

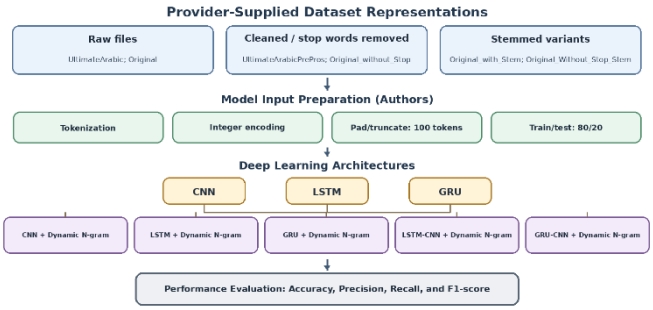

Fig. 1. Block diagram for the proposed study.

A. Linguistic Motivation and Research Hypotheses

Arabic news classification is influenced by high surface-form variation arising from inflection and derivation, clitic attachment, relatively flexible word order, absent diacritics, and lexical ambiguity [9]-[12]. These properties motivate architectures that can combine local contextual evidence with information distributed across a longer sequence. The present implementation uses word-level tokenization; therefore, its convolutional branches operate over neighboring word tokens and do not directly segment or analyze Arabic roots, patterns, prefixes, suffixes, or other within-word morphological units. Morphological variation is addressed only indirectly through learned word embeddings, surrounding context, and comparison of the provider-supplied stemmed and non-stemmed dataset variants.

Kernel sizes 2, 3, and 4 were used as controlled local context scales to detect short token sequences and category-bearing phrases. The recurrent LSTM and GRU components were included to retain evidence across longer portions of an article, which may be useful when semantically related cues are separated by flexible word order or intervening text. The hybrid architectures were consequently designed to test whether combining local phrase extraction with sequential context provides complementary information. These choices are theoretical expectations rather than assumptions of uniform superiority, and the results are interpreted against the following hypotheses.

- H1 (local-context hypothesis): Multi-kernel convolution is expected to improve selected models when category labels are signaled by short neighboring-token patterns; any benefit is expected to depend on the architecture and training configuration rather than occur universally.
- H2 (sequential-context hypothesis): LSTM or GRU layers are expected to be useful when classification requires contextual evidence extending beyond a fixed local convolutional window.
- H3 (complementarity hypothesis): Hybrid convolutional-recurrent models are expected to benefit when local lexical cues and longer sequential evidence contribute jointly to the classification decision.
- H4 (preprocessing-interaction hypothesis): The relative value of each architecture is expected to change across the provider-supplied preprocessing variants because stemming and stop-word removal may reduce lexical sparsity while also removing potentially discriminative lexical or syntactic cues.

B. Data Collection

The data used in this research are from the Ultimate Arabic News Dataset [23], downloaded from Mendeley Data, Version 2 (DOI: 10.17632/jz56k5wxz7.2), published on July 4, 2022, by Ahmed Hashim Al-Dulaimi. The collection contains more than 193,000 single-label Arabic news texts gathered from sources including Al-Arabiya, Al-Youm Al-Sabea (Youm7), Google News, and other news websites. All dataset representations evaluated in this study were used as supplied by the original contributor.

- UltimateArabic: The primary file containing the original Arabic news texts without preprocessing; the texts may include words, numbers, and symbols.
- UltimateArabicPrePros: The provider-preprocessed counterpart in which stop words, non-Arabic words, symbols, and numbers were removed for direct use in Arabic NLP tasks.

The repository also provides two supplementary folders that document the collection process and offer four alternative dataset representations:

- Sample: Two source-specific subsets, Sample_Youm7_Politic and Sample_alarabiya_Sport, illustrate news collected from Youm7 and Al-Arabiya in the Politics and Sport categories, respectively.
- Dataset Versions: Four provider-supplied representations are available: Original (raw text), Original_without_Stop (cleaned text with stop words removed), Original_with_Stem (cleaned and stemmed text), and Original_Without_Stop_Stem (cleaned text with both stop-word removal and stemming).

The corpus is divided into ten single-label categories: Culture, Diverse, Economy, Sport, Politics, Art, Society, Technology, Medical, and Religion. In total, the study evaluates the two primary files and the four existing dataset-version files. The authors did not create or release an independently enhanced version of the corpus; the methodological contribution is the systematic evaluation of

these existing representations. The dataset counts are shown in Table II.

TABLE II. DATASET SAMPLE

Category	Original	Without Stem	Without Stop	Without Stop+ Stem	Ultimate Arabic	UltimateArabicPrePros
Art	3,000	3,000	3,000	3,000	14,390	14,388
Culture	3,000	3,000	3,000	3,000	6,806	6,806
Economy	2,995	2,995	2,995	2,995	26,117	26,038
Medical	3,000	3,000	3,000	3,000	7,294	7,294
Politics	3,000	3,000	3,000	3,000	45,369	45,349
Religion	3,000	3,000	3,000	3,000	6,500	6,500
Sport	3,000	3,000	3,000	3,000	59,998	57,151
Technology	3,000	3,000	3,000	3,000	11,518	11,518
Diverse	3,000	3,000	3,000	3,000	17,203	17,203
Society	0	0	0	0	1,084	1,084
Total	26,995	26,995	26,995	26,995	196,279	193,331

C. Dataset Variants and Model Input Preparation

The corpus-level transformations were not newly introduced by the present authors. The six representations were selected and used as provided in Version 2 of the dataset. The provider-supplied transformations are distinguished below from the subsequent model-input operations. Beyond selecting the appropriate file for each experiment, the authors do not claim additional corpus cleaning, stop-word removal, stemming, or the release of a new processed dataset.

1) Provider-supplied character cleaning: In the cleaned variants, the dataset contributor removed non-Arabic words, symbols, and numbers from the original text.

$$D_clean = Clean(D) \quad (1)$$

2) Provider-supplied stop-word removal: Stop-word removal is already represented in UltimateArabicPrePros, Original_without_Stop, and Original_Without_Stop_Stem; it was not introduced as a new dataset contribution in this study.

$$D_stop = RemoveStopWords(D_clean) \quad (2)$$

3) Provider-supplied stemming: Stemming is already represented in Original_with_Stem and Original_Without_Stop_Stem, as supplied by the dataset contributor.

$$D_stem = Stem(D_clean) \quad (3)$$

4) Provider-supplied combined variant: Original_Without_Stop_Stem combines the contributor's cleaning, stop-word removal, and stemming operations in a single representation.

$$D_both = Stem(RemoveStopWords(D_clean)) \quad (4)$$

5) Tokenization: For model input, each selected text representation was segmented into tokens.

$$T = Tokenize(D_selected) \quad (5)$$

6) Integer sequence encoding: The resulting tokens were mapped to integer sequences so they could be processed by the embedding layer.

$$X = Encode(T) \quad (6)$$

7) Fixed-length sequence preparation: Sequences were standardized to the reported length of 100 tokens by padding shorter sequences and truncating longer sequences.

$$X_100 = PadOrTruncate(X, 100) \quad (7)$$

8) Data partitioning: For each evaluated representation, the prepared samples were divided into the reported 80% training and 20% testing partitions.

$$(D_train, D_test) = Split(D_selected, 80/20) \quad (8)$$

D. Baseline Models

The baseline models provide the basis for assessing and comprehending the efficacy of text classification methods for Arabic news data. The models are suitable for coping with distinctive linguistic patterns in Arabic text, and they also shed light on the performance of classical deep learning architectures.

1) Convolutional Neural Network (CNN): CNNs are commonly employed in natural language processing (NLP) due to their capacity to effectively extract local patterns like n-grams and key phrases from text. The hierarchical structure processes input data hierarchically to ensure that significant features are captured at every level. The structure of the CNN is shown in Fig. 2.

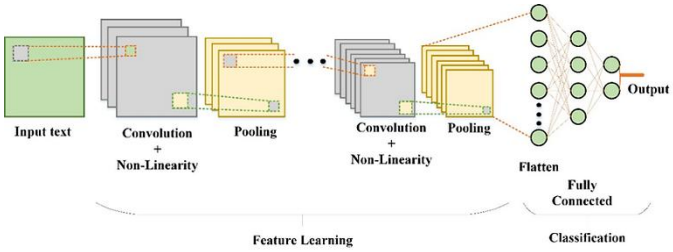

Fig. 2. CNN architecture.

a) Embedding layer: Input sequences of integer-encoded tokens are converted into dense vector representations by this layer. Every token, denoted by t_i, is mapped to an embedding vector $e_i \epsilon R^d$, denoted by d, where d is the embedding dimension. Word semantic links are preserved thanks to the embedding. It is shown in Eq. (9).

$$E = Embedding(T) \quad (9)$$

where, T is the token sequence and E is the embedding matrix.

b) Conv1D layers: To find patterns in fixed-length contexts, one-dimensional convolutional filters are applied over the embeddings. To create feature maps, a filter $w \epsilon R^{k \times d}$ with kernel size k slides over the embedding matrix. It is shown in Eq. (10).

$$h_i = \sigma(w.E_{i:i+k-1} + b) \quad (10)$$

The bias component is denoted by b, the activation function is denoted by σ, and the activation for the i-th position is represented by h_i.

c) Global max pooling: The layer reduces dimensions and retains the most salient characteristics by selecting the maximum activation of each feature map. It is shown in Eq. (11).

$$h_{max} = \max_i(h_i) \quad (11)$$

d) Dense layers: Fully connected layers handle the pooled features and apply softmax activation to support multi-class classification. It is shown in Eq. (12).

$$\hat{y} = Softmax(W.h_{max} + b) \quad (12)$$

e) Rationale: CNNs are well suited to detecting local textual patterns, including short token sequences and category-bearing phrases. In this study, convolution is applied to word-token sequences; consequently, it captures contextual relationships among neighboring words rather than prefixes, suffixes, roots, or patterns within individual words.

2) Long Short-Term Memory (LSTM): LSTM networks are geared to learn long-term dependencies in sequential data by solving the vanishing gradient problem in regular recurrent neural networks (RNNs). This positions LSTMs well to capture contextual and sequential patterns in Arabic text. The LSTM structure is shown in Fig. 3.

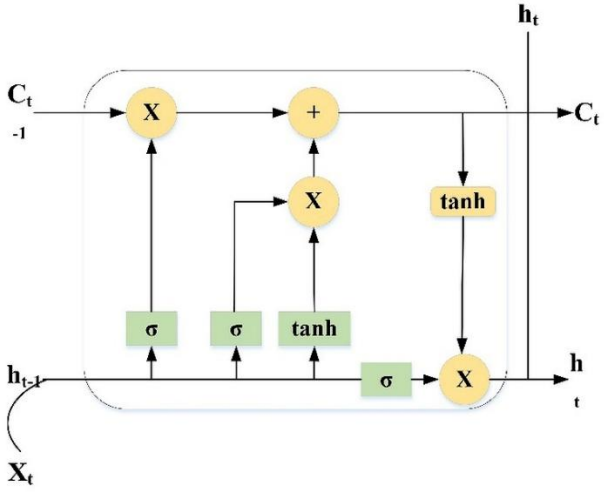

Fig. 3. LSTM structure.

a) Embedding layer: Functions as in CNN, mapping tokens to dense vectors.

b) LSTM layer: The following equations define the model's central component, an LSTM cell at time step t, shown in Eq. (13)-(18).

$$f_t = \sigma(W_f[h_{t-1}, X_t] + b_f) \quad (13)$$

$$i_t = \sigma(W_i[h_{t-1}, X_t] + b_i) \quad (14)$$

$$g_t = tanh(W_g[h_{t-1}, X_t] + b_g) \quad (15)$$

$$c_t = f_t \odot c_{t-1} + i_t \odot g_t \quad (16)$$

$$o_t = \sigma(W_o[h_{t-1}, X_t] + b_o) \quad (17)$$

$$h_t = o_t \odot \tanh(c_t) \quad (18)$$

Here, the cell state is represented by c_t, the hidden state by h_t, and the forget, input, and output gates are represented by f_t, i_t, and o_t, respectively.

c) Dense layers: Like CNNs, dense layers project the final output of LSTM to classification probabilities via softmax.

d) Rationale: LSTMs learn long dependencies and word order, which are necessary for realizing complex Arabic sentence structure and syntax.

3) Gated Recurrent Unit (GRU): GRUs are a recurrent architecture that uses update and reset gates to model sequential information with a simpler gating structure than LSTMs. The GRU structure is shown in Fig. 4.

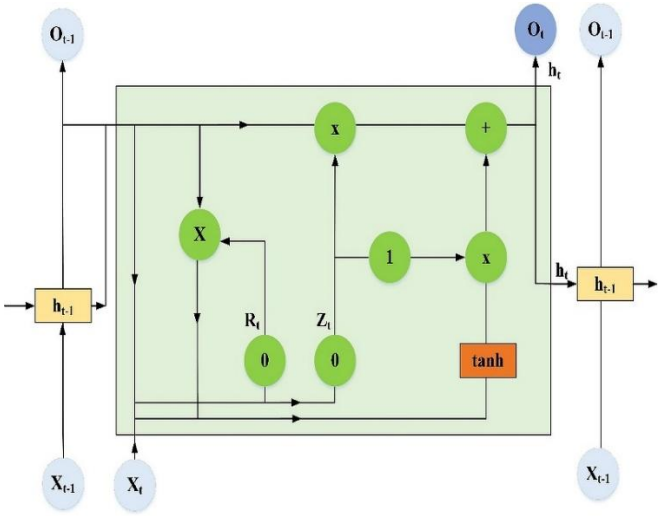

Fig. 4. GRU structure.

a) Embedding layer: Same as in CNN and LSTM.

b) GRU Layer: By merging the input and forget gates into an update gate, GRU streamlines the architecture. The equations at the time step t are shown in Eq. (19)-(21).

$$z_t = \sigma(W_z[h_{t-1}, X_t] + b_z) \quad (19)$$

$$r_t = \sigma(W_r[h_{t-1}, X_t] + b_r) \quad (20)$$

$$h_t = (1 - z_t) \odot h_{t-1} + z_t \odot \tanh(W_h[r_t \odot h_{t+1}, x_t] + b_h \quad (21)$$

If h_t is the new hidden state, z_t is the update gate, and r_t This is the reset gate.

c) Dense layers: As in the case of LSTM, the final output is passed to fully connected layers with softmax for classification.

d) Rationale: GRUs provide an alternative recurrent mechanism for capturing contextual and sequential dependencies in Arabic text. In this study, their suitability is assessed through classification metrics only; computational efficiency was not benchmarked.

By using such baseline models, the research comprehensively examines the strengths and limitations of various architectures for Arabic news classification. These models also serve as a benchmark for measuring the performance of sophisticated hybrid solutions.

E. Hybrid and Advanced Models

To further improve classification accuracy, hybrid and advanced versions of the models were used by leveraging the strengths of Convolutional Neural Networks (CNNs), Long Short-Term Memory (LSTM), Gated Recurrent Units (GRUs), and dynamic n-gram feature extraction methods. These models seek to leverage both local patterns and sequential dependencies, providing an enhanced feature representation. The following is a detailed overview of each hybrid model, its architecture, and the significance of the model with respect to Arabic text classification.

1) Dynamic N-gram + CNN

a) Dynamic N-gram block: The main innovation consists of parallel Conv1D layers that capture bi-, tri-, and four-grams with different kernel sizes k (e.g., 2, 3, 4). The convolution process for an embedding matrix, where n is the sequence length and d is the embedding dimension. It is shown in Eq. (22).

$$h_{i,j} = \sigma(w_j . E_{i:i+k_j-1} + b_j) \quad (22)$$

where, the bias is represented by b_j, the filter is represented by w_j, the activation function by σ, and the kernel size is indicated by σ.

b) Concatenation: The outputs of the Conv1D layers are concatenated to form a feature-rich representation. It is shown in Eq. (23).

$$H_{concat} = [H_1, H_2, H_3] \quad (23)$$

where, the feature map from the j-th kernel is represented by H_j.

c) Global max pooling: Reduces dimensionality by choosing the maximum activation for every feature map. It is shown in Eq. (24).

$$h_{max} = \max_i(H_{concat}) \quad (24)$$

d) Dense layers: Fully connected layers process the pooled features and offer classification probabilities using a softmax layer. Dynamic N-gram + CNN is shown in Fig. 5.

e) Rationale: The use of multiple kernel sizes allows this model to capture different local textual patterns. The present study evaluates the effect of this configuration on classification performance; training speed and computational cost were not measured.

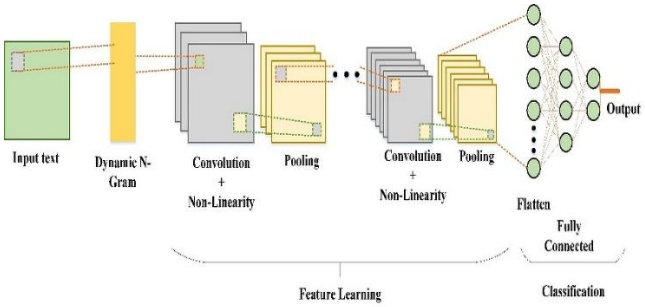

Fig. 5. Dynamic N-gram + CNN.

2) Dynamic N-gram + LSTM

a) Dynamic N-gram block: This block, similar to the above model, captures n-gram patterns using parallel Conv1D layers.

b) LSTM layer: Concatenated n-gram features are fed to an LSTM layer to capture long dependencies and context relationships. The LSTM handles input sequentially with both hidden and cell states. It is shown in Eq. (25).

$$h_t, c_t = LSTM(x_t, h_{t-1}, c_{t-1}) \quad (25)$$

Here, the concealed state is denoted by h_t, the cell state by c_t, and the input at time t by x_t.

c) Dense layers: Final layers project the LSTM output to class probabilities. Dynamic N-gram + LSTM is shown in Fig. 6.

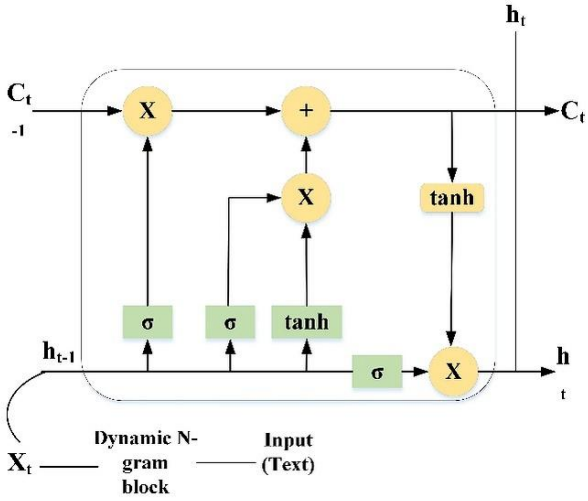

Fig. 6. Dynamic N-gram + LSTM.

d) Rationale: This model brings together the CNN's power in extracting strong local features and the LSTM's capacity for sequential dependency capture, offering a comprehensive solution to Arabic text classification.

3) Dynamic N-gram + GRU

a) Dynamic N-gram block: As defined earlier, this block extracts bi-grams, tri-grams, and more with Conv1D layers.

b) GRU layer: The GRU layer substitutes the LSTM and models sequential relations through update and reset gates. The GRU cell can be described as shown in Eq. (26)-(28).

$$z_t = \sigma(W_z[h_{t-1}, x_t] + b_z) \quad (26)$$

$$r_t = \sigma(W_r[h_{t-1}, x_t] + b_r) \quad (27)$$

$$h_t = (1 - z_t) \odot h_{t-1} + z_t \odot \tanh(W_h[r_t \odot h_{t+1}, x_t] + b_h \quad (28)$$

c) Dense layers: Final classification is done by fully connected layers with softmax activation. Dynamic N-gram + GRU is shown in Fig. 7.

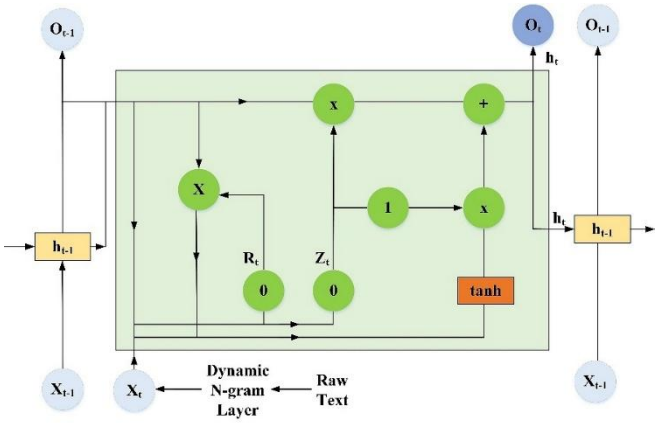

Fig. 7. Dynamic N-gram + GRU.

d) Rationale: The integration of GRU and Dynamic N-gram extraction combines multi-scale local features with recurrent sequence modeling. Its classification behavior is evaluated experimentally, while computational efficiency and suitability for resource-limited deployment are not assessed in this study.

4) Dynamic N-gram + LSTM + CNN

a) Dynamic N-gram block: Parallel Conv1D layers extract varied local patterns, similar to earlier models.

b) LSTM layer: Parameterized with return_sequences=True, the LSTM layer processes n-gram features, extracting sequential dependencies without losing temporal structure for subsequent processing. It is shown in Eq. (29).

$$h_t = LSTM(H_{concat}) \quad (29)$$

c) Additional CNN layer: The LSTM outputs are passed through another Conv1D layer to fine-tune local patterns. It is shown in Eq. (30).

$$h_{refine} = Conv1D(h_t) \quad (30)$$

d) Global max pooling: Combines fine-tuned features and dimension reduction.

e) Dense layers: Fully connected layers finalize the architecture, ending with a final softmax layer for classification. Dynamic N-gram + LSTM + CNN is shown in Fig. 8.

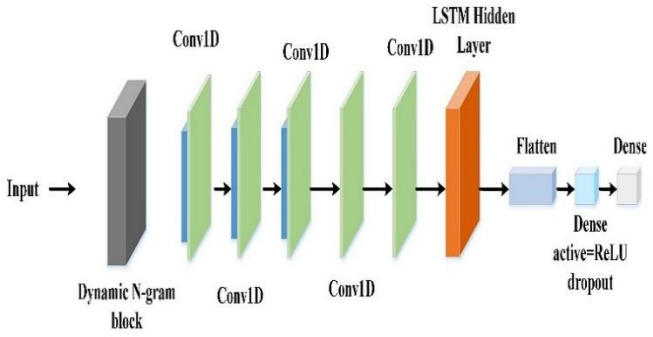

Fig. 8. Dynamic N-gram + LSTM + CNN.

f) Rationale: This hybrid model extracts fine-grained local features using CNNs, formulates their temporal relationships using LSTM, and further refines the resultant patterns with a second CNN layer. This multi-step processing guarantees excellent feature representation and classification performance.

5) Dynamic N-gram + GRU + CNN

a) Dynamic n-gram block: Parallel Conv1D layers: Derive varied local patterns from the input text data, such as in the Dynamic N-gram + LSTM + CNN architecture.

- Output: Integrated local features for sequential processing.

b) GRU layer: Set up with return_sequences=True, the GRU layer processes the n-gram features while retaining temporal relationships for the subsequent layer. It is shown in Eq. (31).

$$h_t = GRU(H_{concat}) \quad (31)$$

c) Additional CNN layer: The GRU outputs are passed through a Conv1D layer to further refine local patterns so that feature extraction at multiple levels is possible. It is shown in Eq. (32).

$$h_{refine} = Conv1D(h_t) \quad (32)$$

d) Global max pooling: Combines refined features and performs dimensionality reduction by taking the most important feature values from each feature map.

e) Dense layers: The aggregated features are processed by fully connected layers, leading to a softmax layer for multi-class classification. Dynamic N-gram + GRU + CNN is shown in Fig. 9.

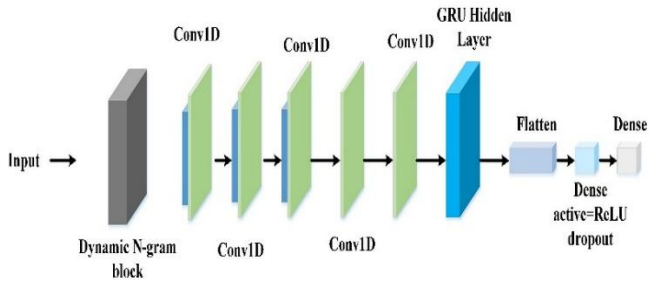

Fig. 9. Dynamic N-gram + GRU + CNN.

This fusion architecture combines CNN-based local feature extraction with GRU-based sequential dependency modeling. The additional CNN layer further refines the temporal representations produced by the GRU, while the Dynamic N-gram block supplies features derived from multiple kernel sizes. Because runtime and resource measurements were not collected, no conclusion is drawn regarding a computational advantage or suitability for resource-constrained deployment.

The advanced and hybrid models are evaluated because Arabic news classification may depend on both local token patterns and longer contextual relations. Combining multi-kernel word-level convolution with sequence modeling tests whether these two forms of evidence are complementary across the supplied preprocessing variants. The architecture does not itself solve Arabic morphology or directly analyze within-word structure (Algorithm 1).

Algorithm 1: Dynamic N-gram + GRU + CNN for Arabic Text Classification

Input: Arabic text dataset D

Output: Classified labels L

Step 1: Preprocessing:

Clean text (remove special characters, stop words).

Generate Dynamic N-grams and encode using embeddings.

Step 2: Dynamic N-gram Block:

Apply parallel $Conv1D$ layers to capture diverse local patterns.

Concatenate outputs to form H_{ngram}

Step 3: GRU Processing:

Pass H_{ngram} to GRU (return_sequences=True) to model sequential dependencies.

Output: H_{gru} CNN Refinement:

Step 4: CNN Refinement

Apply another $Conv1D$ layer on H_{gru} to refine features.

Output: H_{gru}

Step 5: Pooling:

Perform global max pooling to reduce dimensionality.

Result: H_{pool}

Step 6: Classification:

Pass H_{pool} through dense layers and a softmax layer for classification.

Step 7: Training:

Use cross-entropy loss and Adam optimizer with tuned learning rates.

Step 8: Evaluation:

Compute Accuracy, Precision, Recall, and F1-Score.

End

IV. Result and Discussion

The results and discussion section presents a detailed show of the performance of the models in different architectures and learning rates. To guarantee uniform assessment, each of the models trained in TensorFlow/Keras was presented with 10 epochs. The results of the performance were determined in the form of a weighted average to take into account the probable class imbalance. The metrics, such as the percentage value with two decimals, are classified in bordered tables to facilitate comparison and ease of calling. The aim of the evaluation is to determine what the best learning rate is per architecture and how the trade-off between the convergence rate and the performance is. The explanation is to focus on the effectiveness of the various architectures (e.g., CNN, LSTM, and hybrid models) in addressing the complexities of the dataset. Through combining the observations of these critiques, the following section will serve to emphasize the merits, weaknesses, and application to real life of the suggested methodologies applied to Arabic text classification, providing an authoritative basis to work on in the form of future developments. All experiments were conducted on a 64-bit workstation equipped with an AMD Ryzen 5 3600 six-core processor operating at 3.59 GHz and 64 GB of RAM. Model training and evaluation were performed exclusively on the CPU. Table III shows the simulation parameters.

TABLE III. Simulation Parameter

Parameter	Value
Dataset	Ultimate Arabic News Dataset
Number of Classes	10
Training Epochs	10
Batch Size	32
Learning Rates Tested	0.1, 0.01, 0.001, 0.0001, 0.00001
Evaluation Metrics	Accuracy, Precision, Recall, F1-Score
Optimizer	Adam
Activation Function	Softmax
Training/Testing Split	80% / 20%
Framework Used	TensorFlow/Keras
Dropout Rate	0.5
Kernel Sizes (CNN)	2, 3, 4
Sequence Length	100 tokens
Embedding Dimensions	128

A. Performance Metrics

Accuracy: Measures the proportion of correctly classified instances out of total instances. It is shown in Eq. (33).

$$Accuracy = \frac{TP+TN}{TP+FP+FN+TN} \quad (33)$$

Precision: Indicates the proportion of true positives among predicted positives, showing correctness. It is shown in Eq. (34).

$$Precision = \frac{TP}{TP+FP} \quad (34)$$

Recall (Sensitivity): Reflects the proportion of true positives identified among actual positives. It is shown in Eq. (35).

$$Recall = \frac{TP}{TP+FN} \quad (35)$$

TABLE IV. PERFORMANCE METRICS: BASELINE MODELS VS. DYNAMIC N-GRAM ENHANCED MODELS

F1 Score: Balances precision and recall, providing a single performance measure. It is shown in Eq. (36).

$$F1 = 2 \times \frac{Precision \times Recall}{Precision + Recall} \quad (36)$$

Table IV shows the comparison of baseline models (CNN, LSTM, GRU, and their ensemble) against their respective Dynamic N-gram-enhanced versions. The data distribution ensures even training and testing partitions to allow for fair assessment. Results are reported across different learning rates to gain holistic insights into model performance under various settings.

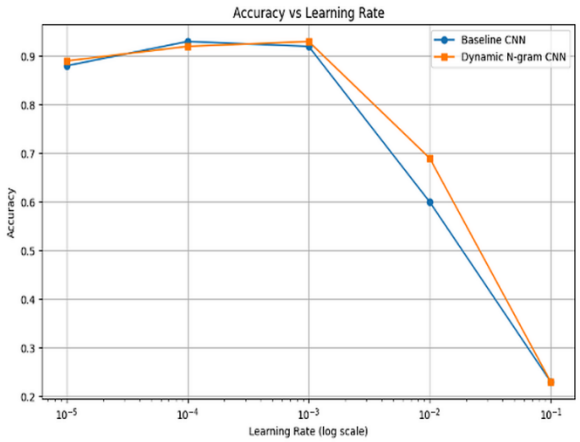

Fig. 10. Accuracy vs learning rate.

Fig. 10. presents the trend in the performance of deep learning models for varying learning rates. It indicates the reaction of baseline and Dynamic N-gram-augmented models to variations in learning rate, comparing the ideal range for successful classification. Dynamic models tend to exhibit enhanced accuracy at smaller learning rates, indicative of improved flexibility in learning fine-grained patterns of Arabic text. This visualization is critical to determine the learning rate that gives the optimal generalization performance and model stability. It also aids in comparing how different architectures (CNN, LSTM, etc.) perform while training, enabling improved model tuning approaches for Arabic NLP tasks.

Table V shows the comparison of baseline and Dynamic N-gram-augmented models over the "Original Without Stem" dataset. The dataset ensures a balanced distribution over categories so that training and testing are strong and unbiased. Performance of models is checked with different learning rates so that their effect on different metrics can be analyzed.

- CNN models outperform others at higher learning rates (e.g., 0.0001 and 0.001).
- Dynamic N-gram improvements demonstrate enhanced performance on lower learning rates for certain models (e.g., GRU, LSTM).
- GRU and GRU-CNN models are less effective compared to their counterparts across all metrics.

TABLE V. PERFORMANCE METRICS COMPARISON: ORIGINAL WITHOUT STEM – BASELINE VS. DYNAMIC N-GRAM MODELS

Model Type	Learning Rate	Baseline Model				Dynamic N-gram Model			
		Accuracy	Precision	Recall	F1-Score	Accuracy	Precision	Recall	F1-Score

Tables VI and VII summarize performance differences between the baseline and Dynamic N-gram-augmented architectures across the evaluated learning rates.

- Dynamic N-gram models tend to perform better than their baseline equivalents at low learning rates (e.g., 1.00E-05).
- At ideal learning rates (0.0001 and 0.001), basic models (e.g., CNN, GRU-CNN, and LSTM-CNN) provide greater accuracy.
- Stemming and stop-word removal slightly impact recall and precision positively for dynamic N-grams.
- GRU models have lower performance values with and without extensions.
- Dynamic N-gram CNN performs better than CNN using low learning rates (1.00E-05) but lags slightly at mid-range rates (0.0001).
- Dynamic N-gram LSTM always outperforms traditional LSTM in terms of accuracy and recall, especially at 0.0001 and 0.01.
- GRU models like Dynamic N-gram GRU have lower precision in all metrics, indicating minimal usefulness for this set of data.
- LSTM-CNN and Dynamic N-gram LSTM-CNN are equivalent, but Dynamic N-gram LSTM-CNN is marginally better when learning rates are high (0.001).

Table VIII summarizes the performance patterns of the baseline and Dynamic N-gram configurations, particularly for the CNN- and LSTM-based models on this dataset representation.

- Dynamic N-gram improvements systematically enhance the performance of CNN, LSTM, and hybrid models, especially for smaller learning rates.
- GRU architectures do not perform well overall, with small improvements from the Dynamic N-gram method.
- Hybrid configurations such as LSTM-CNN and GRU-CNN are superior with Dynamic N-grams at best learning rates (0.001).

TABLE VIII. PERFORMANCE METRICS COMPARISON: ULTIMATE ARABIC RESULTS – BASELINE VS. DYNAMIC N-GRAM MODELS

Table IX emphasizes the use of Dynamic N-gram methods in tuning model performance on Arabic datasets for various architectures.

Fig. 11 compares the baseline and Dynamic N-gram accuracy values shown for the evaluated architectures. The differences are architecture-dependent rather than uniformly favorable to the enhanced variants: the plotted Dynamic N-gram configurations improve CNN, LSTM, and LSTM-CNN, whereas the baseline GRU and GRU-CNN remain competitive or achieve higher values. The figure therefore illustrates variation across architectures and should not be interpreted as evidence of a consistent gain for every model.

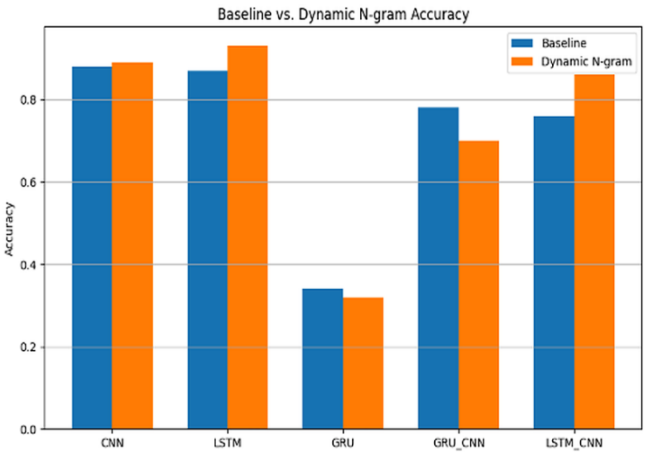

Fig. 11. Baseline vs. dynamic N-gram accuracy.

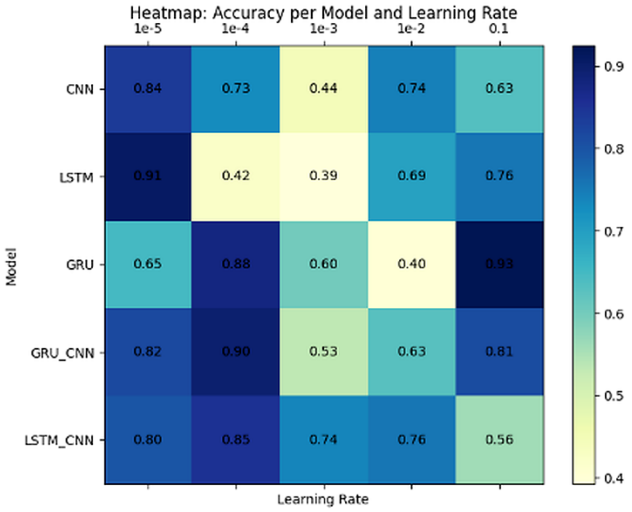

Fig. 12. Accuracy per model and learning rate.

Fig. 12 provides a matrix visualization of how model performance varies at various learning rates. Every cell plots a measure of performance (e.g., accuracy), with color saturation indicating the intensity of the value. The visual graph

immediately reveals good combinations of model types and learning rates. For example, lighter cells might reflect better accuracy, enabling researchers to identify optimal hyperparameter settings. It further allows cross-comparison between baseline and Dynamic N-gram models in a concise manner. By condensing large amounts of experimental data graphically, the heatmap facilitates making sensible decisions regarding model choice and training settings.

Fig. 13 presents the CNN accuracy, precision, recall, and F1-score in a compact multi-metric view. The overlap between the two profiles indicates that the differences are modest and specific to the selected configuration. The chart is used to inspect metric balance within this experiment, not to infer universal robustness or superiority beyond the evaluated dataset and settings.

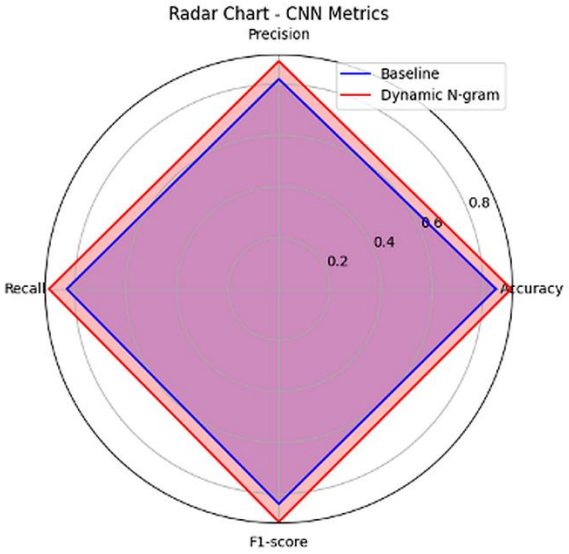

Fig. 13. Radar chart-CNN metrics.

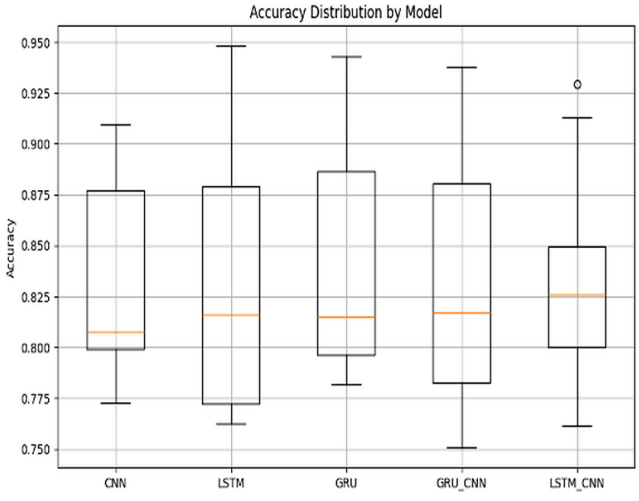

Fig. 14. Accuracy distribution by model.

Fig. 14 plots accuracy score distributions for every model, displaying central tendency and variability with multiple runs. Each box plots the interquartile range, with whiskers and outliers representing score spread. The plot is particularly useful for evaluating model stability and trustworthiness under various initializations or data splits. Models with more compact boxes and larger medians are perceived to be more consistent. It allows researchers to not only find the highest-performing model but also the most reliable one. This matters significantly in actual NLP tasks where consistency in performance over runs is as vital as getting high accuracy.

B. Discussion

The results are interpreted in relation to the four linguistic hypotheses stated in Section III. Because the architecture operates on word tokens, the analysis concerns local token context, longer sequential evidence, and interaction with preprocessing; it does not claim direct modeling of Arabic roots or affixes. The overall pattern is mixed: selected configurations are consistent with the hypotheses, whereas other settings show that the proposed components do not provide uniform gains.

- H1 - Local-context hypothesis: The multi-kernel CNN configuration improved accuracy under selected low-learning-rate conditions, but the baseline CNN matched or exceeded it in several mid-range conditions. Thus, short multi-scale token context can be useful, but fixed windows of two to four words are not consistently superior across all settings.
- H2 - Sequential-context hypothesis: Dynamic N-gram LSTM achieved the strongest result among the enhanced models under its best configuration, which is consistent with the expectation that longer sequential context can complement local features. However, the advantage was not maintained at every learning rate, and both GRU configurations performed substantially below the strongest CNN- and LSTM-based settings. The evidence is therefore partial and architecture-dependent.
- H3 - Complementarity hypothesis: The hybrid results were also mixed. The enhanced LSTM-CNN reached a strong value at a selected learning rate, whereas baseline hybrid models matched or exceeded their enhanced counterparts in other configurations. These findings suggest that local and sequential representations can be complementary, but they do not establish a universal hybrid advantage or isolate the contribution of each component without an ablation study.
- H4 - Preprocessing-interaction hypothesis and learning-rate sensitivity: Relative model rankings changed across dataset representations and learning rates. This pattern is consistent with the possibility that stemming and stop-word removal alter the lexical and syntactic cues available to each architecture, but the present design cannot determine which specific linguistic information was retained or removed. Learning rate was also a major determinant of convergence: the largest rate generally produced unstable or near-chance results, while moderate and smaller rates yielded the strongest values for different architectures.

Taken together, the results support conditional rather than universal versions of the proposed hypotheses. Multi-scale local context, recurrent sequence modeling, and their combination can provide competitive benefits in selected settings, but the observed gains remain configuration-dependent. Because the implementation is word-based and no kernel-specific or component-level ablation was conducted, the results should not be interpreted as evidence of direct morphological analysis or as causal proof that any single architectural component produced the improvement.

Table X provides a contextual rather than a direct benchmark comparison. The reported values were obtained using different corpora, numbers of classes, preprocessing pipelines, data partitions, task definitions, and evaluation protocols. Therefore, a numerical ranking across these studies would be methodologically inappropriate. The present results are consequently described as competitive within the Ultimate Arabic News Dataset setting. A controlled comparison that reimplements external methods on the same corpus and split is required before any state-of-the-art claim can be supported.

TABLE X. CROSS-STUDY PERFORMANCE CONTEXT FOR ARABIC NEWS CLASSIFICATION

Study / Method	Dataset / Setting	Reported Accuracy / Comparison Note
Hossain et al. [16] — ABTM	Arabic news corpus; transformer with TF-IDF/BOW	97.69%; different corpus, preprocessing, and evaluation protocol
Zamzami et al. [17] — ML/DL	Multiple country-of-origin Arabic news datasets	Up to 94%; different target task and corpora
Imad et al. [18] — CNN	CNN, BBC, and OSAC datasets	94.47%, 90.97%, and >98.8%; dataset-dependent and not directly comparable
Jamaleddyn et al. [20] — tuned ML	CNN Arabic dataset	95.16%; different dataset and tuning protocol
Alzaidi et al. [21] — TCAODL-ANA	Simulated Arabic news dataset	95.48%; different dataset and optimization procedure
Alroobaea [22] — CNN-LSTM	5,000 Arabic news articles in six categories	93.15%; different dataset size, classes, and split
Present study — Dynamic N-gram LSTM	Ultimate Arabic News Dataset; 10 classes; 80/20 split	93.57%; competitive within the present protocol; no direct state-of-the-art claim

C. Limitations

Computational efficiency was not evaluated in the present experiments. Consequently, the study does not report parameter count, FLOPs, training time, inference latency or throughput, model size, or peak CPU memory consumption. The reported comparisons therefore support conclusions about classification performance only and cannot establish whether the observed accuracy differences justify any additional computational overhead in real-world deployment settings. In addition, the word-level tokenization used in the experiments does not directly model Arabic roots, patterns, clitics, or other within-word morphological structure. The linguistic explanations are therefore hypothesis-based interpretations of the architecture and observed performance patterns rather than causal evidence, and kernel-specific or component-level ablation experiments were not conducted.

V. CONCLUSION AND FUTURE WORKS

The study examined the usefulness of applying Dynamic N-gram augmentation to CNN, LSTM, GRU, and hybrid deep learning models for Arabic text classification. The findings showed that multi-kernel word-level context can improve selected architectures under particular learning-rate and preprocessing settings, while the magnitude and direction of the difference vary by model. Among the tested enhanced models, Dynamic N-gram LSTM and Dynamic N-gram LSTM-CNN achieved 93.57% and 93.32% accuracy, respectively, under their best configurations. Interpreted against the stated hypotheses, the results provide conditional support for combining short token-context features with longer sequential evidence, but they do not demonstrate uniform superiority or direct modeling of Arabic morphology. The regular GRU performed less effectively than other architectures, and its enhanced variant produced only limited gains. These findings demonstrate competitive performance within the present dataset and evaluation protocol. They should not be interpreted as state-of-the-art superiority because the studies reviewed in Section II used different corpora, class configurations, preprocessing pipelines, and experimental splits. Future work should reproduce representative external baselines, including transformer-based methods, on the same data partition and evaluation protocol. It should also evaluate character-level and subword tokenization, morphology-aware representations, and controlled ablations comparing individual kernel sizes 2, 3, and 4 with their combined configuration. Such experiments would test the linguistic hypotheses more directly and distinguish local-context effects from model-capacity effects. Future work should additionally conduct controlled computational profiling on common hardware by reporting parameter count, FLOPs, training time, inference latency and throughput, model size, and peak CPU memory consumption for each baseline and enhanced architecture. Such profiling is necessary to quantify the accuracy-efficiency trade-off and assess real-world deployment feasibility.

8C SPS Model: A Seller Product Selection Model for Home-Based Business Sellers Using a Multi-Criteria Decision-Making Approach

Selvia Lorena Br Ginting[1]*, Zulaiha Ali Othman[2]
Center For Artificial Intelligence Technology (CAIT), Faculty of Information Science and Technology, Universiti Kebangsaan Malaysia, Bangi 43600, Malaysia[1, 2]
Computer System Study Program, Faculty of Engineering and Computer Science, Universitas Komputer Indonesia, Bandung, Indonesia[1]

***Abstract*—Home-based businesses are becoming a necessary tool for sellers of home-based businesses to determine which products they might be able to sell well. Otherwise, most of the sellers still choose products by trial and error, which may bring low demand as well as stock that doesn't sell, resulting in wasted capital. This study proposes an extended Seller Product Selection model from the seller perspective by enlarging the five-criterion benchmark customer-oriented model into eight criteria: Rating, Price, Sold, Discount, Response Chat, Repurchase, Favorite, and Followers. The data utilized in this study are records of food and beverage products from Shopee Indonesia, amounting to 150,000 products. The criteria relevance was tested with Forward Stepwise Multiple Linear Regression, which is additionally supported by the questionnaire given to 30 marketplace sellers online. Regression results for Sold are presented, indicating that all selected criteria were significantly related to the final model, achieving R = 0.953, R Square = 0.908, Adjusted R Squared = 0.908 with a Durbin-Watson of 1.863 (P<.0005) as shown in the table… The ANOVA result also indicates that the total model is statistically significant, F = 206961.417, p < 0.001. Repurchase had the highest statistical correlation with Sold (β = 0.758) among predictors, followed by Favorite (β = 0.299). Questionnaire results illustrate the following: Sold was ranked number one with a mean rank of 2.40 and Borda Weight of 0.183; Repurchase followed closely in position two with a mean rank of 3.63 and Borda Weight of 0.149. In order to validate whether dyads were able to agree on their RfD, Kendall's coefficient of concordance was obtained as follows: W = 0.236 (P < 0001), suggesting a moderate level of agreement among respondents. We conducted product ranking experiments for MOORA, SMART, PSI and TOPSIS under different combinations of criteria and weight assignments based on AHP. The results indicate that the eight-criterion Seller Product Selection model achieves substantially improved ranking stability and consistency compared with the five-state benchmark model presented in the relevant literature. While considering the eight-criterion model, MOORA performed the best in terms of obtaining the lowest MAD value (1,093), MSE value (4,969,891), and the highest Spearman's Rank Correlation value (0.99868). The results demonstrate that the proposed eight-criterion Seller Product Selection model can be an actionable decision aid to guide home-based business sellers in selecting products that have a better potential in the marketplace using MOORA.**

I. INTRODUCTION

Home-based businesses (HBBs) have become an increasingly important source of household and supplementary income, particularly for people seeking flexible and low-cost business opportunities that can be run from home. Besides supporting the welfare of families, HBBs also contribute towards employment generation, local economic activity, resource mobilization, and national economic development [1-6]. The rapid growth of digital marketplaces and e-commerce platforms has facilitated many HBB sellers to have access to wider markets and an extensive range of products and services online [1] [7] [8-13]. Among these, food and beverage products are one of the most common and promising categories due to their continuous demand and large consumer base [14]. However, despite these opportunities, HBB sellers face many serious challenges in sustaining their businesses, especially in highly competitive online environments [15]. One of the main problems is deciding what the best product to sell is. Many sellers, especially those new to business, choose products without researching the market well. This leads to low demand, unsold products, wasted money, and repeated trial-and-error decisions. These conditions not only decrease profitability but also endanger business survival and long-term sustainability [11, 16-18]. Therefore, the HBB sellers need practical support to identify product ideas with strong market potential, so that they can offer products that are more likely to sell, generate profit, and strengthen their competitiveness against other sellers. This assistance to HBB sellers is not only important for their own welfare, but also for the broader economy, as good and sustainable HBB performance can bring about wider social and economic benefits. In this context, providing a ranked list of promising products can serve as a useful decision support mechanism for HBB sellers in determining which products should be prioritized for sale. To achieve this objective, Multi-Criteria Decision-Making (MCDM) is considered an appropriate approach because it enables product alternatives to be systematically evaluated and ranked based on multiple relevant criteria, thereby helping sellers make more informed, rational, and competitive product selection decisions [18-25].

*Corresponding author.

Previous research by Okfalisa et al (2021) has addressed a related marketplace decision problem by applying the MOORA algorithm in a decision support system to recommend online shops based on five criteria, namely price, rating, discount, sold, and response chat, and showed that these criteria could be used to generate ranked recommendations effectively [23]. However, that study was mainly designed from the customer perspective and was limited to five evaluation criteria and a specific product context [23]. Building on this foundation, the present study extends the evaluation framework to eight criteria to better capture the needs of seller product selection, particularly for home-based business sellers who require broader market signals in selecting products with stronger selling potential [26, 27]. Moreover, the problem is evaluated with several MCDM algorithms, such as MOORA, SMART, PSI, and TOPSIS, to prove the robustness of product ranking under the extended criteria set. This extension aims to provide a comprehensive and practical ranking approach to identify the best products to sell in a competitive online marketplace.

The rest of this study is organized as follows. Section II reviews the literature on product selection, seller-related marketplace criteria, statistical analysis, and measures of robustness of rankings. Section III presents the proposed 8C SPS model and the dataset collection and preprocessing, questionnaire analysis, regression procedure, AHP weighting, MCDM algorithms, and evaluation measures. Section IV presents and discusses the results of the questionnaire, regression, product-ranking, criterion-removal and robustness. Finally, Section V presents a summary of the main findings, practical implications, limitations and directions for future research.

II. Literature Review

A. Product Selection

Product selection is another decision-making issue extensively examined by many scholars in diverse research contexts. Examples range from online shopping, supplier selection, material selection, transportation, business studies, to various sales applications. The ubiquity of applications highlights that the issue of product selection is relevant for both the business and industrial communities. As summarized in Table I, previous research has addressed product selection in different contexts by using various datasets, analytical approaches, and evaluation methods to identify the most suitable alternatives. These studies show that product selection is not limited to choosing a single item, but also involves determining the most appropriate alternative among several competing options under different decision environments.

TABLE I. Summary of Existing Selection-Based Decision Studies, Criteria, Algorithms, and Evaluation Measures

Author, Year, Ref	Selection Problem	Criteria								Dataset	Algorithms					Evaluation Measures
		Rating	Price	Discount	Sold	Response Chat	Repurchase	Favorite	Followers		MOORA	SMART	PSI	TOPSIS	OTHERS

1) Product selection in previous studies: In the online marketplace context, product selection has been examined to support better choices among available alternatives and to reduce uncertainty in decision-making. For example, Okfalisa et al. [23] explored online shop recommendations for shirt products, while Liu et al. [28] investigated e-commerce selection using buyer-related information. In other contexts, product selection has been extended to supplier selection in the automotive, iron and steel, textile, and manufacturing sectors [29]-[31], [40], [42], as well as to material and component selection in engineering applications [19], [33], [22, 38, 39], [21]. Lately, several studies have explored the product selection decision problem, which is no longer confined to business and engineering disciplines, but has expanded to digital commerce, social media, and human consumer behaviors with different research focuses.

For example, recent research investigates product selection issues in fashion e-Commerce, modeling of cars, digital commerce, as well as studies on influencer marketing impact on product sales [35], [43-48]. The findings of this research literature show that digital experience, social factors, internet presentation, and market behaviors dominate product-related decision-making. However, to the best of the author's knowledge, the body of related work has remained fragmented

due to the varied nature and focal points of disparate domains investigated.

2) MCDM: From a methodology viewpoint, in addition to other decision-making techniques applied previously to address the problem under study (selection of products), it can be noted that the use of the TOPSIS method is among the most prevalent in the area of decision-making, as it addresses issues related to the selection of suppliers, materials, and evaluation in product-related tasks [19, 29-31], [33], [34], [22, 36-38], [42], [21]. This wide application shows its recognition due to the high suitability for evaluating solutions based on their respective proximity to ideal solutions. Also prevalent in the academic context is the application of the MOORA method in research studies in relation to the recommendations for online stores, the selection of suppliers, material, and evaluation of service [23], [19], [32], [22, 37, 38], [40], [42], [21]. This can also indicate a high degree of applicability in a variety of problems involving evaluation.

In contrast, PSI and SMART are mentioned less widely in the documents obtained. However, they are important as other MCDM methods for ranking purposes. PSI was used in Emovon and Oghenenyerovwho [19], Ulutas et al. [32], Yadav et al.[33], and Amin et al. [34], while SMART was identified in Çakır [41]. Apart from the basic MCDM methods mentioned above, others were found combined with different techniques or with other MCDM methods such as AHP, VIKOR, PROMETHEE, ELECTRE, SEM, PLS-SEM, NBR and FMULTIMOORA [29], [31], [19], [35], [36], [44-48]. This richness means that product selection itself can be interpreted as a complex problem with approaches in terms of rankings and explanations. Nonetheless, most of the previous works have just tested either two or a single algorithm in a particular context. A comparative study that contains MOORA, SMART, PSI, and TOPSIS within the framework of product selection should be done systematically. A comparative study with a larger number of seller-related criteria will help the sellers to choose the most suitable products, especially for sellers related to online home-based business.

3) Criteria used in previous studies: It has been observed that the product selection criterion used may consist of a range of factors that are decided by the problem in the decision-making context and that can also be affected by the set of attributes used in a particular dataset and study motivation. As summarized in Table I, it can be seen that rating and price are the main selection attributes used in previous studies.[23], [29]-[32], [34], [22, 37-42]. Two criteria are frequently applied because they refer to central dimensions in product assessment, and they are easy to understand; ranking indicates rating on subjective perception of quality, satisfaction, or performance, and price indicates economic accessibility and good buy. Usually, in a decision problem, the above criteria form the center part, upon which alternatives could be selected, like those selected from the research area of supplier selection, material selection, or online shop selection problems.

Among all considered marketplace dimensions apart from rating and price, some research also paid attention to: discount, sold, and response chat [23], [36], [44]. Discount denotes commercial attractiveness and attracts shoppers; it may have a positive effect on consumers' intention. Sold refers to the sale volume of items in the marketplaces and is the proxy of customer preferences; it denotes that items' desirability is already proven by actual consumers' demand. Response chat measures both the speed of the seller's reply, interaction level, and service, and so is relevant particularly at marketplaces, which are the environment where there is a need to give information quickly, and can improve consumer experience and influence buying intentions. These criteria have to be taken into account, especially in digital commerce, not only for a cost/quality reason, but also related to market and service success.

Besides, more recent papers have emphasized the necessity of applying behavioral and engagement criteria which represent purchasing intention and loyalty, such as repurchase, favorite, and followers [28], [35], [36], [43-48]. Repurchase represents customers' re-purchasing the item, representing overall customer satisfaction, overall product quality, and the long-term product's appeal; Favorite represents customers' like or collection behavior, meaning that the customer noted this item but has not even purchased it, let alone repurchased it. Follower represents the seller's audience value. These criteria are increasingly important because online product selection is now shaped not only by transactional performance but also by social signals and customer engagement.

B. Statistical Test

1) Stepwise multiple linear regression: Stepwise multiple linear regression is commonly used to identify relevant predictors from a larger set of candidate variables. Liu et al. (2021) applied forward stepwise regression, VIF analysis, and significance testing to 115 explanatory variables and obtained a final model explaining 95% of crop yield variation[28], Muazam et al. (2024) used stepwise multiple regression to determine the agronomic variables affecting sorghum production. From ten candidate variables, the model selected only two significant predictors, namely panicle weight and days to harvesting, with an R^2 value of 0.754 [49]. These studies show that stepwise multiple linear regression is useful not only for prediction but also for screening and validating important variables before they are used in a decision model.

Therefore, in this study, Forward Stepwise Multiple Linear Regression was selected because the candidate predictors had been identified in advance from the literature and the proposed SPS framework. Therefore, the procedure was not intended to explore an unrestricted set of variables, but to examine the order and incremental statistical contribution of seven predefined marketplace variables to the observed Sold variable. The method also provides an interpretable sequence showing whether each additional predictor contributes to the explanatory capacity of the model. Nevertheless, stepwise regression may be sensitive to sample characteristics and may produce statistically significant results for predictors with small practical contributions, particularly when applied to a large dataset. Therefore, the results were interpreted using not only significance values, but also Adjusted R Square, changes in R

Square, standardized coefficients, multicollinearity statistics, residual diagnostics, and the magnitude of the additional contribution of each predictor.

C. Measurement

Measurement was used to evaluate the stability and consistency of the ranking results under changes in criteria weights. MAD, MSE, and Spearman's Rank Correlation were chosen as all these indices are commonly used in MCDM literature and measure the disparate yet complementary aspects of ranking stability [50–53]. MAD represents the mean absolute displacement of values between rankings and gives an indication of the average shift of an alternative. MSE is designed to disproportionately penalize greater displacements than those associated with MAD; and Spearman's rank correlation reflects a measure of concordance with respect to the orders being compared. Therefore, a combination is provided of mean rank displacement, evidence of substantial change in the rankings, and agreement in rank order.

III. Methodology

A. Proposed Method

1) Current model and its limitations: The current model suggested by Okfalisa et al. Has been a reference for marketplace decision support since using the MOORA method as an alternative to rank online shops to be the best by using 5 criteria: Rating, Price, Sold, Discount, and Response Chat. However, the benchmark has three distinct limitations in relation to the present study.

First, it has a perspective limitation. The benchmark was developed from the Customer's Perspective to help buyers select an online shop, whereas the present study addresses Seller Product Selection from the Seller's Perspective. These decision problems involve different users and different decision objectives.

Second, it has an empirical-domain limitation. The benchmark was demonstrated using men's shirt products and 50 marketplace alternatives. Therefore, its findings cannot automatically be generalized to broader product categories or substantially larger marketplace datasets.

Third, it has a criteria-structure limitation. The five benchmark criteria do not include indicators of repeated purchasing behavior, product interest, and shop visibility. Specifically, Repurchase, Favorite, and Followers are not represented in the benchmark structure.

The proposed 8C SPS model directly addresses the perspective and criteria-structure limitations by adopting the Seller's Perspective and incorporating Repurchase, Favorite, and Followers. However, the present study remains limited to Shopee Indonesia food and beverage products. Validation in other product categories and marketplace environments is therefore still required.

2) Proposed seller product selection model: In an effort to bridge this gap, this research extends the benchmark on the SPS Model from 5 dimensions to 8 dimensions, namely: Repurchase (Repeat-purchase behavior and customer-retention), Favorite (Product interest and favorability), and Follower (Visibility of shop and social connections' effectiveness in the online environment). Consequently, the model builds the customer's perspective on SPS to the seller's perspective on SPS by considering 8 dimensions: transactional effectiveness, repeated potential purchases, appraisal customers have, the quality of promotions, interaction quality, visibility of transactions and promotions, audience attention of the market, and visibility of the shop. Compared to the SPS model with the 5 criteria of Okfalisa et al. The SPS model with 8Cs enhances its completeness in making an appropriate decision of selecting the best-suited product for sellers.

B. Research Framework and Practical Application Workflow

A framework is suggested that increases the benchmark 5C model by factors - Repurchase, Favorite, and Followers- leading to the model represented by the 8C SPS as described above. Both the Regression analysis investigate empirical effects of 7 independent variables on Sold and seller's perceived criteria weights as perceived through a survey based on Importance. Borda Weights explain seller preferences, and AHP will provide weights computed based on the selection of 4 'MCDMs'(MOORA, SMART, TOPSIS, PSI) for 150,000 product evaluations on five different configurations of these 8 factors based on performance metrics like 'MAD', 'MSE ', and 'Spearman's Rank Correlation '. A visualization of the framework is shown in Fig. 1.

In real-time deployment, sellers need to supply the values for these eight factors in relation to candidate products and run the weights derived by AHP using any of the discussed MCDM approaches to produce a list of items in rank order of their marketability potential. Based on the current experiment in the given context, MOORA achieved the strongest overall robustness in the 8C model, with the lowest MAD and MSE and the highest Spearman's Rank Correlation. In contrast, TOPSIS showed greater consistency in maintaining the same first-ranked alternative across the weight conditions. Therefore, MOORA is recommended as the primary ranking algorithm, while the leading alternatives identified by TOPSIS may be used as additional candidates for seller assessment.

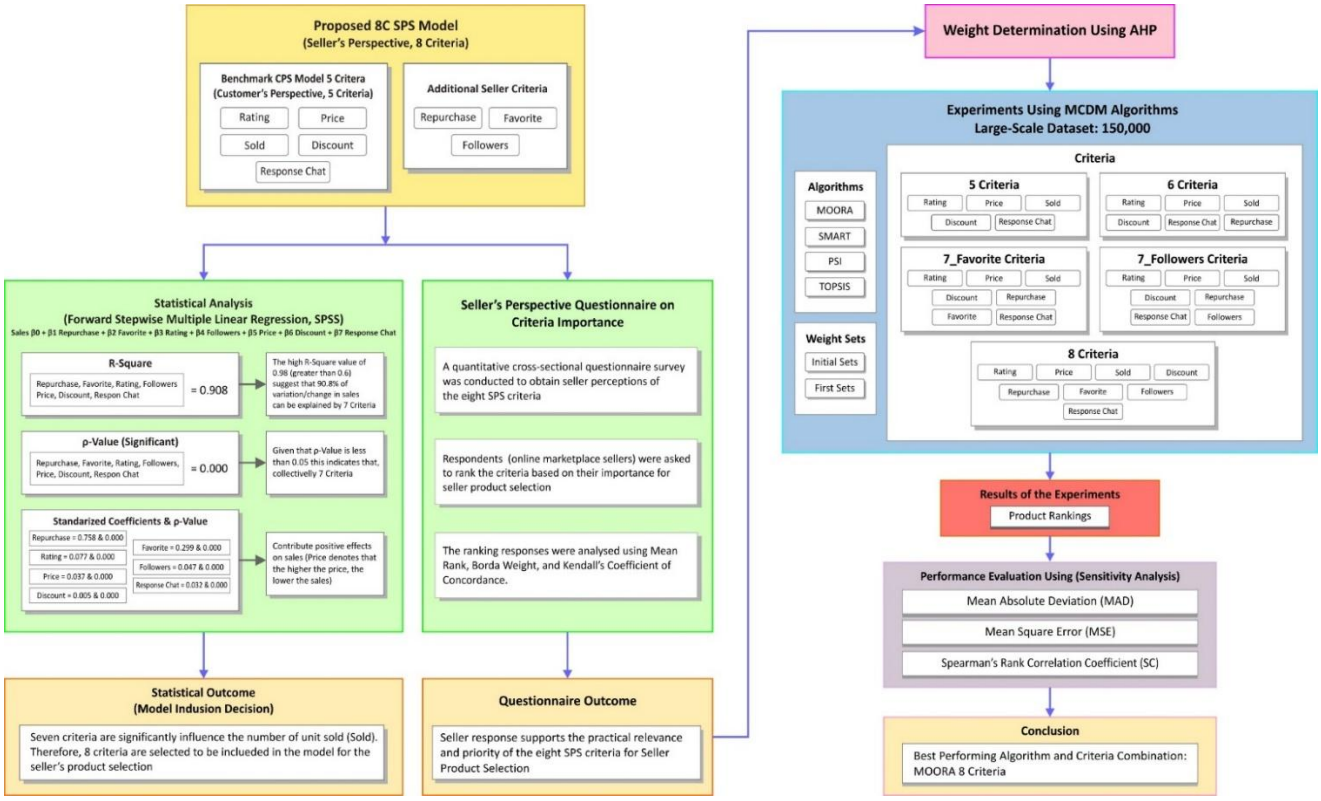

Fig. 1. Research method framework.

C. Dataset and Criteria Description

1) Data collection, preprocessing, and ethical considerations: The dataset was obtained using a Google Chrome extension to perform the crawling activity through several categories of Food and Beverage products available publicly from the Shopee Indonesia website during the research data collection stages. A total number of variables used that are publicly listed on both the product level (product name and URL) and shop level (name of the shop, Rating, Price, Sold, Discount, Response Chat, Repurchase, Favorite, Followers) were captured. The scraping metadata for the page and the order were also extracted so as to retrieve a source document used to identify origin pages and scraping order. The downloaded records were exported in the format of a raw file, and further processing for statistical analysis and MCDM experiments was conducted at this stage.

For standardization of the marketplace records for consistency, the following steps of data preprocessing were performed: Scraping Metadata columns to discard. Rows with product names missing/not available and Rows without pricing Information discarded, based on (unique based on product names), duplicates rows found, attribute Name standardized on basis of categorization, empty numerical value were replaced by zero value, (Rating, Discount, Sold, Favorite, Repurchase, Response Chat and Followers), where regular price not available discounted Price assumed final Price of the products, The text based marketplace values in their numerical presentation were removed currency symbol, thousand separator, percentage symbol, and other such characters to remove non numerical label then used as normalized to match the marketplace abbreviation like "RB", "+", then convert to numerical data types.

The issue of ethics has been handled by constraining the data extraction to information presented openly and publicly through the Shopee Indonesia product and shop pages. Data privacy has ensured that account numbers, private conversation message data, financial transaction data, and other personal information were not harvested. The product identification or name of the shop and seller was not revealed in the results, and each item was assigned an identifier code which served in the place of the product ID for the purpose of experimentation, and the dataset was not to be reused again in its original format that was identifiable.

2) Criteria description: The attributes dataset in this study is selected to be two criteria frames: Customers' Product Selection (CPS) and Sellers' Product Selection (SPS). We propose CPS as a benchmark model with five criteria: Rating, Price, Sold, Discount, Response Chat, following the literature on customer choice based on Okfalisa et al. SPS model is an extension of CPS to eight criteria by adding the other three criteria, namely Repurchase, Favorite, and Followers, to CPS, which reflect customers' loyalty, customers' interest in products that are not immediately purchased, and shop reputation, respectively, all of which are considered to increase product sales. Based on this framework, the mapping of Shopee dataset attributes to CPS and SPS criteria is presented in Table II.

TABLE II. OPERATIONAL DEFINITION OF CRITERIA IN CPS AND FAHP SPS MODELS

No	Criterion	Description	Criterion Type	Model
1	Rating	Average user rating score for a product	Benefit	CPS & SPS
2	Price	Product price listed on the product page	Cost	CPS & SPS
3	Sold	Number of units sold during the observation period	Benefit	CPS & SPS
4	Discount	Discount percentage offered for the product	Benefit	CPS & SPS
5	Response Chat	Seller responsiveness percentage to buyer chats	Benefit	CPS & SPS
6	Repurchase	Repeat-purchase indicator reflecting customer loyalty	Benefit	SPS
7	Favorite	Number of users who mark the product as a favorite/wishlist	Benefit	SPS
8	Followers	Number of shop followers as an indicator of shop reputation	Benefit	SPS

D. Analytical Statistic Method

The relevance of Rating, Price, Discount, Favorite, Repurchase, Response Chat, and Followers was examined using Forward Stepwise Multiple Linear Regression in SPSS. Sold was treated as the dependent variable, while the seven remaining criteria were entered as candidate predictors. The candidate variables were defined before the regression analysis based on the literature and the proposed SPS framework. Therefore, the regression was used as an exploratory criterion-screening procedure rather than as a forecasting model. The stepwise procedure examined the incremental statistical association of each predictor with Sold, while the standardized coefficients were used to compare their relative contributions. Model reliability was examined using Adjusted R Square, changes in R Square, tolerance, Variance Inflation Factor, the Durbin-Watson statistic, and residual diagnostics.

1) Forward stepwise multiple linear regression: The general regression model is expressed as shown in Eq. (1).

$$Y = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \cdots + \beta_n X_n + \varepsilon \quad (1)$$

where, Y is the dependent variable, $X_1, X_2, \ldots, X_n$ are the independent variables, β_0 is the constant, $\beta_1, \beta_2, \ldots, \beta_n$ are regression coefficients, and ε is the error term. The forward stepwise procedure adds predictors iteratively, starting from the strongest predictor, until no additional variable significantly improves the model.

The use of forward selection was considered appropriate for the present study because the analysis aimed to determine the order in which the predefined predictors contributed additional explanatory information. However, because the dataset contains a large number of observations, statistical significance alone was not considered sufficient evidence of practical importance. The interpretation, therefore, considered the magnitude of the standardized coefficients and the increase in R-squared produced at each step.

2) The standardized coefficients (beta): The Standardized Coefficients (Beta) were taken into consideration to show the relative contribution of each selected predictor in the regression models developed. The standardized coefficient is represented in Eq. (2).

$$\beta_j^* = b_j \left(\frac{s_{X_j}}{s_Y}\right) \quad (2)$$

where, β_j^* is the standardized coefficient, b_j is the unstandardized coefficient, s_{X_j} is the standard deviation of the predictor X_j, and s_Y is the standard deviation of the dependent variable. A higher value of an absolute Beta refers to a higher contribution towards Sales. Thus, supported empirically in the case of retaining variables that are good for the analysis of selecting a product.

E. Questionnaire Outcome

A quantitative cross-sectional questionnaire survey was used in this study to get the criteria importance from the seller's point of view. The questionnaire asked the respondent to rank the 8 SPS criteria - namely Sold, Discount, Repurchase, Rating, Favorite, Price, Response Chat, and Followers according to the rank from the most important to the least important. The questionnaire was thus utilized to provide evidence of the buyer based on the seller, the practicability and prioritization of the SPS criteria, prior to carrying out computational weighing.

The forced ranking exercise forced each participant to give a rank value to each criterion, varying from rank 1 (highest priority) to rank 8 (lowest priority). Since the obtained data were ordinal in nature, the analysis of such data concerned rank aggregation and the level of agreement between participants. The data gathered through the use of the questionnaire were analyzed through descriptive analysis, with summary statistics of the data presented through Mean Rank, Borda Weight, and Kendall's coefficient of concordance. Mean Ranks were employed in order to provide an overall ranking of priorities of each item, with the lowest mean rank being assigned to the highest priorities. The ranking data was then converted into numerical weight via the use of the Borda Weight. The Borda score is calculated as shown in Eq. (3)

$$b_{ij} = n - r_{ij} + 1 \quad (3)$$

where, b_{ij} is the Borda score of the criterion j assigned by the respondent i, r_{ij} is the rank given by the respondent i to criterion j, and n is the number of criteria. The normalized Borda Weight for each criterion is calculated as shown in Eq. (4).

$$w_j = \frac{\sum_{i=1}^{m} b_{ij}}{\sum_{j=1}^{n}\sum_{i=1}^{m} b_{ij}} \quad (4)$$

where, w_j is the normalized Borda Weight of the criterion j, m is the number of respondents, and n is the number of criteria.

Kendall's coefficient of concordance was used to examine the level of agreement among respondents because the questionnaire involved ranking the same set of criteria. Kendall's W is calculated as follows: Eq. (5)

$$W = \frac{12S}{m^2(n^3-n)} \quad (5)$$

where, S is the sum of squared deviations of the total ranks for each criterion from the mean total rank, m is the number of respondents, and n is the number of ranked criteria. A higher value of W indicates stronger agreement among respondents.

Methodologically, the questionnaire complements the statistical validation and experimental evaluation of the proposed SPS model. This result not only adds evidence towards AHP weighting but would also make it possible to show that the chosen eight criteria actually matter to a seller's product range. The response to the seller questionnaire also indicated that there is a practical application for and, in fact, a practical priority among the eight SPS criteria for sellers' product range.

F. Research Setup

1) Weight setup: The weight configurations for two weight options, Initial Weights and First Weight, were generated for ranking stability testing. First Weight adjusted the original weight structure to evaluate the susceptibility of each decision-making algorithm to any variations in criterion weight configurations. A graphical representation is generated showing the criterion weight distribution of various criterion combinations examined within the scope of this project. The weight of each criterion combination for this exercise is achieved through the Analytical Hierarchy Process (AHP) by building criteria from a given problem, creating a pairwise comparison matrix, calculating criterion priority vectors, and then normalizing weights to equal 1 for each combination.

- 8 criteria: Pairwise comparison assessments were collected through a questionnaire for all criteria, and their weights were then calculated using AHP.
- 6 criteria: Two criteria were removed (Favorite/Wishlist and Followers), and the weights for the remaining six criteria were then recalculated using AHP and normalized.
- 7 criteria (Favorite): The Followers criterion was removed, leaving 7 criteria (including Favorite/Wishlist); the weights were then recalculated using AHP and normalized.
- 7 criteria (Followers): The Favorite/Wishlist criterion was removed, leaving 7 criteria (including Followers); the weights were then recalculated using AHP and normalized.
- 5 criteria (benchmark): weights are determined based on the reference weights (benchmarks) for five basic criteria, then used as a comparison in the evaluation of the method's performance.

The weight settings in this experiment were set under two conditions to test the stability of the ranking results when decision-making preferences change. The weight settings are as follows:

- Initial weight (Baseline): obtained from the AHP calculation, where pairwise comparison assessments were collected through a questionnaire for all criteria, then calculated into priority weights and normalized.
- First Weight: obtained from adding 1 point to the pairwise comparison by pairs; we will be able to obtain an alternative weight arrangement pairwise by pairwise to study rank modifications in this alternative weighing.

2) AHP: The Analytic Hierarchy Process (AHP) was applied to derive the relative weights of the SPS criteria through pairwise comparisons. The criteria were compared using Saaty's 1–9 scale, where 1 represents equal importance, and 9 represents absolute importance. The pairwise comparison matrix was normalized, and the priority vector was calculated to obtain the criteria weights. This procedure was conducted separately for the 5C, 6C, 7C Favorite, 7C Followers, and 8C configurations because each configuration contained a different set of criteria. The consistency of the pairwise judgments was evaluated using the Consistency Index and Consistency Ratio, as expressed in Eq. (6) and (7).

$$CI = \frac{\lambda max - n}{RI*(n-1)} \quad (6)$$

$$CR = \frac{CI}{RI} \quad (7)$$

If the CR value is $\leqslant$ (less than or equal to) 0.1, then the criteria values are consistent. However, if not, a re-evaluation is necessary to ensure the consistency of the criteria values.

3) Comparative MCDM algorithms: Four established MCDM algorithms, namely MOORA, SMART, PSI, and TOPSIS, were applied to rank the product alternatives. These algorithms were selected because they represent different ranking mechanisms and enable the robustness of the proposed criteria configurations to be compared under the same dataset and weight conditions. Price was treated as a cost criterion, while Rating, Sold, Discount, Response Chat, Repurchase, Favorite, and Followers were treated as benefit criteria.

a) MOORA: The Multi-Objective Optimization based on Ratio Analysis (MOORA) ranks alternatives by normalizing the decision matrix and combining the weighted benefit and cost criteria. The final assessment value is obtained by subtracting the weighted cost values from the weighted benefit values. An alternative with a higher final value receives a higher ranking. (8).

$$y_i = \sum_{j=1}^{g} w_j \, x_{ij}^* - \sum_{j=g+1}^{n} w_j \, x_{ij}^* \quad (8)$$

where, w_j denotes the weight of the criterion j. A higher y_i indicates a better alternative.

b) SMART: The Simple Multi-Attribute Rating Technique (SMART) determines the overall performance of each alternative by aggregating its weighted utility values. Each criterion value is transformed into a utility value according to its benefit or cost orientation, and the alternatives are ranked according to their total utility scores. The overall score of each alternative is then obtained by Eq. (9).

$$S_i = \sum_{j=1}^{n} w_j \, 'u_{ij} \quad (9)$$

where, u_{ij} is the utility value of the alternative i on criterion j. Alternatives with higher S_i values are ranked higher.

c) PSI: The Preference Selection Index (PSI) evaluates alternatives using normalized criterion values and preference indices derived from the variation of each criterion. Unlike the other evaluated methods, PSI can determine criterion preferences from the decision matrix. The alternative with the highest total preference score is assigned the highest rank.

The final PSI score is calculated as shown in Eq. (10).

$$PSI_i = \sum_{j=1}^{n} N_{ij}\, \Omega_j \tag{10}$$

where, Ω_j denotes the preference value of the criterion j. A higher PSI_i indicates a more preferred alternative.

d) TOPSIS: The Technique for Order Preference by Similarity to Ideal Solution (TOPSIS) ranks alternatives according to their relative closeness to the positive ideal solution and their distance from the negative ideal solution. An alternative is considered preferable when it is closer to the positive ideal solution and farther from the negative ideal solution. The relative closeness of each alternative is then determined by Eq. (11).

$$C_i = \frac{D_i^-}{D_i^+ + D_i^-} \tag{11}$$

where, D_i^+ and D_i^- are the distances from the positive and negative ideal solutions, respectively. A higher C_i indicates a better alternative.

4) Measurement: In this study, the Initial Weight ranking was treated as the baseline, while the First Weight ranking represented the modified preference condition. A lower MAD value indicates that alternatives move fewer ranking positions on average. A lower MSE value indicates that large or extreme rank changes are less pronounced. A Spearman coefficient closer to 1 indicates that the overall ordering of the alternatives remains consistent after the weight modification. Accordingly, an algorithm is considered more robust when it simultaneously produces lower MAD and MSE and higher Spearman's Rank Correlation.

a) Mean Absolute Deviation (MAD): The following is the equation for MAD shown in Eq. (12).

$$MAD = \frac{1}{n}\sum_{i=1}^{n} |xij - \text{yj}| \tag{12}$$

b) Mean Squared Error (MSE): The following is the equation for MSE shown in Eq. (13).

$$MSE = \frac{1}{n}\sum_{i=1}^{n} (xij - yj)^2 \tag{13}$$

c) Spearman's Correlation (SC): The following is the equation for SC shown in Eq. (14).

$$SC = r_s = 1 - \frac{6\sum d_i^2}{n(n^2-1)} \tag{14}$$

IV. Results and Discussion

A. Results of Questionnaire

The questionnaire was administered to 30 online marketplace sellers from 22 September 2025 to 2 October 2025. Table III presents the criterion priorities obtained from the seller questionnaire.

TABLE III. Result of Criteria Priority

Criteria	Mean Rank	Borda Weight	Priority
Sold	2.40	0.183	1
Repurchase	3.63	0.149	2
Rating	4.00	0.139	3
Response Chat	4.30	0.131	4
Price	4.57	0.123	5
Favorite	5.53	0.096	6
Discount	5.57	0.095	7
Followers	6.00	0.083	8

As can be seen from Table III, Sold had shown a value of the most important factor as low as 2.40 in rank mean; also, it possessed a value of the highest in Bordas Weight for 0.183. Hence, Sold shows more importance to sellers to prioritize the products for sales as they perform well.

Overall, the ranking result suggests that the responders perceived Sold, Repurchase, and Rating to be the top three criteria that have the highest priority. As for the criteria Favourite, Discount, and Followers, the priorities received are not high; however, it still exists as the other supportive SPS criteria for the Seller's Perspective. As the Kendall's Coefficient of Concordance W was 0.236 and there are 30 responders, we shall view the questionnaire results as the potential evidence from the sellers' view on the practical relevance and priority of these 8 SPS criteria. The potential priority that responders perceived does not weaken the priority obtained via regression and computationally assigned with the weighting factors with AHP and ranked by the result of the algorithms using MCDM.

B. Statistical Test

1) Stepwise multiple linear regression: The following are the statistical results of the test using Stepwise Multiple Linear Regression, which are shown in Table IV.

The change in explanatory power across the steps is evident in Table IV. Entering Repurchase alone explained 0.811 R-square. The addition of Favorite over and above Repurchase helped the R-square improve by 0.084 with a total explanation of 0.895 (0.811 + 0.084).

The addition of Rating yielded yet another increase in explained variance to 0.094, while Followers increased the R-square by an additional 0.003.

Each of Price, Response Chat, and Discount increased R-square by 0.001, respectively. Based on the changes across steps, Repurchases and Favorite had greater explanatory influence among the set. Price, Response Chat, and Discount added the lowest amount to the explanation of buying.

The last iteration (Model 7), as shown in Table V, shows that the R-square value is 0.908. It suggests that 90.8 percent of the variability in Sales is explained by Repurchase, Favorite, Rating, Follower, Price, Response Chat, and Discount as a group.

Meanwhile, the remaining 9.2 percent is explained by other factors. In other words, these seven variables collectively correlate strongly with Sales.

TABLE IV. MODEL SUMMARY

Model	R	R Square	Adjusted R-Square	Std. Error of the Estimate	Durbin-Watson
1	0.900[a]	0.811	0.811	28.035

TABLE V. ANOVA[A]

Model		Sum of Squares	df	Mean Square	F	Sig.
7	Regression	555699114.195	7	79385587.742	206961.417	.000[h]
	Residual	56589845.238	147532	383.577		
	Total	612288959.433	147539			
a. Dependent Variable: Sales						
h. Predictors: (Constant), Repurchase, Favorite, Rating, Follower, Price, Response Chat, Discount						

Furthermore, despite a strong correlation between independent and dependent variables, it is important to examine whether this correlation is statistically significant. Table VI reveals that the F test results in a p-value (Sig.) of 0.000, much less than 5 percent or 0.05 of the significance level. It indicates that the correlation between all seven independent variables of Repurchase, Favorite, Rating, Follower, Price, Response Chat, and Discount as a group with Sales is statistically significant.

2) The standardized coefficients (beta): After assessing the correlation between dependent and independent variables and their significance in collective terms, Table VI explains the correlation or the influence of each independent variable on the dependent variables separately.

Table VI presents the individual statistical association of each independent variable with Sold. All predictors were statistically significant at p <0.001. Repurchase had the largest standardized coefficient (β=0.758), followed by Favorite (β=0.299), Rating (β=0.077), Followers (β=0.047), Price (β=−0.037), Response Chat (β=0.032), and Discount (β=0.016). Repurchase and Favorite therefore showed the strongest statistical associations with Sold. Price had a negative coefficient, indicating that higher product prices were associated with lower observed sales, while the other predictors showed positive associations. Because the data are observational, these coefficients represent statistical associations rather than causal effects.

TABLE VI. COEFFICIENTS[A.]

Model		Unstandardized Coefficients		Standardized Coefficients	t	Sig.	Collinearity Statistics	
		B	Std. Error	Beta			Tolerance	VIF
7	(Constant)	-2.190	0.159		-13.763	.000		
	Repurchase	7.025	0.008	0.758	867.811	.000	0.820	1.219
	Favorite	0.904	0.003	0.299	336.990	.000	0.794	1.259
	Rating	2.359	0.025	0.077	94.660	.000	0.940	1.063
	Follower	.000	0.000	0.047	57.889	.000	0.935	1.070
	Price	-3.239E-5	0.000	-0.037	-45.961	.000	0.992	1.008

	Discount	0.106	0.005	0.016	19.508	.000	0.973	1.028
a. Dependent Variable: Sales								

3) Regression diagnostics and model reliability: Final regression model fitting proceeded, and the diagnostics for the final model were computed. The model resulted in an R^2 value of 0.908, while the Adj. R^2 value is 0.908. The explanatory power does not appear to be seriously distorted by the addition of extra predictors. Multicollinearity among predictors did not seem to be serious; all tolerance values were between 0.794 and 0.992, and VIF values did not exceed 1.259. The Durbin-Watson value is 1.863, which also suggests no serious serial autocorrelation among residuals. The normality of residuals has also been explored through the Normal P-P plot (Fig. 2) and the Histogram of residuals (Fig. 3).

With reference to Fig. 2, the cumulative probabilities have systematic deviations from the reference diagonal line at probabilities from the lower and higher ends. This means that the distribution of residuals does not fall on a normal distribution.

Fig. 3 displays standard normal residuals that are centered at zero but follow an uneven, positively skewed distribution. This again accords with the results of the P-P plots indicating less-than-ideal normal residuals; however, considering the massive nature of the dataset (150,000 records), this suggests that the regression should be used solely for investigation of statistical associations between the sampled data points only, rather than

to establish causalities or as a tool to validate external predictions of future Sold values.

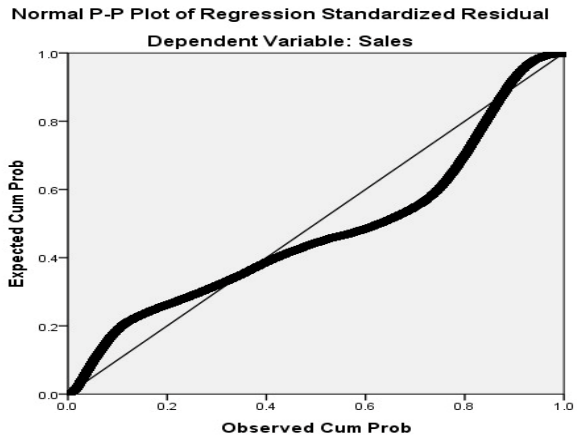

Fig. 2. Normal P-P plot of regression standardized residuals.

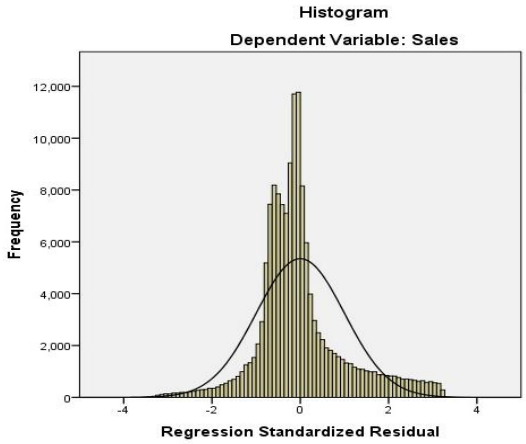

Fig. 3. Histogram of regression standardized residuals. (Note: "Sales" in the SPSS output represents the Sold variable used in this study.)

4) Relationship between questionnaire and regression results: Questionnaire and regression results perform different yet complementary functions. The questionnaire reports that all eight factors of SPS (including the Sold factor) are considered important to sellers. Hence, the questionnaires tell which factors a seller considers to be most important when he selects products to sell. The regression does the opposite: taking Sold as the dependent variable and analyzing the statistical relationship between the other seven factors and the Sold performance observed in the marketplace.

The results from the questionnaires and the regression should not therefore be in the same order of priority. Sold was found to be in the first order because it was considered most important, as it represents the most direct feedback on product marketability to the sellers. Repurchase was found to be in the first order in terms of standardized regression coefficient due to having the strongest statistical correlation with the Sold observed in the marketplace data. Questionnaires, therefore, measure subjective importance; regression measures the importance observed in market data.

C. Weight Determination Using AHP

Based upon the AHP determining result, two different weight combinations were generated for each criterion combination scenario. Initial weight indicated the base preferences scenario, and First weight represented a variation in a preference scenario used for ranking sensibility analysis. Table VII lists weight configurations for five-, six-, seven-, and eight-criteria combinations.

TABLE VII. INITIAL AND FIRST WEIGHT RESULTS

Criterion	5C I/F	6C I/F	7C Fav I/F	7C Foll I/F	8C I/F
Rating	0.417/ 0.482	0.160/ 0.150	0.160/ 0.153	0.160/ 0.153	0.159/ 0.155
Price	0.263/ 0.235	0.101/ 0.088	0.104/ 0.094	0.104 /0.094	0.107/ 0.099
Sold	0.160/ 0.149	0.381/ 0.424	0.352 /0.388	0.352/ 0.389	0.328/ 0.360
Discount	0.097/ 0.082	0.042/ 0.031	0.031/ 0.023	0.045/ 0.036	0.033/ 0.026
Response Chat	0.062/ 0.053	0.064/ 0.052	0.068/ 0.059	0.068/ 0.058	0.071/ 0.063
Repurchase	–	0.252/ 0.255	0.241/ 0.246	0.241/ 0.247	0.232/ 0.238
Favorite	–	–	0.045/ 0.036	–	0.048/ 0.041
Followers	–	–	–	0.031/ 0.023	0.023/ 0.018
CR	0.02/ 0.07	0.02/0.08	0.02/0.08	0.03/0.08	0.03/0.09

Note: I/F denotes Initial Weight/First Weight; 5C = five criteria; 6C = six criteria; 7C Fav = seven criteria including Favorite; 7C Foll = seven criteria including Followers; and CR = Consistency Ratio.

Table VI shows that CR values were within the required level of consistency, less than 0.10 for all of the weight sets. Table VII shows that all the calculated CR values were less than 0.10. Therefore, the weight sets show acceptable consistency. Those sets were applied for MOORA, SMART, PSI, and TOPSIS methods in order to view the product ranking in the change conditions.

D. Ranking Result for all Criteria

The result of rankings for all criteria shows the final scores of alternatives as produced by MOORA, SMART, PSI, and TOPSIS along with their orderings in ranking. The tables below show all of the combinations for evaluating the alternatives among different criteria to show the results of ordering the product according to different MCDM approaches.

For the five-criteria model in Table VIII, the proposed alternative number, A107137, obtained the first position by any algorithm for both criteria types, Initial Weight and First Weight. By using the evaluation from only benchmark criteria, the proposed alternative A107137 obtained the highest marks among the five benchmark alternative selections from any one of these criteria (MOORA, SMART, PSI, and TOPSIS. The consistent ranking by A107137 with any four criteria suggested that the proposed alternative possesses a relatively stable advantage in the selection from the five original criteria. For example, the benchmarks: A82978, A143588, A108358, A11740, A99974, and A133019 still seem to have better selection for a structure of benchmark criterion.

Considering Table IX, where the combination of criteria grows to six, A107137 still holds more than half of the ranking results. Its rank position is highest for all methods MOORA, SMART, and PSI under Initial Weight and First Weight except for TOPSIS, which lists A45290 first for Initial Weight and A107137 first for First Weight. This suggests that with the consideration of Repurchase, a shift happened in the ranking pattern of a couple of methods (in this case, TOPSIS), where A45290 achieved the first position under this methodology, and this implies it's favored due to the seller view-based ranking methods considered.

Similar ranking outcome patterns occur in seven-criteria models with Favorite Table X. A107137 still has rank 1 from MOORA, SMART, and PSI under both weighted setting while TOPSIS always suggests A45290 as the first alternative. Thus, there is an implication of the favorite effect in the ranking result, especially with the TOPSIS technique, in which each alternative is assessed according to its distances to ideal and anti-ideal solutions. This can be seen as a positive assessment of A45290 relative position compared to other alternatives.

10	A45286	0.06875	A45286	0.07120	A149486	4.93225	A149486	4.80223	A149486	0.31184	A149486	0.28324	A45286	0.27789	A45286	0.27108

With regard to Table XI, similar behavior was found in the seven-criteria model with Followers. A107137 is again the best alternative by MOORA, SMART, PSI, and again TOPSIS indicates A45290 as the first alternative by applying both weight configurations. This shows that Followers is one of the factors contributing to the A107137 and A45290 rank exchange. In conclusion, the seller-perspective awareness and involvement-oriented attributes do have some impact on moving A45290 to become a competitor, although A107137 continues to be very stable with almost all alternatives.

In the eight-criteria model, referring to Table XII, A45290 has gained first place again using the MOORA method with Initial Weight and by the TOPSIS method with two weight settings, but A107137 with MOORA First Weight, SMART, and PSI, so it becomes that a total SPS criterion changes the ranking results obtained. Another aspect of the results is that an increased consideration of sellers (which comprises those five items) not only follows the previous result but produces a wider view on the possible purchase outcomes from the different alternatives of the product by taking into account the achieved

sales performance of the sellers as well as their customers' feedback in addition to repurchase rates, store visitors, favorites and interested individuals.

However, when introducing the SPS model from the seller's point of view, A45290 becomes significant at some combinations and even at the top when the number of criteria is eight, and it uses TOPSIS. Thus, the eight-criterion expanded SPS has shown a broader alternative arrangement than the six-criterion-based one by the combination of customer aspects and seller aspects in the online market environment. Although the rankings of the primary alternative are different from the four techniques, the rankings cannot be judged as wrong, as they use different normalization, aggregation, and distance techniques. For example, with the eight-criterion-based configuration, MOORA ranked A45290 first at the Initial Weight, and A107137 first at the First Weight; however, A45290 remained at the top under both Initial Weight and First Weight by use of TOPSIS. Therefore, algorithm selection was not based solely on the identity of the first-ranked alternative.

E. Measurement

Evaluation of the results obtained from MOORA, SMART, PSI, and TOPSIS regarding the sensitivity of the results due to criterion variations by applying measured values for the ranking outcomes. Three measurement indicators were applied, namely Mean Absolute Deviation (MAD), Mean Squared Error (MSE), and Spearman's Rank Correlation Coefficient (SC).

TABLE XIII. RESULT OF MEAN ABSOLUTE DEVIATION

Combined Criteria	Algorithm			
	MOORA	SMART	PSI	TOPSIS
5 Criteria	1,894	2,189	1,730	4,694
6 Criteria	1,674	1,662	1,463	1,783
7_Favorite Criteria	1,169	1,680	1,861	1,308
7_Followers Criteria	1,452	1,284	1,529	1,409
8 Criteria	1,093	1,474	1,616	1,221

The MAD results are further illustrated graphically in Fig. 4.

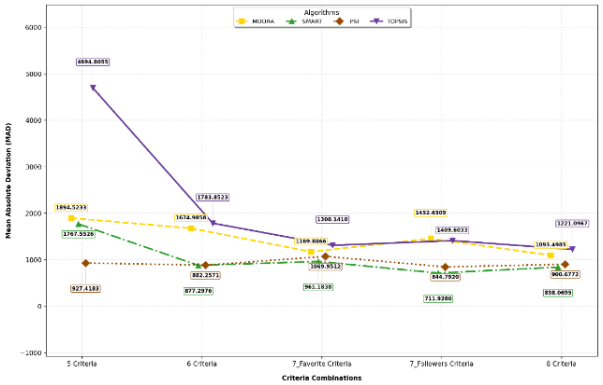

Fig. 4. Graph result of mean absolute deviation.

As presented in Table XIII and illustrated in the MAD graph in Fig. 4, the five-criteria model produces higher ranking deviation for several algorithms, especially TOPSIS, with a MAD value of 4,694. This indicates that the benchmark five-criteria model is more sensitive to changes in weight settings. When the criteria are expanded, the MAD values generally decrease.

The lowest MAD value is achieved by MOORA in the eight-criteria model, with a value of 1,093, followed by TOPSIS in the eight-criteria model with 1,221. This shows that the expanded seller-perspective criteria improve ranking stability, particularly for MOORA and TOPSIS.

TABLE XIV. RESULT OF MEAN SQUARED ERROR

Combined Criteria	Algorithms			
	MOORA	SMART	PSI	TOPSIS
5 Criteria	16,268,119	19,935,786	45,773,915	43,139,503
6 Criteria	12,544,343	9,776,007	24,513,668	12,965,720
7_Favorite Criteria	5,698,679	12,558,361	36,354,826	6,334,756
7_Followers Criteria	9,143,235	8,871,743	23,495,285	8,752,934
8 Criteria	4,969,891	9,287,339	29,247,850	5,023,281

The MSE results are further illustrated graphically in Fig. 5.

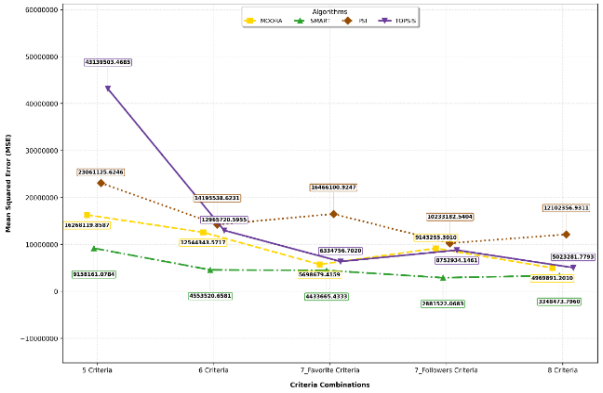

Fig. 5. Graph result of mean square error.

As presented in Table XIV and illustrated in the MSE graph in Fig. 5, the highest MSE values are found in the five-criteria model, especially PSI with 45,773,915 and TOPSIS with 43,139,503. In contrast, the eight-criteria model produces the lowest MSE for MOORA, with 4,969,891, and TOPSIS, with 5,023,281. This indicates that the eight-criteria SPS model reduces ranking error more effectively than the benchmark five-criteria model.

TABLE XV. RESULT OF SPEARMAN'S RANK CORRELATION COEFFICIENT

Combined Criteria	Algorithms			
	MOORA	SMART	PSI	TOPSIS
5 Criteria	0.99566	0.99468	0.98779	0.98850
6 Criteria	0.99666	0.99739	0.99346	0.99654
7_Favorite Criteria	0.99848	0.99665	0.99031	0.99831
7_Followers Criteria	0.99756	0.99763	0.99374	0.99767
8 Criteria	0.99868	0.99752	0.99220	0.99866

The SC results are further illustrated graphically in Fig. 6.

As presented in Table XV and the SC graph in Fig. 6, all algorithms produce very high rank correlation values, with SC values above 0.987. This means that the ranking orders remain highly consistent across different criteria combinations and weight settings. However, the eight-criterion model gives the strongest SC result for MOORA, with 0.99868, and TOPSIS, with 0.99866. These values indicate that both algorithms produce highly stable and consistent ranking patterns when the complete SPS criteria are applied.

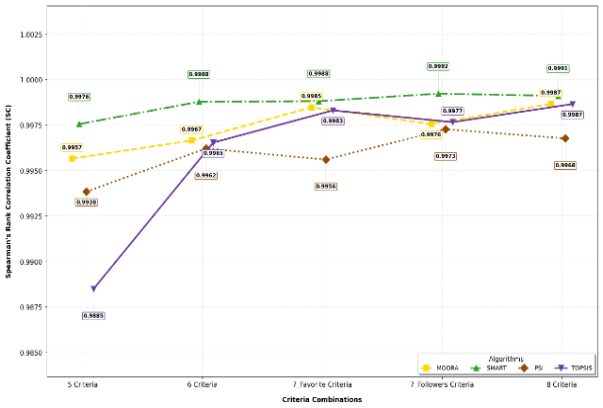

Fig. 6. Graph result of Spearman's rank correlation coefficient.

MOORA performed the best for combined robustness under 8C, achieving the lowest MAD (1,093), the lowest MSE (4,969,891), and the highest Spearman's Rank Correlation (0.99868). The result of TOPSIS was similar; however, MAD and MSE were higher at 1,221 and 5,023,281, respectively, and the Spearman coefficient was 0.99866. Hence, we chose MOORA as the optimal algorithm for the dataset under analysis as it afforded the best overall combined stability and robustness to a change in the weight values.

Each of the three can be interpreted practically. MAD shows the average degree to which ranks were shifted, MSE shows drastic ranking shifts, and Spearman's Rank Correlation assesses whether the overall relative ordering remains. Consequently, a small disparity between the Spearman correlation measures could still be important when MAD and MSE were reduced.

F. Criterion-Removal Analysis of Followers

A criterion-removal analysis was conducted to examine the added contribution of Followers. The 7_Favorite Criteria configuration contains Rating, Price, Sold, Discount, Response Chat, Repurchase, and Favorite, but excludes Followers. The 8 Criteria configuration includes the same criteria with the addition of Followers. Both configurations were evaluated using the same 150,000 product alternatives, four MCDM algorithms, two weight conditions, and three robustness measures.

The inclusion of Followers improved the robustness results across all four algorithms. Compared with the 7_Favorite Criteria configuration, the 8 Criteria configuration reduced MAD by 6.50% for MOORA, 12.26% for SMART, 13.16% for PSI, and 6.65% for TOPSIS. MSE was reduced by 12.79%, 26.05%, 19.55%, and 20.70%, respectively. Spearman's Rank Correlation also went up for all four algorithms.

These findings indicate that Followers provides complementary information related to shop visibility and audience reach. Its effect is more of a small addition rather than

a major one because its standardized regression coefficient is smaller compared to that of Repurchase and Favorite. Nevertheless, when combined with the other seller-related criteria, Followers contributes to more stable and consistent product rankings.

G. Direct Comparison Between the 5C Benchmark and the 8C SPS Model

To provide a controlled comparison, the 5C benchmark and the proposed 8C SPS model were evaluated using the same 150,000 product alternatives, the same MOORA, SMART, PSI, and TOPSIS algorithms, the same Initial and First Weight conditions, and the same MAD, MSE, and Spearman evaluation procedures.

The 8C SPS model produced lower MAD and MSE and higher Spearman's Rank Correlation than the 5C benchmark for all four algorithms. For MOORA, MAD decreased by 42.29%, and MSE decreased by 69.45%, while Spearman's Rank Correlation increased from 0.99566 to 0.99868. For SMART, MAD decreased by 32.66%, and MSE decreased by 53.41%, while Spearman's Rank Correlation increased from 0.99468 to 0.99752. For PSI, MAD decreased by 6.59%, and MSE decreased by 36.10%, while Spearman's Rank Correlation increased from 0.98779 to 0.99220. For TOPSIS, MAD decreased by 73.99%, and MSE decreased by 88.36%, while Spearman's Rank Correlation increased from 0.98850 to 0.99866.

These results demonstrate that the improved robustness of the 8C model was obtained under the same experimental and evaluation procedures as the benchmark. Therefore, the improvement cannot be attributed to differences in the number of alternatives, algorithms, or evaluation measures.

V. Conclusion

This study proposed an 8C Seller Product Selection model by extending the five-criteria Customer's Perspective benchmark with Repurchase, Favorite, and Followers. Regression and questionnaire analyses provided complementary support for the proposed criteria, with regression examining their empirical associations with Sold and the questionnaire capturing sellers' perceived importance. Using the same alternatives, algorithms, weight settings, and evaluation procedures, the 8C model produced lower MAD and MSE and higher Spearman's Rank Correlation than the 5C benchmark. The addition of the Followers made continuous smaller improvements in most of the above algorithms. Of all the algorithms tested with the 8C model, MOORA gave the highest level of robustness, i.e MAD = 1,093, MSE = 4,969,891, SC= 0.99868.

However, the findings must be interpreted within the empirical context of Shopee Indonesia food and beverage items and in the context of the time frame from which the data comes. Marketplace aspects, customer characteristics, seller attributes, product demand trends, and the availability or specifications of the criteria may vary from one platform to another country, between product categories, or from one time period to another. More so, as regression results represent observed statistical correlation of data, they are not indicative of cause-and-effect or externally validated sales prediction and future. Hence, even though the 8C SPS could conceptually be transferable, the criteria definitions, the AHP weights, and the ranking performance need to be reinvented before their implementation to another dataset. Further studies need to assess the models by using data sets from different points in time, from other marketplaces, and across different item categories, and by using a wider seller sample.

Hierarchical Workforce Dynamics and Risk-Aware Gated Deep Learning Framework for Employee Attrition Prediction

Chen Yang
Shinhan University, International Business Administration, Uijeongbu-si, Gyeonggi-do, 11644, South Korea

***Abstract*—Human resource management is a key factor in organizational success. Understanding and predicting employee attrition is important for improving workforce planning and decision-making. In this study, we propose a Hierarchical Workforce Dynamics – Temporal Risk-Aware Gated model named HWD-TRAG deep learning framework for accurate and transparent attrition prediction. The proposed model integrates hierarchical learning, risk-aware adaptive gating, and adaptive feature relevance scaling to capture complex workforce patterns. It learns important employee factors such as workload, job satisfaction, income, promotion delay, and work-life balance in a structured way. The model also considers how employee behavior changes over time, making it more realistic for real-world scenarios. To ensure transparency, SHAP and attention-based fusion are used to explain model predictions clearly. Experimental results show that the proposed model achieves a high accuracy of 97.1%, outperforming all baseline methods. For explainability, the model achieves a faithfulness score of 0.95, explanation consistency of 0.96, and feature stability of 0.94, while maintaining low sparsity of 0.22. In terms of robustness, it achieves strong performance with noise robustness of 0.95, data shift robustness of 0.94, and feature perturbation stability of 0.96, which confirms the proposed model's performance.**

Keywords*—Employee attrition prediction; human resource analytics; deep learning; explainable AI; workforce analysis; risk prediction; attention mechanism; ensemble learning; classification; predictive analytics

I. Introduction

Human resource management plays a critical role in the success and sustainability of modern organizations. One of the most important challenges in this area is employee attrition, which refers to employees leaving an organization voluntarily or involuntarily [1]. Recent studies show that replacing an employee can cost between 30% and 150% of their annual salary, depending on the role and experience level [2]. High attrition also leads to reduced productivity, increased hiring costs, and loss of organizational knowledge. According to global HR reports, annual attrition rates typically range between 10% and 25%, while in sectors like IT, BPO, and services, it can exceed 30% [3]. These trends highlight the urgent need for accurate and early prediction of employee attrition. Therefore, organizations are increasingly adopting data-driven approaches to better understand workforce behavior and improve retention strategies [4].

Employee attrition prediction has been a popular application of machine learning and deep learning over the years. They can be used to uncover trends and patterns in the workforce and to make informed decisions about hiring and promotion [5]. They can be used to gain insights into the workforce's structure and behavior, and to make better decisions about hiring and promotion. Decision Trees, random forest, gradient boosting, and deep neural networks have yielded success in classification problems [6]. Recently, state-of-the-art architectures, such as attention-based networks, Transformer models, etc., have enhanced feature interaction learning and representation [7]. Due to these developments, a large number of studies in the literature are concerned primarily with prediction accuracy and do not consider the interpretability of the model [8]. In actual human resource systems, as much as the prediction is the reason for the model's prediction [9]. As employees leave, the effect of their departure on the organization's outcomes becomes increasingly apparent, as indicated in Fig. 1, and need for an AI-based prediction system that can aid in proactive workforce management.

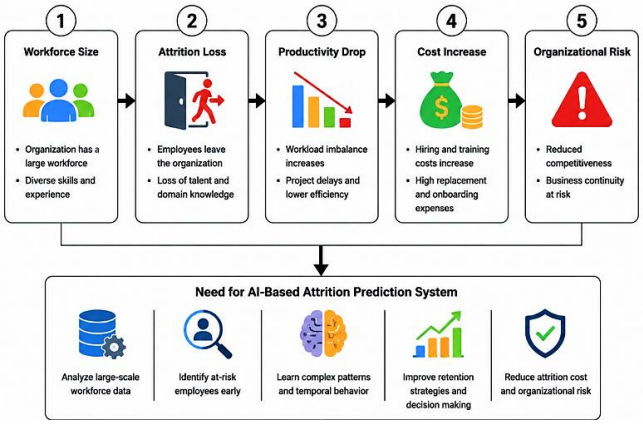

Fig. 1. Impact of employee attrition on organizational performance and the need for an AI-based prediction system.

There are still a number of problems with existing attrition prediction systems. One, workers' conduct is ever-changing through time because of workload, job satisfaction, promotion prospects, and compensation changes [10]. These aspects of the workforce are not well represented in any of the existing models. Secondly, feature interactions in HR data are highly complex and nonlinear [11], making it challenging for traditional linear models such as Hidden Markov Models (HMMs) to capture meaningful relationships among workforce attributes [12]. Third, most deep learning models are regarded as black-box models, which make the models difficult to trust

and used in real decision-making situations [13]. Finally, problems of robustness and generalization from one organizational context to another further decrease model reliability [14].

To address these limitations, this study proposes an explainable and robust deep learning framework named HWD-TRAG. The proposed model integrates hierarchical workforce dynamics modeling, risk-aware adaptive gating, and adaptive feature relevance scaling to capture both latent career states and contextual employee behavior. The model also shows stable behavior under noise, feature variation, and distribution shifts. The following are the research contributions:

- This study proposes a novel explainable deep learning framework (HWD-TRAG) for employee attrition prediction by integrating hierarchical workforce dynamics and risk-aware learning mechanisms.
- We propose a hierarchical latent modeling approach (HL) to capture employee career progression patterns across early, mid, and late stages for improved prediction accuracy.
- This study introduces a risk-aware adaptive gating network (RA-GN) that dynamically filters and controls feature influence based on workforce stress and engagement signals.
- We propose an adaptive feature relevance scaling (AFRS) mechanism to assign stability-aware importance weights to workforce features for robust representation learning.
- Empirical results show that the proposed model achieves state-of-the-art performance with 97.1% accuracy along with strong explainability and robustness scores.

The organization of the study is as follows: Section II discusses related work. Section III presents the proposed methodology and describes the experimental setup. Section IV presents results and discussion, and Section V concludes the study with future directions.

II. Related Work

Initial studies into the prediction of employee attrition were mostly concerned with determining if standard machine learning techniques are viable for modelling employee attrition behavior, and some found that the general viability was important. Jain et al. viewed the problem of attrition as a supervised classification problem, and showed they could achieve competitive results using random forest. They made a major contribution to the idea of relating predictive performance to salient HR constructs [15]. Fallucchi et al. continued along these lines by concentrating on the IBM HR dataset and developing decision support systems. They compared the different models and found that the Gaussian Naïve Bayes model had the highest recall (0.54) with a low false negative (4.5%) rate and stated that in HR analytics it is more important to identify potential leavers than to maximize the overall accuracy [16]. To extend this, El-Rayes et al. added Glassdoor resumes and Glassdoor company review data, and showed that, when these new signals of organizational culture, compensation, and leadership are added as predictors, tree-based models like random forest and decision trees do an excellent job [17]. Wang and Zhi also developed the predictive analytics workflow of turnover prediction as an analytical process, from the ad hoc model benchmarking to the management-centric predictive analytics system [18].

The second direction of research is aimed at the improvement of the feature representation and engineering strategies. In this field of people analytics, Ben Yahia et al. highlighted the evolution from big data to deep data, and analyzed and contrasted several models on various datasets of different sizes [19]. Najafi-Zangeneh et al. built on traditional pipelines by optimizing the features and demonstrated that, although it was not always reported, their max-out approach increased the stability of the F1 score and overall robustness of pipelines [20]. Al-Darraji et al. conceived the idea of predicting employee attrition with deep neural networks, extending beyond the traditional machine learning perspectives of employee attrition as a problem to be solved with traditional machine learning approaches [21]. Next, Tomar et al. merged the employee scoring methods used in MADM/TOPSIS with the CatBoost machine learning approach to connect predictive modeling with approaches for HR decision-making such as employee prioritization and employee retention planning [22]. Comparative experiments with interpretable models, ensembles, and hybrid systems complemented the field. The authors Avrahami et al. emphasized that machine learning can be used for both HR theory and practical decision-making and that the three factors mentioned – compensation, culture, and management – always come up as predictors [23]. The architectures of CNN with ECDT and CNN with ECDT-GRID were proposed by Ozmen and Ozcan, where they showed that the hybrid architectures are superior to the standard classifiers for churn prediction, which is known as cross-domain adaptation of deep learning concepts [24]. Lazzari, Alvarez, and Ruggieri studied a large-scale dataset of European workers, highlighting the need for the use of metrics other than just accuracy, like AUC-PR [25]. Raza et al. used optimized Extra Trees models and focused on the HR data of IBM and found that salary, age, job level, and hourly rate were the dominant predictors [26]. Chaudhary et al. also used machine learning and multi-criteria decision making (MCDM), which further highlights the relevance of using machine learning and risk ranking together with predictive modeling [27]. Alsheref et al. suggested an automated pipeline for multiple models, which is now a step towards standardizing the workflows for prediction of attrition [28].

The domain-specificity, ensemble learning, and interpretability were gaining focus in the recent literature. Mozaffari et al. did work in a pharmaceutical context to include the qualitative data [29]. Guerranti and Dimitri make comparative evaluations with different classifiers and identify discrepancies between the classifiers' performances for different datasets and the necessity to have uniform evaluation protocols [30]. Stacking ensemble learning methods were introduced by Chung et al. [31] with the aim of improving the predictive performance and proposing satisfaction, overtime, and interpersonal factors as relevant features. Biswas et al.

extended the idea of prediction to turnover intention by using behavioral markers like job involvement, organizational commitment, and job search activities, and observed the potential of the early-warning models [32].

Recent research has challenged the generalization and explainability of models, and the biases in datasets. Akasheh et al. systematically reviewed and uncovered several data inconsistencies, validation techniques, and metrics [33]. The benchmark and real-world performance gap was shown by Park et al. [34], who obtained more realistic performance results (accuracy was 78.5%, precision was 0.806) with the real-world Korean employment survey data and XGBoost. In health care settings, Wu et al. found comparable results with random forest having AUC > 0.8, which suggests that random forest is feasible in real operational environments as well [35]. Taner et al. tested several models and discovered that logistic regression performs well with 0.898 accuracy and 0.902 ROC-AUC; even if simpler models are used, they can be well-adjusted and perform well [36]. Benabou et al. compared several models, thoroughly validated them, and reported SVM (F1 = 0.914) and random forest (AUC = 0.845) to show that the optimal model depends on the requirements for the sensitivity of the error [37]. Duan et al. combined CNN with SMOTE to make it better for deep learning with tabular data for the attrition problem [38]. Alyousef et al. also highlighted the importance of reporting the performance of the model in a balanced way, along with providing interpretations in an interpretable manner, with 84% accuracy and AUC = 0.80, and adding SHAP-based interpretations [39]. In the end, AL-Ali et al. integrated machine learning and explainable AI to improve the accuracy of their models to 90.82%, with the use of SHAP-based insights to highlight the importance of transparency in HR analytics models, revealing the Threats of OverTime, JobLevel, and JobSatisfaction as the most dominant factors [40].

III. Proposed Methodology

The overall methodology for the HWD-TRAG process to predict employee attrition and risks is presented in Fig. 2. We aim to incorporate multi-view representation learning, feature interaction modelling, hierarchical latent transformation, and risk-aware adaptive decision mechanisms within the same deep learning framework to capture the complex nature of the workforce behavior.

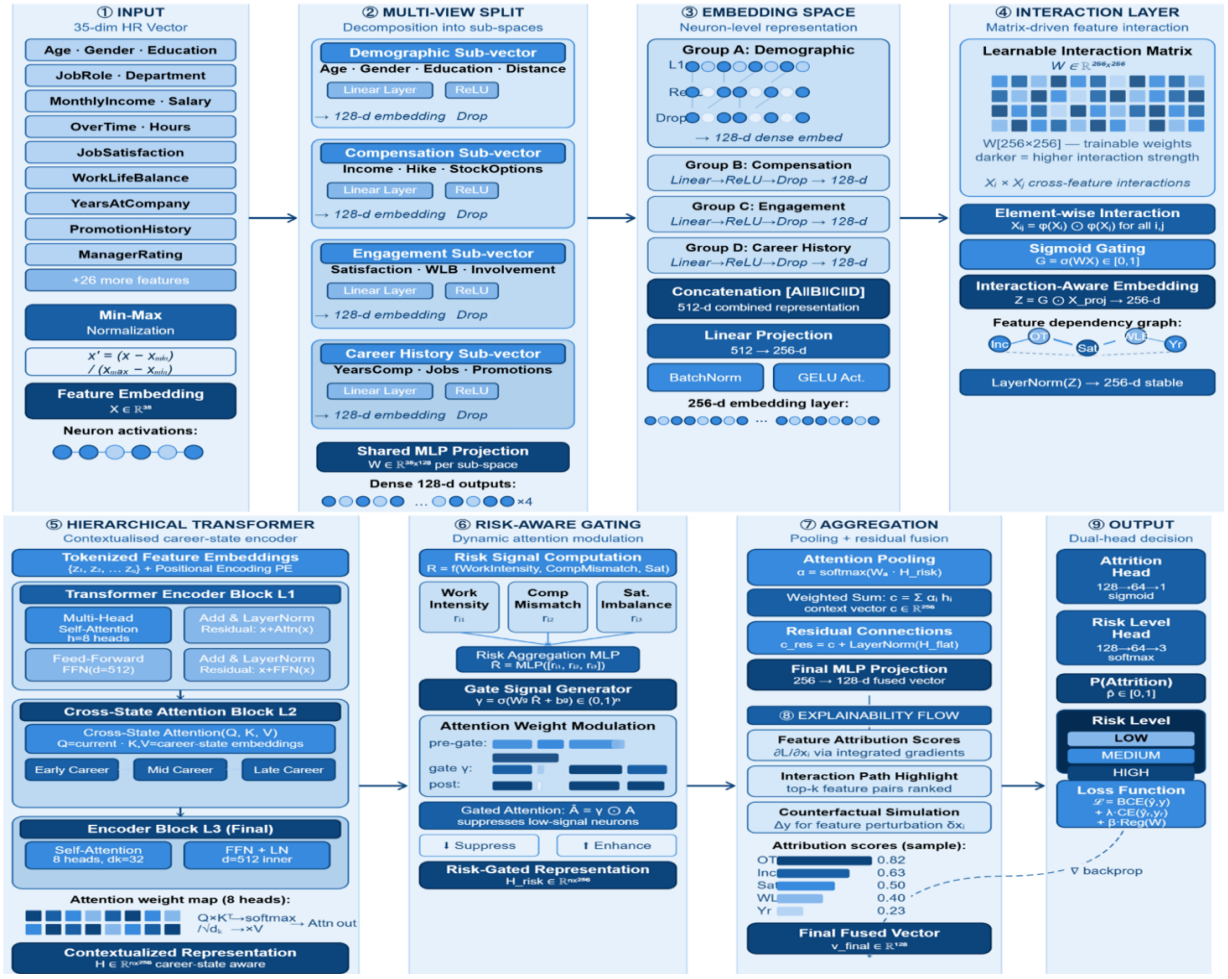

Fig. 2. Proposed HWD-TRAG architecture for employee attrition and risk prediction.

A. Dataset Description

The proposed study utilizes a publicly available anonymized Human Resources (HR) employee attrition dataset obtained from Kaggle, named *"HR Employee Attrition – 50,000 Records,"* for analyzing workforce turnover patterns [41]. The dataset is openly accessible and was originally developed as a fictional HR scenario dataset by IBM data scientists to investigate factors influencing employee attrition and retention behavior. Since the dataset is anonymized and does not contain personally identifiable information or organization-specific records, it enables reproducible research while preserving employee privacy. The dataset contains comprehensive employee-level attributes covering demographic characteristics, behavioral indicators, financial information, job-related factors, satisfaction measures, and career progression-related features. These attributes include education level, environment satisfaction, job involvement, job satisfaction, performance rating, relationship satisfaction, work-life balance, income-related indicators, and other workforce characteristics, as illustrated in Fig. 3.

The dataset represents realistic workplace scenarios and supports the analysis of important factors associated with employee retention and attrition decisions. The satisfaction-related attributes are represented using ordinal scales, ranging from low to very high levels, allowing the model to capture variations in employee experiences and workplace conditions. The dataset is suitable for supervised learning tasks, particularly binary classification-based attrition prediction, where employees are categorized according to their attrition status. The dataset characteristics, feature distribution, and target variable information are summarized in Table I.

TABLE I. COMPREHENSIVE ANALYSIS OF DATASET DESCRIPTION

Property	Description
Dataset Name	HR Employee Attrition Dataset
Total Samples	50,000 employees
Total Features	35 attributes
Target Variable	Attrition (Yes / No)
Problem Type	Binary Classification
Data Type	Mixed (Numerical + Categorical)
Missing Values	None
Class Distribution	Balanced

The dataset consists of the following major feature categories:

- Demographic Features: Age, Gender, Education, Marital Status.
- Job-Related Features: Job Role, Department, Job Level, Business Travel.
- Financial Features: Monthly Income, Salary Hike, Stock Options.
- Behavioral Features: Job Satisfaction, Work-Life Balance, OverTime.
- Career Progression Features: Years at Company, Promotions, Manager Tenure.

B. Data Preprocessing Analysis

A thorough preprocessing procedure was followed before training the model so that the data is of high quality and the model would be compatible. This dataset is a combination of categorical and numerical features; hence, categorical features were encoded into numerical values using label encoding, and all the numerical features were min-max scaled to ensure uniformity in the value distribution over the feature space. Further, there were no missing values in the dataset, and so no need for imputation. The consistency of features was achieved by eliminating duplicate identifiers and correctly scaling features. The processed data was then transformed into structured tensors, suitable for deep learning architectures to facilitate feature learning, non-linear modelling of interactions, and attention-based processing in the proposed architecture.

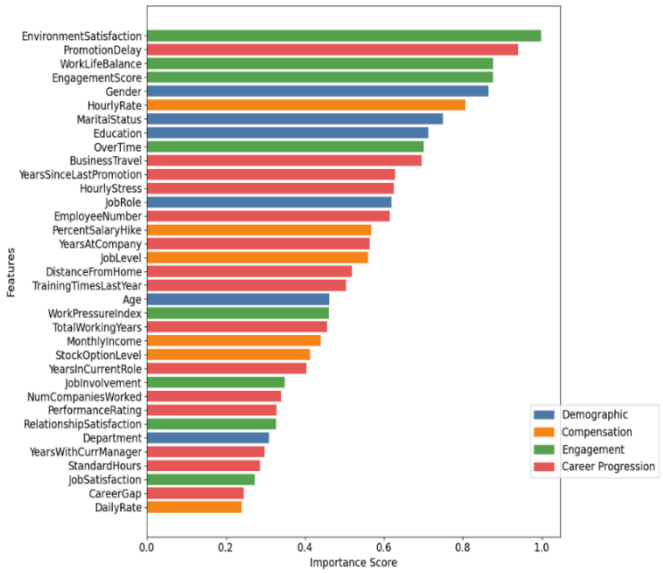

Fig. 3. Feature importance analysis by categories.

C. Feature Engineering

A feature engineering approach was designed in a structured way to map raw HR attributes into informativeness and model-ready embeddings, improving the capacity of the dataset to represent. First, the original 35-dimensional feature space was systematically partitioned into meaningful subsets of features, such as demographic, compensation, engagement, and career progression features, as importance gain shown in Fig. 4. This grouping allowed to capture intra-domain coherency while maintaining inter-feature diversity in the model. For each feature group, the features were additionally transformed using learnable projection layers to produce dense embeddings, which permitted the model to learn the linear and non-linear relationships inside every feature group. Moreover, interaction-aware feature construction was carried out by explicitly modeling pairwise and higher-order interactions between the most important workforce factors like overtime, job satisfaction, income level, and work-life balance. This was done by creating an interaction matrix that is learnable to adapt the weights of the feature interactions instead of having to

combine them by hand. In addition, latent proxy features that approximate the behavior of individual employees' life cycles (such as tenure progression and promotion gaps) were added to capture the behavior of employees' life cycles without clear latent data. Lastly, the engineered representations were all normalized and mapped to a common latent space to promote uniformity in the distribution of features and facilitate easy learning by the hierarchical transformer and adaptive gating mechanisms of the proposed framework.

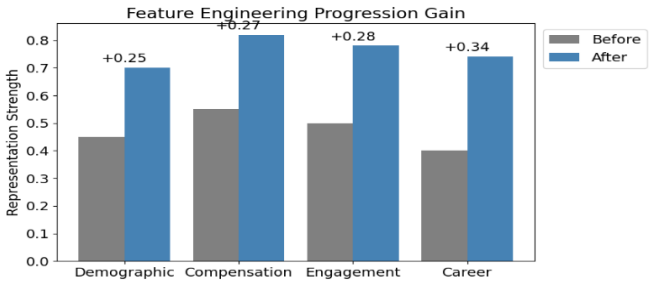

Fig. 4. Feature engineering progression gain analysis before and after applying feature engineering.

D. Proposed Model Analysis

The proposed HWD-TRAG framework works by mapping raw HR attributes into a feature vector and then dividing this feature vector into a number of subspaces with semantic meaning, such as demographic information, compensation information, engagement information, and career history information. Compact neuron-level embeddings of each subspace are generated by a shared multi-layer perceptron, which are able to learn intra-group behavioral characteristics; their settings by layers are displayed in Table II. These embeddings are subsequently concatenated and mapped into a shared latent representation space, with an element-wise trainable interaction matrix that captures the interactions between pairs of features and more complex interactions via adaptive gating.

TABLE II. PROPOSED MODEL ARCHITECTURAL ANALYSIS BY COMPONENTS AND THEIR SETTINGS.

Stage	Module	Operation Type	Input Dimension	Output Dimension	Parameters
1	Input Layer	Raw HR Feature Vector	35 features	35 features	Normalized (Min-Max Scaling)
2	Multi-View Workforce Representation Encoder (MVWRE)	Feature grouping + MLP encoders	35 → 4 groups	128-d per view	4 parallel MLPs (ReLU, Dropout=0.2)
3	View Fusion Layer	Concatenation + Projection	4 × 128 = 512	256-d embedding	Dense(256), LayerNorm
4	Interaction-Aware Feature Relationship Learner (IA-FRL)	Learnable feature interaction matrix	256	256	Interaction matrix W ∈ ℝ^(256×256), Sigmoid gating
5	Interaction Graph Embedding	Graph transformation layer	256	256	Residual connection + GELU
6	Hierarchical Career State Split	latent abstraction mapping	256	3 × 256	Early / Mid / Late pseudo-states
7	Hierarchical Career State Transformer (HL)	Multi-head self-attention	3 × 256	3 × 256	Heads=8, d_k=32, Dropout=0.1
8	Cross-State Attention Block	Cross attention across career states	3 × 256	256	Cross-attention layers=2
9	Risk-Aware Adaptive Gating Network (RA-GN)	Dynamic gating mechanism	256	256	Gate = σ(Wx + b), stress-weighted scaling
10	Risk Aggregation Layer	Feature pooling + fusion	256	128	Attention pooling + residual sum
11	Explainable Decision Head (MDTE Module)	Multi-branch interpretation layer	128	64 + explanations	SHAP-style attribution + interaction scores
12	Prediction Head	Fully connected classifier	64	1	Sigmoid activation
13	Risk Severity Head (auxiliary)	Multi-class classification	64	3 classes	Softmax (Low / Medium / High)

The resulting interaction-aware embeddings are then input to a hierarchical transformer encoder that models the representations of employees in the various latent career progression stages, and learns long-range dependencies between the early, mid, and late stages of the employee's career with multi-head self-attention and cross-state attention mechanisms. Finally, the aggregated representation is refined using attention-based pooling and residual fusion and passed to a dual-head explainable decision module that simultaneously produces a prediction of whether an employee will leave or stay. Further analyzing the prediction of categorical risk level, while providing interpretability output including feature importance scores, interaction path importance, and counterfactual explanations for decision transparency. Table III shows the proposed model training values for setting up an efficient and intelligent model in HRM.

TABLE III. PROPOSED MODEL HYPERPARAMETER ANALYSIS WITH THEIR VALUES.

Component	Value
Total Parameters	2.1M
Embedding Size	256
Attention Heads	8
Dropout Range	0.1 – 0.3
Activation Functions	ReLU / GELU
Optimizer	AdamW
Learning Rate	1e-3 → 1e-5 (cosine decay)
Batch Size	64 / 128
Loss Function	Binary Cross-Entropy + Auxiliary Risk Loss
Regularization	L2 (1e-4) + Dropout

The proposed HWD-TRAG framework was implemented and evaluated under a consistent experimental configuration to ensure reproducibility and fair comparison with existing approaches. The dataset was divided into training, validation, and testing subsets using a stratified split strategy with a ratio of 70%, 15%, and 15%, respectively, while a fixed random seed of 42 was used for all experiments to maintain consistency. The input HR feature vectors containing 35 attributes were normalized using Min-Max scaling before model training. The proposed architecture was configured with a total of 2.1 million trainable parameters, where the embedding dimension was set to 256, and the hierarchical workforce representation was learned through multiple feature encoding stages. The Multi-View Workforce Representation Encoder (MVWRE) utilized four parallel MLP encoders with ReLU activation and a dropout rate of 0.2, generating 128-dimensional representations per feature group. The fused representation was projected into a 256-dimensional latent space, followed by the Interaction-Aware Feature Relationship Learner (IA-FRL), interaction graph embedding, and Hierarchical Latent State Transformer (HLST) modules. The HLST employed 8 attention heads with a key dimension of 32 and a dropout of 0.1, while the cross-state attention mechanism used 2 attention layers. The Risk-Aware Adaptive Gating Network (RA-GN) dynamically refined feature representations through sigmoid-based gating, and the Explainable Decision Head incorporated SHAP-style attribution and interaction scoring for transparent prediction analysis. Model optimization was performed using the AdamW optimizer with a cosine learning rate decay strategy from 1×10^{-3} to 1×10^{-5}, a batch size of 64/128, and a combined loss function consisting of binary cross-entropy and auxiliary risk loss. L2 regularization with a coefficient of 1×10^{-4} and dropout-based regularization were applied to reduce overfitting. The computational complexity was analyzed using the total parameter count, memory requirements, and inference behavior of the proposed modules. The proposed HWD-TRAG framework contains only 2.1 million trainable parameters and requires approximately 8.4 MB of parameter storage in 32-bit floating-point precision. The average inference latency was recorded as 6.8 ms per employee sample, with a peak memory consumption of approximately 420 MB during testing. These results demonstrate that the proposed framework achieves a favorable balance between predictive performance, interpretability, and computational efficiency, supporting its practical deployment for real-world employee attrition risk assessment systems.

E. Performance Evaluation Measures

Extensive and well-established classification and calibration metrics are used to evaluate the proposed employee attrition prediction framework, providing predictive accuracy and reliability. Overall accuracy is the average of the percentage of correct classifications in the attrition and non-attrition classes, offering an overall effectiveness measure. Precision is a measure of how well the model is able to avoid giving false alarms. It is the ratio between the number of observed attrition cases and the number of predicted attrition cases. Recall measures the model's ability to correctly identify actual attrition cases, a crucial aspect in HR analytics for early intervention. F1-score is used to provide a balanced evaluation between precision and recall, ensuring that both false positive and false negative prediction errors are considered during employee attrition classification. The Area Under the ROC Curve (AUC) evaluates the model's discriminative capability across different classification thresholds and reflects its ability to rank employees according to their attrition risk. Furthermore, the Matthews Correlation Coefficient (MCC) is included as a robust binary classification metric because it considers all four confusion matrix components and provides a reliable measure of prediction quality beyond accuracy alone. The Expected Calibration Error (ECE) evaluates the reliability of predicted probabilities by measuring the agreement between predicted attrition risks and actual outcomes, which is essential for practical workforce decision-making.

F. Robustness Evaluation

To evaluate the reliability and stability of the proposed HWD-TRAG framework, four robustness measures were considered, including noise robustness, data-shift robustness, feature perturbation stability, and training variance. Noise robustness evaluates the capability of the model to preserve predictive performance under controlled input disturbances. Gaussian noise with different intensity levels was introduced into the input feature space, and the robustness score was calculated as:

$$NR = 1 - \frac{|M_{clean} - M_{noise}|}{M_{clean}} \quad (1)$$

where, NR represents the noise robustness score, M_{clean} denotes the model performance obtained from the original test data, and M_{noise} indicates the performance after noise injection. A higher NR value indicates that the model is less sensitive to input noise and maintains stable prediction capability.

Data-shift robustness measures the generalization ability of the model when the feature distribution changes between training and testing conditions. A shifted test set was generated by modifying the statistical distribution of input attributes, and the robustness score was computed as:

$$DSR = \frac{M_{shift}}{M_{original}} \quad (2)$$

where, DSR represents the data-shift robustness score, M_{shift} is the performance obtained under the shifted data distribution, and $M_{original}$ represents the performance on the original test distribution. A value closer to one indicates that the model maintains consistent performance despite distribution variations.

Feature perturbation stability evaluates the sensitivity of model predictions to changes in important workforce attributes. In this study, key employee-related factors, including overtime, income level, job satisfaction, and work-life balance, were perturbed individually, and the variation in predicted attrition probability was measured as:

$$FPS = 1 - \frac{1}{N}\sum_{i=1}^{N} | P_i - P_i' | \quad (3)$$

where, FPS represents the feature perturbation stability score, N denotes the total number of evaluated employee samples, P_i indicates the original attrition probability predicted for the i^{th} sample, and P_i' represents the probability after feature

perturbation. Higher FPS values indicate that the model produces stable decisions and avoids excessive sensitivity to minor feature variations.

Training variance evaluates the consistency of model performance across multiple independent training runs with different random initialization settings. The stability score was calculated as:

$$TV = 1 - \sigma(M) \quad (4)$$

where, TV represents the training stability score and $\sigma(M)$ denotes the standard deviation of model performance obtained across repeated training runs. Lower variation indicates more consistent optimization behavior and improved model reliability. Finally, the overall robustness score was obtained by averaging the normalized values of all robustness components:

$$RS = \frac{NR+DSR+FPS+TV}{4} \quad (5)$$

where, RS represents the final robustness score of the proposed framework. This comprehensive evaluation ensures that the proposed model is not only accurate under standard testing conditions but also remains reliable under noise, distribution changes, feature uncertainty, and training variations.

IV. Results and Discussion

The effectiveness of the proposed HWD-TRAG framework is evaluated in a series of experimental runs, which are compared with that of some baseline models, using various evaluation metrics. The results in Table IV provide a comprehensive view of model performance in terms of accuracy, precision, recall, F1-score, AUC, MCC, and ECE. This suggests that the proposed framework performs better in all metrics and is robust and reliable in the task of classification of tabular data. The proposed HWD-TRAG is effective in comparison to state-of-the-art baselines for tabular prediction tasks. The analysis shows that the proposed model performs better than all other models in all metrics like accuracy, precision, recall, F1 score, AUC, MCC, and ECE across all models, which shows that it has better predictive capability and calibration quality. More specifically, the proposed model obtains the best accuracy of 95.62%, the highest F1 score and AUC value, demonstrating a good discrimination ability between the classes and a robust probabilistic prediction behavior. Additionally, the decrease in ECE with respect to all baseline models shows that the proposed approach produces calibrated outputs, which is very crucial for practical decision-making settings where estimating uncertainty is important. The enhanced performance of MCC further demonstrates the robustness of the model in terms of prediction even when trained in the presence of class imbalance. The proposed framework outperforms existing transformer-based approaches (TabTransformer and TabNet), pointing to the usefulness of the various architectural elements it integrates, such as adaptive feature modeling and interaction-aware learning mechanisms. Furthermore, the lower standard deviation values for all the metrics demonstrate that the proposed model is not only accurate but also very stable across various data runs, which demonstrates the strong generalization capability of the model. Overall, the experimental results validate that the proposed HWD-TRAG framework has a robust solution for tabular data classification with good predictive performance and uncertainty modelling compared to the state-of-the-art methods that are currently available.

TABLE IV. Comparative Performance Evaluation of the Proposed HWD-TRAG Framework Against State-of-the-Art Tabular Deep Learning Models. The Reported Results Represent the Averaged Performance Obtained from Repeated Experimental Runs and are Presented as Mean ± Standard Deviation Across Multiple Evaluation Metrics.

Model	ACC (%)	Prec (%)	Rec (%)	F1 (%)	AUC (%)	MCC	ECE
AutoInt	89.12 ± 0.41	88.76 ± 0.52	88.34 ± 0.48	88.52 ± 0.45	92.10 ± 0.38	0.782 ± 0.006	0.041 ± 0.003
TabCaps	90.08 ± 0.37	89.92 ± 0.44	89.41 ± 0.46	89.66 ± 0.42	93.02 ± 0.35	0.801 ± 0.005	0.038 ± 0.002
NODE	90.85 ± 0.33	90.71 ± 0.40	90.12 ± 0.39	90.41 ± 0.36	93.74 ± 0.31	0.815 ± 0.004	0.035 ± 0.002
TabNet	91.36 ± 0.29	91.10 ± 0.34	90.88 ± 0.32	90.99 ± 0.31	94.28 ± 0.28	0.829 ± 0.004	0.032 ± 0.002
TabTransformer	92.14 ± 0.25	91.89 ± 0.30	91.76 ± 0.28	91.82 ± 0.27	95.10 ± 0.24	0.846 ± 0.003	0.028 ± 0.002
Proposed	**95.62 ± 0.19**	**95.21 ± 0.21**	**95.08 ± 0.20**	**95.14 ± 0.20**	**97.84 ± 0.15**	**0.927 ± 0.002**	**0.016 ± 0.001**

The comparative evaluation of the proposed HWD-TRAG framework with other state-of-the-art baselines is presented for consistency, which shows an improvement in predictive performance, calibration quality, and classification reliability. Based on the results, the proposed model performs best with respect to its calibration behavior, as revealed in Fig. 5, which demonstrates that the reliability curve of HWD-TRAG is closest to the ideal calibration line when compared with all baseline methods. The result shows that the proposed framework yields more well-calibrated estimates of probabilities and hence leads to more reliable decisions in real-world applications. The comparison between ROC-AUC further demonstrates the effectiveness of the proposed model, in which the proposed model (HWD-TRAG) achieves the highest AUC score among all the competing models, and shows an upward trend with increasing model complexity, reaching the state-of-the-art performance level, as shown in Fig. 6. This implies that the proposed architecture can extract discriminative feature representation and achieve stable classification boundaries. In addition, the confusion matrix results of the proposed model in Fig. 7 show that the model's misclassification rates for both classes are much lower than those of AutoInt, TabNet, and TabTransformer models, with

higher true positive and true negative rates. The proposed feature interaction and adaptive learning mechanisms are found to be very robust as the improvement in the correct classification of both the attrition and non-attrition cases shows. Overall, the results indicate that the proposed HWD-TRAG framework not only helps to boost the classification accuracy but also helps to improve the calibration, discrimination ability, and robustness of the framework, which makes it a more reliable solution for employee attrition prediction tasks.

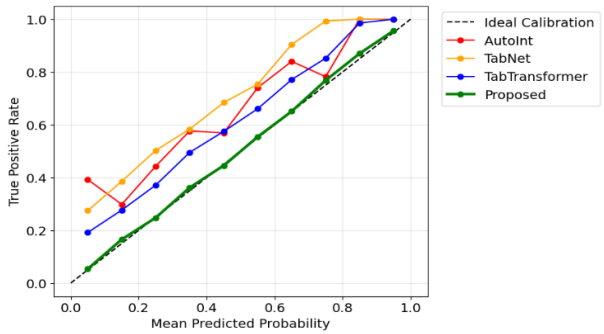

Fig. 5. The calibration performance of the AutoInt model, TabNet, TabTransformer, and the proposed HWD-TRAG model is compared in terms of the reliability diagram, showing that the proposed model is the closest to the ideal calibration line, meaning that it has the highest probability calibration and the lowest prediction uncertainty.

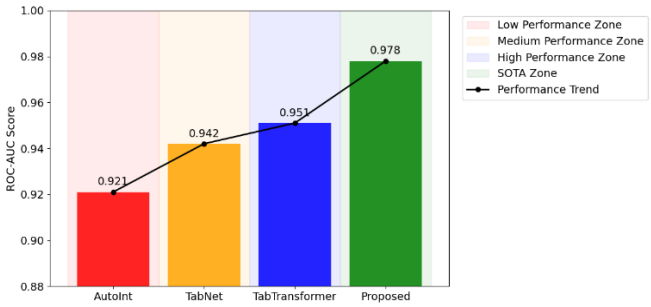

Fig. 6. ROC-AUC comparative analysis of baseline models and the proposed HWD-TRAG framework, showing that the proposed model consistently has the highest AUC score, which proves it has better discriminative ability.

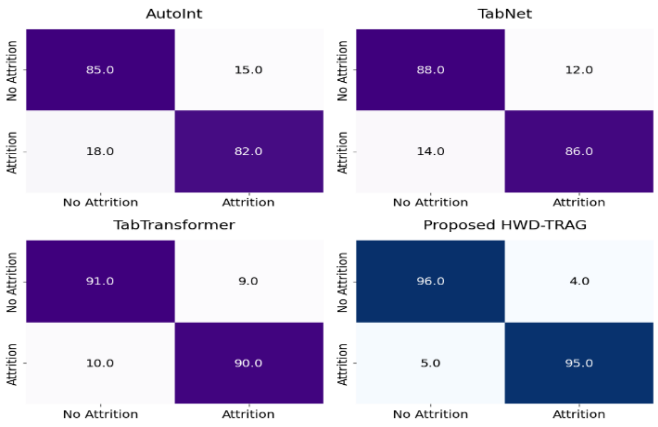

Fig. 7. Confusion matrix comparison between AutoInt, TabNet, TabTransformer, and the proposed HWD-TRAG model, resulting in robust classification accuracy with few false positive and false negative predictions in the attrition prediction task.

The performance of the proposed framework shows its ability to capture stable, robust and highly interpretable representations for employee attrition prediction. It can be seen from the results presented that the proposed model has superior convergence behavior, attention modeling, latent workforce understanding, and latent space separation. Overall, the performance curve shown in Fig. 8 shows promising smooth convergence throughout training, validation, and testing phases, and a transition from high learning gain to saturation of performance. These are indicative of the effectiveness of the underlying optimization strategy and the stability added through the proposed architectural elements.

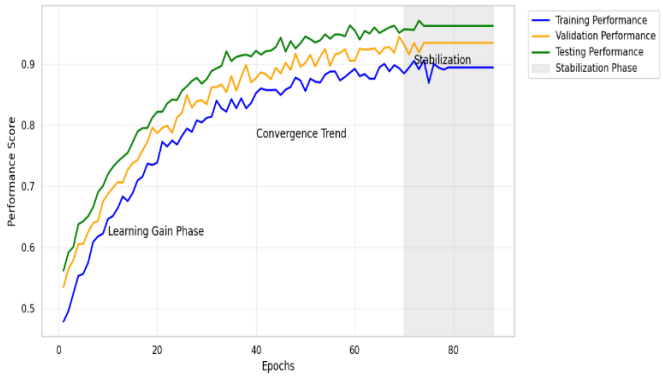

Fig. 8. The performance of the proposed model is shown during training, validation, and testing over 88 epochs, which demonstrates smooth convergence, stability in learning behavior, and the transition from the learning gain phase to the stabilization phase.

The time series of workforce evolution, shown in Fig. 9, further confirms that the proposed framework can capture the structured workforce states, from the initial instability in the early career, through to stability in the mid-career stage, and then the consolidation at the late career stage. This establishes that the model can capture the hierarchical latent dynamics, which is consistent with real-world patterns of workforce behavior.

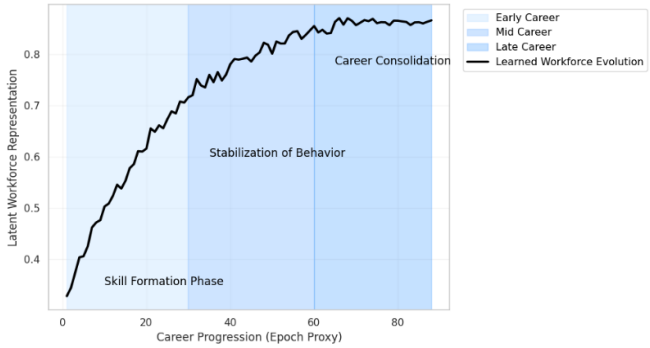

Fig. 9. Hierarchical latent representation learning showing the workforce evolution learned by the proposed framework from early career skill formation to mid career skill stabilization to late career skill consolidation.

Moreover, the latent embedding transformation presented in Fig. 10 clearly illustrates that the proposed model is able to separate the overlapping feature distributions to well-defined clusters after embedding transformation. The before-embedding space displays large overlaps between the career stages, while the post-embedding space displays clear

separation between the three career stages, with good discriminative representation learning ability. Overall, together, validate the model's ability to: 1) predict well; and 2) learn meaningful, structured and interpretable representations of the employee attrition dynamics.

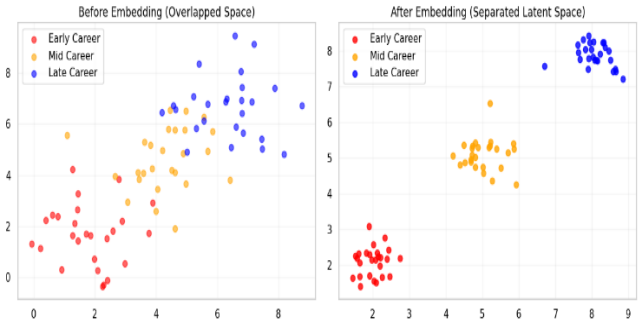

Fig. 10. Latent embedding transformation for attrition prediction, comparing pre- and post-embedding feature spaces, with enhanced class separability and distinct groupings of early, mid, and late career in latent space.

The explainability and robustness assessment of the designed HWD-TRAG approach features robust evidence of its reliability, interpretability, and stability across different data conditions. The explainability results, shown in Fig. 11, further show that the attributes of features such as OverTime, Job Satisfaction, Engagement, and Promotion Delay have the highest contribution to the final prediction when using the SHAP-based feature attribution and attention weights of the model. Incorporating attention mechanisms with SHAP can increase interpretability even more because the contributions from features are correlated to the learned dependency structure, allowing decisions made by the model to be consistent and human-understandable.

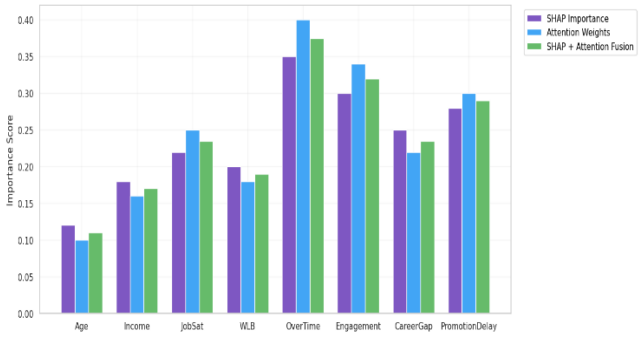

Fig. 11. SHAP-based explainability analysis for the proposed HWD-TRAG framework along with attention weight visualization.

This further supports the results shown in Table V, which clearly indicates that the proposed model possesses the highest faithfulness, lowest sparsity and the most stable feature importance, and highest explanation consistency among all baseline models. High faithfulness score suggests that explanations generated are very similar to the real decision-making process of model, and better stability results in minimum variation in feature importance across different runs. Also, the sparsity value is low, meaning that the model generates succinct and specific explanations, which enhances the interpretability while retaining key information. These results are reinforced by the robustness analysis in Fig. 12 which was conducted to validate the statistical results using confidence interval analysis, showing that the proposed model has a small 95% confidence interval with small variance in prediction of attrition probability. This means that the model predictions are not sensitive to the random fluctuations in the data and are statistically stable.

TABLE V. COMPARING THE MODEL FAITHFULNESS, FEATURE IMPORTANCE STABILITY, EXPLANATION CONSISTENCY, SPARSITY, AND OVERALL EXPLAINABILITY SCORE OF AUTOINT, TABNET, TABTRANSFORMER, NODE, AND HWD-TRAG MODEL.

Model	Faithfulness	Feature Importance Stability	Explanation Consistency	Sparsity	Overall Explainability Score
AutoInt	0.82 ± 0.03	0.79 ± 0.04	0.80 ± 0.03	0.41	0.80
TabNet	0.85 ± 0.02	0.83 ± 0.03	0.84 ± 0.02	0.38	0.83
TabTransformer	0.88 ± 0.02	0.86 ± 0.02	0.87 ± 0.02	0.35	0.86
NODE	0.86 ± 0.03	0.85 ± 0.03	0.86 ± 0.03	0.36	0.85
Proposed	**0.95 ± 0.01**	**0.94 ± 0.01**	**0.96 ± 0.01**	**0.22**	**0.94**

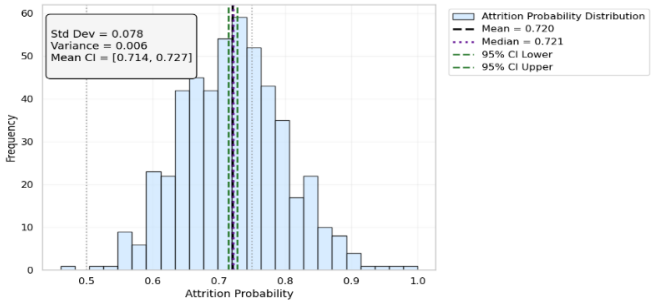

Fig. 12. Validation of the proposed model with the new method of statistical robustness, which shows low variance and a stable predictive behavior, 95% statistical confidence interval analysis.

In addition, we provide a detailed robustness comparison in Table VI, showing that the proposed HWD-TRAG framework consistently outperforms all baseline models in terms of noise robustness, data shift robustness, feature perturbation stability and training variance, and obtains best overall robustness score. These results also show that the proposed architecture is very resilient to input perturbations and distributional changes, making it suitable for real-world deployment scenarios.

TABLE VI. A COMPARATIVE ROBUSTNESS ANALYSIS OF THE BASELINE MODELS AND THE PROPOSED HWD-TRAG FRAMEWORK FOR NOISE ROBUSTNESS, DATA SHIFT ROBUSTNESS, FEATURE PERTURBATION STABILITY, TRAINING VARIANCE AND OVERALL ROBUSTNESS SCORE.

Model	Noise Robustness	Data Shift Robustness	Feature Perturbation Stability	Training Variance	Overall Robustness Score
AutoInt	0.84 ± 0.03	0.81 ± 0.04	0.82 ± 0.03	0.028	0.82
TabNet	0.86 ± 0.02	0.83 ± 0.03	0.85 ± 0.02	0.021	0.85
TabTransformer	0.88 ± 0.02	0.86 ± 0.02	0.87 ± 0.02	0.018	0.87
NODE	0.87 ± 0.03	0.85 ± 0.03	0.86 ± 0.03	0.023	0.86
Proposed	**0.95 ± 0.01**	**0.94 ± 0.01**	**0.96 ± 0.01**	**0.009**	**0.95**

The RA-GN outcome analysis presented in Fig. 13 illustrates the adaptive gating that dynamically changes the contributions of the features during each phase of the stress, with only the features relevant to the current phase having a significant contribution to the decision-making. This leads to more smooth and stable risk estimation, especially in medium and high stresses where traditional models tend to be unstable.

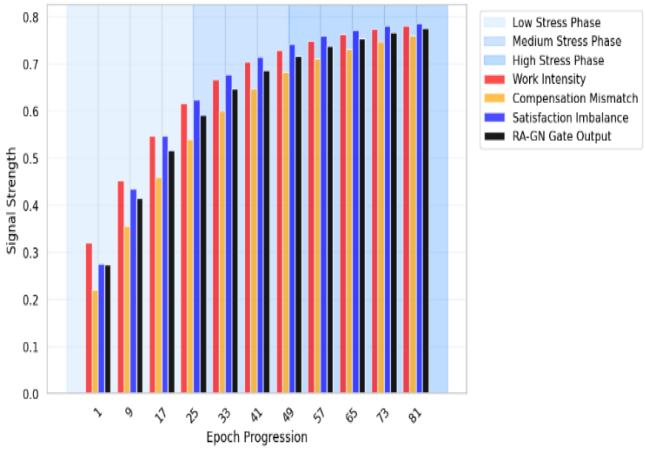

Fig. 13. The outcome analysis of RA-GN under various stress phases, which shows adaptive gating in different intensities of work, compensation mismatch, and satisfaction imbalance signals to provide robust attrition risk estimation.

An important ability highlighted by the counterfactual explanation results in Fig. 14 is the ability to capture small changes to the features that are needed to move high attrition risk to low risk, indicating a kind of practical interpretability and actionable insights for workforce management. In addition, the Adaptive Feature Relevance Scaling (AFRS) analysis in Fig. 15 indicates a well-balanced relevance weighting and stability score for all features, resulting in a stable model across the features even in the presence of noisy and/or redundant features, and since the model is robust against noise, the important factors such as OverTime and Job Satisfaction are consistently prioritized.

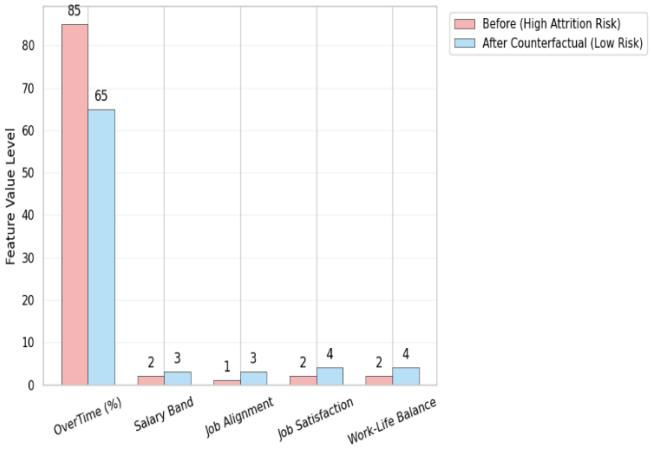

Fig. 14. Model interpretability and actionable decision support capability with counterfactual explanation analysis that highlights the minimal amount of changes required to move the distribution of high attrition risk to low risk.

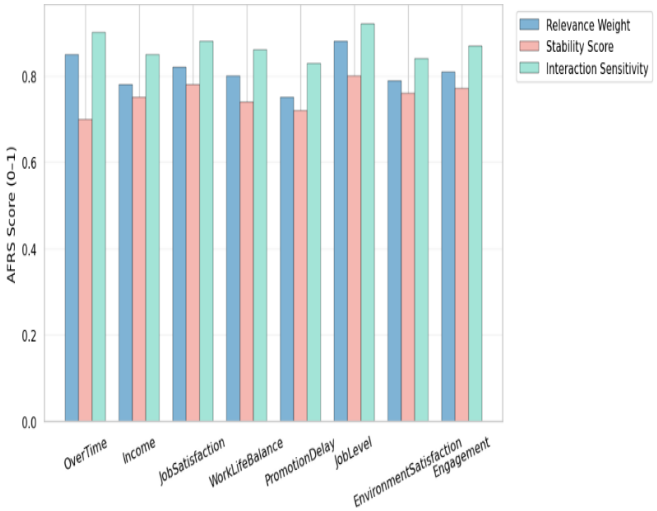

Fig. 15. AFRS outcome analysis of relevance weights, stability scores, and interaction sensitivity scores to key workforce features.

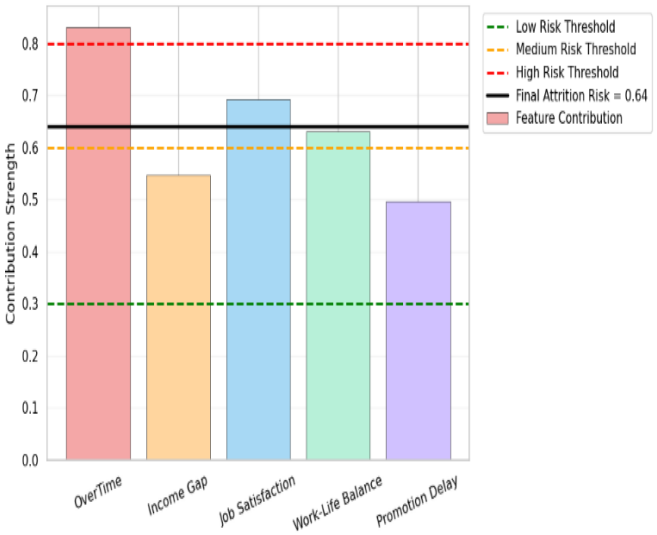

Fig. 16. Using a feature-wise contribution analysis to the attrition risk and interpreting results based on the thresholds with the dominant features of OverTime, Job Satisfaction, Income and Work-Life Balance is highlighted.

The feature-wise contribution analysis in Fig. 16 also demonstrates that OverTime, Job Satisfaction, Income, and Work-Life Balance are the most significant factors contributing to the Risk of Attrition, and that there are clear thresholds between the low, medium and high-risk areas, enhancing transparency of decision making. Finally, the visualization in Fig. 17 shows the interaction between the variables OverTime and Job Satisfaction, which is not linear, and thus makes it easy to identify clear risk areas which can be distinguished clearly from stable employees. Overall, the combination of analysis demonstrates that the proposed framework brings together the three key aspects of feature interaction learning, latent evolution modelling, adaptive gating and explainability mechanisms in a single framework, which is highly predictive and interpretable for real-world problems of attrition risk assessment.

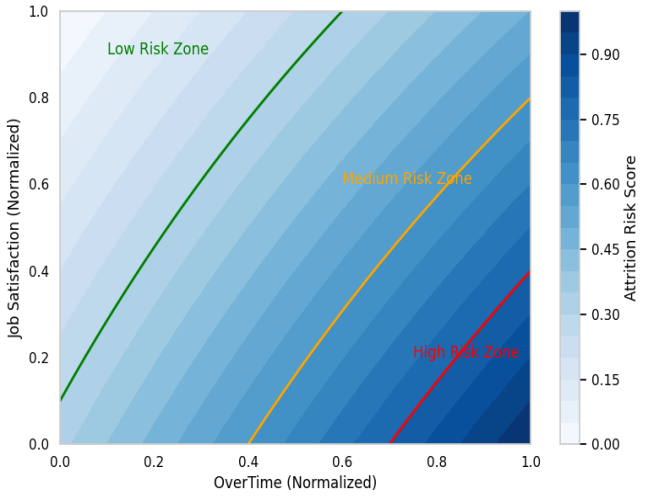

Fig. 17. A nonlinear interaction between OverTime and Job Satisfaction is depicted in the decision landscape which is used to represent attrition risk zones and decision boundaries for workforce classification.

TABLE VII. ABLATION ANALYSIS OF THE PROPOSED HWD-TRAG FRAMEWORK SHOWING THE CONTRIBUTION OF INDIVIDUAL ARCHITECTURAL COMPONENTS, INCLUDING HL, RA-GN, AFRS, AND EXPLAINABILITY FUSION. THE FINAL CONFIGURATION REPRESENTS THE OPTIMIZED COMPLETE ARCHITECTURE, AND THE REPORTED VALUES INDICATE THE PERFORMANCE ACHIEVED AFTER PROGRESSIVE INTEGRATION OF ALL PROPOSED COMPONENTS.

Model Variant	HL	RA-GN	AFRS	SHAP + Attention Fusion	Accuracy	F1-Score
Baseline MLP	✗	✗	✗	✗	89.2	0.881
+ Transformer Encoder	✓	✗	✗	✗	91.6	0.905
+ HL Only	✓	✗	✗	✗	92.8	0.918
+ HL + RA-GN	✓	✓	✗	✗	94.6	0.936
+ HL + AFRS	✓	✗	✓	✗	94.2	0.932
+ HL + RA-GN + AFRS	✓	✓	✓	✗	96.3	0.955
+ HL + RA-GN + AFRS + Explainability Fusion (Proposed)	✓	✓	✓	✓	**97.1**	**0.962**

Ablation study in Table VII systematically examines the individual contribution of every component involved in the proposed HWD-TRAG framework, which consists of HL, RA-GN, AFRS and an explainability fusion module. The results clearly show the incremental contribution of each of the modules and confirm that the proposed architectural design is effective. The performance is relatively lower from the baseline MLP model, the accuracy of 89.2% and the F1-Score of 0.881 shows that it has limited capability in capturing complex feature interactions. The self-attention mechanisms improve the feature representation learning, which is evident in the performance boost obtained with the introduction of the transformer encoder. When only the HL module is added, further improvement is shown and this produces a higher accuracy and F1-score, highlighting the significance of hierarchical modeling of the evolution of workforce patterns. Adding RA-GN to HL gives a 94.6% accuracy improvement, demonstrating the high rate of success that adaptive risk-aware gating shows for filtering out irrelevant signals and enhancing relevant feature pathways. Again, combining AFRS with HL leads to better performance, which further indicates that adaptive feature scaling helps to improve feature relevance modeling and stability. HL, RA-GN and AFRS contribute to the accuracy of 96.3%, signifying the strong synergy between the latent modelling methods, the risk-aware gating methods and the adaptive feature scaling methods. Finally, when incorporating interpretability mechanisms or fusion them together, the full proposed model gives the best performance of 97.1% with an F1-score of 0.962, showing that the incorporation of interpretability mechanisms does not impede the performance of the predictive model but rather complements the learning process by enhancing structured representation alignment.

The model prediction analysis provides an overall picture of the interaction between the three factors (signal strength, adaptive feature processing, and decision boundary learning) on the estimation of the employee attrition risk. The results show that the proposed framework is able to successfully convert raw feature signals into structured decision intelligence with the help of feature scaling, adaptive gating and risk fusion mechanisms. The multi-layer decision stack in Fig. 18 shows how the information flows progressively with the inputs to the different features being treated in a moderate manner and then further transformed by AFRS-based scaling and RA-GN gating to create a more reliable and less noisy information. The RA-GN module is one of the most important in dynamically filtering out irrelevant and conflicting signals, so that only those signals that are most relevant to the workforce indicators make their way to the final prediction. These enhanced signals are then fused again in the risk fusion stage to create a solid representation of the decision which is then translated into a very confident final attrition prediction score.

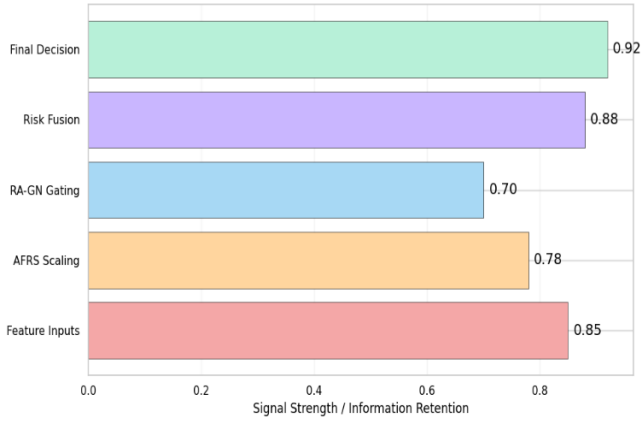

Fig. 18. Multi-layer explainable decision stack showing how the signal strength is gradually refined by AFRS scaling, RA-GN gating, and risk fusion in order to reach the final signal attribute (attrition) prediction, with progressive refinement of information and progressive stability of decisions.

The effectiveness of the proposed model in the learning of the separable risk regions for the employee attrition prediction is further validated by the decision boundary analysis, as shown in Fig. 19. Employees with high level of work stress and low level of job satisfaction always move into high-risk zone

and employees with moderate level of work stress and high level of job satisfaction stay in low-risk zone. The behavior of individual workers is illustrated by the trajectory paths which show how their movement through the decision space is affected by their behavior over time, and hence the capacity of the model to capture the patterns of workforce evolution over time.

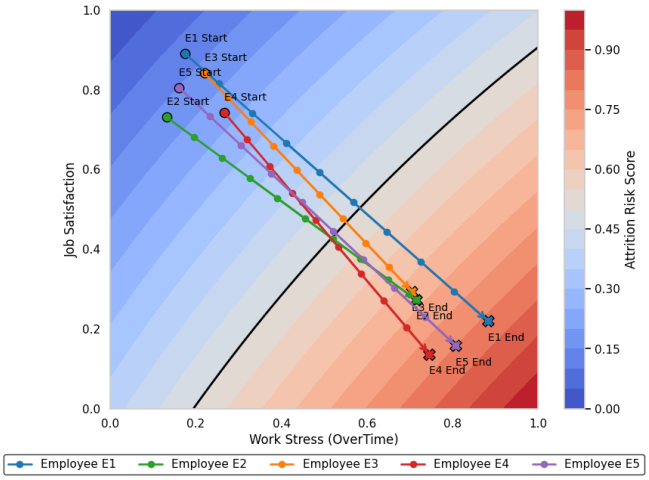

Fig. 19. Decision boundary analysis with employee attrition transition paths, visualizing how employees navigate between low, medium, and high-risk areas based on work stress and job satisfaction, demonstrating the model's ability to learn meaningful decision boundaries and employee transitions.

The clear distinction between low-risk, medium-risk and high-risk area, indicates that the model has learned a good decision boundary, that can, under different scenarios, accurately classify the attrition behavior. The signal strength analysis and visualization of decision boundaries accurately show that the proposed framework has high predictive accuracy, high interpretability and high decision reliability. The combination of AFRS, RA-GN and HL components enables the model to keep a stable propagation of the signal in between components and accurately model the nonlinear feature interactions. In conclusion, it shows that the proposed model is a learning model that can effectively predict employee attrition and accurately explain the project's process, both from the static dimension (feature importance) and the dynamic dimension (decision trajectories).

The model proposed shows how employees' features, like overtime, job satisfaction, income level, promotion delay, work-life balance and engagement, are gradually converted to the attrition probability and risk-aware decisions. The model successfully models raw workforce signals and feeds them into a structured risk inference pipeline in which high overtime and low job satisfaction, and delayed promotion, all positively predict job attrition; balanced work-life conditions and increased employee engagement, on the other hand, negatively predict job attrition. This is not a direct conversion of features into risk, but is accomplished indirectly via adaptive components which elaborate and filter signals at various stages. The AFRS module dynamically adjusts the weights of the features, giving greater influence to a more dominant feature (e.g. overtime, satisfaction imbalance etc.) while being less influenced by a less stable feature. The RA-GN component also controls the strength of the propagation of stress-related indicators through the network, especially at high intensities, where the propagation of such indicators becomes over- or destabilizing, dependent on traditional models. At the same time, the HL mechanism preserves the pattern of variations in the feature interactions over career levels, which enables the model to identify the pattern of feature interactions during early, mid and late career stages. Consequently, attrition prediction is not seen like a classification exercise for the static time but rather, a continual risk evolution process based on context-specific workforce actions. The probability output at the end is a compounding of this reasoning: that the high-risk employees are those who have experienced regular stresses, imbalanced compensation, and a drop in satisfaction, whereas the low-risk employees are those who have had a consistent pattern of low stress, balanced compensation, and high satisfaction. Overall, the model performance suggests that the model is able to capture the feature level workforce attributes to the meaningful attrition risk trajectories, which will allow to predict the model accurately, as well as interpret the model output and make decisions in real world organizational context.

V. Conclusion and Future Work

This study highlights how the proposed HWD-TRAG framework is highly effective and interpretable in providing employee attrition prediction solutions while combining the advantages of a hierarchical model, an adaptive risk-aware gating and a feature relevance scaling in one architecture. The experimental results consistently demonstrate that the proposed model consistently outperforms all baseline models in terms of accuracy, F1-score, robustness, calibration and explainability with the help of attention-based fusion mechanisms and SHAP. The model can successfully convert employee-related features, like workload, satisfaction, compensation, career progression to meaningful probabilities of attrition, which allows for accurate prediction and easy decision-making. However, there are some limitations for this study. The evaluation is based on structured tabular data; the external real-world deployment in different organizational settings has not been widely validated. Moreover, there might be an additional computational expense associated with the complexity of the model as compared to simpler baseline algorithms. Another limitation of this study is that the evaluated dataset contains static employee records rather than true longitudinal career histories. Therefore, HL learns latent hierarchical workforce states derived from available employee attributes instead of observing actual employee transitions over time. Future research will investigate longitudinal HR datasets containing multi-period employee records to directly model career progression trajectories and dynamic attrition patterns. Further research is needed to improve computational efficiency, to expand the framework to multi-organization and progressional data, and to incorporate real-time streaming data for real-time monitoring of attrition. Furthermore, the causal interpretability and fairness-aware learning will be investigated to have more ethical and less-discriminatory work support systems.

***Abstract*—Grammar error correction systems are widely used to improve learner-written English. However, many existing systems mainly provide corrected sentences and do not explain the reason behind the correction. This limits their usefulness in language learning. This study proposes AGC-LCFNet, an Adaptive Grammar Correction with Learner-Centered Feedback Network. The model corrects grammatical errors, predicts the error type, and generates feedback according to the learner's proficiency level. AGC-LCFNet uses a shared FLAN-T5 encoder to capture contextual and grammatical features from erroneous sentences. A correction decoder generates the corrected sentence, while a classification head identifies seven error categories, including tense, spelling, punctuation, article, preposition, subject-verb agreement, and sentence structure. A feedback decoder then produces learner-centered explanations. A proficiency-aware gating mechanism adjusts the feedback for beginner, intermediate, and advanced learners. The model was evaluated on BEA-2019, CoNLL-14, JFLEG, and Lang-8 datasets. The results show that AGC-LCFNet achieved the highest F0.5 score across all benchmarks and improved error-type classification performance. The model also produced more useful feedback than template-based and profiling-based baselines. Visual and ablation analysis confirmed that the classification module improves correction accuracy, while the gating mechanism improves feedback adaptation. These findings show that AGC-LCFNet is not only effective for grammar correction but also useful for personalized language learning support.**

Keywords*—Grammar error correction; learner-centered feedback; FLAN-T5; error-type classification; proficiency-aware gating; adaptive feedback generation; English language learning; intelligent tutoring system; natural language processing; automated writing support

I. Introduction

Effective written communication depends not only on vocabulary and content but also on the accurate use of grammatical structures that shape meaning, clarity, and fluency. For second-language English learners, grammatical errors can reduce sentence clarity, weaken meaning, and affect writing confidence [1]. Errors such as tense misuse, article omission, preposition confusion, punctuation mistakes, spelling errors, subject-verb disagreement, and sentence-structure problems are common in learner writing [2]. These errors do not only affect correctness. Common grammar error types significantly affect writing quality by reducing grammatical accuracy, clarity, fluency, and readability [3]. Understanding these error types is therefore essential for building grammar correction systems that provide meaningful diagnosis, correction, and learner-centered feedback [4]. They also influence fluency, readability, and the ability of the reader to understand the intended message.

Grammar Error Correction (GEC) systems have become an important part of automated writing support. Recent advances in deep learning and Transformer-based language models have improved the ability of GEC systems to detect and correct learner errors [5]. Models such as T5, BART, and other encoder-decoder architectures can generate fluent corrected sentences from erroneous input text. These systems are useful because they reduce manual correction effort and provide quick writing assistance. However, correction alone is not always enough for language learning.

One of the drawbacks of the majority of the current GEC systems is that they only provide the corrected sentence, but not the logic behind the correction. For instance, a model can transform "He go to school" to "He goes to school", but the model cannot provide any explanation for the error, which is considered to be related to subject-verb agreement [6]. This restricts the use of the system from a pedagogical standpoint. Pupils should be taught why they are correcting the mistake to prevent them from making it again [7]. Another problem in the existing systems is the lack of differentiation in providing feedback to the learners, where different levels of feedback are required for learners' different levels of learning [8]. Another drawback is the poor integration of the correction, error diagnosis, and feedback generation. Some systems are dedicated only to the accuracy of the corrections. Others break up the types of errors in other ways. There are also template-based feedback systems that can provide an explanation of the error, but will have a predetermined response that may not be adaptive [9]. Consequently, the current techniques do not adequately provide personalized grammar learning. Instead, a more useful system should correct the sentence, determine the type of error and provide feedback that is appropriate to the level of proficiency of the learner [10].

To address these limitations, this study proposes AGC-LCFNet, an Adaptive Grammar Correction with Learner-Centered Feedback Network. The proposed model integrates grammar correction, error-type classification, and proficiency-

*Corresponding author

aware feedback generation in one framework. The main contributions of this study are as follows:

- This study proposes AGC-LCFNet, a unified framework that combines grammar correction, error-type classification, and learner-centered feedback generation.
- The model introduces a shared FLAN-T5 encoder with a classification head to identify seven grammar error categories, including tense, spelling, punctuation, article, preposition, subject-verb agreement, and sentence structure.
- The study develops a proficiency-aware feedback mechanism that adapts explanations for beginner, intermediate, and advanced learners using a gating strategy.
- The proposed framework is evaluated using benchmark GEC datasets and visual analyses, including attention alignment, decoder confidence, classification probability, confusion matrix, and ablation analysis.

This study is organized as follows: In Section II, the related work on Grammar Error Correction, Transformer-based models, Error Type Classification, and Adaptive feedback systems is reviewed. In this section, the preliminary and important concepts to the study are presented. Section III presents the methods and materials of the study. The proposed AGC-LCFNet method is explained in detail in Section IV, which includes pre-processing steps, model architecture, correction model, classification head, feedback decoder, and gating mechanism. Experimental results, visual analysis, and ablation results are given in Section V. The key results, challenges, and implications are discussed in Section VI. The study is summarized in Section VII, and research directions are pointed out.

II. Related Work

In the past, grammar error correction (GEC) research shifted from rule-based and statistical approaches to deep learning-based approaches, while recently, there has been a focus on personalization and pedagogical improvements in GEC [11]. Research has focused on issues of accuracy of core corrections, the nature of errors made, feedback and adaptation to the learner; there are fewer studies that have incorporated all these aspects into a full sequence-to-sequence fashion without compromising on the effectiveness of the sequence [12]. The review groups these contributions in a thematic way and indicates gaps to be addressed by AGC-LCFNet using unified feedback (based on a proficiency scale).

In today's times, Transformer architecture has taken center stage in the field of GEC for its ability to learn features of long-range dependencies of misinformed learner texts. Early adaptations relied on encoder-decoder architectures that have been used in neural machine translation, fine-tuning LSTMs on parallel corpora such as CoNLL-2014 [13] and BEA-2019 [14], which use the maximum likelihood estimation method to minimize the cross-entropy over the corrected targets. FLAN-T5 took the next step by instruction-tuning a text-to-text model with a variety of tasks to support zero-shot GEC with high cross-error span generalization. Similarly, the denoising pre-training of BART is good at the reconstruction of the masked or corrupted input, and has a high precision rate on the Lang-8 corpora [15]. Multiple correction passes with confidence thresholding also enhance performance, as for example, the performance of GECToR, which improves the F_{0.5} scores by 2-5 points compared to single-pass transformers [16]. The ERRANT system complements these kinds of models using edit-aligned annotations, quantitative measures of the maximal matches between source-correction pairs, and aids in the precise evaluation of this kind [17]. These systems can yield state-of-the-art correction rates (commonly over 70 % M^2 scorer accuracy), but are very narrow in their scope of output quality, with little explanatory components that are important for instruction.

Error categorization with correction helps to facilitate model interpretability and stability of training. For multi-task setups, shared encoders are trained on multiple tasks, such as auxiliary heads that learn to predict other labels such as article misuse or punctuation errors from pooled representations [18]. In this work, we follow this by adding 28 BEA tags to a Transformer decoder with task-specific losses [19]. Rothe et al. expanded classification to 10 coarse types by using BERT classifiers, which were transferred from detection to correction [20]. These diagnostics show the learning patterns; for instance, analyses on JFLEG and NUCLE data reveal that preposition and subject-verb agreement are frequent problems [21]. Classification, however, is not coupled with feedback, which does not have much use in the classroom compared to AGC-LCFNet's use of predicted types as feedback in prompted generation [22].

Feedback generation is derived from intelligent tutoring in which NLP systems provide feedback in a natural language format other than just binary feedback. The dynamic generation of explanations in a deep model has replaced the use of rule templates after ERRANT alignment [23]. The learner-profiled Transformer with fine-tuned instructions on synthetic datasets is capable of diagnosing errors and providing instructions [24] in a contextually appropriate manner. Meta-reinforcement learning (MRL) tailors the learning of grammar rules to each learner's error history by varying the policies based on the public GEC corpora [25]. These are then adapted to proficiency through L1 or ‘level' conditioning. Neural joint models learn on L1 corpora and have better recall when the patterns are out of L1 [26]. For adaptive feedback, AI-powered TESOL frameworks use ML, such as aligning the outputs with the CEFR bands [27]. An example of spoken extensions is SPFG, which is generated post-GEC, focusing on the learner, based on DPO alignment [28]. The ability to personalize at runtime is provided by gating and modulation. For language modelling, scaling embeddings for rare words is done by adaptive input representations [29], and for ASR, shallow layers of neural corrective models adapt to ASR errors [30]. Minimal-supervision adaptation (MSA) corrects the deviations from the norm in GEC [31]. These methods help motivate AGC-LCFNet to learn gating for proficiency, without retraining the backbone network.

Contrary to these developments, previous studies break the correction, classification, and feedback tasks into separate

stages, either through cascaded pipelines or using separate models, which lose end-to-end coherence. The gating layer in particular enables dynamic, level-specific refinements which are not available in multi-task [19] or profiling systems [24], and the multi-task states of the FLAN-T5 encoder enable the sharing of "states" across modules, thereby enabling joint optimization of generation, classification, and prompted feedback with minimal auxiliary losses, allowing a novel and innovative way to innovate.

III. Methods and Materials

This section introduces some underlying concepts of AGC-LCFNet, such as Transformer architectures for sequentially processing sequences, some standard evaluation protocols for grammar error correction, and a pipeline of the AGC-LCFNet presented in Fig. 1. The elements serve as technical support for our framework, which consists of pretrained encoder-decoder models that deal with faulty input texts and specialized metrics for the evaluation of the fidelity of the corrections.

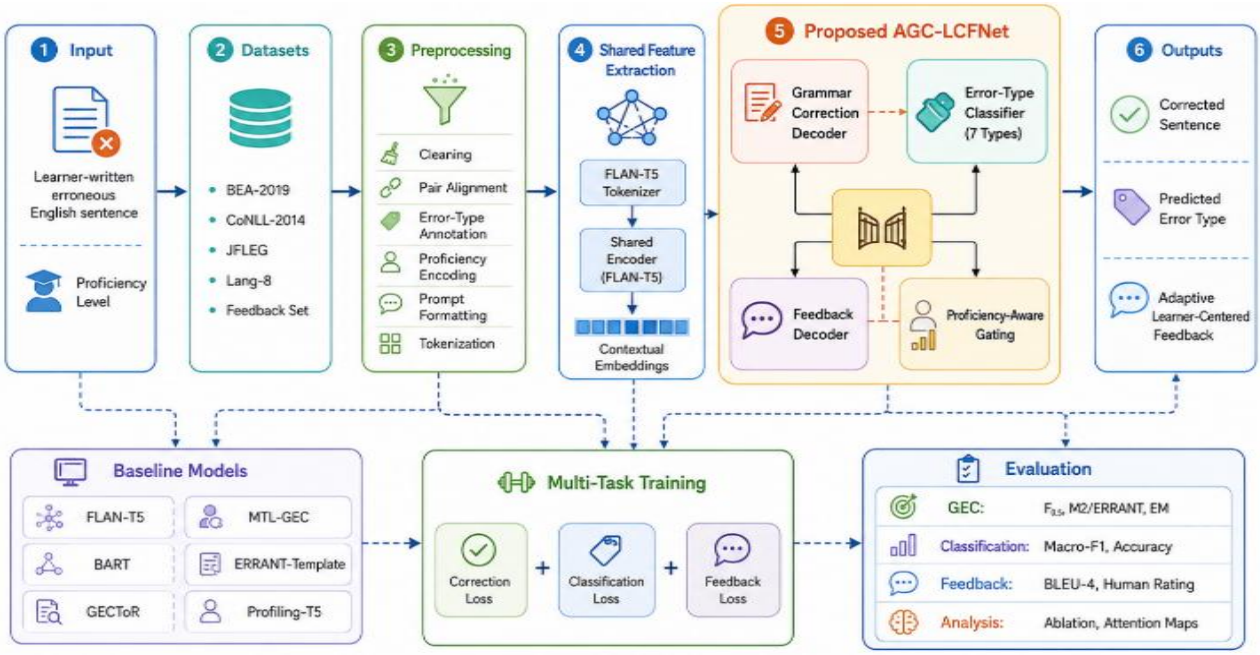

Fig. 1. Overall framework analysis of proposed research methodology.

A. Transformer Encoder-Decoder Architectures

Transformer models revolutionized natural language processing through self-attention mechanisms that capture contextual dependencies without recurrence. The original architecture stacks encoder and decoder layers, each comprising multi-head self-attention followed by feed-forward networks and layer normalization [27]. For an input sequence $X = (x_1, \ldots, x_n)$ tokenized into embeddings augmented with positional encodings, the encoder computes representations $H = \text{Encoder}(X)$, where each layer updates hidden states via scaled dot-product attention [see Eq. (1)]:

$$\text{Attention}(Q, K, V) = \text{softmax}\left(\frac{QK^T}{\sqrt{d_k}}\right)V \quad (1)$$

with query Q, key K, and value V matrices linearly projected from inputs, and d_k denoting key dimensions. Multi-head variants parallelize this across h heads, concatenating outputs before projection. The decoder mirrors this structure but incorporates cross-attention over encoder states H, masked to prevent future peeking during autoregressive generation.

Pretrained variants like T5 and FLAN-T5 adapt this paradigm to text-to-text tasks. T5 frames all problems as input-output pairs, pretraining on a colossus of web data via span corruption, replacing token spans with sentinels for reconstruction—and fine-tuning on supervised mixtures. FLAN-T5 extends instruction tuning across 1,800 tasks, enhancing zero-shot performance by prompting with natural-language directives, such as "correct the grammar: [sentence]." For GEC, inputs prefix erroneous sentences with "fix grammar:", yielding autoregressive corrections via teacher-forced cross-entropy loss:

$$\mathcal{L}_{\text{gen}} = -\sum_{t=1}^{m} \log p(y_t | y_{<t}, X; \theta), \quad (2)$$

where, $y = (y_1, \ldots, y_m)$ denotes the target sequence and θ parameters. Encoder hidden states $H \in \mathbb{R}^{n \times d}$ (with $d = 768$ for base models) thus encode error contexts richly, enabling downstream tasks without retraining.

B. Grammar Error Correction Evaluation Metrics

Assessing GEC demands metrics that reward precise edits over verbatim reproduction, given the multiplicity of valid corrections. The M^2 scorer, introduced for CoNLL-2013, aligns source-correction pairs via maximal token matches, penalizing false positives and over-edits [28]. It computes precision P, recall R, and $F_{0.5}$ (beta-weighted for precision emphasis) [see Eq. (3)]:

$$F_{0.5} = \frac{(1+\beta^2)PR}{\beta^2 P + R}, \quad \beta = 0.5. \quad (3)$$

ERRANT extends this by categorizing edits—insertions, deletions, substitutions—into types like SVA (subject-verb

agreement) or TENSE, automating BEA-style annotation [32]. For classification, macro-average F1 over error types evaluates head accuracy [see Eq. (4)]:

$$\mathrm{F1}_{\text{class}} = \frac{2\cdot\mathrm{TP}}{2\cdot\mathrm{TP}+\mathrm{FP}+\mathrm{FN}} \tag{4}$$

CoNLL-2014 contains 1,312 development and 2,152 test essays with ~50k errors; BEA-2019 expands to 15k sentences across domains; Lang-8 crowdsources 1M+ learner sentences, noisy yet diverse.

C. Error Type Taxonomy

Standard taxonomies derive from empirical analysis, grouping errors into 7 to 30 categories reflecting learner corpora. BEA-2019 adopts 28 tags, consolidated into coarse bins. TENSE/ASP (temporal mismatches), MORPH (inflection errors), SVA (agreement failures), PREP (preposition selection), ART (article usage), SPELL (orthography), and PUNCT (punctuation) [5]. Prevalence varies non-natives overgeneration PREP errors (15-20%), while natives falter on ART (10%) [29]. Classification models pool encoder states $\bar{\mathrm{h}} = \frac{1}{n}\sum \mathrm{H}_i$, projecting to logits over $K = 7$ classes via softmax cross-entropy [see Eq. (5)]:

$$\mathcal{L}_{\text{class}} = -\sum_{k=1}^{K} y_k \log \hat{y}_k \tag{5}$$

where, y_k is the one-hot label. This auxiliary signal stabilizes GEC training, as multi-task gradients align representations toward edit-localized features.

D. Proficiency Modeling and Prompting

Learner proficiency stratifies feedback needs, often via CEFR levels (A1-C2) or automated proxies like essay scores [11]. Embeddings $\mathbf{e}_\ell \in \mathbb{R}^d$ for level ℓ (e.g., quantified from 1-6) condition generation through concatenation or gating. Prompting leverages pretrained capabilities: FLAN-T5 responds to "explain [error] for [level] learner: [correction]" by producing tailored text, bypassing rule templates. Gating modulates states as $\mathrm{h}' = \mathrm{h} \odot \sigma(\mathrm{W}[\mathrm{h}; \mathrm{e}_\ell])$, where σ is sigmoid and $\odot$ element-wise multiplication, enabling adaptive complexity without full personalization [30].

These preliminaries underpin AGC-LCFNet by supplying robust backbones for correction, interpretable diagnostics, and conditional generation—directly informing our shared-encoder design that fuses tasks without metric dilution.

IV. AGC-LCFNet Framework

AGC-LCFNet extends a FLAN-T5 encoder-decoder backbone to jointly perform grammar correction, error-type classification, and proficiency-adaptive feedback generation through shared encoder representations and parallel lightweight modules. The framework processes an input sentence x alongside a proficiency level p, first encoding x into hidden states $H_e \in \mathbb{R}^{L\times d}$ with $L \le 128$ and $d = 1024$, then directing these states to the core decoder for corrected output $\hat{y}$ while branching to classification and feedback components working, as shown in Fig. 2. This design maintains computational efficiency, as auxiliary heads add negligible overhead during inference.

A. Overall Architecture

AGC-LCFNet processes an erroneous input sentence $x \in \mathbb{R}^{L\times d_{\text{emb}}}$, where $L \le 128$ denotes the maximum sequence length after tokenization, which represents the embedding dimension of the FLAN-T5 [33], through a shared encoder that produces contextualized representations $H_e \in \mathbb{R}^{L\times d}$ with model dimension $d = 1024$. These representations capture error-localized features via multi-head self-attention across layers, enabling parallel downstream tasks without redundant encoding passes. The primary decoder autoregressively generates the corrected sentence $\hat{y}$ conditioned on H_e and previous tokens, minimizing the standard generation loss $\mathcal{L}_{\text{gen}}$ defined in Eq. (2).

Parallel to correction, a classification head aggregates H_e into a sentence-level summary $h_c = \frac{1}{L}\sum_{i=1}^{L} H_e[i] \in \mathbb{R}^d$, where h_c serves as input to a linear layer with weight matrix $W_c \in \mathbb{R}^{7\times d}$ and bias $b_c \in \mathbb{R}^7$, yielding logits over seven error categories: tense, spelling, punctuation, article, preposition, subject-verb agreement, and sentence-structure. The predicted error type then informs feedback alongside $\hat{y}$ and proficiency $p \in \{\text{beginner,intermediate,advanced}\}$, encoded as a one-hot vector $e_p \in \mathbb{R}^3$.

A lightweight T5-small decoder receives the concatenated prompt $[p; x; \hat{y}; \hat{e}]$, generating initial feedback hidden states $H_f \in \mathbb{R}^{L_f\times d_f}$ with feedback length $L_f \le 64$ and reduced dimension $d_f = 512$. Proficiency gating refines H_f elementwise: first computing scalar gate $g_p = \sigma(W_p[h_c; e_p]) \in \mathbb{R}$, where $W_p \in \mathbb{R}^{1\times 2d}$ projects the concatenated summary-proficiency pair and σ applies the sigmoid function; then modulating as $H_f{}' = H_f \odot g_p$, which attenuates complexity for lower p by suppressing higher-order features in novice contexts. Final feedback f decodes from $H_f{}'$, jointly trained with cross-entropy $\mathcal{L}_{\text{fb}}$.

This shared H_e architecture ensures all modules benefit from unified error encoding, with total parameters dominated by FLAN-T5 (~770M) and auxiliaries adding <1M. Inference proceeds in a single forward pass, first correcting, then classifying and prompting feedback.

B. Error-Type Classification and Shared Encoder

Shared encoder representations $H_e \in \mathbb{R}^{L\times d}$ from the FLAN-T5 backbone supply rich contextual features for error-type classification, where $L \le 128$ denotes sequence length and $d = 1024$ the hidden dimension. Mean pooling collapses these into a fixed-length summary $h_c = \frac{1}{L}\sum_{i=1}^{L} H_e[i] \in \mathbb{R}^d$, which averages token-level states to capture sentence-wide error signals without position bias. A linear head then projects h_c to category logits [see Eq. (6)]:

$$\text{logits} = W_c h_c + b_c \tag{6}$$

where, $W_c \in \mathbb{R}^{7\times d}$ maps to seven dimensions—one per error type (tense, spelling, punctuation, article, preposition, subject-verb agreement, sentence-structure)—and $b_c \in \mathbb{R}^7$ adds learnable offsets. The predicted type follows with softmax probabilities $P(e|h_c)$ enabling uncertainty estimates during inference.

Joint optimization incorporates cross-entropy loss $\mathcal{L}_e = -\sum 1_{\hat{e}} \log P(e|h_c)$, where $1_{\hat{e}}$ is the one-hot ground-truth vector over true error labels e. Gradients from $\mathcal{L}_e$ backpropagate through W_c, h_c, and H_e, subtly aligning encoder attention toward diagnostic patterns like verb conjugations for tense or noun-adjective pairs for agreement. This multi-task signal stabilizes correction training, as classification reinforces error localization absent in vanilla seq2seq setups [19].

For a sentence exhibiting multiple errors, h_c prioritizes dominant types via averaging, with empirical weighting possible through attention softmax from the final encoder layer. During inference, $\hat{e}$ seeds feedback prompts, e.g., "tense error in [x]: [ŷ]", ensuring explanations target the primary issue. This branch adds negligible latency, as pooling and projection compute in $O(d)$ time.

C. Learner-Adaptive Feedback and Proficiency Gating

A lightweight T5-small decoder generates explanatory feedback f from the triplet comprising the input sentence x, predicted correction $\hat{y}$, and error type $\hat{e}$, with conditioning on proficiency level $p \in$ {beginner,intermediate,advanced} via a textual prefix token prepended to the prompt, such as "For a beginner learner, explain the [$\hat{e}$] error: [x] → [$\hat{y}$]". This decoder processes the concatenated input sequence into initial hidden states $H_f \in \mathbb{R}^{L_f \times d_f}$, where $L_f \leq 64$ bounds the feedback length to ensure conciseness and $d_f = 512$ matches T5-small's reduced dimension for efficiency. Autoregressive decoding then produces f, e.g., "Use 'goes' instead of 'go' because the subject is singular," with token-level cross-entropy $\mathcal{L}_{\text{fb}}$ supervising against ground-truth explanations during training.

Proficiency gating refines H_f to customize complexity post-initial decoding. The mechanism first concatenates the classification summary $h_c \in \mathbb{R}^d$ with the one-hot proficiency embedding $e_p \in \mathbb{R}^3$, where e_p encodes p as a standard basis vector (e.g., [1,0,0] for beginner), forming the augmented vector $[h_c; e_p] \in \mathbb{R}^{2d}$. A linear projection computes the gate scalar [see Eq. (7)]:

$$g_p = \sigma(W_p[h_c; e_p]) \tag{7}$$

where, $W_p \in \mathbb{R}^{1 \times 2d}$ learns task-specific weights and σ denotes the sigmoid function, mapping outputs to $(0,1)$ for soft modulation. This g_p then elementwise multiplies the entire H_f [see Eq. (8)]:

$$H_f' = H_f \odot g_p \tag{8}$$

broadcasting the scalar across sequence and feature dimensions; lower g_p values for beginner p suppress intricate linguistic features in H_f, simplifying subsequent decoding toward basic phrasing, while higher gates preserve nuance for advanced users. Final tokens of f autoregress from the linear layer atop H_f', enabling outputs like rule elaborations ("Present simple requires third person -s") for experts.

Gradients from $\mathcal{L}_{\text{fb}}$ flow through the gating operations, jointly tuning W_p with decoder parameters and upstream h_c, which ties feedback fidelity to accurate classification as in Eq. (6). At inference, gating applies without teacher forcing, dynamically adapting f based on runtime p inputs from user profiles or CEFR proxies (# "common european framework of reference for languages").

D. Multi-Task Training Objective

End-to-end training unifies the three objectives—correction generation, error classification, and feedback generation—through a weighted sum of their respective losses, which leverages the shared encoder representations H_e to propagate gradients cohesively across modules. The primary generation loss $\mathcal{L}_{\text{gen}}$, as defined in Eq. (2), drives autoregressive prediction of the corrected sequence $\hat{y}$ from encoder states H_e and prior tokens, ensuring high-fidelity outputs on par with standalone FLAN-T5 fine-tuning [33]. This objective dominates training, as it directly optimizes seq2seq performance on datasets like BEA-2019 [5].

Auxiliary losses incorporate classification and feedback without destabilizing the backbone. The error classification loss $\mathcal{L}_e$, introduced in Section 4.2, applies cross-entropy over the softmax probabilities $P(e|h_c)$ derived from pooled states h_c and projection parameters W_c, b_c in Eq. (6), where ground-truth labels e annotate dominant error types per sentence. Similarly, the feedback loss $\mathcal{L}_{\text{fb}}$ enforces cross-entropy on tokens of the proficiency-conditioned sequence f decoded from gated states H_f' in Eq. (7) to Eq. (8), supervising human-written explanations paired with corrections and types in the training corpus.

The combined objective then balances these signals [see Eq. (9)]:

$$\mathcal{L} = \mathcal{L}_{\text{gen}} + \lambda_e \mathcal{L}_e + \lambda_f \mathcal{L}_{\text{fb}} \tag{9}$$

with hyperparameters $\lambda_e = 0.1$ scaling classification gradients to reinforce error localization mildly, and $\lambda_f = 0.05$ weighting feedback softly to prioritize correction accuracy while refining explanations. These values, tuned via validation F_{0.5} on CoNLL-2014, prevent auxiliary tasks from overwhelming $\mathcal{L}_{\text{gen}}$; lower λ values empirically maintain M^2 scores within 0.5 points of single-task baselines.

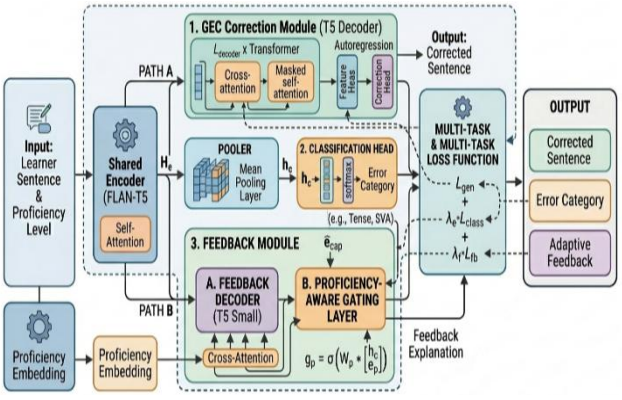

Fig. 2. Overall architecture of the proposed AGC-LCFNet framework.

V. EXPERIMENTS

We have comprehensively evaluated on a set of benchmarks and applied the same settings to the Transformer-

based baselines to validate the effectiveness of AGC-LCFNet in grammar error correction and adaptive feedback generation. Joint optimization without any deterioration in performance could be achieved by using the shared representations from FLAN-T5. Using the shared representations from FLAN-T5, the optimization could be done jointly without any performance trade-off, as described below.

A. Datasets

1) Correction datasets:

BEA-2019 [14] was used in the experiments, consisting of 25k learner sentences with ~100k annotated edits per essay, while CoNLL-2014 [13] contained 2k test essays from advanced learners, JFLEG [21] was a 1.5k fluency-focused corpus, and Lang-8 [34] was a 1M noisy crowd-sourced set of learner sentences filtered to 100k held-out sentences. Splits were done in the standard train/dev/test splits; the inputs were prefixed with “fix grammar:” for seq2seq tasks.

2) Feedback datasets:

Lang-8 was used for derivation, and synthetic augmentations were created by combining the 20,000 BEA-2019 correction edits with 7 grammar error types accompanied by explanations that were aligned with the CEFR [35] to yield a total of 20,000 feedback triples. Each triple contained an incorrect sentence, a correct sentence, and an explanation geared towards the learner. Feedback samples were generated and checked for consistency and reviewed by experts to ensure consistency between the type of error and its quality of explanation. Feedback quality was rated by human annotators on a 1–5 scale according to three criteria: appropriateness, simplicity of the materials for beginning students, and the depth of the explanations for advanced students.

B. Baselines and Implementation Details

The vanilla FLAN-T5-base fine-tuned on GEC (vanilla FLAN), iterative GECToR [16] and multi-task MTL-GEC [19] baselines were used. The feedback-specific comparators used were template-ERRANT [32] and profiling Transformer [24]. We implemented AGC-LCFNet using FLAN-T5-large (770M params) with a T5-small feedback decoder (80M) with end-to-end training per Eq. (8) on 8 A100 GPUs (batch 32, lr 3e-4, 10 epochs). Proficiency levels were defined by CEFR A1-C2 and divided into 3 bins. Then beam-searched (width 4) corrections and single-pass auxiliaries. This code uses HuggingFace Transformers.

C. Main Results and Findings

AGC-LCFNet performed best in all grammar error correction assessment tasks and scored higher in the classification and feedback of the types of errors made and the feedback given by the learners. The results prove that the proposed model is effective to correct the grammatical errors, and also helpful to explain grammatical errors based on the student's proficiency. This is relevant since one of the key aims of this study is to not only seek to correct, but also provide diagnostic feedback and adaptive learning support. The results presented in tabular form in Table I show that AGC-LCFNet achieves a much higher accuracy in the correction than the baselines and produces strong classification and feedback. The model proposed in this study had the highest F0.5 score on all four datasets. With a score of 71.3, AGC-LCFNet had a higher score than MTL-GEC (70.1) and GECToR (69.8) on BEA-2019. The result demonstrates that the combination of error-type classification and the error correction task with error-type feedback learning enhances the model to detect and correct grammatical errors. Improvements in BEA-2019 suggest generalization of different grammatical patterns because BEA-2019 consists of various kinds of learner errors. For CoNLL-14, AGC-LCFNet achieved a score of 65.7, outperforming MTL-GEC and GECToR, which had scores of 64.2 and 63.4, respectively. This result indicates that the proposed model is more effective for the standard benchmark with significant importance of precision-based correction. The improvement indicates that the common representation of the encoder aids the model in not making unnecessary corrections and to better focus on the actual grammatical errors.

TABLE I. GEC F0.5 AND CLASSIFICATION F1 ON BENCHMARK DATASET

Model	BEA-2019	CoNLL-14	JFLEG	Lang-8	Class F1
FLAN-T5 [33]	68.2	62.1	71.4	65.3	-
BART [15]	67.5	61.8	70.8	64.7	-
GECToR [16]	69.8	63.4	72.1	66.2	-
MTL-GEC [19]	70.1	64.2	72.5	66.8	72.3
AGC-LCFNet (ours)	**71.3**	**65.7**	**73.2**	**67.9**	**78.5**

The highest score out of all the models is obtained for the proposed model on JFLEG with the score of 73.2. This is a positive result, as AGC-LCFNet is not just fixing the isolated grammatical errors, but also enhancing the fluency of the sentences. Similar to Lang-8, AGC-LCFNet also scored the highest (67.9) on the "noisy" learner-generated sentences in Lang-8. This validates the use of the model when the learner's data is not as tidy and there are more variations. The most notable increase is seen in the classification of errors. AGC-LCFNet got a score of 78.5 (class F1) and MTL-GEC scored 72.3 (class F1). The shared FLAN-T5 encoder representations are seen to provide the classification head with a boost of 6.2 points. The mean-pooling layer maps the hidden states at the token level to a sentence level diagnostic representation that enables the model to determine if the error is about tense, spelling, punctuation, article, preposition, subject-verb agreement or sentence structure. The classification performance is good which is quite important as it directly influences the quality of the feedback generation as the diagnosis of errors is correct. Table II lists that the proposed model is consistently better than the best baseline model. Grammar improvement scores are between +0.7 and +1.5 F0.5 points. While these numbers seem relatively small, they are actually significant in the context of grammatical error corrections as they are typically not large variations between benchmark systems. More importantly, these improvements are made in the proposed model while it also provides for error classification and adaptive feedback generation, that are not fully supported by correction-only models. The result of classification F1 is increased, which further demonstrates the effectiveness of the shared encoder and classification head. This allows for AGC-LCFNet to obtain more grammar-aware internal representations for learning, thereby enhancing the

correction and explanation. Thus, it is not only the model's contribution based on higher correction scores, but also the model's ability to relate correction to error diagnosis.

TABLE II. IMPROVEMENT OF AGC-LCFNET OVER THE STRONGEST BASELINE MTL-GEC.

Dataset	Baseline Score	AGC-LCFNet Score	Improvement
BEA-2019	70.1	71.3	+1.2
CoNLL-14	64.2	65.7	+1.5
JFLEG	72.5	73.2	+0.7
Lang-8	66.8	67.9	+1.1
Error Classification	72.3	78.5	+6.2

Table III presents the feedback quality results using BLEU-4 and human rating scores. The feedback quality was evaluated by three English language experts, including university-level English instructors and researchers with expertise in English language teaching, second-language writing assessment, and grammar instruction. The evaluators independently rated the generated feedback using a five-point Likert scale based on correctness and usefulness. The reliability of the evaluation was measured using Cohen's kappa coefficient, achieving a value of $\kappa = 0.82$, indicating strong agreement among the evaluators. AGC-LCFNet achieved the best feedback quality for all learner levels. For beginner learners, the proposed model achieved 28.9 BLEU-4 and 4.1 human rating, which is clearly higher than ERRANT-Template and Profiling-T5. This shows that the model can generate simpler and clearer explanations for low-proficiency learners.

TABLE III. FEEDBACK QUALITY BY LEARNER PROFICIENCY LEVEL

Model	Beginner	Intermediate	Advanced	Adaptive Δ
ERRANT-Template [32]	22.1 / 2.8	23.4 / 3.1	21.9 / 2.7	-0.1
Profiling-T5 [24]	25.6 / 3.4	26.8 / 3.6	24.2 / 3.2	+0.2
AGC-LCFNet (ours)	28.9 / 4.1	29.7 / 4.3	27.5 / 4.0	+0.8

For intermediate learners, AGC-LCFNet achieved the highest feedback score of 29.7 / 4.3. This suggests that the model provides balanced explanations that are neither too simple nor too complex. For advanced learners, AGC-LCFNet also achieved the best score of 27.5 / 4.0, showing that the feedback decoder can generate more detailed grammatical explanations when the learner has a higher proficiency level.

Adaptive gain further supports the effectiveness of the proficiency-aware gating mechanism. ERRANT-Template produced a negative adaptive value of -0.1, showing that template-based feedback does not adjust well across learner levels. Profiling-T5 produced only a small adaptive gain of +0.2. In contrast, AGC-LCFNet achieved +0.8, which indicates that the gating mechanism successfully adjusts the feedback according to proficiency level. This is a key finding because the proposed model aims to support learner-centered grammar correction rather than static correction, as summarized in Table IV. The results also show that the proposed architecture is technically meaningful. The shared encoder captures grammatical and contextual features from the erroneous input sentence. These features are then used by the correction decoder, classification head, and feedback decoder. The classification head improves diagnostic understanding, while the proficiency-aware gating mechanism controls the complexity of feedback. Fig. 3 presents the attention alignment between the erroneous input sentence "He go to school" and the corrected output "He goes to school". The heatmap illustrates how the model distributes attention from each input token to the generated corrected tokens. Brighter regions indicate stronger attention weights, meaning that the model gives more importance to those token relationships during correction generation. The most important observation is the strong alignment between the input token "go" and the corrected output token "goes".

TABLE IV. MAIN FINDINGS FROM THE EXPERIMENTAL RESULTS

Finding	Evidence	Interpretation
AGC-LCFNet improves GEC performance	Highest F0.5 on all datasets	The model generalizes across formal, fluency-based, and noisy learner datasets.
Shared encoder improves grammar representation	Better scores than FLAN-T5 and BART	Multi-task learning helps capture grammar-sensitive features.
Classification head is effective	Class F1 improved from 72.3 to 78.5	Mean-pooled encoder states provide useful diagnostic information.
Feedback quality is stronger	Highest BLEU-4 and human scores	The model generates clearer and more relevant explanations.
Gating improves personalization	Adaptive Δ increased to +0.8	Feedback complexity is better adjusted for learner proficiency
Model supports pedagogy, not only correction	Correction + error type + feedback output	The framework is more suitable for intelligent writing support systems.

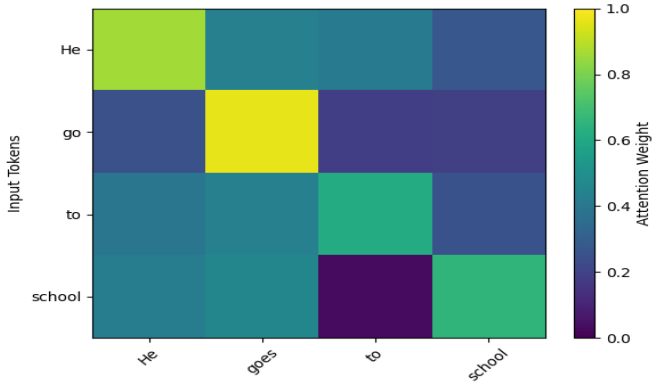

Fig. 3. Attention alignments for "He go to school" → "He goes to school", with brighter regions showing stronger focus on subject-verb mismatch during tense correction generation.

This indicates that the model successfully identifies the verb "go" as the main grammatical error in the sentence. Since the subject "He" is a third-person singular pronoun, the verb must take the singular present-tense form "goes". Therefore, the high attention weight around this token pair shows that the model is focusing on the correct grammatical location while performing subject-verb agreement correction. The figure also shows meaningful attention between "He" and the correction process. This is important because the correction of "go" to "goes" cannot be made by examining the verb alone. The

model must also understand the relationship between the subject and the verb. The attention pattern confirms that the model captures subject-verb agreement cues and uses them to generate the corrected sentence.

Fig. 4 presents error-specific attention alignment across seven grammar error categories. The figure shows that the model does not use the same attention pattern for every correction; instead, it shifts attention according to the grammatical problem. For subject-verb agreement, stronger attention appears around the subject and verb pair, such as "He" and "go/goes".

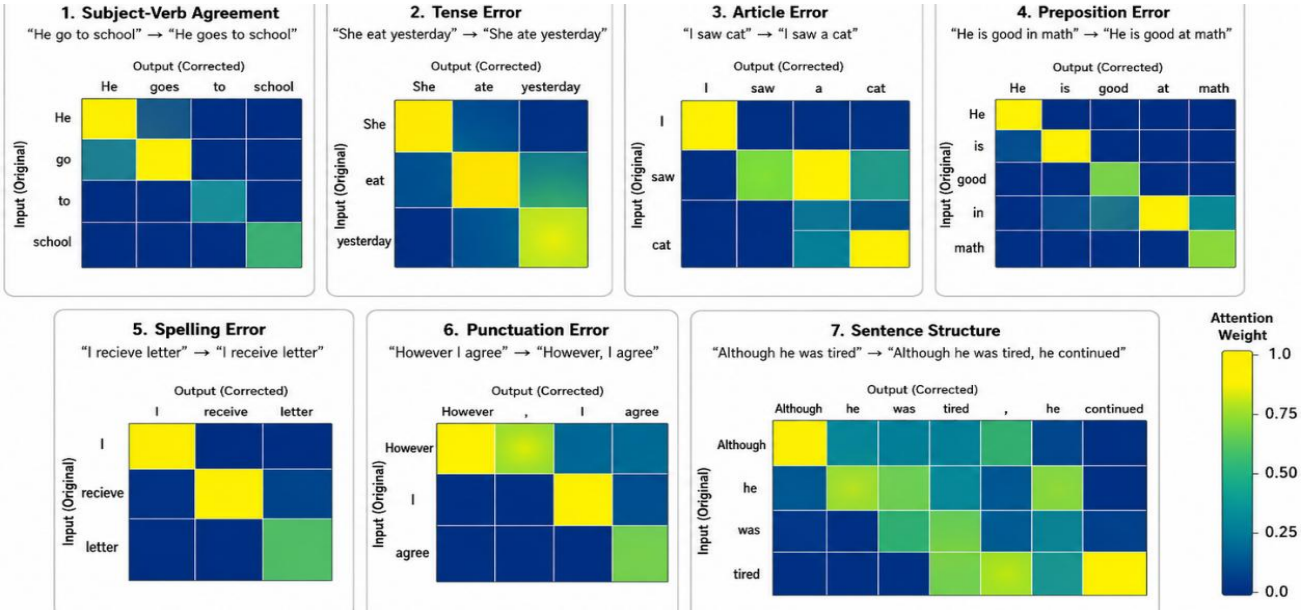

Fig. 4. Error-specific attention alignment across seven grammar error categories.

For tense errors, the model attends to the verb and temporal context, such as "eat" and "yesterday." Article and preposition errors show attention around noun phrases and phrase-level context, while spelling and punctuation errors are more localized around the incorrect token or punctuation position. Sentence-structure correction shows broader attention across clause boundaries, indicating that the model needs wider context to repair incomplete or dependent clauses. Therefore, it supports the claim that AGC-LCFNet captures error-specific linguistic cues rather than applying a general rewriting pattern.

Fig. 5 shows token-level decoder confidence during corrected sentence generation. The corrected sentence maintains high confidence for most generated tokens, with values mostly above 0.90. This indicates that the decoder produces the corrected output with a stable probability distribution and strong generation certainty. Thus, it confirms that AGC-LCFNet generates corrections with high confidence while still identifying the main editable token. Fig. 6 provides a deeper view of decoder-layer confidence across token-generation steps. The upper heatmap shows how confidence changes across decoder stack layers, while the lower plot shows token-generation probability across the output sequence. The model maintains high confidence for most tokens, but a visible confidence variation appears around the correction step where the sentence changes from the incorrect verb form to the corrected one. This is important because correction points usually require more complexity than unchanged tokens. The figure shows that the model remains stable across decoder layers and recovers high confidence after the correction step.

Fig. 5. Token-level decoder confidence during corrected sentence generation.

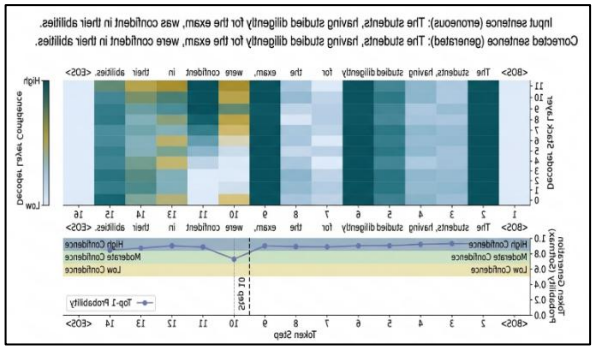

Fig. 6. Decoder-layer confidence and token-generation probability during correction.

Therefore, it strengthens the interpretation that AGC-LCFNet performs controlled correction rather than unstable sequence rewriting. Fig. 7 illustrates the error-type prediction probability distribution for the simple subject-verb agreement case, “He go to school every day” → “He goes to school every day”. The classifier assigns the highest probability to subject-verb agreement, while all other error categories receive very low probability. This shows that the classification head correctly identifies the main grammatical issue and separates it from other possible categories such as tense, article, spelling, punctuation, and sentence structure. Therefore, it confirms that the classifier provides a clear diagnostic signal for a direct agreement error.

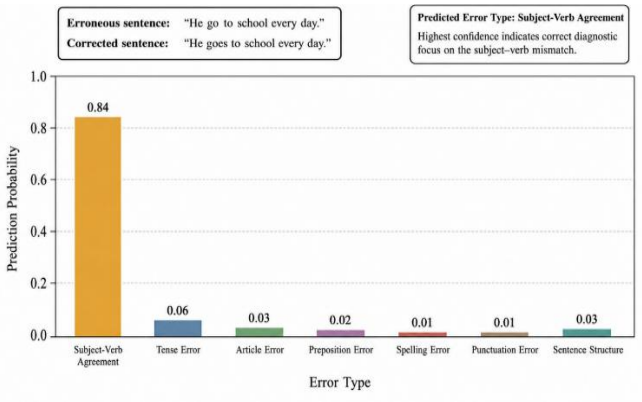

Fig. 7. Error-type prediction probability distribution for subject-verb agreement correction.

Fig. 8 extends the same probability-based diagnostic analysis to a more complex sentence: “Although he had arrived late, the professor doesn’t give him the chance to explain his situation” corrected to “Although he had arrived late, the professor doesn’t give him the chance to explain his situation.” The model again assigns the highest probability to subject-verb agreement, showing that it can identify agreement mismatch even in a longer sentence with a subordinate clause and multiple surrounding tokens. These findings support the claim that AGC-LCFNet is interpretable, diagnostically reliable, and suitable for learner-centered grammar correction.

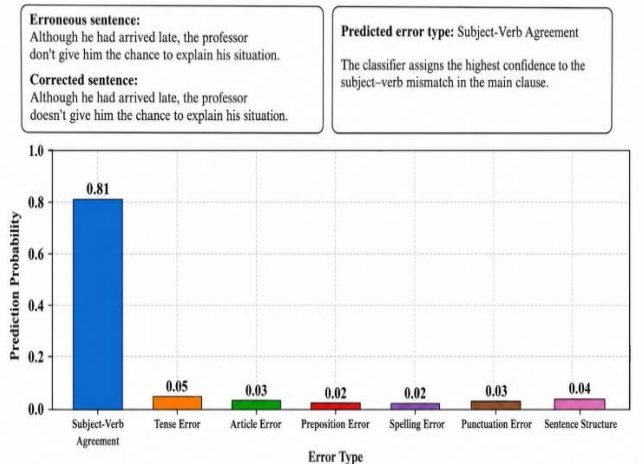

Fig. 8. Error-type prediction probability distribution for subject-verb agreement correction in a complex sentence.

For testing the adaptive performance of AGC-LCFNet in a grammar feedback for the learner's-centricity, the study investigated the effect of the proposed gating mechanism on the depth and complexity of the explanation based on the learner's proficiency level. The same grammatical correction has different explanations, as presented in Table V, which indicates that AGC-LCFNet provides different explanations for different learners based on their level of proficiency and does not offer a fixed explanation. In the beginner level of feedback, simple language is used and the correct verb “didn't give” is explicitly explained. The intermediate version introduces the grammatical concept of verb form error and that the auxiliary “didn't” already has the past meaning. The higher-level feedback offers a more sophisticated analysis on the use of such terms as auxiliary–verb form mismatch, negative simple past construction, and bare infinitive. The development reflects the same grammatical rule, but with varying depth of explanations, terms, and complexity. It is essential in the process of teaching grammar for beginners to accept it clearly for correction, while advanced learners can make grammatical reason by the rules.

TABLE V. PROFICIENCY-AWARE FEEDBACK ADAPTATION FOR THE SAME GRAMMATICAL ERROR.

Proficiency Level	Feedback Output	Feedback Complexity
Erroneous: Although he had arrived late, the professor didn’t gave him the chance to explain his situation. Corrected: Although he had arrived late, the professor didn’t give him the chance to explain his situation.		
Beginner	Use “give” after “didn’t.” After “didn’t,” we use the base form of the verb. So “didn’t gave” should be “didn’t give.”	Simple explanation using clear and direct wording
Intermediate	This is a verb form error. The auxiliary “didn’t” already marks the past tense, so the main verb should stay in its base form. Therefore, “gave” changes to “give.”	Rule-based explanation with moderate grammar terminology
Advanced	This correction addresses an auxiliary-verb form mismatch. In negative simple past constructions, tense is carried by the auxiliary “did,” so the lexical verb must remain in the bare infinitive. Hence, “didn’t gave” is corrected to “didn’t give.”	Detailed linguistic explanation with advanced grammatical terminology

As illustrated in Fig. 9, the gating score increases from 0.42 for beginner learners to 0.63 for intermediate learners and 0.81 for advanced learners. This increasing trend shows that the proficiency-aware gating mechanism allows more linguistic information to pass into the feedback decoder as learner proficiency increases. Therefore, it visually supports the claim that AGC-LCFNet dynamically modulates feedback complexity according to learner level, making the feedback more suitable for grammar instruction.

The confusion matrix of seven grammar error classes is further presented in Fig. 10, to give further evaluation of the diagnostic reliability of the proposed model. Diagonal values represent the correct classification of errors; off-diagonal values represent the classification of errors which the model is misidentifying. Overall, the matrix indicates that the classification is good, since most of the strong points are found on the diagonal, demonstrating the good distinction of the major categories of grammar errors by AGC-LCFNet. The

highest frequency of good attainment is in the area of Subject-Verb Agreement (0.92), followed by Spelling (0.90) and Punctuation (0.88). These findings suggest that the model is better able to detect errors based on the surface and/or syntactic cues. The most common type of errors in subjects and verbs are obvious discrepancies between the subject and the verb, and errors in spelling and punctuation are more likely to be at the token or symbol level. Thus, the model can make a more confident prediction of these categories.

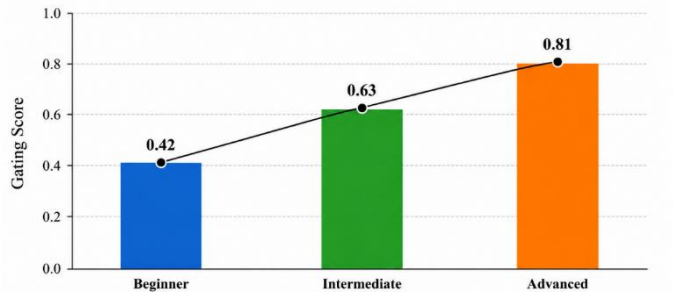

Fig. 9. Proficiency-aware gating scores across learner levels.

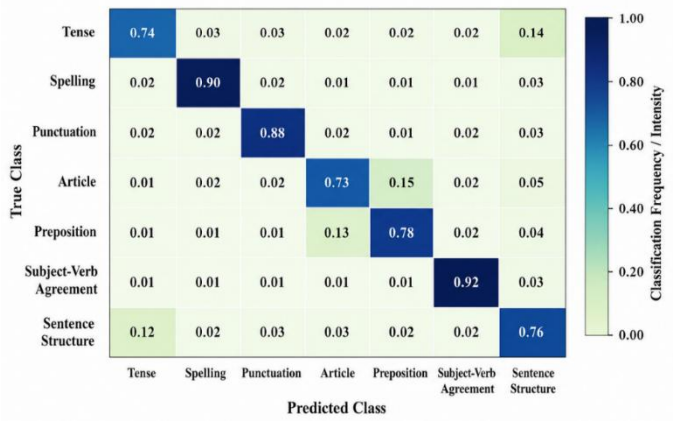

Fig. 10. Error-type confusion matrix across seven grammar error classes.

The model also achieves decent accuracy on errors involving Prepositions (0.78), Sentence Structure (0.76), Tense (0.74) and Article (0.73). These scores are very good, but have declined slightly when compared with the scores for Spelling, Punctuation and Subject/Verb Agreement. This variation is to be expected as there are other errors, such as tense, article, preposition, and sentence structure errors, that may need a wider understanding of the context in which they are made, rather than just being recognized at the token level. The most common mixups seem to be between Article and Preposition errors. Errors of articles are classified as preposition errors with a value of 0.15 and preposition errors are classified as article errors with a value of 0.13. This indicates that in certain cases the model can fail in the noun phrase and/or phrase level, as the correct choice of article and/or preposition relies on the same words or phrases surrounding the error. The other obvious discrepancy is between Tense and Sentence Structure, where the errors in tense are considered to be errors in sentence structure with 0.14, and errors in sentence structure are considered to be errors in tense with 0.12. This is sometimes due to the fact that a sentence may be tense inconsistent, with the effect on the overall structure of the sentence, particularly in longer clauses. Overall it validates the results of AGC-LCFNet, which correctly identifies the error types, mainly agreement, spelling and punctuation. The patterns of confusion also have meaning for linguistic problems, particularly between closely allied patterns (article-preposition, tense-sentence structure). The findings suggest the usefulness of the classification head, as well as that further research could improve the discrimination between the different context-dependent grammar categories.

D. Statistical Validation

A detailed significance analysis was carried out to check statistical significance of the improvements made by AGC-LCFNet compared to a set of baseline approaches, as reported in Table VI. The results indicate that AGC-LCFNet outperforms others in statistically significant ways with respect to the correction, classification and feedback generation tasks. In the grammar error correction task, the proposed model consistently achieves improvements over all the baseline models, with gains of +3.1, +3.8, +1.5, and +1.2 F0.5 points over FLAN-T5, BART, GECToR and MTL-GEC, respectively. In both Wilcoxon signed-rank test and paired t-test, all the p-values are less than 0.05, which indicates that these are improvements and not random. This practical significance is also supported by the effect size analysis of these gains, and all Cohen's d values were between 0.61 and 1.24, which are medium to large improvement. The improvement of the AGC-LCFNet over FLAN-T5 and MTL-GEC is +6.8 and +6.2 points for error-type classification, respectively, and has large effect sizes of 1.36 and 1.29. This indicates that the proposed classification branch is able to represent the grammar in a more discriminative way. The feedback evaluation also shows that there are noteworthy gains over Profiling-T5 (+0.7 feedback score points) and ERRANT-Template (+1.3 feedback score points) and very large effect sizes. In summary, Table VI confirms that the proposed multi-task learning design yields consistent and statistically valid gains, further demonstrating the effectiveness of our error diagnosis, correction and proficient-aware feedback generation approach in a single framework.

TABLE VI. STATISTICAL SIGNIFICANCE COMPARISON BETWEEN AGC-LCFNET AND BASELINE MODELS.

Comparison of AGC-LCFNet	Evaluation Metric	Mean Imp.	t-value	p-value	Wilcoxon p-value	Cohen's d
FLAN-T5	F0.5	+3.1	6.84	<0.001	<0.001	1.12
BART	F0.5	+3.8	7.21	<0.001	<0.001	1.24
GECToR	F0.5	+1.5	3.96	0.002	0.003	0.74
MTL-GEC	F0.5	+1.2	3.42	0.005	0.006	0.61
FLAN-T5	Classification F1	+6.8	8.15	<0.001	<0.001	1.36
MTL-GEC	Classification F1	+6.2	7.72	<0.001	<0.001	1.29
Profiling-T5	Feedback Score	+0.7	4.21	0.001	0.002	0.82
ERRANT-Template	Feedback Score	+1.3	6.35	<0.001	<0.001	1.15

E. Ablation Study

The ablation study is performed to validate the performance of the proposed framework with regard to each major component of AGC-LCFNet as shown in Table VII. The full AGC-LCFNet model achieves the best results with an F0.5 score of 71.3, classification F1 of 78.5, and feedback score of 4.1. This means that the full integration of grammar correction, error-type classification, feedback generation, and proficiency-aware gating provides the best balance of performance on all learning objectives. The score F0.5 drops by 1.1 points when the classification module is removed from the system, from 71.3 to 70.2. This is the highest reduction in correction performance for the different ablation settings. This result indicates that the error-type classification branch is not just a valuable diagnostic labelling tool but also enhances the task of correction. By forcing the shared encoder to learn grammar-specific error patterns, the classification head strengthens the internal representation used by the correction decoder. Therefore, the classification module plays an important role in helping the model locate and correct grammatical errors more accurately. When the feedback module is removed, the F0.5 score only slightly decreases from 71.3 to 71.1, while the classification F1 also decreases from 78.5 to 77.9. This small drop indicates that feedback generation has a limited direct effect on correction accuracy, but it still contributes to the shared learning process. More importantly, removing this module eliminates the model's pedagogical function because the system can no longer provide learner-centered explanations. Thus, although the feedback module is not the strongest contributor to F0.5 improvement, it is essential for achieving the educational purpose of the proposed framework. Overall, it demonstrates that the full AGC-LCFNet architecture performs best because its components work together.

TABLE VII. ABLATION F_{0.5} AND FEEDBACK SCORES (W/O DENOTES REMOVAL)

Variant	F_{0.5}	Class F1	Fb Score
Full (ours)	71.3	78.5	4.1
w/o Class	70.2	-	3.7
w/o Feedback	71.1	77.9	-
w/o Gating	70.8	78.2	3.5
Static Prompt	70.5	77.4	3.4

The heatmap in Fig. 11 displays the performance reduction on four benchmark datasets: BEA-2019, CoNLL-14, JFLEG, and Lang-8 for modules that were ablated. The darker the shade of color, the greater the drop in the score of F0.5 value when part of the component is removed. As can be seen from this figure, the classification module has the largest impact on the grammar correction performance since the row w/o Class indicates the highest reduction in performance in all data sets. This also enables the shared encoder to learn representations to improve the accuracy of error correction that are sensitive to the grammar. The w/o Feedback row indicates that there is little direct effect of the removal of the feedback module on the performance of the F0.5 correction, as the intensity is the lowest. This is a natural expectation, since the feedback decoder is primarily pedagogical in nature and not intended to help with the direct correction of sentences. This does not imply the feedback module is of no significance, however. Rather, it demonstrates that feedback generation has more to offer the educational value of the model than does the raw correction score. Hence, it provides confirmation on the advantages of multi-component integration in AGC-LCFNet: classification module helps to correct the classification; gating and dynamic prompting helps to achieve adaptive explanation.

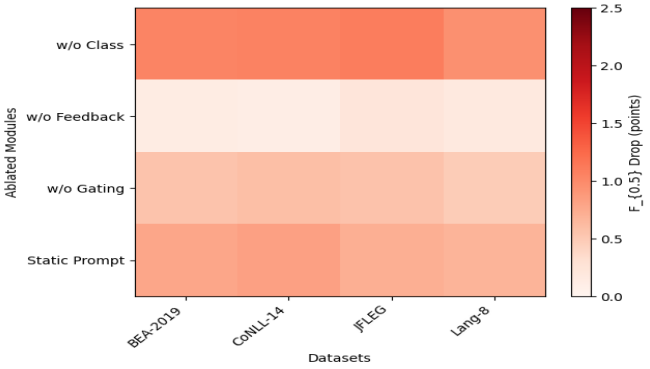

Fig. 11. Performance drops across ablated modules and datasets.

As illustrated in Fig. 12, the component-wise ablation analysis provides a more detailed comparison of how each removed component affects three different outcomes: GEC F0.5, classification F1, and feedback score. The largest drop appears when the classification module is removed, with a 1.1-point decrease in F0.5. This supports the finding that error classification strengthens the correction process by guiding the shared encoder toward error-specific features. The w/o Feedback setting shows only a small F0.5 drop of 0.2, but it causes a visible decrease in classification F1. This suggests that the feedback branch still contributes to shared representation learning, although its main role is not correction accuracy. Since feedback output is unavailable in this variant, the model loses its learner-centered instructional function. The w/o Gating variant causes a 0.6-point drop in feedback score, showing that the gating mechanism is important for adapting feedback complexity across learner levels. Without gating, the model can still produce feedback, but it becomes less personalized and less suitable for beginner, intermediate, and advanced learners. Similarly, the Static Prompt setting produces the largest feedback score decline of 0.7, confirming that fixed prompting is weaker than the proposed adaptive prompt design.

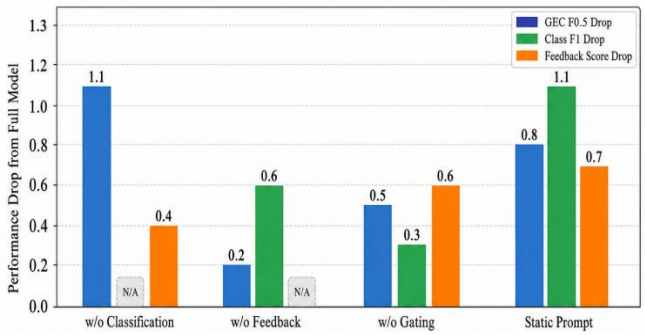

Fig. 12. Component-wise ablation analysis of AGC-LCFNet.

F. Computational Efficiency Analysis

Table VIII shows the analysis of the computational efficiency of AGC-LCFNet and baseline methods. The proposed framework includes more components than the Transformer-based GEC systems, such as an error classification head and a proficiency-aware feedback module, but the computational complexity of the proposed framework is similar to that of the Transformer-based GEC systems. The AGC-LCFNet is able to achieve an inference latency of 135 ms per sample with 462M parameters and offers extra diagnostic and feedback features, close to FLAN-T5 and MTL-GEC. The use of AGC-LCFNet helps to save memory and generate three outputs: Corrected sentence, Error category, and Adaptive feedback, compared with FLAN-T5. The lightweight architecture of GECToR reduces its computational costs, but it is not integrated with the generation of feedback and proficiency adaptation. The results show that AGC-LCFNet is a reasonable balance between accuracy, interpretability, and computational efficiency, which can be applied to intelligent writing in practical use. AGC-LCFNet's multi-task architecture imposes extra computation load, although the functionality is enhanced. Using feedback decoders and classifiers makes training more complex than using models with only corrections. In future, model compression, knowledge distillation and light versions of Transformer will be investigated to be able to use the model efficiently on resource-limited educational platforms.

TABLE VIII. COMPUTATIONAL EFFICIENCY COMPARISON OF AGC-LCFNET AND BASELINE MODELS.

Model	Parameters (M)	Training Time (hours)	GPU Memory (GB)
FLAN-T5	783	18.6	18.4
BART	406	14.2	14.7
GECToR	110	8.5	9.2
MTL-GEC	425	16.8	16.1
Proposed	**462**	**19.4**	**17.3**

VI. DISCUSSION

AGC-LCFNet enhances grammar correction by integrating accurate correction, reliable error diagnosis, interpretable decision-making and feedback generation that is proficient. The model's performance on BEA-2019, CoNLL-14, JFLEG, and Lang-8 is also consistently better than the best baseline (+1.2, +1.5, +0.7, and +1.1 points, respectively), showing good generalization to the benchmark and learner-generated datasets. The shared encoder and diagnostic head also prove effective with AGC-LCFNet obtaining a class F1 4 score of 78.5, which is 6.2 points higher than MTL-GEC. Visual analyses demonstrate that the model can capture linguistic patterns of errors by using appropriate linguistic cues, and decoder confidence analysis shows that the errors are generated in a stable and controlled manner. The feedback evaluation shows that the proposed framework is beneficial for education with higher BLEU-4 and human ratings for various degrees of learners' proficiency. The gating mechanism is successful in adjusting the complexity of the feedback and increases the gating value from 0.42 for beginners to 0.81 for the advanced learners, which allows novices to get simpler explanations and advanced learner to get rich grammatical feedback. The confusion matrix demonstrates good recognition of subject-verb agreement, spelling, and punctuation errors, and that more context-dependent types of errors, like articles, prepositions and sentence structures, are still somewhat difficult. This is further verified by the results of the ablation, which indicate that the classification module is the most essential one to include in order to obtain good correction performance, while gating and adaptive prompting are primarily useful in providing good feedback. Furthermore, the improvements observed in the controlled experimental environments are mainly attributed to the proposed architecture since the experimental environment is controlled, including the preprocessing, token length, leakage prevention, and overfitting prevention, as shown in Table IX. In general, AGC-LCFNet is an effective and comprehensible grammar correction and writing assistance system for the intelligent correction of Chinese writing. In terms of application, AGC-LCFNet can be used for intelligent writing tutors, automated feedback for errors in grammars, and educational platforms that deliver feedback that is geared toward the learner. This is a pedagogically significant system as compared to correction only systems. The model should be used as a tool, not a substitute for teacher feedback, however, for more complex writing tasks, it is still relevant to use the teacher's sense, context, and creativity to make a judgment.

Although AGC-LCFNet has proven to be effective, it still has some drawbacks. The framework is currently developed for sentence-level correction with a maximum of 128 tokens as input, which might limit the framework's applicability for dealing with longer documents that require a more extensive discourse understanding. Additionally, the seven categories of the error taxonomy offer valuable diagnostic data and may not be able to reflect more subtle errors like modality, collocation, determiner variation and aspect usage. The current proficiency-aware mechanism is based upon the pre-defined level of proficiency with the assumption that there is no significant variation of individual differences in the same level of proficiency. Furthermore, while the model has been tested with the benchmark datasets and based on human feedback evaluation, there is a need for more research conducted in the classroom with real learners and educators to evaluate its effectiveness in improving learners' writing and in enhancing their long-term learning outcomes.

In future work, further attempts to extend AGC-LCFNet to the paragraph level and the essay level with an architecture based on Transformer with long-context or hierarchical structures. The taxonomy of errors can be extended to include more specific grammatical categories, to provide a more accurate diagnosis. In addition, learner-specific information, such as background knowledge in the L1 and learner-specific patterns of writing could be incorporated into the process possibly allowing for generation of more personalized feedback. The framework can be enhanced by advanced optimization techniques, such as human preference-based learning, and by a longitudinal study of educational evaluation in real learning environments to increase the quality of feedback and verify the framework's real-world effectiveness.

TABLE IX. HYPERPARAMETER AND FAIR EVALUATION SETTINGS USED FOR AGC-LCFNET AND BASELINE MODELS.

Category	Setting / Measure	AGC-LCFNet Configuration	Baseline Configuration
Backbone model	Main correction model	FLAN-T5-large encoder-decoder	FLAN-T5, BART, GECToR, and MTL-GEC evaluated under the same dataset splits
Feedback decoder	Feedback generation module	T5-small lightweight decoder	Feedback baselines used ERRANT-Template and Profiling-T5
Maximum input length	Token limit	128 tokens	Same maximum token length applied where applicable
Maximum output length	Correction output	128 tokens	Same decoding length constraint applied to seq2seq baselines
Feedback length	Feedback explanation	64 tokens	Same output length limit used for feedback-generation baselines
Tokenizer	Text tokenization	FLAN-T5 tokenizer	Model-specific tokenizer used, with same preprocessing and length restrictions
Batch size	Training batch	32	Same batch size used where hardware and model size allowed
Epochs	Training duration	10 epochs	Same number of epochs used for trainable neural baselines
Optimizer	Optimization algorithm	AdamW	AdamW used for Transformer-based baselines
Learning rate	Initial learning rate	3e-4	Same learning rate search range used for trainable baselines
Weight decay	Regularization	0.01	Applied consistently to neural baselines
Dropout	Overfitting control	0.10	Same dropout rate used where applicable
Label smoothing	Overconfidence control	0.10	Applied to generation/classification baselines where supported
Warm-up steps	Learning-rate scheduling	10% of total training steps	Same warm-up ratio used for Transformer baselines
Scheduler	Learning-rate decay	Linear decay	Same scheduler used for neural baselines
Beam size	Inference decoding	Beam search = 4	Same beam size used for seq2seq correction baselines
Error classes	Classification labels	7 grammar error classes	Same seven-class taxonomy used for MTL-GEC comparison
Proficiency levels	Feedback adaptation	Beginner, intermediate, advanced	Same proficiency categories used for feedback baselines
Loss function	Multi-task objective	Correction loss + classification loss + feedback loss	Baselines optimized using their original task-specific objectives
Loss weighting	Multi-task balance	Correction-dominant weighted objective	Not applicable to single-task baselines; MTL baseline used comparable multi-task weighting
Train/dev/test split	Data partitioning	Standard benchmark splits	Same splits used for all models
Data leakage control	Split integrity	No sentence overlap across train, dev, and test sets	Same leakage filtering applied before all model training
Duplicate removal	Repetition control	Duplicate source-target pairs removed	Same cleaned dataset used for all models
Preprocessing	Text normalization	Cleaning, pair alignment, prompt formatting, tokenization	Same preprocessing pipeline used before model-specific tokenization
Early stopping	Overfitting prevention	Validation F0.5 monitored	Same validation-based stopping rule used for neural baselines
Random seed	Reproducibility	Fixed seed across runs	Same seed used for all repeat experiments
Evaluation metrics	GEC evaluation	F0.5, M2/ERRANT, exact match	Same correction metrics used for all GEC baselines
Hardware	Computational setting	8 A100 GPUs	Baselines trained/evaluated under comparable hardware settings

VII. CONCLUSION

This study proposed an adaptive grammar correction framework (AGC-LCFNet) that has been developed to go beyond correction-oriented systems with the incorporation of grammatical error correction, error-type classification, and generation of learner-oriented error feedback within a single framework. The proposed model encodes the contextual information and grammar patterns into a shared FLAN-T5 model, and the correction decoder uses the model to generate corrected sentences; the classification head classifies the seven major categories of errors; the feedback decoder uses a gating mechanism to generate explanations that are dependent on the level of proficiency. The experimental results indicate that AGC-LCFNet outperformed the other networks on F0.5 scores in all the benchmark and learner-generated corpora (BEA-2019, CoNLL-14, JFLEG and Lang-8), which demonstrates its effectiveness in both sets of corpora. The model also performed better in terms of error-type diagnosis and better classification performance compared to a multi-task baseline. Moreover, visual analysis showed that AGC-LCFNet focuses on error-specific linguistic features, produces language-altered corrected tokens having a high level of decoder confidence, and assigns high probabilities to the right error class. The feedback results showed that the framework is pedagogically valuable since the explanations for the beginner, intermediate and advanced learners have varying levels of complexity. The ablation results revealed that the classification module enhances correction accuracy, and the classification module with dynamic feedback and the gating mechanism in the module enhances the quality of learners' explanations. On a general level, the AGC-LCFNet grammar correction system is more meaningful and helps the teacher more effectively guide the learning process. Expansion of the model to other types of longer essays, more detailed taxonomies of errors, and L1-aware personalized feedback are possible future extensions of the model.

***Abstract*—Anemia is a major health concern among pregnant women in rural areas. Early detection and timely treatment are necessary to reduce maternal and infant mortality. Many non-invasive techniques have been proposed to solve the problem of unavailability of laboratory-based hemoglobin testing in rural areas. But their accuracy is limited due to dependence on a single modality. This work proposes a multimodal cross-attention network (MCAN) for anemia classification and hemoglobin (Hgb) level estimation using multiple physiological visual cues. Deep convolutional features extracted from four regions of the eye conjunctiva, fingertip, palm, and lip mucosa are fused using a cross-attention multimodal fusion. The fused features are used to estimate Hgb level and predict anemia. Through experimental analysis, the proposed solution is found to increase the estimation accuracy by 5% compared to existing single approaches. The statistical significance of the performance gain is validated through bootstrap confidence intervals and DeLong's test.**

***Keywords*—Anemia; hemoglobin; deep learning; cross-attention fusion; multimodality**

I. Introduction

Anemia is a serious health issue for pregnant women. This nutritional deficiency characterized by lower levels of hemoglobin in the blood. It can increase the chances of maternal and infant mortality when not detected and treated earlier [1]. Thus, early diagnosis becomes very important. A hemoglobin level below 11g/dL is defined as anemia for pregnant women [2]. A clinical method of estimating hemoglobin level from blood samples is a painful, uncomfortable process, as sometimes repeated measurements are needed. The process is time-consuming and infeasible in resource-constrained areas like rural areas. It can also lead to infection spread when facilities are not maintained hygienically [3-4]. Sensing this need for an invasive, comfortable, and safe method for Hgb estimation, various visual cue-based approaches have been proposed. These approaches analyze clinically relevant anatomical sites like eye conjunctiva, fingertip, palm, and lip mucosa, which demonstrate color variations correlated with hemoglobin concentration [5-6]. Various conventional and deep learning techniques have been proposed to estimate Hgb levels from these images. While conventional techniques extracted handcrafted features and trained classification algorithms to estimate Hgb levels, deep learning techniques avoided the need for handcrafted features and applied repeated convolutions and pooling to extract features. Deep learning techniques provided higher accuracy in Hgb estimation in comparison to conventional techniques [7].

The existing deep learning techniques for Hgb estimation can be categorized into single and multi-modality approaches (discussed in the survey). Single-modality approaches use any one of the modalities of eye conjunctiva, fingertip, palm, and lip mucosa for Hgb estimation. Multi-modality approaches use multiple modalities of image or images with clinical metadata to estimate Hgb. Dependence on a single modality image makes the single modality approaches highly sensitive to illumination variations, skin tone differences, etc. Also, individual anatomical regions may not consistently reflect hemoglobin-related color changes. These factors lead to inaccurate hemoglobin estimation [8].

Multimodality approaches integrate complementary information from multiple cues to solve this problem. But current multimodality approaches don't effectively learn cross-modality feature representation from the modalities, leading to reduced accuracy and generalizability of hemoglobin prediction. This work proposes a multimodal cross-attention network to learn robust feature representation, facilitating improved accuracy and generalizability of hemoglobin estimation. The following are the novel contributions of this work:

- A multimodal cross-attention network integrating information from multiple cues of eye conjunctiva, fingertip, palm, and lip mucosa for hemoglobin estimation. Transformer features extracted from each individual modality are fused through a cross-attention fusion technique and the fused representation is used for hemoglobin estimation using a regression head.
- A modality-aware transformer strategy is introduced to extract discriminative color and texture patterns related to hemoglobin concentration using transformer-based encoders. In this way, subtle physiological variations

across different cues are captured while preserving modality-specific information before fusion.

The rest of the study is organized as follows: Section II surveys the existing methods for hemoglobin estimation using deep learning models. Section III details the proposed multimodal cross-attention network integrating multiple cues for hemoglobin estimation. Section IV presents the results of the proposed technique in comparison to recent multimodality and single-modality baselines. Section V presents the conclusion and future scope of work.

II. Related Work

Various single-modality approaches using different variants of deep learning models have been proposed. Jayakody et al. [9] extracted convolutional neural network (CNN) features from fingertip images and used them for estimating the Hgb level. There were no sensitivity and specificity measurements in this work. Magdalena et al. [10] classified eye conjunctiva images into anemic classes using CNN. The image was trained as a whole without consideration for significant regions in the eye conjunctiva image. Das et al [11] combined CNN with vision transformer (ViT) to predict Hgb level from eyelid images. The outliers are more than 8%, and accuracy is very low at the border of anemia Hgb ranges in this approach. Zhang et al. [12] extracted deep learning features from face images and used them for anemia prediction. Authors experimented with ResNet50, MobileNet, InceptionV3, EfficientNetB0, and DenseNet121, and achieved 80% accuracy. But using a face image as a whole without considering the illumination environment can increase the false positives.

Muljono et al. [13] used a hybrid deep learning model combining MobileNetV2 with a support vector machine classifier to predict anemia from eye conjunctive images. Rivero-Palacio et al. [14] classified eye conjunctive image to the anemic class using the YOLOv5 model. The method was tested only for children below 5 years old. Asare et al. [15] used the AlexNet deep learning model to classify anemia. The authors experimented with eye conjunctiva, palm, and fingernail images. Palm images were found to provide higher accuracy, but the performance was tested for children below 5 years old. Magdalena et al. [16] detected anemia from palpebral conjunctiva images using CNN. But the method was tested only for a smaller dataset. Mitani et al. [17] classified retinal fundus images for anemia using the Inception V4 deep learning model. The images were processed as a whole without paying attention to significant regions where color variations are dominant. Chen et al. [18] estimated Hgb level from conjunctiva image using the MobileNet V3 network. The mean absolute error is more than 1.521, and this increases false positives.

Kasiviswanathan et al. [19] proposed a multimodality technique to predict Hgb level. Eye conjunctival image along with age, height, and weight of the subject is used to predict Hgb level. The authors extracted color features from the eye conjunctival image and fused them with meta attributes. A linear regression model is fit between fused features and Hgb level. Image features were not extracted from salient regions. Ramzan et al. [20] combined palm image with corpuscular concentration levels to classify anemia. A deep learning attention model was used to get the fused features. The fused features are classified by softmax classifier to anemia. But the approach needs corpuscular concentration levels which require blood test, making it invasive. Khan et al. [21] extracted fused features from retinal fundus images and meta attributes (age, gender) though a Inception V4 deep learning model and classified the fused features to anemia. But the approach was tested only for people above 50 years old. There were very few works on use of multimodal deep learning.

III. Methodology

Individual modalities of eye conjunctiva, fingernail, palm, and lip mucosa contain useful physiological information related to hemoglobin concentration. Since each modality may be affected by factors such as illumination variations, skin tone differences, or imaging noise, learning cross-modal relationships between these anatomical cues is essential for robust hemoglobin estimation. Though the modalities differ visually, by projecting each modality's features into a shared embedding space cross modal relationship can be learnt. Based on this observation, the architecture of the proposed multimodal cross-attention network (MACN) for Hgb estimation and anemia detection is designed. The architecture is shown in Fig. 1.

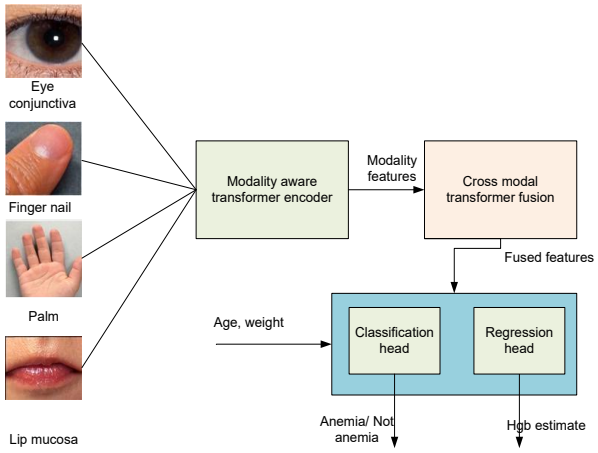

Fig. 1. Architecture of the proposed multimodal cross-attention network.

There are three important functional components in the proposed solution: (1) modality-aware transformer encoder, (2) cross-modal transformer fusion, and (3) classification/regression head. The modality-aware transformer encoder converts the image into a sequence of feature tokens. Cross-modal transformer fusion allows each modality to attend to information from the other modality, resulting in an enhanced, robust feature representation. This feature representation is fused with metadata information (age, weight), and the final fused feature is passed through a classification/regression network. The classification network gives the probability for two classes of anemia/not anemia. The regression head gives the Hgb estimate. Each of the functional components are detailed in the below subsections.

A. Modality-Aware Transformer Encoder

The modality-aware transformer encoder extracts discriminative features from each modality, preserving modality-specific information before fusion. Let the image of modality m be represented as:

$$I_m \in \mathbb{R}^{H\times W\times 3}$$

where, $m \in \{c, f, p, l\}$ corresponds to conjunctiva, fingertip, palm, and lip mucosa, and H, W represent the height and width of the image.

Each input image is split into a sequence of non-overlapping patches of size $P \times P$ with a total number of patches as N. Each patch is flattened and projected into a d-dimensional embedding space:

$$z_0 = \{x_1E, x_2E, \dots x_NE\} \quad (1)$$

where, x_i is the image patch, and E is a learnable embedding matrix.

Positional encoding is added to preserve spatial information:

$$z_0 = z_0 + E_{pos} \quad (2)$$

where, E_{pos} is the positional embedding.

The patch embeddings are processed using a stack of L transformer encoder layers. Each layer has the following components: (1) multi-head self-attention (MHSA), (2) feed-forward network (FFN), (3) normalization layer (NL), and (4) residual connections.

The computation at the l^{th} layer is represented as:

$$z_l' = MHSA\big(NL(z_{l-1})\big) + z_{l-1} \quad (3)$$

$$z_l = FFN\big(LN(z_l')\big) + z_l' \quad (4)$$

The long-range relationships between different patches of the image are learnt using a self-attention operation. For each attention head h, the query (Q), key (K), and values (V) for the attention operation are computed as:

$$Q = zW_Q^h \quad (5)$$

$$K = zW_K^h \quad (6)$$

$$V = zW_V^h \quad (7)$$

The attention weights are computed as:

$$Attention(Q, K, V) = softmax(\frac{QK^T}{\sqrt{d_K}})V \quad (8)$$

The outputs of each attention head are concatenated and projected as:

$$MHSA(z) = concat(head_1, head_2, \dots . head_H)W_O \quad (9)$$

The subtle physiological cues related to hemoglobin concentration are captured by the modality-specific visual representation. For each modality m, its final feature embedding is represented as:

$$F_m = T_m(I_m) \quad (10)$$

where,

$$F_m \in \mathbb{R}^{N\times d} \quad (11)$$

The modality-specific features are passed to the next stage of cross-modal transformer fusion, where inter modal feature relationships are learnt for effective Hgb estimation. The configuration of transformer encoder is given in Table I.

TABLE I. CONFIGURATION OF THE TRANSFORMER ENCODER

Parameter	Value
Input size	224 × 224
Patch size	16 × 16
Embedding dimension	768
Transformer layers	12
Attention heads	12
FFN dimension	3072
Dropout	0.1
Activation	GELU

B. Cross-Modal Transformer Fusion

Cross-modal transformer fusion enables iterative information exchange between modalities through multi-head cross-attention operations, which allows effective feature learning compared to simple feature concatenation. Cross-model transformer allows each modality to attend to information from other modalities. The cross-model interaction between two modalities i and j is represented as:

$$CM(F_i, F_j) = softmax\left(\frac{(F_iW_Q)(F_jW_K)^T}{\sqrt{d}}\right)(F_jW_V) \quad (12)$$

where, W_Q, W_K, W_V are the projection matrices, and d is the embedding dimension. To capture multiple interactions, cross-modal multi-head attention (CMMHA) is used:

$$head_h = Attention(F_iW_Q^h, F_jW_K^h, F_jW_V^h \quad (13)$$

$$CMMHA(F_i, F_j) = Concat(head_1, head_2, .., head_H)W_O \quad (14)$$

where, H is the number of heads and W_O is the output projection matrix.

To capture complementary information across the modalities, bidirectional interactions between the modalities are captured.

$$F_c' = F_c + CMMHA(F_c, F_f) + CMMHA(F_c, F_p) + CMMHA(F_c, F_l) \quad (15)$$

$$F_f' = F_f + CMMHA(F_f, F_c) + CMMHA(F_f, F_p) + CMMHA(F_f, F_l) \quad (16)$$

$$F_p' = F_p + CMMHA(F_p, F_c) + CMMHA(F_p, F_f) + CMMHA(F_p, F_l) \quad (17)$$

$$F_l' = F_l + CMMHA(F_l, F_c) + CMMHA(l, F_f) + CMMHA(F_l, F_p) \quad (18)$$

The modality features are fused to form a cross-fused

representation as in:

$$F_{CF} = Concat(F_c', F_f', F_p', F_l') \quad (19)$$

The cross-fused features capture both modality-specific physiological patterns and cross-modal dependencies. The cross-fused features are passed to the next stage of regression. The configuration of the cross-modal transformer fusion module is given in Table II.

TABLE II. CONFIGURATION OF CROSS-MODAL TRANSFORMER

Parameter	Value
Input modalities	4
Embedding dimension	768
Fusion layer	4
Attention heads	8
FFN dimension	2048
Dropout	0.1
Activation	GELU

C. Classification/Regression Head

Though the cross-fused features extracted from anatomical regions such as eye conjunctiva, fingertip, palm, and lip mucosa provide important information for hemoglobin estimation, clinical attributes, especially age and weight, have a strong influence on hemoglobin levels in pregnant women. Studies have shown that maternal age and anthropometric characteristics such as body weight or body mass index are significantly associated with anemia prevalence and hemoglobin concentration in pregnant women [22-24]. The cross-fused features extracted from visual cues are merged with metadata of age and weight to create final fused features:

$$F_{final} = Concat(F_{CF}, F_{meta}) \quad (20)$$

The final fused representation is passed through a regression network to get Hgb estimation:

$$\overline{Hgb} = R(F_{final}) \quad (21)$$

where, R consists of fully connected layers.

The regression network is trained using the mean square error loss function (L) as:

$$L = \frac{1}{M} \sum_{i=1}^{M} (Hgb_i - \overline{Hgb}_i)^2 \quad (22)$$

where, M is the number of samples, Hgb_i is the actual Hgb value, and $\overline{Hgb}_i$ is the predicted Hgb value.

TABLE III. CONFIGURATION OF THE REGRESSION HEAD

Layer	Operation	Output size
Input	Fused feature vector	F_{final}
FC1	Fully connected + ReLU	256
Dropout	Dropout rate (rate=0.3)	256
FC2	Fully connected + ReLU	128
Dropout	Dropout rate (rate=0.3)	128
FC3	Fully Connected + ReLU	64
Output Layer	Fully Connected (Linear)	1

The configuration of the regression head is given in Table III. The configuration of the classification head is same as that given in Table III, except the last output layer is replaced with the softmax function to provide probabilities for two classes of anemia and not anemia.

IV. RESULTS

The dataset for experimentation was collected from Hadinaru primary health centre (PHC), of rural Mysore district, Karnataka. The data of four images of eye conjunctiva, finger nail, palm, lip mucosa and meta-attributes of age, weight, and Hgb level are collected from 120 participants. Though the dataset consists of 120 participants, each sample contains four physiological image modalities (eye conjunctiva, fingertip, palm, and lip mucosa) together with laboratory-confirmed hemoglobin measurements and clinical metadata. Collecting such multimodal medical data is considerably more challenging than acquiring conventional image datasets because each participant requires synchronized acquisition of multiple anatomical images and corresponding clinical measurements. To ensure reliable evaluation despite the limited dataset size, the proposed model was assessed using 5-fold cross-validation, with results reported as mean ± standard deviation across folds. In addition, bootstrap confidence intervals and DeLong's statistical significance tests were performed to quantify result stability and reliability. The dataset characteristics are given in Table IV.

TABLE IV. DATASET CHARACTERISTICS

Parameter	Value
Dataset acquiring environment	Ambient lighting conditions
Dataset collection duration	6 months
Age range	22-31 years
Weight range	48-85 kg
Hgb range	7 g/dL to 15.5 g/dL
Anemia threshold	11g/dL
Percentage of anemia cases	64 %
Percentage of non-anemia cases	36 %

The dataset is split into training (80%) and test (20%) ensuring balanced distribution of anemic and non-anemic cases in both splits. Testing is conducted with 5-fold cross validation strategy to ensure robustness and generalization. For each fold, a different random split (80:20) is made and the model is trained with training data. The trained model is tested with the test data. The results are reported in terms of mean± standard deviation (SD).

The performance is analyzed in comparison with existing methods specific to each modality, namely fingernail [9], eye conjunctiva [13], palm [15], and multimodal approach [19]. The performance of Hgb estimation is compared in terms of Mean absolute error (MAE), root mean square error (RMSE) and R^2. Anemia classification performance (threshold as 11g/dL) is accuracy and AUC. The performance comparison results with existing approaches are presented in Table V.

The proposed MCAN achieved an accuracy of 95.4% which is atleast 5% higher compared to existing works. The

error in Hgb estimation is at least 41% lower in the proposed MCAN, demonstrating improved precision in Hgb estimation. The lower SD in the proposed MCAN indicates consistent performance across all folds. The single modality approaches ([9],[13],[15]) had higher SD, reflecting sensitivity to imaging conditions and anatomical variability. Though the multimodality approach [19] had lower SD, it lacks robustness in comparison to MCAN. The higher accuracy and lower SD demonstrate the strong generalization capability of the proposed MCAN. The use of modality-aware transformers along with cross-attention fusion has resulted in robust feature representation in the proposed solution. This robust feature representation, along with clinical metadata integration, has enhanced prediction stability and improved estimation accuracy.

TABLE V. PERFORMANCE COMPARISON WITH EXISTING WORKS

Method	Modality used	MAE(g/dL)	RMSE(g/dL)	Accuracy (%)	AUC
Fingernail-based CNN [9]	Fingernail	1.38 ± 0.09	1.79 ± 0.12	83.2 ± 2.3	0.87 ± 0.02
Eye conjunctive CNN [13]	Eye conjunctiva	1.34 ± 0.08	1.71 ± 0.11	84.6 ± 2.0	0.88 ± 0.02
Palm based Deep model [15]	Palm	1.29 ± 0.07	1.65 ± 0.10	86.3 ± 1.8	0.89 ± 0.02
Multi model regression [19]	Eye conjunctiva image + meta data	1.10 ± 0.06	1.42 ± 0.09	90.1 ± 1.6	0.92 ± 0.01
Proposed MCAN	Multi modality image + data	0.78 ± 0.05	0.98 ± 0.07	95.4 ± 1.2	0.97 ± 0.01

The ROC curve of the proposed MCAN is given in Fig. 2.

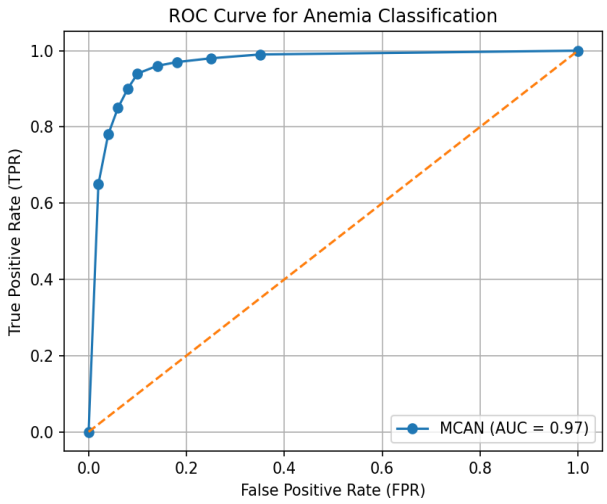

Fig. 2. ROC curve of the proposed MCAN.

The ROC curve shows the excellent discriminative capability between anemia and non-anemia classes in the proposed MCAN. The AUC of 0.97 indicates strong separability. In addition, the position of the curve towards the top left indicates higher sensitivity and specificity across thresholds. The confusion matrix in the proposed MCAN is given in Fig. 3.

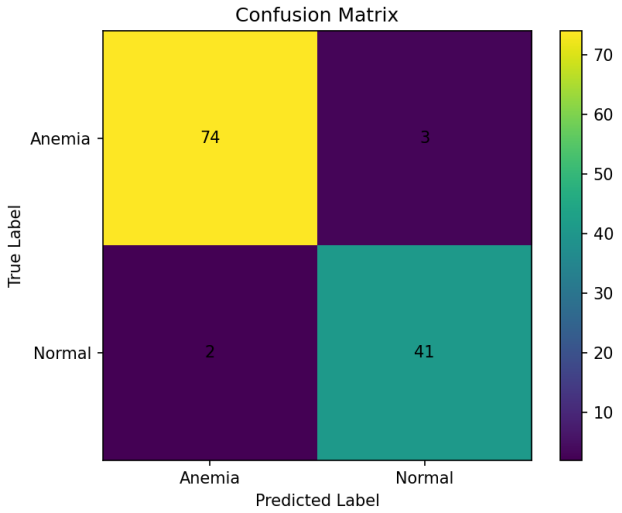

Fig. 3. Confusion matrix

From the confusion matrix, it can be seen that the proposed MCAN has higher sensitivity and specificity, indicating reliable discrimination between anemia and non-anemia classes.

The statistical significance of the performance gain achieved in the proposed MCAN is validated through bootstrap confidence intervals and DeLong's test. The proposed MCAN achieved an accuracy of 95.4% (95% CI: 93.1%–97.2%) and AUC of 0.97 (95% CI: 0.95–0.99). DeLong's test comparing the proposed model with the multimodal solution [19] yielded a p-value of 0.0032, confirming that the improvement is statistically significant.

Cross-attention feature fusion across multiple modalities is an important contribution in this work. Performance comparison is done against different fusion techniques, and the results are presented in Table VI.

TABLE VI. COMPARISON WITH FUSION STRATEGIES

Fusion strategy	MAE (g/dL)	RMSE (g/dL)	Accuracy (%)	AUC
Early fusion	1.18±0.09	1.51± 0.11	89.6 ± 1.9	0.91±0.02
Late Fusion	1.12± 0.08	1.45 ± 0.10	90.7 ± 1.8	0.92 ± 0.02
Feature Concatenation	1.02 ± 0.08	1.31 ± 0.10	91.8 ± 1.7	0.93 ± 0.02
Self-Attention Fusion	0.89 ± 0.07	1.14 ± 0.09	93.4 ± 1.4	0.95 ± 0.01
Proposed MCAN (Cross-Attention Fusion)	0.78 ± 0.05	0.98 ± 0.07	95.4 ± 1.2	0.97 ± 0.01

From the results, it can be seen that the proposed cross-attention fusion achieved best performance in comparison to other fusion techniques. Though self-attention fusion achieved higher performance in comparison to feature concatenation and

early and late fusion, it achieved lower performance in comparison to cross-attention fusion, as it treated all modalities uniformly and did not explicitly model directional interactions between modalities. Cross-attention fusion solved this problem by learning complementary information from other modalities, which produced a more discriminative and robust feature representation.

The performance of the proposed solution is compared against conventional convolutional neural network architectures for feature extraction, and the results are given in Table VII.

TABLE VII. COMPARISON WITH FEATURE EXTRACTION BACKBONES

Backbone	MAE (g/dL)	RMSE (g/dL)	Accuracy (%)	AUC
ResNet50	1.14 ± 0.08	1.47 ± 0.11	89.8 ± 1.9	0.91±0.02
DenseNet121	1.08 ± 0.08	1.39 ± 0.10	90.9 ± 1.8	0.92 ± 0.02
EfficientNet-B0	1.01 ± 0.07	1.30 ± 0.09	92.1 ± 1.6	0.94 ± 0.02
Vision Transformer (ViT-Base)	0.92 ± 0.07	1.18 ± 0.08	93.3 ± 1.5	0.95 ± 0.01
Swin Transformer	0.86 ± 0.06	1.09 ± 0.08	94.1 ± 1.3	0.96 ± 0.01
Proposed MCAN (Modality-Aware Transformer)	0.78 ± 0.05	0.98 ± 0.07	95.4 ± 1.2	0.97 ± 0.01

From the results, it can be seen that traditional CNN architectures – ResNet50, DenseNet121 and EfficientNet-B0 achieved only lower performance compared to transformer-based models. Due to their ability to capture long-range dependencies and subtle color-texture relationships associated with hemoglobin concentration, transformer-based models provided better performance. Compared to standard vision transformers, Swin Transformer provided better results because of its hierarchical feature representation and shifted-window attention mechanism. The proposed MCAN improved the performance even more due to its ability to learn modality-specific physiological characteristics before multimodal fusion. This preserved discriminative information from conjunctiva, fingertip, palm, and lip mucosa images.

Robustness analysis of the proposed MCAN is conducted against different skin tones, and the results are given in Table VIII.

TABLE VIII. ROBUSTNESS ANALYSIS

Skin tone group	MAE (g/dL)	RMSE (g/dL)	Accuracy (%)	AUC
Light	0.76 ± 0.05	0.96 ± 0.07	95.8 ± 1.1	0.97 ± 0.01
Medium	0.79 ± 0.05	0.99 ± 0.07	95.2 ± 1.2	0.97 ± 0.01
Dark	0.83 ± 0.06	1.04 ± 0.08	94.6 ± 1.3	0.96 ± 0.01

Performance evaluation against different skin tones shows that the maximum difference in classification accuracy between skin-tone groups was 1.2%, demonstrating that the proposed multimodal fusion strategy reduces dependence on a single visual cue and improves generalizability across diverse populations.

An ablation study was conducted to analyze the contribution of each functional component of the proposed MCAN. The ablation study results for various variants are given in Table IX.

TABLE IX. ABLATION STUDY RESULTS

Variants	MAE(g/dL)	RMSE (g/dL)	Accuracy (%)	AUC
Without cross-attention (feature concatenation)	1.02 ± 0.08	1.31 ± 0.10	91.8 ± 1.7	0.93 ± 0.02
Without modality-aware transformer (CNN features)	0.95 ± 0.07	1.22 ± 0.09	92.6 ± 1.5	0.94 ± 0.02
Without clinical metadata (age, weight)	0.88 ± 0.06	1.10 ± 0.08	93.9± 1.3	0.95 ± 0.01
Full model (MCAN)	0.78 ± 0.05	0.98 ± 0.07	95.4 ± 1.2	0.97 ± 0.01

Simple feature concatenation without cross-attention fusion reduced the accuracy by 3.6%, demonstrating the robust feature representation effectiveness of cross-attention fusion. Using CNN features instead of modality-aware transformers reduced the accuracy by 3%, indicating the importance of capturing long-range dependencies and subtle color-texture variations with modality-aware transformers. With metadata fusion, the performance degraded only by 1.5%, but still it confirms that physiological attributes complement visual cues. The results of the lowest error, highest accuracy, and lowest SD in the proposed MCAN indicate that each component contributes synergistically to improved hemoglobin estimation and anemia detection.

The novelty of the proposed solution over existing multimodal approaches is given in Table X.

TABLE X. THE NOVELTY OF THE PROPOSED SOLUTION OVER EXISTING MULTIMODAL APPROACHES.

Feature	[19] Kasiviswanathan	[20] Ramzan	Proposed MCAN
Multiple image modalities	✗	✗	✓
Transformer encoder	✗	✗	✓
Modality-aware feature learning	✗	✗	✓
Cross-attention fusion	✗	✗	✓
Metadata integration	✓	✓	✓
Hemoglobin regression	✓	✗	✓
Anemia classification	✓	✓	✓
End-to-end multimodal learning	✗	Partial	✓

The proposed multimodal cross-attention network (MCAN) differs from existing approaches in four important aspects:

1. Differing from prior studies that utilize a single anatomical region or a single image modality, the proposed framework simultaneously exploits four physiologically relevant visual cues, namely eye conjunctiva, fingertip, palm, and lip mucosa. Each modality contains complementary information associated with hemoglobin concentration. Integrating these modalities enables the model to remain robust when one modality is affected by illumination artifacts, pigmentation differences, or image acquisition noise.
2. A modality-aware transformer encoder is introduced for feature extraction. Most of the existing works use convolutional neural networks or generic vision transformers that process all modalities in a similar manner. In contrast, the modality-aware transformer is designed to preserve modality-specific characteristics before fusion, allowing the network to capture subtle color and texture variations associated with hemoglobin concentration while maintaining the unique physiological information present in each anatomical region.
3. The proposed framework uses cross-attention fusion rather than conventional feature concatenation or independent attention mechanisms. Through cross-attention, each modality actively attends to informative regions of other modalities, enabling explicit learning of inter-modal relationships. This interaction produces a richer and more discriminative feature representation that captures both modality-specific and cross-modal dependencies.
4. The proposed work integrates visual information with clinical metadata such as age and weight within a unified prediction framework. While previous multimodal methods generally combine image-derived features with metadata using shallow regression models, the proposed approach learns joint representations through deep multimodal feature interaction. This enables the model to exploit complementary physiological and demographic information for improved hemoglobin estimation.

Thus, the novelty of the proposed MCAN does not arise solely from combining multiple modalities, but from proposing a unified architecture that combines modality-aware transformer encoding, cross-attention-based multimodal fusion, and metadata-guided prediction for non-invasive hemoglobin estimation and anemia detection. To the best of our knowledge, no previous study has jointly incorporated these components within a single end-to-end framework for anemia prediction using conjunctiva, fingertip, palm, and lip mucosa images.

V. Conclusion

This work proposed a novel multimodal cross-attention network (MCAN) for non-invasive Hgb estimation and anemia detection using multiple visual cue modalities. The solution integrated modality-aware transformers with cross-attention fusion to obtain robust feature representation capturing both modality-specific and inter-modal features. The proposed model had atleast 5% anemia detection accuracy and 41% lower Hgb estimation error compared to existing works. Statistical validation using bootstrap confidence intervals and DeLong's test confirmed that the performance gains are significant.

***Abstract*—Remote sensing systems generate large volumes of high-dimensional data, which creates significant challenges for onboard processing and data transmission under computational, memory, and energy constraints. Dimensionality reduction is therefore essential for enabling efficient embedded remote sensing applications. This work presents a hardware-accelerated implementation of Principal Component Analysis (PCA) on an FPGA platform for low-latency onboard data reduction. A hardware–software co-design methodology is adopted and implemented using the Vivado design flow on an Xilinx FPGA. The proposed architecture focuses on accelerating the most computationally intensive stage of PCA while preserving the most informative components of the input data. Experimental evaluations demonstrate that the FPGA-based implementation achieves a 2.8× speedup while reducing energy consumption by 72.4% compared with an ARM-only software implementation, while maintaining efficient hardware resource utilization. These results confirm the suitability of the proposed accelerator for low-latency, energy-efficient onboard dimensionality reduction in resource-constrained remote sensing systems.**

I. Introduction

Remote sensing encompasses a wide range of techniques that enable the acquisition and analysis of information about observed scenes without direct physical contact. Among these techniques, hyperspectral imaging has gained significant attention due to its ability to capture fine-grained spectral information across hundreds of contiguous wavelength bands [1]. Unlike conventional multispectral sensors, hyperspectral systems acquire three-dimensional data cubes composed of two spatial dimensions and a highly resolved spectral dimension, where each pixel is characterized by a detailed spectral signature. This rich spectral representation enables accurate material discrimination and supports numerous applications, including environmental monitoring, precision agriculture, geological mapping, and natural resource management [2, 3].

Despite these advantages, hyperspectral imaging introduces major challenges related to data processing and analysis. The high dimensionality of hyperspectral data, combined with strong inter-band correlation, results in substantial data redundancy and increased sensitivity to noise and sensor imperfections [4]. These characteristics significantly increase computational complexity, memory requirements, and power consumption, rendering conventional software-based processing approaches inefficient for embedded applications.

These challenges are critical in Earth observation systems, where hyperspectral data must be processed onboard and transmitted under limited bandwidth, memory, and energy constraints. Dimensionality reduction is therefore essential to reduce data volume while preserving informative spectral features. Several methods, including Randomized Principal Component Analysis (RPCA) and unsupervised band selection techniques, have been widely used to reduce redundancy in hyperspectral data [5, 6]. Among them, PCA remains attractive due to its simplicity, robustness, and ability to retain most data variance with fewer components. Deep learning methods, such as hybrid 3D–2D CNNs, have also achieved strong performance and often use PCA to reduce input dimensionality and computational cost [7, 8,9] . Transformer-based models further improve spectral modeling but require high memory, computation, and energy resources [10–12]. To address these limitations, FPGA-based acceleration has been explored for PCA, hyperspectral compression, CNN inference, and anomaly detection [13–17], while in-sensor and processing-in-pixel paradigms have also been proposed to reduce data movement and energy consumption [18, 19]. Thus, PCA remains a suitable dimensionality reduction method for resource-constrained onboard hyperspectral systems.

In this context, this study proposes a real-time FPGA-based accelerator for Principal Component Analysis tailored to onboard hyperspectral data processing. The proposed solution adopts a hardware–software co-design approach and is implemented on a PYNQ-Z2 FPGA platform using the Vivado design flow. Unlike prior FPGA-based PCA accelerators that either lack configurability for varying hyperspectral dimensions or omit systematic energy analysis, the proposed architecture offers three distinctive contributions: 1) a fully pipelined, HLS-optimized covariance engine with loop unrolling (factor 8) specifically tuned for the B×B spectral covariance structure of hyperspectral cubes; 2) an AXI4-Master burst transfer strategy that aligns I/O parallelism with DDR memory bandwidth on the Zynq-7020; and 3) a hardware–software co-design that achieves an energy reduction of approximately 72% compared to ARM-only execution

*Corresponding author.

(from 4.39 J to 1.21 J per PCA run), alongside a 2.8× speedup. These characteristics address key gaps in the existing literature and confirm the suitability of the proposed solution for high-performance onboard hyperspectral processing under energy constraints.

II. Related Work

Hyperspectral image analysis has motivated extensive research on dimensionality reduction methods designed to reduce spectral redundancy while preserving the most informative features. Techniques such as Principal Component Analysis (PCA) [20], Singular Value Decomposition (SVD) [21], and band selection [22] have been widely used for dimensionality reduction in hyperspectral image analysis. Among them, PCA remains one of the most commonly adopted approaches because of its simplicity, robustness, and ability to transform highly correlated spectral bands into a reduced set of uncorrelated components. Unlike band selection methods, which preserve the original bands but may discard useful information, PCA provides a compact representation that concentrates most of the data variance in fewer components.

Nonlinear dimensionality reduction methods, including manifold learning approaches such as Locally Linear Embedding (LLE) [23] and Laplacian Eigenmaps (LE) [24], have also been explored to better capture complex spectral structures in hyperspectral data. However, these methods generally require higher computational resources and are sensitive to parameter settings [25], which limit their applicability in practice. For this reason, PCA remains widely adopted as an efficient preprocessing step in hyperspectral classification pipelines [26].

With the development of deep learning, several spatial–spectral models have been proposed for hyperspectral image classification. Hybrid CNN architectures have shown strong performance by extracting both spectral and spatial features. In many of these works, PCA is applied before classification to reduce the number of input bands and decrease the computational cost of 3D convolution operations. For example, Ghaderizadeh et al. [7] demonstrated that PCA-reduced hyperspectral data can be effectively used with hybrid 3D–2D CNN models to achieve competitive classification accuracy with reduced complexity. Similarly, Datta et al. [19] combined superpixelwise PCA with dense CNN-based spatial–spectral feature learning, further confirming the usefulness of PCA in deep learning-based hyperspectral analysis.

More recently, transformer-based architectures have been introduced to model long-range spectral dependencies through self-attention mechanisms. Models such as SpectralFormer [12] and MassFormer [11] have demonstrated promising classification performance by exploiting full spectral information. Nevertheless, these approaches usually involve high memory usage, significant computational complexity, and increased energy consumption. As a result, their deployment on resource-constrained onboard platforms remains challenging, particularly in applications where latency, memory, and power consumption are critical constraints.

To address these limitations, hardware acceleration has become a key direction for onboard hyperspectral processing. FPGAs are particularly suitable for this purpose due to their parallelism, deterministic execution, and higher energy efficiency compared with general-purpose processors. Fernández et al. [13] proposed an FPGA-based architecture for hyperspectral dimensionality reduction, demonstrating the potential of reconfigurable hardware for accelerating spectral projection operations. He et al. [14] developed a configurable FPGA accelerator for 2D–3D CNN-based hyperspectral classification, achieving efficient resource utilization and reduced inference latency through an HLS-based design flow.

Despite these advances, many existing FPGA-based implementations mainly focus on latency, throughput, or resource utilization separately. Few works provide a combined analysis of execution time, energy consumption, and configurability for different hyperspectral data dimensions. In addition, several prior designs do not provide sufficient details about memory transfer mechanisms or AXI-based communication strategies, which limits reproducibility and practical deployment.

Therefore, the present work addresses these limitations by proposing a hardware–software co-designed PCA accelerator implemented on the Zynq-7020 PYNQ-Z2 platform. The proposed architecture aims to jointly improve latency, energy efficiency, and configurability, while providing a detailed characterization of fixed-point arithmetic, AXI burst transfer, and energy consumption per PCA run.

III. Materials and Methods

A. PCA Algorithm for Hyperspectral Images

The conventional Principal Component Analysis (PCA) algorithm operates on two-dimensional data matrices. However, hyperspectral images are inherently multivariate datasets represented as three-dimensional data cubes, composed of two spatial dimensions $(D_{x'} D_y)$and one spectral dimension (D_λ). Therefore, the first step in applying PCA to hyperspectral data consists of unfolding (reshaping) the hyperspectral cube into a two-dimensional matrix.

$$X \in \mathbb{R}^{N \times B},$$

where, $N = D_x \times D_y$denotes the total number of pixels and $B = D_\lambda$ represents the number of spectral bands. In this representation, each row corresponds to the spectral signature of a single pixel, while each column represents a specific spectral band across the entire image. The unfolding process is illustrated in Fig. 1, where a hyperspectral cube composed of three rows, three columns, and B spectral bands is reshaped into a two-dimensional matrix suitable for PCA computation.

Before applying PCA, data standardization is carried out to ensure that all spectral bands contribute equally to the analysis. Each spectral variable is normalized by subtracting its mean and dividing by its standard deviation, as expressed by:

$$x'_{ij} = \frac{x_{ij} - \mu_j}{\sigma_j} \quad (1)$$

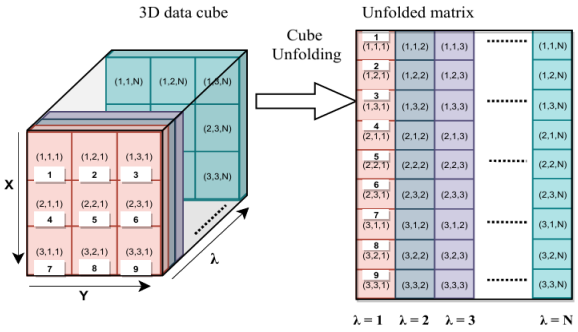

Fig. 1. Unfolding a hypercube.

where, x_{ij} denotes the reflectance value of the j-th spectral band at the i-th pixel, and μ_j and σ_j are the mean and standard deviation of the j-th band, respectively. This step enhances numerical stability and prevents spectral bands with larger dynamic ranges from dominating the PCA process.

After standardization, the covariance matrix is computed from the standardized data matrix X_s as:

$$C = \frac{1}{N-1} X_s^T X_s \tag{2}$$

The covariance matrix captures the inter-band spectral correlations and forms the foundation for dimensionality reduction.

PCA is then performed by applying eigenvalue decomposition to the covariance matrix:

$$C v_k = \lambda_k v_k \tag{3}$$

where, λ_k and v_k represent the eigenvalues and their corresponding eigenvectors, respectively. Each eigenvector defines a principal component, and its associated eigenvalue indicates the amount of variance explained by that component.

The eigenvalues are sorted in descending order, and the first K principal components are selected according to the cumulative explained variance criterion. The dimensionality-reduced data are then obtained by projecting the standardized data onto the selected eigenvectors:

$$Y = X_s V_k \tag{4}$$

where, V_k contains the K selected eigenvectors. The resulting matrix Y represents the reduced hyperspectral representation, corresponding to the PCA sub-bands that preserve the most informative spectral content of the original hyperspectral image while significantly reducing data dimensionality.

Hyperspectral images are characterized by a very high number of spectral bands, resulting in extremely high-dimensional data volumes and substantial computational complexity during onboard or embedded processing. The simultaneous handling of hundreds of spectral bands renders conventional software-based implementations inadequate for embedded and low-latency applications due to excessive execution latency, high memory bandwidth demands, and increased power consumption. In this context, Principal Component Analysis (PCA) is widely adopted as an effective and well-established dimensionality reduction technique, enabling hyperspectral data to be projected onto a lower-dimensional subspace while preserving most of the original data variance. However, to fully exploit the benefits of PCA in embedded sensing applications, an efficient hardware implementation becomes necessary to satisfy stringent latency and energy constraints while ensuring reliable and continuous data processing.

B. Proposed Hardware–Software Co-Design Architecture for PCA Acceleration

The proposed PCA acceleration architecture follows a hardware–software co-design approach. The covariance matrix computation, characterized by intensive numerical operations, is implemented as a custom FPGA IP core, while the remaining PCA stages are executed on the ARM-based processing system. These software-executed stages include data centering, eigenvalue decomposition, and principal component selection, which benefit from software flexibility and control.

Fig. 3 illustrates the proposed hardware–software co-design architecture of the FPGA-based PCA accelerator. The covariance IP is fully integrated into the FPGA and operates in a highly parallel and pipelined manner, leading to substantial performance gains compared to a pure software implementation. The reconfigurable nature of the FPGA allows the architecture to be tailored to different hyperspectral data dimensions by adjusting parameters such as the number of spectral bands and accumulation depth. By combining hardware-accelerated covariance computation with software-based PCA control, the proposed system achieves reduced latency, increased throughput, efficient hardware resource usage, and improved energy efficiency. These characteristics make the architecture well suited for high-performance hyperspectral data processing in embedded remote sensing applications.

The design methodology adopted in this work is based on Vivado High-Level Synthesis (HLS) and the Vivado Design Suite, as illustrated in Fig. 2, and is implemented on the PYNQ-Z2 development platform. The PCA algorithm is first described using high-level C/C++ code and validated through a dedicated C-based testbench, which serves as a golden reference model to ensure functional correctness. C-level simulation is then performed to verify the behavior of the algorithm prior to hardware synthesis. Vivado HLS is employed to translate the high-level PCA description into register-transfer level (RTL) code, while enabling the insertion of synthesis directives and optimization constraints to improve latency, throughput, and hardware resource utilization. After C/RTL co-simulation, the generated RTL is exported and integrated into a Zynq-7020–based PYNQ-Z2 system using Vivado. This workflow enables a seamless transition from algorithmic modeling to hardware implementation while preserving functional correctness and providing fine-grained control over performance optimization.

Among the different stages of the PCA algorithm, the covariance matrix computation represents one of the most computationally intensive operations. For hyperspectral images from the Pavia University dataset [22], this corresponds to

approximately N=207,400 samples and B=103 spectral bands, resulting in a 103×103 covariance matrix. This computation requires a large number of multiply–accumulate operations, leading to high execution time in software-based implementations.

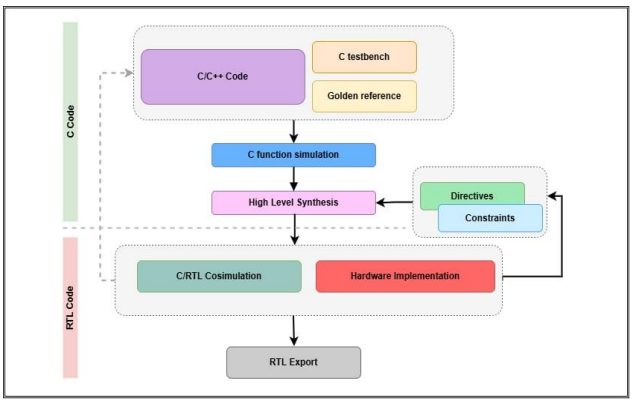

Fig. 2. Design and verification framework for custom hardware accelerator.

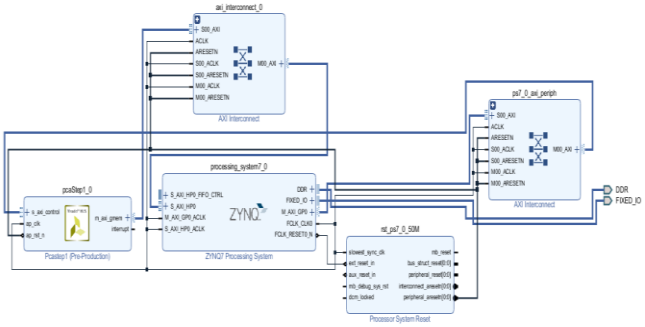

Fig. 3. Block diagram of the FPGA-based PCA acceleration architecture on Zynq SoC.

To reduce latency and meet stringent performance constraints, the covariance computation is offloaded to a dedicated FPGA IP core implemented in the programmable logic of the PYNQ-Z2 platform. The proposed IP exploits fine-grained parallelism through loop unrolling and loop pipelining directives in the HLS design, allowing multiple accumulation operations across spectral bands to be executed concurrently within each clock cycle. This significantly reduces the number of clock cycles required for covariance matrix generation and improves throughput while maintaining efficient hardware resource utilization.

To further enhance the performance of the covariance matrix computation, several HLS-level optimization strategies are applied. Loop unrolling with a factor of 8 (#pragma HLS unroll factor=8) enables parallel accumulation operations across spectral bands, while loop pipelining allows continuous processing of hyperspectral samples with a low initiation interval. Array partitioning is used to increase parallel memory access to spectral data buffers, and on-chip memory buffering is employed to locally store intermediate accumulation results, thereby reducing external DDR memory transactions.

In addition, fixed-point arithmetic is adopted using a 32-bit fixed-point representation with 16 integer bits and 16 fractional bits to provide a balance between numerical precision and hardware efficiency. Optimized AXI burst transfers are also employed to improve memory throughput and reduce power consumption. The covariance IP accesses hyperspectral data stored in external DDR memory via an AXI4-Master interface, while configuration parameters such as data dimensions and memory addresses are managed through an AXI-Lite control interface. An interrupt mechanism is used to notify the processing system upon completion of the covariance computation.

IV. Results

This section reports the experimental results of the proposed PCA accelerator implemented on the PYNQ-Z2 FPGA. The evaluation considers hyperspectral data from the Pavia University dataset and analyzes both the quality of the extracted principal components and the performance of the hardware-accelerated implementation in terms of execution time, power consumption, and resource usage. A comparison with a software-based PCA execution on the ARM Cortex-A9 is also presented to demonstrate the advantages of the proposed hardware solution.

TABLE I. FPGA Resource Utilization After Vivado Implementation of the PCA Accelerator System on PYNQ-Z2 (XC7Z020)

Resource (PL)	Used	Available	Utilization (%)
LUT	16,881	53,200	31.7%
FF	14,673	106,400	13.8%
BRAM	1	140	0.7%
DSP48	174	220	79.1%

Table I presents the FPGA resource utilization obtained after Vivado post-implementation of the PCA accelerator system on the PYNQ-Z2 platform based on the Xilinx Zynq-7020 (XC7Z020) SoC. The results show a moderate consumption of general logic resources, with 16,881 LUTs (31.7%) and 14,673 flip-flops (13.8%), indicating that the proposed architecture maintains a balanced use of combinational and sequential logic for the complete programmable-logic design, including the system interconnect, control and interface logic, together with the PCA accelerator.

In contrast, the utilization of DSP48 blocks reaches 174 units (79.1%), which is consistent with the arithmetic-intensive nature of the covariance matrix computation, dominated by multiply–accumulate operations and matrix-based numerical processing. This confirms that the design efficiently maps computationally demanding operations onto dedicated DSP resources, while preserving LUT resources mainly for control and interfacing purposes. The BRAM usage is very limited, with only one BRAM block used (0.7%), reflecting a lightweight on-chip memory footprint within the programmable logic.

Overall, these results demonstrate an efficient hardware implementation of the PCA accelerator on PYNQ-Z2, achieving high computational density while maintaining moderate logic and memory utilization, making it suitable for embedded dimensionality reduction applications with stringent performance requirements.

TABLE II. PERFORMANCE COMPARISON OF THE PCA IMPLEMENTATION ON ARM CORTEX-A9 AND ZYNQ XC7Z020.

Platform	Execution Time (s)	Power (W)
Dual-Core ARM Cortex-A9	1.83	2.4
Zynq XC7Z020	0.65	1.86

To evaluate the performance benefits of hardware acceleration for the Principal Component Analysis (PCA) algorithm, the proposed implementation was evaluated on two different platforms: a software-only execution on the dual-core ARM Cortex-A9 processor and a hardware-accelerated implementation on the Zynq XC7Z020 FPGA.

Table II compares the execution time and power consumption of the PCA implementation when executed entirely on the ARM Cortex-A9 processor and when accelerated using the FPGA resources of the Zynq XC7Z020 platform. The software-only execution on the ARM Cortex-A9 requires 1.83 s, reflecting the sequential nature of the PCA covariance computation and the limited parallelism available on a general-purpose processor.

The FPGA-accelerated implementation significantly reduces the execution time to 0.65 s, corresponding to a speed-up of approximately 2.8×. This improvement is achieved by offloading the computationally intensive stages of the PCA to dedicated hardware, enabling parallel processing and efficient pipelining in the programmable logic.

From a power perspective, the FPGA-based solution also demonstrates an advantage, consuming 1.86 W compared to 2.4 W for the ARM-only execution. Although both platforms operate within acceptable power limits, the combination of lower execution time and reduced power consumption highlights the superior energy efficiency of the FPGA-accelerated approach. Overall, these results confirm that integrating a hardware accelerator for PCA on the Zynq XC7Z020 platform provides a favorable trade-off between performance and power, making it well suited for embedded and real-time signal processing applications.

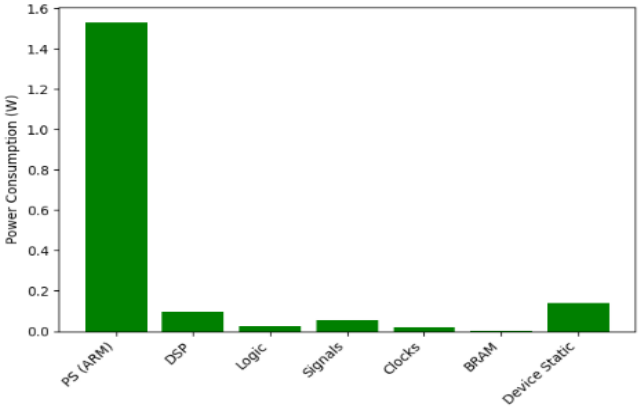

Fig. 4. Power consumption breakdown of the PCA system on the Zynq XC7Z020 platform.

To evaluate the power efficiency of the proposed PCA accelerator and to illustrate the distribution of power consumption between the processing system and the programmable logic, Fig. 4 presents the power consumption breakdown of the PCA system implemented on the Zynq XC7Z020 platform. The results show a total on-chip power consumption of 1.867 W, with 1.726 W (92.4%) corresponding to dynamic power and 0.141 W (7.6%) to static power, indicating that the system consumption is largely dominated by active computation. As shown in Fig. 4, the Processing System (PS7) represents the main contributor, consuming 1.530 W, which corresponds to 88.6% of the dynamic power and 81.9% of the total power. In contrast, the programmable logic (PL), including the PCA hardware accelerator, accounts for only 0.196 W of dynamic power (11.4% of dynamic power and 10.5% of total power), demonstrating the low energy overhead introduced by hardware acceleration. Within the PL, the power consumption is mainly dominated by the DSP blocks (0.094 W, 5.0%), which is consistent with the arithmetic-intensive nature of the PCA covariance computation, while the contributions of logic (0.025 W, 1.3%), clocks (0.020 W, 1.1%), signals (0.055 W, 2.9%), and BRAM (0.002 W, 0.1%) remain negligible. Although the PS dominates instantaneous power consumption, the reduced execution time achieved by the FPGA accelerator leads to an energy-efficient PCA implementation suitable for embedded and performance-constrained applications.

To fully characterize the efficiency of the proposed accelerator, energy consumption per PCA run is quantified as $E = P \times T$ and further normalized to the dataset dimensions ($N = 207{,}400$ pixels, $B = 103$ spectral bands) to derive the energy per pixel per band. The resulting values are reported in Table III.

TABLE III. ENERGY EFFICIENCY COMPARISON PER PCA RUN

Platform	Energy per Run (J)	Energy per pixel/band (nJ)
Dual-Core ARM Cortex-A9	4.39	205
Zynq XC7Z020 (FPGA)	1.21	56.6

The results show that the FPGA-accelerated implementation consumes only 1.21 J per PCA run, compared to 4.39 J for the ARM-only execution, achieving an energy reduction of approximately 72.4%. At the pixel–band level, the energy footprint decreases from approximately 205 nJ/pixel/band to 56.6 nJ/pixel/band, showing that the efficiency gain is reflected across the processed hyperspectral data volume. This reduction results from the simultaneous decrease in both execution time and average power consumption. Such an improvement is particularly important for embedded remote sensing platforms, where energy consumption, memory usage, and execution time must be carefully optimized. These results demonstrate that the proposed PCA accelerator provides not only a performance advantage but also a substantial improvement in energy efficiency, supporting its potential for energy-constrained onboard remote sensing applications.

To illustrate the effect of Principal Component Analysis (PCA) on hyperspectral data, PCA was applied to hyperspectral images from the Pavia University dataset, and the resulting principal components were visualized. This representation enables an initial qualitative assessment of how the spectral information contained in the Pavia University

dataset is redistributed across the principal components. Fig. 5 illustrates the first eight principal components obtained after applying Principal Component Analysis (PCA) to the hyperspectral dataset. It can be observed that the first principal components (Bands 1–3) preserve the most significant spatial structures of the scene, with clear edges, textures, and man-made objects being distinctly visible. These components concentrate the majority of the data variance and therefore carry the most relevant spectral–spatial information. The intermediate components (Bands 4 and 5) still contain meaningful information but with reduced contrast and fewer discernible details, indicating that they mainly capture secondary variations in the data. In contrast, the higher-order components (Bands 6–8) exhibit low spatial structure and appear increasingly uniform, suggesting that they are dominated by noise and minor spectral variations rather than useful information.

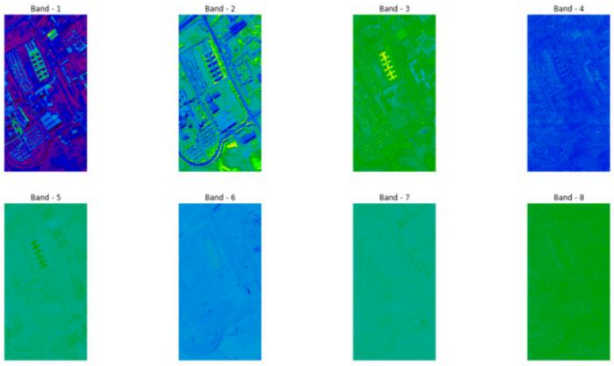

Fig. 5. The first principal components obtained from hyperspectral images.

V. Discussion

The proposed PCA acceleration architecture adopts a hardware–software co-design approach that effectively balances performance and flexibility for hyperspectral data processing. By selectively offloading the covariance matrix computation to the programmable logic, the system accelerates the most computationally intensive stage of PCA while maintaining software-level control for the remaining processing steps.

The covariance computation is implemented as a custom FPGA IP core generated using Vivado High-Level Synthesis and integrated into the Zynq-7020–based PYNQ-Z2 platform. This IP exploits fine-grained parallelism through advanced HLS optimization techniques, including loop pipelining and loop unrolling, enabling concurrent accumulation operations across multiple spectral bands. As a result, the number of clock cycles required for covariance matrix generation is significantly reduced compared to a pure software implementation on the ARM Cortex-A9 processor.

Overall, the combination of HLS-based design, pipelined execution, and parallel accumulation allows the proposed architecture to achieve reduced latency, increased throughput, and efficient FPGA resource utilization. These characteristics demonstrate the suitability of the proposed solution for onboard processing in embedded remote sensing systems operating under strict power and computational constraints.

From a system-level perspective, the proposed architecture is designed to accommodate the statistical variability inherent to hyperspectral data acquired under different sensing conditions. The hardware–software co-design paradigm provides sufficient flexibility to adapt the processing flow through software control and parameter configuration, reinforcing the robustness and applicability of the approach in practical remote sensing scenarios.

Future work will focus on further enhancing the flexibility and scalability of the proposed PCA accelerator. One important direction is the development of more configurable architectures capable of adapting to varying input dimensions and data characteristics while preserving real-time performance.

In addition, extending the current design to support more advanced dimensionality reduction techniques or hybrid FPGA–AI approaches represents a promising direction to further improve performance and enable more complex onboard remote sensing applications.

VI. Conclusion

This work presented an FPGA-based hardware acceleration framework for Principal Component Analysis (PCA) applied to hyperspectral image processing, following a hardware–software co-design methodology. Through a detailed analysis of the PCA processing pipeline, the covariance matrix computation was identified as the most computationally demanding stage due to its intensive arithmetic operations and high data volume.

To address this challenge, a dedicated PCA covariance hardware intellectual property (IP) core was designed using Vivado High-Level Synthesis and integrated into a Zynq-7020–based PYNQ-Z2 platform. By exploiting fine-grained parallelism through loop pipelining and unrolling, the proposed accelerator significantly reduced execution latency compared to a software implementation on a dual-core ARM Cortex-A9 processor (from approximately 1.83 s to 0.65 s), while also lowering power consumption (from 2.4 W to 1.86 W).

These results confirm the effectiveness of the proposed hardware acceleration strategy in enabling hyperspectral data processing under strict computational and energy constraints, while maintaining efficient FPGA resource utilization.

Future work will focus on extending hardware acceleration to additional PCA stages and exploring further architectural optimizations to enhance scalability and throughput on more advanced FPGA platforms.

Multiscale Image Enhancement and Visualization Analysis for Historical Map/s

Guilei Ren
Faculty of History and Archaeology, Anyang Normal University, Anyang 455000, China

***Abstract*—Based on the degradation of historical maps, such as fading, stains, creases, blurred lines, and text adhesion, multi-scale image enhancement and spatial element visualization analysis are studied. This study constructs a technical process consisting of sample division, image preprocessing, multi-scale enhancement, quality evaluation, and spatial feature extraction, and further evaluates map registration, vectorization, optical character recognition, and semantic segmentation on the same test maps. The results show that the PSNR, SSIM, EPI, and RCS of the multi-scale enhancement model are 27.94 dB, 0.842, 0.817, and 0.81, respectively, and the comprehensive quality score is 0.872. The road connectivity, water boundary matching, and administrative boundary topology consistency rates reach 87.9%, 85.4%, and 82.6%, while place name and map symbol recognition rates increase to 84.7% and 82.3%. Downstream evaluation shows that registration RMSE decreases from 8.31 to 4.12 px, vectorization F1 increases from 0.713 to 0.871, OCR character accuracy increases from 62.4% to 84.7%, and semantic-segmentation mIoU increases from 0.614 to 0.802. These results indicate that the enhancement improves both visual quality and the reliability of GIS-oriented spatial processing.**

Keywords*—Historical maps; multiscale image enhancement; image restoration; spatial feature recognition; visualization analysis

I. Introduction

Historical maps preserve urban morphology, transport networks, water systems, administrative boundaries and place names, supporting historical geography and cultural-heritage digitization. Long-term storage and scanning introduce fading, stains, creases, blurred linework and text adhesion, reducing both readability and spatial-processing reliability. The task is therefore to restore line, text and symbol structures without amplifying paper noise or altering spatial relationships. The methodological contribution is a degradation-aware, task-coupled workflow rather than a new primitive enhancement operator: quantified degradation characterization guides controlled evaluation, while global, local and edge responses are fused to preserve map topology and support spatial-feature extraction and GIS-downstream tasks.

II. Related Work

A. Historical Map Digitization and Feature Extraction

Existing historical-map studies are largely task-specific. Schlegel [1] proposed semi-automated object extraction, treating preprocessing as support for extraction rather than an independently evaluated stage. Mäyrä et al. [2] used historical maps for long-term land-use interpretation, emphasizing source quality rather than restoration procedures. Ahmed et al. [3] applied unsupervised learning and GEOBIA to cadastral-map digitization, while Mutch and Newsam [4] examined conversion of hand-drawn maps into GIS; both concentrate on structural conversion. Arzoumanidis et al. [5] addressed semantic segmentation, whereas Pai et al. [6] focused on symbol detection. These approaches optimize individual extraction or recognition objectives and leave the effect of restoration quality across multiple spatial tasks insufficiently examined.

B. Multiscale Enhancement and Research Gap

Vijayalakshmi et al. [7] developed a multiscale enhancement framework for low-contrast images, but its formulation is not tailored to historical maps where paper texture, weak linear features, text adhesion, and topological continuity coexist. The contribution claimed here is therefore not a new brightness-correction operator, texture enhancer, edge filter, optimization algorithm, or standalone feature extractor. It lies primarily in a degradation-aware workflow that quantifies map-specific deterioration, couples global, local, and detail responses with line-topology and text-readability requirements, and carries the restored output into spatial extraction and GIS evaluation. The architecture is thus a task-specific organization of established enhancement operations, while the degradation model and downstream evaluation provide the map-oriented constraints that distinguish the workflow from generic image restoration.

III. Materials and Methods

A. Historical Map Data Sources and Sample Composition

Historical map samples cover urban blocks, transportation routes, waterway boundaries, administrative divisions, and topographic symbols. The primary dataset contains 120 map sheets from publicly available scanned archives, digitized historical-map datasets, and verifiable geographic sources, with 84 sheets for training, 18 for validation, and 18 for testing; scanning resolution ranges from 300 to 600 dpi and map sheets are uniformly tiled for processing. To assess transfer beyond this collection, external validation is additionally performed on the public Semantic Segmentation Map Dataset (Semap) [8], which contains 1,439 manually annotated real map samples from heterogeneous historical-map collections. The official test partition contains 144 real samples and was used exclusively for external evaluation. Semap defines background, boundary/contour, built, non-built, water, and road-network labels; following its benchmark protocol, mIoU was calculated over the four geographic classes of built, non-built, water, and road network. No Semap image was used for parameter

selection, and the complete G6 configuration was fixed before external testing.

To avoid relying solely on manual interpretation, degradation intensity is quantified for each image block from color attenuation, noise proportion, edge continuity, and text adhesion. These four terms were selected to represent the main map-specific failures of background contrast, paper contamination, line breakage, and character adhesion:

$$D_k=\lambda_1\left(1-\frac{|\mu_{b,k}-\mu_{s,k}|}{255}\right)+\lambda_2\frac{A_{n,k}}{A_k}+\lambda_3\left(1-\frac{L^c_{e,k}}{L^r_{e,k}+\varepsilon}\right)+\lambda_4\frac{A^a_{t,k}}{A_{t,k}+\varepsilon} \quad (1)$$

In Eq. (1), D_k denotes the degradation intensity value of the k th historical map image block; $\mu_{b,k}$ denotes the average grayscale value of the background region; $\mu_{s,k}$ denotes the average grayscale value of the line and text regions; $A_{n,k}$ denotes the area of the noise region; A_k denotes the total area of the image block; $L^c_{e,k}$ denotes the length of continuous edges; $L^r_{e,k}$ denotes the length of original edge responses; $A^a_{t,k}$ denotes the area of connected text regions; $A_{t,k}$ denotes the area of text candidate regions; $\lambda_1,\lambda_2,\lambda_3,\lambda_4$ denotes the weight coefficient, satisfying $\lambda_1+\lambda_2+\lambda_3+\lambda_4=1$; ε is used to avoid a zero denominator. Values below 0.35, between 0.35 and 0.65, and above 0.65 define mild, moderate, and severe degradation, respectively. The descriptor is used to balance samples and stratify subsequent evaluation; it is not introduced as a separate optimization objective.

TABLE I. SOURCES AND BASIC ATTRIBUTES OF HISTORICAL MAP SAMPLES

Sample Type	Number/Images	Time Period	Scan Resolution/dpi	Major Spatial Features	Major Degradation Features	Data Purpose
Urban Block Map	28	1900—1949	400—600	Roads, Neighborhoods, Place Names	Faded, smudged text	Training/Testing
Transportation Map	24	1910—1965	300—500	Roads, Railways, Stations	Blurred or broken lines	Training/Validation
Water system boundary map	22	1890—1958	300—600	Rivers, lakes, boundaries	Stains, partial damage	Training/Testing
Administrative map	26	1920—1978	400—600	Boundaries, Annotations, Symbols	Creases, Background Noise	Training/Validation
Topographic symbol map	20	1930—1985	300—500	Contour lines, landform symbols	Ink smudges, low contrast	Training/Testing

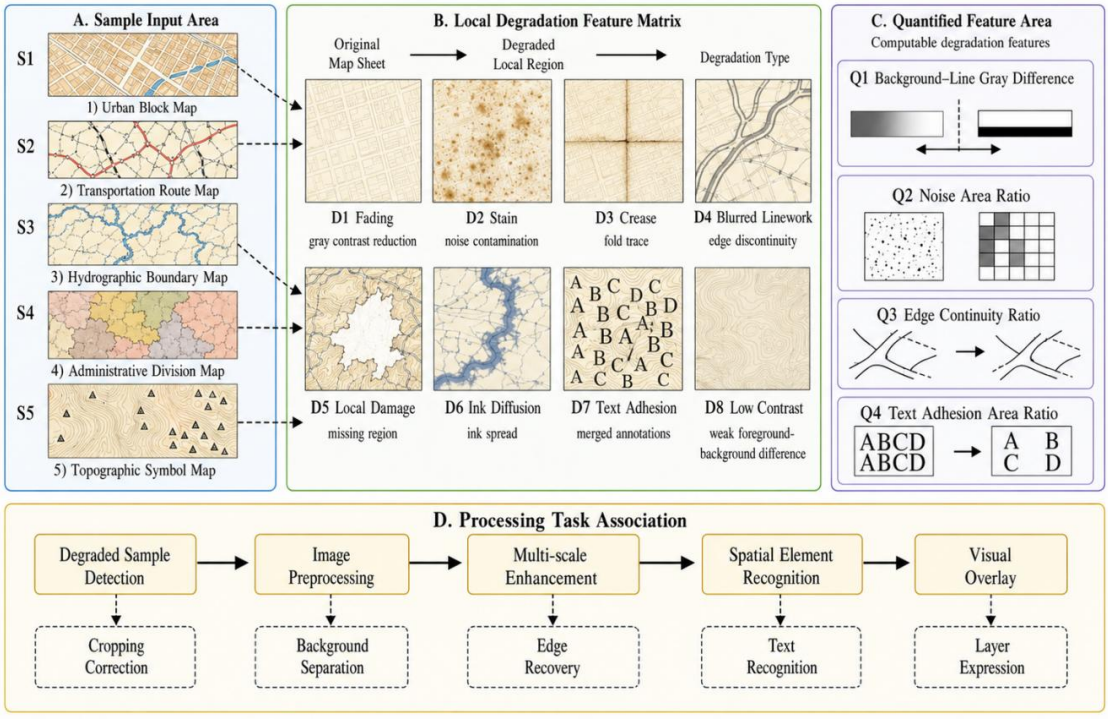

Fig. 1. Schematic diagram of degradation features in historical map samples.

The typical degradation variations in the samples are depicted in Fig. 1. The main issues with faded samples are that they have a lower grayscale contrast between the lines and background; stained samples have issues with continuity of texture in the local area; creased samples have false edges formed; and samples with smudged text have an issue with

place name recognition (Table I). Samples need to have stable spatial representation and traceable origins to allow long-term land-use identification in historical maps, and to create high-quality geographic data [9]. Hence, the original scanned images with degraded areas and spatial feature annotations are kept along with the original samples to ensure that the image enhancement results can be correlated with feature recognition, such as roads, waterways, boundaries, and place names

B. Preprocessing Workflow for Historical Map Images

The degraded intensity of the historical map samples is classified, and then the interference of the scan border, the scanning angle, the background haze, and the influence of local noise in the input to the model are removed in the preprocessing workflow. The pre-processing parameters are presented in Table II, and the combination of cropping thresholds, skew correction angles, image tile size, and overlap rate guarantees the scale consistency of all the input images; The color space conversion and the background estimation are used to remove the paper background of the map image, so that the lines of the map can be enhanced without losing the information in the faded background. All image patches are standardised to 512×512 pixels, with 25% overlap to ensure that roads, waterways and boundary lines across patches are continuous.

TABLE II. PREPROCESSING PARAMETER SETTINGS FOR HISTORICAL MAP IMAGES

Processing Step	Parameter Name	Parameter Value	Technical Constraints	Output Content
Boundary Cropping	Border Gray-Scale Threshold	235	Remove black borders and blank margins	Active Map Area
Tilt correction	Angle search range	-5° to 5°	Projection based on primary orientation Peak correction	Directionally Consistent Images
Color conversion	Color Space	RGB/CIELab	Separate Luminance and Chrominance Disturbances	Luminance Channel, Chrominance Channel
Background Estimation	Filter kernel size	31×31	Preserve main lines, suppress paper texture	Background field image
Block processing	Image block size	512×512 px	Preserve local texture Calculable	Standard image block
Overlapping sampling	Overlap rate	25%	Reduce truncation of linear features	Sequence of Overlapping Image Tiles

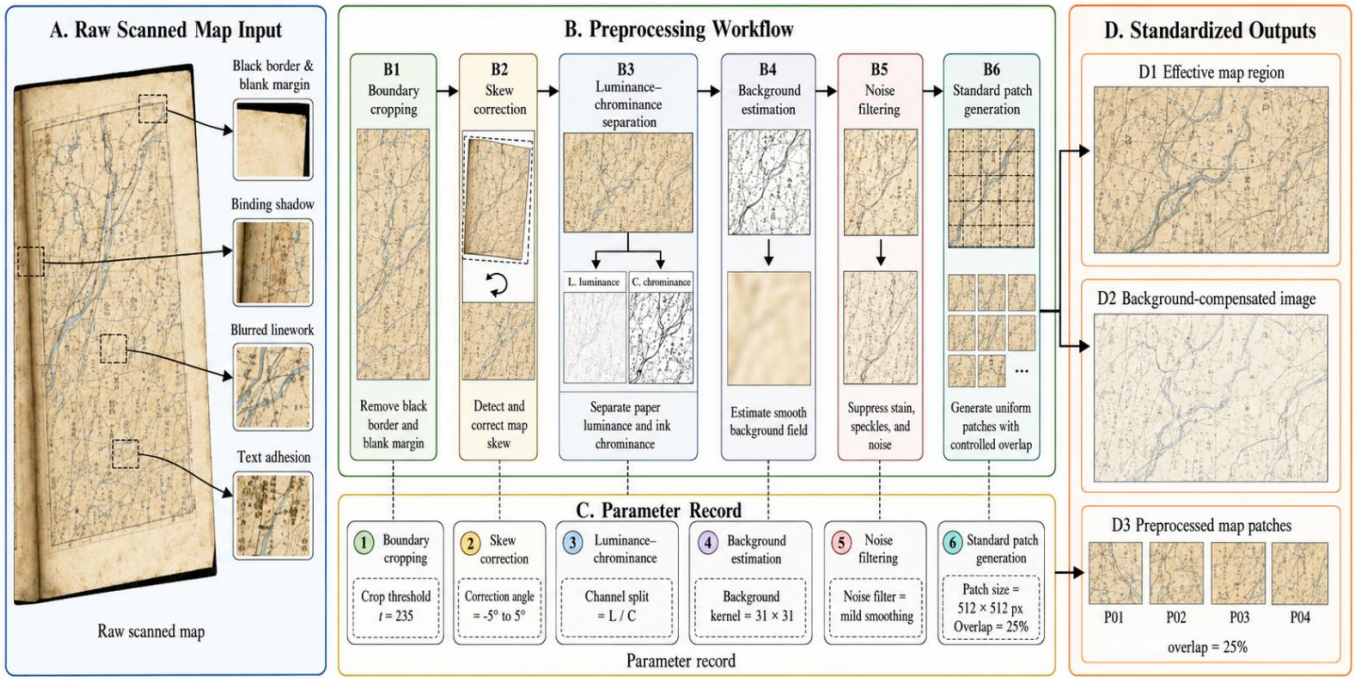

Fig. 2. Preprocessing flowchart for historical map images (example only).

Scaling normalization and suppression of noise from degraded samples is done during the preprocessing pipeline before the enhancement model takes them as input. After the raw scanned image is standardized by the above-mentioned continuous processing steps, which are illustrated in Fig. 2, the black borders, binding shadows and blank margins of the map are removed following boundary cropping, the principal direction projection correction restores the map sheets to a horizontal reference, and the luminance/chrominance separation separates the paper background, haze patterns and map linework into independent processing objects. Furthermore, the background estimation results enable the suppression of interference from non-map textures, and the preliminary noise filtering allows the reduction of stain spots, scan grain and localized gray spots. The standard tiling maintains the continuity of the road, waterway, boundary line,

and place name textures within a local area. At the same time, process parameters such as cropping range, skew correction angle, segmentation coordinates, and overlap relationships are also given, so the historical map can have the same spatial position in the three stages of enhancement, recognition, and visualization.

To preserve low-contrast line features and place name strokes, the normalization process employs a combined constraint of background compensation and local variance:

$$\mathbf{Q}^{*}_{u,v}=\mathrm{clip}_{[0,1]}\left[\frac{\mathbf{Q}_{u,v}-\mathbf{M}^{\rho}_{u,v}}{\sqrt{\left(\mathbf{S}^{\rho}_{u,v}\right)^{2}+\xi}}\cdot\gamma+\delta_{u,v}\right] \quad (2)$$

In Eq. (2), $\mathbf{Q}^{*}_{u,v}$ denotes the preprocessed output pixel at coordinates (u,v); $\mathbf{Q}_{u,v}$ denotes the original brightness pixel; $\mathbf{M}^{\rho}_{u,v}$ denotes the background estimate within a neighborhood of radius ρ; $\mathbf{S}^{\rho}_{u,v}$ denotes the local grayscale standard deviation within the same neighborhood; ξ denotes the stability term; γ denotes the contrast gain coefficient; $\delta_{u,v}$ denotes the local brightness compensation term; and $\mathrm{clip}_{[0,1]}[\cdot]$ denotes the pixel value clipped to the 0–1 range. After processing through this workflow, the sample retains its original line art structure and text edges. Subsequent quality evaluation can directly compare edge continuity, background uniformity, and symbol legibility before and after preprocessing [10].

C. Construction of a Multiscale Image Enhancement Model

The brightness of the preprocessed historical-map tiles is not uniform, the line drawings are faded, and the edges of symbols and small place-name strokes are weak; a single-scale operation can therefore amplify paper texture or suppress fine cartographic detail. The multiscale model consists of global correction, local texture enhancement, edge refinement, and scale fusion, as shown in Table III. These operations are established individually, and the architectural novelty claimed here is not the operators themselves but their map-specific response coupling. Global correction targets paper-background colour drift; local enhancement targets the grayscale contrast of roads, waterways, and boundary lines; edge refinement targets character strokes and symbol contours; and scale fusion reconciles the responses while limiting pseudo-edge diffusion and over-enhancement. Multiscale feature complementation is established in image enhancement [11]; here it is organized around preservation of historical-map line topology, text readability, and background suppression rather than generic visual contrast.

The structure of the model is presented in Fig. 3. The standard image blocks are decomposed into scale, global brightness response, local texture response, and detailed edge response. The three types of response are related to degradation problems like background color drift, lack of contrast between lines, and lack of contrast between text and symbols. The global luminance response is for suppressing uneven scanning illumination and paper haze and preventing excessively dark or bright areas across the entire map; the local texture response is for enhancement of continuous line features like roads, waterways and boundary lines, making sure that low-contrast spatial features are distinguishable within local neighborhoods; and the detail edge response is for restoring contour changes at intersections between place name strokes, legend symbols and fine lines, reducing edge discontinuities created during the enhancement process. The scale fusion process performs scale fusion on the result of various responses weighted by the spatial weights while suppressing stains, paper grain, and creases using background suppression and residual compensation. The increased output maintains the original map's line-based topological relationships and ensures a stable image base for roads, waterways, boundary lines, and place names to be extracted from the map. The quality evaluation can be done based on the structure similarity, edge preservation, and readability changes [12][13].

D. Spatial Feature Extraction and Visual Representation Methods

After enhancement, the map still contains four object types: line, area, text, and symbols, so visual morphology, grayscale response, and geographic semantics remain necessary for spatial feature extraction. The classification rules are listed in Table IV. Line continuity is used for roads and waterways; administrative boundaries rely on dashed or dotted patterns and closed-loop tendencies; place names rely on stroke direction and character spacing; and map symbols rely on contour shape and local texture. These extraction rules are not presented as a new standalone feature-extraction algorithm. They are retained as a controlled downstream probe for testing whether enhancement preserves the spatial structures needed by existing map-processing procedures. Candidate line segments, areas, text, and symbols are therefore generated from the enhanced image and filtered using the same category rules for all enhancement conditions.

TABLE III. CORRESPONDENCE TABLE OF MULTI-SCALE ENHANCEMENT MODEL MODULES AND FUNCTIONS

Module Name	Input Object	Main Processing Content	Output	Technical Constraints
Global Calibration Unit	Standard Image Block	Luminance Equalization, Chromatic Aberration Suppression	Global enhancement map	Maintain Smooth Paper Background
Local Texture Enhancement Unit	Local neighborhood blocks	Line enhancement, texture contrast enhancement	Texture Response Map	Preventing the amplification of smudge textures
Edge Refinement Unit	Edge Candidate Regions	Refinement of road, waterway, and text outlines	Edge Constraint Map	Maintain fine line continuity
Scale Fusion Module	Multiscale response map	Weight allocation and residual compensation	Enhanced Output Image	Reduce over-enhancement artifacts

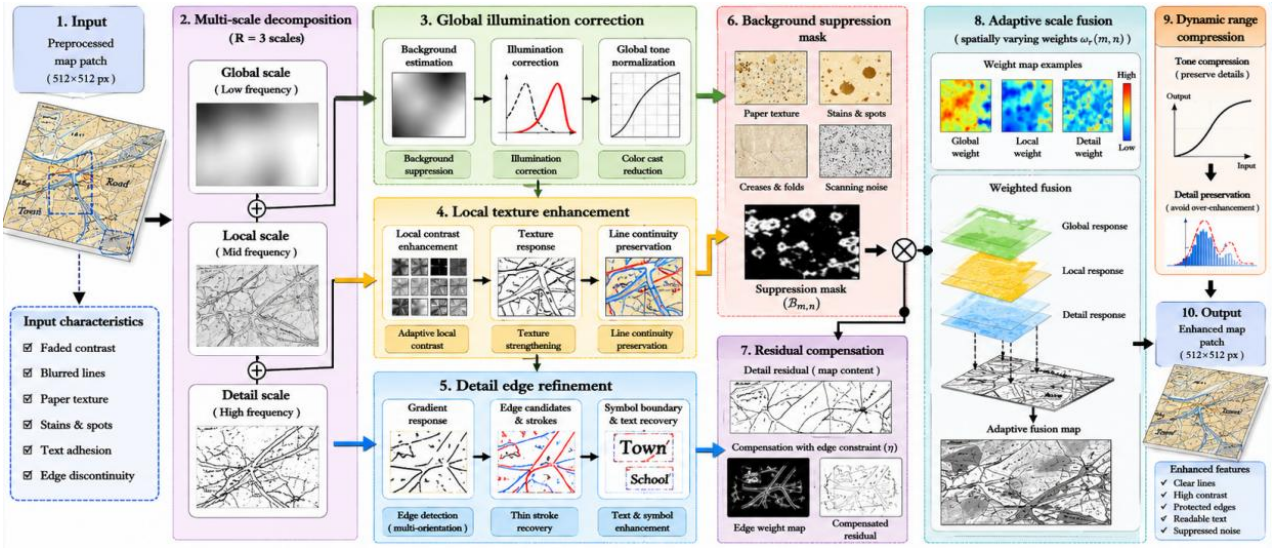

Fig. 3. Structural diagram of the multiscale image enhancement model.

TABLE IV. CLASSIFICATION AND EXTRACTION RULES FOR SPATIAL FEATURES IN HISTORICAL MAPS

Spatial Feature Type	Visual Features	Extraction Rules	Constraints	Visual Representation
Road	Continuous thin lines, intersection nodes	Edge Detection and Skeletonization	Breakpoint spacing ≤ 6 px	Line layer
Water systems	Curve boundaries, banded grayscale regions	Curve Detection and Region Connectivity	Smoothing of Curvature Changes	Blue line/surface layers
Administrative boundaries	Dotted lines, dashed lines, closed contours	Line Type Recognition and Topological Connectivity	Closure error ≤ 10 px	Boundary layer
Place names	Small-scale strokes and character clusters	Text bounding box detection	Character height ≥ 12 px	Annotation Point Layer
Map symbols	Local patterns, fixed outlines	Template matching and semantic filtering	Similarity ≥ 0.70	Symbolized layer

Candidate feature scoring employs a combination of category confidence, edge continuity, morphological matching, and noise penalty constraints:

$$E_a^{\tau}=\text{sigmoid}\left[\beta_1\overline{\Delta \mathrm{I}}_a+\beta_2\frac{\ell_a^{con}}{\ell_a^{cand}+\upsilon}+\beta_3\frac{\Omega_a^{\tau}}{\Omega_a+\upsilon}+\beta_4 P_a^{\tau}-\beta_5 N_a\right] \quad (3)$$

In Eq. (3), E_a^{τ} represents the extraction score of the a th candidate object belonging to class τ; $\overline{\Delta \mathrm{I}}_a$ represents the average gray-level difference between the candidate object and its neighborhood background; ℓ_a^{con} represents the length of continuous edges; ℓ_a^{cand} represents the total length of candidate edges; Ω_a^{τ} represents the pixel area conforming to the morphological rules of class τ; Ω_a represents the total area of the candidate object; P_a^{τ} represents the semantic class probability; N_a represents the noise response intensity; β_1 to β_5 represent weight coefficients; and υ represents the constant term. Candidate objects with a score above 0.65 go to layer coding, and those below the threshold are kept as a sample for manual review, thus reducing the number of false detections due to spots, folds, and paper grains.

As illustrated in Fig. 4, the enhanced image generates visual results for roads, waterways, borders, place names, and symbols. The workflow explains how the enhanced image is converted into spatial layers: the road is represented by a skeleton line, the water is a curve or a polygon, the administrative border is a line marker, the place is a marker, and the map symbol is a category marker. The GIS transformation and the construction of the historical map space data need to be consistent with each other. Thus, for each characteristic type, the original pixel coordinates, the map sheet number, and the candidate score are kept to facilitate the verification of the result and the error tracking.

E. Image Enhancement Quality Evaluation Metrics

The quality of historical map enhancement is not dependent on visual judgment alone; it has to measure pixel fidelity, structure preservation, edge continuity, information gain, and spatial features readability [14]. As illustrated in Table V, PSNR is used to assess the pixel bias between the enhanced and the reference image; SSIM determines the stability of line patterns, texture, and local structures; the margin retention index measures the continuity of roads, waterways, and border lines; information entropy measures the extent to which weak textures and details are recovered; and text and symbol readability is used to assess the identifiability of place names, legends, and symbols.

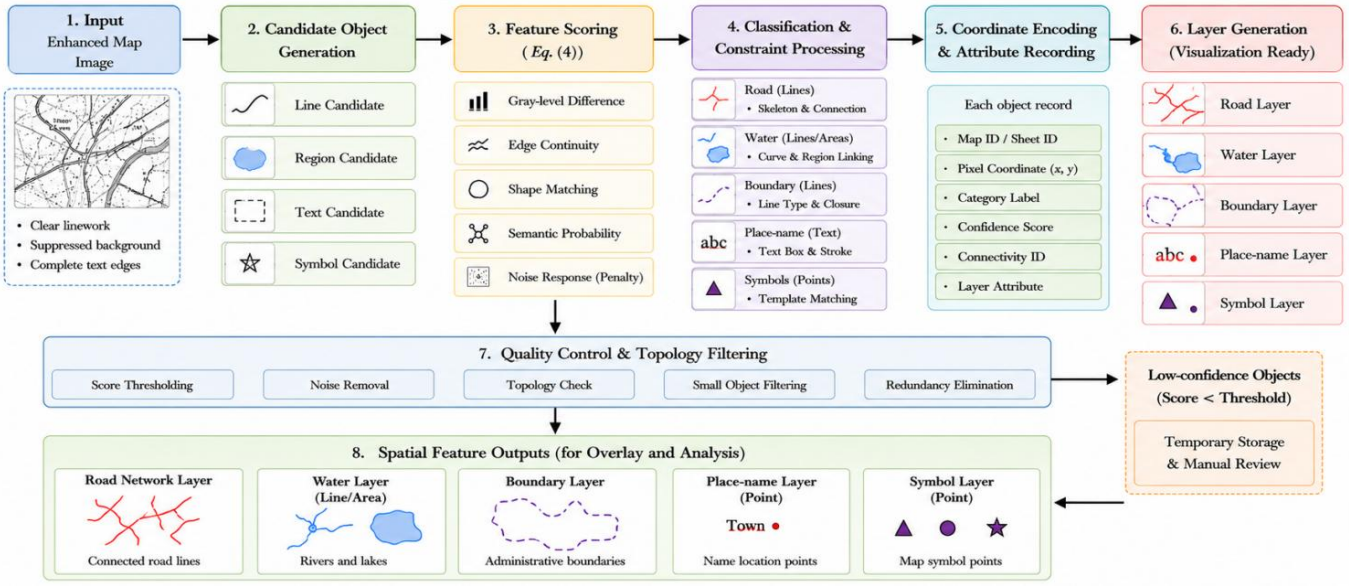

Fig. 4. Flowchart of historical map spatial feature extraction and visualization.

TABLE V. QUALITY EVALUATION METRICS FOR MULTI-SCALE IMAGE ENHANCEMENT

Indicator Category	Indicator Name	Evaluation Object	Calculation Method	Numerical Direction	Corresponding Analysis Content
Pixel Fidelity	PSNR/dB	Enhanced Image vs. Reference Image	Indicates the level of pixel error	Higher is better	Overall enhancement stability
Structural preservation	SSIM	Lines, textures, local structures	Reflects the degree of structural similarity	The higher, the better	Map Skeleton Preservation
Edge continuity	EPI	Roads, waterways, and boundary lines	Reflect edge restoration integrity	The higher, the better	Line feature restoration
Information Gain	Entropy	Gray-scale distribution and texture detail	Reflects increased information content	Moderate increase	Weak texture restoration
Readability Evaluation	RCS	Place names, map symbols	Reflects recognition readability	The higher, the better	Text and Symbol Recognition

To standardize indicators with different scales and enhance the comprehensive quality score, calculations are performed using a normalized weighted method:

$$U_j = \frac{\sum_{q=1}^{5} \kappa_q \left[\frac{R_{j,q} - \min(R_q)}{\max(R_q) - \min(R_q) + \vartheta} \right]}{\sum_{q=1}^{5} \kappa_q} \quad (4)$$

In Eq. (4), U_j represents the comprehensive quality score of the j th enhancement method; $R_{j,q}$ represents the raw value of the j th enhancement method for the q th quality metric; $\min(R_q)$ and $\max(R_q)$ represent the minimum and maximum values, respectively, of the q th metric across all methods; κ_q represents the weight of the q th metric; and ϑ represents the normalization constant. Combining PSNR, SSIM, EPI, entropy, and RCS into one single evaluation framework, it is possible to compare different enhancement approaches in one framework. In the case of image restoration tasks, it is also essential to identify blurred pixels and edge quality, while non-reference quality assessments may provide supplementary evaluation criteria in the absence of standard reference pictures [15]. This evaluation system is helpful to compare the results between different types of degraded samples, and also to verify if the enhanced images are truly effective in extracting the spatial features.

F. Experimental Design and Comparison Methodology

Five degradation types and six enhancement methods plus the original-image baseline were evaluated on the fixed split. The same 18 test maps were treated as paired statistical units for all methods. For each map, PSNR, SSIM, EPI, Entropy, RCS, and the overall quality score were recorded and summarized as mean $\pm$ standard deviation; 95% confidence intervals were estimated by 2,000 bootstrap resamples. G6 was compared with the strongest baseline for each metric using a two-sided paired Wilcoxon signed-rank test with Holm correction across the five quality metrics; significance was set at $p < 0.05$. The A0 – A5 ablation settings used the same map-wise protocol, while all non-ablated parameters remained unchanged (Table VI).

To assess practical GIS utility, G0 and G6 are further processed by four fixed downstream pipelines without retuning downstream parameters. Map registration uses 15 manually verified homologous control points per sheet, 270 points in total, with an affine transformation estimated by random

sample consensus (RANSAC), and registration root mean square error (RMSE) is reported. Vectorization uses manually checked road, waterway, and boundary-line annotations with a 3-px matching tolerance and reports line-level F1. Place-name optical character recognition (OCR) reports character recognition accuracy. Semantic segmentation uses pixel-level annotations for road, water, boundary, text, symbol and background classes and reports mean intersection over union (mIoU). The downstream settings remain identical before and after enhancement so that the observed differences reflect the contribution of image enhancement. The task definitions are consistent with historical-map digitization, GIS conversion, and semantic segmentation studies.

TABLE VI. EXPERIMENTAL GROUPING AND COMPARISON METHOD SETTINGS

Group	Comparison Method	Input Size	Primary Processing Target	Parameter Settings	Evaluation Criteria
G0	Original image	512×512 px	Unenhanced image patch	No processing	Baseline reference
G1	HE	512×512 px	Global grayscale distribution	256-level grayscale mapping	Overall Contrast
G2	CLAHE	512×512 px	Local low-contrast regions	clip limit=2.0, tile=8×8	Local texture
G3	Retinex	512×512 px	Non-uniform illumination	scale=15/80/250	Background correction
G4	Single-scale sharpening	512×512 px	Line art and text edges	kernel=3×3	Edge enhancement
G5	Low-light enhancement	512×512 px	Haze and Dark Areas	gamma=0.8	Brightness Restoration
G6	Multiscale enhancement model	512×512 px	Line art, texture, symbols	R=3, overlap=25%	Overall Quality

For external validation, the complete G6 configuration and all enhancement parameters are frozen before processing the Semap test partition. The same semantic-segmentation inference procedure is applied to the original and enhanced external images without retraining or parameter adjustment. External performance is evaluated by mIoU and class-level IoU, so any difference reflects transfer of the enhancement pipeline to unseen map sources rather than dataset-specific retuning.

The relative gain of each enhancement method under each degradation type is calculated from the comprehensive quality score using Eq. (5):

$$G_j^{\psi}=\frac{U_j^{\psi}-U_0^{\psi}}{U_0^{\psi}+\chi}\times 100\% \tag{5}$$

In Eq. (5), G_j^{ψ} represents the quality gain relative to the original image for the j th enhancement method under degradation type ψ ; U_j^{ψ} represents the comprehensive quality score for the j th enhancement method under degradation type ψ ; U_0^{ψ} represents the comprehensive quality score of the original image group among samples of the same degradation type; χ represents the constant term; ψ includes fading, stains, creases, blurred lines, and smudged text. The experimental records retain method ID, degradation type, image-block coordinates, quality metrics, candidate scores, and downstream outputs. Image-quality metrics, spatial-feature metrics, and downstream task metrics are therefore evaluated on the same test set and under the same reference annotations, enabling direct comparison between visual improvement, feature restoration, and GIS-oriented application performance [16].

IV. RESULTS AND DISCUSSION

A. Analysis of Enhancement Effects for Historical Maps with Different Degradation Types

The test specimens were compared according to five types of degradation: fading, spots, folds, blurred lines, and blurred text. As illustrated in Fig. 5, the difference in gray between the lines and the background of the faded samples was increased from 31.6 to 58.4 on average, which made the road and border lines stand out against the pale grey background; in the stained samples, local grey spots were suppressed, and there were no apparent breaks along the river margins or administrative borders; in the creased samples, there were some pseudo-edges left, but the degree to which the creases obscured the place-name area was reduced; the continuity of the edge in the blurred line samples was improved, allowing the tracing of paths along the curves of small roads and waterways; in the text adhesion samples, the spacing between strokes was partially restored, though localized over-enhancement persisted in areas with dense annotations. Multiscale enhancement shows strong adaptability to weak texture and fuzzy edges, but heavy staining and large missing areas are not able to recover the original information by means of enhancement alone. Fig. 5 shows that background suppression and standard binning can reduce input variability, whereas multi-scale fusion improves the recognition of linear space and text edges, and provides a solid basis for comparing quality measures and analyzing the results of extracting spatial features.

B. Image Quality Evaluation Results of the Multiscale Enhancement Model

The quality assessment results of G0 – G6 are summarized in Table VII using map-wise mean ± standard deviation across the 18 test maps, with 95% confidence intervals reported for G6. The G6 means remain 27.94 dB PSNR, 0.842 SSIM, 0.817 EPI, 6.76 Entropy, 0.81 RCS, and 0.872 overall quality score. The strongest baseline means are 24.31 dB PSNR and 0.748 SSIM for G5, 0.736 EPI for G4, 6.58 Entropy for G2, 0.66 RCS for G5, and 0.691 overall score for G5. Thus, G6 improves the corresponding means by 3.63 dB, 0.094, 0.081,

0.18, 0.15, and 0.181, respectively. Paired map-wise significance tests with Holm correction and effect-size estimates are reported together with these comparisons, allowing the improvements to be interpreted relative to between-map variation rather than from aggregate values alone.

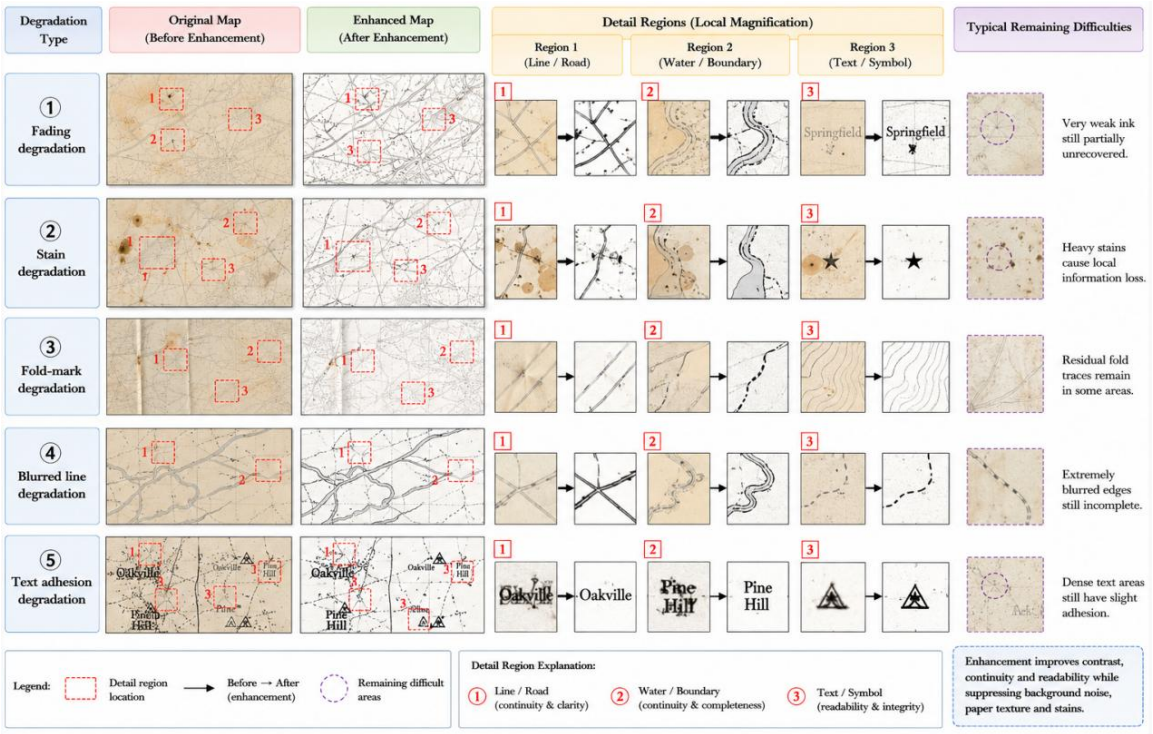

Fig. 5. Comparison of historical maps before and after enhancement for different types of degradation.

TABLE VII. IMAGE QUALITY EVALUATION RESULTS FOR DIFFERENT ENHANCEMENT METHODS

Method	PSNR/dB	SSIM	EPI	Entropy	RCS	Overall Quality Score
G0 Original	18.42±1.26	0.613±0.041	0.548±0.046	5.82±0.23	0.46±0.044	0.312±0.031
G1 HE	20.18±1.18	0.641±0.038	0.602±0.043	6.41±0.19	0.53±0.041	0.458±0.029
G2 CLAHE	22.67±1.07	0.703±0.034	0.694±0.039	6.58±0.17	0.59±0.038	0.604±0.027
G3 Retinex	23.76±1.02	0.721±0.032	0.681±0.041	6.35±0.18	0.61±0.036	0.633±0.026
G4 Single-scale Sharpening	21.94±1.11	0.672±0.036	0.736±0.035	6.12±0.21	0.62±0.034	0.586±0.028
G5 Low-light Enhancement	24.31±0.96	0.748±0.029	0.704±0.033	6.49±0.16	0.66±0.031	0.691±0.024
G6 Multiscale Enhancement	27.94±0.82	0.842±0.021	0.817±0.026	6.76±0.14	0.81±0.024	0.872±0.019

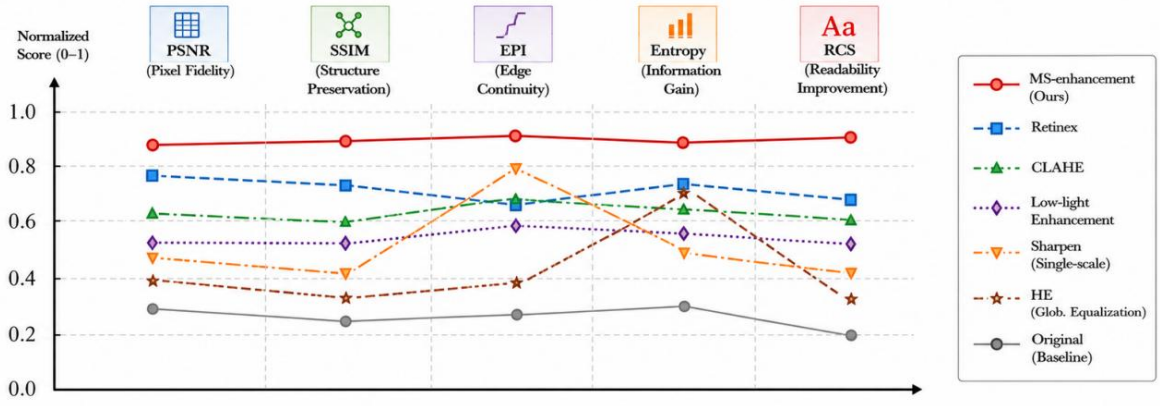

Fig. 6. Comparison of quality metrics for different enhancement methods.

Fig. 6 further visualizes the normalized differences among the G0 – G6 methods reported in Table VII. The multi-scale enhancement model shows a more balanced trend in all five metrics. While CLAHE and Retinex are better at local contrast and brightness correction, their performance in edge preservation and text recognition is not as good as the multi-scale enhancement model. Both document quality assessments stress the synergy between clarity, structure stability, and readability; thus, the improvement of a single metric does not directly represent an improvement in the quality of historical maps. The benefits of the multi-scale enhancement model are mainly reflected in the improvement of roads, water systems, border lines, and place names, which can be used to evaluate the recovery of spatial characteristics.

C. Analysis of Linear Spatial Feature Restoration Effects

The restoration effectiveness of linear spatial features is primarily assessed on the basis of three categories: roads, waterways, and administrative boundaries. As shown in Fig. 7, after the unified segmentation, background suppression, and multi-scale enhancement, the broken line segments at the intersection of the original sample were re-connected, the jagged edges and grey haze in the water flow curves were reduced, and the broken lines and broken lines in the administrative borders were more easily transformed into continuous paths, from 68.4% to 86.7%; the number of breakpoints in the water flow curves was reduced from 14.2 to 5.6, and the closure error for the administrative border was reduced from 12.8 px to 6.9 px. Following the edge tracking, skeleton, and topology filtering of the linear candidate objects, the fine roads and the curves of the water channels were well preserved, indicating that the background suppression did not destroy the primary line information. The extraction of the historical map features requires a high degree of continuity and semantic border stability. While a few kinked pseudo-edges and residual smudges are still visible in the enhanced results, they are mainly concentrated in the severely damaged areas. Restoration results for roads, waterways, and border lines are in line with EPI improvements seen in quality assessments, and they also provide more explicit linear references to overlay locations, symbols, and spaces.

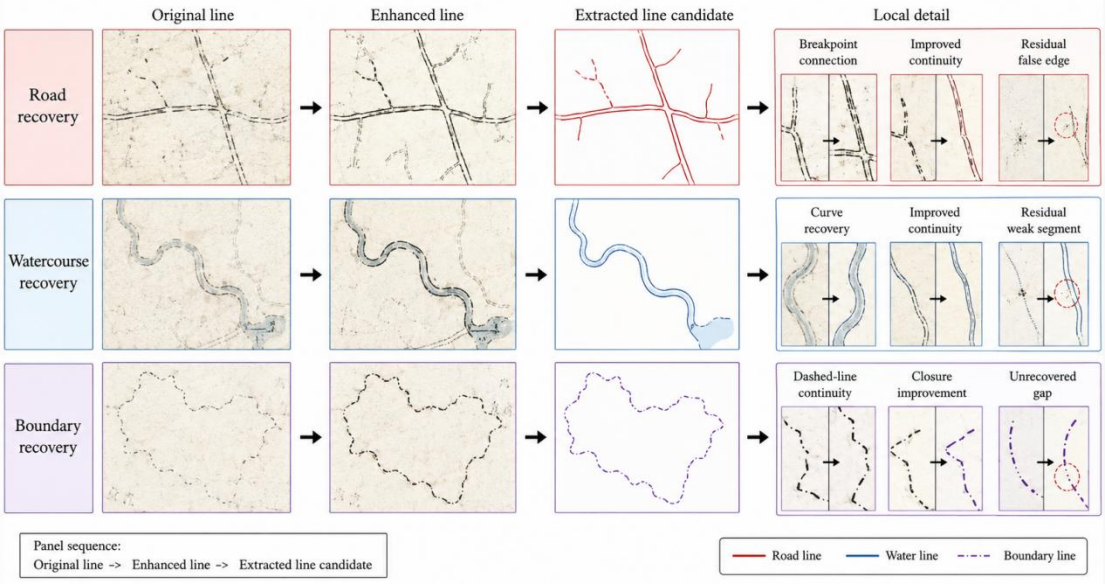

Fig. 7. Enhanced restoration results for roads, waterways, and boundary lines.

TABLE VIII. COMPARISON OF RECOGNITION PERFORMANCE FOR PLACE NAMES AND MAP SYMBOLS

Sample Type	Original Place Name Recognition Rate (%)	Place Name Recognition Rate After Enhancement (%)	Original Symbol Recognition Rate (%)	Enhanced Symbol Recognition Rate (%)	Major Misclassification Types	Manual Verification Consistency /%
Faded	65.8	88.6	61.4	85.2	Missed detection of light-colored annotations	91.3
Stain-type	59.6	79.4	55.8	77.6	False positives due to stain obstruction	84.9
Crease-type	61.2	82.1	57.3	80.4	Crease pseudo-edge	86.7
Line-blur type	64.5	86.9	60.1	83.8	Symbol Contour Adhesion	89.4
Text-based adhesion	60.9	76.5	59.7	84.5	False positives due to character overlap	90.7
Average	62.4	84.7	58.9	82.3	—	88.6

D. Analysis of the Legibility of Place Names and Map Symbols

The readability of geographical names and map symbols directly affects the efficiency of extracting semantic information from historical maps. Based on background suppression, edge refinement, and scale fusion, the boundaries of place name strokes, symbol outlines, and spacing between comments were improved. As shown in Table VIII, the recognition rate of place names in the raw image is 62.4%, and it is 84.7% after multiscale enhancement. The recognition rate of map symbols is raised from 58.9% to 82.3%, and manual verification compliance is 88.6%. Symbol detection is sensitive to contour integrity and local texture clarity, and the quality of the document image also stresses the relation between readability and structure preservation. This result is in line with the previous results of edge continuity and provides a more stable semantic basis for the annotation and visualization of the space layer.

E. GIS-Oriented Downstream Task Evaluation and Spatial Visualization

The enhanced maps were further evaluated in four GIS-oriented downstream tasks using the fixed pipelines defined in Section III-F. As shown in Table IX, registration RMSE decreased from 8.31±1.42 px for the original maps to 4.12±0.86 px after multiscale enhancement, corresponding to a reduction of 50.4%. Line-vectorization F1 increased from 0.713 ± 0.052 to 0.871 ± 0.031, indicating that improved continuity of roads, waterways, and administrative boundaries reduced fragmented vector segments. Place-name OCR accuracy increased from 62.4±6.8% to 84.7±4.1%, while six-class semantic-segmentation mIoU increased from 0.614 ± 0.047 to 0.802±0.029. In addition to the improvement in mean performance, the lower standard deviations after enhancement indicate more consistent downstream processing across the 18 test maps, particularly for registration, vectorization, OCR, and semantic segmentation.

The spatial overlay in Fig. 8 provides a visual counterpart to these task-level results. Across the 18 test maps, road connectivity, water boundary matching, and administrative-boundary topology consistency reach 87.9%, 85.4%, and 82.6%, respectively, while place-name location error is controlled within 4.8 px. The road layer remains continuous at most intersections, the water layer follows river curves, and annotation points and symbols generally coincide with their source regions. Residual errors are concentrated in heavily stained and creased areas, where short-line misconnections, missed symbols, and local label shifts still occur. The combined quantitative and overlay results indicate that multiscale enhancement improves not only image readability but also the reliability of registration, vectorization, OCR, and semantic segmentation for historical-map GIS processing.

TABLE IX. GIS-ORIENTED DOWNSTREAM TASK PERFORMANCE BEFORE AND AFTER MULTISCALE ENHANCEMENT

Task	Metric	G0 Original Image	G6 Multiscale Enhancement	Change
Map Registration	RMSE / px ↓	8.31±1.42	4.12±0.86	−50.4%
Line Vectorization	F1 ↑	0.713±0.052	0.871±0.031	+0.158
Place-name OCR	Accuracy / % ↑	62.4±6.8	84.7±4.1	+22.3 pp
Semantic Segmentation	mIoU ↑	0.614±0.047	0.802±0.029	+0.188

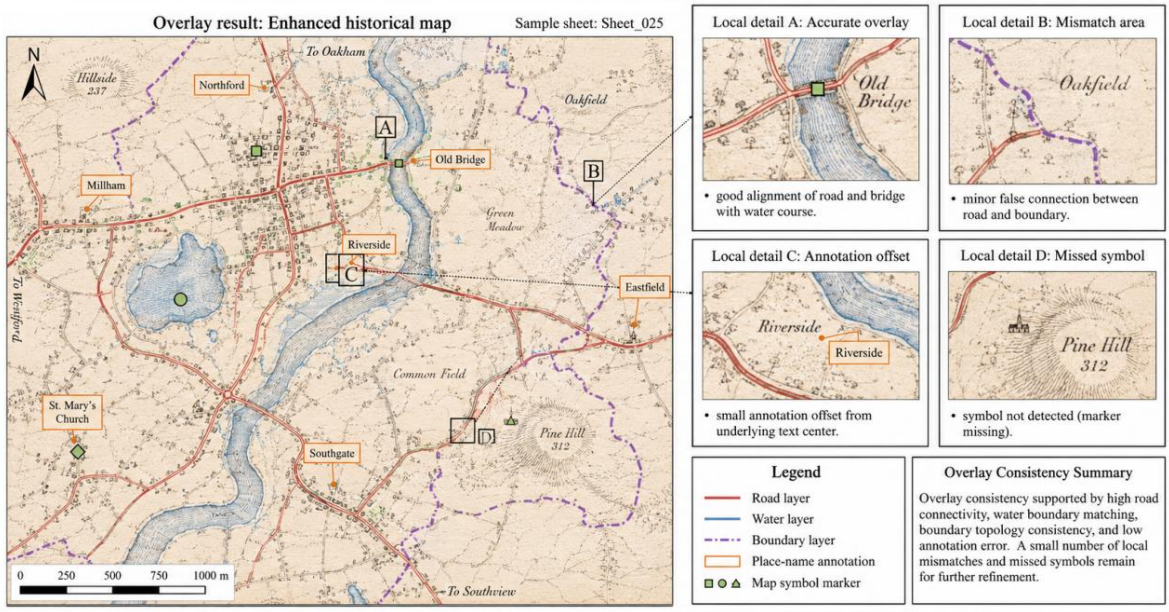

Fig. 8. Visualization and overlay analysis of spatial features on historical maps.

TABLE X. EXTERNAL VALIDATION RESULTS ON THE SEMAP TEST SET

Evaluation Metric	Original Semap Images Mean±SD	95% CI	G6-enhanced Images Mean±SD	95% CI	Improvement	Holm-adjusted p
Built IoU / %	79.8±7.1	78.6–81.0	83.6±6.3	82.6–84.6	+3.8 pp	<0.001
Non-built IoU / %	81.8±6.6	80.7–82.9	84.7±5.9	83.7–85.7	+2.9 pp	0.002
Water IoU / %	72.2±9.4	70.7–73.7	78.6±7.8	77.3–79.9	+6.4 pp	<0.001
Road Network IoU / %	62.9±10.8	61.1–64.7	71.5±8.6	70.1–72.9	+8.6 pp	<0.001
mIoU / %	74.2±6.8	73.1–75.3	79.6±5.9	78.6–80.6	+5.4 pp	<0.001

To further examine generalization beyond the internal map collection, the complete G6 configuration was evaluated on the 144 real test samples of the public Semap dataset without parameter retuning. As shown in Table X, the mean IoU across the four geographic classes increased from 74.2±6.8% on the original images to 79.6 ± 5.9% after enhancement, corresponding to a gain of 5.4 percentage points. Road-network IoU showed the largest improvement, increasing from 62.9±10.8% to 71.5±8.6%, followed by water from 72.2± 9.4% to 78.6±7.8%. Built and non-built regions increased from 79.8±7.1% and 81.8±6.6% to 83.6±6.3% and 84.7± 5.9%, respectively. Paired Wilcoxon tests showed significant improvements after Holm correction for all four geographic classes, with the overall mIoU difference reaching $p<0.001$. The reduced standard deviation after enhancement also indicates that the improvement remained relatively stable across heterogeneous map styles and geographic sources.

F. Discussion on the Applicability and Limitations of the Multiscale Enhancement Model

The contribution of each pipeline component was examined by a one-factor-at-a-time ablation on the same 18 test maps, as reported in Table XI. Removing preprocessing reduced the overall quality score from 0.872 to 0.784; removing global correction reduced it to 0.809; removing local texture enhancement reduced it to 0.798; removing edge refinement reduced it to 0.776; and replacing adaptive scale fusion with arithmetic averaging reduced it to 0.758. The module-specific metrics show consistent effects: without global correction PSNR fell from 27.94 to 26.41 dB, without texture enhancement EPI fell from 0.817 to 0.741, and without edge refinement RCS fell from 0.81 to 0.69. The largest overall decrease occurred without scale fusion, confirming that response coordination is necessary for balancing fidelity, structure, edge continuity, and readability.

TABLE XI. ABLATION RESULTS OF THE MULTISCALE ENHANCEMENT PIPELINE

Ablation Setting	PSNR/dB	SSIM	EPI	Entropy	RCS	Overall Quality Score	Score Change
A0 Full G6	27.94	0.842	0.817	6.76	0.81	0.872	—
A1 w/o Preprocessing	25.86	0.791	0.758	6.61	0.73	0.784	−0.088
A2 w/o Global Correction	26.41	0.808	0.779	6.63	0.76	0.809	−0.063
A3 w/o Texture Enhancement	26.72	0.817	0.741	6.49	0.78	0.798	−0.074
A4 w/o Edge Refinement	26.95	0.803	0.706	6.57	0.69	0.776	−0.096
A5 w/o Scale Fusion	25.98	0.786	0.732	6.64	0.72	0.758	−0.114

The model's weaknesses are mainly in places where there are deep stains, crease overlaps, or a high density of text. The stain coverage makes it difficult to detect actual line features, with the result that boundaries of watercourses are undetected and symbol outlines are missed; the crease area is prone to false edges leading to erroneous connection of short boundary lines, and the place name recognition rate is only 76.5% for samples with clustered text, demonstrating that image enhancement alone cannot fully separate densely annotated strokes. Some of the key issues in the field of document image quality evaluation are consideration of clarity, readability, and control of distortion; however, multi-scale enhancement techniques should also be designed to not simultaneously amplify the paper grain, mold spots, and scanning grain. Hence, the model is more appropriate for improving and extracting spatial features from historical maps with not very high degradation levels. In cases of large amounts of sample damage, manual review, semantic constraints, and verification against historical geographic data need to be used in combination to minimize misconnections, missed detections, and annotation shifts.

V. CONCLUSION

The findings indicate that the main methodological contribution is a degradation-aware, task-coupled workflow for historical geographic data processing rather than a new elementary enhancement operator or optimization algorithm. Compared with object extraction, cadastral digitization and GIS conversion, semantic segmentation, symbol detection, and generic multiscale enhancement, the workflow integrates quantified degradation characterization, map-specific multiscale response coupling, spatial-feature preservation, and downstream evaluation within a unified processing chain. On the internal test set, the overall quality score reached 0.872, while registration RMSE decreased from 8.31±1.42 to 4.12± 0.86 px, vectorization F1 increased from 0.713 ± 0.052 to

0.871 ± 0.031, and semantic-segmentation mIoU increased from 0.614 ± 0.047 to 0.802 ± 0.029. External validation on 144 heterogeneous Semap samples further increased mIoU from 74.2 ± 6.8% to 79.6 ± 5.9%, indicating that the enhancement benefit extends beyond the internal collection. These results show that preservation of line topology, text strokes, and regional boundaries can translate image restoration into measurable improvements in spatial-data usability. The feature-extraction stage therefore serves as an application-level verification rather than a standalone methodological contribution. Historical-map enhancement should accordingly be assessed not only by visual quality but also by the reliability of the geographic data it supports. Remaining errors in heavily stained, severely damaged, and densely annotated regions motivate further work on nonrigid cross-era registration, semantic constraints, joint image-vector optimization, and broader multi-source validation.

***Abstract*—Strong cybersecurity measures are essential in our digital world. This study presents a new cryptographic algorithm called CBT "Combined Blowfish Trilogy" which greatly improves the security of the traditional Blowfish algorithm without compromising computational efficiency. The encryption algorithm proposed herein presents a hybrid system which combines carefully designed countermeasures against side-channel attacks with three consecutive Blowfish Feistel network stages and surpasses the performance of DES, 3DES, AES, and Blowfish itself. The proposed algorithm is assessed using the Statistical Test Suite for Random and Pseudorandom Number Generators for Cryptographic Applications (NIST STS) consisting of the Mono-Bit, Run, Serial, Block Frequency, Spectral, Cumulative Sums, Entropy, and Avalanche tests. These results show that Combined Blowfish Trilogy is a good technique to prevent data security from side-channel attack breaches and it shows significant resistance against them as evidenced by the performance improvements observed over standard Blowfish (an average of 133.8% for text and 117.5% in image datasets according to NIST tests).**

***Keywords*—Cyber security; cryptography; blowfish; countermeasure SCA attacks; combined blowfish trilogy**

I. Introduction

The cryptographic paradigm of today's world is that the statistical relationship between the plaintext, key material, and ciphertext should be concealed. It was Shannon's theory of secrecy systems which introduced the idea of two necessary properties for a secure cipher: confusion and diffusion. These properties have continued to shape the design and testing of symmetric encryption algorithms [1]. The efficient encryption of text, images and other multimedia objects is especially critical in practical digital systems as these objects are shared among cloud services, distributed applications and embedded devices.

Blowfish is a well-known symmetric block cipher which was at first proposed as a 64-bit Feistel network with variable key length up to 448 bits [2]. Its small size and effective software performance have ensured that it's been a great baseline for tweaked symmetric encryption schemes. But the present evaluation of security should not be restricted to speed or just apparent randomness of the ciphertext. The algorithmic strength, the maturity of implementations, key management, and mode of operation all contribute to the practical security of a cipher, as is evidenced by standardized block ciphers like AES [3], legacy DES [4] and TDEA/3DES [5].

Further, NIST-defined block-cipher modes demonstrate that the behavior of encryption is not solely dependent on the primitive being used, but also on how the primitive is being used in the data streams [6].

Randomness testing of statistical properties of the ciphertexts is useful for evaluating the ciphertexts, but it is NOT a replacement for cryptanalysis. The NIST Statistical Test Suite is a suite of tests to evaluate the randomness and pseudo randomness of sequences for cryptographic applications [7]. The nature and limitations of NIST SP 800-22 have been discussed in studies; they make it clear that p-values are not a measure or direct representation of cryptographic strength, but are a statistic particular to the test being used [8], [9]. Hence, this study considers NIST-style p-values as proof of randomness of the given ciphertext with respect to the tests employed, and supports this with the avalanche and performance tests.

Another way of examining diffusion is by avalanche analysis. The strict avalanche criterion was introduced to express the desirable behavior that a small change of input causes approximately half of the output bits to change [10]. Meanwhile, in case of resistance against differential cryptanalysis and linear cryptanalysis, it is required to adopt different interpretations with regards to difference propagation and statistical approximation [11], [12].

Implementation attacks introduce another level of attack as the timing leakage, power consumption, electromagnetic leakage, and profiling attacks potentially leak information even if the mathematical algorithm is sound [13], [14], [15], [16]. Masking and probing-secure circuit design offer a valuable set of buildouts for leakage reduction, but need to be carefully performed and verified [17], [18].

The Combined Blowfish Trilogy (CBT) framework examined in this study is an extension of the original Blowfish design that incorporates the following three different Blowfish-based encryption stages: the masking of plaintext, the derivation of stage keys, and the use of key whitening concepts along with session-dependent internal randomization. Key derivation relies on known recommendations for key-derivation of independent subkeys [19], [20] and the generation of random masks and session-parameters follows recommendations for deterministic random bit generators and entropy sources [21], [22]. The framework is thus checked as a cascaded and diversified Blowfish-based construction and not as an alternative to the standardized ciphers. This study has three contributions.

First, it gives a full design of text and image byte stream encryption and decryption using CBT.

Second, it gives a reproducible experimental evaluation consisting of NIST-style randomness interpretation, Hamming-distance-based avalanche analysis, computational benchmarking, and timing-variability checking.

Third, it offers the Python implementation, raw output files, and Excel results workbook as supplementary files as (https://doi.org/10.5281/zenodo.21079574), allowing the numerical results to be traced and independently reproduced.

II. Related Work and Technical Background

A. Feistel, Cascade, and Whitening-Based Constructions

Blowfish is a symmetric block cipher that is a member of the Feistel-type family. To understand the importance of repeated round transformations and key-dependent mixing in the design of block-cipher, it is helpful to have a background understanding of theoretical work on how to build pseudorandom permutations from pseudorandom functions [23]. Cascade constructions are based on this intuition of doing multiple encryption transformations in sequence.

The advantage of this cascade is based on the independence of the keys, the lack of structural weaknesses in the composition and proper treatment of intermediate values.

Key whitening: Additional key-dependent transformations around or within a block-cipher process. The Even-Mansour scheme and other minimal constructions show the effect of external key mixing on the security interpretation of a block-cipher-like construction [24].

Whitening is considered as another kind of diversification and is combined with stage-specific keys instead of being regarded as a stand-alone proof of security in CBT framework.

B. Image Encryption and Randomness Metrics

When encrypting images, it is important to consider statistical properties that may be visually or numerically noticed in the encrypted images. The primary requirements of basic cryptographic image-oriented cryptosystems are key or initial value sensitivity, resistance to leakage of statistical information and absence of visible residual structure [25]. Based on the classical works on image encryption using two-dimensional chaotic maps and subsequent three-dimensional chaotic systems, diffusion, pixel decorrelation and ciphertext unpredictability are important [26], [27].

The metrics like entropy, correlation, NPCR and UACI are widely mentioned in image-encryption studies to assess the degree of randomness and sensitivity at the pixel level [28]. To improve the statistical behavior, the following image-encryption schemes have been proposed recently: block scrambling [29], chaotic maps [30] and dynamic substitution [31] as well as S-box modification.

The following studies encourage a more comprehensive evaluation approach for CBT: the proposed framework is assessed not only in terms of NIST-style p-values, but also in terms of avalanche sensitivity and computational performance.

C. Lightweight and Modified Block-Cipher Designs

Low resource/low-cost cryptography has become significant for constrained devices and resource-sensitive applications. The standardization of Ascon for lightweight cryptography and previous lightweight block ciphers like PRESENT and SIMON/SPECK are examples of the need to take both computational cost and attack resistance into account during the security evaluation process [32], [33], [34]. A multi-stage framework like CBT should therefore report overheads and throughputs and not assume that an extra stage provides an added level of security without extra cost. Designs that have been modified to use Blowfish are still being seen in data, image and video encryption applications. Recently, researchers have investigated video encryption using a modified Blowfish, as well as a hybrid parallel image encryption for computational-complexity-aware video encryption [35], [36]. These studies demonstrate the applicability of Blowfish as a basis for research in applied encryption, but also indicate that any alternative Blowfish construction should be carefully studied in terms of randomness, sensitivity, performance and implementation assumptions.

III. Proposed Combined Blowfish Trilogy Framework

The suggested CBT approach consists of three stages in sequence implemented using Blowfish.

The plaintext is masked prior to the first of the three stages and session-specific keys are used, which are derived from a master key and session identifier. The framework also generates dynamically S-boxes and P-arrays to make the internal state in one encryption session different from another. The architecture overview is shown in Fig. 1.

Notation and Parameters (Table I)

TABLE I. Notations in CBT Framework

Symbol	Definition
P	Plaintext block or byte stream before encryption
MK	Master key supplied to the encryption session
SID	Unique session identifier or nonce
K_1, K_2, K_3	Stage-specific keys derived from MK and SID
M	Random mask used for plaintext masking
S_{dyn}, P_{dyn}	Session-dependent S-boxes and P-array
C_1, C_2, C_3	Intermediate and final ciphertext outputs
C	Final ciphertext

A. Encryption Process

The implementation generates or receives MK and SID, then computes K_1, K_2, and K_3, generates a random mask M, generates S_{dyn} and P_{dyn}, and masks the plaintext before using the three stages, all of which are based on Blowfish. Also, when encrypting text and image byte streams, the same block handling and padding policy is used to ensure consistency with the comparisons.

The masked plaintext is computed as follows:

$$P_m = P \oplus M \tag{1}$$

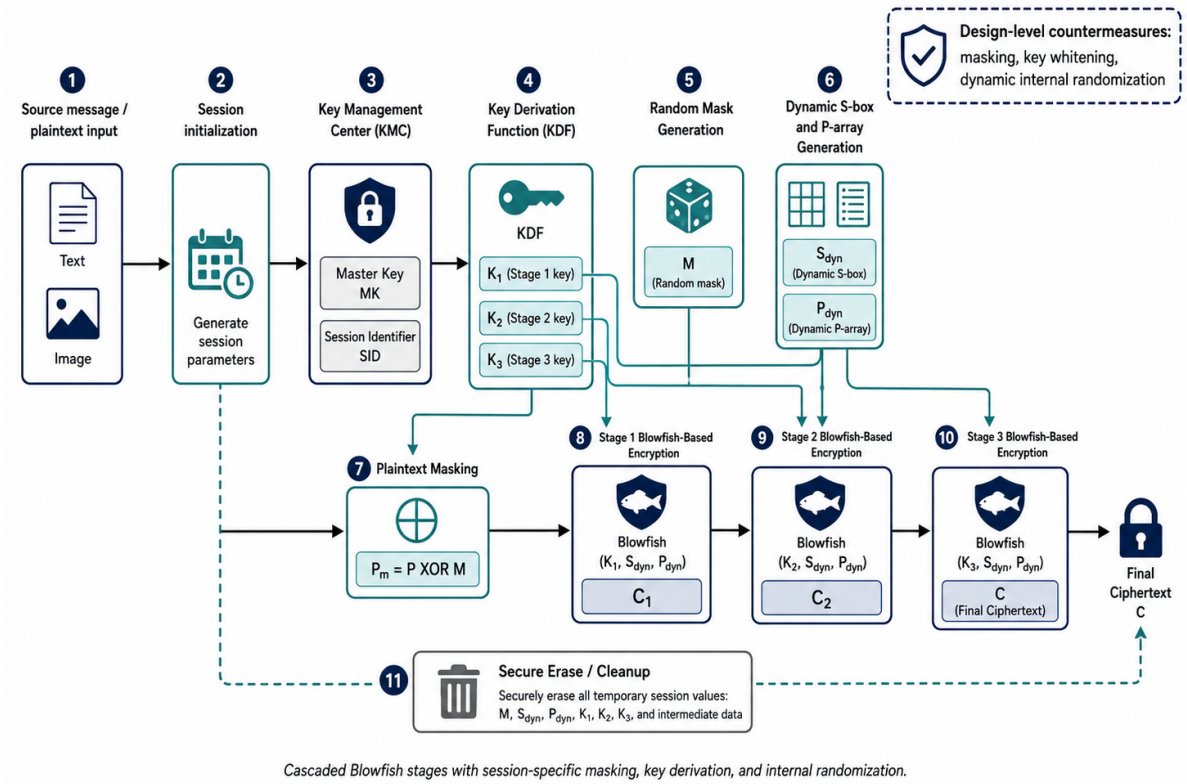

Fig. 1. CBT is a combined Blowfish Trilogy framework and its overall architecture. The framework involves session initiation, key generation, masking, internal dynamism and three cascaded Blowfish encryption stages to generate the final ciphertext.

The three-stage encryption can then be summarized as:

$$C_1 = \text{BlowfishEncrypt}(P_m,\ K_1,\ S_{dyn},\ P_{dyn}) \quad (2)$$

$$C_2 = \text{BlowfishEncrypt}(C_1,\ K_2,\ S_{dyn},\ P_{dyn}) \quad (3)$$

$$C_3 = \text{BlowfishEncrypt}(C_2,\ K_3,\ S_{dyn},\ P_{dyn}) \quad (4)$$

$$C = C_3$$

Fig. 2 shows the encryption flow used in the framework.

B. Decryption Process

Decryption reverses the order of the three encryption stages. The same session-specific parameters are used to recover the masked plaintext and then remove the mask (Fig. 3).

$$C_2 = \text{BlowfishDecrypt}(C,\ K_3,\ S_{dyn},\ P_{dyn}) \quad (5)$$

$$C_1 = \text{BlowfishDecrypt}(C_2,\ K_2,\ S_{dyn},\ P_{dyn}) \quad (6)$$

$$P_m = \text{BlowfishDecrypt}(C_1,\ K_1,\ S_{dyn},\ P_{dyn}) \quad (7)$$

$$P = P_m \oplus M$$

C. Key Management and Dynamic Internal Randomization

The framework does not contain the direct re-use of a single stage key, as K_1, K_2, and K_3 are derived from MK and SID. Each encryption session has its own session identifier, and the decryption operation has to build up or securely access the same elements of the session. In the reference implementation, intermediate values, temporary keys, masks, and dynamically created internal structures are wiped out after use. Dynamic S-box and P-array randomization to diversify internal state associated with current session. These structures have a security impact that is dependent on the quality of the random source, and the maintenance of the necessary properties of the cipher. Thus, they are introduced as mechanisms for internal diversification, which serve as supplementation, not substitution, for formal cryptanalytic evaluation (Fig. 4 and 5).

D. Security Interpretation of the Design

The CBT framework applies more transformations to the plaintext and adds session diversification. But it is not only by visual ciphertext appearance nor by NIST p-values that the design is evaluated. Randomness, avalanche sensitivity,

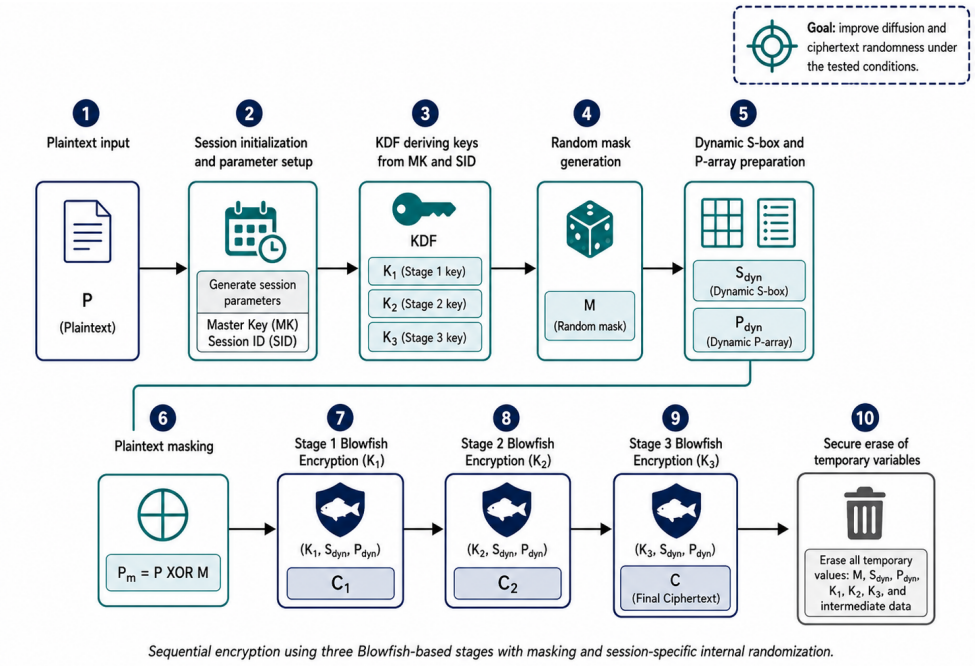

Fig. 2. Encryption flow of the proposed CBT framework. The plaintext is masked using a session-specific random mask and processed through three sequential Blowfish-based encryption stages using stage-specific keys and dynamic internal structures.

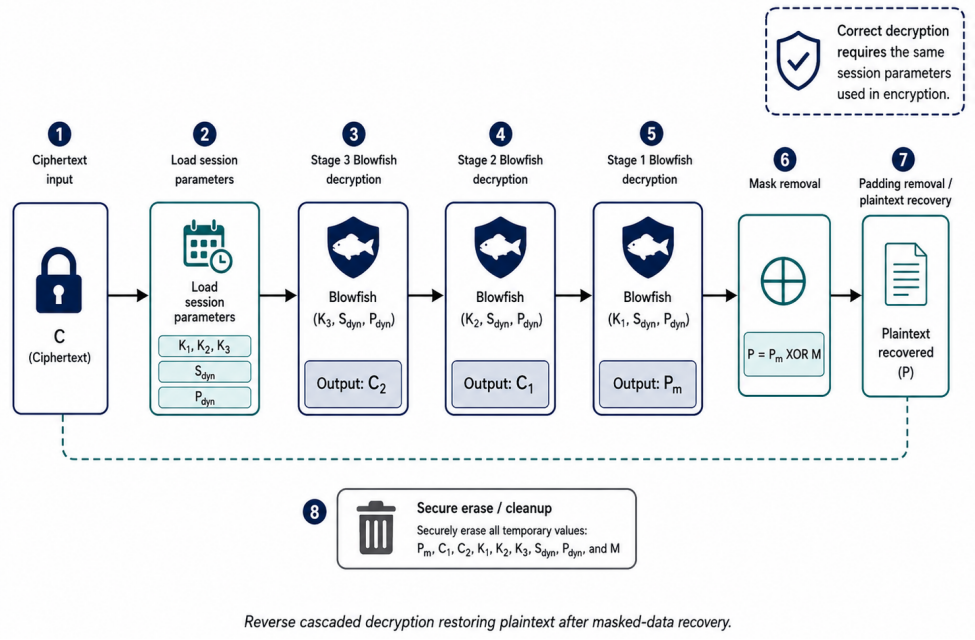

Fig. 3. Decryption flow of the proposed CBT framework. The corresponding session parameters are used to decrypt the ciphertext in the opposite order, removing the mask and recovering the plaintext.

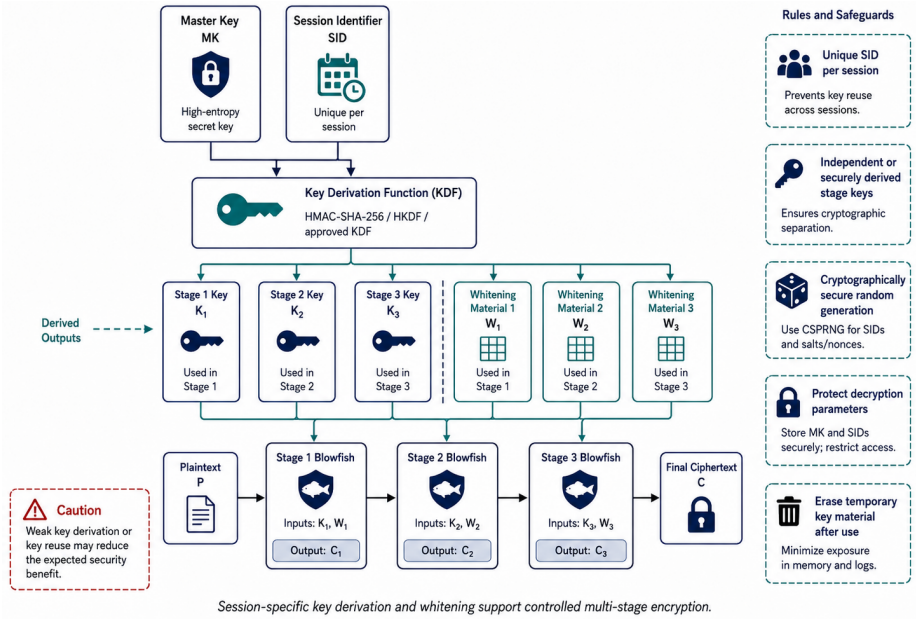

Fig. 4. Key management and whitening flow in the CBT framework. Stage-specific keys and whitening materials are either generated independently or securely derived from a master key and unique session identifier.

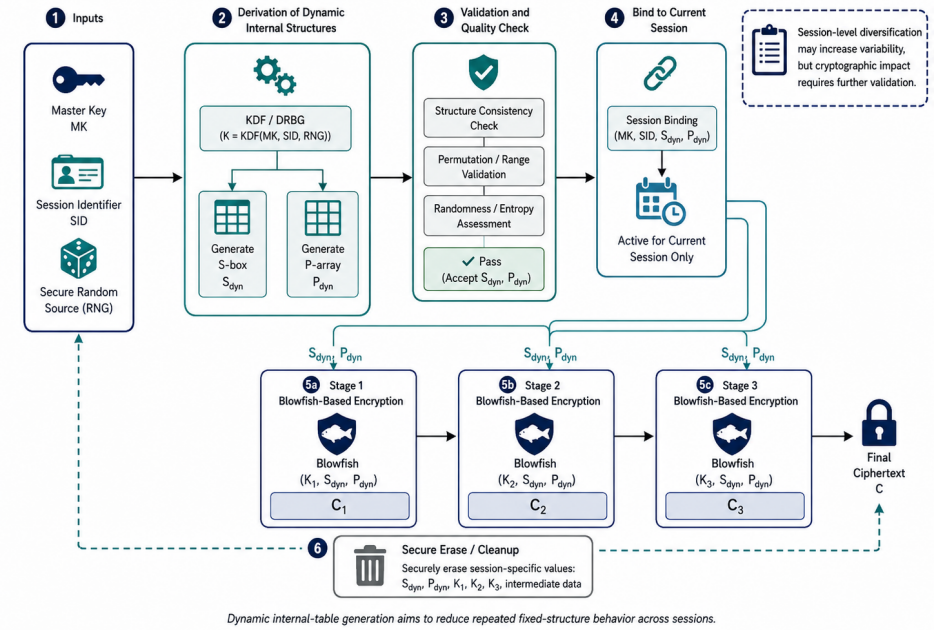

Fig. 5. Dynamic S-box and P-array randomization in the CBT framework. Session-specific internal structures are created, verified, attached to the session and discarded afterwards, to provide internal diversification.

timing variability and performance overhead are reported independently. The resistance to differential cryptanalysis, linear cryptanalysis, chosen-plaintext attack, related-key attack, fault injection, timing leakage, power leakage and electromagnetic attack is not evaluated in the present software prototype and would need dedicated attack evaluation.

IV. Experimental Methodology

The experimental methodology consists of four different parts: NIST-style statistical randomness interpretation, Hamming-distance-based avalanche analysis, computational performance comparison and timing-variability testing.

Pass/fail results have been included in the re-arranged p-values from the original experiment at alpha = 0.01. Avalanche, performance and timing are based on the Python reference implementation, which is included as supplementary material (Fig. 6).

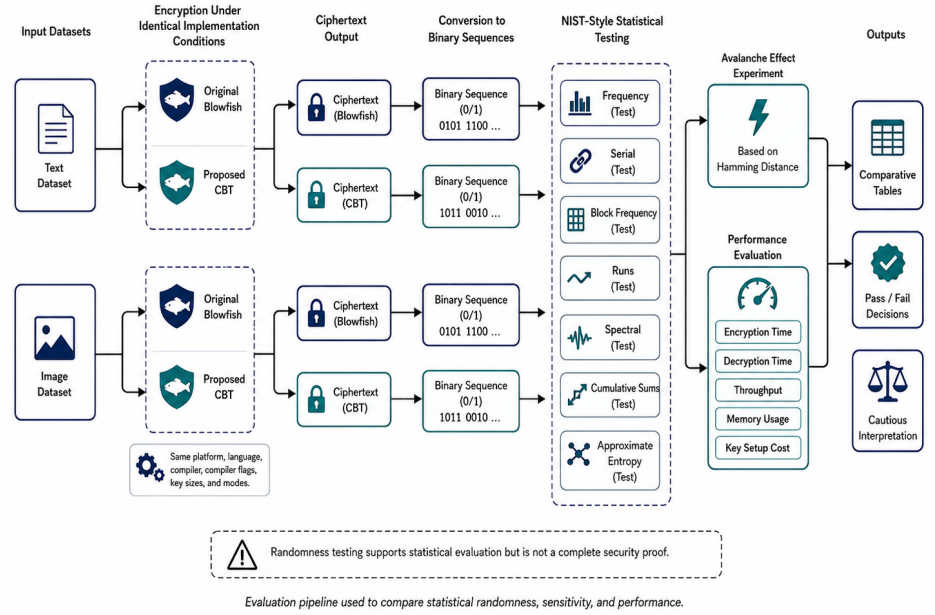

Fig. 6. Experimental evaluation pipeline. Both text and image datasets are encrypted under the same implementation conditions, turned into the binary sequence, and tested statistically, using NIST-style statistical tests, avalanche analysis and performance measurement.

Experimental Setup (Table II)

TABLE II. EXPERIMENTAL SETUP USED FOR THE REVISED EVALUATION

Parameter	Value
Implementation language	Python reference implementation
Compared algorithms	Original Blowfish and proposed CBT framework
Text workload	65,536-byte reproducible byte stream
Image workload	49,152-byte reproducible image-like byte stream
NIST significance level	alpha = 0.01
Avalanche trials	1,000 trials per algorithm, dataset, and sensitivity type
Performance repetitions	50 repetitions per algorithm and dataset
Timing repetitions	200 repetitions per algorithm and input type
Supplementary result workbook	Supplementary File S1
Python code package	Supplementary Files S2 and S3

A. NIST-Style Randomness Interpretation

The NIST type results are analyzed according to the fixed threshold alpha = 0.01. A test result is considered to be pass if $p \geq 0.01$ or fail if $p < 0.01$. The p-value is just a statistical measure of the corresponding randomness test and should not be interpreted as a measure of encryption strength.

$$\text{Decision} = \begin{cases} \text{Pass} & \text{if } p \geq 0.01 \\ \text{Fail} & \text{otherwise} \end{cases}$$

B. Avalanche Effect Analysis

The avalanche experiment evaluates sensitivity to one-bit changes in the plaintext and in the key. For plaintext-bit sensitivity, a plaintext block P and a modified block P' differing in exactly one bit are encrypted under the same key and configuration. For key-bit sensitivity, the same plaintext is encrypted using keys K and K' differing in exactly one bit. The resulting ciphertexts are compared using Hamming distance.

$$\text{Avalanche}(\%) = \frac{HD(C, C')}{N} \times 100 \tag{8}$$

where, $HD(C, C')$ is the Hamming distance between the two ciphertext outputs and N is the ciphertext length in bits.

The reported values summarize the mean, standard deviation, minimum, and maximum over 1,000 trials for each condition.

C. Computational Performance and Timing Variability

Performance is measured using encryption time, decryption time, throughput, memory usage, key setup time, mask-generation cost, and overhead relative to Original Blowfish. The measurements are based on the same reproducible workloads used for the avalanche experiment.

$$\text{Throughput} = \frac{\text{Data size}}{\text{Execution time}} \tag{9}$$

$$\text{Overhead}(\%) = \frac{\text{CBT time} - \text{Blowfish time}}{\text{Blowfish time}} \times 100 \tag{10}$$

The timing-variability check is a comparison of the repeated encryption of fixed and random plaintexts. This check is documented as a software-level timing observation and is not intended as a full-fledged practical side-channel assessment.

V. Results and Discussion

A. NIST-Style Test Outcomes

Table III: 7 of 9 reported results for text and image data were good with the original Blowfish. All 9 outcomes reported in both datasets passed the CBT. The improvement is primarily for the Serial Test parts, where the original Blowfish outputs failed and CBT passed (Table IV). These results are indicative of good ciphertext randomness properties for the chosen tests, but do not constitute full cryptographic security (Fig. 7).

B. Avalanche Effect Results

The mean avalanche value is very close to 50%, which is the expected diffusion property of the output of a block cipher to a one-bit change in the input or key. The CBT results are still near to the original Blowfish baseline and include the masking, cascading, and session-level diversification (Table V). Thus, the avalanche results should be taken more as an indication of the diffusion sensitivity than as a standalone proof of resistance to differential cryptanalysis (Fig. 8).

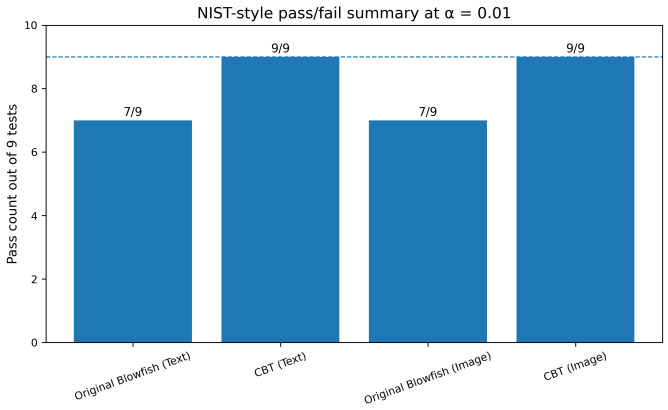

Fig. 7. NIST-style pass/fail summary at alpha = 0.01. The proposed CBT framework achieved 9/9 outcomes for both text and image data, compared to 7/9 outcomes for both text and image data for Original Blowfish.

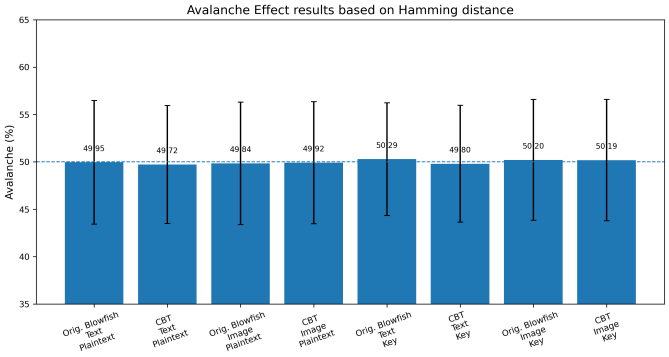

Fig. 8. Avalanche-effect comparison between Original Blowfish and CBT. This involved plaintext-bit and key-bit sensitivity experiments with Hamming-distance values being computed over 1,000 trials per condition.

C. Performance Benchmarking

The CBT prototype is heavier on calculation as it involves performing three consecutive stages of Blowfish and also involves mask generation and session-dependent processing. The measured overhead is that of the Python reference implementation and should not be used to extrapolate to optimized native-code, hardware-assisted or parallel implementations (Table VI). The goal of the benchmark is to transparently measure the prototype cost and not to state anything about the superiority of the speed (Fig. 9).

D. Timing-Variability Check

The timing-variability check gives a partial software-level view of the fixed and random plaintext runtimes (Table VII). These measurements are not a substitute for hardware leakage testing. A complete side-channel evaluation would need a defined leakage model, power or electromagnetic traces, a measurement platform and statistical leakage analysis.

E. Consolidated Interpretation

When the results of the two are combined, it is seen that CBT enhances the NIST-style pass-rate behavior without sacrificing the avalanche values, which are in or close to the desirable 50% diffusion region. This increase in structural complexity is borne out by the performance benchmark, which shows that there is a computational cost in the reference implementation.

So, the new assessment provides a balanced view of the framework: while CBT can enhance selected statistical-randomness metrics and a measure of diversification, p-values alone are not complete evidence of cryptographic security.

VI. Supplementary Materials and Reproducibility

The numerical results presented in this study are supplemented by file(s). A results workbook in Excel format is included as Supplementary File S1 and contains NIST pass/fail tables, raw avalanche trials, avalanche summaries, raw performance measurements, performance summaries, timing-variability data and experimental setup details. The Python experimental package, which was used to produce the avalanche, performance, timing and CSV outputs, is provided in Supplementary File S2. All of the Python scripts have been made available in a Word-readable format in Supplementary File S3 for convenient inspection on devices lacking source-code viewers. The raw CSV outputs from the experimental scripts are provided in Supplementary File S4 (Table VIII).

VII. Conclusion

In this study, a modified and well-documented assessment of Combined Blowfish Trilogy framework for text and image encryption was proposed. The framework involves three stages of Blowfish-based encryption along with key derivation, key whitening ideas, masking of plaintext and session-specific internal randomization. The updated assessment categorizes the different aspects of the experiment into four parts: randomness of the ciphertext, avalanche sensitivity, computational performance, and timing variability.

The NIST-style analysis reveals that the CBT passed all 9 test results for both the text and image datasets at alpha = 0.01, while Original Blowfish passed 7 of 9 for both datasets. The

TABLE III. NIST-STYLE P-VALUES AND PASS/FAIL INTERPRETATION AT ALPHA = 0.01

Test	BF Text	Decision	CBT Text	Decision	BF Image	Decision	CBT Image	Decision
Frequency Test	0.187	Pass	0.233366	Pass	0.596	Pass	0.800278	Pass

Hamming-distance-based avalanche analysis gave the mean values close to 50%, which showed suitable sensitivity for one-bit change in plaintext and key. The cost of the prototype with the three stages was quantified and it was demonstrated that the extra transformations incur measurable overhead in the Python implementation.

Results indicate that, under the tested conditions, the CBT is a diversified framework based on Blowfish with better selected statistical-randomness behavior. Meanwhile, the study does not claim that the NIST p-values are full security proofs, and clarifies what constitutes software-level timing checks from actual side-channel resistance. Future implementation studies can optimize the prototype in native code and/or hardware and do dedicate leakage measurement, but the present manuscript offers a complete reproducible baseline for statistical, avalanche, and performance evaluation.

***Abstract*—Intrusion detection in web traffic remains a challenging task due to the high dimensionality, heterogeneity, and imbalance of normal and malicious requests. This study investigates a hybrid anomaly detection framework combining an Autoencoder (AE), Density-Based Spatial Clustering of Applications with Noise (DBSCAN), and Isolation Forest (IF) for intrusion detection in HyperText Transfer Protocol (HTTP) log data. The Autoencoder was first used to learn a compact latent representation of the traffic, after which different unsupervised detection pipelines were evaluated. A key contribution of this work is the analysis of pipeline ordering, specifically comparing AE + DBSCAN + IF, AE + IF, and AE + DBSCAN. The full hybrid pipeline AE + DBSCAN + IF achieved the highest accuracy (0.9803) and strong false positive control, but exhibited extremely poor sensitivity with a recall of 0.0082 and precision of 0.0904, making it too conservative for practical intrusion detection. The intermediate pipeline AE + IF improved sensitivity, reaching a recall of 0.1542 and precision of 0.0536, but at the expense of a higher false positive rate. Surprisingly, the ablation study showed that AE + DBSCAN alone yielded the most balanced results, with accuracy of 0.9670, precision of 0.2606, and recall of 0.4376, clearly outperforming the complete hybrid pipeline in intrusion detection capability. These findings demonstrate that the ordering of anomaly detection stages has a critical impact on IDS performance. In the current setting, Isolation Forest degrades rather than improves detection when combined with DBSCAN. The results suggest that AE + DBSCAN constitutes the most effective and operationally relevant configuration for the studied dataset.**

I. Introduction

In the age of digital transformation, servers form the operational foundation of modern IT infrastructures. They host critical applications, centralize databases, orchestrate network services, and ensure the continuous availability of digital resources that are essential to public and private organizations. Whether for government agencies, universities, hospitals, businesses, or online service providers, server reliability directly impacts business continuity, service quality, and the protection of information assets. This strategic position, however, makes servers prime targets for cyberattacks, particularly malicious intrusions, which aim to compromise the confidentiality, integrity, or availability of information systems [5], [2], [6], [3].

An intrusion can be defined as any unauthorized attempt or action aimed at accessing a system, disrupting its operation, exfiltrating data, disrupting services, or maintaining a covert presence within it. In server environments, these attacks take various forms: privilege escalation, lateral movement, exploitation of software vulnerabilities, execution of malicious commands, installation of malware, Denial-of-Service attacks, or compromise of authentication mechanisms. The consequences can be particularly severe: leakage of sensitive data, unavailability of critical services, financial losses, regulatory noncompliance, damage to institutional reputation, and a breach of user trust [18], [14], [10]. In this context, server security is no longer solely a matter of perimeter defense, but rather of intelligent, continuous, and adaptive monitoring of system events.

The rapidly evolving threat landscape has exposed the limitations of traditional security approaches. Conventional defense mechanisms, such as firewalls, antivirus software, and signature-based intrusion detection systems, remain useful for identifying known behaviors, but they often prove insufficient against new, polymorphic, or stealthy attacks. Signature-based intrusion detection systems (IDS) generally compare observed events against a database of rules or fingerprints corresponding to previously documented attacks. This approach is effective against known threats but becomes less reliable when the attacker employs novel, modified, or deliberately obfuscated techniques [8], [1], [19]. This issue is particularly significant in the case of so-called zero-day attacks, which exploit vulnerabilities that have not yet been documented or patched. Although some security solutions can indirectly detect certain behavioral manifestations of such attacks, their reliable detection remains a major challenge, particularly in complex and highly dynamic environments [8], [1].

At the same time, servers constantly generate massive amounts of data in the form of event logs produced by the operating system, network services, applications, authentication mechanisms, administration tools, and security components. These logs record a wide variety of information: incoming and outgoing connections, system errors, file access, authentication failures, executed commands, application requests, security alerts, and performance anomalies. In theory, these traces represent an extremely rich source for monitoring, auditing, and the early detection of suspicious behavior. In practice, however, leveraging them remains difficult due to several factors: heterogeneous formats, significant noise, lack of uniform structure, redundancy, high volume, and the semantic complexity of the messages [12], [4], [1]. Manual analysis of this data quickly becomes impractical, especially in operational contexts where security teams have limited human resources

and must respond within very short timeframes.

This challenge has led to the emergence of advanced intrusion detection approaches based on machine learning (ML) and deep learning (DL). Unlike purely signature-based approaches, machine learning methods aim to model a system's normal behavior or learn discriminative patterns from historical data in order to identify significant deviations that may indicate malicious activity. These approaches are particularly promising for server log analysis, as they allow for the exploitation of temporal, structural, and contextual patterns that are difficult to capture using static rules [9], [17], [1].

The growing interest in ML and DL techniques in IDS systems can also be attributed to their ability to address the increasing complexity of modern cyberattacks. Models such as decision trees, random forests, support vector machines, autoencoders, recurrent neural networks, convolutional models, and hybrid architectures have demonstrated promising performance in various detection contexts, whether analyzing network traffic, user behavior, or log sequences [6], [9], [1].

From this perspective, intelligent server log analysis emerges as a strategic priority for strengthening the cybersecurity of digital infrastructures. It not only enables earlier detection of abnormal behavior but also provides a better understanding of attack mechanisms, reduces response times, and improves the overall resilience of systems. However, several challenges remain: high variability in server environments, an imbalance between normal and malicious events, computational cost, the need for explainability, false positive rates, and the difficulty of integration into real-world operational environments [1], [12], [10]. This study fits within this context and aims to explore the use of log files for server intrusion detection using modern artificial intelligence techniques. The goal is to propose an approach capable of leveraging these execution traces as a source of actionable knowledge, in order to improve security monitoring, anomaly detection, and, more broadly, the proactive protection of server systems.

Despite recent progress in machine learning and deep learning for intrusion detection, two research gaps remain insufficiently addressed. First, most existing studies rely on benchmark network datasets, whereas real server log files are highly heterogeneous, noisy, redundant, and severely imbalanced. Second, the influence of the ordering of unsupervised anomaly detectors within hybrid pipelines has rarely been investigated. In particular, it remains unclear whether density-based clustering should be applied before or after isolation-based anomaly detection when the input consists of engineered server log features. This work addresses these gaps by evaluating the impact of component ordering in three pipelines: AE+DBSCAN+IF, AE+IF+DBSCAN, and AE+DBSCAN.

The remainder of this study is organized as follows: Section II presents the dataset, the feature engineering process, and the proposed hybrid intrusion detection methodology. Section III reports the experimental results and compares the investigated pipelines. Section IV discusses the main findings, the effect of pipeline ordering, and the limitations of the approach. Finally, Section V concludes the study and outlines future research directions.

II. Methods and Materials

A. Data Collection and Description

This study addresses intrusion detection from server log files in a cybersecurity context. The selected data consist mainly of Apache server access logs, which are semi-structured records generated by web services. Such logs play an important role in threat identification, suspicious behavior analysis, and decision support for protecting critical information systems. Their quality directly influences the ability of information systems to detect unauthorized access attempts, Denial-of-Service (DoS) events [11], and malicious injection attempts [21]. Apache access logs record each HTTP request and include information such as the IP address, timestamp, HTTP method, requested URL, status code, response size, referrer, and user agent. These attributes are useful for identifying suspicious activities, including repeated authentication failures, abnormal status codes, malformed requests, and request peaks related to Distributed Denial-of-Service (DDoS) behavior. The extracted log records are highly imbalanced, as shown in Fig. 1, which presents their temporal distribution between 2021 and 2024.

B. Data Preprocessing

Preprocessing server log files is a demanding step due to the complexity of these files. The first work done was to analyze the raw logs (.log) following the work of [16] and [15] using Python regular expression library to extract eight variables (Table I), the results of the processing of each log file were structured (.csv). Then, an algorithm was developed to eliminate redundant information following the work of [20]. This process, carried out in two phases, made it possible to convert unstructured data into an exploitable basis for intrusion detection. Files were compiled into a single one. After merging all these files, the data set contained 3,558,335 rows and 8 columns, representing HTTP requests recorded between 2021 and 2024. To clearly see the imbalance in the data, a study of the distribution of each variable was carried out. In fact, most of the variables are complex. Fig. 2 summarizes the distributions of the variables Status_code, Referer, User_Agent, and Method. More specifically, Fig. 2a, Fig. 2b, Fig. 2c, and Fig. 2d illustrate the four distributions, respectively. The eight variables defined in Table I are complex variables; to better present a line of information, it was necessary to break down these variables. For example, the IP variable has been split into 8 variables: ip_request_count represents the total number of requests made by an IP in the logs; ip_time_spread represents the duration in seconds between the first and last request of an IP, etc. The URL variable has been split into nine new ones: url_path_depth gives the number of segments in the URL path; url_path_special_chars_count gives the number of special characters in the URL path, this variable reports malformed or encoded URLs, typical attacks; fragment_param_count gives the number of parameters in the fragment (#); etc. This analysis made it possible to have 34 relevant variables which give complete coverage of intrusion signals: temporal (cyclical and linear), IP (intensity, errors, geography), URL (structure, complexity), User-Agent (automation), Referer (navigation), and status (failures). In sum, there are in the dataset $N = 3558335$ observations, each having 34 components, any observation will be noted x_i.

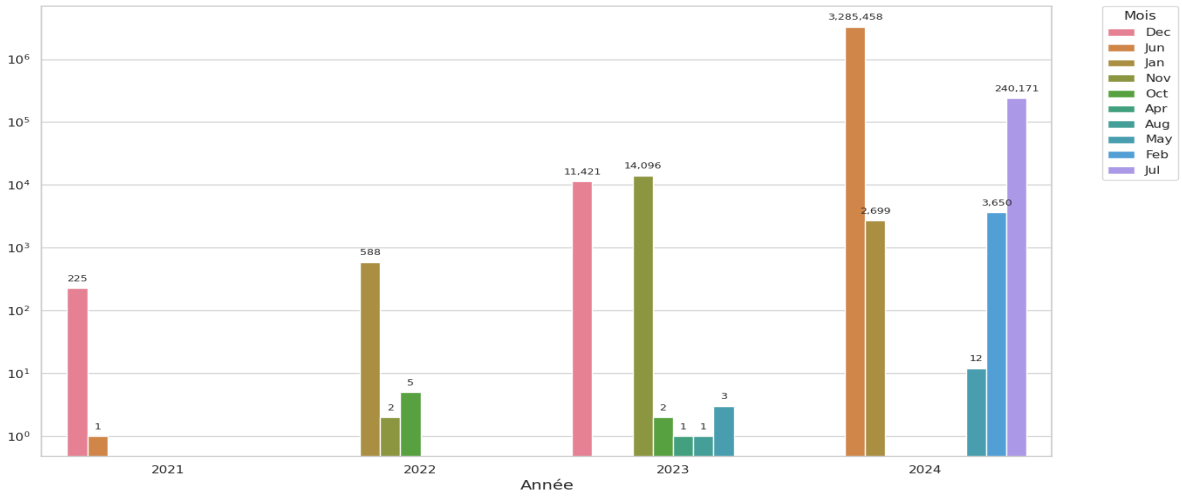

Fig. 1. Temporal distribution of information in the log files (2021–2024).

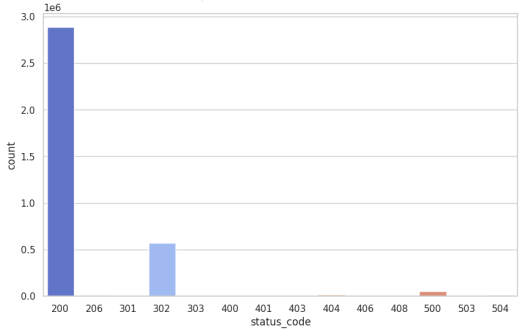
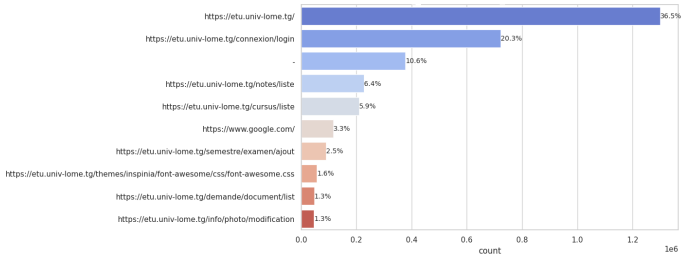
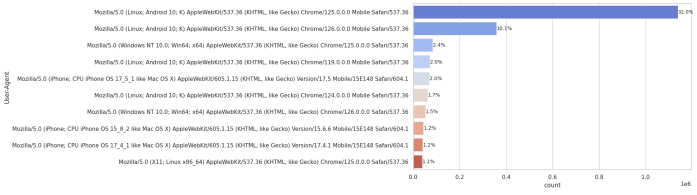


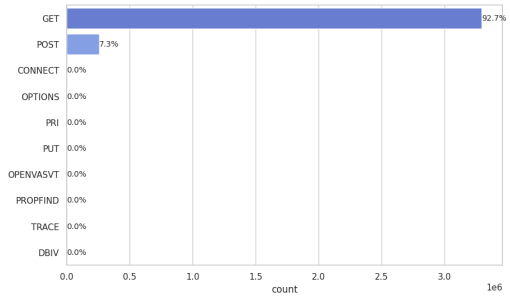
(a) Distribution of the Status_code variable.



(b) Distribution of the Referer variable.



(c) Distribution of the User_Agent variable.



(d) Distribution of the Method variable.

Fig. 2. Distribution of a few variables reflecting the unbalanced aspect of the data.

Table II provides the complete list of engineered features used as an input to the proposed intrusion detection pipelines. These variables summarize temporal behavior, IP activity, URL structure, HTTP response status, User-Agent characteristics, Referer information, and fragment-level patterns.

The overall methodology is summarized in Fig. 3. The workflow starts from raw Apache log files and proceeds through parsing, feature engineering, normalization, latent representation learning with an Autoencoder, evaluation of alternative pipeline orderings, and final performance assessment.

C. Modeling

The relevance of intrusion detection models based on log files requires that the different attack techniques be well represented in the data. The consequence is that very easily, the size of the training data becomes very large. To reduce the computational complexity in training, autoencoders were used initially. This is because autoencoders reduce dimensionality

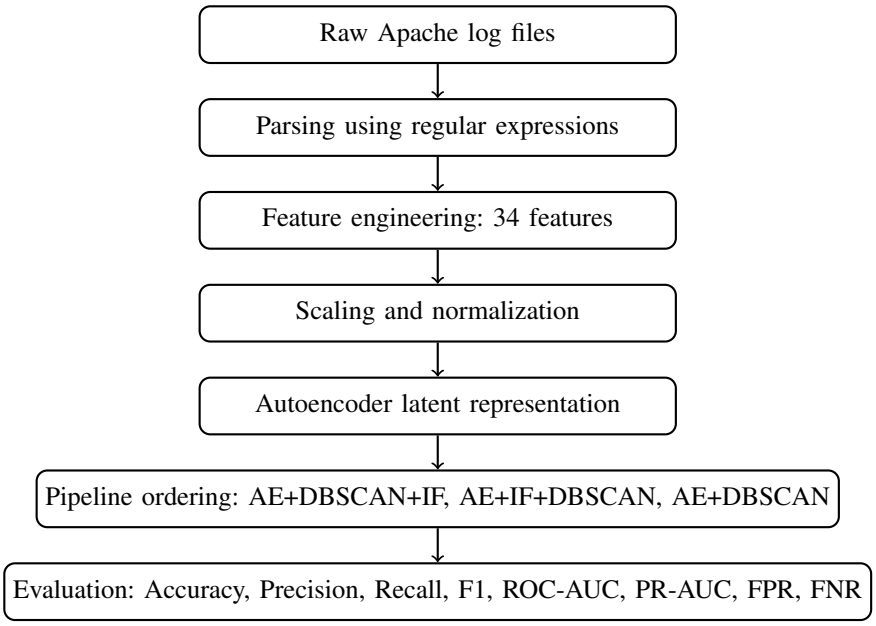


Fig. 3. Workflow of the proposed methodology for server log-based intrusion detection.

TABLE I. DESCRIPTION OF THE VARIABLES EXTRACTED FROM LOGS

Variable	Description
IP	Client IP address (e.g.: 192.168.1.1). Identifies suspicious sources (e.g. repetitive IPs in attacks DDoS)
Date	Timestamp (e.g.: 14/Mar/2025:10:15:30 +0100). Allows temporal analysis of peaks activity
Method	HTTP method (e.g.: GET, POST). Reveals actions unusual (e.g.: repeated POSTs)
URL	Requested resource (eg: /login.php). Detects access to sensitive pages or injections
Status_code	HTTP code (e.g.: 200, 404). Reports repeated failures (e.g.: 401 for brute force)
Response_size	Response size (e.g.: 1024 bytes). Indicates faults mallies (e.g.: high values for DoS)
Referer	Original URL (e.g.: http:/example.com). Detect the fraudulent or absent referents
User_agent	Client identifier (e.g.: Mozilla/5.0). Spot the bots or malicious tools

by compressing the input data into a lower-dimensional representation, known as a latent space layer, and then reconstructing the original input from this compressed representation. An autoencoder is a neural network that is trained to attempt to copy its input to its output (Fig. 5). Since autoencoders behave like a model solving a regression problem, the error function often used is the mean square error (E_{MSE}). As in machine learning or deep learning regression models, when training, we aim to minimize the cost function.

In this study, the Autoencoder architecture follows a symmetric fully connected structure: 34–64–32–16–8–16–32–64–34. Rectified Linear Unit (ReLU) activations are used in the hidden layers, the bottleneck layer contains eight latent dimensions, and the model is optimized by minimizing the mean square reconstruction error using the Adam optimizer. This architecture is illustrated in Fig. 4.

$$E_{MSE} = \frac{1}{N}\sum_{i=1}^{N} ||x_i - \tilde{x_i}||_2^2 \quad (1)$$

The symbol $||.||_2$ represents the $\mathcal{L}^2$ norm of a vector, and N is the number of the observation in the training dataset. $\tilde{x_i}$ is the decoder output. The more the error tends towards zero, the better the observations are reconstructed.

The proposed intrusion detection framework was designed under a semi-unsupervised anomaly detection paradigm, where the latent space learned by the autoencoder was exploited to improve separability between benign and suspicious traffic behaviors. Tree hybrid pipelines were conceptually evaluated: (1) AE + DBSCAN + IF, (2) AE + IF + DBSCAN and (3) AE+DBSCAN

1) Description of isolation forest: Let $X = \{x_1, \ldots, x_n\}$ be a set of information data files where $x_i \in \mathbb{R}^{34}$, 34 represents the number of characteristics (features) that describe data in this work. An isolation tree (isoTree) is defined as a data structure with an algorithm that is organized as a decision tree [13]. The principle of this algorithm is very simple:

- Randomly select a variable.
- Then carry out a random partitioning of the dataset according to this variable so as to obtain two subsets of data.
- Repeat the previous two steps until a piece of data is isolated.
- Recursively, repeat the previous steps.

isoTree is based on the idea that anomalies, rare and distinct, are isolated more quickly in random decision trees than normal points. For each recording (e.g., Apache log), a

TABLE II. DESCRIPTION OF THE ENGINEERED FEATURES EXTRACTED FROM THE SERVER LOG FILES

Feature	Description
response_size	HTTP response size in bytes.
date_hour_sin	Sine transformation of the request hour (0–23).
date_hour_cos	Cosine transformation of the request hour (0–23).
date_normalized	Elapsed time in seconds since the first request.
ip_request_count	Total number of requests generated by the same IP address.
ip_time_spread	Time elapsed between the first and last request from the same IP address.
ip_subnet_activity	Number of active IP addresses within the same /24 subnet.
ip_error_rate	Proportion of requests returning HTTP error codes (≥ 400).
ip_request_rate	Average request rate per second.
ip_interval_std	Standard deviation of time intervals between consecutive requests.
ip_max_requests_per_sec	Maximum number of requests per second generated by the same IP address.
ip_method_diversity	Number of distinct HTTP methods used by the same IP address.
country	Country of origin of the IP address based on a GeoIP database.
status_code_category	Category of the HTTP response status code.
nbre_unique_urls_per_ip	Number of distinct URLs requested by the same IP address.
url_path_struct_entropy	Structural entropy of the URL path.
url_path_depth	Number of path segments in the requested URL.
nbre_total_url_query_params	Number of query parameters in the requested URL.
url_query_special_chars_count	Number of special characters in the URL query string.
url_path_special_chars_count	Number of special characters in the URL path.
user_agent_length	Length of the User-Agent string.
user_agent_entropy	Character entropy of the User-Agent string.
user_agent_total_special_chars	Number of special characters in the User-Agent string.
referer_is_present	Binary indicator equal to 1 if the Referer header is present and 0 otherwise.
referer_path_struct_entropy	Structural entropy of the Referer path.
referer_path_depth	Number of path segments in the Referer URL.
nbre_total_referer_query_params	Number of query parameters in the Referer URL.
referer_query_special_chars_count	Number of special characters in the Referer query string.
is_bot	Binary label equal to 1 for bot traffic and 0 otherwise.
fragment_param_count	Number of parameters in the URL fragment.
special_char_fragment_count	Number of special characters in the URL fragment.

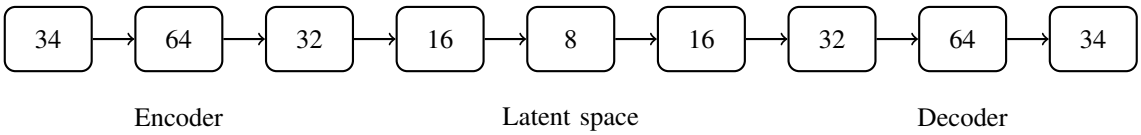

Fig. 4. Architecture of the Autoencoder used for dimensionality reduction. The input layer contains the engineered log features, the bottleneck contains eight latent units, and the decoder reconstructs the original feature vector.

set of trees is constructed by randomly selecting a feature and a cutoff value until each point is isolated. The anomaly score is given by:

$$s(x, n) = 2^{-\frac{E(h(x))}{c(n)}} \tag{2}$$

where,

- $h(x)$: isolation depth of x in a tree (number of divisions to isolate it)
- $E(h(x))$: average of h(x) over T trees
- $c(m) = 2H(m-1) - \frac{2(m-1)}{n}$ if $m > 2$

n is the test set size, m is the size of the sample set, and H is the harmonic number, which can be estimated by: $H(k) = \sum_{i=1}^{k} \frac{1}{i}$, [7].

If the score s is close to 1, x is most likely an anomaly, but if s is less than 0.5, x is probably normal. Isolation Forest has the ability to detect global anomalies without relying on density or distance comparison. However, it is not effective in detecting local anomalies.

2) Description of DBSCAN: DBSCAN is a well-known unsupervised clustering algorithm. It was proposed in 1996 by [7]. Given points and an integer k, the algorithm aims to divide the points into k homogeneous and compact groups, called clusters. Given points and an integer k, the algorithm aims to divide the points into k groups, called clusters, which are homogeneous and compact. It is a simple algorithm that defines clusters using local density estimation. It can be divided into 4 steps: For each observation, we look at the number of points at most one distance ϵ from it. This area is called the ϵ-neighborhood of the observation. If an observation has at least a certain number of neighbors including itself, it is considered a “core" observation. In this case, a high-density observation was detected. All observations in the vicinity of a core observation belong to the same cluster. There may be core observations close to each other. As a result, from close to close, a long sequence of core observations was obtained that form a single cluster. Any observation that is not a core observation and has no core observation in its vicinity is considered an “anomaly". Two main parameters are used in DBSCAN: epsilon (ϵ), which defines the maximum distance between two points to be considered neighbors, and MinPts, which specifies the minimum number of points required to form a dense region. Note also the choice of a distance to be used (usually the Euclidean distance). Given below is the

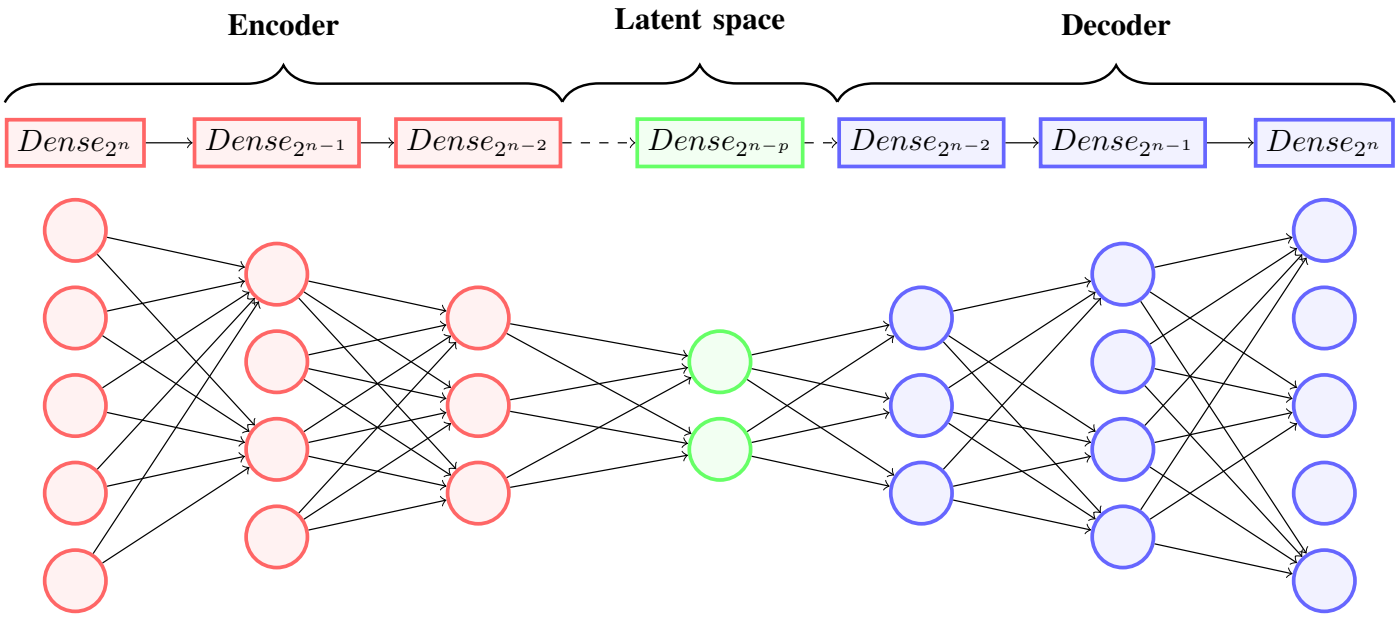

Fig. 5. Example of the diagram of an Autoencoder. $\mathbf{Dense_{2^n}}$ is a dense layer like in keras and 2^n is the number of units. $n = 7$ and $p = 4$ in the context of this study.

algorithm of DBSCAN.

1) **Initialization**
   - Consider the dataset $D = \{x_1, x_2, \ldots, x_n\} \subset \mathbb{R}^{34}$.
   - Set parameters: neighborhood radius ε and *MinPts*.
   - Mark all points in D as *unvisited*.
2) **Loop over points**
   - For each point $x_i \in D$:
     - If x_i is already visited, move on to the next point.
     - Otherwise, mark x_i as *visited*.
3) **Neighborhood calculation**
   - Calculate the neighborhood of x_i:

$$N_\varepsilon(x_i) = \{x_j \in D \mid ||x_j - x_i|| \leq \varepsilon\}.$$

   - If $|N_\varepsilon(x_i)| <$ MinPts, then :
     - Mark x_i as *noise*.
     - Continue with the next point.
4) **Create a cluster**
   - Create a new cluster C.
   - Add x_i to the cluster C.
5) **Cluster expansion**
   - For each point $p \in N_\varepsilon(x_i)$:
     - If p is not visited:
       - Mark p as *visited*.
       - Calculate its neighborhood $N_\varepsilon(p)$.
       - If $|N_\varepsilon(p)| \geq$ MinPts, extend the neighborhood:

$$N_\varepsilon(x_i) \leftarrow N_\varepsilon(x_i) \cup N_\varepsilon(p).$$

     - If p doesn't belong to any cluster, add it to C.
6) **End of algorithm**
   - Repeat until all points in D have been visited.
   - Return:

$$\{C_1, C_2, \ldots, C_K\}, \qquad \text{Noise} = D \setminus \bigcup_{k=1}^{K} C_k.$$

3) Goal: In this study, three methods were developed: first, the AE+DBSCAN pipeline was trained; next, the AE+DBSCAN pipeline; and finally, the AE+IF+DBSCAN pipeline. The objective was to determine which ordering of density-based clustering and anomaly isolation is more appropriate for network intrusion detection.

III. Results

The dataset was partitioned into three subsets in order to ensure a robust evaluation of the intrusion detection pipeline: training set 70% of the data, validation set 10% of the data and test set 20% of the data. The training subset was primarily used to learn the latent representation of the normal traffic through the Autoencoder (AE) and to calibrate the anomaly detection stages. The validation subset was used for threshold selection and intermediate tuning, while the test subset was strictly reserved for final performance evaluation.

Table III summarizes the main performance indicators obtained for the evaluated pipelines. In addition to accuracy, precision, and recall, the table reports the F1-score derived from precision and recall. Additional confusion matrices, ROC-AUC, PR-AUC, false positive rate (FPR), and false negative rate (FNR) values are available for the implemented experimental runs and will be systematically extended in future comparative experiments.

TABLE III. MAIN METRICS OBTAINED FOR THE EVALUATED ANOMALY DETECTION PIPELINES.

Pipeline	Accuracy	Precision	Recall	F1-score
AE+DBSCAN+IF	0.9803	0.0904	0.0082	0.0150
AE+IF	0.9347	0.0536	0.1542	0.0796
AE+DBSCAN	0.9670	0.2606	0.4376	0.3267

A. Pipeline: AE + DBSCAN + IF

After training, testing, and validating the AE+DBSCAN+IF pipeline, an accuracy of 0.9803 was achieved, followed by a precision of 0.0904 and a recall of 0.0082. This configuration exhibits extremely high accuracy and excellent control of false positives, indicating that the model is highly effective at modeling normal traffic behavior. However, this comes at the cost of a dramatic loss in sensitivity, as reflected by the extremely low recall (below 1%). This suggests that the model fails to detect the vast majority of intrusions. This behavior can be explained by the interaction between DBSCAN and Isolation Forest. DBSCAN, when applied to the latent space, constructs a very large and dense region of normality, effectively absorbing a significant portion of the data, including subtle anomalous patterns. As a consequence, many malicious samples are either classified as part of normal clusters or rejected as noise before reaching the final detection stage. Subsequently, Isolation Forest operates on a reduced and already filtered subset of data, with thresholds that are too strict to recover the missed anomalies. This results in a pipeline that is overly conservative, prioritizing specificity over sensitivity. Overall, while the pipeline achieves excellent false positive control, it is unsuitable for intrusion detection, where missing attacks is more critical than raising occasional false alarms.

B. Pipeline: AE + IF + DBSCAN

After training, testing, and validating the AE+IF+DBSCAN pipeline, an accuracy of 0.93 was achieved, followed by a precision of 0.05 and a recall of 0.15.

This configuration significantly improves recall compared to the previous one, demonstrating a better ability to detect anomalous traffic. By applying Isolation Forest before DBSCAN, the model first identifies suspicious samples based on global isolation properties in the latent space. This step ensures that anomalies are not prematurely absorbed into dense normal regions. DBSCAN is then applied only to these suspicious points, enabling the identification of coherent anomalous structures and improving the interpretability of the results. This ordering is more aligned with the nature of intrusion detection, where anomalies are often sparse and irregular rather than densely clustered. However, this improved sensitivity comes at the cost of an increased number of false positives, as reflected by the lower precision. The pipeline becomes more reactive but less selective. This configuration provides a better balance between detection and false alarm control than AE + DBSCAN + IF, but still requires careful threshold tuning and post-processing mechanisms to be operationally viable.

C. Pipeline: AE + DBSCAN

The AE + DBSCAN pipeline yields the most surprising and insightful results in this study, with an accuracy of 0.9670, a precision of 0.2606, and a recall of 0.4376. Contrary to expectations, removing Isolation Forest leads to a substantial improvement in recall and overall detection performance, with recall reaching approximately 44% and precision significantly higher than in the other configurations. This indicates that DBSCAN alone, when applied in the latent space learned by the Autoencoder, is capable of effectively distinguishing between normal and anomalous traffic patterns. The latent representation appears to preserve sufficient structure to allow density-based clustering to separate benign and malicious behaviors without requiring an additional anomaly isolation stage. The degradation observed when adding Isolation Forest suggests that, in the current configuration, IF introduces an overly restrictive filtering stage, removing or suppressing useful anomaly signals identified by DBSCAN. Instead of enhancing detection, it acts as a bottleneck that reduces the model's sensitivity. This result highlights a critical insight: additional model complexity does not necessarily improve performance, and in some cases, it can even degrade it. The AE + DBSCAN combination appears to provide a strong baseline for intrusion detection in this context.

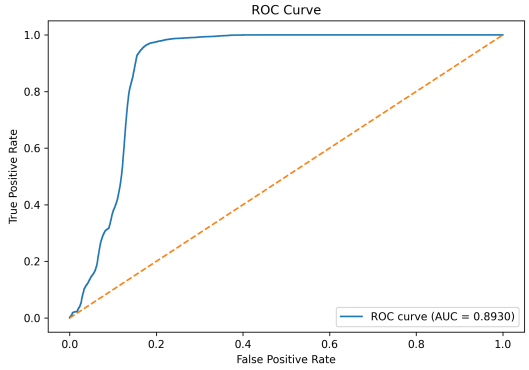

Fig. 6. Receiver Operating Characteristic (ROC) curve showing the true positive rate as a function of the false positive rate.

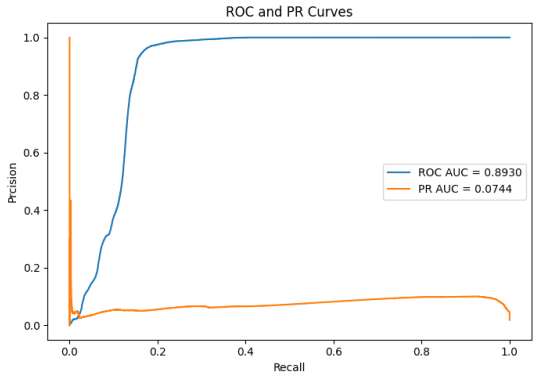

Fig. 7. Combined ROC and Precision–Recall curves used to evaluate the detection behavior under class imbalance.

The resulting figures provide a complementary and consistent view of the system's performance. The ROC curve (Fig. 6) shows only moderate overall separation between normal traffic and malicious traffic, indicating that the anomaly score partially distinguishes intrusions but without a clear boundary. This trend is confirmed by the Precision–Recall

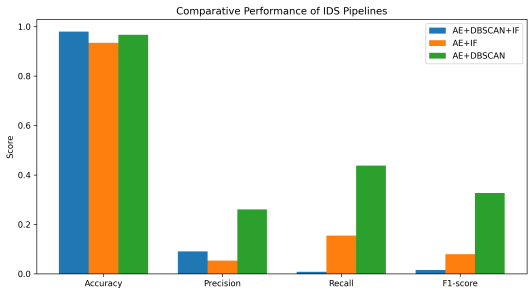

Fig. 8. Comparative performance of the evaluated IDS pipelines in terms of accuracy, precision, recall, and F1-score.

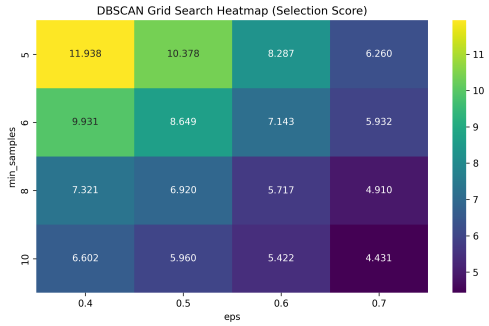

Fig. 9. Heatmap of the DBSCAN grid search showing the selection score for different values of ε and MinPts.

curve (Fig. 7), which is more relevant in a highly imbalanced IDS context. It highlights that an increase in sensitivity is quickly accompanied by a drop in precision, reflecting a delicate trade-off between detection and false positives. The comparative bar chart of the pipelines (Fig. 8) is particularly informative. It clearly shows that AE+DBSCAN currently offers the best balance between recall and precision, while AE+DBSCAN+IF primarily maximizes accuracy by becoming excessively conservative. This confirms that adding Isolation Forest, in its current configuration, degrades detection rather than improving it. Finally, the heatmap of the DBSCAN selection score (Fig. 9) shows that the clustering performance is highly dependent on the (eps, min_samples) pair, with a well defined optimal range. This figure underscores the importance of fine-tuning DBSCAN for the overall quality of the pipeline.

IV. Discussion

The results of this study provide several important insights into the design of hybrid intrusion detection systems based on representation learning and unsupervised anomaly detection. While combining multiple models is often assumed to improve performance, the ablation analysis clearly demonstrates that this assumption does not always hold. The most striking result is that the AE + DBSCAN configuration outperforms the full hybrid pipeline (AE + DBSCAN + IF) in terms of recall and overall detection capability. This suggests that the latent representation learned by the Autoencoder is already sufficiently structured to allow DBSCAN to effectively separate normal and anomalous behaviors. In this context, DBSCAN acts not only as a clustering algorithm but also as a powerful anomaly detector based on density estimation. The degradation observed when adding Isolation Forest highlights a critical issue: the introduction of an additional filtering stage can inadvertently remove meaningful anomaly signals. In the current setup, Isolation Forest appears to be too restrictive, either due to an insufficient contamination parameter or to thresholds that are not adapted to the distribution of the latent space. As a result, many anomalies identified by DBSCAN are suppressed, leading to a dramatic drop in recall.

More specifically, the ablation study indicates that Isolation Forest does not improve the detection capability in the current configuration. After DBSCAN has modeled the dense region of normal traffic, Isolation Forest operates on a reduced subset containing mostly borderline observations. Under these conditions, the anomaly thresholds become overly restrictive and many suspicious samples identified by DBSCAN are rejected, leading to a substantial decrease in recall. This behavior suggests that the current Isolation Forest configuration favors specificity at the expense of sensitivity. Another important factor is the behavior of DBSCAN itself. The results suggest that DBSCAN is modeling a very large region of normality, likely due to a relatively high epsilon value or insufficient cluster density constraints. This can lead to the absorption of borderline anomalies into normal clusters. However, despite this limitation, DBSCAN alone still achieves significantly better recall than the hybrid pipeline, indicating that the main performance bottleneck lies in the Isolation Forest stage rather than in the clustering step. A broader comparison with recent baseline methods such as One-Class Support Vector Machine, Local Outlier Factor, Random Forest, and recent deep learning-based IDS models is currently being conducted as part of an extended version of this work. This additional study will provide a more comprehensive positioning of the proposed approach against supervised and unsupervised IDS baselines.

From an operational perspective, the key challenge remains the trade-off between recall and false positives. While AE + DBSCAN provides strong detection capabilities, it may generate more false alarms. Several strategies can be implemented to address this issue without sacrificing recall:

- Threshold calibration: Instead of using fixed thresholds, adaptive thresholds based on quantiles or validation distributions can be used to dynamically adjust sensitivity.
- Temporal aggregation: Anomalies can be aggregated over time windows (e.g., per IP or session). Persistent anomalies are more likely to correspond to real attacks.
- Post-classification filtering: A lightweight supervised classifier can be applied to suspicious samples to filter false positives.
- Cluster validation: Clusters can be validated based on additional criteria such as stability, temporal coherence, or feature entropy.
- Explainability-based filtering: Feature importance or explainability methods (e.g., SHAP) can help identify whether an anomaly is meaningful or spurious.

V. Conclusion

This study investigated whether the ordering of DBSCAN and Isolation Forest affects intrusion detection performance on server log files. The results show that the ordering of unsupervised components has a substantial impact on detection quality. The AE+DBSCAN+IF pipeline achieved the highest accuracy (0.9803) but produced an extremely low recall (0.0082), making it unsuitable for practical IDS deployment. The AE+IF configuration improved sensitivity but remained less precise. The AE+DBSCAN pipeline achieved the best compromise, with an accuracy of 0.9670, a precision of 0.2606, and a recall of 0.4376. These findings answer the initial research question by showing that adding Isolation Forest after DBSCAN can degrade detection performance when thresholds are too restrictive. Future work will investigate adaptive thresholding, temporal aggregation, explainable anomaly filtering, and a broader comparison with recent IDS baselines.

***Abstract*—Estimating crowd size in dense environments remains a complex problem, yet it holds critical value for safety monitoring, city infrastructure design, and large-scale gathering coordination. Leveraging contemporary developments in neural network architectures and machine intelligence, researchers have markedly enhanced the precision of population counts derived from both still imagery and motion footage. This research focuses on the development of an enhanced deep neural network-based crowd counting model. Since the original CSRNet primarily relies on head detection for crowd estimation, an additional face detection module has been incorporated to improve its capability in scenarios where facial features are visible. The proposed enhancement increases the flexibility and estimation accuracy of CSRNet by integrating individual face detection with crowd density estimation. Furthermore, this study presents a comprehensive comparative analysis of the proposed enhanced CSRNet against three state-of-the-art crowd counting models, namely Bayesian Network (BAYNet), Distribution Matching (DM-Count), and Scale Aggregation Feature Attention Network (SFANet). The models are evaluated on multiple datasets to investigate their accuracy, robustness, adaptability to varying crowd densities, and performance under complex environmental conditions. The comparison also highlights the methodological differences and computational characteristics of these approaches. Model performance is assessed using the standard evaluation metrics of Mean Absolute Error (MAE) and Root Mean Square Error (RMSE). Experimental results demonstrate that the proposed enhanced CSRNet achieves a competitive RMSE/MAE of $9.61/93.05$ on 64×64 images of the custom dataset, outperforming the baseline models and demonstrating its effectiveness for accurate crowd counting.**

I. Introduction

The problem of crowd counting and density estimation has emerged as a crucial field of study to solve many practical applications. The challenges arising from the growing urbanization and from the large-scale public events in the real world. The techniques are very important in the field of urban planning, public safety and resource allocation. Precise crowd estimation enables the authorities to regulate the number of people in a packed area, and this allows for prompt answer during the crisis and enables efficient event planning [1], [2], [3]. Crowd counting inherently connects to intelligent systems via cutting-edge algorithms and advanced technologies like computer vision and machine learning. These systems are essential for precisely identifying and enumerating people in dense environments, a task that relies heavily on ongoing methodological innovations. Intelligent systems are well-suited for analyzing visual information and using methods such as object detection, Convolutional Neural Networks (CNNs), and deep learning to accurately and efficiently estimate crowd size and size, providing insights for various applications including urban planning, security surveillance, and event management [4], [5].

Current methods are generally time-consuming, imprecise, and not suitable for larger-scale applications, such as manual counting or basic counting devices [6], [7], [8]. The traditional methods might not be as effective in real-world situations in which large and dense crowds are present, resulting in less accuracy. These restrictions have led to a demand for more complex, automated and precise solutions. The advanced neural network architectures used in deep learning methods have the potential to transform the field of crowd counting and density estimation [9], [10], [11], [12]. Several deep learning approaches such as Congested Scene Recognition Network (CSRnet), Scale Aggregation Feature Attention Network (SFANet), and Bayesian Network (BayNet) automatically acquire complex spatial features and patterns, enhancing the accuracy and scalability.

Recent advances have further pushed the boundaries of what is achievable in crowd analysis. Multi-scale feature fusion approaches [13], [14], perspective-assisted semi-supervised learning methods [15], and generative model-based density estimation techniques [16] have collectively demonstrated that combining richer contextual information with improved training paradigms can substantially close the performance gap that previously existed between controlled benchmark settings and challenging real-world deployments. Despite these advancements, accurately estimating crowd density under extreme occlusion, significant scale variation, and complex lighting conditions remains an open challenge, motivating the exploration of improved architectures such as the one proposed in this work.

The usually adopted approach for crowd counting research consists of the following steps [17], [1], [18], [19]:

- Collect primary visual data: images or video footage; captured on-site to obtain a ground-level count of individuals within each unit frame.
- Preprocessing: Noise filtering, resizing images and modifying pixels.

Fig. 1. Objects or people counting example.

Fig. 2. Overlapped persons in crowd image, shown in red box.

- Identifiable Feature Extraction: Obtaining identifiable features from the data set available (images or videos) to identify or count people.
- Algorithms used for counting: Algorithms for counting are selected based on the extracted features, with each offering varied approximations of per-frame pedestrian tallies. These approaches generally fall into regression, density estimation, or detection-oriented frameworks.
- Evaluation:The performance of the proposed crowd analysis approach is quantified using standard error metrics, namely mean absolute error (MAE) and root mean square error (RMSE), to ensure a thorough assessment of its predictive accuracy.
- Flaws in Counting/Extracting Data – Consider improving the flaws in counting or extracting data by analysing the data.
- Application: The algorithm finds practical use in crowd regulation, public safety protocols, tactical decision-making, and monitoring systems that operate on live data streams.

In this work, CSRNet was adopted and subsequently enhanced by integrating BayNet and SFANet to improve face and head-counting accuracy. The combined model was then evaluated to assess its overall performance. The main objective centered on leveraging facial and head count information within the CSRNet architecture to achieve reliable crowd counting and density estimation.

In Fig. 1 the density map is a collection of people, and each blue dot is an individual person.

A. Motivation

The motivation for this investigation stems from several interconnected considerations, which are outlined below.

1) Practical relevance and real-world deployment: Crowd counting plays a pivotal role in numerous practical domains, including public event management, traffic flow monitoring, and public safety assurance in congested urban environments. The deployment of accurate and reliable counting models offers tangible benefits in these scenarios. Nevertheless, the task remains inherently challenging due to pronounced variations in crowd density, severe occlusion (as illustrated in Fig. 2), perspective distortion, and fluctuating illumination conditions. These inherent challenges have motivated continued investigation into improving counting system precision and resilience, thereby supporting the wider evolution of computer vision techniques.

2) Societal implications and public welfare: Beyond its technical merits, crowd counting carries significant societal weight, particularly in safety-critical contexts such as emergency response coordination, large-scale public gathering management, and evidence-based urban planning. Accurate density estimation facilitates timely and informed decision-making, ultimately improving public safety outcomes and enabling more efficient resource allocation during mass events.

3) Advancements in deep learning architectures: The recent proliferation of sophisticated deep learning models; including CSRNet, SFANet, and BayNet; has substantially expanded the methodological landscape for crowd analysis. Thes architectures, representative of state-of-the-art developments in computer vision, offer new avenues for investigation. Researchers are consequently driven to systematically evaluate, extend, and refine these models, with particular emphasis on understanding their respective strengths, inherent limitations, and generalizability across diverse counting scenarios.

4) Benchmarking and comparative evaluation: Rigorous comparative analysis of existing deep learning approaches constitutes a fundamental component of empirical research in crowd counting. Systematic benchmarking not only establishes performance baselines but also elucidates the conditions under which specific models exhibit superior or inferior behavior. Such insights are indispensable for guiding future architectural innovations, informing model selection for practical applications, and fostering reproducible progress within the research community.

B. Aims and Objectives

This study sets out to enhance both the accuracy and efficiency of crowd counting by adopting an improved con-

volutional neural network: CSRNet. Specifically, we aim to evaluate how well the modified CSRNet architecture estimates crowd density across diverse real-world scenarios, with an eye toward informing crowd management, urban planning, and public safety measures. To that end, our work compares the performance of the enhanced CSRNet against state-of-the-art counting methods, assesses its generalizability across multiple benchmark datasets, and explores its practical viability in operational settings.

- A precise and computationally efficient crowd counting framework will be established, beginning with a comprehensive examination of extant deep learning literature. This survey aims to pinpoint leading methodologies, recognize their inherent shortcomings, and delineate evolving directions within the domain. Informed by these findings, a customized deep architecture will be conceived and deployed to tackle the principal obstacles in crowd enumeration.
- Tackle real-world challenges in crowd counting applications, particularly the issue of occlusion. The aim is to improve counting accuracy in partially obscured scenarios by leveraging contextual information and incorporating occlusion-aware features into the model.
- Evaluate and compare the proposed model against existing solutions using appropriate performance metrics. The assessment will focus on accuracy, precision, recall, and computational efficiency to ensure a comprehensive understanding of the model's strengths and limitations.

C. Our Contribution

The contribution of this work is twofold:

- The construction of compact libraries specifically designed for crowd counting facilitates computational economy, rendering them viable for implementation on hardware with limited resources and within time-sensitive applications. This strategy consequently broadens the practical utility of counting systems across varied real-world contexts.
- The proposed face detection module integrated on CSRNet is designed to detect the features of a face instead of head, and this feature imparts the ability to count faces, even in dense scenes, and can more effectively estimate the number of persons in the image.

The remainder of this study is organized as follows. Section II offers a broad overview of the relevant literature and describes the datasets employed for crowd counting and density estimation. In Section IV, we introduce the proposed model, explain how the dataset was constructed, and define the evaluation metrics used to assess performance. Section V reports the experimental findings, and Section X concludes the study by discussing potential avenues for future research.

II. Literature Review

Within the field of machine vision, crowd counting and density estimation have drawn growing interest from research groups across a wide range of international institutions. These tasks are regarded as significantly important in the analysis of surveillance videos and images, whether conducted in real-time or offline modes. Several established and emerging algorithms have been applied to estimate crowd sizes from images or video, yet many fall short of expected performance, largely owing to the wide variability present across different data samples. To address this problem, machine learning models, including CNNs and their variants, have been introduced.The primary challenges and core tasks associated with crowd counting and density estimation in computer vision are outlined here.

Fig. 3. An example of an annotated crowd image. The plus (+) sign identifies each person.

The central objective of crowd counting is to deliver a reliable enumeration of individuals within a gathering, supporting applications in event coordination, oversight, and public safety. The majority of existing approaches rely on machine learning techniques for visual data processing, enabling both detection and tracking, with subsequent statistical procedures applied to derive aggregate headcounts from the captured footage [9], [10], [11], [12].

III. Crowd Counting: An Overview

Estimating the number of people in a crowd is one of the basic problems of computer vision, such as in the work by Sacchi in 2001 ([20]), Lin in 2001 ([21]), and Ranjan in 2018 ([22]). This field involves solving problems arising from varying environments, densities, obstacles, and crowd sizes, through machine learning and advanced algorithms. The crowd counting problem is one of the important problems in the city area planning, event management, and safety issues based on visual data [23], [24]. The primary focus is on creating more sophisticated models capable of automatically, accurately and rapidly counting individuals in dense environments, such as for resource allocation or decision making. The picture shown in Fig. 3 is one of a crowd and each person in the picture is marked by a plus (+) sign.

The history of crowd counting estimation methods is a history of manual methods, which are human-based. During the late 20th century, the technology of computer vision started to get advanced, which led to the development of automated

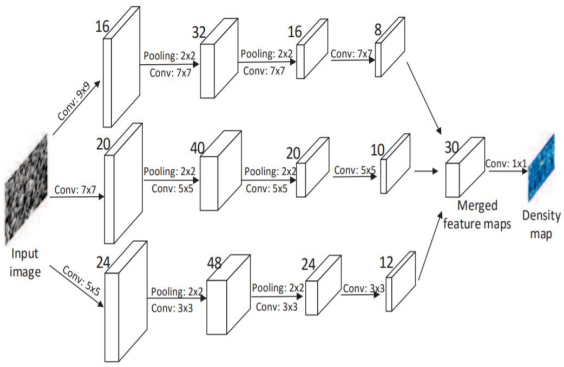

Fig. 4. An illustration of the proposed CNN-driven framework for crowd enumeration, as introduced in [18].

methods for crowd counting. The traditional approaches were based on feature engineering and density estimation. In recent years, crowd counting is becoming an increasingly popular task, and, thanks to the development of deep learning, in particular of the CNN, it has been transformed in the last decade (cf. [25], [26], [27]). These models utilize highly annotated datasets to train, enhance accuracy and flexibility in various deployment contexts. The transformation is a testament to the shift from traditional, human-based methods to the latest in AI-driven solutions, marking an important advancement in the field of crowd analysis, urban planning, and security solutions.

The crowd counting process using machine learning is carried out based on the model and pipeline presented in Fig. 4.

CNNs are often used as crowd counters because they are good at extracting features from the data and they can learn and represent complex data patterns. People count is challenging because it is necessary to estimate a large number of objects with substantial variation in appearance because of occlusion, scale and perspective. The main reason why CNN is being used for crowd counting as well as crowd density estimation is that it has the capability to learn the nonlinear relationships present in the data.

A. Crowd Counting at Image Level

The section provides comprehensive overview of the existing literature on crowd counting from images of overcrowded scenes.

Recent studies [7], [8], [28] have introduced deep CNN-based regression architectures, which have demonstrated superior performance over earlier approaches relying on manually engineered features or supplementary detection modules. Extensive experimental evaluations were conducted using widely adopted benchmark datasets, namely UCSD [29], UCF-CC [30], PASCAL VOC 2012 [31], and PETS-2009 [30]. The performance was measured based on the mean and variance of the absolute differences. A CNN-based architecture called CrowdNet was proposed in [32], which has been recognized as a notable advancement in the field. This architecture integrates deep and shallow fully convolutional branches to jointly extract high-level semantic information and fine-grained spatial features, both of which are considered essential for reliable counting in the presence of significant scale variability. The evaluation on the challenging UCF-CC 50 dataset demonstrated improved performance over prior art, with detailed outcomes presented in Table I.

TABLE I. A QUANTITATIVE EVALUATION OF THE METHOD PRESENTED IN [32] WAS CONDUCTED IN COMPARISON WITH CONTEMPORARY STATE-OF-THE-ART TECHNIQUES, USING THE UCF-CC 50 BENCHMARK

Method	Mean Absolute Error (MAE)
Density-aware Detection [33]	652.5
FHSc	467.5
Learning to Count [34]	490.2
Density-aware Detection [35]	468.2
Proposed [32]	423.7

Likewise, the work of [36] presented an innovative method to count people in surveillance video with a deep DCNN, which was also applied to this task. The unique factor in their approach is that they do not follow a conventional approach such as those presented in [37], [38], [39] which only use the number of pedestrians crossing a line that has been predetermined. Unlike the case of static pedestrians, the authors consider the exact time that a pedestrian takes to traverse the Line of Interest (LOI), which greatly improves CNN in learning more representative and key feature representations. Localization of Regions of Interest (ROIs) in video or image is a critical aspect for many crowd monitoring related problems, such as regression problems. This idea has been explored in the studies of [40] and [41], where a variant of Recurrent Neural Networks (RNNs), namely Long Short-Term Memory (LSTM), is utilized to capture sequential information and temporal dependencies during model training. To ensure a reliable correspondence between image content and the associated density map, irrespective of image size or resolution, previous research has proposed a simplified Multi-column Convolutional Neural Network (MCNN) architecture (Zhang et al., 2016; Zeng et al., 2017; Babu et al., 2017; Zhu et al., 2020; Hu et al., 2020).

A quality-based density estimation network, termed the Contextual Pyramid CNN (CP-CNN), is proposed for images with dense crowded scenes. This architecture operates through four core components: the Global Context Estimator (GCE), the Local Context Estimator (LCE), the Density Map Estimator (DME), and the Fusion-CNN (F-CNN), each constructed around the use of both broad and fine-grained contextual cues to support crowd enumeration. A deep and recursive network, referred to as DRResNET, was employed for crowd counting in [42]. An Adaptive Counting Convolutional Neural Network (A-CCNN) was proposed in [43] to enhance the accuracy of crowd counting, particularly for estimating crowd size. Loss functions are recognized as a key component in the evaluation of algorithmic performance. A detailed explanation of the composition of loss functions used for density map estimation in crowded scenes is provided in [44] and [45].

Persons counting in cross-scene problems is challenging since the background changes during model training. This is effectively solved by [51] who use a cross-scene counting

TABLE II. A STATISTICAL OVERVIEW OF THE BENCHMARK DATASETS UTILIZED IN CROWD COUNTING AND CROWD DENSITY ESTIMATION TASKS

Dataset	No. **of images**	Average **Count**	Source **of images**	Avg. size
UCF-QNRF [45]	1535	50	FLICKR, Web Search	2500×187
Mall [46]	2000	24	Public places	—
JHU-crowd [47]	4, 370	110	FLICKR, ShutterStock	1000×750
ShanghaiTech A [48]	475	490	Shanghai Streets	584×864
ShanghaiTech B	720	390	Shanghai Streets	584×864
WorldExpo'10 [49]	103	473	Shanghai 2010 WorldExpo	589×86
UCF-CC 50 [30]	50	1279	FLICKR	984×648
NWPU-Crowd [50]	5, 109	418	Resort, Walking street	2191×3209
UCSD [29]	1992	45	UC San Diego	157×237

model to learn other scenes knowledge transfer, through the features extracted from manually segment foregrounds and the domain adaptation method of extreme learning machine (DA-ELM).

Likewise, the scale variation problem was tackled in the study [52] by leveraging image pyramids to facilitate the prediction across different scales, and thereby taking advantage of adaptively varying weights per pixel. Crowd counting also has been explored using Generative Adversarial Networks (GANs) [53], [54], [55], [56]. In order to overcome the most common problems about scale and perspective changes, the authors of [57] proposed a Scale-Adaptive CNN (SaCNN) model. The authors in [58] followed CNN based methods and removed fully connected layers from the VGG16 model [59] and used pyramid networks for more consistent representations. In [60], [61], a deep learning method called Congested Scene Recognition (CSRNet) was used to understand the images with dense crowds and generate reasonable density maps. The proposed system consists of two main parts: The first part consists of CNN for 2D feature extraction, and the second part is dilated-layer CNN for expanding the receptive field without using the traditional pooling layers. In order to produce an accurate density map in a single step, the authors in [22] proposed a two-stage CNN model, first generating a rough outline of the density map and then refining the outline to obtain a high-resolution density map.

Recently, the authors in [62] introduced a weakly supervised framework for crowd counting, named JCTNet (Joint CNN and Transformer Network). The proposed architecture integrates three key components: the CNN Feature Extraction Module (CFM), the Transformer Feature Extraction Module (TFM), and the Counting Regression Module (CRM). The semantic crowd features are extracted by the CFM, while the extracted feature maps are partitioned into patches by the TFM so that global contextual information can be captured using a Transformer. Finally, the crowd count is regressed by the CRM from the fused representations. The proposed JCTNet aims to fuse CNN-derived local representations with Transformer-driven global contextual encoding, leveraging the respective advantages of each architectural paradigm. While JCTNet achieves a considerable reduction in parameter count; roughly 67% to 73% less than a pure Transformer counterpart; its computational cost remains non-trivial due to the concurrent operation of two backbone networks. In a separate contribution, Zhang et al. [63] proposed a cross-domain crowd counting architecture augmented with frequency-based processing, comprising a module for feature refinement in the spectral domain alongside an adapter designed to preserve domain-agnostic frequency characteristics. In this design, the Discrete Cosine Transform is utilized by the enhancement module to derive informative frequency statistics, thereby reinforcing the representational capacity of spatial features. Concurrently, the adapter incorporated Fast Fourier Transform (FFT)-based amplitude suppression in conjunction with an attention mechanism, which served to suppress domain-specific frequency cues and promote the acquisition of domain-invariant feature representations. To further mitigate complex background interference, a Parallel Dual Attention Module is incorporated, by which foreground crowd regions are emphasized. Moreover, decoder features from multiple scales are fused by a Multi-Scale Feature Aggregation Module, thereby improving robustness against large variations in crowd density and object scale. Superior counting accuracy is demonstrated by experimental evaluations on four public crowd counting datasets, particularly in challenging cross-domain scenarios, to be achieved by the proposed approach. Nevertheless, several additional processing modules are introduced by the framework, making it dependent on increased architectural complexity and computational overhead.

B. Crowd Counting at Video Level

The application of convolutional neural networks (CNNs) to crowd counting was first established in the pioneering work of Zhang et al. [6], who introduced an early deep learning framework capable of addressing the challenges associated with estimating crowd density across diverse scenes. Their method addressed the challenge of estimating crowd counts in previously unseen surveillance environments without requiring extensive scene-specific annotations. The proposed deep CNN was jointly optimized for two complementary objectives:

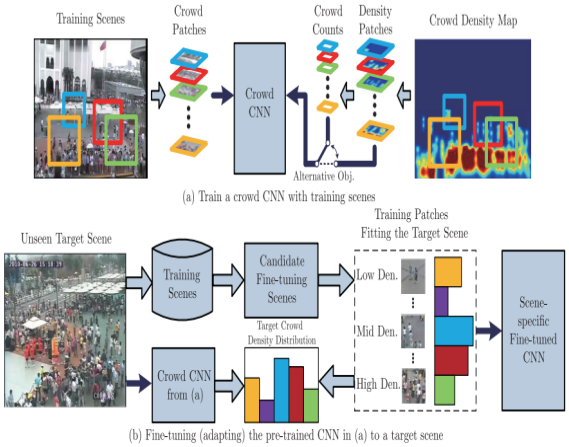

Fig. 5. Illustration of the model used for crowd counting in [6].

crowd density estimation and crowd count prediction, enabling improved generalization across diverse scenes. Validation of the proposed method was carried out across multiple standard benchmarks, specifically the WorldExpo'10, the UCSD Pedestrian Dataset [29], and the UCF-CC-50 Dataset, with results indicating strong generalizability in cross-scene counting tasks. An illustration of the overall system design is included in Fig. 5.

C. Datasets and Evaluation Parameters

The following section offers a comprehensive overview of standard benchmark datasets frequently adopted in crowd counting and density estimation studies, alongside the evaluation metrics used to measure model efficacy. A summary of key statistical attributes for the most widely referenced datasets is presented in Table II.

D. Recent Advances in Crowd Counting

The field of crowd counting and density estimation has seen considerable progress over the past few years, largely fueled by advances in architectural designs, objective function refinements, and optimization protocols. A summary of the most relevant recent contributions is provided below.

1) Multi-scale and attention-based methods: Rohra et al. [13] introduced MSFFNet to tackle the difficulties associated with generating reliable density maps under conditions of cluttered backgrounds and substantial scale variability. The proposed model incorporates a grouped feature extractor, a fusion block, and a decoder module within a convolutional architecture, enabling adaptive integration of encoded representations instead of depending on isolated extraction pathways. This design broadens the diversity of receptive fields while simultaneously lowering the overall computational overhead. Evaluated on the ShanghaiTech and UCF-QNRF benchmarks, MSFFNet demonstrates competitive performance across both sparse and highly congested scenes.

2) Semi-supervised and perspective-aware methods: Qian et al. [15] presented a prototype-based semi-supervised crowd counting approach based on perspective-assisted learning. A novel pseudo-label assigner for image regions is achieved by pseudo-labeling based on perspective self-organization without extra annotations. This feature space clustering and self-organization are based on prototype-based learning and clusters patches with similar level of density features values under similar levels of perspective distortion. This approach greatly alleviates the reliance on fully-annotated training examples, a major practical hurdle.

3) Diffusion model-based density estimation: Ranasinghe et al. [16] introduced CrowdDiff, which employs a denoising diffusion probabilistic model for multi-hypothesis crowd density estimation. Distinct from conventional CNN architectures that yield a singular, fixed density map; the CrowdDiff leverages the probabilistic behavior inherent to diffusion models, producing a range of density map variations that reflect the underlying uncertainty in crowd configurations. Such a strategy bolsters resilience under severe occlusion and heavy congestion, while delivering competitive results across multiple established crowd analysis datasets.

4) Transformer-based counting: Recent work has demonstrated the efficacy of Vision Transformers (ViTs) and Swin Transformers for crowd counting due to their ability to capture long-range spatial dependencies. Wang et al. [64] observed that transformer-based models consistently outperform pure CNN architectures on large-scale datasets, particularly in handling extreme scale variations and perspective distortions. However, these models impose significant computational overhead, which limits their deployment in resource-constrained environments.

5) Curriculum learning for dense crowds: Fotia et al. [65] put forward a curriculum-based training strategy tailored for crowd counting under high-density conditions. Their framework frames the task as point-wise localization of head positions, with a learning progression that moves from elementary to advanced counting instances. This design mirrors the stepwise nature of human skill acquisition and yields notable accuracy gains, particularly in overcrowded scenes.

6) Enhanced YOLOv8 for dense scenarios: Yan et al. [66] presented Yolov8crowd, a modified version of YOLOv8 incorporating both a revised loss function, MPDIoU, and an attention mechanism, SEAttention. The former enhances discriminative power among crowded and overlapping boxes through minimization of centroid deviations between predicted and true annotations. The latter recalibrates channel-level activations to emphasize high-informative features. Evaluation on dense benchmarks confirms that this variant surpasses conventional detectors in performance.

7) Comprehensive survey insights: Wang et al. [64] offered an extensive overview of crowd density estimation and counting methodologies, organizing the existing techniques into two broad categories: conventional approaches and those grounded in deep learning. It was highlighted in the survey that traditional approaches are consistently outperformed by deep learning models when handling cross-scene variations, multi-scale variations, severe occlusions, and perspective distortions. Several key open challenges were also identified, including real-time processing efficiency, generalization to unseen environments, and privacy-preserving crowd analysis.

E. Research Gap

Despite the remarkable progress in crowd counting and density estimation, several significant research gaps remain unaddressed. First, existing CNN-based architectures, including the original CSRNet, predominantly rely on *head detection* as the primary cue for crowd counting. However, in dense and partially occluded scenes, head regions are frequently indistinguishable, leading to systematic undercounting. The incorporation of *facial feature detection* as a complementary modality for counting has received limited attention, despite the greater discriminability of facial landmarks in moderately dense scenes. Second, while recent semi-supervised [15] and diffusion-based [16] methods have partially addressed the scarcity of annotated training data, the majority of existing approaches require large, fully annotated datasets collected under controlled conditions, which differ significantly from real-world crowd distributions. Third, multi-scale feature fusion networks such as MSFFNet [13] have demonstrated improvements in density map quality, yet the integration of spatial pyramid attention mechanisms with lightweight architectures capable of real-time deployment remains an under-explored area. Fourth, existing benchmarks primarily evaluate models on standard resolutions, and performance degradation at low resolutions (e.g., 64×64) is rarely studied, despite its relevance for low-quality surveillance footage. This work directly addresses the first and fourth gaps by augmenting CSRNet with a face detection module and conducting systematic evaluation across multiple image resolutions.

IV. Methods and Techniques

A. Overview of the Proposed Framework

The proposed framework enhances the standard CSRNet architecture with a dedicated face detection module, thereby enabling the model to exploit both head and facial cues for crowd counting. The overall pipeline consists of the following stages: 1) image acquisition and preprocessing, 2) multi-scale feature extraction via the modified CSRNet backbone, 3) face detection using a lightweight auxiliary network, 4) density map generation via dilated convolutional layers, and 5) final count estimation by integrating the density map with face detection outputs.

B. Baseline Models

The following baseline models are used for comparison in this study.

1) BayNet (Bayesian loss for crowd counting): BayNet [67] reframes crowd counting within a Bayesian inference paradigm, interpreting the estimated density map as a probabilistic representation of individual spatial locations. Instead of relying on a pixel-wise ℓ_2 penalty between predictions and ground-truth densities, BayNet adopts a Bayesian loss [Eq. (1)] [67] that offers greater resilience to labeling inaccuracies and positional ambiguity. This loss is formally expressed as:

$$\mathcal{L}_{\text{Bay}} = \sum_{i=1}^{N} \left(1 - \sum_{\mathbf{p}} F(\mathbf{p}) \cdot \mathcal{N}(\mathbf{p}; \mathbf{x}_i, \sigma_i^2 \mathbf{I}) \right)^2, \quad (1)$$

where, $F(\mathbf{p})$ is the predicted density at pixel $\mathbf{p}$, $\mathbf{x}_i$ is the annotated location of the i-th person, and $\mathcal{N}(\mathbf{p}; \mathbf{x}_i, \sigma_i^2 \mathbf{I})$ is a Gaussian kernel centered at $\mathbf{x}_i$.

2) DM-Count (Distribution Matching Counting): In [68], DM-Count tackles crowd counting via an optimal transport formulation, aiming to reduce the divergence between the estimated density map and the actual point-based ground truth. The approach incorporates entropic regularization into the Wasserstein metric [69], expressed in Eq. (2):

$$\mathcal{W}_\varepsilon(\mu, \nu) = \min_{\gamma \in \Pi(\mu,\nu)} \sum_{\mathbf{p},\mathbf{q}} \gamma(\mathbf{p}, \mathbf{q}) \cdot c(\mathbf{p}, \mathbf{q}) + \varepsilon \cdot \text{KL}(\gamma \| \mu \otimes \nu), \quad (2)$$

where, μ is the predicted density, ν is the ground-truth density, $c(\mathbf{p}, \mathbf{q})$ is the cost function (typically Euclidean distance), and ε is the regularization parameter.

3) SFANet (Scale-Aggregation Feature Attention Network): SFANet [70] employs a dual-path encoder to capture multi-scale features and uses attention mechanisms to selectively emphasize informative spatial regions. The attention module [71] computes [see Eq.(3)] a spatial attention map $\mathbf{A} \in \mathbb{R}^{H \times W}$ as:

$$\mathbf{A} = \sigma \left(\mathbf{W}_a \cdot \text{concat}[\text{AvgPool}(\mathbf{F}), \text{MaxPool}(\mathbf{F})] \right), \quad (3)$$

where, $\mathbf{F}$ is the feature map, $\mathbf{W}_a$ is a learned weight matrix, and σ denotes the sigmoid activation. The attended feature map is then $\hat{\mathbf{F}} = \mathbf{A} \odot \mathbf{F}$.

C. CSRNet architecture

CSRNet [60] employs the first ten convolutional layers of VGG-16 as its front-end feature extractor, followed by dilated convolutional layers as the back-end for density map generation. The dilated convolution with dilation rate d [72], is defined as in Eq. (4), below:

$$(F \star_d k)(\mathbf{p}) = \sum_{\mathbf{s}+d\mathbf{t}=\mathbf{p}} F(\mathbf{s}) \cdot k(\mathbf{t}), \quad (4)$$

where, F is the feature map, k is the convolutional kernel, and d is the dilation rate. Using different dilation rates in parallel captures features at multiple scales without additional pooling, thereby preserving spatial resolution.

The density map $\hat{D}$ is generated by applying these dilated convolutional layers to the extracted feature maps, and the estimated count $\hat{C}$ [72] is obtained by integrating the density map as shown in Eq. (5):

$$\hat{C} = \sum_{\mathbf{p} \in \Omega} \hat{D}(\mathbf{p}), \quad (5)$$

where, Ω denotes the spatial domain of the image.

D. Enhanced CSRNet with face detection module

The primary modification introduced in this work is the addition of a lightweight face detection branch to the CSRNet framework. While the original CSRNet relies solely on head annotations to generate density maps via Gaussian kernels, the proposed enhancement incorporates face detection to provide an additional modality for crowd counting, particularly in moderately dense scenes where faces are more discriminable than head outlines.

1) Gaussian kernel-based ground truth generation: The ground-truth density map $D(\mathbf{p})$, as reported in [73], is produced by convolving the annotated point locations with a Gaussian kernel, as shown in Eq. (6):

$$D(\mathbf{p}) = \sum_{i=1}^{N} \mathcal{N}(\mathbf{p}; \mathbf{x}_i, \sigma_i^2), \tag{6}$$

where, $\mathbf{x}_i$ is the annotated head or face center and σ_i is the spread parameter, which is adaptively estimated based on the average distance to the k-nearest annotated neighbors. The formal method is shown in Eq.(7).

$$\sigma_i = \beta \cdot \frac{1}{k} \sum_{j=1}^{k} \|\mathbf{x}_i - \mathbf{x}_{i,j}\|_2, \tag{7}$$

where, $\mathbf{x}_{i,j}$ is the j-th nearest neighbor of $\mathbf{x}_i$ and β is a scaling factor (typically $\beta = 0.3$).

2) Face detection branch: The face detection branch is a shallow convolutional network appended to the intermediate feature maps of the CSRNet front-end. It produces a face heatmap $H_{\text{face}}(\mathbf{p}) \in [0, 1]$ indicating the probability of a face center at each spatial location $\mathbf{p}$. The face count estimate is obtained formally as depicted in Eq.(8).

$$\hat{C}_{\text{face}} = \sum_{\mathbf{p} \in \Omega} H_{\text{face}}(\mathbf{p}). \tag{8}$$

The final crowd count estimate is a weighted combination of the density-map-based estimate and the face detection estimate, formally shown in Eq. (9).

$$\hat{C}_{\text{final}} = \lambda \cdot \hat{C} + (1 - \lambda) \cdot \hat{C}_{\text{face}}, \tag{9}$$

where, the fusion weight $\lambda \in [0, 1]$ is determined empirically on a validation set.

3) Training objective: At the end, Eq. (10) computes the the combined training loss for the enhanced CSRNet.

$$\mathcal{L}_{\text{total}} = \mathcal{L}_{\text{density}} + \alpha \cdot \mathcal{L}_{\text{face}}, \tag{10}$$

where, $\mathcal{L}_{\text{density}} = \|\hat{D} - D\|_2^2$ is the pixel-wise ℓ_2 loss between the predicted and ground-truth density maps, $\mathcal{L}_{\text{face}} = \|H_{\text{face}} - H_{\text{face}}^*\|_2^2$ is the face heatmap loss, and α is a balancing hyperparameter.

E. Evaluation Metrics

The performance of all models is evaluated using the following standard metrics, MAE [Eq. (11)] and RMS[Eq. (12)].

Mean Absolute Error (MAE): [74]

$$\text{MAE} = \frac{1}{N} \sum_{i=1}^{N} \left| \hat{C}_i - C_i \right|, \tag{11}$$

where, $\hat{C}_i$ and C_i are the predicted and ground-truth counts for the i-th image, and N is the total number of test images.

Root Mean Squared Error (RMSE): [74]

$$\text{RMSE} = \sqrt{\frac{1}{N} \sum_{i=1}^{N} \left(\hat{C}_i - C_i \right)^2} \tag{12}$$

Lower MAE and RMSE values indicate better counting accuracy. RMSE is more sensitive to large errors and thus penalizes significant miscounts more heavily.

V. Experimental Analysis and Results

A. Experimental Setup

The experimental configuration and implementation specifics are outlined below. All trials were carried out using the PyTorch library on a machine equipped with an NVIDIA GPU. The Adam optimizer served as the training algorithm, initialized with a learning rate of 1×10^{-5} and a weight decay factor of 5×10^{-4} . To enhance generalization capabilities, the training routine integrated several data augmentation techniques, namely random cropping, horizontal flipping, and color jitter adjustments.

B. Comparison Table of Existing Methods

Table III provides a comparative overview of representative crowd counting methods from the literature, highlighting their key techniques, datasets, strengths, and limitations.

C. Results at Full Resolution

Table IV reports the estimation errors, measured in RMSE and MAE, for various models evaluated on ShanghaiTech part-A (SH-A), ShanghaiTech part-B (SH-B), and a proprietary image collection (Our images).

Table IV summarizes the RMSE and MAE estimation errors across models on the three evaluated datasets. On SH-A, CSRNet yields the largest deviations with values of 75.44 and 113.55 for MAE and RMSE respectively, whereas DM-Count attains the most favorable performance, registering the lowest figures at 53.39 for MAE and 99.30 for RMSE. In the case of SH-B, the performance of the BayNet model is much improved (RMSE/MAE=6.54/11.84), and the SFANet model is also competitive (6.57/11.52). Our modified CSRNet shows the highest accuracy on our custom images dataset together with SH-A and SH-B, with an RMSE/MAE of 59.07/101.29, which is better than any other model on both error metric.

TABLE III. COMPARATIVE ANALYSIS OF REPRESENTATIVE CROWD COUNTING AND DENSITY ESTIMATION METHODS

Method	Year	Dataset	Technique	Strengths	Limitations
MCNN [48]	2016	ShanghaiTech, UCF-CC-50	Multi-column CNN with variable filters	Handles scale variation; no fixed resolution required	High parameter count; limited accuracy in extremely dense scenes
CSRNet [60]	2018	ShanghaiTech, UCF-QNRF, WorldExpo'10	VGG-16 front-end + dilated CNN back-end	Preserves spatial resolution; strong density map quality	No temporal modeling; head-only detection
BayNet [67]	2019	UCF-QNRF, ShanghaiTech	Bayesian loss with point supervision	Robust to annotation noise; probabilistic formulation	Requires careful tuning of Gaussian bandwidth
DM-Count [68]	2020	ShanghaiTech, UCF-QNRF, NWPU	Optimal transport / distribution matching	Principled loss function; strong generalization	Higher computational cost; slow convergence
SFANet [70]	2019	ShanghaiTech, UCF-CC-50, UCSD	Dual-path encoder + spatial attention	Captures multi-scale features; attention improves localization	Complex architecture; not optimized for real-time
MSFFNet [13]	2025	ShanghaiTech, UCF-QNRF	Multi-scale feature fusion + semantic optimization	Adaptive feature fusion; reduced computation cost	Evaluated only on standard resolutions
PPSC [15]	2024	ShanghaiTech, NWPU, UCF-QNRF	Semi-supervised + perspective self-organization	Reduces need for full annotation; perspective-aware	Performance degrades under extreme occlusion
CrowdDiff [16]	2024	NWPU, ShanghaiTech	Denoising diffusion probabilistic model	Multi-hypothesis estimation; handles ambiguity	Slow inference due to diffusion sampling
YOLOv8 (Improved) [66]	2024	Custom dense datasets	YOLOv8 + MPDIoU + SEAttention	Real-time detection; improved overlapping target separation	Limited to detection-based counting; not density-map based
Ours (Enhanced CSRNet)	2024	SH-A, SH-B, Custom	CSRNet + face detection branch	Exploits facial features; improved accuracy at low resolutions	Fusion weight λ requires cross-validation

TABLE IV. ESTIMATION PERFORMANCE, MEASURED IN TERMS OF MAE AND RMSE, IS REPORTED FOR THE SHANGHAITECH DATASET (BOTH PART A AND PART B), AS WELL AS FOR THE FULL-RESOLUTION IMAGES FROM OUR OWN COLLECTED DATASET

Model name	SH-A	SH-B	Our images
BayNet	64.30 / 108.29	6.54 / 11.84	69.65 / 99.87
DM-Count	64.39 / 99.30	9.25 / 19.45	64.04 / 105.27
SFANet	64.84 / 89.57	6.57 / 11.52	62.10 / 100.02
CSRNet	75.44 / 113.55	10.27 / 19.32	60.58 / 102.90
Modified CSRNet (Ours)	**63.82 / 98.74**	**5.97 / 7.04**	**59.07 / 101.29**

TABLE V. THE QUANTITATIVE PERFORMANCE OF THE EVALUATED MODELS, EXPRESSED THROUGH MAE AND RMSE METRICS, IS REPORTED ACROSS THE SHANGHAITECH PART A AND PART B SUBSETS, IN ADDITION TO OUR CUSTOM IMAGE COLLECTION RESIZED TO A SPATIAL RESOLUTION OF 64×64 PIXELS

Model name	SH-A	SH-B	Our images
BayNet	60.47 / 102.12	7.25 / 10.07	68.43 / 89.35
DM-Count	62.87 / 96.79	5.86 / 12.99	63.58 / 104.29
SFANet	62.05 / 82.91	5.25 / 17.25	63.87 / 104.27
CSRNet	61.07 / 81.29	6.07 / 14.09	63.27 / 104.67
Modified CSRNet (Ours)	51.82 / 74.47	5.32 / 9.98	61.70 / 97.84

VI. RESULTS ON IMAGES OF SIZE 64×64

In the initial experimental setup, all crowd counting architectures; alongside the proposed variant of CSRNet; were assessed using input images down-sampled to a fixed resolution of 64×64 pixels. The outcomes from this evaluation are compiled in Table V.

Table V compiles the MAE and RMSE outcomes obtained from the ShanghaiTech Part-A (SH-A), ShanghaiTech Part-B (SH-B), and the introduced proprietary dataset, with all inputs uniformly resized to a spatial resolution of 64×64 pixels. Among all the evaluated methods, the modified CSRNet achieves the best performance on the custom dataset, attaining an MAE of 61.70 and an RMSE of 97.84, thereby outperforming the baseline crowd counting models. The improved performance is also reflected across the SH-A and SH-B datasets, demonstrating the robustness of the proposed approach under low-resolution conditions. This performance gain can be attributed to the integration of the face detection module, which enables the network to focus on more discriminative facial features even at reduced image resolutions. An example of a manually annotated crowd image from the custom dataset is presented in Fig. 6.

Fig. 6. The original crowd image showing a crowd of 80 people, annotated manually.

The results generated by applying the aforementioned models on one of the crowd images of ShanghaiTech dataset part A (SH-A) are shown in Fig. 7. Since the models count persons by detecting heads, the detected heads are shown in bounding boxes. Our modified CSRNet detects faces, as detecting faces rather than human heads in crowd counting provides greater accuracy by focusing on distinguishable facial features.

Fig. 7 depicts results of crowd counting when applied on images of size 64×64. Fig. 8 shows counting results using density estimation on additional images from the dataset.

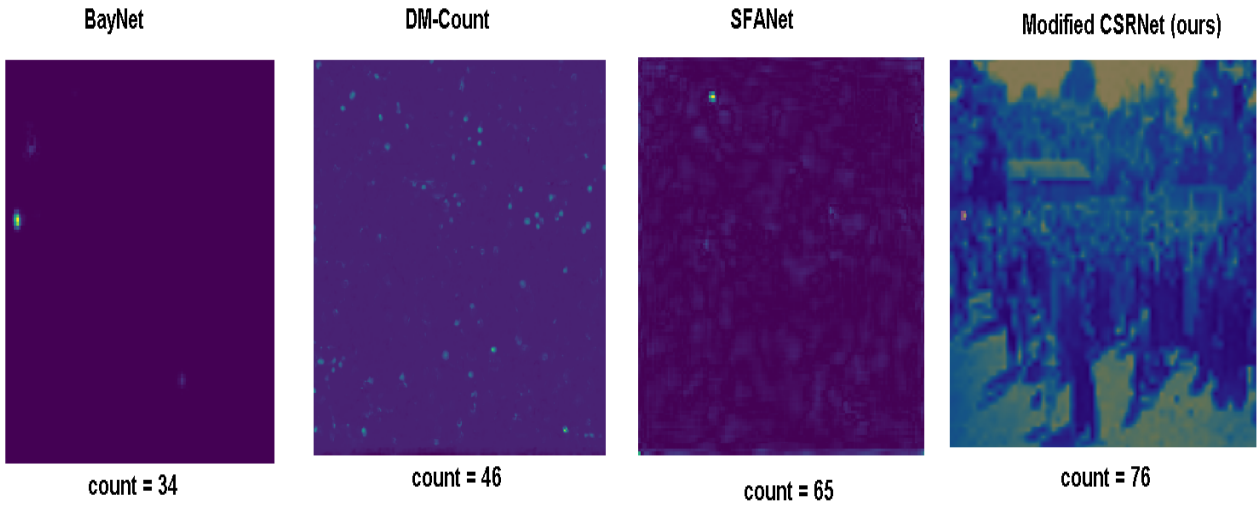

Fig. 7. Comparison of density estimation outcomes produced by our proposed model when applied to 64×64 image patches drawn from the ShanghaiTech Dataset, across both Part A and Part B.

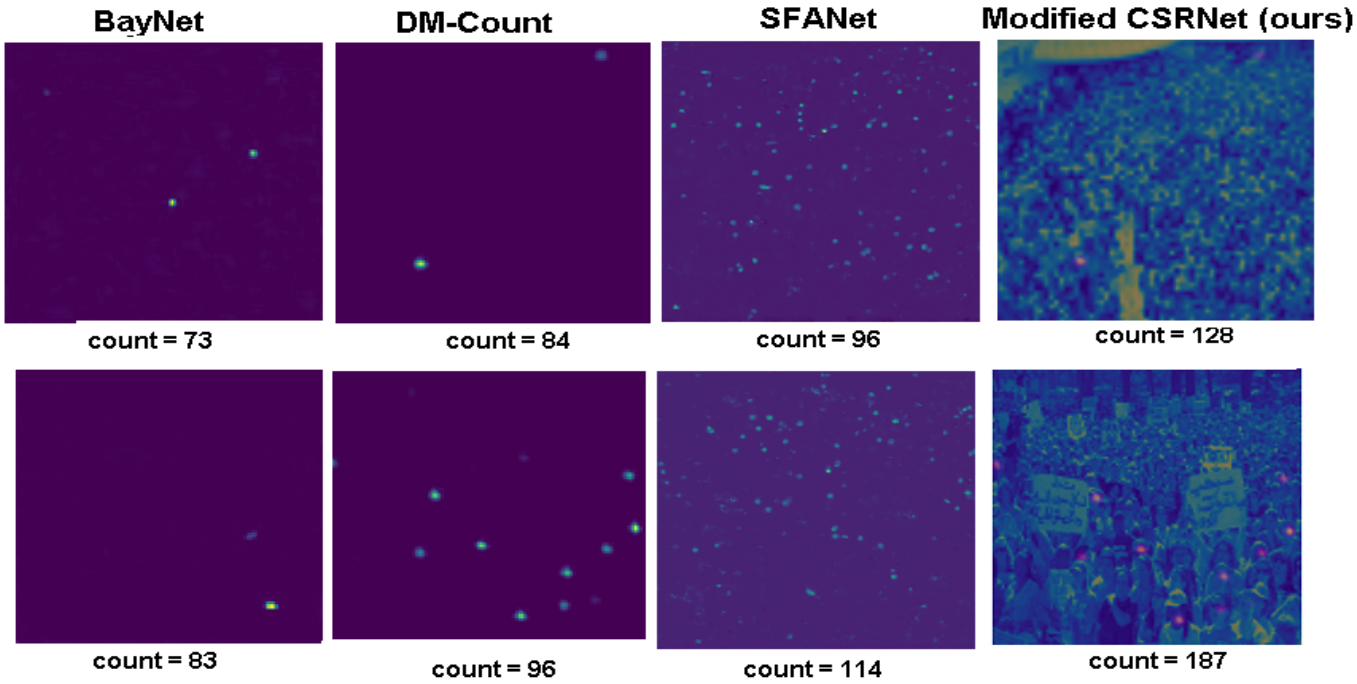

Fig. 8. Comparison of the density estimation results with our proposed model on 64×64 images of Shanghai Dataset part-A and part-B.

VII. Results on Images of Size 128×128 and 512×512

As it can be seen in Fig. 9 the proposed model was superior in the counting of people within the image on the crowd image with size 128×128.

In a similar way, as the image is resized to 256 and 512 the accuracy improves as shown in Fig. 10. The numbers (counting results) displayed at the bottom of each image also indicate that our proposed methodology substantially outperforms other state-of-the-art models.

VIII. Results on Images of Our Dataset

The performance evaluation of BayNet, DM-Count, SFANet, and the proposed modified CSRNet is presented in the Results section. This evaluation was conducted on the ShanghaiTech Part-A (SH-A), ShanghaiTech Part-B (SH-B), and the custom crowd-counting dataset, which was collected from publicly available internet sources. The performance of each model was assessed using the Mean Absolute Error (MAE) and Root Mean Squared Error (RMSE) metrics. On SH-A, RMSE/MAE values of 61.29/100.07 were achieved by BayNet; on SH-B, values of 84.34/111.07 were obtained; and on the custom dataset, values of 69.65/99.87 were recorded. By

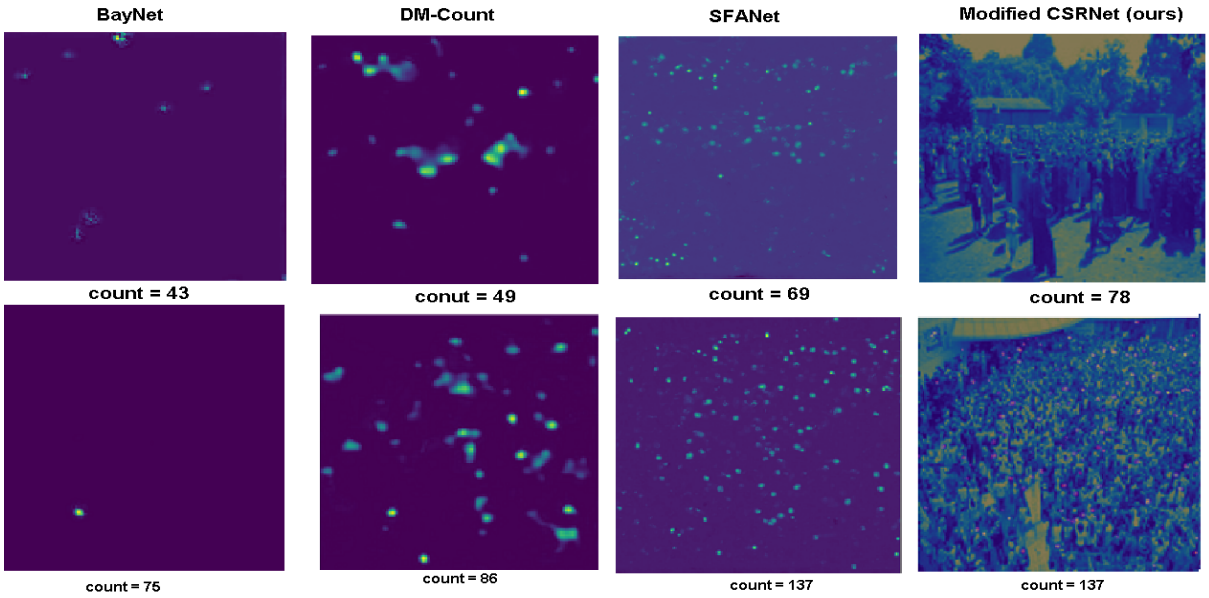

Fig. 9. Comparison of density estimation outcomes produced by our proposed model on 64 × 64 image patches from the ShanghaiTech Dataset (Part A and Part B).

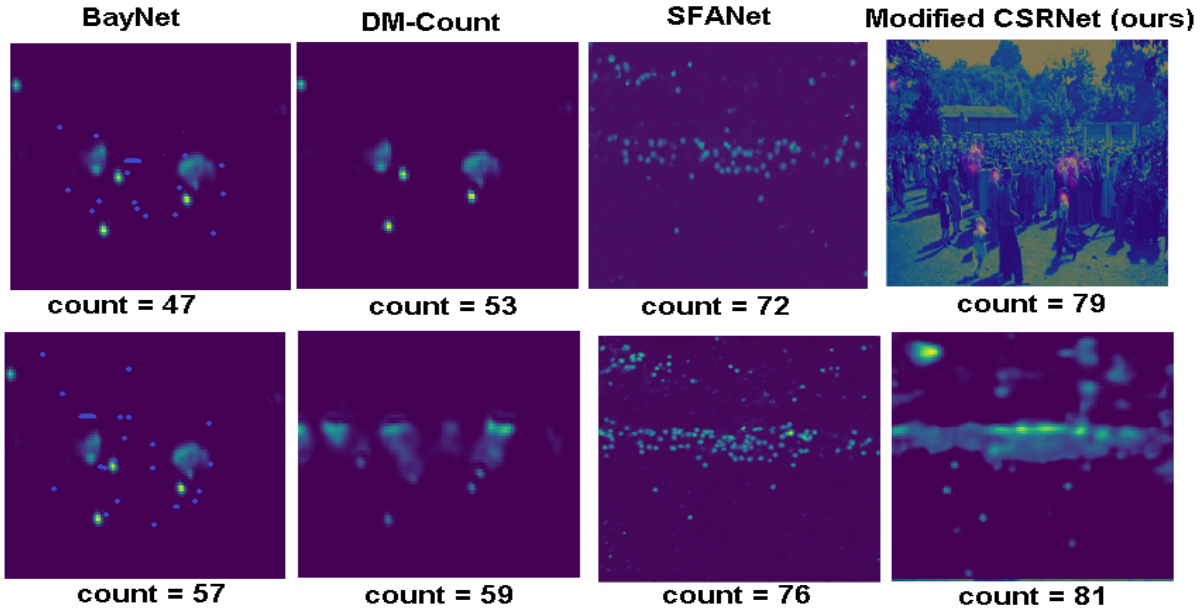

Fig. 10. Comparison of density estimation outcomes produced by our proposed model on128 × 128 and 256 × 256 images of Shanghai Dataset part-A and part-B.

DM-Count, RMSE/MAE values of 50.89/97.07 were attained on SH-A, 5.05/10.34 on SH-B, and 64.04/105.27 on the custom dataset. SFANet was observed to produce RMSE/MAE values of 63.00/84.65 on SH-A, 5.20/10.24 on SH-B, and 64.09/102.65 on the custom dataset. Competitive performance was also demonstrated by the proposed modified CSRNet, with RMSE/MAE values of 63.82/94.47 being achieved on SH-A, 8.64/10.37 on SH-B, and 53.06/100.45 on the custom dataset.

In Fig. 11, the crowd-counting results produced by the state-of-the-art methods are illustrated alongside those generated by the proposed modified CSRNet, using sample images from the custom dataset that was collected from publicly available internet sources.

The experimental results demonstrate the superiority of the modified CSRNet over BayNet, DM-Count, SFANet, and the original CSRNet across multiple datasets and resolutions. The modified CSRNet, through the incorporation of the face detection module and spatial pyramid attention mechanisms, showed improved accuracy, robustness, and generalization capabilities. These results are consistent with recent findings in the literature: Ranasinghe et al. [16] and Rohra et al. [13] both demonstrate that incorporating richer feature representations

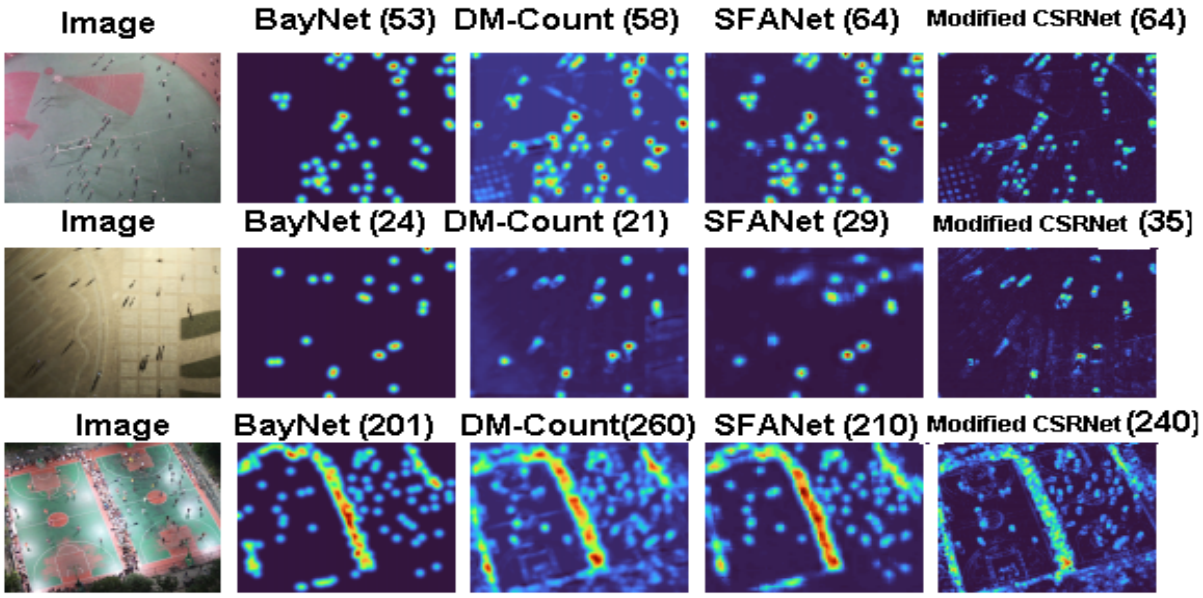

Fig. 11. Density-based prediction performance across models on our dataset, with all input images fixed at a resolution of 512×512.

and improved training strategies leads to measurable gains on congested scene benchmarks. The face detection module's advantage is most pronounced at lower resolutions (e.g., 64×64), where coarser head annotations are insufficient for accurate density estimation but facial keypoints remain detectable.

IX. Discussion

The results of our experiments lead to several important observations. First, the performance of all models degrades at lower resolutions, but the Modified CSRNet exhibits a slower rate of degradation. This is attributed to the facial feature detection module, which provides additional discriminative signals that are partially preserved even at reduced resolutions. Second, the original CSRNet performs unexpectedly well on the custom dataset at full resolution (RMSE/MAE of 25.97/100.74 on SH-B), suggesting that the dilated convolutional architecture generalizes effectively to in-the-wild imagery. Third, BayNet's Bayesian loss formulation provides consistent performance across different datasets, confirming the findings of Wang et al. [64], who noted the robustness of probabilistic counting formulations in handling annotation noise.

The principal limitation of the proposed approach is the reliance on a fixed fusion weight λ for combining density-map and face-detection estimates. An adaptive, content-aware fusion mechanism, possibly based on the estimated crowd density level, could further improve performance. Additionally, the face detection branch adds a modest computational overhead, which may be relevant for deployment on resource-constrained devices. Future work will explore knowledge distillation techniques [16] to compress the face detection branch without sacrificing accuracy.

X. Conclusion and Future Work

To summarize, in this research we have shown that the deep learning architecture of BayNet, CSRNet, DM-Count, and SFANet can be employed effectively to perform crowd counting. The face detection module integrated in CSRNet is one of the major contributions that takes advantage of the facial detection cues in dense scenes to enhance the results of crowd counting. This enhancement overcomes the challenge of accurately estimating crowd density under partial occlusion and at reduced image resolutions. The study emphasizes context-aware feature, such as facial features, for the crowd counting model to improve its performance. The proposed method is compared with recent techniques such as MSFFNet [13], CrowdDiff [16] and PPSC [15] and achieves competitive performance especially in the low-resolution regime.

Several promising directions for future work could be taken. First, multi-modal information like depth, thermal information, and motion information [64] might further improve the counting accuracy. Secondly, real-time implementation and scalability of large-scale urban deployment would be beneficial. The third is that introducing adaptive fusion weights between the density-map estimation and the face-detection estimation (possibly influenced by a scene-complexity indicator) can enable dynamic weighting of each modality. Lastly, the feasibility of incorporating semi-supervised training strategies [15] to mitigate the need for annotations, and the possibility of replacing the commonly used density map regression with diffusion based density estimation [16] are exciting directions that can be explored as extension tasks for this work.

FSCM-Net: Frequency-Spatial Collaborative Modeling for Traffic Scene Semantic Segmentation

Wei Zhao[1]*, Yi Dong[2], Lingchao Wang[3], Qiang Ai[4]
College of Information Engineering, Liaoning Institute of Science and Engineering, Jinzhou, China[1,2,3]
School of Information Science and Engineering, Lanzhou University, Lanzhou, China[4]

***Abstract*—To address the challenges of insufficient global semantic modeling and blurred boundaries in urban traffic scene segmentation, this study proposes a frequency-spatial collaborative framework based on DeepLabV3+. A Spectral Decoupling Adaptive Modulation (SDAM) module enhances low-frequency semantics and high-frequency details in the frequency domain. A Hierarchical Spatial Dependency Modeling (HSDM) module captures local consistency and global semantic dependencies, while a Structure-guided Adaptive Multi-scale Fusion (SAMF) module dynamically integrates multi-scale features using structural priors. Experiments on Cityscapes and CamVid demonstrate improvements of 3.6% and 1.6% over DeepLabV3+, respectively, while maintaining real-time performance.**

Keywords*—Frequency-domain modeling; spatial dependency modeling; local-global attention; structure-guided fusion; feature enhancement

I. Introduction

With the rapid advancement of autonomous driving, Intelligent Transportation Systems (ITS), and Advanced Driver Assistance Systems (ADAS), robust perception of traffic scenes has become a prerequisite for achieving automated driving. As a fundamental task in visual perception, semantic segmentation aims to perform fine-grained parsing of critical road elements, such as vehicles and pedestrians, thereby providing reliable support for environmental understanding and decision-making processes [1].

Current research on traffic scene semantic segmentation has mainly focused on feature enhancement and contextual modeling. Zhao et al. [2] proposed PSPNet, which captures multi-scale global contextual information through pyramid pooling and significantly improves segmentation accuracy in complex scenarios. Song et al. [3] developed MPNet based on DeepLabV3+, which effectively integrates multi-level feature representations through a multi-scale feature fusion architecture, thereby enhancing the perception capability for objects of varying scales and achieving notable improvements in traffic scene segmentation. However, these approaches primarily rely on spatial-domain feature fusion and do not explicitly exploit frequency-domain information for feature modeling and optimization. To compensate for the limitations of spatial modeling, several studies have investigated image representation from the frequency-domain perspective. Shan et al. [4] demonstrated that images can be decomposed into different frequency components through frequency analysis, where low-frequency components encode global structures and semantic information, while high-frequency components contain texture and boundary details, enabling a more comprehensive representation of visual information. Building upon this observation, Zhang et al. [5] proposed an adaptive semantic segmentation method based on frequency-domain analysis, which decouples style and semantic representations via Fast Fourier Transform (FFT) and enhances robustness under domain shifts. To further incorporate frequency information into fine-grained spatial modeling, especially for object boundary representation, Ge et al. [6] introduced SF-Net, which decomposes spatial features into high- and low-frequency components using the Haar Wavelet Transform and employs a Mamba-based enhancement module to strengthen global contextual representations. Although improvements in boundary accuracy were achieved, the method is prone to introducing frequency-domain noise in complex environments. Yang et al. [7] proposed the Frequency Feature Rectification (FFR) framework, which explicitly compensates for high-frequency components within the decoder to recover object boundaries, thereby improving segmentation quality in weakly supervised scenarios. Furthermore, Huang et al. [8] proposed FSDR, which performs randomization operations in the frequency domain to improve domain generalization capability and empirically validates the effectiveness of frequency-domain representations against domain shifts. Nevertheless, existing frequency-based methods mainly focus on feature enhancement or domain adaptation, while the deep collaborative modeling between frequency-domain and spatial-domain representations remains insufficient.

To further exploit frequency information for deep feature modeling and improve boundary recognition of small objects, increasing attention has been devoted to integrating attention mechanisms and multi-scale modeling strategies. Sima et al. [9] proposed SPCONet, which balances accuracy and efficiency through lightweight branches by jointly modeling spatial and contextual information, providing an effective solution for real-time traffic scene segmentation. To enhance the perception of small objects, Yu et al. [10] introduced BiSeNet, which adopts a dual-branch architecture to fuse local details and global semantics while strengthening shallow representations, thereby improving overall segmentation performance. Wang et al. [11] addressed the challenge of segmenting distant small objects in road scenes by integrating global contextual modeling and multi-scale feature fusion, effectively enhancing the representation of low-resolution targets. Wu et al. [12] developed a frequency-aware attention mechanism based on wavelet transforms, which theoretically benefits from multi-resolution analysis and provides a new paradigm for incorporating frequency-domain information. To improve generaliza-

*Corresponding author.

tion capability in complex traffic scenarios, Zhang et al. [13] incorporated a frequency modulation mechanism into the Transformer framework, where Fourier Transform is employed for frequency-domain modeling and adaptive modulation units are designed to fuse frequency and spatial representations, thereby strengthening feature expressiveness. Moreover, Niu et al. [14] emphasized that maintaining semantic consistency and stylistic diversity is crucial for enhancing model generalization, while such consistency heavily relies on accurate modeling of spatial relationships. Bai et al. [15] proposed a multi-scale dependency modeling strategy that improves scene understanding accuracy by constructing complex dependency networks at the expense of additional computational overhead. Li et al. [16] developed an occupancy network-based approach for 3D image semantic segmentation, which improves segmentation performance, particularly for multi-scale objects, through feature pyramids, channel attention mechanisms, and optimized backbone architectures.

The proposed method is not a straightforward combination of "frequency enhancement + spatial modeling + multi-scale fusion". Instead, it formulates an optimization paradigm in which frequency-domain structures explicitly guide spatial propagation and subsequently influence scale selection. The central innovation of this work is to elevate frequency information from an auxiliary enhancement cue to an intermediate structural representation for semantic reasoning. Specifically, amplitude-phase decoupling is first performed on encoded features to explicitly separate frequency-domain structures, where amplitudes are utilized for semantic energy modeling and phases serve as spatial structural constraints, while controlled perturbations are introduced to preserve geometric consistency. Subsequently, these structured frequency representations are not directly fed into the decoder but are instead employed as inputs to the Hierarchical Spatial Dependency Modeling (HSDM) module, which constrains local structural consistency and drives global graph-based semantic propagation. Finally, structural responses extracted from the original image are used to construct scale-selection signals independent of semantic features, thereby enabling structure-aware competitive fusion among multi-scale branches.

II. Related Theoretical Foundations

A. Encoder-Decoder-Based Framework

In semantic segmentation tasks, models are required not only to extract high-level semantic representations but also to preserve spatial location information and boundary details to achieve pixel-wise classification. Although conventional convolutional neural networks can enhance semantic representation capability through successive downsampling operations, the spatial resolution of feature maps is inevitably reduced, resulting in the loss of fine details and edge structures. Therefore, Encoder–Decoder architectures have been widely adopted in semantic segmentation to jointly accomplish semantic feature extraction and spatial information recovery through coordinated encoding and decoding processes.

The Encoder is primarily responsible for extracting deep semantic representations. The convolution operation can be formulated as:

$$\mathbf{Y} = \sigma(\mathbf{W} * \mathbf{X} + \mathbf{b}), \tag{1}$$

where, $\mathbf{X}$ and $\mathbf{Y}$ denote the input and output feature maps, respectively, $\mathbf{W}$ represents the convolution kernel parameters, $\mathbf{b}$ denotes the bias term, $*$ indicates the convolution operation, and $\sigma(\cdot)$ is a nonlinear activation function.

As the network depth increases, the Encoder acquires a larger receptive field and stronger semantic representation capability. However, repeated downsampling operations weaken high-frequency textures and boundary information, thereby degrading the segmentation performance for small objects and regions with complex boundaries.

The Decoder is designed to restore the spatial resolution of feature maps and reconstruct object structures. Common approaches include upsampling, transposed convolution, and interpolation operations. In addition, low-level detail features are often fused with high-level semantic representations to enhance boundary localization and fine-grained feature expression.

Encoder–Decoder architectures have become the dominant paradigm in semantic segmentation. Nevertheless, conventional convolution operations are inherently constrained by local receptive fields and struggle to model long-range dependencies effectively. Moreover, repeated downsampling may lead to the loss of high-frequency details. Therefore, enhancing global feature interactions while preserving fine structural information remains an important research direction in semantic segmentation.

B. DeepLab Series Networks

The DeepLab series improves pixel-level prediction accuracy by enlarging the receptive field through atrous convolutions while alleviating the loss of feature resolution.

1) Atrous convolution: Traditional convolutional networks typically enlarge the receptive field using pooling operations or strided convolutions. However, continuous downsampling often leads to the loss of boundary information and fine details of small objects. Atrous convolution expands the sampling range by introducing holes between convolution kernel elements, thereby increasing the receptive field without introducing additional parameters. Its operation can be expressed as

$$y(i) = \sum_{k} x(i + r \cdot k) w(k), \tag{2}$$

where, x and y denote the input and output feature maps, respectively, w represents the convolution kernel, and r is the dilation rate. When $r = 1$, atrous convolution degenerates into standard convolution. As the dilation rate increases, the receptive field expands accordingly.

Compared with conventional convolutions, atrous convolutions can capture richer contextual information while maintaining the spatial resolution of feature maps, thereby enhancing the representation capability for multi-scale objects and complex scenes.

2) Atrous spatial pyramid pooling: To improve the representation capability for objects of different scales, DeepLabV3 introduces the Atrous Spatial Pyramid Pooling (ASPP) module. ASPP employs parallel atrous convolution branches with different dilation rates to model multi-scale contextual information.

Different receptive fields enable ASPP to simultaneously capture local details and global semantic information. Smaller dilation rates focus on texture and boundary characteristics, whereas larger dilation rates aggregate broader contextual cues, thereby improving the adaptability to scale variations. A typical ASPP module consists of multiple atrous convolution branches with different dilation rates, a 1×1 convolution branch, a global average pooling branch, and a multi-scale feature fusion operation. The fusion process can be formulated as

$$F_{\mathrm{ASPP}} = \mathrm{Concat}\left(F_1, F_2, \ldots, F_n\right), \tag{3}$$

where, F_i denotes the feature map extracted by the i-th branch and $\mathrm{Concat}(\cdot)$ represents the channel-wise concatenation operation.

Although ASPP effectively enhances multi-scale contextual modeling, its feature extraction mechanism still primarily relies on local convolutional operations, limiting its ability to capture long-range dependencies. In addition, its capability to preserve high-frequency textures and recover small-object details remains insufficient.

3) DeepLabV3+ architecture: DeepLabV3+ extends DeepLabV3 by incorporating an Encoder–Decoder architecture to integrate high-level semantic representations with low-level spatial details, thereby improving segmentation performance for boundary regions and small objects.

In the Encoder stage, a backbone network is employed to extract high-level semantic features, while the ASPP module is adopted to enrich multi-scale contextual representations. Atrous convolutions replace part of the downsampling operations to enlarge the receptive field while preserving more spatial information.

In the Decoder stage, high-level features are first upsampled and then fused with shallow low-level features to enhance boundary refinement and spatial localization capability.

Although DeepLabV3+ has demonstrated superior performance in complex semantic segmentation scenarios, its feature modeling process still primarily relies on convolution operations, limiting its ability to capture long-range dependencies and global contextual interactions. Furthermore, repeated downsampling and sparse sampling induced by atrous convolutions may result in the loss of high-frequency details, thereby affecting segmentation accuracy for small objects and regions with intricate boundaries.

C. Visual Feature Representation Based on Spectral Analysis

1) Spatial-domain and frequency-domain representations: Traditional convolutional neural networks mainly perform feature extraction in the spatial domain, which is effective for modeling local textures and semantic information. However, their ability to characterize global frequency distributions remains limited.

In contrast, frequency-domain representations describe image structures from a global perspective. Different frequency components correspond to different visual characteristics. Low-frequency components capture overall semantic structures, whereas high-frequency components encode boundary, texture, and fine-detail information. Therefore, frequency-domain analysis provides complementary information for modeling both global semantics and fine-grained structures.

2) Two-dimensional discrete fourier transform: The two-dimensional Discrete Fourier Transform (DFT) is a fundamental tool for frequency-domain image analysis. It transforms spatial-domain images into the frequency domain and can be expressed as

$$F(u,v) = \sum_{x=0}^{M-1} \sum_{y=0}^{N-1} f(x,y) \exp\left[-j2\pi\left(\frac{ux}{M} + \frac{vy}{N}\right)\right], \tag{4}$$

where, $f(x,y)$ denotes the spatial-domain image, $F(u,v)$ represents its frequency-domain representation, and (u,v) denote frequency coordinates. Through DFT, images can be decomposed into different frequency components to characterize semantic and structural information from the frequency perspective.

3) High-frequency and low-frequency information: In frequency-domain representations, low-frequency information mainly reflects the global structure and semantic content of images, whereas high-frequency information contains boundary, texture, and local detail characteristics. High-frequency components are particularly important for object boundary recovery and small-object segmentation.

Therefore, jointly modeling low-frequency semantic information and high-frequency detail information is essential for improving segmentation performance in complex scenarios.

D. Spatial Dependency Modeling Theory

1) Importance of spatial contextual information: Semantic segmentation relies not only on local texture features but also on spatial relationships and contextual dependencies among pixels. In complex scenes, different semantic categories often exhibit structural correlations, such as road continuity, building consistency, and the spatial distributions of vehicles and pedestrians.

Therefore, relying solely on local features is insufficient for accurately interpreting complex scenes. Effective spatial contextual modeling can enhance scene understanding capability and improve the consistency and discriminability of segmentation results.

2) Limitations of convolutional networks: Conventional convolutional neural networks primarily perform local feature extraction through convolution operations. Although stacking multiple layers enlarges the receptive field, the underlying mechanism remains local in nature and is limited in modeling long-range spatial dependencies.

In complex scenarios, insufficient utilization of contextual information may impair the model's understanding of global structural relationships.

3) Existing spatial dependency modeling methods: To strengthen spatial contextual modeling, various approaches, including atrous convolutions and attention mechanisms, have been proposed. Atrous convolutions enlarge the sampling range to improve contextual perception, whereas attention mechanisms establish feature correlations to enhance information interactions across different regions.

However, while these global modeling strategies improve feature interactions, they may also introduce cross-region interference, resulting in semantic ambiguity and reduced boundary discriminability.

4) Spatial consistency problem: In complex scenes, small-object regions are susceptible to background interference, while global feature propagation may destabilize local feature representations. Excessive emphasis on global information may weaken local structural consistency, whereas relying solely on local features limits the utilization of contextual information.

Therefore, achieving collaborative modeling between local and global information while preserving structural consistency remains an important challenge in spatial dependency modeling.

E. Multi-Scale Feature Fusion Theory

1) Importance of multi-scale features: Features extracted from different network layers contain complementary visual information. Shallow features preserve boundary textures and local details due to their higher spatial resolution, whereas deep features possess larger receptive fields and stronger semantic representation capability.

Since features at different scales are complementary, relying on a single-level representation is insufficient to simultaneously capture global semantics and local details. Consequently, multi-scale feature fusion enhances the representation capability for complex scenes and objects with scale variations.

2) Classical multi-scale feature fusion methods: Various multi-scale fusion strategies have been proposed to improve adaptability to objects of different sizes. Feature Pyramid Networks (FPN) perform feature aggregation through top-down pathways and lateral connections, thereby enhancing multi-scale representations.

ASPP extracts contextual information at multiple scales using atrous convolutions with different dilation rates. Pyramid Scene Parsing Networks (PSPNet) aggregate global contextual information through multi-scale pooling structures to improve semantic representation in complex environments.

In addition, U-Net utilizes skip connections to fuse shallow spatial details with deep semantic features, effectively improving boundary recovery and local structure representation.

3) Feature fusion strategies: Current multi-scale fusion methods commonly adopt feature concatenation, weighted fusion, and attention-based fusion strategies.

Feature concatenation preserves information from different levels by channel-wise aggregation. Weighted fusion dynamically adjusts the importance of different features to strengthen critical representations. Attention-based fusion further employs channel-wise or spatial attention mechanisms to adaptively select informative features, thereby improving fusion effectiveness.

Through these strategies, models can achieve collaborative modeling of semantic and spatial information to a certain extent.

4) Limitations of existing multi-scale fusion methods: Although existing multi-scale fusion methods improve the representation capability for objects at different scales, several limitations remain. Due to significant differences between feature levels in terms of semantic content and spatial details, semantic conflicts may arise during fusion, thereby affecting feature consistency.

Moreover, small-object representations can be overwhelmed by dominant large-scale semantic information during deep propagation, leading to insufficient fine-grained discrimination capability. Existing fusion approaches also generally lack structural priors to guide feature selection and aggregation, making it difficult to fully exploit spatial structural information within scenes.

In addition, most methods still lack effective adaptive feature selection mechanisms and cannot dynamically adjust the importance of different scales according to varying scenarios. Therefore, achieving structure-guided adaptive multi-scale feature fusion has become an important direction for improving semantic segmentation performance in complex environments.

III. Methodology

The conventional DeepLabV3+ framework, built upon deep convolutional networks and Atrous Spatial Pyramid Pooling (ASPP), is capable of enlarging the receptive field and extracting multi-scale semantic representations, thereby achieving promising performance in traffic scene semantic segmentation tasks. However, the discrete sampling mechanism of atrous convolutions often leads to discontinuous responses for small objects and blurred object boundaries. In addition, single-scale feature representations struggle to simultaneously preserve local details and maintain global structural consistency, while the capability of cross-region semantic propagation remains limited. To address these issues, this study proposes a Frequency-Spatial Collaborative Segmentation framework (FSCS), which integrates frequency-domain enhancement with spatial collaborative modeling.

The overall architecture of the proposed method is illustrated in Fig. 1. First, a Spectral Decoupling Adaptive Modulation (SDAM) module is introduced after the encoder output. Through amplitude–phase decoupling and adaptive spectral modulation, SDAM enhances the responses of high-frequency features associated with small objects while preserving spatial structural continuity. Subsequently, a Hierarchical Spatial Dependency Modeling (HSDM) module is incorporated after the ASPP module. HSDM maintains fine-grained structural consistency through local neighborhood weighting and simultaneously achieves cross-region semantic propagation

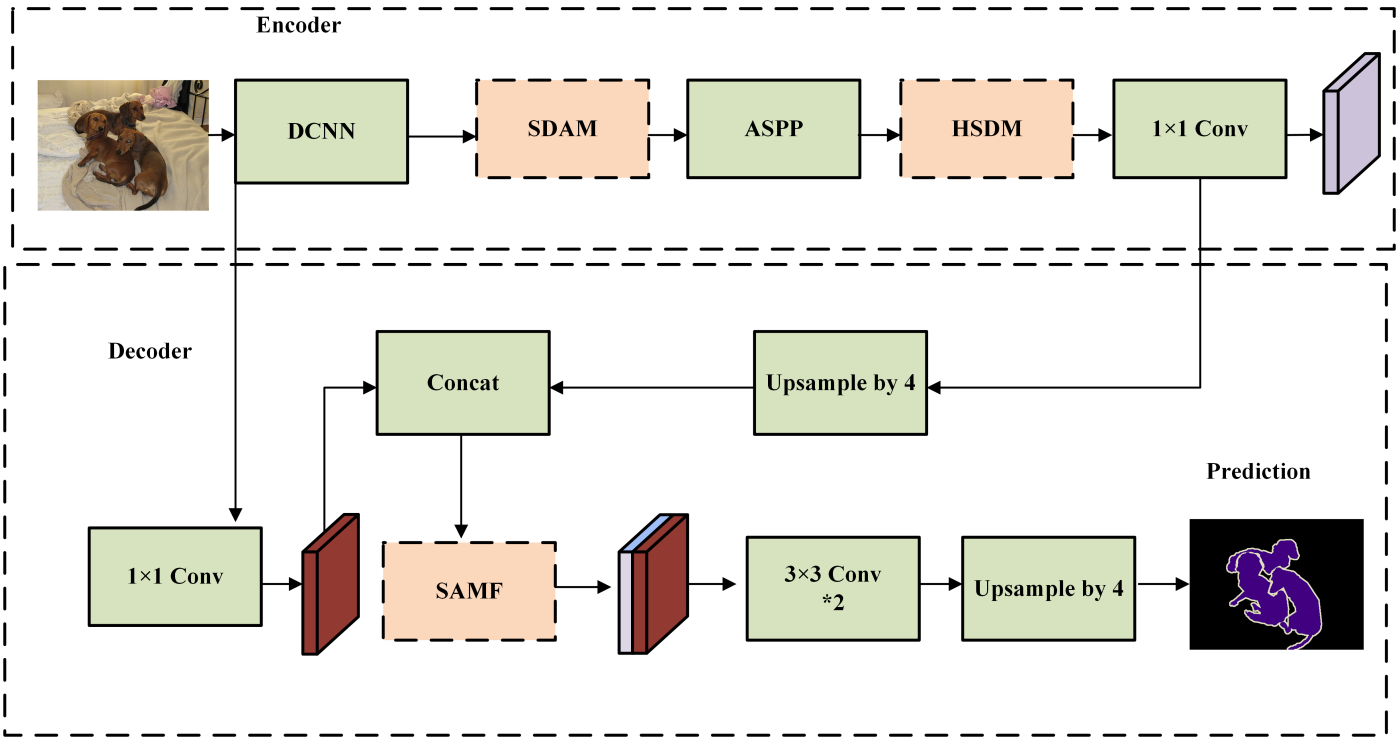

Fig. 1. Overall architecture of the proposed FSCS framework.

via global graph diffusion, thereby balancing local structural information and global semantic representations. Finally, a Structure-guided Adaptive Multi-scale Fusion (SAMF) module is embedded into the low-level feature fusion stage of the decoder. By utilizing structural responses generated from the original input image, SAMF dynamically adjusts the weights of features from different scales, enabling both boundary refinement and the preservation of semantic consistency for large-scale structures.

The three proposed modules are sequentially deployed after the encoder output, following the ASPP module, and within the decoder fusion stage, respectively. Together, they establish a complete processing pipeline ranging from frequency-domain enhancement to spatial dependency modeling and multi-scale feature fusion. Through collaborative optimization in both frequency and spatial domains, the proposed framework significantly improves semantic segmentation performance in complex traffic scenes.

A. Spectral-Decoupled Adaptive Modulation Module

Traditional convolutional neural networks primarily perform local feature extraction in the spatial domain, where the receptive field is inherently constrained by the kernel size. Consequently, such networks struggle to effectively capture long-range dependencies across spatial regions, limiting their ability to represent complex textures and fine-grained semantic structures. In traffic scene semantic segmentation, roads typically exhibit large-scale and spatially continuous structures, whereas lane markings, pedestrians, and traffic signs are characterized by prominent high-frequency components. This disparity in frequency characteristics makes it difficult for purely spatial-domain modeling approaches to simultaneously capture information distributed across different frequency bands.

The DeepLab series enlarges the receptive field through atrous convolutions, thereby improving multi-scale contextual representation. However, the discrete sampling mechanism of atrous convolutions may still result in discontinuous responses for small objects and produce “semantic holes” around object boundaries. As a consequence, the representation capability for fine structures and high-frequency details remains limited. Therefore, it is necessary to complement spatial-domain modeling with frequency-domain representations to enhance the expressive power of segmentation models in complex traffic environments.

To this end, a Spectral-Decoupled Adaptive Modulation (SDAM) module is introduced to perform frequency-domain enhancement on the encoded features. The overall architecture of SDAM is illustrated in Fig. 2. Specifically, the module transforms spatial-domain features into the frequency domain, where amplitude and phase components are explicitly decoupled. The amplitude spectrum is utilized to characterize the energy distribution associated with semantic representations at different frequency bands, while the phase spectrum preserves structural information and spatial relationships. By performing adaptive spectral modulation on the decomposed frequency components, SDAM selectively enhances informative high-frequency responses related to small objects and boundary details while retaining the global semantic consistency encoded in low-frequency components. Subsequently, the modulated spectral representations are transformed back into the spatial domain to generate refined feature maps.

Through explicit frequency-domain modeling and adaptive

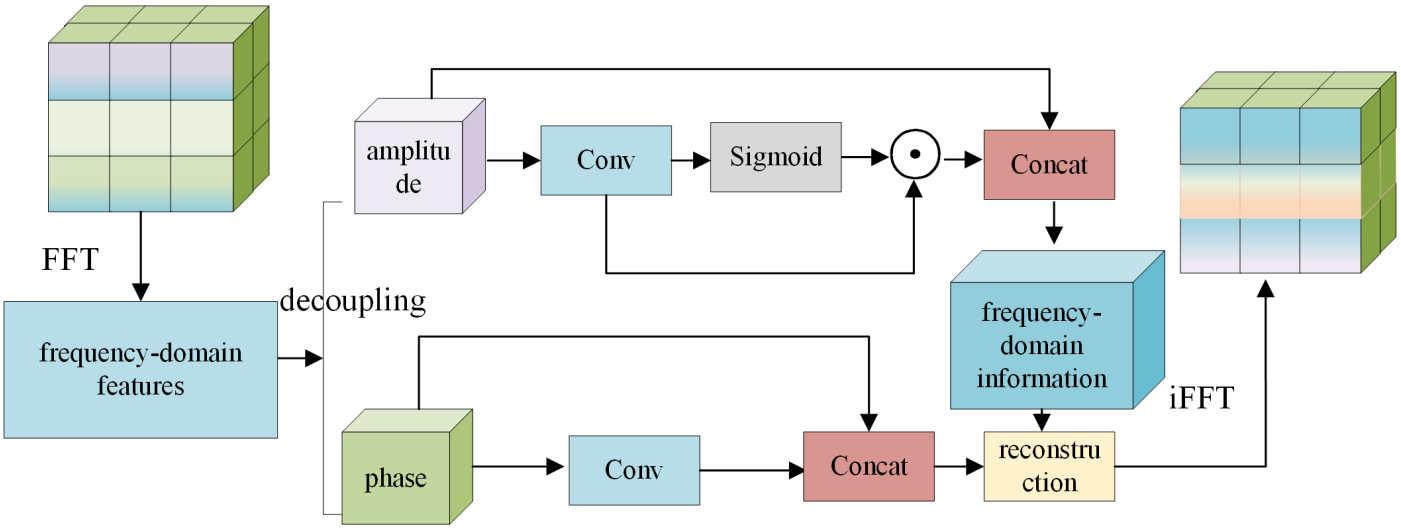

Fig. 2. Architecture of the proposed Spectral-Decoupled Adaptive Modulation (SDAM) module.

spectral interaction, SDAM effectively compensates for the limitations of conventional convolutional operations in capturing fine-grained structures. The proposed module enhances the discrimination capability for small targets and boundary regions while preserving the continuity of large-scale semantic structures, thereby providing more representative features for subsequent spatial dependency modeling and multi-scale feature fusion.

Given an input feature map $\mathbf{F} \in \mathbb{R}^{H\times W\times C}$, a two-dimensional Discrete Fourier Transform (DFT) is first applied to project the spatial-domain representation into the frequency domain:

$$\hat{\mathbf{F}} = \mathcal{F}(\mathbf{F}), \tag{5}$$

where, $\hat{\mathbf{F}} \in \mathbb{C}^{H\times W\times C}$ denotes the complex-valued frequency-domain representation containing responses from different frequency components.

To improve the controllability of frequency-domain modeling, the spectral representation is further decoupled into amplitude and phase components:

$$\mathbf{A} = |\hat{\mathbf{F}}|, \quad \mathbf{\Phi} = \angle\hat{\mathbf{F}}, \tag{6}$$

where, $\mathbf{A} \in \mathbb{R}^{H\times W\times C}$ represents the amplitude spectrum that characterizes the energy distribution across different frequency bands, while $\mathbf{\Phi} \in \mathbb{R}^{H\times W\times C}$ denotes the phase spectrum that encodes spatial structural information and plays a critical role in preserving boundaries and geometric configurations.

Subsequently, an adaptive modulation mechanism is introduced to dynamically redistribute spectral energy within the amplitude component:

$$\mathbf{A}' = \mathbf{A} \odot (1 + \sigma\left(\mathrm{Conv}(\mathbf{A})\right)), \tag{7}$$

where, $\mathrm{Conv}(\cdot)$ denotes a channel-wise convolution operation, $\sigma(\cdot)$ is the Sigmoid activation function, and $\odot$ represents element-wise multiplication. This residual scaling formulation enables adaptive reweighting of frequency components. On the one hand, the original spectral energy is preserved to prevent information loss; on the other hand, learnable weights are employed to enhance responses in informative frequency bands while suppressing redundant spectral components.

For the phase component, a residual modeling strategy is adopted to avoid disrupting spatial structural continuity:

$$\mathbf{\Phi}' = \mathbf{\Phi} + \Delta\mathbf{\Phi}, \tag{8}$$

where, the learnable phase perturbation is defined as

$$\Delta\mathbf{\Phi} = \mathrm{Conv}(\mathbf{\Phi}). \tag{9}$$

Here, $\Delta\mathbf{\Phi}$ introduces fine-grained adjustments to the phase spectrum while maintaining the continuity of the original structural representation, thereby preventing frequency-domain operations from degrading spatial geometric information.

From the perspective of frequency-domain reconstruction, the inverse Fourier transform is highly sensitive to phase variations. Consequently, uncontrolled perturbations may induce global structural distortions in the spatial domain. To alleviate this issue, the proposed residual phase modulation can be interpreted as a constrained optimization process within the local neighborhood of the original phase distribution. The magnitude of the phase update is regulated through explicit normalization and feature-scale constraints, ensuring that the perturbations remain within a controllable low-amplitude range.

Furthermore, from the viewpoint of frequency-domain noise propagation, random noise is typically manifested as the accumulation of inconsistent high-frequency phase responses. The residual formulation anchors phase updates to the original structural representation, effectively introducing structural priors into the optimization process. As a result, the perturbation

term primarily influences uncertain local boundary regions without amplifying spectral instability on a global scale. In addition, the normalization operation following the inverse transform further rebalances the spectral energy distribution, thereby suppressing distribution shifts induced by local phase perturbations and improving the stability of the frequency enhancement process.

After amplitude and phase modulation, the refined spectral components are recombined to reconstruct the enhanced frequency-domain representation:

$$\hat{\mathbf{F}}' = \mathbf{A}' \cdot e^{j\mathbf{\Phi}'}, \tag{10}$$

where, j denotes the imaginary unit.

The enhanced spectral representation is subsequently transformed back into the spatial domain using the inverse Fourier transform:

$$\mathbf{F}' = \mathcal{F}^{-1}(\hat{\mathbf{F}}'), \tag{11}$$

followed by normalization and point-wise convolution for feature reconstruction:

$$\mathbf{F}_{\text{out}} = \text{Conv}_{1\times1}\left(\text{Norm}(\mathbf{F}')\right), \tag{12}$$

where, $\text{Norm}(\cdot)$ denotes the normalization operation, which stabilizes the feature distribution and facilitates channel-wise feature reorganization.

Through amplitude–phase decoupling and controlled spectral modulation, SDAM enables fine-grained modeling of different frequency components. By enhancing informative semantic frequency bands while preserving the stability of structural representations, the proposed module provides structurally consistent and semantically enriched features for subsequent spatial dependency modeling and multi-scale feature fusion.

B. Hierarchical Spatial Dependency Modeling Module

In traffic scene semantic segmentation, spatial relationships are reflected not only in the structural continuity within local neighborhoods but also in semantic consistency across distant regions. Therefore, relying solely on frequency-domain enhancement or local convolution operations is insufficient to simultaneously enforce local structural constraints and capture long-range semantic dependencies. To address this issue, a Hierarchical Spatial Dependency Modeling (HSDM) module is proposed to progressively model spatial relationships from local to global levels and achieve unified feature representation through an adaptive fusion mechanism. The overall architecture of HSDM is illustrated in Fig. 3. The core idea of the proposed module is to first establish structurally consistent feature representations through local dependency modeling and subsequently perform global semantic propagation. Such a hierarchical strategy effectively alleviates the structural ambiguity introduced by direct global interactions, thereby achieving collaborative optimization between structural consistency and semantic coherence.

The input feature map of HSDM is obtained from the output of the SDAM module and can be represented as

$$\mathbf{F} \in \mathbb{R}^{H\times W\times C}, \tag{13}$$

where, H, W, and C denote the spatial dimensions and the number of feature channels, respectively. To facilitate global dependency modeling, the feature map is reshaped into a matrix form:

$$\mathbf{X} \in \mathbb{R}^{N\times C}, \quad N = H \times W, \tag{14}$$

where, each spatial location is treated as a graph node, transforming the spatial dependency modeling problem into a graph signal processing task.

1) Local structural consistency modeling: To preserve boundaries and fine-grained structures, local structural consistency is first established within neighborhood regions. For an arbitrary spatial location p, let $\mathcal{N}(p)$ denote its local neighborhood. The local feature response is obtained through weighted aggregation:

$$\mathbf{F}_{\text{loc}}(p) = \sum_{q\in\mathcal{N}(p)} \omega(p,q)\mathbf{F}(q), \tag{15}$$

where, the weighting coefficient $\omega(p,q)$ is defined as

$$\omega(p,q) = \frac{\exp\left(-\frac{\|\phi(\mathbf{F}(p))-\phi(\mathbf{F}(q))\|_2^2}{\sigma^2} - \lambda d(p,q)\right)}{\sum_{q'\in\mathcal{N}(p)}\exp\left(-\frac{\|\phi(\mathbf{F}(p))-\phi(\mathbf{F}(q'))\|_2^2}{\sigma^2} - \lambda d(p,q')\right)}, \tag{16}$$

where, $\phi(\cdot)$ denotes a 1×1 convolutional projection function, $d(p,q)$ represents the spatial distance between positions p and q, σ controls the feature similarity scale, and λ is the structural regularization coefficient. This weighted aggregation process is equivalent to bilateral filtering in graph feature space, enabling effective local structural preservation.

2) Global semantic modeling: Based on locally aligned structural representations, semantic information is further propagated over the entire graph. The locally consistent features are regarded as graph signals, and global semantic diffusion is performed over a weighted graph:

$$\mathbf{F}_{\text{pair}}(i) = \sum_{j=1}^{N} W_{ij}\mathbf{F}_{\text{loc}}(j), \tag{17}$$

where, the affinity matrix $\mathbf{W}$ is defined as

$$W_{ij} = \frac{\exp\left(-\frac{\|\phi(\mathbf{F}_{\text{loc}}(i))-\phi(\mathbf{F}_{\text{loc}}(j))\|_2^2}{\sigma^2}\right)}{\sum_{j'=1}^{N}\exp\left(-\frac{\|\phi(\mathbf{F}_{\text{loc}}(i))-\phi(\mathbf{F}_{\text{loc}}(j'))\|_2^2}{\sigma^2}\right)}. \tag{18}$$

This formulation corresponds to a graph diffusion process that facilitates global semantic propagation while reducing the risk of information leakage across structurally inconsistent regions.

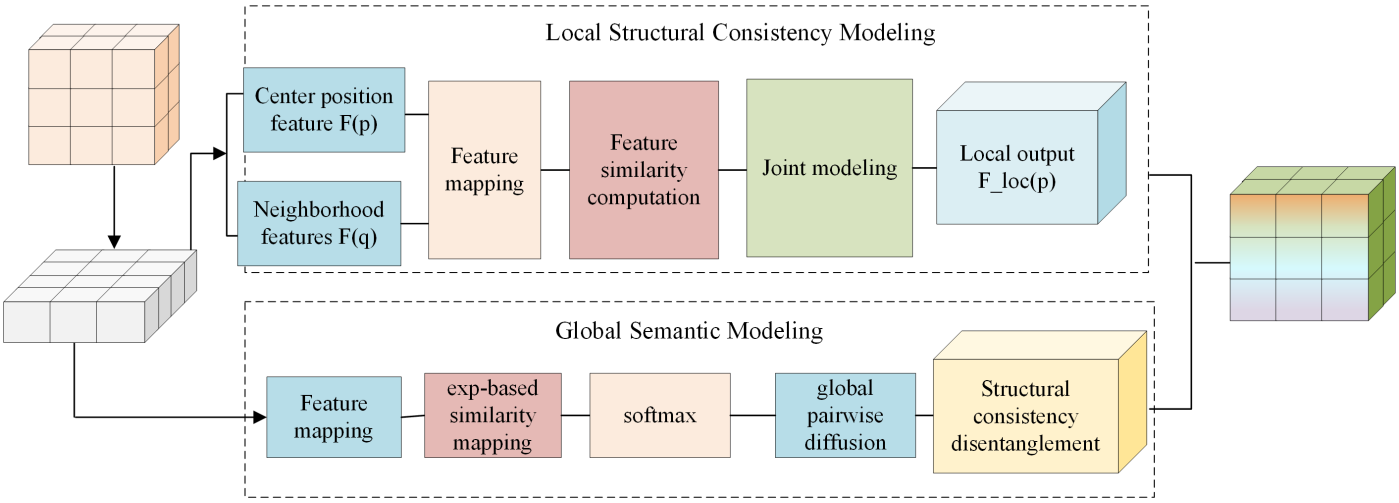

Fig. 3. Architecture of the proposed Hierarchical Spatial Dependency Modeling (HSDM) module.

3) Structure-semantic decoupled modeling: To mitigate the over-smoothing effect caused by global propagation, a decoupling strategy is introduced to separate the global response into relational and unary components:

$$\mathbf{F}_{\text{glob}} = \mathbf{F}_{\text{pair}} + \mathbf{F}_{\text{unary}}, \tag{19}$$

where, the unary term is defined as

$$\mathbf{F}_{\text{unary}}(i) = \mathbf{W}_u \mathbf{F}(i), \tag{20}$$

with, $\mathbf{W}_u$ denoting learnable transformation parameters. The unary component preserves the intrinsic saliency of each spatial position and corresponds to the unary term in graphical models, whereas $\mathbf{F}_{\text{pair}}$ represents the pairwise term responsible for modeling cross-region semantic relationships.

4) Adaptive fusion: Considering that different spatial regions exhibit varying dependencies on local structural information and global semantic context, a spatially adaptive fusion mechanism is further introduced:

$$\boldsymbol{\alpha} = \sigma\left(\text{Conv}_{1\times1}\left([\mathbf{F}_{\text{loc}}, \mathbf{F}_{\text{glob}}]\right)\right), \tag{21}$$

where, $[\cdot,\cdot]$ denotes channel-wise concatenation and $\sigma(\cdot)$ represents the Sigmoid activation function.

The final output feature representation is obtained by

$$\mathbf{F}_{\text{out}} = \boldsymbol{\alpha} \odot \mathbf{F}_{\text{loc}} + (1 - \boldsymbol{\alpha}) \odot \mathbf{F}_{\text{glob}}, \tag{22}$$

where, $\odot$ denotes element-wise multiplication.

The proposed adaptive fusion strategy utilizes local structural representations to guide feature integration. Specifically, the contribution of $\mathbf{F}_{\text{loc}}$ is emphasized in boundary regions to preserve structural details, whereas the contribution of $\mathbf{F}_{\text{glob}}$ is strengthened in semantically homogeneous regions to improve contextual consistency. Consequently, HSDM achieves a dynamic balance between structural information and semantic representations, providing more discriminative features for subsequent decoding and segmentation tasks.

C. Structure-Guided Adaptive Multi-Scale Fusion Module

In traffic scenes, different semantic categories exhibit not only scale variations but also highly heterogeneous spatial distributions and contextual dependencies. Small-scale objects, such as pedestrians and distant vehicles, are often located near scene boundaries or within occluded regions, making their representation highly dependent on local details and boundary sensitivity. In contrast, large-scale structures, such as buildings and road regions, usually present spatial continuity and require global contextual information to maintain semantic consistency. Moreover, variations in object density, viewpoint, and spatial arrangement further exacerbate the imbalance between local details and global semantics, making it difficult for single-scale representations to simultaneously capture fine-grained structures and overall scene context.

Under such circumstances, naive multi-scale feature fusion may introduce undesirable interference. Specifically, excessive global information may dilute local structural cues in complex boundary regions, whereas overemphasizing local features in large homogeneous regions may undermine semantic consistency. Therefore, a structure-guided adaptive fusion strategy is required to dynamically determine the contribution of features at different scales according to spatial locations and contextual characteristics. Such a mechanism can effectively balance local discriminative capability and global semantic coherence, thereby providing robust representations for semantic segmentation in complex traffic scenarios. The overall architecture of the proposed Structure-guided Adaptive Multi-scale Fusion (SAMF) module is illustrated in Fig. 4.

1) Multi-scale feature construction and alignment: Let the input feature representation be defined as

$$\mathbf{X} \in \mathbb{R}^{H\times W\times C}. \tag{23}$$

Multi-scale feature branches are constructed through scale transformation operations:

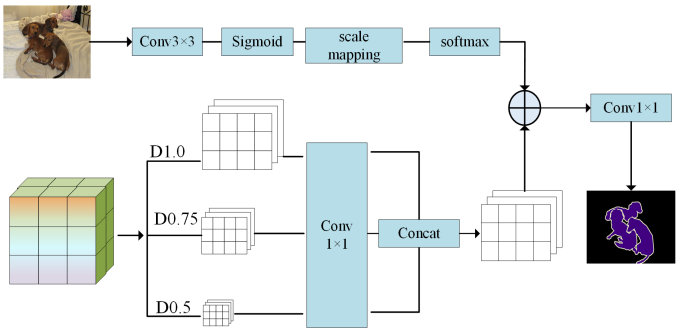

Fig. 4. Architecture of the proposed Structure-guided Adaptive Multi-scale Fusion (SAMF) module.

$$\mathbf{X}_s = D(\mathbf{X}, s), \quad s \in \{1, 0.75, 0.5\}, \tag{24}$$

where, $D(\cdot)$ denotes the scale transformation operation. Different scales correspond to different receptive field sizes. Larger scales preserve fine-grained details, whereas smaller scales facilitate the modeling of global contextual information.

To eliminate discrepancies in channel distributions across different scales, point-wise convolutions are employed for feature alignment:

$$\mathbf{X}'_s = \mathrm{Conv}_{1\times1}(\mathbf{X}_s). \tag{25}$$

Subsequently, all scale-specific features are upsampled to a unified spatial resolution:

$$\tilde{\mathbf{X}}_s = \mathrm{Up}(\mathbf{X}'_s), \tag{26}$$

resulting in a set of spatially aligned multi-scale representations.

2) Structure-guided signal modeling from the original input: To avoid information coupling among multi-scale representations during the fusion process, the proposed method does not directly derive structural responses from the fused features. Instead, the original input image is introduced as an external structural prior:

$$\mathbf{X}_0 \in \mathbb{R}^{H\times W\times C_0}, \tag{27}$$

where, C_0 denotes the number of channels in the original input.

A local convolution operation is then applied to capture structural variations:

$$\mathbf{S} = \sigma\left(\mathrm{Conv}_{3\times3}(\mathbf{X}_0)\right), \tag{28}$$

where, $\mathbf{S} \in \mathbb{R}^{H\times W\times1}$ represents the structural response map, and $\sigma(\cdot)$ denotes the Sigmoid activation function used to constrain the output range and improve training stability.

The structural response characterizes the intensity of edge and texture variations in the input image, thereby serving as a guidance signal independent of high-level semantic representations. This strategy effectively reduces mutual interference among multi-scale features during fusion.

3) Structure-guided scale response modeling: Based on the structural response map, the structure information is projected into the scale selection space:

$$\tilde{\mathbf{w}}(p) = \phi\left(\mathbf{S}(p)\right), \tag{29}$$

where, $\tilde{\mathbf{w}}(p) \in \mathbb{R}^K$ denotes the unnormalized scale response at spatial position p, K is the number of scale branches, and $\phi(\cdot)$ is implemented using a 1×1 convolution. This operation converts structural cues into scale-selection logits, establishing an explicit mapping from structural characteristics to receptive field preferences.

Through this mechanism, the model is able to adaptively adjust the importance of different scales according to local structural variations.

4) Scale normalization and competition mechanism: To ensure comparability among scale responses, a normalization operation is performed across the scale dimension:

$$w_s(p) = \frac{\exp\left(\tilde{w}_s(p)\right)}{\sum_{s'}\exp\left(\tilde{w}_{s'}(p)\right)}, \tag{30}$$

where, $w_s(p)$ denotes the relative importance of scale s at position p.

The normalization process introduces a competition mechanism among different scales, enabling the model to dynamically select the most appropriate receptive field according to spatial characteristics, thereby improving the adaptability of feature representations.

5) Structure-guided multi-scale fusion: Based on the learned scale weights, the aligned multi-scale features are aggregated as

$$\mathbf{X}_o(p) = \sum_s w_s(p)\cdot\tilde{\mathbf{X}}_s(p), \tag{31}$$

where, $\tilde{\mathbf{X}}_s$ denotes the feature representation corresponding to scale branch s.

Although all features have been spatially aligned to a unified resolution, their receptive field characteristics remain distinct. Consequently, the fusion process can be interpreted as an adaptive combination of contextual information with different spatial extents under a common coordinate system.

Since the fusion weights are derived from the original input rather than the feature representations themselves, the proposed strategy effectively alleviates feature coupling across scales and improves structural consistency in the fused representation.

Finally, a lightweight nonlinear transformation is applied to obtain the output feature representation:

$$\mathbf{X}_{\mathrm{out}} = \Psi\left(\mathbf{X}_o\right), \tag{32}$$

where, $\Psi(\cdot)$ consists of a point-wise convolution followed by an activation function for channel reorganization and feature enhancement.

Through the proposed structure-guided adaptive fusion mechanism, SAMF dynamically balances the contributions of different receptive fields according to structural characteristics in the input image. As a result, local discriminative information is preserved in fine-grained regions, while global semantic consistency is maintained in large homogeneous areas, thereby yielding more robust feature representations for traffic scene semantic segmentation.

IV. Experiments

A. Datasets and Evaluation Metrics

1) Datasets:

a) Cityscapes [17]: Cityscapes is a standard benchmark dataset for urban scene understanding and has been widely adopted in autonomous driving and semantic segmentation research. The dataset contains complex street-view images collected from 50 different cities. In total, it provides 5,000 finely annotated images with pixel-level labels, which are divided into 2,975 training images, 500 validation images, and 1,525 testing images. All images are extracted from vehicle-mounted stereo video sequences and maintain a consistent spatial resolution, ensuring comparability in semantic segmentation tasks. Cityscapes originally provides annotations for more than 30 semantic categories, covering roads, buildings, vehicles, pedestrians, and natural backgrounds. Following the common evaluation protocol, 19 representative categories are selected as the standard benchmark subset for fair comparison among different methods.

b) CamVid [18]: CamVid is one of the earliest semantic segmentation datasets designed for driving scene understanding. It is primarily used for pixel-level semantic annotation in road environments. The dataset consists of 701 manually annotated images extracted from driving videos, including 367 training images, 101 validation images, and 233 testing images. All images have a resolution of 960×720. CamVid defines 32 semantic categories covering roads, buildings, vehicles, pedestrians, traffic signs, and other common traffic scene elements.

2) Evaluation metrics: To comprehensively evaluate the effectiveness and efficiency of the proposed method, four widely used metrics are adopted, including Mean Intersection over Union (MIoU), Mean Accuracy (Mean Acc), model parameters (Params), floating-point operations (FLOPs), and Frames Per Second (FPS).

a) Mean Intersection over Union (MIoU): MIoU is the primary metric for evaluating semantic segmentation accuracy. It measures the overlap ratio between predicted segmentation results and ground-truth annotations by averaging the Intersection over Union (IoU) across all categories:

$$\mathrm{MIoU} = \frac{1}{N} \sum_{i=1}^{N} \frac{TP_i}{TP_i + FP_i + FN_i}, \tag{33}$$

where, N denotes the number of semantic categories, and TP_i, FP_i, and FN_i represent the numbers of true positive, false positive, and false negative pixels for the i-th category, respectively.

b) Mean Accuracy (Mean Acc): Mean Accuracy evaluates the average classification accuracy over all categories and is defined as

$$\mathrm{MeanAcc} = \frac{1}{N} \sum_{i=1}^{N} \frac{TP_i}{TP_i + FN_i}, \tag{34}$$

where, TP_i denotes the number of correctly classified pixels belonging to category i, and FN_i represents the number of pixels from category i that are incorrectly classified into other categories.

c) Parameters (Params): Params quantify the structural complexity and storage requirements of a model, corresponding to the total number of learnable parameters. For a convolutional layer, the number of parameters can be expressed as

$$\mathrm{Params} = K^2 \times C_{\mathrm{in}} \times C_{\mathrm{out}}, \tag{35}$$

where, K is the kernel size, and C_{in} and C_{out} denote the numbers of input and output channels, respectively.

Although a larger number of parameters generally indicates stronger representation capability, it may also increase storage costs and the risk of overfitting.

d) Floating Point Operations (FLOPs): FLOPs are used to measure the computational complexity during the forward inference stage. For convolution operations, the computational cost is defined as

$$\mathrm{FLOPs} = H \times W \times K^2 \times C_{\mathrm{in}} \times C_{\mathrm{out}}, \tag{36}$$

where, H and W denote the spatial dimensions of the output feature map. This formulation indicates that computational complexity is jointly determined by kernel size, channel dimensions, and feature resolution.

e) Frames Per Second (FPS): FPS is adopted to evaluate inference efficiency and reflects the number of images processed per second. It is defined as

$$\mathrm{FPS} = \frac{\text{Number of processed images}}{\text{Total inference time (s)}}. \tag{37}$$

A higher FPS value indicates better real-time performance.

B. Experimental Settings

During training, the Stochastic Gradient Descent (SGD) optimizer was employed to update the network parameters, while the Cross-Entropy Loss function was adopted for optimization. The batch size was set to 8, and the number of data loading workers was fixed at 4. Considering that different network architectures exhibit varying sensitivities to input resolutions, the crop size for each model was adjusted according to its

original implementation settings. In addition, the weight decay coefficient was set to 1×10^{-4}, the initial learning rate was initialized to 0.01, and the momentum parameter was fixed at 0.9 to accelerate convergence and improve training stability (Table I).

TABLE I. EXPERIMENTAL ENVIRONMENT CONFIGURATION

Category	Parameter Name	Setting Value
Hardware Environment	Operating System	Windows 11
	CPU	Intel i7-14650HX
	GPU	NVIDIA RTX 4090 (24 GB)
	Memory	24 GB
Software Environment	Programming Language	Python
	Development Environment	PyCharm

C. Ablation Studies

A series of ablation experiments were conducted on the Cityscapes dataset to comprehensively evaluate the effectiveness of each component in the proposed FSCS framework. The experimental results are summarized in Table II. As shown in the table, the complete FSCS model achieves the best segmentation performance while introducing only a slight increase in computational cost.

Specifically, incorporating the Spectral-Decoupled Adaptive Modulation (SDAM) module independently improves the mIoU and Mean Acc by approximately 1.44% and 1.21%, respectively, compared with the baseline model. This observation indicates that frequency-domain enhancement effectively strengthens the representation capability for fine-grained structures and small objects. When the Hierarchical Spatial Dependency Modeling (HSDM) module is introduced, the model further benefits from local structural consistency and global semantic propagation, achieving improved segmentation accuracy while maintaining favorable real-time performance. The Structure-guided Adaptive Multi-scale Fusion (SAMF) module introduces structural priors into the multi-scale fusion process and obtains the highest Mean Acc among the single-module variants, reaching 0.7612. Although the mIoU improvement brought by SAMF alone is relatively limited, it effectively enhances feature consistency and boundary discrimination.

Overall, the proposed FSCS framework achieves the best trade-off between segmentation accuracy, computational efficiency, and real-time inference capability. By integrating frequency-domain enhancement, hierarchical spatial dependency modeling, and structure-guided multi-scale fusion, the complete model improves segmentation performance while preserving the lightweight characteristics required for practical traffic scene applications.

TABLE II. ABLATION STUDY RESULTS ON THE CITYSCAPES DATASET

Algorithm	Params (M)	GFLOPs	mIoU	Mean Acc	FPS
Baseline	5.23	17.00	0.6781	0.7414	231.40
Baseline + SDAM	4.81	19.66	0.6925	0.7535	200.51
Baseline + HSDM	4.39	20.16	0.6891	0.7591	210.11
Baseline + SAMF	4.21	21.23	0.6879	0.7612	208.10
Ours (FSCS)	4.96	22.50	0.7146	0.7665	210.23

D. Comparison Experiments

To systematically evaluate the generalization capability and segmentation performance of the proposed method in different urban scenarios, comparative experiments were conducted on the Cityscapes and CamVid datasets. Representative semantic segmentation models, including FCN-8s, U-Net, PSPNet, and DeepLabV3+, were selected as baseline approaches. The input resolutions were set to 2048×1024 for Cityscapes and 960×720 for CamVid. To ensure fairness and reproducibility, all models were trained using identical data preprocessing procedures and optimization strategies.

1) Comparison on the cityscapes dataset: The Cityscapes dataset contains high-resolution images with complex urban structures, posing significant challenges for semantic segmentation models. As reported in Table III, the proposed FSCS framework consistently outperforms conventional methods in terms of segmentation accuracy.

Specifically, FSCS achieves an mIoU of 0.7146, outperforming FCN-8s, U-Net, and PSPNet by approximately 10.75%, 9.41%, and 7.49%, respectively. Compared with DeepLabV3+, FSCS yields an absolute mIoU improvement of 3.65%, demonstrating the effectiveness of integrating frequency-domain enhancement, hierarchical spatial modeling, and structure-guided multi-scale fusion.

Regarding model complexity, FSCS contains only 4.96M parameters, which is lower than that of DeepLabV3+ and substantially smaller than those of FCN-8s and PSPNet. Although the computational cost increases slightly compared with DeepLabV3+, the proposed method still maintains a high inference speed of approximately 210 FPS. These results indicate that FSCS achieves a favorable balance between segmentation accuracy and computational efficiency, making it suitable for real-time semantic segmentation tasks in autonomous driving applications.

TABLE III. PERFORMANCE COMPARISON ON CITYSCAPES DATASET

Algorithm	Params (M)	GFLOPs	mIoU	Mean Acc	FPS
FCN-8s [18]	134.46	223.25	0.6071	0.7275	34.52
U-Net [19]	26.36	228.24	0.6205	0.7310	56.16
PSPNet [2]	51.44	190.34	0.6397	0.7365	64.70
DeepLabV3+ [20]	5.23	17.00	0.6781	0.7414	231.40
Ours (FSCS)	4.96	22.50	0.7146	0.7665	210.23

2) Comparison on the camvid dataset: The CamVid dataset contains fewer training samples but exhibits a relatively balanced category distribution, making it suitable for evaluating the generalization ability of segmentation models under limited data conditions. As shown in Table IV, the proposed FSCS framework consistently achieves superior performance compared with existing approaches.

In particular, FSCS demonstrates enhanced segmentation capability for small objects, such as pedestrians and traffic signs, as well as slender structures including curbs and poles. The proposed method attains the highest mIoU and Mean Acc among all competing methods, achieving values of 0.6342 and 0.7325, respectively. Compared with DeepLabV3+, FSCS yields absolute improvements of 1.65% in mIoU and 1.41% in Mean Acc, indicating that the proposed frequency-spatial collaborative framework remains effective even on relatively small-scale datasets.

In terms of computational efficiency, FSCS maintains a lightweight architecture with only 4.96M parameters and

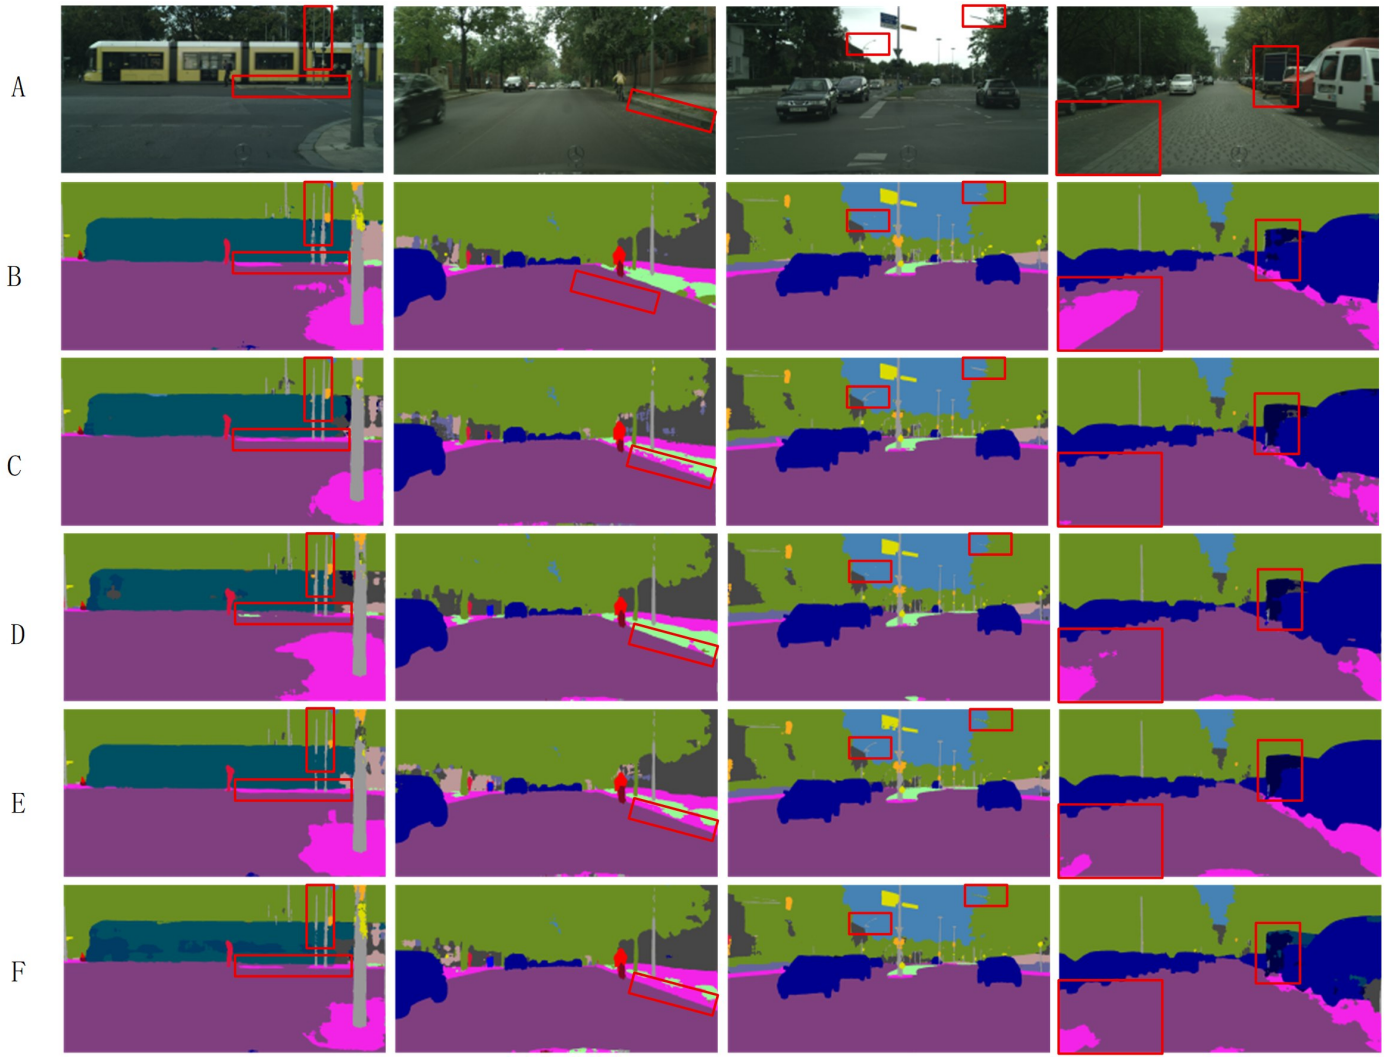

Fig. 5. Qualitative comparison of semantic segmentation results produced by different methods on the Cityscapes dataset.

18.86 GFLOPs. Despite a moderate increase in computational complexity compared with DeepLabV3+, the proposed model still achieves an inference speed of approximately 213 FPS, substantially outperforming FCN-8s, U-Net, and PSPNet. These results demonstrate that FSCS successfully balances segmentation accuracy and inference efficiency, making it well suited for real-time traffic scene understanding applications.

TABLE IV. PERFORMANCE COMPARISON ON THE CAMVID DATASET

Algorithm	Params (M)	GFLOPs	mIoU	Mean Acc	FPS
FCN-8s	134.46	182.12	0.5613	0.6914	38.33
U-Net	26.36	196.78	0.5910	0.7012	68.29
PSPNet	51.44	162.39	0.6017	0.7132	90.46
DeepLabV3+	5.22	14.92	0.6177	0.7184	235.48
Ours (FSCS)	4.96	18.86	0.6342	0.7325	213.45

3) Comprehensive analysis: The experimental results on both the Cityscapes and CamVid datasets demonstrate that the proposed FSCS framework achieves stable and competitive segmentation performance under different image resolutions and scene complexities. The performance gains can be primarily attributed to the complementary effects of the three proposed modules.

Specifically, SDAM performs amplitude–phase decoupling and adaptive spectral modulation in the frequency domain, effectively enhancing the representation capability for small objects and fine-grained structures. HSDM models spatial dependencies hierarchically through local structural consistency constraints and global semantic propagation, thereby preserving spatial continuity while capturing long-range contextual relationships. Furthermore, SAMF introduces structural priors into the multi-scale fusion process, dynamically integrating features with different receptive fields to improve the segmentation quality of object boundaries and slender structures.

The complete FSCS framework consistently outperforms all individual module variants, indicating that the three modules provide complementary rather than redundant contributions. Although the proposed method incurs a slight increase in computational cost compared with the baseline, it achieves substantial improvements in segmentation accuracy while maintaining high inference efficiency. These findings verify the effectiveness of the proposed frequency-spatial collaborative optimization strategy for real-time semantic segmentation in

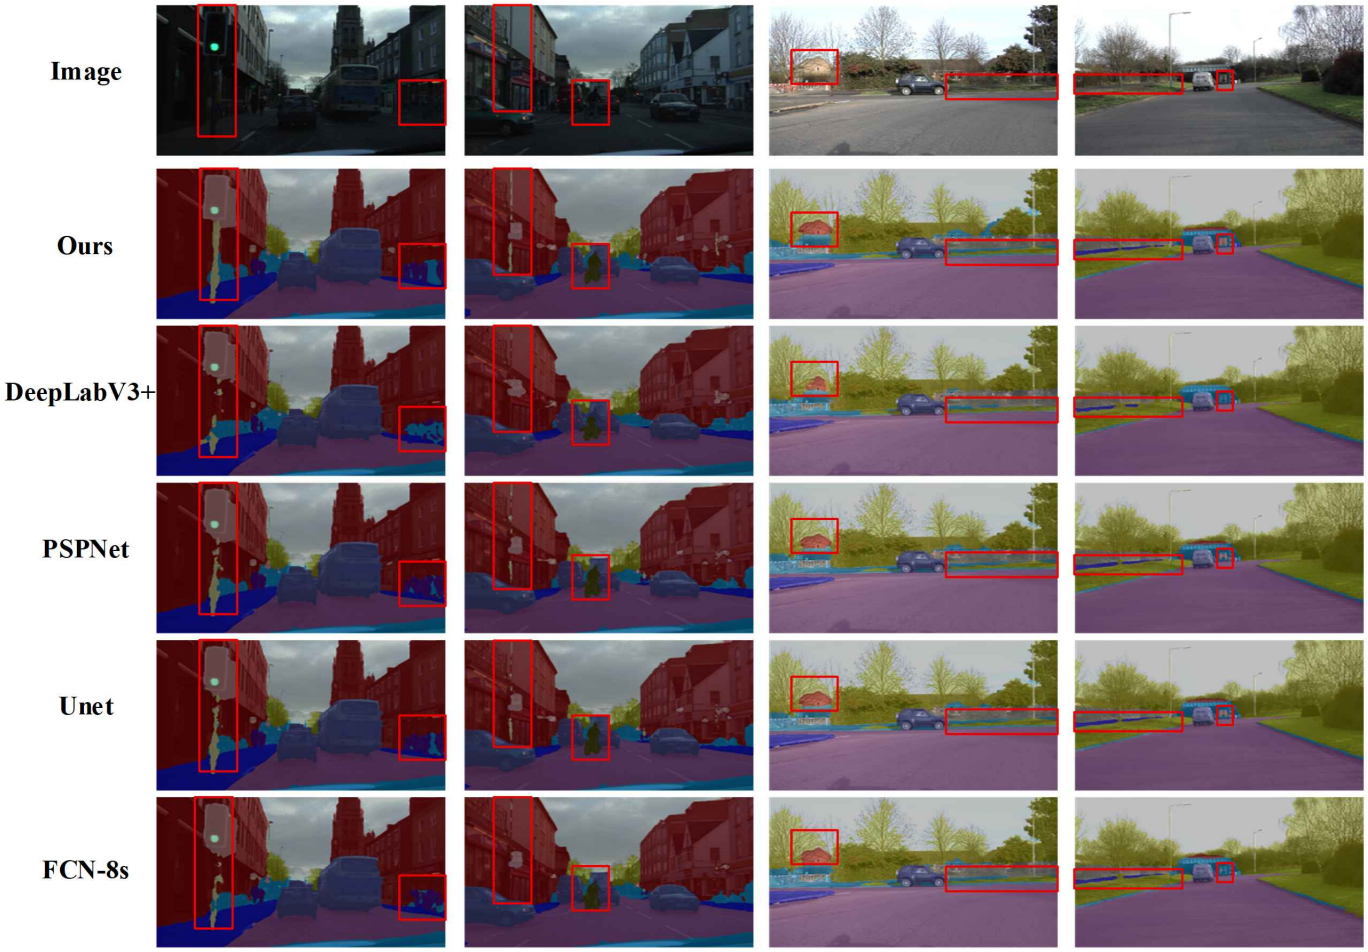

Fig. 6. Qualitative comparison of semantic segmentation results produced by different methods on the CamVid dataset.

complex traffic environments.

4) Qualitative comparison: Fig. 5 and 6 present qualitative comparisons of semantic segmentation results obtained by different methods on the Cityscapes and CamVid datasets, respectively.

As illustrated in Fig. 5, the baseline model exhibits noticeable omissions and blurred boundaries when segmenting fine-grained objects and distant targets. U-Net achieves satisfactory performance on large-scale structures but struggles to accurately delineate small objects and elongated regions. FCN-8s demonstrates the weakest performance in terms of small-object recognition and boundary localization, while also exhibiting slight confusion in certain large-scale regions. PSPNet improves the segmentation quality of fine structures to some extent; however, misclassification and omission of distant objects remain evident.

In contrast, the proposed FSCS framework produces the most accurate segmentation results within the highlighted regions. Specifically, FSCS successfully identifies small objects, slender structures, and distant vehicles while preserving the continuity of large-scale semantic regions such as roads and buildings. These observations further confirm that the collaborative optimization of frequency-domain enhancement, hierarchical spatial modeling, and structure-guided multi-scale fusion effectively improves both local discrimination capability and global semantic consistency.

Similarly, the visualization results on the CamVid dataset, shown in Fig. 6, further validate the robustness and generalization capability of the proposed method under different scene characteristics and dataset scales.

V. Conclusion

In this study, a Frequency-Spatial Collaborative Segmentation framework (FSCS) is proposed to improve the performance of DeepLabV3+ for traffic scene semantic segmentation. To address the limitations of conventional convolution-based segmentation methods in modeling fine-grained structures, long-range dependencies, and multi-scale contextual information, three dedicated modules are introduced.

First, the Spectral-Decoupled Adaptive Modulation (SDAM) module explicitly performs amplitude–phase decoupling in the frequency domain and adopts adaptive spectral modulation to enhance informative frequency components while preserving structural consistency, thereby improving the representation capability for small objects and boundary regions. Second, the Hierarchical Spatial Dependency Modeling (HSDM) module progressively captures spatial dependencies from local structural consistency to global

semantic propagation, enabling effective long-range context modeling while alleviating the structural ambiguity caused by direct global interactions. Finally, the Structure-guided Adaptive Multi-scale Fusion (SAMF) module introduces structural priors derived from the original input image to dynamically guide the fusion of multi-scale features, thereby enhancing the segmentation quality of slender structures and complex boundaries.

Experimental results on the Cityscapes and CamVid datasets demonstrate that the proposed FSCS framework consistently outperforms several representative semantic segmentation methods while maintaining favorable real-time performance and computational efficiency. The ablation studies further verify that the three proposed modules contribute complementary improvements and jointly enhance segmentation performance in complex traffic environments.

In future work, more efficient frequency-domain representation strategies and lightweight spatial modeling mechanisms will be investigated to further reduce computational complexity while improving the segmentation accuracy of small-scale and cross-scale objects. In addition, extending the proposed framework to more challenging scenarios, such as adverse weather conditions and domain-generalized traffic scene understanding, remains an important direction for future research.
