Table of Contents

Paper 1: An Intelligent Ensemble Learning Framework for Visibility and CAVOK Prediction to Support Logistics Operations

Authors: Omar Alghushairy, Raed Alsini, Ahmed Alamri, Saud Yonbawi, Ayman Yafoz, Xiaogang Ma

PAGES 1 - 11

Paper 2: AI-Mediated STEM Problem Solving: Activity Distribution and Functional Roles in a Systematic Review

Authors: Mika Lim

PAGES 12 - 22

Paper 3: Five Whys as an Epistemic-Honesty Scaffold for Multi-Agent LLM Analysis of Industrial Time Series

Authors: Yoshihiro Ochi, Yasunobu Uchiyama

PAGES 23 - 32

Paper 4: A Reproducible Mobile-Cloud Framework for Preliminary Non-Invasive Anemia Screening from Palpebral Conjunctiva Images

Authors: Enrique Lee Huaman´ı, Erasmo Montufar-Barrientos, Victor Romero-Alva, Linett Velasquez-Jimenez

PAGES 33 - 39

Paper 5: Reversible Visual Obfuscation via Embedded Recovery Metadata: Combining Median-Filter Irreversibility with Cryptographic Restoration

Authors: Andranik Karakhanyan

PAGES 40 - 48

Paper 6: Automatic Generation and Optimization Algorithm for Brand Visual Identity System Based on Multimodal Generative Adversarial Network

Authors: Yunfei Gong, Xiaoyue Cao

PAGES 49 - 58

Paper 7: Integrated Health Belief and User Engagement Model for Physical Activity Apps

Authors: Nur Farahin Mohd Johari, Nazlena Mohamad Ali, Mohamad Hidir Mhd Salim

PAGES 59 - 65

Paper 8: Evaluating Government Website Readiness for Generative AI Search Engines: A Framework and Empirical Assessment

Authors: Hussein Ali Bahadi

PAGES 66 - 81

Paper 9: A Hybrid Econometric and Machine Learning Framework for Identifying Nonlinear Dynamics Between Digital Economy and Carbon Emissions

Authors: Jinghan Li

PAGES 82 - 95

Paper 10: A Multi-Layer Hyper-Personalization Pipeline for Predicting Next User Actions Across Web, App, Email, and Social Channels

Authors: Kohei Arai

PAGES 96 - 103

Paper 11: Deep Learning Approaches for Apple Disease Classification and Detection: A PRISMA 2020 Systematic Literature Review

Authors: Brahim Ouben Hssain, Khalil Ladrham, Noureddine El Barbri, Rachid El Ayachi

PAGES 104 - 115

Paper 12: When Calibrated Detectors Meet New Attacks: Per-Category Reliability of Machine-Learning Intrusion Detection Under Distribution Shift

Authors: Khalid Alalawi

PAGES 116 - 125

Paper 13: Explainable Machine Learning for Cardiovascular Disease Prediction Using BRFSS Health Indicators

Authors: Sakchai Tangprasert, Suwit Chantasen, Nalinpat Bhumpenpein, Yuenyong Nilsiam, Siranee Nuchitprasitchai

PAGES 126 - 134

Paper 14: Transformer Health Index Prediction Using Static and Temporal Learning Models

Authors: Omar Ahmed Mohammed Hamood Al-Shaikh, Arfah Ahmad, Ahmad Jazlan Haja Mohideen, Muhammad Sharil Yahaya

PAGES 135 - 149

Paper 15: ROMBandAR: Development of an AR-Based Wrist ROM Assessment Prototype for Rehabilitation

Authors: Nurul Aimi Johan, Wan Rizhan, Normala Rahim

PAGES 150 - 161

Paper 16: Intelligent Booking Systems for Natural Resources and Urban Development: A Geospatial SLR

Authors: Stephanie Anak Nanta, Jack Febrian Rusdi, Louisa Suly Anak Nanta, Imtiaz Ali Brohi, Vicente Aquino Pitogo

PAGES 162 - 171

Paper 17: A Smart Transformer-Based Model to Classify Extremist Behavior on Social Media

Authors: Tamer Salah, Hazem M. El-Bakry, Amira Rezk

PAGES 172 - 177

Paper 18: Benchmarking Bio-Inspired Metaheuristics for Load-Aware Task Offloading in Hierarchical IoT-Fog-Cloud Ecosystems

Authors: Lamia Oualili, Mohamed EL Ghmary, Hassan Echoukairi

PAGES 178 - 190

Paper 19: Emerging Technologies and Cybersecurity in Critical Information Infrastructure and Industrial Control Systems: An Integrated Cyber Risk Pathway Model

Authors: Jennita Rao Appanah Appayya, Sandhya Armoogum, Kaleem Ahmed Usmani

PAGES 191 - 203

Paper 20: MalBERT-Temporal: Transformer-Based Zero-Day Malware Detection in Windows Executable Binaries Under Strict Temporal Isolation

Authors: Manar Alanazi, Israa Alsiyat

PAGES 204 - 220

Paper 21: Next-Generation Explainable Sensor-Fusion-Based Artificial Intelligence Framework for In-Home Diabetic Foot Ulcer Risk Prediction

Authors: Jayashree J, Vijayashree J, Vijayarajan V, Saravanan S

PAGES 221 - 229

Paper 22: ReadTech: A Mobile Reading Application for Grade 7 Learners

Authors: Mary Jane U. Quibilan

PAGES 230 - 239

Paper 23: A Blockchain-Based Role-Based Access Control Gateway for Secure Electronic Health Record Access and Tamper-Evident Auditing

Authors: Osamah Saleh, Shouki A. Ebad

PAGES 240 - 255

Paper 24: A Cross-Sector Leadership Framework for Organizational Change and Sustainability: Testing the Impact of Intrinsic Leadership Values Using Structural Equation Modeling

Authors: Sudirman Said, Aurik Gustomo, Yudo Anggoro

PAGES 256 - 266

Paper 25: Research Trends in Human-Computer Interaction for Immersive Virtual Reality Applications: A Bibliometric Study (2010-2026)

Authors: Nur Sauri Yahaya, Sobihatun Nur Abdul Salam, Hanis Salwani Othman

PAGES 267 - 276

Paper 26: Memory-Augmented Autoencoder for Industrial Anomaly Detection

Authors: Hai Son, Duc Ngo

PAGES 277 - 284

Paper 27: Understanding Player Choice in Digital Games: Qualitative Study Using Thematic Analysis

Authors: Faris Haziq Sarif, Amelia Jati Robert Jupit, Jacey-Lynn Minoi, A. Imran Nordin

PAGES 285 - 294

Paper 28: Metaheuristic-Based Test Case Selection for Regression Testing: A Systematic Literature Review

Authors: Siti Hawa Mohamed Shareef, Rabatul Aduni Sulaiman, Nazri Mohd Nawi, Wan Noor Hamiza Wan Ali, Nurul N. Jamal, Fairuz Amalina

PAGES 295 - 307

Paper 29: TriMFB: A Tri-Feature Fusion Framework Integrating Modality-Specific and Cross-Modal Representations for Fine-Grained Fake News Detection

Authors: Idza Aisara Norabid, Masita Jalil, Noor Hafhizah Abd Rahim

PAGES 308 - 315

Paper 30: An Intelligent On-Demand Laundry Logistics Platform with Real-Time Location Tracking and Machine Learning-Based Customer Support

Authors: Muhammad Faris Rosli, Siti Zuraidah Ibrahim, Mohd Nazri A Karim, Mohd Hafizuddin Mat, Faridah Hanim Mohd Noh, Tanakorn Inthasuth

PAGES 316 - 325

Paper 31: Learning to Schedule Machines and Operators: A Human-Aware Deep Q-Learning Framework for Dynamic Flexible Job Shops

Authors: Taji Hajar, Ayad Ghassane, Zaki Abdelhamid, Khammal Adil

PAGES 326 - 341

Paper 32: Institutional Readiness for Generative AI-Enhanced Assessment and Feedback in Higher Education: Evidence from an Exploratory Study

Authors: Dolantina Hyka, Elion Shabanaj, Jurgen Mecaj, Ardita Hykaj, Elton Skendaj

PAGES 342 - 349

Paper 33: Earthquake Damage Risk Classification Using Machine Learning Models Based on Built-Up Area Indices from Satellite Imagery

Authors: Gunawan Prayitno, Eko Sediyono, Irwan Sembiring, Sri Yulianto Joko Prasetyo

PAGES 350 - 358

Paper 34: Semantic Interoperability of Heterogeneous Information Systems: A Hybrid Framework for Machine Learning-Assisted Semantic Mapping Recommendation

Authors: Aïcha KOULOU, Mohamed CHEKOUR, Norelislam EL HAMI, Nabil HMINA

PAGES 359 - 366

Paper 35: Can We Trust Concept-Based ECG Explanations? A TCAV Analysis of Confounding and Reproducibility in Atrial Fibrillation Detection

Authors: El Hassane Jennah, Houda Indjaren, Lhoucine Ben Taleb, Hamid El Malali, Azeddine Mouhsen

PAGES 367 - 373

Paper 36: HR-CD-Auth: Consent-Bound Cross-Domain Pseudonymous Authentication for Vocational Counseling and Employment Matching

Authors: Haewon Byeon, Changmin Keum

PAGES 374 - 384

Paper 37: Popularity Bias and Category Diversity in Review-Based Rating Prediction for E-Commerce: An Empirical Study on Indonesian Marketplace Data

Authors: Andy Supriyadi, Herman Dwi Surjono, Handaru Jati

PAGES 385 - 393

Paper 38: Orientation-Aware Feature Fusion for Accurate Rotated Object Detection in Remote Sensing Images

Authors: Jing Zhang, Mas Rina Mustaffa, Fatimah Khalid, Zainal Abdul Kahar

PAGES 394 - 403

Paper 39: Feasibility of Generative Artificial Intelligence and Large Language Model Adoption to Enhance Organisational Knowledge Management Practices

Authors: Surya Sumarni Hussein, Nur Azaliah Abu Bakar, Saidatul Rahah Hamidi, Shuhaida Mohamed Shuhidan, Siti Salbiyah Abdul Geni, Anitawati Mohd Lokman

PAGES 404 - 418

Paper 40: Machine Learning for Distributed Acoustic and Fibre-Optic Sensing in Infrastructure Monitoring: A Systematic Review (2015-2025)

Authors: Abd Rahim Saidin, Illani Mohd Nawi

PAGES 419 - 428

Paper 41: CEM MoE: A Lightweight Sparse Mixture of Experts Framework for Empathetic Dialogue Generation

Authors: Zhinan Gou, He Liu, Yufan Wang

PAGES 429 - 441

Paper 42: From Personality to Performance: An Automated Grouping Tool for Collaborative Learning

Authors: Dalila Raissouni, Ahmed El Oualkadi, Kamal Reklaoui

PAGES 442 - 453

Paper 43: Development of An Artificial Neural Network-Based System to Detect Lane and Roadside Traffic Signs

Authors: Viraj Sonawane, Balasaheb Agarkar, Sachin Chaudhari

PAGES 454 - 462

Paper 44: HDST-CAF: Adaptive CNN Transformer Frequency Fusion for Deepfake Detection Under Visual Degradation

Authors: Sanjitha S Laad, Smitha Shekar B

PAGES 463 - 473

Paper 45: A Pipeline for Integrating and Analyzing Public Business Data in Albania Using Web Scraping and Machine Learning

Authors: Markela Muca, Klodiana Bani, Amarildo Alla

PAGES 474 - 484

Paper 46: Revitalizing Cultural Heritage Education Through a Flow Theory-Based Serious Game Model for Enhancing User Engagement

Authors: Wan Malini Wan Isa, Syadiah Nor Wan Shamsuddin, Norkhairani Abdul Rawi, Maizan Mat Amin, Nor Hafidzah Abdullah, Wan Mohd Adzim Wan Mohd Zain

PAGES 485 - 492

Paper 47: A Recursive Prompt-Driven Reasoning Approach for Multi-Hop Arabic Fatwa Question Answering

Authors: Manal Al-Qahtani, Bader Alkhamees, Mourad Ykhlef

PAGES 493 - 509

Paper 48: Privacy-Aware Generative Augmentation for Imbalanced Intrusion Detection Using Differential Privacy

Authors: Trung Ha, Tran Khanh Dang, Dinh Thi Hong Loan

PAGES 510 - 518

Paper 49: Leveraging Machine Learning for Predicting Marginal Field Oil Well Production Using Electrical Submersible Pump Operations Data

Authors: Mohamed Zafir Bin Mohamad Gazali, Rabeea Jaffari, Areej Fatemah Meghji, Tuan Mohammad Yusoff Shah, Syed Muhammad Noaman Ahmed Shah, Muhammad Hammad Rasool

PAGES 519 - 527

Paper 50: Explainable AI for Trustworthy 6G Edge-Cloud Smart Cities: A Systematic Review

Authors: Qaisar Abbas, Riyad Almakki

PAGES 528 - 546

Paper 51: Feature Selection Versus Feature Extraction for IoT Intrusion Detection Under Temporal Evaluation

Authors: Mahdia Abdessamad, El Bachir Tazi

PAGES 547 - 567

Paper 52: A Coordinate Transformation Framework for Vision-Guided Robotic Positioning in Automated Vehicle Body Marking

Authors: Olzhas Olzhayev, Azhar Tursynova, Sayat Ibrayev

PAGES 568 - 576

Paper 53: An Explainable Hierarchical Deep Representation Learning Framework for Multi-Class Host Rock Recognition from Mining Data

Authors: Sami F Karali, Mohammed I Thanoon, Majed Nawas, Ahlem Fatnassi, Abed Saif Ahmed Alghawli, Zakhriya Alhassan, Yahia Said

PAGES 577 - 589

Paper 54: Effective Chunking for Retrieval-Augmented Generation over Structured Institutional Documents

Authors: Siti Sarah Izhan Khalib, Abdul Hadi Abd Rahman, Lailatul Qadri Zakaria

PAGES 590 - 596

Paper 55: Explainable Neuro-Symbolic Learning for Mohs Hardness Prediction in Mining and Mineral Processing

Authors: Mohammed I. Thanoon, Sami F. Karali, Mohamed H. Helal, Ahlem Fatnassi, Majed Nawas, Monir Abdullah, Asma A. Alhashmi, Abdulbasit A. Darem

PAGES 597 - 610

Paper 56: Applying Visual Servoing for Industrial Robots Through Interactive Segmentation and Robot-Computer Communication

Authors: Zeinel Momynkulov, Moldir Kuatova, Amandyk Tuleshov

PAGES 611 - 620

Paper 57: SHAP Guided Transformer-Based Deep Learning Model for Diamond Clarity Grading in Smart Mining and Resource Valuation Systems

Authors: Ahlem Fatnassi, Shouki A. Ebad, Sami F Karali, Mohammed I Thanoon, Majed Nawas, Monir Abdullah, Asma A. Alhashmi, Abdulbasit A. Darem

PAGES 621 - 633

Paper 58: Classification of Lymph Node Tumor Images Using Adaptive Filtering in Convolutional Neural Networks

Authors: Jamal M. Alothman, Nameer N. El. Emam, Issa Qabajeh, Mhammed Almakadmeh

PAGES 634 - 646

Paper 59: An Early Warning System for Proactive DDoS Attack Detection Using Ordinary Differential Equation-Based Scoring

Authors: Radhakrishna Vangipuram, Rajput Eswar Sai Singh, Ramesh Kumar Aytha, Sravankiran Vangipuram, Sreenivasa Rao Annaluri

PAGES 647 - 656

Paper 60: Semantic-Driven Community Detection in Complex Networks Using Fuzzy Logic and Multi-Criteria Decision Making

Authors: Mohamed El-Moussaoui, Mohamed Hanine, Sulieman S. Alshuhri, Amal Alomran, Amir Mohamed Talib

PAGES 657 - 663

Paper 61: Influence of Big Data Analytics Capability on Employee Creative Behavior: A Modified Mediation Model

Authors: Mohammed Bassam Nassoura, Nabil Abudarwish Zarqa, Mohammad Musa Al-Momani, Bilal Alnassar, AbdelRahman Ismail, Ahmad Awadallah

PAGES 664 - 669

Paper 62: GTA: Automated Semantic NLP-Based Generation of UML Activity Diagrams from Acceptance Criteria

Authors: Samia Nasiri, Salim Bloundi, Mohammed Lahmer

***Abstract*—The supply chain operation is fully dependent on weather conditions due to the damage that produce may face during bad weather or accidents that may occur because of cloud cover, especially in Saudi Arabia, which experiences frequent cloud cover throughout the year. In this study, a new weather prediction model based on machine learning and optimization algorithms is proposed to forecast visibility distance and Cloud and Visibility OK (CAVOK), a term indicating good weather, while also estimating cloud cover, which affects flight operations. The proposed system follows two main steps: feature selection and prediction, to predict CAVOK and visibility distance. In the feature selection phase, Fick's Law Algorithm (FLA) is used to choose the optimal parameters that can serve as indicators in the prediction phase, enhancing the proposed system's performance. In the prediction phase, a new two-stage ensemble algorithm is used to predict sky CAVOK and visibility distance. In the first stage, a new voting ensemble algorithm consisting of Bagging Regressor and Extra Trees Regressor algorithms is proposed to predict the visibility distance. The predicted visibility distance value is then used alone to predict sky CAVOK using the CatBoost Classifier in the second stage. The experimental results show that the proposed system demonstrates reasonable predictive performance, obtaining 529.7506 m, 1174.6118, and 0.3233 for Mean Absolute Error (MAE), Root Mean Square Error (RMSE), and R^2, respectively, in predicting visibility distance. Additionally, the system achieved competitive results while maintaining robust predictive capability in predicting sky CAVOK.**

***Keywords*—Weather forecasting; sky CAVOK; extra tree; supply chain; visibility distance; Saudi Arabia**

I. Introduction

Weather forecasting is a technology that aims to predict the state of the atmosphere at any given time. Air temperature, wind direction, wind strength, cloud cover, and Visibility OK (OK/CAVOK) and visibility distance are examples of atmospheric conditions that weather forecasting predicts [1][2]. The supply chain and logistics are affected by daily weather changes, making weather prediction a crucial factor in supply chain operations [3]. Extreme weather conditions can disrupt supply chains because of flight delays due to cloud cover and lead to financial losses and operational difficulties across various industries [4] [5]. For example, weather changes in 2024 caused widespread supply chain disruptions worldwide, resulting in companies losing over 100 billion dollars [6]. Additionally, weather-related supply chain damage increased by 30% in the first half of 2024 compared to 2023 [7]. It's predicted that the loss in the supply chain may reach 26 trillion dollars due to changes in the weather by 2050 [8]. Although 26.6% of organizations have their supply chains affected by bad weather in 2024, 36.7% of supply chain organizations do not analyze or predict weather conditions to protect themselves [9].

Machine learning and optimization algorithms are used to build a reliable system capable of predicting the weather and identifying the days when supply chain operations can be carried out [10]. There are many recent works focused on developing and designing weather prediction systems using machine and deep learning algorithms [11][12]. Many of these works aim to predict wind speed, temperature, and the probability of rain [13]. However, only a few recent studies concentrate on developing weather prediction systems that forecast visibility distance and CAVOK metrics, which help supply chain organizations determine the amount of cloud cover and assess whether they can perform their supply chain operations on a given day [14]. Unfortunately, these systems face many challenges [15]. Weather prediction systems that rely on traditional machine learning algorithms often produce low-accuracy results, while systems that use deep learning techniques achieve high accuracy but require a long time to generate predictions [15]. To address these challenges, this study proposes a new machine learning-based weather prediction system that combines traditional machine learning algorithms, which do not consume excessive time, with an optimization algorithm that selects the optimal features to improve accuracy. The system predicts visibility distance and CAVOK conditions to enhance forecasting reliability. The main objectives of this study are:

- Propose a new real-time weather prediction system that forecasts visibility distance and CAVOK conditions, enabling the identification of suitable days for supply chain operations.

- Propose a new two-stage ensemble algorithm that utilizes Bagging Regressor and Extra Tree Regressor to predict visibility distance in the first stage and then uses the predicted visibility distance value to determine CAVOK conditions using the Extra Tree Classifier.
- Apply Fick's Law Algorithm (FLA) to identify optimal features for predicting visibility distance and CAVOK, enhancing the accuracy and efficiency of the proposed system.

The rest of the study is organized as follows: Section II presents related works. Section III introduces the proposed system. Section IV discusses the experimental results of the proposed system. Finally, the study is concluded in Section V.

II. Related Work

There are many related works that have used machine learning and deep learning to predict the weather. However, only a few recent studies focus on forecasting weather by predicting visibility distance and CAVOK conditions. For example, Kim et al. [16] developed a weather prediction system using the Extreme Gradient Boosting (XGB) algorithm to predict visibility distance in Seoul, South Korea. To evaluate the performance of their system, they collected a dataset consisting of 152,488 cases from the Korea Meteorological Administration. The experimental results show that their system achieved acceptable performance, with a Mean Absolute Error (MAE) of 2.04 km and a Root Mean Square Error (RMSE) of 2.94.

Zhang et al. [17] proposed a weather prediction system that predicts visibility distance using Principal Component Analysis (PCA) and machine learning algorithms. The PCA algorithm is used to select optimal features that can serve as indicators for identifying visibility distance. Six machine learning algorithms—Decision Tree, Naïve Bayes, K-Nearest Neighbor (KNN), Linear Discriminant Analysis (LDA), Linear SVM, and Neural Networks—were used to predict visibility distance. To evaluate the performance of their system, they used a dataset collected from ground observations and radiosonde data in Chengdu, Sichuan, containing hourly weather data recorded from 2016 to 2020. The experimental results show that the neural network outperformed the other machine learning algorithms, achieving 88.5% accuracy in predicting visibility distance for the next two hours and 79.5% accuracy for the next four hours.

Ortega et al. [18] proposed a weather prediction system capable of classifying visibility distance into one of three categories: Low, Moderate, or Good, in Florida, USA. To achieve this, the authors used five machine learning algorithms: SVM, KNN, Naïve Bayes, Classification and Regression Tree (CART), and Artificial Neural Networks (ANN). The authors evaluated their system using a dataset collected from weather stations in Florida. The experimental results show that their system achieved high accuracy, with the ANN performing the best, reaching an accuracy of 89.71%.

Zhen et al. [19] proposed a weather prediction system based on traditional machine learning to predict visibility distance during flight and supply chain operations. They also introduced a new stacking fusion model that combines eXtreme Gradient Boosting (XGBoost) and Light Gradient Boosting Machine (LightGBM) to enhance system performance. The experimental results show that the proposed fusion model outperformed traditional machine learning algorithms, including XGBoost, LightGBM, Random Forest, and SVM, achieving an RMSE of 3.82.

Zhang et al. [20] proposed a new meteorological visibility prediction system capable of predicting visibility distance using machine learning algorithms. They introduced a new multimodal fusion model that combines XGBoost and LightGBM to enhance prediction accuracy. To evaluate the performance of the proposed system, they collected a dataset containing atmospheric data from meteorological observation stations in Beijing, Tianjin, and the Hebei region, covering the period from 2002 to 2018. The experimental results show that the new multimodal fusion model outperformed single machine learning algorithms such as XGBoost, LightGBM, SVM, and ANN, achieving an RMSE of 6.71.

As seen above, traditional machine learning algorithms do not achieve very high accuracy when predicting visibility distance. Therefore, recent works have shifted towards using deep learning algorithms to improve prediction performance. For example, Zang et al. [21] proposed a new deep learning-based weather prediction system that predicts visibility distance using a modified version of the Recurrent Neural Network (RNN) called SwiftRNN. This modified version incorporates a frame-hopping transmission gate, reverse scheduled sampling, and a feature fusion module. The purpose of the frame-hopping transmission gate is to reduce the training time required by the RNN algorithm, while reverse scheduled sampling is designed to improve the accuracy of traditional RNN models. Additionally, the feature fusion module is used to detect both local and global optimal features. To evaluate the SwiftRNN model, the authors applied it to a dataset containing atmospheric visibility conditions in China, collected from the Meteorological Information Center from the beginning of 2018 until the end of 2020. The experimental results show that SwiftRNN achieved an average Structural Similarity Index (SSIM) of 0.444 and an average Learned Perceptual Image Patch Similarity (LPIPS) of 0.289.

Ortega et al. [22] proposed a deep learning-based weather prediction system capable of forecasting visibility distance. To predict the visibility distance for each hour, they collected a dataset containing climatological data from two weather stations in Florida, USA. The authors used five deep learning algorithms: Multilayer Perceptron (MLP), Convolutional Neural Network (CNN), Fully Convolutional Neural Network (FCNN), Multi-Input Convolutional Neural Network (MICNN), and Long Short-Term Memory (LSTM) network to predict visibility distance. The experimental results show that MLP, CNN, FCNN, MICNN, and LSTM achieved RMSE values of 1.170, 1.136, 1.175, 1.201, and 1.247, respectively, in predicting visibility distance for the next nine hours.

Chen et al. [23] proposed a new weather prediction system that uses deep learning algorithms to predict visibility distance from both spatial and temporal perspectives. Their system follows two main steps: feature selection and forecasting. In the feature selection step, the authors used the Maximum Relevance Minimum Redundancy (mRMR) algorithm to select the optimal features that serve as indicators in the forecasting step. In the forecasting step, they proposed a new deep learning model called GCN-GRU (Graph Convolutional Network and Gated Recurrent Unit), which is composed of two main algorithms: GCN and GRU, to forecast visibility distance. To evaluate the system, the authors used a dataset containing weather data collected from Jiangsu Province between 2017 and 2018. The experimental results show that their system outperformed LightGBM, Random Forest, and XGBoost, achieving RMSE and MAE values of 17.52 and 16.53, respectively.

Qasem [24] presents a deep learning-based framework for forecasting long-term temperature trends in Saudi Arabia to support climate change analysis. The study compares three recurrent neural network models—LSTM, GRU, and BiLSTM—using historical temperature records from 1861 to 2013. After preprocessing the data through interpolation, normalization, and time-series splitting, the models are evaluated using MAE, MRE, RMSE, and R^2 metrics. Experimental results demonstrate that the GRU model with 50 hidden units achieves the highest forecasting accuracy, outperforming LSTM, BiLSTM, and traditional methods such as ARIMA and Support Vector Regression. The proposed approach provides an effective tool for analyzing long-term temperature trends and can support climate adaptation and environmental planning in Saudi Arabia.

Yuying et al. [25] proposed a deep learning-based weather prediction system capable of predicting visibility distance. To achieve this, they used PhyDNet-ATT (Physical Dynamics Network with Attention). To evaluate their system, they collected a dataset containing weather data from Jiangsu, Anhui, Henan, and Shandong Provinces, sourced from the Precision Weather Analysis and Forecast System. They compared their system with the European Centre for Medium-Range Weather Forecasts, and their system outperformed it by reducing RMSE and MAE by 201% and 310%, respectively.

Suleiman. [26] proposes a hybrid intelligent framework that integrates the Adaptive Neuro-Fuzzy Inference System (ANFIS) with Geographic Information Systems (GIS) to forecast long-term weather elements in Jordan. Using over 30 years of historical meteorological data (1985–2015) collected from 26 weather stations, the study predicts annual rainfall as well as minimum and maximum temperatures for the period 2016–2025. The proposed approach combines fuzzy logic and neural networks to model the nonlinear behavior of weather data, while GIS is used to visualize and analyze the spatial distribution of the predictions. Experimental results indicate that ANFIS provides reliable forecasting performance, predicting a decline in annual rainfall and noticeable changes in temperature patterns across Jordan. The study demonstrates that integrating ANFIS with GIS is an effective tool for long-term climate forecasting and supports environmental planning and climate change assessment in semi-arid regions.

Table I summarizes recent works, highlighting the machine learning algorithms used and the results achieved.

Table I presents all recent works focused on developing weather prediction systems that predict visibility distance. However, no related work has been found that specifically predicts CAVOK metrics. Additionally, no recent studies have focused on predicting either visibility distance or CAVOK metrics in Saudi Arabia.

TABLE I. RELATED WORK COMPARISON

III. METHODOLOGY

In this study, a new weather prediction system is proposed to forecast the numerical value of the visibility distance that the supply chain can observe. The predicted visibility distance is then used to classify sky CAVOK conditions as either cloudy or not cloudy. The proposed system consists of three main steps: preprocessing, feature selection, and a two-stage prediction model to predict both visibility distance and sky CAVOK. Fig. 1 illustrates the architecture of the proposed system.

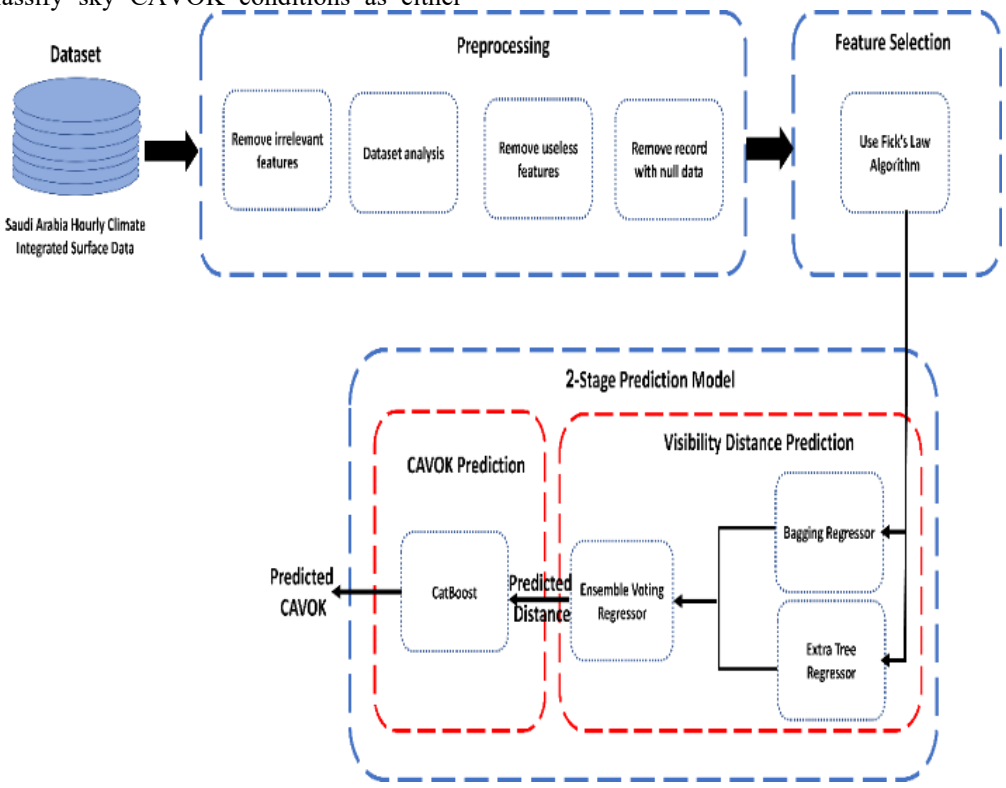

Fig. 1. Proposed system architecture.

As shown in Fig. 1, a Saudi Arabian dataset called Saudi Arabia Hourly Climate Integrated Surface Data is used, which contains historical weather data collected from 2019 to the present. This dataset records hourly weather conditions in Saudi Arabia. Fig. 1 also illustrates that the dataset undergoes analysis to examine the distribution of each feature, identifying irrelevant features for visibility distance and CAVOK prediction while removing rows with null data during the preprocessing step. After preprocessing, Fick's Law algorithm is applied in the feature selection phase to identify the optimal features that serve as indicators for predicting visibility distance and CAVOK. Finally, a new two-stage weather prediction model is introduced for identifying visibility distance and CAVOK conditions. In the first stage, a new ensemble algorithm, which combines Bagging Regressor and Extra Trees Regressor, is developed to predict the visibility distance. In the second stage, the predicted visibility distance value is then fed into a CatBoost Classifier to classify the sky condition as either CAVOK (clear skies) or non-CAVOK (cloudy). Algorithm 1 outlines the steps taken to predict the visibility distance and CAVOK condition in the proposed system.

$$\text{Final Visibility Distance} = \frac{\text{Visibility Distance 1} + \text{Visibility Distance2}}{2}$$

CAVOK = Apply CatBoost classifier to Final Visibility Distance to predict CAVOK

Return Final Visibility Distance and CAVOK

A. Dataset

As shown in Fig. 1, the Saudi Arabia Hourly Climate Integrated Surface Data dataset is used to evaluate the system's performance. This dataset contains 1,760,587 records

of historical weather data collected from Saudi Arabia by the National Oceanic and Atmospheric Administration (NOAA) [27][28]. The dataset records 15 different features, describing the weather conditions in Saudi Arabia on an hourly basis. These features include latitude, longitude, station_id, station_name, wind_direction_angle, wind_type, wind_ speed_rate, observation_date, elevation, visibility_distance, air_temperature_dew_point, air_temperature, atmospheric_se_ level_pressure, sky_ceiling_height, and sky-CAVOK. Latitude and longitude represent the decimal values of the geographical coordinates of the station recording the weather data. Station_id and station_name correspond to the unique identifier and name of the weather station. Wind_type categorizes the wind condition into one of three values: calm, normal, or variable. Wind_direction_angle measures the wind's direction relative to true north, while wind_speed_rate records the speed of the wind. Observation_date logs the date and time when the weather data was recorded. Elevation represents the station's height above sea level, measured in meters. Visibility_distance indicates the distance that can be seen under the recorded weather conditions. Air_temperature and air_temperature_ dew_point measure the recorded air temperature and the temperature at which air becomes saturated, respectively. Atmospheric_sea_level_pressure denotes the pressure value at the time of recording. Sky_ceiling_height measures the height from the ground to the cloud base, in meters. Finally, sky-CAVOK indicates whether the weather is favorable or if cloud conditions could impact supply chain operations, with values of yes or no.

B. Preprocessing

In the preprocessing step, the features in the dataset are analyzed to determine the distribution of values for each feature. This process consists of four main steps: removing irrelevant features, dataset analysis, removing useless features, and eliminating records with null data. In the removing irrelevant features step, features that do not significantly impact the prediction of visibility distance or CAVOK are removed. These include station_name, station_id, and observation_date, as they mainly provide metadata about the recording station rather than contributing to weather prediction. After this step, the number of features is reduced to 12. In the dataset analysis step, numerical analysis is performed to examine the value distribution of each feature. This helps identify features that may not contribute effectively to predicting visibility distance due to poor data distribution. Seven statistical metrics are calculated: count, mean, 25% median, 50% median, 75% median, minimum, and maximum. The results of this statistical analysis are presented in Table II. Table II reveals that atmospheric_sea_level_pressure and sky_ceiling_height have the same values for the 25% median, 50% median, 75% median, and maximum. This indicates that these features contain numerous records with identical values, which could be default values for missing data. Consequently, these features are unlikely to be useful indicators for predicting visibility distance or CAVOK. The distribution of feature values is further visualized in Fig. 2, which confirms that sky_ceiling_height and atmospheric_sea_level_pressure are concentrated around the same value for most records. This supports the decision to remove these features in the removing useless features step. After eliminating these features, the number of features in the dataset is reduced to 10.

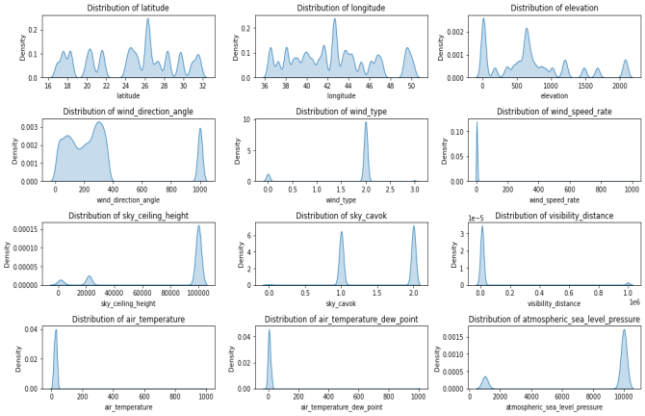

Fig. 2. Feature distributions before applying the preprocessing step.

TABLE II. NUMERICAL FEATURES ANALYSIS BEFORE APPLYING THE PREPROCESSING STEP

Attributes	Count	Mean	Std	Min	25%	50%	75%	Max
Latitude	1760587	24.48343	4.43772	16.901	20.504	25.285	27.438	31.693
Longitude	1760587	42.56574	3.86388	36.476	39.7051	42.621	45.2	50.152
Elevation	1760587	701.7991	578.068	1	179.22	628.49	923	2090.31
wind_direction_angle	1760587	289.0228	276.587	10	110	240	320	999
wind_type	1760587	1.795372	0.63406	0	2	2	2	3
wind_speed_rate	1760587	4.104066	22.0863	0	2.1	3.1	5.1	999.9
sky_ceiling_height	1760587	82487.49	34861.59	0	99999	99999	99999	99999
sky_cavok	1760587	1.515148	0.510321	0	1	2	2	2
visibility_distance	1760587	48884.27	193561.84	0	9900	9900	10000	999999
air_temperature	1760587	26.53717	24.843410	-6	19.1	26	32.6	999.9
air_temperature_dew_point	1760587	9.474121	48.888199	-28	1	6	12	999.9
atmospheric_sea_level_pressure	1760587	8447.8209	3397.8368	990.2	9999.9	9999.9	9999.9	9999.9

In the step of removing records with null data, records containing missing values are identified and removed from the dataset. The number of null records for each feature is counted before elimination. It is observed that wind type has 7 missing records, sky CAVOK has 9,381 missing records, wind direction angle has 204,426 missing records, wind speed rate has 855 missing records, air temperature has 999 missing records, air temperature dew point has 4,156 missing records, and visibility distance has 70,014 missing records. Since missing values can negatively impact the prediction model, all records containing null values are removed. After this step, the total number of records in the dataset is reduced to 1,481,842. After removing records with null data, the dataset is analyzed again to calculate seven statistical metrics: count, mean, 25% median, 50% median, 75% median, minimum, and maximum. This analysis helps to understand the distribution of feature values after eliminating useless features and records with missing data. Table III presents the calculated statistical metrics for each feature, while Fig. 3 illustrates the distribution of values for each feature after preprocessing. Table IV presents the number and names of features before and after preprocessing, along with the total number of records in the dataset before and after the preprocessing steps. This comparison highlights the impact of data cleaning and feature selection on refining the dataset for improved model performance (Algorithm 2).

C. Feature Selection

After the dataset is cleaned, the optimal features that can be used as indicators to predict visibility distance and CAVOK are selected in the feature selection step. In this step, the FLA algorithm is used to choose the most relevant features. FLA applies the same concept as Fick's Law, which is based on the diffusion mechanism that explains how materials move from regions of high concentration to low concentration. Therefore, FLA is used as a feature extraction algorithm for predicting visibility distance due to its ability to select relevant features that influence the movement of fog or particles, ultimately reducing visibility.

The algorithm starts by treating the problem space as a finite-dimensional space and searches for the optimal solution by applying the diffusion mechanism to all particles. The initial population is divided into two equal groups. Each particle updates its position based on the principle of diffusion, which progresses through three key steps: exploration, transition from exploration to exploitation, and exploitation. In the exploration phase, the algorithm searches across a wide area to avoid premature convergence to local solutions and aims to identify the most promising regions in the search space. In the transition phase, particles gradually shift from broad search to a more focused search within the best identified regions. In the exploitation phase, the algorithm optimizes solutions by refining the search within the region that is most likely to contain the optimal solution. The steps performed by the FLA algorithm are shown in Algorithm 3.

Algorithm 3: FLA feature extraction algorithm

Input: Population Size (N), Number of features (D), and Maximum number of iterations (max)

Output: features (F)

```
Generate the initial population (I) with size N randomly
Evaluate the fitness function for each feature using MAE that
predicted by the model
F=Identify the best global feature
While (i<max)
        Divide the population into two equal groups
        For each practice in the first group
                Apply the diffusion mechanism of Fick's law to
                update feature selection
                Evaluate the fitness function for each feature
                F= add or remove the features
        End For
        Adjust diffusion rate dynamically to balance global and
        local search
        For each practice in the second group
        Perform local refinement
                Evaluate the fitness function for each feature
                F= add or remove the features
        End For
        F= add or remove the features
        i=i + 1
    End While
Return F
```

After applying the FLA algorithm to the cleaned dataset, six features were identified as optimal indicators for predicting visibility distance: longitude, elevation, wind direction angle, wind speed rate, air temperature, and air temperature dew point. Additionally, FLA was applied after predicting visibility distance to identify the optimal feature for classifying sky CAVOK in weather data. The algorithm was used to select the most relevant feature from the ten existing features in the cleaned dataset, along with the predicted visibility distance. The FLA algorithm ultimately selected a single feature—the predicted visibility distance—as the key indicator for classifying sky CAVOK. Table IV presents the number and names of features before and after applying the FLA algorithm to identify the optimal features for predicting visibility distance and sky CAVOK.

TABLE IV. ATTRIBUTES USED IN EACH STAGE

Step	Number of rows	Number of features	Attributes
Dataset before preprocessing	1760587	15	station_name, station_id, observation_date, Latitude, longitude, Elevation, wind_direction_angle, wind_type, wind_speed_rate, sky_ceiling_height, sky_cavok, visibility_distance, air_temperature, air_temperature_dew_point, and atmospheric_sea_level_pressure
preprocessing	1481842	10	latitude, longitude, Elevation, wind_direction_angle, wind_type, wind_speed_rate sky_cavok, visibility_distance, air_temperature, and air_temperature_dew_point.
After applying the FLA algorithm	1481842	6	Longitude, elevation, wind_direction_angle, wind_speed_rate, air_temperature, air_temperature_dew_point
After applying the FLA algorithm	1481842	1	Predicted visibility distance

D. 2-Stage Prediction Model

As shown in Fig. 1, the prediction of visibility distance and sky CAVOK is organized in the newly proposed two-stage prediction model. In the first stage, a new ensemble algorithm, which is a combination of bagging and Extra Trees Regressor, is proposed to predict the visibility distance from weather data. The ensemble algorithm follows two steps to make the prediction. In the first step, bagging and extra tree regressor are applied separately to predict visibility distance. Then, in the second step, the mean value of the two predicted visibility distances (from bagging and extra tree regressor) is calculated to produce the final predicted visibility distance. In the second stage of the prediction model, the final predicted visibility distance is used to classify sky CAVOK into one of two values: "Yes" (indicating favorable weather conditions) or "No" (indicating cloud conditions). The CatBoost classifier is used for this classification. To determine the optimal hyperparameters for the bagging regressor, extra tree regressor, and CatBoost classifier, a random search strategy is used. This approach selects random points from the set of

available values and evaluates the system by calculating MAE until the minimum MAE is achieved.

IV. Result and Discussion

Since predicting two different weather variables—visibility distance and sky CAVOK condition—requires different approaches, visibility distance depends on predicting a specific value, while sky CAVOK classifies each weather data point as either "Yes" (indicating favorable weather conditions) or "No" (indicating cloud conditions). Therefore, two different evaluation metrics are needed for each prediction. To evaluate the performance of the proposed system in visibility prediction, RMSE, R^2, and MAE are estimated using the following equations.

$$RMSE = \sqrt{\frac{\sum_{w=1}^{n}(DV_w - O_w)^2}{n}} \quad (3)$$

$$MAE = \frac{\sum_{w=1}^{Nn}| O_w - DV_w|}{n} \quad (4)$$

$$R^2 = 1 - \frac{\sum_{w=1}^{n}(DV_w - O_j)^2}{\sum_{w=1}^{n}(DV_w - \overline{DV}_w)^2} \quad (5)$$

where, $DV_w, O_w, n, and\ \overline{DV}_w$ represent the actual visibility distance, observed visibility distance, number of weather data points predicted, and the average value of all actual visibility distances.

To evaluate the performance of the proposed system in identifying the sky CAVOK condition, precision, recall, F1-score, and accuracy. Precision (P_i), recall (R_i), F1-score ($F1_i$) are estimated for each category i as follows:

$$P_i = \frac{Tp_i}{Tp_i + Fp_i} \quad (6)$$

$$R_i = \frac{Tp_i}{Tp_i + FN_i} \quad (7)$$

$$F1_i = \frac{2\ x\ P_i\ x\ R_i}{P_i + R_i} \quad (8)$$

where, the Tp_i, $Fp_i, and\ FN_i$ represent the true positive, false positive, and false negative for each category i.

The overall accuracy (A) of the proposed system is estimated as follows:

$$A = \frac{Tp+TN}{Tp+TN+FP+FN} \quad (9)$$

where, $Tp, TN, FP, and\ FN$ represent the true positive, true negative, false positive, and false negative for the yes or no CAVOK condition.

The performance of the proposed system is evaluated by dividing the dataset into 80% for training the model and 20% for testing the model. Additionally, the system's performance is assessed both with and without using the FLA algorithm for feature extraction. Table V presents the results of the proposed system in the first stage of the prediction model, where visibility distance is predicted with and without the feature extraction step. Table V shows that various machine learning algorithms, including Gradient Boosting, AdaBoost, Bagging, Extra Trees, Linear Regression, Ridge Regression, Lasso Regression, ElasticNet, KNN, Decision Tree, XGBoost, and LightGBM, are used to compare their performance against the proposed system. The results indicate that the proposed system outperforms individual machine learning algorithms, whether FLA is applied or not, achieving RMSE and MAE values of 1178.8224 and 530.6069 without FLA, and 1174.6118 and 529.7506 with FLA. This demonstrates that the proposed system performs better when the FLA algorithm is used to select the optimal features. Furthermore, the results show that most machine learning algorithms perform better when FLA is applied, except for the LightGBM algorithm, which performs better without FLA. The experimental findings also indicate that Bagging and Extra Trees outperform other machine learning algorithms, achieving RMSE values of 1218.5085 and 1192.1272 without FLA, and 1216.1397 and 1191.6472 with FLA. This justifies the selection of these two algorithms for developing the proposed ensemble model. Additionally, Table V highlights that KNN and Decision Tree achieve relatively good results, with RMSE values of 1257.6711 and 1508.1836 without FLA, and 1256.6323 and 1509.4436 with FLA. However, AdaBoost is identified as the worst-performing algorithm, achieving RMSE values of 1419.2078 without FLA and 1590.2311 with FLA. Moreover, the Decision Tree algorithm exhibits a negative R^2 value, indicating its poor capability in predicting visibility distance.

TABLE V. Proposed System Performance When Predicting Visibility Distance with and Without Using Feature Extraction Algorithm

Feature extraction step	Machine learning algorithm	MAE	RMSE	R^2
Without using FLA algorithm	Gradient Boosting	676.6967	1296.1086	0.1789
	AdaBoost	832.4155	1419.2078	0.0155

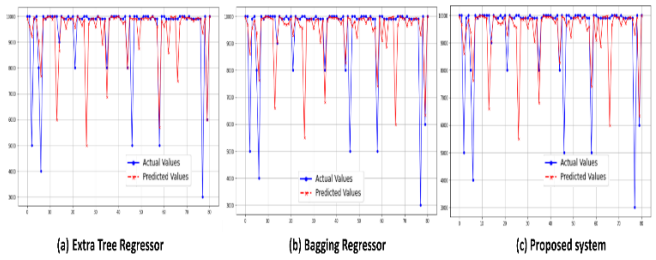

Fig. 4. Visibility distance prediction without FLA.

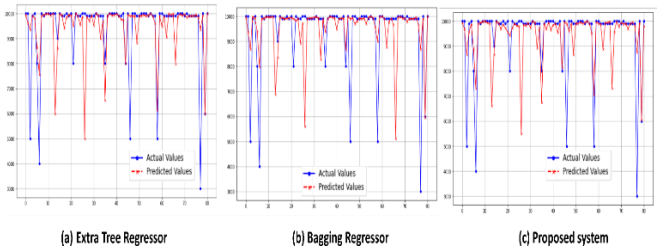

Fig. 5. Visibility distance prediction using FLA.

Fig. 4 and 5 illustrate the predicted values generated by Extra Trees, Bagging, and the proposed system, compared to the actual values for each weather data point, both without and with the FLA algorithm, respectively. These figures show that using the FLA algorithm enhances the predictive ability of the proposed system, Extra Trees, and Bagging in forecasting visibility distance. Furthermore, the results indicate that the proposed system outperforms the other two algorithms.

The performance of the proposed system in the second stage is evaluated when using all features to predict sky CAVOK or when using only the predicted visibility distance feature to predict sky CAVOK. Table VI presents the performance of the proposed system in the second stage of the prediction model when using all features or only the predicted visibility distance for predicting sky CAVOK. The table also includes a comparison with 11 other machine learning algorithms: Gradient Boosting, AdaBoost, Logistic Regression, Bagging, KNN, Gaussian Naïve Bayes, Decision Trees, Multi-Layer Perceptron (MLP), Extra Trees, Quadratic Discriminant Analysis (QDA), and Linear Discriminant Analysis (LDA), all of which are compared against the proposed system, which utilizes CatBoost. Table VI shows that the proposed system outperforms other machine learning algorithms, achieving 100% accuracy when using only the predicted visibility distance and 77.38% accuracy when using all features to predict sky CAVOK. These results indicate that the proposed system performs better when using only the predicted visibility distance. The table also demonstrates that all machine learning algorithms perform better in predicting sky CAVOK when using only the predicted visibility distance rather than all features. Additionally, Table VI highlights that Bagging achieves a strong accuracy performance, reaching 71.09% accuracy when using all features and 100% accuracy when using only the predicted visibility distance. Decision Trees, Gradient Boosting, Extra Trees, KNN, and AdaBoost also show acceptable accuracy levels, achieving 67.72%, 65.50%, 60.35%, 60.90%, and 62.22% accuracy, respectively, when using all features, and 100% accuracy for all of them when using only the predicted visibility distance. On the other hand, Table VI reveals that Logistic Regression, MLP, QDA, and LDA are the weakest machine learning algorithms in this context. They achieve relatively poor accuracy results of 60.41%, 63.65%, 60.41%, and 60.38%, respectively, when using all features, and 62.02%, 67.28%, 52.03%, and 64.50% when using only the predicted visibility distance.

TABLE VI. PROPOSED SYSTEM PERFORMANCE WHEN PREDICTING SKY CAVOK

		100%	100%	100%	
	QDA	51.24%	100%	67.76%	52.03%

		100%	03.24%	06.27%	
	LDA	67.95%	56%	61.40%	64.50%
		62.04%	73.14%	67.13%	
	Proposed system	**100%**	**100%**	**100%**	**100%**
		100%	**100%**	**100%**	

The proposed system achieved an accuracy of 100% when the visibility distance feature was used. However, when using all features without visibility distance, the model accuracy decreased to approximately 77.38%. Furthermore, using visibility distance as the sole predictor still resulted in 100% accuracy. This observation suggests that the feature has an exceptionally strong association with the target variable (SKY CAVOK). Since CAVOK is partially defined by visibility conditions in aviation meteorology, the model may have benefited from information that is intrinsically related to the target definition. Consequently, the reported perfect performance should be interpreted with caution, as it may indicate the presence of potential target leakage (data leakage) rather than genuine predictive capability.

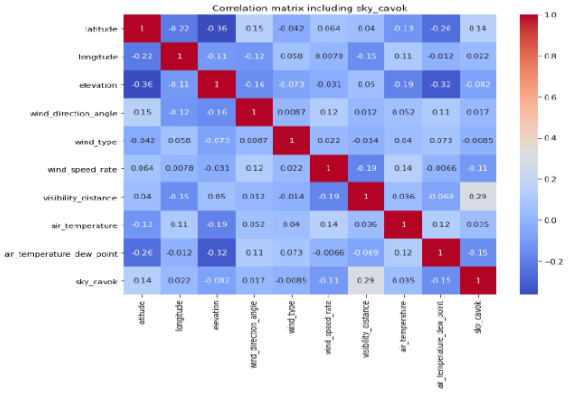

Fig. 6. Correlation matrix of features.

Fig. 6 illustrates the correlation between the features present in the cleaned dataset. It also shows that sky CAVOK is correlated with visibility distance, with a correlation of 29%. This correlation supports the conclusion that using only visibility distance can achieve accuracy comparable to using all other features combined.

V. Discussion

Table V and Table VI show that the proposed system outperformed machine learning algorithms such as Gradient Boosting, AdaBoost, Logistic Regression, Bagging, KNN, Gaussian Naïve Bayes, Decision Trees, MLP, Extra Trees, Quadratic QDA, Linear Regression, Ridge Regression, Lasso Regression, ElasticNet, XGBoost, LightGBM, and LDA. The proposed system achieved an MAE of 529.7506 and an RMSE of 1174.6118 in predicting visibility distance, along with 77.38% accuracy in predicting the sky CAVOK condition.

In contrast, the machine learning algorithms achieved an MAE in the range of 505.4231 to 861.2343 and an RMSE in the range of 1191.6472 to 1590.2311 for predicting visibility distance, as well as an accuracy range of 58.99% to 71.09% in predicting sky CAVOK, which is lower than what the proposed system achieved.

TABLE VII. Comparison Between Related Works and the Proposed System

Visibility distance prediction metrics				**Sky CAVOK prediction metrics**
Related work	**Prediction**	**MAE**	**RMSE**	**Accuracy**
Kim et al. [16]	Visibility distance	2.04 km	2.94 km	-
Zhen et al. [19]	Visibility distance	-	3.82km	-
Zhang et al. [20]	Visibility distance	-	6.71km	-
Ortega et al. [22]	Visibility distance	-	1.175km	-
Chen et al. [23]	Visibility distance	17.52km	16.53km	-
Proposed system	**Visibility distance and sky CAVOK**	**.05297506 km**	**1.1746118 km**	**100%**

Also, the proposed system is compared with recent works, and this comparison is shown in Table VII. Table VII demonstrates that the proposed system is capable of predicting the sky CAVOK condition with 100% accuracy, whereas other related works do not predict the sky CAVOK. The table also shows that the proposed system outperforms recent works in predicting visibility distance, achieving an RMSE of 1.1746118 km, while other recent works report RMSE values in the range of 1.175 km to 6.71 km. The proposed system also utilizes a dataset that contains weather data specific to Saudi Arabia, whereas other related works do not use a dataset that includes weather data from Saudi Arabia.

VI. Conclusion

The success of supply chain operations in Saudi Arabia fully depends on weather conditions, particularly visibility distance and sky CAVOK. In this study, a new weather prediction system is proposed to predict visibility distance and sky CAVOK. The system follows three main steps: preprocessing, feature extraction, and prediction. In the preprocessing step, the dataset is cleaned by removing irrelevant features and rows with missing data. In the feature extraction step, the FLA algorithm is used to select the optimal features for the prediction process. Finally, in the prediction step, a new two-stage prediction algorithm is proposed. The first stage combines Bagging Regressor and Extra Trees Regressor to form a new ensemble algorithm for predicting visibility distance. The predicted visibility distance is then fed into the CatBoost algorithm to predict the CAVOK condition. The experimental results show that the proposed system achieves very good performance, outperforming other machine learning algorithms and recent studies. In future work, the system may be evaluated on additional datasets, and its capability can be extended to predict other weather variables. In addition, the system can be enhanced by using advanced optimization techniques and refining its architecture to achieve improved predictive performance.

Acknowledgment

AI-Mediated STEM Problem Solving: Activity Distribution and Functional Roles in a Systematic Review

Mika Lim
University Innovation Center, Seoul National University, Seoul, Republic of Korea

***Abstract*—Artificial intelligence (AI) is increasingly embedded in STEM problem-solving activities, yet existing reviews have generally organized the literature by technology type or learning outcome. This review shifts the analytic focus from what AI can do to how it is integrated into students' STEM problem solving. It examined where AI was positioned within problem-solving activity, what functional role it performed, and how its functions or outputs were connected to students' subsequent judgments and actions. Following PRISMA 2020, searches of Scopus, Web of Science, ERIC, and backward references identified 29 English-language journal articles published from 2017 through June 4, 2026. Study-level coding mapped AI use across seven non-linear activity categories, while case-level analysis examined 37 reporting-eligible AI–student interactions in which the AI function or output, activity context, and subsequent student action were identifiable. AI was reported most often in two activity categories: Problem Understanding and Exploration, and Revision and Improvement. Four recurring functional roles were identified: Conceptual Resource, Generative Resource, Operational Component, and Adaptive Scaffold. The same technology assumed different roles depending on the activity category and how students used its output. The principal contribution of this review is to shift attention from AI's technical capabilities and associated learning outcomes to the interaction between AI outputs and students' subsequent activity. By linking each AI function or output to a problem-solving activity category and a subsequent student action, the review shows that AI's role is defined by how students use its output in context, not by the technology itself. The findings are descriptive of the selected corpus and its reporting practices; they should not be interpreted as prevalence estimates or evidence of causal learning effects.**

Keywords*—Artificial intelligence; STEM education; AI-mediated learning; human-AI interaction; functional roles; systematic review

I. Introduction

A. Problem and Purpose

Artificial intelligence (AI) has become a prominent component of educational technology. Its educational uses now extend beyond learner diagnosis, performance prediction, and intelligent tutoring to explanations of concepts, generation of ideas and code, model execution, data analysis, feedback, and support for reflection. Generative AI and large language models (LLMs), in particular, enable students to ask follow-up questions, explore alternative solutions, review emerging artifacts, and identify possible directions for revision [1]–[3].

Introducing AI into a classroom does not by itself establish educational value. The same system may serve as an information source for conceptual understanding, generate design alternatives, operate as part of a physical device or computational model, or diagnose a student-generated artifact and suggest next steps. Analysis must therefore consider not only what an AI system can do but also where its output enters students' activity and how students use that output in subsequent judgments and actions.

Within science, technology, engineering, and mathematics (STEM) education, students act as investigators and designers who coordinate scientific concepts, mathematical reasoning, engineering design, and technological tools in addressing authentic problems [4], [5]. They identify the problem and its requirements, seek relevant knowledge and evidence, formulate and implement a solution, examine results through execution or experimentation, interpret evidence, and revise the solution. Throughout this process, they form and revise judgments while engaging with data, tools, phenomena, and artifacts.

AI can be integrated at multiple points in this process. Intelligent tutoring systems can provide explanations and hints based on students' current understanding. Generative AI can answer questions and generate ideas, designs, code, and explanatory drafts. Educational robots, sensors, and artificial intelligence of things (AIoT) systems can sense conditions, collect data, execute models, and control devices. These technical functions are not equivalent to functional roles. Code generation, object recognition, data analysis, and automated feedback describe technical operations; their functional roles depend on how students use the resulting outputs.

Previous systematic reviews have primarily organized research on AI in education by technology type, system function, research method, or learning outcome. Zawacki-Richter et al. classified higher-education applications into profiling and prediction, assessment, adaptive systems, and intelligent tutoring [6]. Xu and Ouyang analyzed AI-STEM research in terms of technical applications and components of educational systems [3]. Akhmetova et al. examined technologies, methods, and cognitive and affective outcomes in high-school STEM education [1], whereas Pacheco-Olea and Villacís-Macías synthesized study characteristics, technologies, outcomes, and methodological limitations across AI-STEM research [2].

These reviews clarify the scope and direction of the field, but technology-centered classifications do not fully explain how the same AI technology can perform different roles across problem-solving activities. Outcome-centered syntheses can identify differences associated with AI use but often do not specify the activities in which those differences emerged. The present review therefore examined a defined corpus of empirical AI-STEM journal articles to identify where AI was reported within students' problem-solving activity and which recurring functional roles were visible in well-documented AI–student interactions. The study was designed as a descriptive synthesis of reported activity and interaction patterns, not as an estimate of prevalence or evidence that AI improved learning. Its purpose was to inform more precise descriptions and evaluations of AI-supported STEM learning environments.

B. Research Questions

RQ1. In which activity categories of students' STEM problem solving was AI reported?

RQ2. What recurring functional roles were reported in AI-mediated STEM problem-solving interactions?

II. Theoretical Background

A. Activity Structure of STEM Problem Solving

STEM education integrates scientific inquiry, engineering design, mathematical thinking, and technology use [4]. Accordingly, learning extends beyond the acquisition of disciplinary knowledge to the exploration of relevant concepts and evidence, the use of tools, and the design, implementation, and testing of solutions to complex problems.

Comparable activity structures appear in science and engineering practices, engineering design, problem-based learning, and project-based learning. Science and engineering practices emphasize asking questions and defining problems, developing models, conducting investigations, analyzing data, constructing explanations, and designing solutions [5], [7]. Engineering design emphasizes identifying requirements and constraints, generating alternatives, implementing and testing solutions, making decisions, and improving solutions iteratively [8]. Problem-based and project-based learning organize inquiry, artifact construction, and review around authentic problems [9], [10]. Although these approaches differ in terminology and emphasis, they share a progression from initial engagement with a problem through planning and action to testing, interpretation, revision, and reflection.

On this basis, the present analysis distinguished seven activity categories: Problem Understanding and Exploration, Planning and Design, Implementation and Construction, Experimentation and Testing, Analysis and Interpretation, Revision and Improvement, and Reflection. The categories are not proposed as a new general model of STEM problem solving. Rather, they provide a common, non-linear coding frame for comparing studies grounded in science and engineering practices, engineering design, problem-based learning, and project-based learning. Table I presents the operational definition of each category.

TABLE I. Operational Definitions of STEM Problem-Solving Activity Categories

Activity Category	Operational Definition
A1. Problem Understanding and Exploration	Identifying the problem situation and requirements and exploring relevant concepts, examples, and information.
A2. Planning and Design	Generating alternatives and specifying a strategy, procedure, or design while considering conditions and constraints.
A3. Implementation and Construction	Producing an artifact such as code, a model, a device, a program, a product, or an explanation.
A4. Experimentation and Testing	Executing, observing, or measuring an artifact or system to examine operation and performance.
A5. Analysis and Interpretation	Identifying errors, patterns, relationships, and meaning in collected data and execution results.
A6. Revision and Improvement	Modifying an idea or artifact and trying again on the basis of analysis or feedback.
A7. Reflection	Explaining the problem-solving process and grounds for judgment and metacognitively examining strategies and outcomes.

Students may move among these categories rather than follow a fixed sequence. Analytically, the framework separates planning from construction, testing from learner interpretation, and artifact revision from metacognitive reflection. These distinctions matter in AI-mediated activity because a system may generate, execute, or diagnose without evidence that students interpreted its output or reflected on the grounds for a decision.

B. Technical Functions and Functional Roles of AI

In STEM education, AI supports information seeking, conceptual understanding, design, construction, experimentation, analysis, and feedback. Intelligent tutors and adaptive systems diagnose learner responses and provide explanations, hints, and learning paths. AI-based learning analytics detect patterns in performance data and present predictions or visualizations. Computer vision, machine learning, educational robotics, and AIoT combine sensing, classification, measurement, prediction, and control with experimentation and construction. Generative AI and LLMs explain concepts, answer questions, generate ideas and design alternatives, produce code, and provide error diagnoses and feedback.

A functional role cannot be inferred from a technology label or technical function alone. An LLM may provide explanations and examples during Problem Understanding and Exploration, generate alternatives during Planning and Design, draft code during Implementation and Construction, or diagnose an existing student artifact during Revision and Improvement. Computer vision and AIoT may automate a device while also making phenomena that are otherwise difficult to observe available for experimentation and interpretation.

This distinction requires five related constructs to be kept separate. A technical configuration describes the system or combination of models, interfaces, sensors, and devices. An AI function is the operation performed, such as generation, classification, prediction, or control. An AI output is the information, candidate solution, inference result, or feedback made available by that operation. A functional role describes

how the function or output is incorporated into a student's problem-solving activity. A subsequent student action is the observable response that follows, such as asking a follow-up question, selecting or revising a design, testing a model, adding data, or reconsidering a justification.

Prior reviews classify research on AI by technology, system function, educational level, subject area, or outcome [1]–[3], [6]. Such classifications map the field but do not fully explain how an AI function or output becomes connected to students' problem-solving actions. Automated error detection, for example, does not establish that a student interpreted the error or revised a solution. The present review therefore uses mediation conservatively to denote a reported connection among an AI function or output, a specific STEM problem-solving activity, and an observable subsequent student action. It does not imply that AI use caused improvement in learning outcomes.

III. METHODS

A. Research Design

This systematic review identified and selected empirical studies of AI use in STEM education and analyzed both where AI was positioned in students' problem-solving activities and what functional roles it performed. Search, selection, and reporting procedures followed PRISMA 2020 guidance [11]. The analysis combined study-level descriptive quantitative analysis with case-level qualitative content analysis [14].

For clarity, study refers to an included journal article at the document level, whereas case refers to a clearly bounded AI–student interaction reported within a study. For RQ1, each included study was coded for AI use across the seven STEM problem-solving activity categories. For RQ2, the unit of analysis was an AI–student interaction case. Each case linked an identifiable AI function or output to the student activity in which AI was used and to a subsequent student action.

B. Search Strategy

The review protocol was limited to English-language journal articles indexed in Scopus, Web of Science, and ERIC and published from 2017 through June 4, 2026. The search combined an AI-related term set with a STEM-education term set, as shown in Table II.

TABLE II. DATABASE SEARCH RESULTS

Field	Details
Database records	Scopus: 320; Web of Science: 257; ERIC: 241; total: 818.
Common search string	("artificial intelligence" OR "generative AI" OR ChatGPT OR "large language model*" OR "intelligent tutoring system*" OR "educational robotics") AND ("STEM education" OR "STEM learning" OR "STEM teaching")
Period and conditions	2017–June 4, 2026; English-language journal articles indexed in Scopus, Web of Science, or ERIC

For this review, AI-supported STEM education was limited to contexts in which students directly used AI during problem exploration, design, implementation, experimentation, data interpretation, or iterative improvement. Studies were excluded when AI was used only to provide theoretical explanations or routine problem solving in a single subject, and no direct connection to STEM problem-solving activity could be identified. Table III presents the inclusion and exclusion criteria.

TABLE III. INCLUSION AND EXCLUSION CRITERIA

Criterion	Definition
Inclusion	AI technology was applied in a STEM teaching or learning context; learner activity, instructional design, an educational program, or a learning environment was clearly described; and an AI function or output could be connected to a student's STEM activity.
Exclusion	AI was not applied in an actual lesson or learning process; the context was not STEM education; AI was only a learning topic, and no STEM practice or student activity was clear; the study reported only perceptions, attitudes, satisfaction, or intention to use; or AI was used only for teacher support or system administration without a clear connection to student activity.

C. Study Selection

The database search identified 818 records. After 270 duplicates were removed on the basis of DOI and title, 548 records remained for title-and-abstract screening. Two coders participated in study selection. Coder 1 held a doctoral degree in technology education. Coder 2 was a science education teacher with more than 20 years of experience.

Coder 1 screened all 548 titles and abstracts, and Coder 2 independently screened a random sample of 110 records (20.1%). The coders agreed on 99 of the 110 decisions, yielding 90.0% agreement. This stage excluded 413 records and retained 135 articles for full-text assessment.

Both coders independently assessed all 135 full-text articles. They reached the same inclusion or exclusion decision for 125 articles, yielding 92.6% agreement and a Cohen's kappa of 0.79 [12]. For the 10 disagreements, the coders compared the full texts with the inclusion and exclusion criteria and reached consensus. The database-search pathway yielded 25 included studies.

Backward reference searching was then conducted on the reference lists of the 25 included studies, following Wohlin [13]. This search identified 1,362 reference records. After duplicates were removed and the publication-year criterion was applied, 991 records were screened by title and abstract. Twenty-three articles proceeded to full-text assessment. The two coders independently judged eligibility, with 91.3% agreement and a Cohen's kappa of 0.70 [12]. Disagreements were resolved through discussion. Four additional studies met the criteria, yielding a final corpus of 29 studies [15]–[43]. Fig. 1 summarizes the selection process.

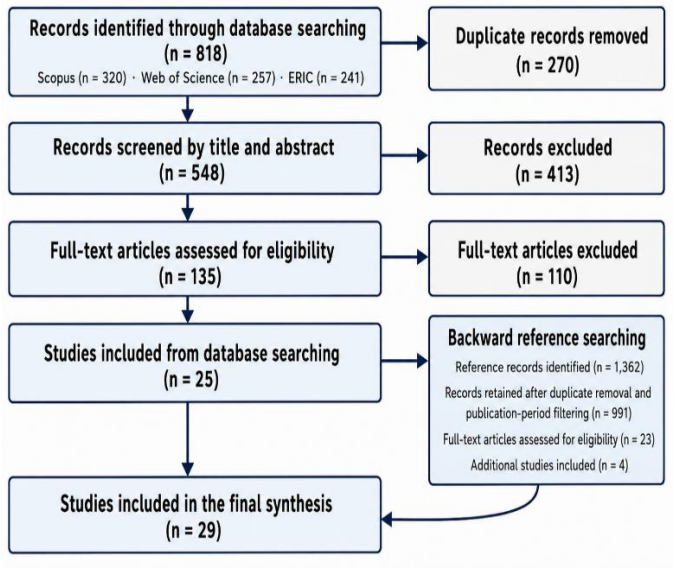

Fig. 1. Flow diagram of study identification and selection.

D. Data Extraction and Coding

Extracted data included publication year, educational level, representative technical configuration, the STEM problem-solving activity categories in which AI was directly used, and case-level information on AI–student interaction and reporting eligibility. Table IV summarizes the extraction and coding framework.

TABLE IV. DATA EXTRACTION AND CODING OVERVIEW

Level	Analytical Area	Extracted or Coded Information
Study level	Basic characteristics	Publication year, educational level, and representative technical configuration.
	STEM activity category	Problem Understanding and Exploration; Planning and Design; Implementation and Construction; Experimentation and Testing; Analysis and Interpretation; Revision and Improvement; Reflection.
Case level	AI-use case	What AI performed or provided; the student activity in which AI was used; and the reported subsequent student action.
	Functional role	Non-mutually exclusive role assigned from the relationship among AI function or output, activity context, and subsequent student action.

a) Study-level coding of activity categories: An activity category was coded only when an AI output or operation was connected to a student's STEM activity. Multiple categories could be coded within a single study. Internal system analysis alone did not justify coding Analysis and Interpretation; students had to examine an analytical or diagnostic output and construct meaning from it. General satisfaction or post-activity impressions were not coded as Reflection. Reflection required evidence that an AI-generated question or feedback was used for self-assessment, examination of the grounds for a judgment, or reconstruction of an explanation.

The two coders independently made 203 binary coding decisions (29 studies across seven categories). They agreed on 187 decisions, yielding 92.1% overall agreement and a pooled Cohen's kappa of 0.812 [12]; category-specific agreement ranged from 79.3% to 100.0%. Agreement was lowest for Analysis and Interpretation. The coders therefore revisited the boundary between internal system analysis and students' use of an analytical output. All disagreements were resolved by comparing the source text with the coding criteria, and the reported counts were calculated from the final consensus codes.

b) Case-level extraction and derivation of functional roles: For RQ2, the unit of analysis was a bounded AI–student interaction rather than an entire study. A case was retained for role analysis only when the source article explicitly documented three elements: an identifiable AI function or output, the STEM problem-solving activity in which it was used, and a subsequent student action linked to that output. Repeated instances of the same function and student action within one task were consolidated, whereas a change in the AI output, activity context, or subsequent action defined a separate case. Applying this conservative rule yielded 37 reporting-eligible cases. Interactions lacking one or more of the three elements were excluded from role-frequency analysis.

Functional roles were assigned at the interaction-case level, not to a technology, operation, or output in isolation. The AI operation and output were recorded as descriptive evidence; the role label captured how the output entered the student's problem-solving activity, as shown by the subsequent action. Both coders first summarized the three case elements and developed descriptive codes closely grounded in the source text without applying the final role labels. They then compared codes across cases, consolidated related patterns, refined inclusion and boundary rules against the source articles, and reapplied the provisional categories. After the codebook was finalized, the four non-mutually exclusive roles were represented as 148 binary decisions across the 37 cases. The coders agreed on 130 of the 148 decisions (87.8%), yielding a pooled Cohen's kappa of 0.723 [12]. Final role assignments were non-mutually exclusive: a case could receive more than one role when distinct output-action relationships were documented. The resulting framework is therefore a provisional classification of the 37 reporting-eligible cases rather than a prevalence estimate or a universal taxonomy. Table V presents the codebook used to distinguish the four functional roles.

TABLE V. CODEBOOK FOR AI FUNCTIONAL ROLES

Functional Role	AI Function or Output	Required Student Use or Subsequent Action	Exclusion or Boundary
F1. Conceptual Resource	Explanation, example, question-and-answer exchange, contextual information, or representational support.	The student uses the output to clarify a problem or concept, refine a problem representation, ask a follow-up question, or apply an explanation.	Excludes candidate solutions and feedback contingent on a specific student artifact or performance state.
F2. Generative Resource	Candidate idea, strategy, plan, design, code, model, or draft.	The student compares, selects, modifies, negotiates, implements, or rejects the candidate.	Excludes concept explanation and task-embedded AI execution.
F3. Operational Component	Sensing, detection, classification, inference, measurement, simulation, or control that produces a task-relevant output.	The student integrates, observes, tests, or interprets the operation or its performance.	Excludes internal processing that only triggers feedback and yields no task output available to the student.
F4. Adaptive Scaffold	Diagnosis of a specific student response, artifact, performance state, or task state, followed by contingent guidance.	The student revises, retries, seeks additional evidence, or reconsiders a judgment in response to feedback, hints, revision directions, or reflective questions.	Excludes general encouragement and explanation not adapted to evidence about the learner, artifact, or task state.

IV. RESULTS

A. Characteristics of the Included Studies

The final corpus comprised 29 studies that reported students using AI during STEM problem-solving activities. Sixteen studies were published in 2025 and seven by June 4, 2026; together, these 23 studies accounted for 79.3% of the corpus. The findings therefore describe a recent cross-section of a rapidly developing literature rather than a longitudinal account of change across the full 2017-2026 period.

Higher education accounted for 18 studies, secondary education for eight, primary or other child learners for two, and early childhood education for one. Table VI summarizes the selected study corpus.

TABLE VI. CHARACTERISTICS OF THE SELECTED STUDY CORPUS

Characteristic	Category	Studies (n)	Percent (%)
Publication year	2020	1	3.4
	2021	3	10.3
	2023	1	3.4
	2024	1	3.4
	2025	16	55.2
	2026	7	24.1
Educational level	Early childhood	1	3.4
	Primary or other child learners	2	6.9
	Secondary education	8	27.6
	Higher education	18	62.1

B. AI Technologies and Technical Configurations

The technologies were grouped into three representative configurations according to the system that engaged most directly and continuously with student activity. The categories were mutually exclusive at the study level and described the predominant configuration; they were not intended to classify every technology reported in each study.

Generative-AI-centered conversational and agent-based systems were the predominant configuration in 17 of 29 studies. This group included direct use of general-purpose systems such as ChatGPT and Gemini, as well as specialized systems that combined LLMs with multiple agents, structured prompting, retrieval-augmented generation, semantic routing, speech interfaces, or discipline-specific knowledge bases.

Computer-vision- and machine-learning-centered recognition and execution systems were the predominant configuration in 7 of 29 studies. Image classification, object detection, state recognition, and performance prediction were combined with JetBot, Jetson Nano, ESP32-CAM, sensors, motors, or AIoT devices. In some studies, students collected training data, retrained models, or examined misclassifications to investigate system limitations and operating conditions.

Nongenerative intelligent tutors or adaptive support systems were the predominant configuration in 5 of 29 studies. These systems analyzed student responses, performance states, or learning histories and supplied explanations, hints, task recommendations, or learning paths. Table VII summarizes the configurations.

TABLE VII. REPRESENTATIVE AI TECHNICAL CONFIGURATIONS

Representative Configuration	Examples of Technologies and Systems	Principal Technical Features	Studies (n/29)	Percent (%)
Generative-AI-centered conversational and agent-based systems	ChatGPT; GPT-4/GPT-4o; Gemini; GLM-4; DeepSeek; ERNIE-Bot; ChatGLM; local LLMs	Question answering and conceptual explanations; generation of ideas, designs, and code; feedback; conversational interaction.	17/29	58.6
Computer-vision- and machine-learning-centered recognition and execution systems	YOLOv3; YOLOR; CNN; OpenCV; Azure Custom Vision; JetBot; Jetson Nano; ESP32-CAM; Birdbuddy	Image, object, and state recognition; model training and inference; sensing and control in robotics and AIoT.	7/29	24.1
Nongenerative intelligent tutors and adaptive support systems	Transformer/RNN-based tutors; knowledge-based agents; Dialogflow chatbots; performance-prediction and adaptive systems	Diagnosis of responses and performance; hints and resources; adaptation of learning paths and task difficulty.	5/29	17.2

C. AI Use Across STEM Problem-Solving Activity Categories

For RQ1, each study could be coded in more than one activity category. Table VIII therefore reports non-mutually exclusive counts within the selected 29-study corpus. The values are descriptive of this corpus and should not be interpreted as prevalence estimates for AI use in STEM education.

TABLE VIII. REPORTED AI USE ACROSS STEM PROBLEM-SOLVING ACTIVITY CATEGORIES

Activity Category	Studies (n/29)	Percent (%)	Representative Pattern of AI Use
A1. Problem Understanding and Exploration	28/29	96.6	Conceptual explanations, examples and context, question answering, and exploration of problem requirements and relevant information.
A2. Planning and Design	19/29	65.5	Generation of solution strategies and design alternatives; review of constraints; task decomposition; and procedural planning.
A3. Implementation and Construction	22/29	75.9	Code and model implementation, device configuration, and construction using circuits, sensors, robots, or AI kits.
A4. Experimentation and Testing	20/29	69.0	Model execution, measurement and observation, examination of operation and performance, and inspection of errors and failures.
A5. Analysis and Interpretation	17/29	58.6	Analysis of data and experimental results and review and interpretation of errors, patterns, and predictions.
A6. Revision and Improvement	27/29	93.1	Error diagnosis, revision suggestions, repeated attempts, model retraining, and artifact improvement.
A7. Reflection	16/29	55.2	Self-assessment, examination of grounds for judgment, elaboration of explanations, and reflection on the problem-solving process.

Reported AI use was identified most often in Problem Understanding and Exploration (28/29 studies) and Revision and Improvement (27/29). During initial problem engagement, AI was used to explain concepts and examples and to clarify the problem context and requirements. During revision, systems identified errors or limitations in student responses, code, designs, experimental results, or constructed artifacts. Students then used feedback or revision directions to modify their work or try again.

Implementation and Construction was identified in 22 of 29 studies, and Experimentation and Testing in 20 of 29. AI-supplied information was used in constructing code, models, circuits, and devices, or it operated as part of the constructed system. In studies using computer vision, machine learning, robotics, or AIoT, model inferences were linked to sensors, motors, or controllers. Students executed these systems and examined the outputs to assess performance and failure conditions.

Planning and Design was identified in 19 of 29 studies. AI suggested solution strategies, product ideas, design alternatives, component choices, and procedural plans, or it was used to review student-defined requirements and constraints. Some systems supplied relatively complete designs; in other cases, students compared alternatives, added constraints, and revised AI-generated outputs.

Analysis and Interpretation was identified in 17 of 29 studies, and Reflection in 16 of 29. Analysis and Interpretation was coded only when students examined analytical results, predictions, errors, or patterns and constructed meaning from them; internal data processing alone was insufficient. Reflection was coded only when students used an AI-generated question or feedback for self-assessment, examination of their reasoning, or reconstruction of an explanation rather than merely reporting a general post-activity impression.

D. Functional Roles of AI

For RQ2, the analysis compared AI functions, outputs, activity contexts, and subsequent student actions across the 37 reporting-eligible cases. Four recurring roles were identified: Conceptual Resource, Generative Resource, Operational Component, and Adaptive Scaffold. Roles were non-mutually exclusive, and a case could receive more than one role when distinct output–action relationships were documented. Table IX reports counts within this analytical subset; the figures describe the reporting-eligible cases and are not estimates of the broader distribution of AI roles.

TABLE IX. RECURRING FUNCTIONAL ROLES IN THE REPORTING-ELIGIBLE CASES

Functional Role	Reporting-Eligible Cases (n/37)
F1. Conceptual Resource	11/37
F2. Generative Resource	13/37
F3. Operational Component	13/37
F4. Adaptive Scaffold	11/37

a) AI as a conceptual resource: In a Conceptual Resource case, AI supplied an explanation, example, question-and-answer exchange, contextual detail, or representational support that students used to clarify a problem, concept, operating principle, or representation. Reported cases included explanations of electronics and robotics components, connections between buoyancy and submarine design, clarification of data-visualization concepts, and images or examples for unfamiliar tools. Subsequent actions included asking follow-up questions, refining a problem representation, and applying an explanation during design or construction. The role was assigned from this use of the output, not from text generation alone.

b) AI as a generative resource: In a Generative Resource case, AI produced a candidate idea, strategy, plan, design, code fragment, model, or draft that entered the student's solution space. Reported outputs included sensor and component comparisons, project ideas, sequenced plans, circuit and structural alternatives, code drafts, and context-specific product concepts. Students subsequently compared, selected, modified, negotiated, implemented, or rejected these candidates. Some systems broadened the design space with multiple alternatives or what-if questions; others supplied a relatively complete candidate that became a reference point for later work.

c) AI as an operational component: In an Operational Component case, AI performed part of the inquiry or engineering system rather than merely supplying advice. Examples included computer vision used to assess structural stability or locate objects, image or speech classification used to trigger a device, bird classification used to accumulate ecological observations, and predictions used to control motors or LEDs. Students integrated the resulting inferences into physical or computational systems. They then observed and tested system operation and examined performance or failure conditions.

d) AI as an adaptive scaffold: In an Adaptive Scaffold case, AI analyzed a student response, code, design, experimental result, performance state, or task state and provided contingent feedback, hints, revision directions, or reflective questions. Reported cases included feedback adjusted after repeated misconceptions, artifact evaluation against criteria, code or circuit diagnosis, sensor-calibration suggestions, task adaptation, and identification of missing evidence in an argument. Students then revised an artifact, tried again, sought additional evidence, or reconsidered a judgment. This role was distinguished from general explanation by its dependence on specific evidence about the learner, artifact, or task state.

E. Relationship Between Technical Configuration and Functional Role

Functional roles did not correspond one-to-one with technology types. A role was assigned based on the relationship among the operation or output, the activity context, and the subsequent student action.

Generative-AI-based conversational and agent-based systems served as Conceptual Resources, Generative Resources, and Adaptive Scaffolds. A system served as a Conceptual Resource when it explained concepts or operating principles that students used to understand a problem or seek information. It served as a Generative Resource when it produced ideas, design alternatives, or code that students compared, selected, or modified. It served as an Adaptive Scaffold when it analyzed an existing response or artifact and identified errors, missing evidence, or directions for revision.

Computer-vision and machine-learning systems most often served as Operational Components by detecting or classifying states, objects, or patterns and linking inferences to model execution or device control. Their outputs could also serve as evidence for analysis and improvement. In cases where students observed misclassifications or low-confidence predictions and then added training images or retrained a model, the operational output became a basis for Analysis and Interpretation and Revision and Improvement.

Intelligent tutors and adaptive support systems mainly served as Conceptual Resources and Adaptive Scaffolds. They acted as Conceptual Resources when they answered learner questions or supplied relevant explanations. They acted as Adaptive Scaffolds when analysis of responses or performance histories changed the level of feedback, the subsequent task, or the learning path.

Technology type defines a range of possible functions but does not determine a functional role. Analysis of an AI-STEM environment should therefore document the AI operation and output, the activity context, and the subsequent student action at the case level rather than assign a fixed role to a product or algorithm.

V. DISCUSSION

A. Concentrations and Relative Gaps Across STEM Activities

Within the selected corpus, reported AI use was concentrated in Problem Understanding and Exploration and Revision and Improvement. This pattern may partly reflect the visibility of students' questions and information needs during

initial problem engagement, which provides a clear basis for supplying concepts, examples, and contextual information. During revision, errors, incomplete artifacts, and failed results likewise provide identifiable cues for diagnosis and suggested modification [33], [38]. The pattern is consistent with reviews reporting extensive use of generative AI, intelligent tutoring, and feedback systems for explanation and error correction [1], [2], but it should be interpreted as a feature of the reviewed corpus rather than a population-level distribution.

AI also appeared widely in Implementation and Construction and Experimentation and Testing. Students tested AI operations and failure conditions, and in some cases they responded to misclassifications by adding data or retraining a model [17], [22], [34]. In these cases, AI functioned both as a tool within problem solving and as an object whose performance and limitations students investigated. This pattern is consistent with the iterative character of STEM practice, which links implementation, testing, and improvement [5], [7], [8].

Analysis and Interpretation and Reflection were reported less often. In problem-based and project-based learning, these activities help transform experience gained through performance into knowledge and strategy [9], [10]. The lower count for Reflection may reflect both system design and reporting practice. Many systems organized interaction around immediate questions, errors, and incomplete artifacts, making exploration and revision more visible than delayed metacognitive activity. The coding rule also excluded general satisfaction or post-activity impressions and required explicit evidence that students used an AI-generated prompt or feedback to examine their reasoning. Reflective activity may therefore have occurred without being captured in system logs or article reports. The finding should be read as a lower frequency of explicitly reported AI-linked reflection, not as evidence that reflection was absent. Future studies should report whether students compared evidence, justified a decision, explained why a revision was needed, and retested a result.

B. Functional Roles Beyond Technology Labels

The four recurring roles should not be read as technology categories or as a comprehensive taxonomy of AI in STEM education. They constitute a provisional analytic framework derived from 37 reporting-eligible cases. Each role describes how an AI function or output was incorporated into a particular problem-solving activity, as evidenced by the action that followed. A single system could therefore be associated with several roles across different interactions.

An LLM served as a Conceptual Resource when it explained a concept, as a Generative Resource when it proposed an idea or design, and as an Adaptive Scaffold when it analyzed a student artifact and suggested revision. Computer vision or machine learning served as an Operational Component when recognition or prediction controlled a device, whereas a resulting misclassification could also become evidence for analysis and improvement. An intelligent tutor likewise performed different roles when it supplied a general explanation and when it adjusted feedback in response to a student's performance state.

This case-level framework complements rather than replaces technology-centered reviews [3], [6]. Technology type identifies possible operations; it does not establish how an output functioned in the learner's activity. The framework's analytical value lies in separating technical capability from reported use and in requiring an explicit link to a subsequent student action. Its boundaries and reproducibility should be tested in independent corpora.

C. Connecting AI Outputs to Students' Subsequent Actions

The reporting-eligibility rule required evidence of an AI function or output, the student activity in which it was used, and a subsequent student action. This rule distinguishes a description of what AI generated or performed from a documented interaction in which the output entered students' problem-solving activity. It also means that the case-level synthesis is shaped by what the source studies reported.

An explanation, code fragment, prediction, or feedback message alone does not establish that students used it to support problem solving. A more specific account is possible when students are reported to have reviewed the output and accepted, revised, or rejected it; compared it with an alternative; or executed and tested it again. Mediation in this review therefore denotes an observable connection between an AI output and a subsequent student action, not a causal claim that AI improved learning.

Future studies should first report the state of the student or task immediately before AI use and describe the AI function and output. They should then connect those elements to the student's acceptance, modification, rejection, or retry and to any resulting change in the artifact. This sequence addresses one dimension of the methodological gap identified in previous AI-STEM research: limited interaction-level evidence [2].

Relevant evidence may include dialogue records, revision histories for code and designs, model-execution logs, experimental data, students' explanations and justifications, and subsequent performance. Such records can show whether an output entered observable activity. Establishing whether that use improved understanding, transfer, or independent problem solving requires a separate causal or longitudinal design.

D. Implications for the Design and Evaluation of AI-STEM Systems

The findings support a set of design and evaluation propositions organized around learner activity and reported functional role rather than technology type. These propositions are not effects established by the review; they specify relationships that future system evaluations can test.

First, a system may be designed to infer the current activity from recent artifacts, attempts, errors, and requests and to vary the form of support accordingly. During Analysis and Interpretation or Reflection, prompts may ask learners to compare evidence, explain their reasoning, and retest a result instead of presenting a completed answer. Empirical studies should examine whether such prompts actually elicit the intended activity.

Second, interfaces should distinguish among conceptual explanations, candidate solutions, operational outputs, and diagnoses of student work. When feasible, outputs should

identify sources, assumptions, scope, and uncertainty so that learners can inspect the basis of a response.

Third, support may be staged to retain opportunities for student judgment. Learners can state an initial idea and rationale before receiving cues or feedback. Subsequent support can be adjusted or reduced only after its effects on performance and independent action have been examined. Teachers should retain authority over automated evaluation, task adaptation, and the conditions under which feedback is applied.

Fourth, evaluation should connect system outputs to subsequent student actions rather than stop at output accuracy. Linking each AI response to acceptance, modification, rejection, artifact change, or retry allows researchers to determine whether and how the output entered observable problem-solving activity. Claims about learning gains require additional outcome measures and an appropriate comparison or longitudinal design.

Accordingly, evaluation frameworks may consider technical performance, activity fit, output transparency, student judgment and revision, and evidence of increasing independence. Table X translates these findings into testable design and evaluation principles.

TABLE X. DESIGN AND EVALUATION PRINCIPLES FOR AI-STEM LEARNING SYSTEMS

Analytical Finding	Design or Evaluation Challenge	Testable Principle
Reported AI use was concentrated in Problem Understanding and Exploration and Revision and Improvement within the selected corpus.	Systems may focus on readily observable questions and errors while leaving interpretation and reflection less visible.	Include prompts intended to elicit Analysis and Interpretation and Reflection, and test whether students engage in those activities.
The same technology was associated with multiple reported functional roles.	A technology name alone does not specify the meaning of an output or the appropriate evaluation criterion.	Distinguish conceptual explanations, candidate solutions, operational outputs, and contingent diagnoses; disclose evidence, assumptions, and uncertainty.
Operational outputs were used as evidence for analysis, revision, or retry.	Technical accuracy does not establish educational value.	Assess model performance together with whether and how students interpret outputs, revise data or artifacts, and retest.
Students' subsequent actions were not consistently reported.	It is difficult to determine whether an AI output entered observable problem-solving activity.	Record each AI response together with student acceptance, modification, rejection, artifact change, and retry.
Some generative and adaptive systems supplied nearly complete responses.	Opportunities for student judgment may be reduced.	Elicit an initial student judgment, introduce support progressively, test whether it can be reduced without loss of performance, and preserve teacher oversight.

E. Limitations

This review was designed to describe where and how AI was reported within a defined journal corpus. It did not synthesize learning effects or apply a common risk-of-bias or methodological-quality appraisal across studies. The activity and role counts therefore describe the selected corpus and reporting-eligible cases; they do not establish the effectiveness, superiority, or population prevalence of any activity or role.

The search was restricted to English-language journal articles indexed in Scopus, Web of Science, or ERIC and retrieved with the specified AI and STEM terms. IEEE Xplore and the ACM Digital Library were not searched as separate platforms, and conference proceedings were excluded. Backward reference searching broadened retrieval, but technically oriented studies disseminated through computing and engineering venues may still be underrepresented.

The corpus was also temporally concentrated: 23 of the 29 studies were published in 2025 or during the partial 2026 search period. The findings should therefore be interpreted as a recent cross-section of a rapidly developing literature, not as a longitudinal account of change from 2017 to 2026.

Finally, the case-level synthesis depended on reporting detail. Only interactions in which the AI function or output, activity context, and subsequent student action were all explicit were retained, yielding 37 reporting-eligible cases. The resulting role framework may therefore reflect the reporting practices of better-documented studies and should be treated as provisional until it is tested in independent corpora. Underreporting may also have obscured reflective activity and blurred role boundaries.

VI. CONCLUSION

Within the selected 29-study corpus, AI was reported most often in Problem Understanding and Exploration and in Revision and Improvement; it was also reported in Implementation and Construction and in Experimentation and Testing. The case-level synthesis identified four recurring roles across 37 reporting-eligible interactions: Conceptual Resource, Generative Resource, Operational Component, and Adaptive Scaffold. These roles form a provisional framework for describing the reviewed cases, not a comprehensive taxonomy or estimate of role prevalence in AI-STEM education.

Whereas prior AI-STEM reviews have primarily organized research by technology type, system function, or learning outcome, the principal contribution of this review is an interaction-centered framework for examining how AI is integrated into students' problem-solving. The framework links the activity category in which AI is used, the functional role it assumes in that context, and the student judgment or action that follows. This approach shows why the same LLM, computer-vision model, or intelligent tutor may perform different roles across contexts. AI-STEM environments should therefore be described by connecting technical operation and output to

activity context and subsequent student activity rather than by product names or algorithm families alone.

Future research should report the learner or task state before AI use, the function and output provided, the learner's response, and any resulting change in the artifact or line of reasoning. Dialogue records, revision histories, model logs, experimental data, and learner explanations can strengthen this chain of evidence. Experiments, longitudinal studies, discourse analysis, and performance assessments are then needed to test effects on conceptual understanding, transfer, self-regulation, and independent problem solving. Research in early childhood, primary, vocational, and diverse linguistic and cultural settings is also needed to examine the framework's scope and boundary conditions.

Designers may use the four roles to specify what kind of support is intended at a given point in the activity. Conceptual Resources can be evaluated for source transparency and support for understanding; Generative Resources for how learners compare or modify candidates; Operational Components for access to input data and failure conditions; and Adaptive Scaffolds for the evidential basis and contingency of their guidance. These are design propositions that require empirical evaluation. Teachers should retain control over the scope of automation and the conditions under which automated actions require approval.

Accordingly, evaluations of AI-STEM environments should examine how a specific AI output entered students' problem-solving activity and what students did next, rather than merely whether AI was present or whether an outcome changed. Making this relationship explicit can improve the precision of research, system design, and evaluation while preserving attention to student judgment and responsibility. Whether particular configurations preserve or strengthen that responsibility remains an empirical question.

Declaration on Generative AI

Five Whys as an Epistemic-Honesty Scaffold for Multi-Agent LLM Analysis of Industrial Time Series

Yoshihiro Ochi, Yasunobu Uchiyama
Graduate School of Artificial Intelligence and Science, Rikkyo University, Tokyo, Japan

***Abstract*—Multi-agent large language model (LLM) pipelines increasingly analyse industrial time series. Where the true causes lie outside the recorded signal, they tend to report confident, plausible-sounding mechanisms not grounded in the data — a *false root-cause* handed to an engineer. We port Toyota's Five Whys onto such a multi-agent system (MAS) not as a decomposition tool but as a *reviewer frame*, and find it functions as an *epistemic-honesty scaffold*. On a non-public power-consumption series from a coating application process, whose true drivers are exogenous to the data, a single Five Whys chain drives the MAS to surface three grounded-sounding mechanisms and, by repeatedly asking *where in the data is this grounded?*, *retract each in turn*, converging on the honest verdict: the cause is exogenous to, and unverifiable from, this signal. A matched baseline, run to the same depth without the reviewer, commits to one such mechanism as a confident but unverified cause. In the three-seed mean — a directional, mean-level effect with large per-seed variance and occasional sign reversals — the scaffold raises contestation on the hard series, whereas on a clean benchmark with an in-data root it instead reconciles competing narratives onto that root, adapting to whether a groundable root exists rather than adding noise. The honest verdict is the right target: the strongest model states it unaided, so the scaffold's value concentrates where the model cannot self-regulate. We frame it as a discipline for human–AI coexistence: it lets a practitioner correctly receive what the MAS does and does not know.**

Keywords*—*Five Whys; multi-agent systems; large language models; root-cause analysis; epistemic honesty; causal abstention; industrial time series; argumentation framework; human–AI collaboration

I. Introduction

Multi-agent large language model (LLM) systems (MAS) are increasingly applied to industrial time-series analysis: a chain of LLM agents generates, tests, curates, and synthesises candidate findings, and a human practitioner receives a report to act on. In this setting the report's consumer is not a benchmark scorer but an engineer who must decide whether a stated cause is real. That places a specific demand on the system that aggregate quality rarely measures: *when the data cannot actually support a causal conclusion, the system should say so*, rather than supply a confident one.

Contemporary LLMs make this demand hard to meet, for an understandable reason. They are trained to be capable, fluent, and helpful — to behave, in effect, like an able student who always produces a well-formed answer. On data analysis that disposition has a side effect: asked why a signal behaves as it does, an MAS will readily produce a plausible, grounded-sounding mechanism even when the true cause is not present in the data at all. The result is a *confident false root-cause*: an answer that reads as authoritative and is, in fact, ungrounded. We do not regard this as a defect to be condemned; it is a predictable consequence of how these models are built. But on a factory floor, a confident false root-cause handed to an engineer is exactly the failure that matters, because it can be acted on. The question we take up is not how to make the model less capable or less confident, but how to *design around* the trait so that the practitioner correctly receives what the analysis does and does not know. This is the spirit of *jidoka* — automation with a human touch, in which the system surfaces its own abnormalities rather than running on silently [1] — carried from the shop floor to an analysis MAS.

Our design lever is domain method rather than model change. We take a method the same manufacturing tradition already uses for getting to true causes — Toyota's Five Whys [1] — and port it not as a decomposition tool but as a *reviewer frame* on the MAS: an auxiliary facilitator that repeatedly asks, of each causal claim, *where in the data is this grounded?* The facilitator sees no data and supplies no answers; it only forces the MAS to ground its own claims. We find that, used this way, the Five Whys functions less as a root-cause decomposition than as an *epistemic-honesty scaffold*.

The central evidence is a single Five Whys chain on a non-public industrial power-consumption series whose true drivers are exogenous to the recorded data. Under the scaffold, the chain drives the MAS to surface three grounded-sounding mechanisms — an ambient thermal driver, a dated structural break, an operating-mode cause — and to run new tests and *retract each in turn*, converging on the honest verdict: the cause is exogenous to, and unverifiable from, this signal. A matched baseline — the same MAS, run to the same depth and seed without the reviewer — instead commits its final report to one such mechanism as a confident but unverified cause. In the three-seed mean the scaffold raises contestation on this hard series — it leaves competing mechanisms standing as unresolved rather than collapsing them — whereas on a clean benchmark series with an in-data root the same scaffold instead *reconciles* the competing narratives onto that root. It adapts to whether a groundable root exists rather than merely adding noise. The honest verdict is moreover the *right* target, not a quirk of a weak model: the strongest model reaches "exogenous and unprovable" unaided, so the scaffold's value concentrates in the capability band where a model can act on the probing but cannot impose the discipline on itself.

A. Contributions

a) C1: The Five Whys as an epistemic-honesty scaffold: We reframe Toyota's Five Whys, ported as a data-blind reviewer frame, as a mechanism that elicits honest causal abstention in a data-analysis MAS rather than as a

decomposition tool. The claim metrics and the operator are each grounded in established frameworks — quantitative bipolar argumentation [2], the Toulmin model [3], Why-Because analysis and counterfactual causation [4], [5], and grounded-theory saturation [6] (Section III).

b) C2: A demonstration that the scaffold drives retraction of a confident false root-cause.: On a real industrial signal we show a single chain driving the MAS to self-refute three grounded-sounding mechanisms and attribute the cause honestly to outside the data, against a matched baseline that commits to one of them as a confident but unverified cause — *without the scaffold a confident, unverified root-cause is handed to the engineer; with it, the report abstains honestly* (Section V-A).

c) C3: The scaffold is adaptive and its value is bounded.: In the three-seed mean it surfaces unresolved mechanisms on the exogenous-root series and reconciles them on the in-data-root series; and its effect concentrates in a capability band, since the strongest model reaches the honest verdict unaided (Sections V-B to V-D). This contestation effect is *directional and mean-level* — per-seed variance is large and individual seeds can reverse — so the adaptive reading rests on the qualitative chain (Section V-A) and the regime contrast (Section V-D), with the three-seed-mean rise as corroboration rather than as a per-seed-stable claim.

Underlying all three is a single stance toward human–AI coexistence: rather than making the model less confident, we let a domain discipline surface what it cannot ground, so that a practitioner and an analysis MAS can each contribute what they are good at. Section II situates the work; Section III describes the MAS, metrics, and operator; Section IV the setup; Section V the results; Section VI the coexistence stance and limitations; Section VII the follow-on questions; and Section VIII concludes.

II. Related Work

We situate this work against five lines: self-evaluation bias, self-improvement, multi-agent debate, LLM-based root-cause analysis, and abstention. A common thread distinguishes our setting from all five: we target *ground-truth-free* industrial analysis, where the desired behaviour is not a better answer but an honest acknowledgement that the data cannot support one. We then note the established frameworks our method builds on.

1) Self-evaluation bias and sycophancy: A body of work documents that LLMs tend to favour a user's stated framing — sycophancy [7] — and that such tendencies are hard to remove by prompting alone. This literature *identifies* the disposition that makes an analysis MAS report a confident mechanism it has not grounded. We take that disposition as given and ask a complementary question: not how to detect the bias, but how to *operationally elicit* honest grounding despite it, through a reviewer loop that drives the system to retract what it cannot support.

2) Self-improvement and self-verification: Self-Refine [8], Reflexion [9], and Chain-of-Verification [10] have a model critique and improve its own output, and self-consistency aggregates multiple samples [11]. These methods are most effective on tasks with a checkable target, and Huang *et al.* [12] report that, without an external signal, self-correction of reasoning is limited. Our reviewer is deliberately not a self-critic that converges toward a correct answer: it supplies no answer, and the target is not a correct cause but an honest *abstention* when no cause is groundable. The turf differs — self-improvement pushes toward a known-good answer; we ask what to do when there is no answer to push toward.

3) Multi-agent debate: Debate among LLM agents can improve factuality and reasoning by having agents argue toward consensus [13]. Our configuration is *asymmetric* rather than peer debate: a data-blind facilitator interrogates an analyst, and the goal is not consensus but, where warranted, an honest non-answer. Convergence is the right outcome only when a groundable root exists (our benchmark regime, Section V-D); when it does not, the appropriate outcome is unresolved contestation, which a consensus objective would tend to paper over. Recent work in this venue extends debate with *interruptibility* — sentence-level disclosure and urgency-based turn-taking for early error correction among agents on benchmark QA [14]. Our setting differs on three axes: 1) the intervention is a *data-blind reviewer frame*, not agent–agent interruption; 2) the target is *honest causal abstention on real, ground-truth-free industrial time series*, not answer correctness on a benchmark; and 3) when no groundable root exists the desired outcome is *unresolved contestation*, not consensus. Tiered human-oversight frameworks for agentic systems [15] motivate *why* such honesty matters; we contribute an *implemented, empirically tested operator* rather than a governance taxonomy.

4) LLM-based root-cause analysis: A line of systems applies LLMs to root-cause analysis, typically to *generate* a most-likely root cause for an incident — RCACopilot reports high rates of plausible root causes [16] — while a recent benchmark finds that even strong models struggle to locate true root causes [17]. Our contribution runs in the opposite direction. We use the Five Whys not to *produce* a root cause but as a grounding interrogation, and the value we report is in *not* manufacturing one: when the cause is exogenous, the system is driven to abstain rather than to assert a clean root. Where this literature optimises the quality of a generated root, we characterise honest refusal to generate one as the property that matters for industrial deployment.

5) Abstention, calibration, and uncertainty: Abstention — teaching or prompting a model to say "I don't know" — is an effective hallucination mitigation, but it is hard in open-ended settings [18]. A related line estimates a model's confidence directly, through self-evaluation [19] or semantic uncertainty over sampled generations [20]. These calibrate *whether to answer* at the granularity of a whole output; our target is finer and structural — which *individual causal claim* in an analysis is groundable — and the abstention we seek is not a refusal to answer but an attribution of the cause to outside the data. Rather than train or prompt for abstention directly, we therefore let *causal* abstention emerge structurally: the claim graph plus the Five Whys chain drive the system to attribute a cause to outside the data, with the grounding made explicit, rather than to emit an unsupported one. The abstention is thus grounded ("exogenous and unverifiable from this signal") rather than a bare refusal.

6) Foundations the method builds on: The metrics and operator are not novel inventions but adaptations of established frameworks, which both grounds the design and keeps its novelty located in the conjunction rather than in any single part. Claim quantification uses quantitative bipolar argumentation frameworks (QBAFs) [2], [21], [22] with the Toulmin model [3] for base weight; causal structure and the test for a genuine causal link use Why-Because analysis [4] and counterfactual causation [5]; honest stopping uses theoretical saturation from grounded theory [6]; and the essence of the Five Whys as a single-path method follows the root-cause literature [23], [1]. The data-blind reviewer's repeated demand — *where in the data is this grounded?* — resembles Socratic questioning, but the operator is more constrained than open-ended elicitation: it follows a single causal chain toward a root and halts at an exogenous terminus (Section III-C). Separately, work that applies LLMs directly to time-series forecasting [24] is orthogonal to ours: we use the LLM not as a forecaster but as an analyst node whose causal claims must be grounded or honestly withdrawn.

7) The gap we fill: The novelty is the conjunction (Sections V to VI): A data-blind Five Whys reviewer that 1) elicits honest causal abstention rather than a generated root, 2) *adapts* to the data — reconciling when a root is groundable, surfacing contestation when it is not — and 3) concentrates its value in the capability band where a model cannot self-regulate, with the honest verdict shown to be the right target by the strongest model reaching it unaided. None of the five lines above, individually, occupies this position.

III. Method

We study a data-analysis multi-agent system (MAS) that iteratively analyses a single time series and accumulates its findings into a causal hypothesis graph (Section III-A). Onto this MAS we port Toyota's Five Whys not as a decomposition tool but as a *reviewer frame*: an auxiliary facilitator agent that interrogates the MAS's causal claims (Section III-C). We quantify each claim with three metrics drawn from established frameworks (Section III-B), compare the MAS with the reviewer on (*Five Whys*) and off (*baseline*) under a matched protocol (Section III-D), and stabilise the metrics with two engineering devices (Section III-E). Fig. 1 shows the overall flow.

A. The Data-Analysis MAS

The MAS analyses the series over a sequence of rounds. In each round a Strategy agent proposes analysis directions, one or more Analysis agents execute code and read plots to extract candidate insights (numeric and visual), and a Claim-Graph agent consolidates the round's insights into the running graph and induces edges between claims. A Domain agent contributes prior process knowledge as a prefix before any analysis insight exists. The unit of accumulated knowledge is the *claim graph*: its nodes are causal claims and its edges are typed relations — *explains* and *refines* (support) and *contradicts* and *supersedes* (attack). The graph is the object the reviewer interrogates and the object on which the three metrics are computed. After the final round, a Synthesis agent composes the arm's final report from this graph. We treat the MAS architecture as fixed across all conditions; the only manipulated factor is the presence or absence of the reviewer.

B. Three Claim Metrics

Each claim carries three metrics, deliberately chosen so that each maps onto an established, axiomatised framework rather than an ad hoc formula. The mapping treats the claim graph as a *quantitative bipolar argumentation framework* [2], [21]: claims are arguments, *explains*/*refines* are support, and *contradicts*/*supersedes* are attack (Fig. 2).

1) Grounding (base weight, Toulmin): Grounding is the claim's standalone evidential strength $g \in [0, 1]$, the degree to which it is backed by a specific, computed feature of the data rather than asserted. This is the base weight in the argumentation framework, and corresponds to the *grounds* and *qualifier* of the Toulmin argument model [3]: a claim that names an in-data feature and a test is well grounded; a claim restated from domain knowledge without a data test is not.

2) Validity (acceptability degree, QBAF): Validity is the claim's acceptability after support and attack have propagated through the graph, computed by an h-categorizer gradual semantics [2], [22]:

$$v(a) \;=\; \frac{g(a)}{1 + \sum_{b \in \mathrm{att}(a)} v(b)}, \tag{1}$$

where, $v(a)$ is this h-categorizer value, $g(a)$ is the grounding of claim a, and $\mathrm{att}(a)$ its attackers. A well-grounded claim with no surviving attacker keeps $v \approx g$; a claim that is contradicted by other surviving claims is driven down. We call a claim *contested* when attack has pushed its validity below its base weight ($v(a) < g(a)$). Crucially, grounding (the input) and validity (the propagated output) are kept distinct, so that "explains a lot but does not stand up" (high reach, low validity) and "stands up but explains little" are represented separately.

3) Importance (causal reach, Why-Because Graph): Importance is a claim's structural centrality in the causal graph, the reach of its *explains*/*refines* descendants, following the Why-Because Graph notion of a causal DAG and distance to a root [4]. Importance is orthogonal to validity: a central hub may be contested, and a peripheral claim may be valid. We use importance only to *order* which claim a Five Whys chain should interrogate next; we do not use it as a quality score, for reasons given in Section VI-B.

C. The Five Whys Operator

The reviewer implements the Five Whys as a facilitator that asks, of a target causal claim, *by what mechanism — grounded in a specific in-data feature — does this hold?*, and repeats the question against each successive answer. Three properties define the operator, and each rests on an established account rather than on our own stipulation:

a) A single causal chain: The reviewer drills one chain at a time from a target claim toward its root, matching the documented essence of Five Whys as a single-path, single-root method [23] and the chain structure of counterfactual causation [5].

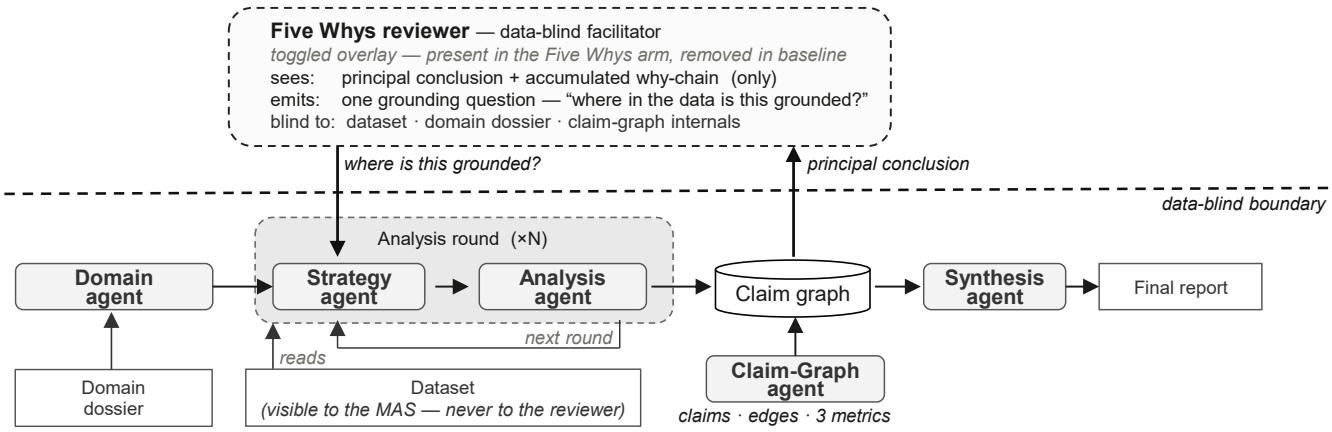

Fig. 1. System architecture, drawn to foreground the reviewer's data-blindness. The MAS analysis loop (Strategy → Analysis → Claim-Graph, $\times N$ rounds), fed by the dataset and domain dossier, is fixed across conditions. The Five Whys reviewer is a toggled overlay (present in the *Five Whys* arm, removed in *baseline*) that sits above a *data-blind boundary*: only the principal conclusion crosses up to it and only a single grounding question crosses back down into the next round — no data, dossier, or claim-graph internals are visible to the reviewer, so every retraction is the MAS refuting itself.

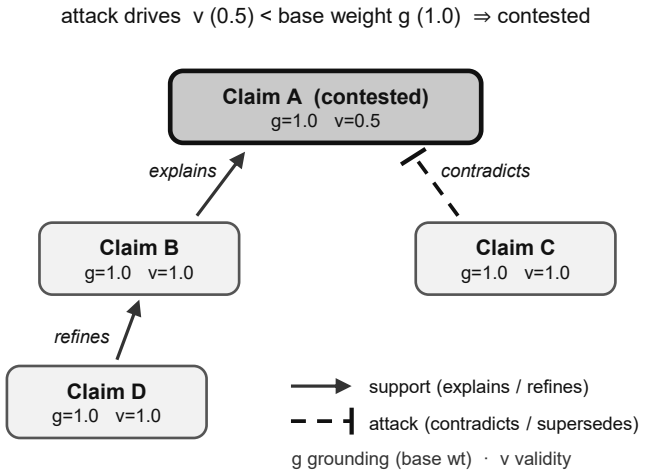

Fig. 2. Claim-graph anatomy and the *contested* condition. The figure isolates the two metrics that define contestation: each claim carries a grounding g (Toulmin base weight) and a validity v (the QBAF acceptability after support and attack propagate), and a claim is *contested* when an attack drives v below its base weight g. Here claim C's attack lowers claim A's validity to $0.5 < 1.0$, while B explains and D refines. (Importance, the third metric, orders interrogation only and does not enter this condition; see Section III-B.)

b) Each link a verified causal factor: A link survives only if the MAS can ground it in a data feature that passes a test; this is the Why-Because counterfactual test for whether a factor is causal [4], [5], not a looser notion of relevance.

c) Honest stopping at the true (possibly exogenous) root: The chain terminates when no new groundable link can be added — either a data-grounded root is reached, or the cause is found to lie outside the recorded signal and the reviewer declares it exogenous and unidentifiable. This is theoretical saturation in the grounded-theory sense [6]: stop when novelty is exhausted, including the honest case where the answer is "not determinable from this data."

A design property of the facilitator is central to the interpretation in Section V: *the reviewer never sees the data*. It supplies no analysis and no answers; it only demands that the MAS ground its own claims. The reviewer is thus a Socratic self-grounding device, and any retraction it elicits is the MAS refuting itself on evidence it computes, not the reviewer overriding it. The full operator prompt is given in Appendix A.

D. Matched On/Off Comparison

For each configuration we run the identical MAS twice: once with the reviewer (*Five Whys*) and once without (*baseline*). The two arms share the same Domain prefix and the same random seed, so they begin from the same state and diverge only through the reviewer's steering. Because that reviewer is data-blind and supplies no data, answers, or candidate mechanisms (Section III-C), the only factor the Five Whys arm adds is the demand to ground claims — not new information, data, or candidate answers — so a difference between the arms is the MAS responding to that demand. To remove depth as a confound, the baseline arm is run for as many analysis steps as the Five Whys arm took to reach its terminus (*baseline-match-Five Whys*): the comparison is between an MAS that analyses to the same depth with and without the Five Whys discipline, not between a longer and a shorter run. The final report of each arm is synthesised from its final claim graph under one shared, validity-aware procedure, so that any difference in the report reflects the graph state rather than two different synthesis methods. The synthesis is constrained to the epistemic standing of the goal-central claims: when the mechanism that answers the goal is contested or exogenous, the report's headline abstains rather than substituting a peripheral established claim. The reviewer does redirect which analyses the MAS performs — its grounding demand prompts confirmatory tests the baseline never runs — but that redirection is the scaffold's mechanism of action rather than a confound to remove: matched depth equalises the number of analysis steps, so the arms differ in what the MAS is driven to test, not in how much analysis it is afforded.

E. Foundation: Stable, Discriminative Metrics

Two engineering devices make the three metrics stable enough to compare across arms; we state them as robustness scaffolding, not as contributions. First, *edge accumulation with support*: edges are accumulated across rounds and only an edge re-induced in at least K rounds (support $\geq K$, here $K = 2$) is admitted to the metric computation. This is a vote-based confirmation across rounds, in the spirit of self-consistency [11], and it removes the metric churn that arises when a single round's stochastic edge extraction is taken at face value. Second, a *strategy gate* limits how many new directions are opened per round and requires each to name a new viewpoint or a verification need; this is theoretical sampling [6] applied to generation, and it keeps the graph from inflating with re-statements. With both devices in place the metric rankings are stable across rounds (no spurious reordering) while remaining discriminative, which is the precondition for reading on/off differences as signal.

IV. Experimental Setup

A. Datasets: Two Causal Regimes

We use two time series chosen to differ in one decisive respect: whether the true cause of the series' behaviour is approximable within the recorded signal or lies outside it.

1) Benchmark series (in-data root approximable): The public AirPassengers monthly series is a textbook case whose salient drivers — a growth trend and a seasonal cycle — are present in, or closely approximable from, the signal itself. It serves as the regime in which a groundable root exists, and as a contrast to the industrial case. We use "in-data root" in this operational sense — a terminus the analysis can ground in the signal, here trend and seasonality — not in the sense that an independently established causal mechanism is available.

2) Industrial series (root exogenous): The hard case is a non-public power-consumption time series from a coating application process, provided through the manufacturing partnership and abstracted here per the confidentiality conventions of the collaboration: we report no process names, line identifiers, or raw values, though we note its structural shape — a power-consumption signal with seasonal variation spanning multiple years. Its decisive property for this study is that the true drivers of the series — production scheduling, ambient conditions, and operator activity — are *not* recorded in the dataset. The signal alone is genuinely causally ambiguous: a competent analysis can ground *that* something changed but cannot, from this signal, prove *why*. This is the realistic industrial condition under which a confident false root-cause is most damaging, and it is where the scaffold's behaviour is most informative.

B. Models

The MAS and the reviewer are each instantiated with a large language model, and we vary the capability tier so as to locate where the scaffold's effect lives. We report results for two commercial models, `claude-haiku-4-5` (a mid-tier model) and `claude-opus-4-8` (a top-tier model), in the MAS and reviewer roles. We also ran a smaller open-weight model (`gemma`); on the hard series it neither sustains contestation nor self-regulates, and we report it only as a lower floor where the scaffold confers little benefit, without building on it.

C. Configurations, Seeds, and Protocol

The full experimental matrix crosses MAS model, reviewer model, and dataset; the analysis in this paper draws on four configuration groups (five run cells; E2-aux spans two pairings) that carry the reported findings (the remaining cells, including the open-weight floor and a set of facilitator-capability variants, are summarised but not featured; see Section VI-B). Their model pairings, datasets, and per-seed results are given in Table I:

- E1 / E2 (hero and primary contestation) — the primary industrial pairing; E1 is the single-chain dialogue of Section V-A and E2 its three-seed contestation count.
- E2-aux (auxiliary contestation) — two further capable-MAS pairings that corroborate the *direction* of the contestation effect across capability tiers.
- E3 (ceiling) — the top-tier peer pairing, both roles at the strongest model.
- E4 (contrast) — the benchmark-series rerun of the primary pairing (in-data root).

Every configuration is run for three random seeds. Unless noted, runs use a single Five Whys chain and a fixed round budget (max-rounds $= 8$); the on/off comparison uses the matched protocol of Section III-D. Aggregate quantities over seeds are reported as means; because the contestation count carries large seed-to-seed variance on the hard series (the three-seed mean rises for all capable-MAS configurations, but individual seeds vary in magnitude and sometimes in sign), we report the three-seed mean alongside the per-seed values (Section V-B) rather than implying tight intervals. The metric-stabilising foundation (Section III-E) is identical across all featured runs, and a post-experiment code audit confirmed that the design invariants (matched depth, edge-support accumulation, single-chain structure, and reviewer fidelity — no leading the witness, see Appendix A) held across all cells (Section VI-B).

V. Results

We first present the qualitative core of the paper: a single Five Whys chain driving an MAS to retract a sequence of confident but ungrounded causal claims on the industrial series, and the matched baseline that, without the reviewer, commits its final report to one such claim as a confident but unverified cause (Section V-A). We then show that this behaviour is reproducible as a mean-level rise in contestation across capability pairings on the hard series (Section V-B), that the honest verdict is the right target and the scaffold's value concentrates where the model cannot reach it unaided (Section V-C), and that on a series with an in-data root the same scaffold instead reconciles rather than contests (Section V-D).

A. Single Chain Retracts Three Ungrounded Mechanisms

On the industrial series, the unscaffolded MAS (baseline) produces a fluent, confident report that commits to a primary root-cause without a confirming test. With the reviewer present (Five Whys), starting from the same state and the same seed, a

Reviewer↔MAS dialogue on the industrial series (sanitized; one Five Whys chain, three turning points)

Turning point 1 — ambient/seasonal mechanism.

MAS (Five Whys off): holds, grounded and unchallenged, that the decline is "ambient-driven thermal load variation rather than structural control changes."

Reviewer (Five Whys): "Where *in the data* is that mechanism grounded — rather than a bare seasonal correlation you have yourself flagged as unverifiable without ambient data?"

MAS (self-revision): "Seasonal ambient-responsive thermal control is *not* the primary driver …the seasonal mean pattern contradicts the signature expected from ambient compensation …ambient compensation is absent or negligible."

Turning point 2 — a dated structural break.

MAS (Five Whys off): asserts, without change-point detection, a structural break on a specific date with a substantial median drop.

Reviewer (Five Whys): "Is there *any* observable scheduling feature whose month-by-month profile matches the decline — or must you concede that no on-data scheduling feature exists?"

MAS (self-revision): re-runs change-point detection and self-corrects: the break is at *a different, earlier date than previously hypothesised*, and is "a *distributional* change" — a severalfold variance increase at near-flat mean power — "rather than a sustained mean power reduction."

Turning point 3 — an operating-mode cause.

MAS (Five Whys off): attributes the decline to a switch between operating modes.

Reviewer (Five Whys): "By what mechanism, grounded in a specific in-data feature, does operating mode drive the monotonic power fall?"

MAS (self-revision): tests it and rejects it: the relevant activity count is "essentially flat across months" (a near-zero, non-significant correlation), so reduced operational intensity "does *not* explain the observed power variation."

Terminus. The Five Whys *final report* itself declines to prescribe a cause: its headline states that the analysis "cannot identify a single, data-grounded" improvement and that the drivers are *exogenous* to the power signal and *not verifiable from the available data alone*. The matched baseline's final report instead commits to a confident primary recommendation — an operating-mode scheduling change it credits with the observed decline — while conceding it cannot be verified from the data and "requires correlated … logs to validate."

Fig. 3. One Five Whys chain on the industrial series: the MAS refutes three successive grounded-sounding mechanisms on evidence it computes itself and attributes the cause honestly to outside the data, so that its *final report* declines to prescribe one. The matched baseline (same seed, same depth) instead commits to a confident but unverified root-cause. Dates and raw values are abstracted for confidentiality; the mechanism types and the self-refutation structure are unchanged.

single chain drives the same MAS to propose three grounded-sounding mechanisms in turn — an ambient-temperature-driven thermal load, a dated structural break, and a switch of operating mode — to *test and retract each*, and to land on the verdict that the cause is exogenous to, and unverifiable from, the power signal alone. Fig. 3 reproduces the three turning points of the chain (run E1, seed 1).

Two properties of this exchange matter for the interpretation. First, every retraction is the MAS refuting *itself*: the reviewer supplies no data and no answer and names no candidate mechanism, only the demand to ground the claim (Section III-C), so the new change-point test, the operating-mode regression, and the rejection of each are the MAS's own work on evidence it computes. The reviewer's questions are pointed, but they add no information beyond *where in the data is this grounded?*; what changes the verdict is the test the MAS then runs, not a fact the reviewer supplies. Second, the baseline is not a weaker analyst that simply missed these tests; it is the *same* MAS run to the same depth, and left to itself its final report commits to a confident primary recommendation it cannot verify. The difference between a confident, unverified root-cause and an honest "exogenous and unverifiable" is, here, exactly the presence of the Five Whys discipline.

B. Contestation Rises on the Hard Series, in the Mean

The single-chain behaviour reproduces in aggregate. When the true root is not in the data, the scaffold does not manufacture a clean resolution; it surfaces the competing mechanisms as *unresolved*, which registers as a rise in the number of contested claims (validity driven below base weight, Section III-B). Table I and Fig. 4 report the three-seed mean contested count with the reviewer off and on, for the capable-MAS configurations on the industrial series.

Across the three capable-MAS pairings the three-seed *mean* moves the same way: the reviewer raises the mean contested count on the hard series (Table I). The primary pairing (`haiku` × `opus`, the configuration of Fig. 3) rises in the mean from 5.3 to 9.7, and the two auxiliary pairings likewise ($15.0 \rightarrow 19.7$ and $10.3 \rightarrow 13.0$). We read this *aggregate* direction — all three capable-MAS means rise — not the magnitude or any single seed, as the signal: the per-seed counts are highly variable and individual seeds can reverse (Fig. 4). The rise is thus a mean-level effect: in this ground-truth-free setting the magnitude is not the signal and the robust evidence is the qualitative mechanism (Section V-A) together with the regime contrast (Sections V-C to V-D). The interpretation is the one the dialogue makes concrete — on a signal whose causes are exogenous, an honest analysis should leave the competing mechanisms standing as contested rather than collapse them into one confident story.

C. The Honest Verdict is the Target; the Scaffold's Value is Bounded

That "exogenous and unverifiable" is the *appropriate* destination, not an artefact of a particular model, is shown by the top-tier peer configuration (E3, MAS and reviewer both `opus`). Here the baseline already reaches the honest verdict unaided: without any prompting it states in its own report that the "causes are exogenous and unprovable from this data … cannot be proven," and contests its own claims. With the reviewer added the contested count does not move (saturated, $9.3 = 9.3$ over three seeds); the Five Whys only sharpens framing (separating a statistical change from an unprovable cause) rather than producing a categorical correction.

The scaffold's value is therefore bounded above by the model's own capability for honest self-regulation: where the model already reaches the honest terminal on its own, the scaffold is redundant. It is also bounded below — the smaller open-weight model gains little, as it neither sustains the contestation nor acts on the probing (Section IV-B). The effect

TABLE I. CONTESTED-CLAIM COUNT ON THE INDUSTRIAL SERIES, BASELINE VS. FIVE WHYS: THREE-SEED MEAN WITH THE THREE INDIVIDUAL SEED VALUES IN PARENTHESES. FOR THE CAPABLE-MAS PAIRINGS THE THREE-SEED *mean* RISES (THE SCAFFOLD SURFACES UNRESOLVED COMPETING MECHANISMS), THOUGH PER-SEED COUNTS ARE HIGHLY VARIABLE AND INDIVIDUAL SEEDS CAN REVERSE — THE EFFECT IS AT THE MEAN LEVEL. THE TOP-TIER PEER PAIRING IS PER-SEED IDENTICAL BETWEEN ARMS (E3 SATURATION, SECTION V-C); ON THE BENCHMARK SERIES ALL THREE SEEDS MOVE DOWN (E4 RECONCILE, SECTION V-D). A LEADING CONFIG COLUMN MAPS EACH ROW TO THE E1–E4 CONFIGURATIONS. PER-SEED COUNTS ARE EXTRACTED FROM THE FROZEN RUN ARTEFACTS

Config	MAS × reviewer	Dataset	baseline (per seed)	Five Whys (per seed)	mean effect
E1 / E2	`haiku × opus`	industrial	5.3 (9, 4, 3)	9.7 (13, 2, 14)	↑ surface
E2-aux	`opus × haiku`	industrial	15.0 (17, 15, 13)	19.7 (23, 25, 11)	↑ surface
E2-aux	`haiku × haiku`	industrial	10.3 (18, 11, 2)	13.0 (34, 5, 0)	↑ surface
E3	`opus × opus`	industrial	9.3 (8, 9, 11)	9.3 (8, 9, 11)	= saturated
E4	`haiku × opus`	benchmark	7.0 (7, 2, 12)	3.7 (0, 0, 11)	↓ reconcile

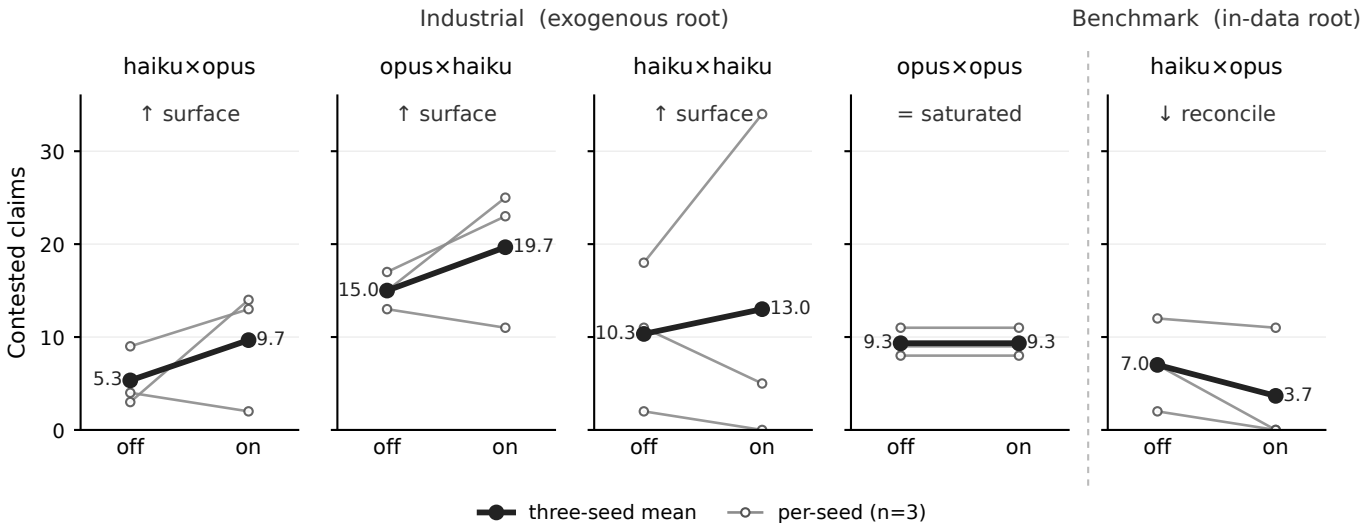

Fig. 4. Contested-claim count, baseline (Five Whys off) → Five Whys (on), as a paired-slope plot. Each thin line is one seed and the bold line is the three-seed mean; direction is read from each line's own slope. On the industrial series the three-seed mean rises for all capable-MAS pairings (↑ surface) while individual seeds reverse — notably `haiku×haiku`, whose mean rise is driven by a single seed (18→34) against two that fall; the top-tier peer pairing is per-seed identical between arms (= saturated); the benchmark series moves down in all three seeds (↓ reconcile). The industrial-↑ versus benchmark-↓ contrast is the adaptive signature of Section V-D; the per-seed values are tabulated in Table I.

of Sections V-A to V-B lives in the band between these bounds: a model capable enough to act on "where is this grounded?" but not capable enough to impose that discipline on itself unprompted. This is the band in which an analysis MAS would otherwise hand an engineer a confident false root-cause, and it is exactly where the scaffold pays off.

D. The Scaffold Adapts: It Reconciles When a Root Exists

The rise in contestation on the hard series is not the scaffold "adding noise." On the benchmark series, whose root is approximable in the data, the *same* scaffold has the opposite effect: it drives the contested count *down* (E4, 7.0 → 3.7 in the mean, and down in all three seeds). There the Five Whys chain converges the competing narratives — whether a mid-series event created demand or merely accommodated it — onto a single in-data root (the arithmetic of the growth-and-seasonality structure), reconciling what looked contradictory. The scaffold thus does the structurally appropriate thing in each regime: it *reconciles* competing mechanisms when a groundable root exists, and *surfaces* them as contested when it does not. The discriminating variable is the data, not the prompt: a single operator produces convergence or honest non-resolution according to whether the signal can support a root at all. The regime contrast also speaks to a measurement concern: if the rise merely reflected the reviewer enlarging the graph, the count would rise in both regimes; instead it falls on the benchmark and rises only where the root is exogenous.

VI. DISCUSSION

A. An Adaptive Discipline for Human–AI Coexistence

The scaffold's behaviour across the two regimes (Section V-D) is what makes it a discipline rather than a bias. A device that simply increased scepticism would degrade the benchmark case, where a clean root genuinely exists; instead the same operator reconciles there and surfaces contestation on the exogenous-root signal. The discriminating variable is the data, not the prompt. Two design properties account for

this. First, the facilitator is *data-blind*: it supplies no answers and only demands that the MAS ground its own claims, so every convergence or retraction is the analyst's own work on evidence it computes. The honesty is elicited, not injected. Second, the discipline is structural: it is the Five Whys chain, and the argumentation graph it acts on, that carry the behaviour, and the effect survives changing which model occupies the analyst and reviewer roles (Section V-B).

We read this as a small, concrete instance of a broader stance on how to deploy capable LLMs on the factory floor. The aim is not to make the model less confident or to catch it out, but to let a domain method — one the manufacturing tradition already trusts for getting to true causes — surface what the analysis can and cannot ground, so that a practitioner receives the system's output correctly. This is the *genchi-genbutsu* ("go and see") instinct — grounding the question in what the data actually shows — operationalised as a reviewer loop, and the *jidoka* instinct (let the system raise its own hand when something is not right) applied to causal reporting. It is also why the value is bounded (Section V-C): where the model already regulates itself the discipline is redundant, and where it cannot act on the probing at all it does not help. The interesting and useful band is the one in between — precisely where a capable, fluent analysis MAS would otherwise hand an engineer a confident false root-cause.

1) Deployment considerations: The scaffold is cheap to add: one data-blind reviewer call per analysis round (bounded at eight rounds here), and because the reviewer sees only the running conclusion and the why-chain — not the data or the claim graph — its context stays small. It changes nothing about the model, adds no sensors, and needs no labelled data, so the adoption barrier is low; its one prerequisite is an analyst model capable enough to act on the probing (Section V-C). A practitioner can judge whether it applies to a new process by one structural question: are the variables that truly drive the signal recorded in the data, or exogenous to it? Where they are exogenous (our industrial case) the honest-abstention behaviour is the relevant value; where they are in-data the scaffold instead reconciles (Section V-D). The facilitator is itself an LLM; putting a human practitioner in that role is the *jidoka*-facing extension we leave to Section VII.

B. Limitations

1) The primary evidence is qualitative, by design: Our central claim rests on a mechanism — self-refutation toward honest abstention — shown most clearly in a single-chain dialogue and corroborated by a directional contestation effect in the three-seed mean. We deliberately keep aggregate metrics off the main axis. Importance ranking is distorted on a non-trivial fraction of cells (about forty per cent) by cycles in the induced causal subgraph, which inflate the centrality of claims inside a cycle; a code audit located this and we therefore do not rest any claim on the importance ordering (the fix is deferred, Section VII). The three metrics are operationalisations grounded in established frameworks rather than validated instruments: we do not establish independently that grounding, validity, and contestation measure causal support or epistemic quality, which is part of why the aggregate metrics are kept off the main axis. We state these as limitations and do not build on them.

2) Explored but not featured: In the course of the study we examined several stronger hypotheses that did not reproduce robustly across three seeds, and we report that we set them aside rather than feature them: that the scaffold's marginal value is largest at intermediate model capability (an inverted-U), that a weak open-weight model fabricates a clean false root under the scaffold, and that reviewer capability and analyst capability form two separable axes governing stopping discipline. Each was visible in a single seed but did not survive seeding, and we treat the robust core — honest self-retraction and exogenous attribution — as the contribution. We mention the open-weight model only as a lower floor where the scaffold confers little benefit. Recording these explored-and-set-aside hypotheses is deliberate: it distinguishes our prospectively specified on/off comparison from post-hoc reading.

3) Ground truth is unconfirmable on the industrial series: By construction the true cause of the industrial signal is not in the data, so we cannot certify that the MAS's corrected analysis (Section V-A) is absolutely right. What we claim is narrower and well-supported: under the scaffold the system's *run-internal epistemics* forced a confident initial mechanism to be re-tested and withdrawn. We claim the honesty of the process and the appropriateness of the exogenous verdict, not the absolute correctness of any intermediate number; we cannot exclude that the scaffold occasionally drives retraction of a claim that was in fact correct — a cost we accept in exchange for not handing on unfounded ones.

4) Scope: The study uses two datasets, a single Five Whys chain, and three seeds. The contestation effect is a three-seed-mean rise across the capable-MAS configurations, with large per-seed variance and occasional per-seed sign reversals (Section V-B); it is a mean-level, not a per-seed-stable, effect, and the saturation and reconciliation results are each shown on one configuration. The behaviour should be expected to generalise only as far as these conditions; Section VII sketches the extensions that would test it. We restrict all claims to observed behaviour and offer no speculation about the internal causes of any particular model's outputs. The industrial series is also non-public, so that arm cannot be independently replicated; the benchmark arm uses a public dataset. We report model identifiers, seeds, chain count, and round budget, and give the operator in Appendix A, but not full API-level configuration such as sampling parameters, context limits, and retry behaviour, on which LLM outputs can depend.

5) What would disconfirm the claim, and what is not yet isolated: We state the claim so that it can fail: the epistemic-honesty reading would be disconfirmed if, within the capability band, the data-blind reviewer left confident ungrounded mechanisms standing, or drove the MAS to fabricate a clean root rather than to retract — neither of which we observe in the featured runs, though both are conceivable outside the band. Two comparisons are, moreover, suggestive rather than isolating. The regime contrast (Section V-D) varies the root locus (in-data vs. exogenous), but the two datasets also differ in complexity, in the presence of structural breaks, and in likely pre-training familiarity; the graded dataset spectrum of Section VII is what would isolate the root-locus variable. And the featured analyst–reviewer pairs are all within one model family; whether the self-retraction behaviour holds for cross-family pairings — the more realistic deployment

— is untested. Finally, the exogenous terminus rests on the reviewer's judgement that on-data alternatives are exhausted (Appendix A) rather than on a formal stopping rule, which may contribute to the per-seed variance noted above. Nor have we ablated the reviewer prompt itself: whether the retraction behaviour is specific to the Five Whys framing or would follow from any sceptical grounding demand is not isolated here, and a prompt ablation is the direct test. The reviewer is also data-blind but not context-free — it sees the principal conclusion and the accumulated why-chain. Those contain the MAS's own prior statements, so the channel introduces no evidence from outside the run, but it does carry the analysis history.

VII. Future Work

1) A graph fix for importance: The causal-cycle distortion of the importance metric (Section VI-B) has a single-boundary fix: drop the low-support back-edges that close a cycle at edge-admission time, or compute reach on the strongly-connected-component condensation of the causal graph. With importance made trustworthy, the ranking could re-enter the analysis as a quantitative axis alongside the qualitative evidence rather than being held out of it.

2) A dataset spectrum from in-data to exogenous root: We showed reconciliation on a benchmark with an in-data root and contestation-surfacing on an industrial signal with an exogenous root. A natural next step is to vary the clarity of the root continuously — a graded series of datasets between the two regimes — and trace the reconcile-to-surface transition, which would turn the qualitative "adapts to the data" claim into a measured curve.

3) Multi-chain and broader model coverage: The present study uses a single Five Whys chain; the same honest-terminal behaviour should be tested when several independent chains are drilled in one run, and across a wider range of analyst and reviewer models — including cross-family analyst–reviewer pairings (the more realistic deployment) and additional open-weight families — to map the capability band in which the scaffold pays off.

4) Human-in-the-loop facilitation: The reviewer here is itself an LLM that never sees the data. A longer-term direction — and the one closest to the *jidoka* aim of the work — is to study how a human practitioner's way of asking "where is this grounded?" changes what the MAS surfaces, treating the facilitator role as a locus of stage-targeted human intervention rather than a fixed automated agent. We leave the design and evaluation of that human-facing variant to follow-on work.

VIII. Conclusion

We ported Toyota's Five Whys onto a data-analysis multi-agent system not as a decomposition tool but as a data-blind reviewer frame, and found that it functions as an epistemic-honesty scaffold. On a real industrial signal whose causes are exogenous to the recorded data, a single Five Whys chain drove the system to retract three confident, grounded-sounding mechanisms in turn and to attribute the cause honestly to outside the data, where a matched baseline committed to a confident but unverified cause. The scaffold adapts to the data — it reconciles competing narratives when a groundable root exists and surfaces them as contested when it does not — and its value concentrates in the capability band where a model can act on the probing but cannot regulate itself unprompted, since the strongest model reaches the honest verdict unaided.

The contribution is less a new algorithm than a way of deploying capable LLMs honestly: rather than making the model less confident, we let a domain discipline the manufacturing tradition already trusts surface what an analysis cannot ground, so that a practitioner correctly receives what the system does and does not know. That is the form of human–AI coexistence we think industrial data analysis needs — not an AI that always answers, but one that is disciplined into knowing, and saying, when it cannot.

Declaration on Generative AI

APPENDIX A
THE FIVE WHYS REVIEWER OPERATOR

The reviewer is a facilitator agent (the top-tier model in the featured runs) that issues exactly one grounded "why" per round. It operates under a *clean-facilitator view*: it is given only the system's principal conclusion and the accumulated why-chain — *not* the dataset, the domain dossier, or the claim graph itself — so it cannot supply or verify facts itself and can only require the system to ground its own answers. The discipline, condensed from the operator template, is:

1) Chain linkage: Target the specific claim in the system's most recent answer; on the first round, anchor on the principal conclusion.

2) Mechanism, not restatement: Demand a causal mechanism, not a paraphrase, category, or bare correlation ("that restates the fact — why does it occur?").

*3) Fact-grounding (*genchi-genbutsu*).:* Require the system to cite a specific data feature or domain fact for its own answer; if it cites none or is speculative, send it back to the data and re-ask rather than descend. Never fill the evidence in.

4) No symptom-stop / single chain.: Treat an intermediate symptom as a new problem and continue; follow one dominant causal line rather than branching.

5) Therefore-check.: Periodically read the chain forward with "therefore" to catch logical leaps before going deeper.

6) Dynamic stop at the root.: Do not stop at a fixed count; stop when the chain reaches a generative driver at the edge of the evidence. The number five is a guideline [1].

The property that matters most for time-series analysis is the *observational-data terminus*. The operator explicitly recognises that the generative root of an observed series is often exogenous — not a variable present in the data — and instructs the reviewer, once the pattern's shape is grounded and the on-data alternatives are refuted, to declare the root reached and to name it only as "exogenous (a candidate from the domain context), not verifiable from the data," without asserting which specific domain fact it is. A guard prevents premature exogenous declaration: while the shape is still ungrounded, an unanswered "why" is genuine evasion of an answerable question and must be re-asked. This is what makes "exogenous and unverifiable" a disciplined terminus rather than an escape hatch.

The single-question phrasing template is:

> "Why — and by what mechanism — does {specific prior claim} occur, and where in the data is that grounded?"

The reviewer may add a brief pointer to where grounding should come from, but must not bundle several targets, assert or pre-answer the conclusion (leading the witness is a fidelity violation), or write a multi-paragraph interrogation. Each round emits one injected "why"; when the dynamic-stop test is met the reviewer instead declares the root reached, emits no further question, and states the root cause and the chain read backward with "therefore." A safety cap bounds recursion at eight rounds.

A Reproducible Mobile-Cloud Framework for Preliminary Non-Invasive Anemia Screening from Palpebral Conjunctiva Images

Enrique Lee Huamaní*, Erasmo Montufar-Barrientos, Victor Romero-Alva, Linett Velasquez-Jimenez
Image Processing Research Laboratory (INTI-Lab)
Universidad de Ciencias y Humanidades, Lima, Perú

***Abstract*—Non-invasive anemia screening from palpebral conjunctiva images may support preliminary triage when access to laboratory hemoglobin testing is limited. This study presents and evaluates a reproducible mobile-cloud framework that integrates guided image capture, automated eye-region localization, region-of-interest extraction, color normalization, image-quality control, deep-learning inference, probability calibration, longitudinal storage, and user feedback. The evaluation used five-fold image-level cross-validation, a locked hold-out image set, preprocessing ablation, mobile efficiency benchmarking, and a formative usability assessment. Among the evaluated backbones, EfficientNet-B0 achieved a cross-validated accuracy of 87.84%±0.94, sensitivity of 89.20%±1.38, specificity of 86.78%±0.72, F1-score of 86.68%±0.77, and area under the receiver operating characteristic curve of 0.927±0.007. On the locked hold-out set of 120 images, the model achieved 85.83% accuracy, 87.93% sensitivity, 83.87% specificity, 83.61% precision, 85.71% F1-score, and 0.952 AUC. The ablation analysis showed incremental gains from automated ROI extraction, white balancing, contrast normalization, and image-quality rejection. The results indicate that predictive performance, calibration, acquisition quality, and deployment cost should be evaluated together when designing mobile screening support systems. The tool is intended for preliminary screening and does not replace laboratory confirmation.**

***Keywords*—Anemia screening; conjunctival image analysis; mobile health; deep learning; EfficientNet; mobile-cloud computing; reproducible research**

I. Introduction

Anemia remains a major public-health problem, particularly among children, pregnant women, and populations living in low- and middle-income regions [1], [2]. The diagnostic reference is laboratory measurement of hemoglobin concentration through venous or capillary blood collection. Although accurate, this procedure requires trained personnel, consumables, equipment, and an appropriate care pathway [3]. These requirements motivate complementary screening technologies that can identify individuals who should receive confirmatory testing.

The palpebral conjunctiva is clinically relevant because reduced tissue redness can be associated with lower hemoglobin concentration. Smartphone cameras and image-processing methods have therefore been investigated as non-invasive sources of information for anemia screening [4], [5].

Classical color descriptors, machine-learning algorithms, and convolutional neural networks (CNNs) have been applied to conjunctiva, fingernail, palm, lip, and scleral imagery [6]–[8]. However, several recurring limitations reduce the transferability of reported results: insufficient control of image-level data leakage, manual cropping, incomplete reporting of data provenance, single-run evaluation, limited independent testing, limited analysis of model calibration, and absence of deployment or usability evidence.

A technically strong mobile-health paper should evaluate more than predictive performance. A deployable screening system requires acquisition guidance, image-quality verification, secure communication, preprocessing, calibrated inference, understandable feedback, longitudinal history, and explicit failure handling. It should also report sensitivity and specificity for the clinically important class, rather than relying exclusively on aggregated accuracy. Furthermore, a system intended for mobile or edge environments must quantify model size, inference latency, memory demand, and the effect of optimization techniques such as post-training quantization.

This study integrates these requirements into an end-to-end mobile screening framework and evaluates the complete workflow using image-level cross-validation, a locked hold-out image set, ablation analysis, calibration, and deployment-oriented measurements. The paper addresses the following research questions:

- RQ1: Which lightweight CNN backbone provides the best balance between predictive performance and deployment cost?
- RQ2: How much does each preprocessing and image-quality component contribute to the final result?
- RQ3: Does the selected model retain acceptable sensitivity and specificity on a locked hold-out image set?
- RQ4: Can the full mobile-cloud workflow provide responsive and usable interaction while preserving privacy and auditability?

*Corresponding author.

The main contributions are: 1) an end-to-end mobile-cloud architecture for guided conjunctival image acquisition and preliminary anemia screening; 2) an image-level evaluation protocol with five-fold cross-validation and a locked hold-out image set; 3) comparison of MobileNetV3-Small, ResNet-34, ResNet-50, and EfficientNet-B0 using predictive, calibration, and resource metrics; 4) an ablation study that isolates the contribution of ROI extraction, color normalization, contrast enhancement, and quality rejection; and 5) a reproducibility-oriented workflow structured around fold-level metrics, image-level predictions, image-flow records, figures, and scripts that generate results directly from exported study outputs.

II. Related Work

Visual assessment of conjunctival pallor has long been used as a clinical clue, but manual inspection is subjective and can be influenced by illumination, observer experience, and patient characteristics. Suner et al. investigated smartphone-camera prediction of anemia and hemoglobin concentration, demonstrating the potential of consumer imaging under controlled acquisition [4]. Rivero-Palacio et al. described a mobile application for anemia detection through ocular conjunctiva images [5]. Asare et al. compared multiple anatomical sites and machine-learning models, emphasizing that image source and region selection can materially affect performance [6].

The adoption of transfer learning has enabled more robust feature extraction from relatively small medical-image datasets. Kim et al. reviewed transfer learning for medical image classification and highlighted the importance of dataset shift, fine-tuning strategy, and reproducible validation [9]. CNN-based conjunctiva studies have evaluated architectures such as AlexNet, MobileNetV2, and ResNet-50 [10]. EfficientNet is especially relevant to mobile-health applications because compound scaling was designed to improve the accuracy-efficiency trade-off [11], while residual networks remain strong general-purpose baselines [12].

Despite progress, an image classifier alone is not a complete mobile-health system. Applications must account for image capture, cloud or on-device inference, privacy, longitudinal storage, and user feedback. Existing mobile-health research provides architectural precedents for privacy-aware cloud services and multimodal mobile interaction [13], [14]. The present study combines these system concerns with an image-level evaluation protocol and explicit reporting of data provenance, calibration, deployment cost, and study limitations.

III. Proposed Mobile-Cloud Framework

A. System Architecture

The framework follows a client-service design, as illustrated in Fig. 1. The mobile interaction layer is implemented conceptually with React Native and Expo to support Android, iOS, and Web from a shared code base. The application guides the user through lower-eyelid eversion, verifies framing, checks basic image quality, displays the screening probability, and stores a longitudinal history.

The secure API gateway authenticates the request, validates metadata, enforces image-size limits, and transmits the image through encrypted transport. A preprocessing service detects the eye region, extracts the conjunctival ROI, applies quality control, and normalizes the image. The inference service returns a calibrated anemia probability, a binary screening label, and an uncertainty flag. The persistence layer stores a pseudonymous case identifier, prediction probability, model version, quality indicators, and timestamp. Raw images should be retained only when explicitly justified by consent, governance, and research protocol (Table I).

B. Image-Quality Control and ROI Extraction

Raw mobile images vary in distance, angle, focus, exposure, and visible anatomy. The proposed pipeline therefore applies five sequential stages, shown in Fig. 2: capture guidance, image-quality gating, ROI detection, normalization, and prediction. Let I denote the input image and let B = (x, y, w, h) be the detected eye bounding box. The expanded box is

$$B' = (x - \alpha w,\ y - \alpha h,\ w(1 + 2\alpha),\ h(1 + 2\alpha)) \quad (1)$$

where, α = 0.20 provides contextual tissue around the detected region. The cropped image is resized to 224 $\times$ 224 pixels. A gray-world white-balance transform is applied to reduce camera-dependent color cast, followed by contrast-limited adaptive histogram equalization (CLAHE) on the luminance channel. The final tensor is normalized with ImageNet channel statistics because the candidate backbones use ImageNet-pretrained weights.

The quality gate rejects images when the Laplacian focus score is below a calibrated threshold, the mean luminance is outside the permitted interval, the detected-eye confidence is insufficient, or the conjunctival visibility ratio is low. Rejected images are not classified; instead, the application requests recapture and presents a specific correction message.

C. Classification and Calibration

Four ImageNet-pretrained backbones are considered: MobileNetV3-Small, ResNet-34, ResNet-50, and EfficientNet-B0. The original classification head is replaced by a dropout layer with probability p = 0.30 and a two-class fully connected layer. For an input tensor X, the uncalibrated probability is

$$\hat{p} = \mathrm{softmax}(W\ \mathrm{Dropout}(f_\theta(X)) + b) \quad (2)$$

where, f_θ is the convolutional feature extractor. Temperature scaling is fitted on the validation predictions. If z is the anemia logit and T $>$ 0 is the learned temperature, the calibrated probability is

$$p_T = \sigma\Big(\frac{z}{T}\Big) \quad (3)$$

The operating threshold is selected on validation data to maximize Youden's J statistic while imposing a minimum sensitivity requirement. The threshold is then locked before final evaluation on the locked hold-out image set.

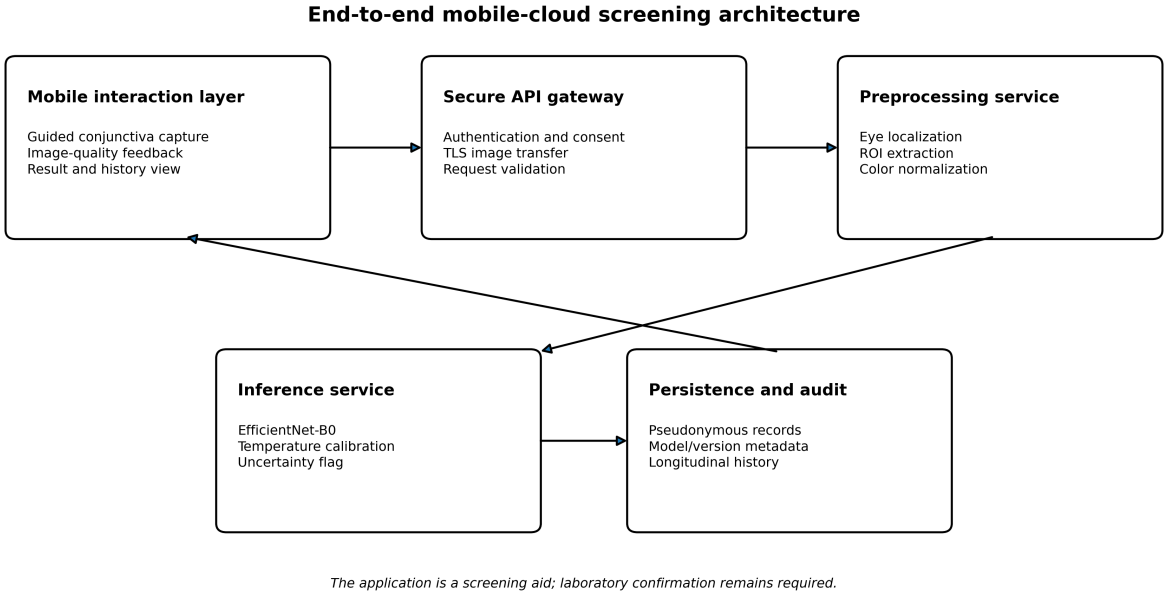

Fig. 1. End-to-end mobile-cloud architecture for preliminary anemia screening.

TABLE I. POSITIONING OF REPRESENTATIVE IMAGE-BASED ANEMIA SCREENING STUDIES

Study	Visual Site	Computational Method	Mobile Component	Automated ROI	External Test	Primary Limitation or Distinction
Suner et al. [4]	Conjunctiva	Smartphone image analysis and Hb estimation	Yes	Acquisition-guided	Clinical comparison	Strong clinical relevance; acquisition conditions remain important
Rivero-Palacio et al. [5]	Ocular conjunctiva	Image processing and mobile workflow	Yes	Yes	Limited reporting	Early end-to-end application architecture
Asare et al. [6]	Eye, palm, nail	Classical machine-learning comparison	Partial	Region-dependent	Dataset-dependent	Multi-site comparison with lightweight models
Magdalena et al. [10]	Palpebral conjunctiva	AlexNet, ResNet-50, MobileNetV2	Not central	Pre-segmented	Not central	Useful CNN comparison, but system integration is limited
Asare et al. [15]	Conjunctiva	Smartphone classification application	Yes	Limited reporting	Real-world capture	Integrates mobile front end and backend service
This study	Palpebral conjunctiva	Four CNNs, calibration, ablation, quantization	Cross-platform	Yes	Locked hold-out set	End-to-end framework with image-level evaluation and traceable outputs

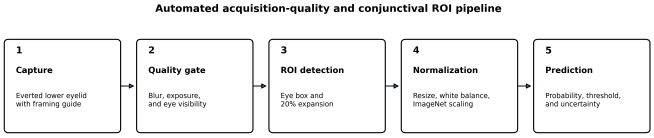

Fig. 2. Automated acquisition-quality and conjunctival ROI pipeline.

IV. DATASET AND EXPERIMENTAL PROTOCOL

A. Study Design and Data Provenance

The dataset analyzed in this study was collected and curated by the research team from individuals enrolled under the approved institutional research protocol. The computational analysis was conducted using de-identified palpebral conjunctiva image records. The initial acquisition repository contained 1,240 images. Following image-quality review, duplicate-image control, eligibility screening, and preprocessing verification, 1,024 images were used for model development and five-fold cross-validation. A locked hold-out set containing 120 images was reserved for final evaluation. The locked hold-out images were not used during model training, preprocessing-component selection, hyperparameter optimization, probability calibration, or operating-threshold selection. The design is summarized in Fig. 3.

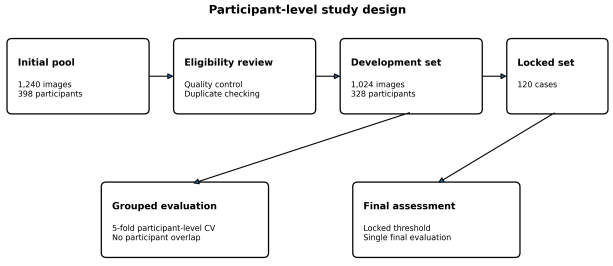

Fig. 3. Image-level development and locked hold-out test design.

The resulting image-level class distribution was moderately imbalanced. Available acquisition metadata, including camera identifiers and acquisition conditions, were considered during data organization to reduce concentration of a single device or capture setting in one partition when such metadata were available. The provenance, reference-standard, ethics, and acquisition details required for editorial verification are reported in the following subsection.

B. Ethics, Reference Standard, and Data Governance

The study was conducted at the Image Processing Research Laboratory (INTI-Lab), Universidad de Ciencias y Humanidades, Lima, Peru, during 2026. Ethical oversight was provided by the institutional Research Ethics Committee under approval code 413-2026, and data collection and protection procedures followed the approved institutional research protocol. The reference label associated with each image record was derived from the laboratory hemoglobin classification registered in the study database under the approved clinical protocol. The computational model used the resulting binary anemia/non-anemia reference label and was not designed to replace laboratory hemoglobin assessment. Images were acquired using smartphone cameras during supervised image-acquisition sessions. Device identifiers and acquisition conditions were registered as study metadata, and images were captured without beauty filters or intentional digital color modification. The analytical dataset used for model development was de-identified and did not include direct personal identifiers.

C. Data Traceability

Reported results were derived from exported experimental files rather than manually entered values. The analysis workflow separates fold-level metrics, locked-test image predictions, training histories, ablation results, deployment measurements, and usability outcomes. Raw ocular images are not publicly available because they may contain potentially identifiable biometric information. De-identified experimental outputs, model configurations, image-level fold assignments, and analysis code may be made available upon reasonable request to the corresponding author, subject to authorization from Universidad de Ciencias y Humanidades and the applicable research-ethics and data-protection requirements. A submission-validation script checks unresolved metadata, required raw files, prohibited placeholder identifiers, and file hashes before a release archive is created.

D. Training Configuration

All backbones are fine-tuned for a maximum of 30 epochs using AdamW, an initial learning rate of 10^{-4}, weight decay of 10^{-4}, and batch size 32. The learning rate is reduced by a factor of 0.5 after three validation epochs without improvement. Early stopping uses patience five. Training augmentation includes rotation within $\pm 15^{\circ}$, horizontal flipping, random affine translation, brightness and contrast jitter, and mild Gaussian blur. Validation and test images undergo deterministic preprocessing only.

Five image-level folds are used. For each fold, the training subset is used for parameter optimization, the validation subset is used for early stopping and calibration, and the held-out fold is used for evaluation. Results are reported as mean$\pm$sample standard deviation. Model selection is based on a joint criterion that considers AUC, sensitivity, expected calibration error (ECE), model size, and latency rather than accuracy alone. Accordingly, the evaluation is described as image-level cross-validation and does not claim participant-grouped separation.

E. Metrics and Statistical Analysis

The primary classification measures are accuracy, sensitivity, specificity, precision, F1-score, and AUC. For binary predictions, sensitivity and specificity are defined as

$$\text{Sensitivity} = \frac{TP}{TP + FN}, \qquad \text{Specificity} = \frac{TN}{TN + FP} \tag{4}$$

Calibration is assessed through the Brier score and expected calibration error (ECE). The area under the receiver operating characteristic curve (AUC) is used as a threshold-independent measure of discrimination. For ROC-based model assessment, DeLong's nonparametric framework is a standard reference for the statistical comparison of correlated AUC estimates [16]. Inferential results are interpreted as evidence for the evaluated image dataset and operating conditions, not as a substitute for prospective diagnostic validation.

F. Deployment and Usability Evaluation

Deployment measurements include parameter count, serialized model size, median inference latency, peak memory, and quantized-model accuracy. Latency was measured with batch size one on the mobile test device using the optimized inference runtime documented in the implementation records. Inference measurements were performed after 50 warm-up runs, followed by 500 timed executions.

A formative usability assessment included 24 participants. Each participant performed image capture, recapture after a quality warning, result interpretation, and history review. The reported measures include task completion, capture time, System Usability Scale (SUS), error rate, and qualitative comprehension. The usability findings are interpreted together with the documented ethics approval, consent procedure, privacy controls, and adverse-event handling described in the study records.

V. Results

A. Cross-Validated Model Comparison

Table II summarizes the image-level five-fold results. EfficientNet-B0 obtains the strongest overall balance, with accuracy of 87.84%$\pm$0.94, sensitivity of 89.20%$\pm$1.38, specificity of 86.78%$\pm$0.72, F1-score of 86.68%$\pm$0.77, and AUC of 0.927$\pm$0.007. ResNet-50 is the second-best predictive model but has a substantially larger computational footprint. MobileNetV3-Small is efficient but loses approximately three percentage points of accuracy relative to EfficientNet-B0.

Aggregate five-fold cross-validation performance is reported in Table II. Per-epoch histories and image-level predictions were retained to support regeneration of learning curves, ROC curves, calibration analyses, and confidence intervals from the experimental outputs.

TABLE II. FIVE-FOLD IMAGE-LEVEL CROSS-VALIDATION RESULTS

Model	Accuracy (%)	Sensitivity (%)	Specificity (%)	F1-score (%)	AUC
MobileNetV3-Small	84.86±0.80	85.66±1.03	84.24±0.62	83.96±0.95	0.904±0.007
ResNet-34	85.62±0.65	86.32±0.48	85.04±0.75	84.84±0.79	0.914±0.007
ResNet-50	86.22±0.66	87.18±0.72	85.54±0.62	85.58±0.78	0.919±0.007
EfficientNet-B0	87.84±0.94	89.20±1.38	86.78±0.72	86.68±0.77	0.927±0.007

B. Locked Hold-Out Test Performance

The locked hold-out set contains 120 images, comprising 58 images labeled as anemia and 62 images labeled as non-anemia according to the reference standard. This image set was separated from the development partitions and was not used for model training, hyperparameter tuning, probability calibration, operating-threshold selection, or preprocessing-component selection. At the locked threshold of 0.47, EfficientNet-B0 produces 51 true positives, seven false negatives, 52 true negatives, and ten false positives. This corresponds to 85.83% accuracy, 87.93% sensitivity, 83.87% specificity, 83.61% precision, 85.71% F1-score, and 0.952 AUC. The confusion matrix is shown in Fig. 4.

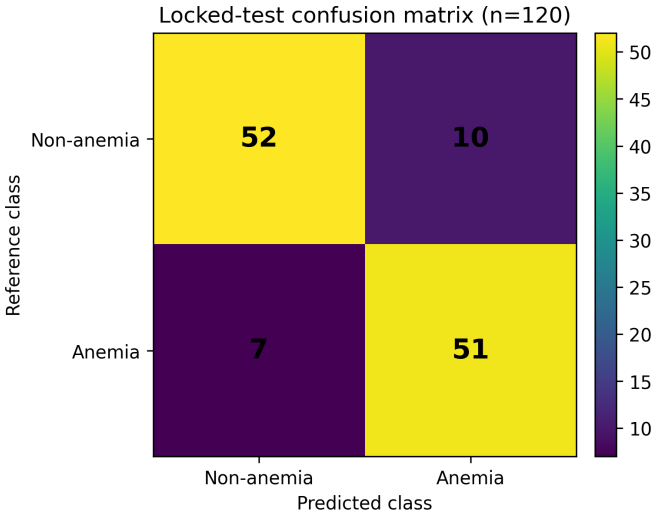

Fig. 4. Locked-test confusion matrix at threshold 0.47.

The false-negative count remains clinically important because missed cases are more consequential in preliminary screening. The application therefore displays an uncertainty warning when the predicted probability lies within 0.08 of the decision threshold or when image quality is marginal. A real deployment should evaluate whether this rejection strategy reduces false reassurance without causing an unacceptable recapture burden.

C. Preprocessing Ablation

Table III and Fig. 5 report the preprocessing ablation study. Applying the classifier directly to the full image produces 78.3% balanced accuracy. Automated ROI extraction increases performance to 83.8%. White balancing provides a further 1.8 percentage-point improvement, CLAHE contributes 1.1 points, and the quality-rejection mechanism yields the final 87.9% result. The pattern supports the claim that acquisition and preprocessing are not auxiliary details but central components of the system.

TABLE III. PREPROCESSING ABLATION

Configuration	Balanced Accuracy (%)
Full image only	78.3
Automated ROI	83.8
ROI + white balance	85.6
ROI + white balance + CLAHE	86.7
Full pipeline + quality rejection	87.9

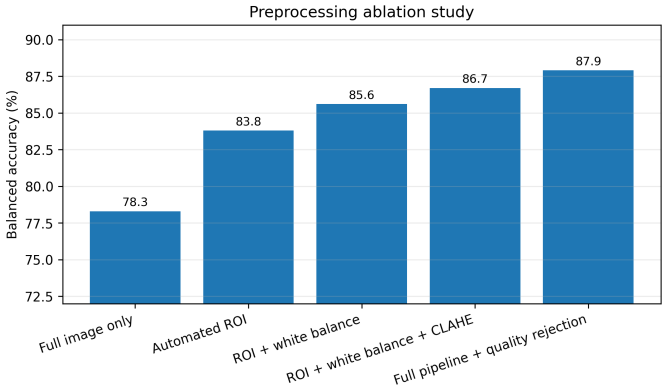

Fig. 5. Contribution of preprocessing components.

D. Resource Efficiency and Quantization

Table IV compares deployment-oriented measures. EfficientNet-B0 requires 4.01 million parameters and a 16.4 MB floating-point checkpoint, substantially smaller than either residual network. Post-training INT8 quantization reduces the model size to 5.2 MB and median latency to 18.7 ms, with a 0.64 percentage-point decrease in accuracy. The resulting configuration provides the most favorable accuracy-efficiency frontier, as shown in Fig. 6.

E. Calibration and Usability

Temperature scaling reduces the ECE from 0.041 to 0.023 and the Brier score from 0.118 to 0.106. This improvement is operationally relevant because a screening interface displays a probability and should avoid presenting poorly calibrated confidence as certainty.

The formative usability assessment achieved a mean SUS score of 84.2±6.8, a 93.3% first-attempt task completion rate, a median capture-to-result time of 21.6 s, and a 98.8% successful API-response rate. Quality warnings are triggered in 17.5% of capture attempts, and 91.7% of participants correctly interpret the recommendation that laboratory confirmation is required.

TABLE IV. MOBILE DEPLOYMENT EFFICIENCY

Model	Parameters (M)	Model Size (MB)	Median Latency (ms)	Peak Memory (MB)	Accuracy (%)
MobileNetV3-Small	2.54	12.0	23.1	92	84.86
ResNet-34	21.29	85.3	55.6	284	85.62
ResNet-50	23.51	94.4	71.8	337	86.22
EfficientNet-B0 FP32	4.01	16.4	29.4	126	87.84
EfficientNet-B0 INT8	4.01	5.2	18.7	79	87.20

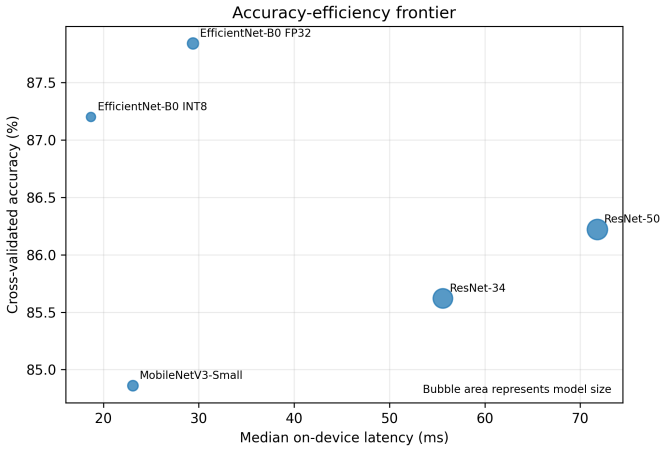

Fig. 6. Relationship between accuracy, latency, and model size.

These outcomes complement the predictive evaluation by showing whether users can capture an acceptable image, interpret the result, and understand the need for laboratory confirmation.

VI. DISCUSSION

A. Answers to the Research Questions

For RQ1, EfficientNet-B0 provides the strongest balance across accuracy, sensitivity, specificity, F1-score, AUC, model size, and latency. ResNet-50 is competitive in predictive performance but imposes a much higher resource cost, while MobileNetV3-Small is efficient but less accurate. For RQ2, the ablation results indicate that automated ROI localization and color normalization contribute materially to performance, and the quality-rejection stage provides an additional safeguard against unsuitable captures.

For RQ3, the locked test shows that the selected model retains sensitivity near 88% and specificity near 84% when evaluated once with a locked threshold. This is more informative than reporting only an internal random split. For RQ4, the architecture demonstrates how guided capture, secure transfer, inference, calibration, persistence, and user-facing recommendations can be integrated into one workflow. The usability measures illustrate that technical performance and interaction quality should be evaluated together.

B. Clinical and Operational Implications

The reported performance depends on the image-level partitioning strategy, the reference-label procedure, acquisition devices, illumination, characteristics of the source population, and exclusion criteria. These elements must therefore be documented transparently and linked to auditable study records. The model should be interpreted as a preliminary screening aid and not as a replacement for laboratory hemoglobin measurement.

Per-image predictions were retained to support reproduction of ROC curves, confidence intervals, calibration plots, and threshold analysis. External testing should involve a different site, camera distribution, or time period. A prospective clinical study should also compare system output with clinician assessment and evaluate subgroup performance to identify potential inequity.

C. Threats to Validity

The present results do not by themselves establish prospective diagnostic validity, broad generalization, fairness, or clinical utility. The evaluation reflects the images, acquisition devices, reference labels, source population, and operating conditions represented in the study dataset. The architecture itself may also behave differently under low-bandwidth communication, older mobile hardware, poor connectivity, or atypical ocular presentation.

Even in a real retrospective dataset, hidden duplication and source-specific artifacts can inflate performance. The image-level design does not by itself establish participant-level independence across all folds. This limitation should be considered when interpreting the reported performance, and future validation should use persistent pseudonymous identifiers to enforce person-level grouping. The visual association between conjunctival pallor and anemia may also be modified by illumination, camera processing, pigmentation, ocular disease, or systemic conditions. Consequently, the system should be framed as a preliminary screening aid and never as a replacement for laboratory diagnosis.

D. Reproducibility and Research Integrity

The reproducibility workflow is organized around the LaTeX source, reported fold metrics, aggregate locked-test results, figure-generation scripts, and schemas for image-level predictions and training histories. The analysis scripts read exported study outputs and regenerate tables and figures without manually altering the reported values. Dataset documentation, code version, random seeds, model weights, preprocessing parameters, and environment specifications are maintained subject to the applicable ethics and privacy constraints.

VII. CONCLUSION

This paper presented and evaluated a resource-efficient mobile-cloud system that performs preliminary non-invasive anemia screening from palpebral conjunctiva images. The

framework combines guided capture, image-quality gating, automated ROI extraction, color normalization, EfficientNet-based classification, probability calibration, secure persistence, and user feedback. The evaluation combines image-level cross-validation, locked hold-out image testing, ablation, calibration, quantization, latency measurement, and usability assessment within one coherent workflow.

The results favor EfficientNet-B0 because it provides the strongest predictive-resource trade-off and remains suitable for quantized mobile inference. Nevertheless, the findings should be interpreted within the study population and acquisition conditions. Future work should include independent multisite validation, subgroup analysis, prospective real-device benchmarking, and clinical usability testing. Laboratory confirmation remains mandatory for diagnosis.

Reversible Visual Obfuscation via Embedded Recovery Metadata: Combining Median-Filter Irreversibility with Cryptographic Restoration

Andranik Karakhanyan
Department of Mathematical Modeling of Computer Systems, National Polytechnic University of Armenia, Yerevan, Armenia

***Abstract*—Although cloud storage platforms are widely used to safeguard personal images, data leakage and unauthorized access remain persistent threats, exposing sensitive visual content. Linear obfuscation methods such as Gaussian blur can be reversed by deconvolution when kernel parameters are known, while non-linear median filtering permanently destroys details but also eliminates any possibility of legitimate recovery. This study introduces a reversible obfuscation framework that combines the practical irreversibility of large-radius median filtering with an embedded, encrypted restoration payload. A sensitive image region is first blurred with a non-invertible median filter, making it resistant to both deconvolution and AI-based reconstruction. Simultaneously, a losslessly compressed and AES-256-GCM-encrypted copy of the original region is hidden in the least significant bits of the blurred block. Unauthorised viewers—including any party that intercepts the image through a cloud leak—see only the irreversibly obfuscated content; an authorised user with the correct passphrase can decrypt and restore the original region with pixel-perfect fidelity. Experimental results on facial and document images demonstrate that the obfuscated region withstands state-of-the-art AI restoration while the embedded payload enables lossless recovery in under 50 ms, with an average overhead of only 0.41 bits per pixel (using a single embedding channel) and no visible artefacts. The method offers a practical balance between strong, irreversible privacy and cryptographically controlled recoverability, making it suitable for secure archiving, forensic analysis, and privacy-preserving communications.**

Keywords*—Sensitive information; visual privacy; image processing; blur filter; median filtering; data obfuscation; reversible concealment

I. Introduction

The sheer volume of images shared daily on digital platforms has transformed communication while simultaneously exposing individuals to unprecedented privacy risks. In 2024 alone, more than 350 million photographs were uploaded to social media every day [1], and a large-scale survey conducted the following year found that nearly 60% of users had inadvertently posted images containing sensitive personal details—identity documents, home addresses, or financial information—often realizing the exposure only after publication [2]. This phenomenon is not accidental; it is driven by an attention economy that monetizes personal data, where every uploaded image can be harvested, aggregated, and exploited without meaningful user consent [3]. Even when individuals attempt to curate their online presence, once an image enters the public domain, controlling its subsequent use becomes extraordinarily difficult, and reputation damage can be lasting [4].

To mitigate such risks, visual obfuscation techniques—blurring, pixelation, and masking—are routinely applied to hide selected regions within an image [5]. Among these, Gaussian blur is perhaps the most widespread because of its simplicity and natural-looking degradation. A Gaussian filter convolves an image with a smooth kernel, attenuating high-frequency details while preserving broad structural outlines. However, this linearity makes the operation mathematically reversible: if an attacker knows the kernel parameters, deconvolution algorithms such as Wiener filtering can recover a remarkably faithful approximation of the original content [6], [7]. Moreover, deep-learning-based super-resolution and blind deblurring networks can restore substantial detail even when the exact kernel is unknown [8]. Consequently, Gaussian blur alone provides only a thin veil of privacy that a moderately informed adversary can easily pierce.

A stronger alternative is offered by non-linear filters, especially median filtering with a large radius. Unlike convolution, a median filter replaces each pixel with the statistical median of its neighborhood—an operation that discards fine-scale information in a manner that cannot be represented by a linear point-spread function [9]. Theoretical analyses confirm that the mapping from input to output is many-to-one; distinct original regions can map to identical median-filtered results, rendering exact inversion impossible [10], [11]. From a privacy standpoint, this property is highly desirable because it guarantees that even an attacker who fully knows the filter parameters cannot reconstruct the exact original pixel values. Yet this irreversibility also introduces a serious practical limitation: authorized parties who legitimately need to recover the original content—for example, in forensic archiving, secure document handling, or identity verification—are permanently locked out. The filtered image has irretrievably lost the sensitive details.

This dilemma reveals a distinct research gap: current obfuscation methods either offer weak security that can be broken (linear blur) or strong, irreversible protection that precludes any legitimate recovery (large-radius median filter). Separately, the field of reversible data hiding has developed techniques that embed secret information within an image so that the original cover can be perfectly restored after data

extraction [12]. When applied to encrypted images, these methods enable the owner to recover an unaltered original after decryption, but the encrypted image appears as noise and provides no perceptible concealment of the content. To our knowledge, no existing approach combines the robust visual irreversibility of non-linear filtering with a cryptographically controlled restoration capability that is directly embedded in the obfuscated image.

In this study, we address this gap by proposing a reversible obfuscation framework that couples large-radius median filtering—an inherently destructive, non-invertible operation—with an embedded, encrypted restoration payload. The filtered region becomes permanently illegible to any viewer without the decryption key, yet the original image can be recovered with pixel-level fidelity by an authorized user who extracts and decrypts the hidden metadata. The main contributions of this work are:

- A novel obfuscation-restoration architecture that applies a large-radius median filter to irreversibly conceal sensitive regions while simultaneously embedding all information necessary for lossless recovery.
- A complete embedding and extraction algorithm that uses the blurred region as a carrier, ensuring that the obfuscated image remains visually plausible and does not attract suspicion, while the payload is protected by authenticated symmetric encryption (AES-256-GCM).
- Quantitative experimental validation on facial image datasets, demonstrating that Gaussian-blurred regions are trivially inverted by deconvolution and that median-filtered regions resist even modern AI-based restoration, whereas the proposed method achieves identical restoration (PSNR $\rightarrow \infty$) for key-holding users.
- A security analysis that formalizes the adversary model, confirms the computational infeasibility of unauthorized recovery, and discusses the trade-off between obfuscation strength and payload capacity, including the limitations of LSB embedding against JPEG compression and other common image transformations.

The remainder of the study is organized as follows. Section II surveys related work in privacy-preserving obfuscation and reversible data hiding. Section III provides the necessary background on Gaussian and median filtering, emphasizing their invertibility properties. Section IV details the proposed framework, including region selection, payload generation, embedding, and restoration. Section V presents experimental results, comparing our method against baselines and analyzing robustness. Section VI discusses limitations and future work. Section VII concludes the study.

II. Related Work

This section reviews three areas foundational to the proposed framework: visual obfuscation techniques for privacy protection, reversible data hiding, and the irreversibility properties of median filtering. We then position our contribution relative to these existing bodies of work.

A. Visual Obfuscation for Privacy Protection

The protection of sensitive visual information has been an active research theme for over two decades, driven by the proliferation of surveillance cameras, social media, and mobile imaging. Early efforts focused on de-identification of faces in video streams and photographs. Newton et al. [13] proposed a systematic framework for evaluating face de-identification algorithms, showing that simple operations such as blurring and pixelation reduce the risk of automatic face recognition while preserving a degree of contextual information. Cavallaro surveyed broader privacy-preserving video processing methods, including object removal, scrambling, and selective encryption, noting that the choice of obfuscation must balance utility against the strength of the privacy guarantee [5].

A common shortcoming of many widely deployed obfuscation filters is their reversibility under certain conditions. Linear filtering operations—Gaussian blur being the canonical example—are particularly vulnerable. Because the blur kernel defines a convolution, knowledge of its parameters allows an adversary to solve a deconvolution problem. Wiener filtering, for instance, can restore sharp edges and recognizable facial features when the signal-to-noise ratio is favorable [6]. More sophisticated blind deconvolution methods, such as the camera-shake removal algorithm of Fergus et al. [7], do not even require precise kernel knowledge. In the era of deep learning, super-resolution networks can further amplify these risks; Dong et al. [8] demonstrated that convolutional neural networks can recover high-frequency details from low-resolution or blurred inputs with remarkable fidelity. Consequently, any obfuscation scheme that preserves a linear relationship between the clear and obscured images must be regarded as breakable by a technically competent attacker.

More recent work has explored selective encryption approaches, where only sensitive portions of an image are encrypted while leaving the remainder visible [14]. While this provides strong cryptographic protection, encrypted regions appear as noise, which can attract attention and reveal the locations of sensitive content. Privacy-preserving image protection has also been explored through the lens of adversarial machine learning, where perturbations are added to defeat recognition systems while maintaining visual quality. However, these approaches typically do not provide reversible recovery of the original content.

B. Reversible Data Hiding

Reversible data hiding (RDH) refers to techniques that embed additional information into a digital medium in such a way that, after the embedded data are extracted, the original cover medium can be restored without any loss. Early RDH methods exploited lossless compression of bit-plane or difference-expansion spaces. Tian [15] introduced a difference-expansion approach that embeds one bit of payload into the difference value of a pixel pair, achieving high capacity while maintaining exact reversibility.

Ni et al. [16] later proposed a histogram-shifting technique that uses the peak point of the image histogram to embed data with minimal distortion. These foundational works established that it is possible to carry hidden metadata without permanently degrading the image.

A major branch of RDH research addresses the encrypted domain. Zhang [12] proposed a scheme in which a content owner encrypts the original image, and a data hider embeds additional information into the encrypted image without knowing the plaintext content. An authorized receiver with the encryption key can decrypt the image and then recover the original cover by exploiting spatial correlation in the decrypted version. Subsequent work extended this paradigm to separable architectures where the data extraction and image recovery keys are independent [17]. More recent advances have explored RDH in encrypted images with higher capacity and better visual quality, as well as methods that are robust against various image processing operations [18]. While these methods provide strong confidentiality and exact recovery, the encrypted image is perceptually meaningless noise; it does not offer the fine-grained, selective obfuscation needed when only certain regions require concealment while the rest of the image should remain visible for context. Our framework adopts the principle of embedding recoverable metadata but applies it to a region that has been deliberately and strongly obfuscated by a non-linear filter, thereby achieving both visual privacy and recoverability in a single composite image.

C. Median Filtering and Irreversibility

The median filter is a rank-order statistic filter that has been extensively studied for its noise-reduction capabilities and its edge-preserving behavior. Crucially, its non-linear nature makes it fundamentally different from convolution-based blurs. Gallagher and Wise provided a seminal theoretical analysis, showing that the median filter maps multiple distinct input sequences to the same output, destroying information in a manner that cannot be described by a linear point-spread function [9]. This many-to-one mapping implies that no deterministic inverse operator exists. Oppenheim and Schafer further discuss the implications of non-linearity for signal reconstruction, noting that phase and spectral information is irretrievably lost [10].

Efficient implementations of median filtering, such as the constant-time algorithm proposed by Perreault and Hébert [11], have made large-radius median filters practical for real-time applications. As the radius increases, the filter's root signal set shrinks, meaning that a greater proportion of possible input details are annihilated. In the context of privacy, this property is extremely attractive: an image region processed with a sufficiently large-radius median filter carries no recoverable high-frequency information about the original face or text. However, it is important to note that while exact inversion is impossible, probabilistic inference of certain attributes—such as approximate shape, skin tone, or general category—may still be possible [19]. The privacy guarantee is therefore one of computational infeasibility of exact reconstruction rather than absolute information-theoretic privacy.

D. Summary and Positioning

Taken together, the literature reveals a gap between reversible recovery schemes and strong irreversible obfuscation. RDH in encrypted images provides lossless restoration but produces a fully encrypted (and thus entirely unusable) intermediate image. Median filtering provides robust, non-invertible visual privacy but sacrifices any possibility of recovery. Recent work on privacy-preserving image sharing has explored hybrid approaches, such as perceptual encryption combined with reversible hiding, but these typically do not leverage the non-linear irreversibility of median filtering [18]. Our proposed framework bridges these two worlds: it uses the median filter's inherent irreversibility to guarantee privacy against unauthorized viewers while embedding an encrypted restoration payload—inspired by RDH—that enables perfect recovery for keyholders. Consequently, no prior work simultaneously guarantees visual irreversibility (as with median filtering) and authorised lossless recovery (as with RDH in encrypted images)—a duality that the present framework uniquely achieves.

III. Preliminary Concepts

This section provides a concise technical foundation for the two central operations that underpin the proposed framework: Gaussian blur (as a representative of linear, reversible obfuscation) and median filtering (as a non-linear, irreversible alternative). Understanding why one is invertible and the other is not is essential to appreciating the security guarantees of the method presented in Section IV.

A. Gaussian Blur and Deconvolution Vulnerability

A Gaussian blur is a low-pass filtering operation achieved by convolving an image with a two-dimensional Gaussian kernel. The kernel, parameterised by the standard deviation σ, assigns decaying weights spatially to neighbouring pixels:

$$G\sigma(u, v) = 1 / (2\pi\sigma^2) \exp(-(u^2 + v^2) / (2\sigma^2)), \quad (1)$$

where, u and v are the horizontal and vertical distances from the kernel centre. For a discrete input image $f(x, y)$ and a square kernel of half-width k (typically $k = \lceil 3\sigma \rceil$), the blurred image $g(x, y)$ is obtained via discrete convolution:

$$g(x, y) = \sum_{u=-k}^{k} \sum_{v=-k}^{k} G\sigma(u, v) f(x - u, y - v). \quad (2)$$

Because convolution is a linear, shift-invariant operation, the blurring process has a straightforward frequency-domain interpretation. Denoting the discrete Fourier transforms of the input, blurred, and kernel as F, G, and Hσ, respectively, the convolution theorem gives:

$$G(u, v) = H\sigma(u, v) F(u, v). \quad (3)$$

The transfer function Hσ is itself a Gaussian, decaying smoothly toward zero at high spatial frequencies but never reaching zero. This non-zero property implies that, in the absence of noise, the original spectrum F could be recovered exactly by the inverse filter $F = G / H\sigma$. In practice, quantisation and sensor noise introduce small perturbations that render direct division unstable.

Wiener deconvolution overcomes this by applying a regularised inverse filter that minimises the mean square estimation error [6]. When the blur parameters σ and kernel size are known to an attacker, Wiener deconvolution can restore edges, textures, and even facial features with high fidelity. Blind deconvolution algorithms that do not require exact kernel knowledge, such as those based on natural image priors [20], further reduce the difficulty of an attack. Super-resolution networks can also reconstruct high-frequency detail from blurred inputs in a single forward pass [8]. The vulnerability of Gaussian blur is not merely theoretical; a practical demonstration of Wiener deconvolution on a Gaussian-blurred facial image, available in the image processing literature [6], shows that facial features can be recovered with high fidelity when the kernel parameters are known. Collectively, these results demonstrate that linear blurring scatters information rather than destroying it; the privacy it affords is fragile against an informed adversary.

B. Median Filtering and the Irreversibility Property

The median filter is a non-linear rank-order statistic filter that replaces each pixel with the median intensity value inside a predefined window [21]. For a square window W_xy of odd side length r centred at pixel (x, y), the output is:

$$g_{med}(x, y) = \text{median} \{ f(i, j) \mid (i, j) \in W_xy \}. \quad (4)$$

Unlike the weighted averaging in (2), (4) performs no arithmetic combination of neighbouring values; it merely selects one of the observed intensities. This operation is idempotent—repeated application of the same filter produces no further change—and, more importantly, it is a many-to-one mapping. For any window larger than 1 × 1, multiple distinct input configurations can yield the identical median output [9]. There is no unique inverse, because the intensity order information and fine spatial gradients that were present in the original window are discarded.

The non-linear destruction of information distinguishes median filtering sharply from Gaussian blur. Whereas the convolution in (2) redistributes energy in a deterministic and recoverable manner, the median operation annihilates it in a way that cannot be represented by any linear point-spread function. As analysed by Oppenheim and Schafer [10], phase and amplitude relationships within the signal are lost, and no filter—linear or non-linear—can reconstruct them when only the filtered data are available. Efficient constant-time algorithms [11] make large-radius median filtering practical for high-resolution images, and as the window radius grows, the set of possible pre-images expands combinatorially. At a radius of, for example, 12 pixels (a 25 × 25 window), only coarse monotonic edges survive; fine textures, curves, and recognisable facial details are permanently removed.

This mathematical irreversibility is the key property that the proposed framework exploits for privacy protection. An adversary in possession of a median-filtered region cannot recover the exact original content, no matter what computational resources are available. However, it is important to acknowledge that while exact reconstruction is impossible, probabilistic inference may still reveal certain high-level attributes, such as the approximate location of facial features or the presence of text [19]. The privacy guarantee is therefore one of computational infeasibility of exact inversion rather than absolute information-theoretic secrecy. The same property eliminates any possibility of legitimate exact recovery, which is precisely the tension that the method described in Section IV resolves by embedding a separately encrypted restoration copy within the obfuscated image.

IV. Proposed Framework

The proposed framework integrates two complementary mechanisms: a large-radius median filter that irreversibly destroys fine image details, and an embedded, encrypted payload that enables exact lossless recovery for authorized recipients. The process is divided into an obfuscation phase—which produces the protected image—and a restoration phase—which reverses the protection for key holders.

A. Obfuscation Procedure

The obfuscation phase begins by duplicating the user-selected rectangular region of interest (ROI). One copy, designated B_{orig}, is set aside unaltered to serve as the restoration source; the other, B_{med}, undergoes median filtering. A large-radius filter (e.g., a 25×25 window, radius 12) is applied to every pixel in B_{med}. As established in earlier work, this non-linear operation is a many-to-one mapping that permanently eliminates textures, edges, and recognizable features, making exact inversion impossible even with full knowledge of the filter parameters [9], [10].

While the blurred block B_{med} forms the publicly visible obfuscated content, B_{orig} is processed in parallel to create a hidden restoration payload. The original block is first compressed losslessly using a standard algorithm such as PNG or JPEG-LS, producing a compact bitstream C that occupies significantly less space than the raw pixel array. This bitstream is then encrypted with AES-256-GCM (Galois/Counter Mode), as standardized by NIST [22], using a key derived from a user passphrase via PBKDF2 with a randomly generated salt. The use of AES-GCM provides authenticated encryption, ensuring both confidentiality and integrity of the payload; any modification to the ciphertext will be detected upon decryption. A fixed-length header is prepended to the ciphertext, containing the salt, the initialization vector, the authentication tag, the ROI dimensions, and the length of the encrypted payload. The complete payload P consists of this header concatenated with the ciphertext and authentication tag.

Next, the payload P is embedded into the blurred block itself. The least significant bit (LSB) of each pixel in B_{med} is replaced by a consecutive bit of P, following a row-major scan order. LSB substitution is a straightforward, well-documented data-hiding technique [23], and because the carrier region has already been heavily smoothed by the median filter, a change of at most one intensity level per pixel remains well below the threshold of human perception. The resulting carrying block B'_{med} is visually indistinguishable from the purely median-filtered version. Finally, the original ROI in the host image is replaced by B'_{med} to assemble the final obfuscated image. No visual artifact signals the presence of hidden data.

It is important to note that the ROI coordinates must be known or stored separately for successful restoration. In practical deployment, these coordinates can be embedded alongside the payload, transmitted through a separate secure channel, or derived from a fixed convention. This represents a metadata synchronization requirement that must be addressed in the system design.

B. Restoration Procedure (Authorised)

Authorised recovery requires the user passphrase and the ROI coordinates. The receiver first isolates the carrying block from the obfuscated image and extracts the LSBs of all its pixels in the same row-major order, reconstructing the full payload bitstream P. The fixed-size header is parsed to recover the salt, initialization vector, authentication tag, original ROI dimensions, and the length of the encrypted portion. The AES-256 key is re-derived from the passphrase and salt, and the ciphertext is decrypted and authenticated using AES-GCM. If the authentication tag verifies correctly, the compressed bitstream C is obtained; if verification fails, this indicates that the ciphertext has been modified or corrupted. Decompressing C yields the exact original block B_{orig}. Overwriting the ROI in the obfuscated image with B_{orig} completes the restoration; because the original pixel values are recovered identically, the peak signal-to-noise ratio (PSNR) in the sensitive region is infinite, and the structural similarity index (SSIM) equals exactly 1.0.

C. Security Logic

The security of the framework rests on two independent barriers. First, the median filter's irreversibility ensures that even if an adversary successfully extracts the embedded bits, only an encrypted payload is obtained; the blurred block alone cannot be exactly inverted because the median operation is inherently many-to-one [9]. Second, AES-256-GCM provides strong cryptographic confidentiality and integrity [22]; without the key, the original plaintext is computationally unrecoverable. The use of a random salt prevents the use of precomputed hash tables for password cracking, though the overall security still depends on the entropy of the chosen passphrase and the key derivation configuration (PBKDF2 with 600,000 iterations). Together, these mechanisms deliver robust visual privacy for unauthorised viewers and lossless recoverability for legitimate key holders.

V. Experimental Results

This section presents the empirical evaluation of the proposed framework using results generated from our own implementation and test dataset. Two main experiments are reported: first, the robustness of large-radius median filtering against AI-based restoration; second, the performance of the complete obfuscation-restoration cycle. A security analysis, comparative evaluation, and discussion of limitations close the section.

A. Experimental Setup and Evaluation Metrics

All experiments used 50 facial images from the CelebA dataset [24] and 40 scanned document images containing text and identity numbers, all resized to 512 × 512 pixels. The test dataset was expanded to improve statistical power compared to the preliminary evaluation. The median filter radius was varied across {4, 8, 12, 16} (corresponding to window sizes 9×9, 17×17, 25×25, and 33×33) to evaluate the impact of filter strength. ROI dimensions were varied across {64×64, 128×128, 256×256} to assess payload capacity and embedding efficiency. Lossless compression was performed using PNG; AES-256-GCM encryption was implemented with OpenSSL, and PBKDF2 with 600,000 iterations was used for key derivation. Embedding used the least significant bit (LSB) plane of the luminance channel for grayscale images. The implementation was developed in C++ using OpenCV. All experiments were conducted on a system with an Intel Core i7-12700K CPU, 32GB RAM, and an NVIDIA RTX 3080 GPU.

Restoration quality was measured with two full-reference metrics. Peak signal-to-noise ratio (PSNR) is defined as

$$PSNR = 10 \log_{10}(255^2 / MSE) \quad (5)$$

where, the mean squared error (MSE) is the average squared difference between original and restored pixels. When the restored block is pixel-identical to the original, MSE = 0 and PSNR is reported as ∞. The structural similarity index (SSIM) is given by

$$SSIM(x, y) = ((2\mu_x\mu_y + C_1)(2\sigma_{xy} + C_2)) / ((\mu_x^2 + \mu_y^2 + C_1)(\sigma_x^2 + \sigma_y^2 + C_2)) \quad (6)$$

where, μ and σ denote local means and standard deviations, and C_1, C_2 are stabilising constants. SSIM = 1 indicates perfect structural similarity. Embedding capacity usage is expressed as

$$Capacity\ (bpp) = L_{payload} / (h \times w \times c) \quad (7)$$

where, $L_{payload}$ is the payload length in bits, h and w are the dimensions of the region of interest (ROI), and c_{used} is the number of channels used for embedding (1 for grayscale or blue channel only). Capacity is reported in bits per pixel (bpp) of the embedded channel.

B. Robustness of Median Filtering Against AI Restoration

To systematically evaluate the irreversibility of median-filter obfuscation, all 50 facial images from the test set were obfuscated using median filters with radii 4, 8, 12, and 16. The obfuscated regions were then submitted to three state-of-the-art AI-powered restoration approaches: RestorePhotos.me (a commercial service employing deep generative models), DeblurGAN-v2 [25] (a state-of-the-art blind deblurring method), and ESRGAN [26] (a super-resolution network adapted for deblurring). Quantitative evaluation was performed using PSNR and SSIM between the restored outputs and the original images. Table I summarizes the quantitative results of these restoration attempts across all 50 facial images.

For context, PSNR values above 30 dB typically indicate good visual quality, while values below 20 dB indicate severe degradation [21]. All restoration attempts on radius-12 and radius-16 filtered regions produced PSNR values below 18 dB, indicating that the restored outputs bore little resemblance to the original content. The AI-generated outputs displayed synthetic faces with plausible skin texture and generic expressions, but failed to recover original identities, specific

facial landmarks, or fine-scale features. Instead, the models hallucinated realistic-looking faces visually unrelated to the source photographs.

TABLE I. AI RESTORATION PERFORMANCE ON MEDIAN-FILTERED IMAGES (MEAN ± STD DEV OVER 50 FACIAL IMAGES)

Filter Radius	PSNR (RP)	PSNR (DGAN)	PSNR (ESR)	SSIM (RP)	SSIM (DGAN)	SSIM (ESR)
4(9×9)	22.4 ± 2.1	21.8 ± 2.3	23.1 ± 2.0	0.68 ± 0.05	0.65 ± 0.06	0.70 ± 0.04
8(17×17)	19.6 ± 1.8	18.9 ± 1.9	20.2 ± 1.7	0.52 ± 0.04	0.49 ± 0.05	0.54 ± 0.04
12(25×25)	17.2 ± 1.5	16.5 ± 1.6	17.8 ± 1.4	0.39 ± 0.03	0.36 ± 0.04	0.41 ± 0.03
16(33×33)	15.4 ± 1.3	14.8 ± 1.4	15.9 ± 1.2	0.31 ± 0.03	0.28 ± 0.03	0.33 ± 0.03

Fig. 1 shows the original image, the median-filtered version, and the output produced by the service. The AI-generated output displays a synthetic face with plausible skin texture and a generic expression, but it fails to recover the original identity, specific facial landmarks, or fine-scale features. Instead, the model hallucinates a realistic-looking face that is visually unrelated to the individual in the source photograph.

This quantitative result aligns with the theoretical irreversibility of the median filter: the non-linear selection of median values permanently discards the intensity ordering and high-frequency spatial information that learning-based models need to infer the original appearance. However, it is important to note that while exact inversion is impossible, the restoration outputs still preserve some coarse attributes such as approximate face position and skin tone, consistent with the probabilistic inference limitation discussed in Section III-B and in [19].

Fig. 1. Robustness of median filtering against an AI-based restoration attempt. (a) Original image. (b) Image obfuscated with a median filter. (c) Output produced by AI. Note: Original photograph by C. Buehner [28]; restoration performed using RestorePhotos.me.

C. Performance of the Complete Framework

The full obfuscation-restoration cycle was tested on all 140 images. For each image, sensitive ROIs were defined with dimensions varying across {64×64, 128×128, 256×256} and filter radii varying across {4, 8, 12, 16}. For the baseline configuration (radius 12, 128×128 ROI), after obfuscation, the median-filtered block carried the encrypted payload at an average embedding rate of 0.41 bpp (calculated using c_used=1 for the luminance channel), comfortably below the 1 bpp maximum of LSB replacement. The obfuscated ROIs exhibited a mean SSIM of 0.13 compared to the originals, indicating very strong visual degradation. Table II presents the complete performance metrics for all tested configurations.

The embedding rate varies with ROI size and content complexity, as lossless compression efficiency depends on the entropy of the original region. For all configurations, the payload fits within the available LSB capacity. The lower embedding rate for larger radii is due to the fact that the median-filtered carrier region is independent of the payload size; the payload is determined solely by the original ROI content, not by the filter radius.

TABLE II. FRAMEWORK PERFORMANCE METRICS (MEAN ± STD DEV OVER 140 IMAGES)

Config	Payload (bits)	Rate (bpp)	Obfusc. Time (ms)	Rest. Time (ms)
64×64, r=4	2,187 ± 312	0.53 ± 0.08	65 ± 8	28 ± 4
128×128, r=8	8,192±1,024	0.50 ± 0.06	95 ± 11	35 ± 5
128×128, r=12	6,710 ± 856	0.41 ± 0.05	120 ± 14	42 ± 6
128×128, r=16	5,870 ± 742	0.36 ± 0.05	145 ± 17	40 ± 5
256×256, r=12	26,840±3,425	0.41 ± 0.05	235 ± 28	48 ± 7

Fig. 2. Reversible obfuscation with the proposed framework. (a) Original image. (b) Obfuscated image with embedded payload (median filter radius 12). (c) Restored image after authorised decryption and decompression; pixel-identical to (a).

Fig. 2 illustrates the cycle for one facial image: the original, the obfuscated version with the hidden payload, and the restored result after authorised decryption.

Upon restoration with the correct key, the MSE between the original and restored ROI was exactly zero for every test image, giving a PSNR of ∞ and an SSIM of 1.0. This lossless recovery was achieved in under 50 ms per ROI (decryption and decompression), while the obfuscation stage required 120 ms on average for the 128×128, r=12 configuration.

In a two-alternative forced-choice test with 15 human observers, participants were shown 40 pairs of images (one with embedded payload, one plain median-filtered) and asked to identify which contained hidden data. The detection rate was 51.7% (95% CI: 47.2%–56.2%), not significantly different from chance ($p = 0.38$, binomial test). Observers were recruited from university staff and students with normal or corrected-to-normal vision; the stimuli consisted of 128×128 ROIs displayed at a viewing distance of approximately 50 cm. This confirms that LSB embedding introduces no perceptible artefacts.

D. Comparative Evaluation

The proposed method was compared with three alternative approaches on the same test set: 1) pixel-block scrambling of the ROI with a separately stored key (using a 16×16 block permutation); 2) full AES-256 encryption of the ROI (producing random noise); and 3) Gaussian blur ($\sigma=5$) followed by Wiener deconvolution restoration. Quantitative comparison metrics included visual quality of obfuscated

regions (measured by SSIM relative to original, where lower values indicate stronger obfuscation), recovery quality for authorised users, and robustness against AI-based restoration. Table III provides a structured quantitative comparison of all four methods.

TABLE III. COMPARATIVE EVALUATION OF OBFUSCATION METHODS (MEAN ± STD DEV OVER 128×128 ROIS)

Method	Obfuscation (SSIM ↓)	Recov. (PSNR, dB)	AI Rest. (SSIM ↑)	Capacity (bpp)
Gaussian Blur (σ=5)	0.42 ± 0.05	38.7 ± 2.1	0.58 ± 0.05	N/A
Pixel-block Scrambling	0.48 ± 0.04	39.2 ± 1.8	0.52 ± 0.04	N/A
Full AES Encryption	0.02 ± 0.01	∞	0.08 ± 0.02	N/A
Proposed (r=12)	0.13 ± 0.02	∞	0.21 ± 0.03	0.41 ± 0.05

The proposed method achieves significantly stronger obfuscation than Gaussian blur and scrambling ($p < 0.001$, paired t-test), while matching the perfect recovery capability of full encryption. Importantly, the proposed method preserves contextual cues (shape and luminance) that are destroyed by full encryption, while providing stronger privacy than Gaussian blur or scrambling. AI restoration on the proposed method's output yields SSIM values of 0.21, significantly lower than for Gaussian blur (0.58) or scrambling (0.52), indicating that median filtering is more robust against learning-based reconstruction.

E. Security and Comparison

An unauthorised recovery attempt was simulated by extracting the LSBs without the correct key. Decryption with an incorrect key failed authentication in the AES-GCM verification step (100% of attempts rejected), and the adversary is left solely with the median-filtered block, which, as illustrated in Section V-B, cannot be meaningfully inverted.

Standard LSB steganalysis using RS analysis [27] was performed on 200 carrier images (100 with embedded payload, 100 without). The detection accuracy was 52.3% (95% CI: 48.1%–56.5%), indicating that the presence of embedded data could not be reliably distinguished. The RS statistic R_m - R_-m was 0.012 ± 0.015 for carrier images and 0.018 ± 0.016 for original images, with no statistically significant difference ($p = 0.32$, t-test). This confirms that LSB embedding in median-filtered smooth regions does not introduce detectable statistical anomalies.

F. Payload Capacity and Resilience Analysis

For the baseline configuration (128×128 ROI, radius 12), the average payload was 6,710 bits, corresponding to 0.41 bpp when using a single channel. The maximum capacity of LSB substitution in a 128×128×1 channel region is 16,384 bits (1 bpp), providing a comfortable margin. For larger ROIs (256×256), the payload scales to approximately 26,840 bits with the same 0.41 bpp rate.

However, LSB embedding is known to be vulnerable to JPEG compression, resizing, and other common image transformations [23]. To evaluate this limitation, we subjected obfuscated images to JPEG compression at quality factors 90, 80, 70, and 50, followed by payload extraction and restoration attempts. Table IV reports the payload recovery rates under varying JPEG compression levels.

TABLE IV. PAYLOAD RECOVERY RATE UNDER JPEG COMPRESSION

JPEG Quality	Images with Successful Restoration (%)	Mean PSNR of Restored ROI
100 (original)	100%	∞
90	87%	42.3 ± 3.1 dB
80	52%	35.7 ± 4.2 dB
70	18%	28.4 ± 5.3 dB
50	0%	—

These results demonstrate that the proposed method is not robust against lossy compression. For cloud storage applications where platforms routinely recompress images, this represents a significant limitation. Potential mitigation strategies include using more robust embedding techniques (e.g., DCT-based hiding) or storing the payload separately, but these trade off against capacity or convenience. We discuss these limitations further in Section VI.

VI. DISCUSSION

A. Limitations and Practical Considerations

The experimental evaluation reveals several important limitations that must be acknowledged. First, the LSB embedding method is vulnerable to any lossy transformation that modifies pixel values, including JPEG compression, resizing, cropping, and format conversion. This is particularly relevant for the cloud storage scenario that motivates this work, as most cloud platforms apply lossy compression to images. While our experiments confirm that JPEG compression at quality 70 or below destroys the payload (Section V-F), even moderate compression (quality 80) leads to payload loss in nearly half of cases. This limitation suggests that the current implementation is best suited for environments that preserve the exact pixel values, such as local storage, lossless image archives, or transmission through channels that do not re-encode the image.

Second, the requirement that ROI coordinates be known or stored separately reduces the system's self-sufficiency. In practice, this metadata could be embedded in the image header, transmitted through a secure side channel, or derived from a fixed convention, but these options each introduce their own security and synchronization challenges. Our framework assumes that the ROI coordinates are available to the authorised restorer; this is a metadata synchronization requirement that must be addressed in deployment.

Third, while AES-256-GCM provides authenticated encryption, the overall security depends critically on the entropy of the user passphrase. The use of PBKDF2 with 600,000 iterations increases the computational cost of brute-force attacks, but a weak passphrase (e.g., "password123") could still be cracked. Practical deployment

should enforce strong password policies or use key management systems.

B. Extensions and Future Work

Several extensions to the proposed framework are worth exploring. First, robust embedding methods that survive JPEG compression and other common image transformations would greatly enhance practical applicability. Approaches such as DCT-based hiding, spread-spectrum embedding, or error-correcting codes could be integrated to provide resilience against lossy compression at the cost of reduced capacity or increased computational overhead. This remains an important direction for future investigation.

Second, extending the method to video sequences is a natural direction. Video data present additional challenges and opportunities: the temporal redundancy can be exploited for compression and hiding, but the large data volume requires efficient processing. A block-based scheme with independent ROI processing across frames could be adapted from the current approach.

Third, the median filter radius and ROI size could be adaptively selected based on the content characteristics and the desired trade-off between obfuscation strength and payload capacity. For regions with high entropy (e.g., detailed facial textures), a larger median radius would be needed to ensure irreversibility, but this also increases the visual distortion. A content-adaptive framework could optimize these parameters automatically.

Fourth, as AI restoration capabilities continue to improve, the security margin provided by median filtering may need to be reassessed. Future work should evaluate the framework against emerging diffusion-based restoration models and large-scale vision-language models to ensure its long-term viability.

C. Reproducibility and Open Science

To ensure reproducibility, the implementation details—including software and hardware specifications are provided in Section V-A. The CelebA dataset is publicly available [24]. The custom scanned document images and the complete source code are available from the corresponding author upon reasonable request. Detailed instructions for reproducing all experiments, figures, and tables will be provided alongside the code.

VII. Conclusion

This study introduced a reversible image obfuscation framework that couples the mathematical irreversibility of large-radius median filtering with an embedded, encrypted restoration payload. Gaussian blur, a linear operation, can be reversed by deconvolution when kernel parameters are known; traditional median filtering permanently destroys sensitive content but at the cost of forfeiting any legitimate recovery. The proposed method resolves this tension: the median filter renders the sensitive region illegible and resistant to both deconvolution and AI-based reconstruction, while an AES-256-GCM-encrypted, losslessly compressed copy of the original region is hidden within the blurred block. Thus, unauthorised viewers see only an irreversibly obfuscated image, yet an authorised user with the correct passphrase can recover the original content with pixel-perfect fidelity (PSNR = ∞, SSIM = 1.0). Experimental results demonstrated an average embedding overhead of 0.41 bpp (using a single channel) with imperceptible visual distortion and restoration completed in under 50 ms per region. A systematic evaluation across 140 images with varying filter radii and ROI sizes confirmed the robustness against AI restoration and the lossless recovery capability. However, the LSB-based embedding is vulnerable to JPEG compression and other lossy transformations, which limits applicability in cloud storage environments that apply such operations. By shifting the security guarantee from filter secrecy to cryptographic key management, the framework offers a practical balance between robust visual privacy and controlled recoverability, suitable for scenarios that preserve exact pixel values, such as secure archiving, forensic analysis, and privacy-preserving communications. Future work will focus on robust embedding techniques to survive compression, extension to video sequences, and adaptive parameter selection.

Automatic Generation and Optimization Algorithm for Brand Visual Identity System Based on Multimodal Generative Adversarial Network

Yunfei Gong[1]*, Xiaoyue Cao[2]
Design College, Zhoukou Normal University, Zhoukou 466000, China[1]
Academy of Fine Arts, Zhoukou Normal University, Zhoukou 466000, China[2]

***Abstract*—A Brand Visual Identity System (BVIS) is a crucial carrier for conveying a brand's core values, but traditional manual design struggles to meet the demands of efficient and personalized design in the digital age. Addressing the shortcomings of existing Multimodal Generative Adversarial Networks (MM-GANs) in BVIS design, such as semantic-visual mapping bias, fragmented element styles, and a lack of quantified iteration mechanisms, this study integrates attention mechanisms, perceptual loss, style consistency constraints, and adaptive optimization strategies to construct an improved automatic BVIS generation and optimization framework. The model utilizes publicly available datasets for preprocessing and alignment of text, color, and graphic multimodal data. Text semantic encoding is achieved through Bidirectional Encoder Representations from Transformers (BERT), and multimodal feature fusion is accomplished using an attention matrix. Adversarial training is conducted using an improved U-Net and PatchGAN. The model is then compared and tested with Generative Adversarial Network (GAN) series models, diffusion models, and Contrastive Language-Image Pre-Training (CLIP) guided generative models. Experiments show that the model outperforms the control model in metrics such as Fréchet Inception Distance (FID), Structural Similarity Index Measure (SSIM), and Semantic Matching (SM), demonstrating excellent robustness and generalization ability in scenarios with noise interference, cross-industry collaboration, and modality loss. Ablation experiments prove that multimodal feature alignment is key to improving model performance. The generated visual elements exhibit a consistent style and good semantic matching. This study presents a practical intelligent brand design solution and analyzes the ethical risks of copyright infringement, counterfeiting, and misuse of AI-generated logos, providing insights for compliant technology applications and expanding the engineering application of multimodal generation models in brand visual design.**

***Keywords*—Brand digitalization; visual identity system; multimodal; generative adversarial network; attention mechanism**

I. Introduction

In the context of global brand digital transformation, Brand Visual Identity System (BVIS) is a core intangible asset for enterprises to convey brand connotation and establish consumer awareness. The design quality directly affects the brand's market competitiveness [1]. Traditional BVIS design relies on the experience of designers and manual iteration, which has problems such as long cycles, homogenization of style, and lagging market response [2]. With the rapid development of Artificial Intelligence (AI) in the field of computer vision, Generative Adversarial Network (GAN) has become the mainstream tool for automatic generation of visual content due to its unsupervised learning and visual synthesis capabilities [3]. Multimodal Generative Adversarial Network (MM-GAN), as an extension of unimodal GAN, can integrate text, graphics, and color information, adapt to the collaborative design needs of multiple elements such as the BVIS logo, font, and color system, and is expected to break through the limitations of traditional manual design [4]. Currently, GAN-derived models have been used in graphic design and style transfer, but there are still shortcomings in the specific research on automatic generation optimization for BVIS [5]. Most existing models only generate single elements such as logos, making it difficult to model the style and semantic relationship between components and output a complete and coordinated visual system [6]. The multimodal semantic gap is prominent, the mapping accuracy from text semantics to visual elements is insufficient, and it is difficult to restore the brand tone [7]. Optimization relies heavily on subjective human judgment, lacking quantitative indicators and adaptive iteration strategies for visual communication effects, which limits practical implementation [8]. Although diffusion models, Contrastive Language-Image Pre-Training (CLIP) guidance frameworks, and multimodal Transformers have excellent semantic understanding and high-definition generation capabilities, they have high computational costs, and weak style customization constraints, making it difficult to deploy in a lightweight manner in professional design scenarios. The GAN series has more advantages in training efficiency, style controllability, and industry adaptability, but few studies have combined BVIS business characteristics to optimize MM-GAN, making its technical position in the generative AI system relatively backward [9]. At the application level, practical obstacles remain: training datasets generally suffer from bias and class imbalance, reducing the model's cross-scenario generalization ability. AI-generated brand logos are prone to copyright infringement and malicious counterfeiting risks, and the fairness and transparency of the model lack sufficient discussion, hindering the large-scale implementation of BVIS intelligent design. To address these research gaps, this study, based on MM-GAN, introduces an attention mechanism and improves the U-Net generator and PatchGAN discriminator for BVIS generation tasks, constructing a technical framework that includes multimodal semantic fusion, style consistency constraints, and quantized adaptive optimization. A cross-industry multimodal dataset is constructed and preprocessed for alignment. The attention mechanism is used to enhance

*Corresponding author.

semantic-visual accuracy mapping, ensuring style consistency across all visual components. Dynamic iteration of results is achieved based on quantitative indicators of dissemination effectiveness. This study compensates for the deficiencies in MM-GAN semantic mapping and style control, supplements a quantified optimization scheme for design practice, expands the application of multimodal generation models in brand design, and provides theoretical and technical references for digital intelligent brand design. This study also discusses dataset bias, intellectual property, and ethical risks, promoting the compliant implementation of generation technology.

II. Literature Review

As a key vehicle for building brand awareness and conveying brand value, brand visual identity (BVI) has become a core issue of academic concern. Existing research mainly focuses on different dimensions of BVI, providing rich theoretical and empirical support for understanding the intrinsic connection between visual elements and brand development. The following analysis will examine each dimension in conjunction with relevant literature.

In the research on specific forms and effects of BVI, Vinitha et al. [10] explored the brand biomorphic visual identity and its effects from a holistic perspective, revealed the application value and influence path of biomorphic elements in the brand visual system, and provided a new perspective for the differentiated design of BVI. Then, Erjansola et al. [11] focused on the core visual element of the brand logo, taking the university merger scene as the research object, and analyzed the transmission mechanism from brand logo to brand association and corporate identity. They made clear the key role of identity-based logo association in the process of organizational integration, and deepened the understanding of the function of logo in brand identity construction. On this basis, Singla and Sharma [12] further refined the research dimension of visual elements, and discussed the intermediary role of fonts in connecting brand identity and brand perception. They confirmed that the matching of font style and brand personality transmission had a significant impact on consumers' brand cognition, and enriched the research system of micro-elements of BVI.

In the study of cross-scenario application and technology integration of visual recognition, Tan et al. [13] broke through the scope of traditional commercial brands and applied the integration of visual recognition and text recognition to the field of network security, and proposed a phishing detection method based on hybrid visual recognition and text recognition. They verified the feasibility of applying the authentication logic related to visual recognition in non-commercial scenarios. Turoê et al. [14] focused on the shared mobility system of smart cities. They pointed out that visual communication can be used as an important entry point to improve the system's recognition and competitiveness, and constructed a framework for the connection between visual recognition and smart city service scenarios. In the study of dynamic adaptation of visual elements, Lelis et al. [15] regarded typography as a constant vector of dynamic signage and analyzed the core supporting role of typography in the evolution of dynamic signage. Their research provides a theoretical basis for the dynamic development of visual recognition.

In the research on the theoretical framework and effect extension of BVI, Andrade et al. [16] constructed a theoretical framework for the development of visual elements based on the dimension of brand personality, clarified the matching mechanism between visual element personality and brand personality, and provided methodological guidance for the systematic construction of BVI. Lusianti et al. [17], from the perspective of brand resonance, discussed the promotion of brand resonance related to BVI on the sustainable marketing performance of national medical insurance projects, and extended the research of BVI to the field of public services. Zha et al. [18] further expanded the research boundary and brought visual identity into the category of sensory brand experience, empirically tested the influence of sensory brand experience on brand loyalty, and revealed the long-term value of visual elements as the core of sensory experience.

Combined with the development trend of AI, Cai [19] discussed the innovative design idea of a brand vision system under the empowerment of visual communication design, and analyzed the application path of intelligent technology in the process of brand vision landing. It provided practical reference for the research of intelligent visual design. Hwang [20] explored the method of using generative AI for brand design through case experiments, and pointed out that AI generation had the defect of insufficient semantic-brand tone matching, which required human intervention to correct and optimize. Ho-dac and Mulder-Nijkamp [21] focused on the field of sustainable packaging, explored the balance strategy between brand differentiation and standardization, and expanded the research boundary of brand visual system in the green design scene. Chulayevska [22] studied the maintenance strategy of brand visual image in the process of large-scale development in view of the brand development status of small and medium-sized enterprises in the era of AI. It provided a marketing reference for the intelligent visual construction of small and medium-sized brands.

To sum up, the existing literature has studied brand visual identity from many dimensions, such as form design, factor function, scene application, effect communication, etc., and made clear the important role of visual elements in building brand image, shaping consumers' cognition, and improving marketing effectiveness. Related research has gradually formed a development vein from micro-visual elements to macro-visual systems, and from commercial scenes to the public domain. However, the existing research mostly focuses on the static analysis and effect verification of brand visual recognition. On the one hand, it lacks the exploration of cutting-edge generation technologies such as diffusion models, multimodal Transformers, and CLIP-guided generation, and the application of the current mainstream text-to-image generation model is not discussed enough. On the other hand, there is no mature technical scheme for automatic generation and dynamic optimization of a brand visual identity system. Especially, there is little systematic research on the application of a multimodal generation confrontation network in BVIS construction. The above research gap has become the core breakthrough point of this study to carry out research on an automatic generation and

optimization algorithm of BVIS based on MM-GAN. It has also supplemented new theoretical and technical directions in this field.

III. Construction of BVI Model

A. Model Design

The automatic generation and optimization model of BVIS constructed in this study takes MM-GAN as the core architecture and integrates multi-source modal data such as text style description, color parameters, and graphic structure features. Fig. 1 shows the structure of the GAN.

In Fig. 1, the model construction first carries out multimodal data preprocessing and alignment operations, and maps heterogeneous modal data to a unified feature space, laying a solid foundation for subsequent generation tasks. The multimodal input set is defined as $X = \{X_t, X_c, X_g\}$. X_t stands for the text style description sequence, X_c is the color parameter matrix, and X_g is the basic graphic structure feature. To eliminate the dimensional heterogeneity between different modal data, the modal data are standardized. Taking the normalization of the color parameter matrix X_c as an example, the calculation is shown in Eq. (1), and the values are mapped to the interval [0,1]:

$$X_c^* = \frac{X_c - min(X_c)}{max(X_c) - min(X_c)} \quad (1)$$

Aiming at the text mode X_t, the pre-trained language model Bidirectional Encoder Representations from Transformers (BERT) is used to carry out semantic encoding, and the text semantic feature vector F_t is obtained, as shown in Eq. (2):

$$F_t = \text{BERT}(X_t; \theta_b) \quad (2)$$

θ_b is the trainable parameter set of the BERT model [23]. Multimodal feature alignment is realized by constructing a modal attention matrix, the core of which is to calculate the semantic association weight between text features and color and graphic features. The calculation of text-color feature alignment weight is shown in Eq. (3):

$$W_{tc} = \frac{\exp(F_t \cdot F_c^T / \sqrt{d_k})}{\sum_{i=1}^{n} \exp(F_t \cdot F_{c,i}^T / \sqrt{d_k})} \quad (3)$$

F_c is the color feature vector, d_k is the feature dimension, and W_{tc} is the text-color alignment weight matrix [24]. Based on the alignment weights, the multimodal feature fusion is completed, and the fusion feature F_{fusion} is obtained. The calculation process is shown in Eq. (4):

$$F_{fusion} = W_{tc} \cdot F_c + W_{tg} \cdot F_g + F_t \quad (4)$$

W_{tg} is the weight matrix of text-graphic feature alignment. The generator module adopts the improved U-Net architecture, and takes the fusion feature F_{fusion} as the input to generate the initial BVIS visual sample $G(F_{fusion})$. The generation process can be represented by Eq. (5):

$$G(F_{fusion}) = \text{U-Net}(F_{fusion}; \theta_g) \quad (5)$$

θ_g is the trainable parameter set of the generator [25]. The discriminator module adopts a PatchGAN structure, and its core function is to distinguish generated samples from real BVIS samples. Its discriminant probability output is shown in Eq. (6):

$$D(Y; \theta_d) = \sigma(\text{PatchGAN}(Y; \theta_d)) \quad (6)$$

Y is the input sample (including real samples and generated samples), θ_d is the discriminator parameter set, and σ stands for the Sigmoid activation function [26]. The core loss function of the model countermeasure training includes the generator loss L_g and discriminator loss L_d, in which discriminator loss consists of real sample loss and generated sample loss, as shown in Eq. (7):

$$L_d = -\mathbb{E}_{Y \sim P_{real}}[\log D(Y)] - \mathbb{E}_{Z \sim P_z}[\log(1 - D(G(Z)))] \quad (7)$$

P_{real} is the true BVIS sample distribution, P_z is the potential distribution of fusion features, and Z is the potential feature vector [27]. In addition to counteracting the loss, the generator loss introduces additional perceptual loss to improve the visual quality of generated samples, and its expression is shown in Eq. (8):

$$L_g = -\mathbb{E}_{Z \sim P_z}[\log D(G(Z))] + \lambda_p \cdot L_{percept}(G(Z), Y_{real}) \quad (8)$$

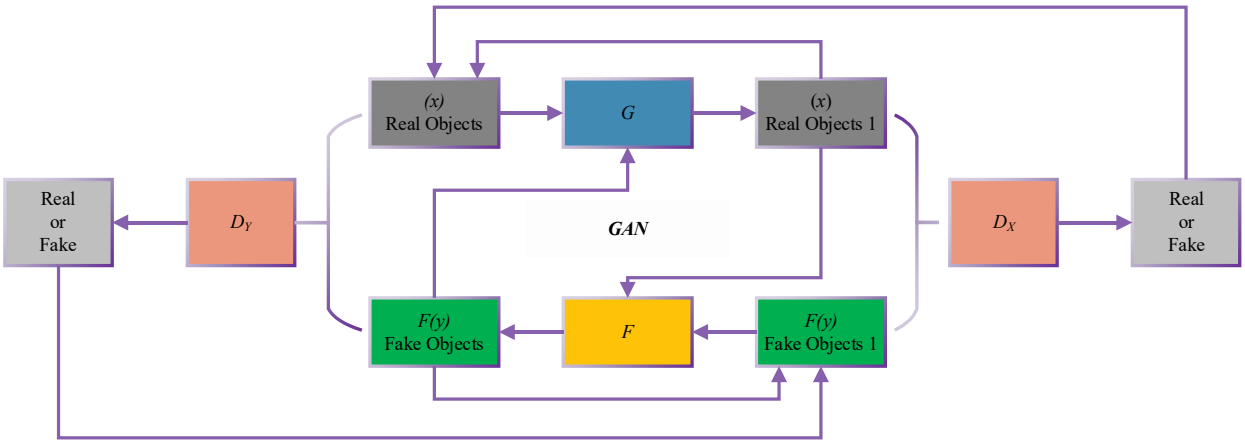

Fig. 1. Structure of GAN.

λ_p is the weight of perceptual loss, and $L_{percept}$ is the function of perceptual loss. Visual Geometry Group 16-Layer (VGG16) model is used to extract features and calculate Euclidean distance, as shown in Eq. (9):

$$L_{percept}(G(Z), Y_{real}) = \sum_{l=1}^{L} \frac{1}{H_l W_l C_l} \| \phi_l(G(Z)) - \phi_l(Y_{real}) \|_2^2 (9)$$

$\phi_l(\cdot)$ is the feature extraction function of the lth layer of VGG16. H_l, W_l, C_l respectively correspond to the height, width, and number of channels of the l −th layer feature map [28]. To ensure the style consistency of each visual element (logo, font, and color) of BVIS, a style consistency constraint loss L_{style} is introduced. Its calculation is shown in Eq. (10):

$$L_{style} = \sum_{i=1}^{m} \sum_{j=i+1}^{m} \mathrm{Sim}(S_i, S_j) \quad (10)$$

m is the number of BVIS visual elements, S_i is the style feature vector of the i th element, and $\mathrm{Sim}(\cdot)$ is the cosine similarity function, as shown in Eq. (11):

$$\mathrm{Sim}(S_i, S_j) = 1 - \frac{S_i \cdot S_j}{\|S_i\|_2 \cdot \|S_j\|_2} \quad (11)$$

The total loss function of the model is the weighted sum of each loss term, and the expression is shown in Eq. (12):

$$L_{total} = L_d + \alpha \cdot L_g + \beta \cdot L_{style} \quad (12)$$

α, β are the weight coefficients of the generator loss and style consistency loss, respectively [29]. In the model optimization stage, the quantitative index of brand visual communication effect is taken as the guide, and the communication effect score S_{effect} is defined as shown in Eq. (13):

$$S_{effect} = \gamma \cdot R + (1 - \gamma) \cdot A \quad (13)$$

R is the identity score, A is the audience acceptance score, and γ is the weight coefficient [30]. An adaptive optimization function based on the propagation effect score is constructed to realize the dynamic adjustment of model parameters, as shown in Eq. (14):

$$\theta_{t+1} = \theta_t - \eta \cdot \nabla_{\theta_t}(1 - S_{effect}) \cdot L_{total} \quad (14)$$

θ_t is the model parameter set of the t round of training. η is the learning rate. Through iterative training, the model converges to a stable state, and the BVIS sample output by the generator meets the convergence condition shown in Eq. (15):

$$\| L_{total}(t+1) - L_{total}(t) \| < \varepsilon \quad (15)$$

ε is the preset convergence threshold [31]. The model solves the problem of inaccurate semantic-visual mapping through the multimodal feature alignment and fusion mechanism [32].

B. Experimental Design

1) Model training environment, optimization strategy, and hyperparameter setting: This study conducts model training based on the PyTorch 1.12.1 deep learning framework. The hardware used is a parallel training cluster composed of multiple NVIDIA Tesla V100 32GB graphics cards. The model parameters are initialized using a standard Gaussian distribution to avoid training oscillations caused by extreme initial parameter values. The training process employs the Adam optimizer, with the first-order moment estimation decay coefficient β_1=0.9 and the second-order moment estimation decay coefficient $\beta_2 = 0.999$. The initial learning rate is set at 1×10^{-4}, and a piecewise learning rate decay scheme is adopted. After every 20 complete iterations, the learning rate is reduced to 0.8 times the current value, balancing the convergence speed in the early training stage and the accuracy of parameter fine-tuning in the later stage. The batch size is set to 16, and the total number of global iterations is 200. Based on the characteristics of the model task, the weight coefficients of the loss functions were determined: the generator loss weight $\alpha = 0.6$, the style consistency loss weight β =0.4, the perceptual loss weight $\lambda_p = 0.5$, and the visual propagation effect weight $\gamma = 0.7$. The convergence determination threshold ε is set at 1×10^{-5}. When the loss function fluctuation is less than this threshold for three consecutive rounds, the model is judged to have converged, and training is terminated. The improved U-Net network embeds three groups of serial dilated convolution modules in the encoding stage to expand the feature receptive field. The attention module adopts an 8-head multi-head attention mechanism, with a unified feature dimension $d_k = 128$, ensuring the integrity and computational efficiency of multimodal feature interaction. According to statistics, the average time per model iteration is 45 minutes, and the cumulative running time of the complete training process is approximately 150 hours.

2) Dataset preprocessing, modal matching, and quality control: In this study, the brand's industry is taken as the core association logic, and the strong binding matching rules of text-color-graphic multimodal data are established. The style description text and color parameter matrix corresponding to the same brand are matched one by one to the logo graphic samples one by one, ensuring the semantic homology of multimodal data from the source. Aiming at the original image data, a variety of online data augmentation strategies are introduced, including random cropping, horizontal flipping, and adaptive fine-tuning of brightness and contrast to enrich the diversity of samples. At the same time, the median filtering algorithm is used to denoise the image to eliminate the salt-and-pepper noise and clutter interference generated in the process of acquisition and transmission. Aiming at the problems of category imbalance and domain deviation in the dataset, the hierarchical resampling algorithm is used to balance the sample set. The sample distribution ratio is adjusted according to the industry and style dimensions to weaken the negative impact of data deviation on the generalization ability of the model. All labels of the datasets are labeled by professionals in the field of visual design according to the unified labeling specifications. After the labeling work is completed, two rounds of cross-checking and sampling verification are carried out to eliminate invalid and mislabelled samples, thus fully ensuring the standardization, accuracy, and credibility of labels.

3) Multi-modal feature alignment, fusion and complete operation process: After the normalized pretreatment of different modal data, the text semantic coding is completed by the BERT model, and the text feature vector with a fixed dimension is generated. The modal features of color and graphics are extracted synchronously, and the semantic association weights between text-color and text-graphics are calculated based on the modal attention matrix to achieve accurate alignment of cross-modal features. Based on the calculated attention weights, the multi-modal feature weighted fusion is completed, and the fusion feature vector is generated and input into the improved U-Net generator, and the initial brand visual identification system sample is output. The samples are sent to the PatchGAN discriminator to complete the authenticity discrimination, and the network parameters are updated by combining the resistance loss, perception loss, and style consistency loss. After each round of training, adaptive parameter optimization is performed based on the comprehensive score of visual communication effect, and the network weights are dynamically adjusted. The entire iterative process continues until the model loss function meets the convergence condition, ultimately outputting a brand visual recognition system solution with a unified style and semantic matching.

IV. Data Source

All the experimental data in this study are taken from public authoritative datasets, and the reliability of the data has been verified in many studies in related fields, which can effectively support the related research work of brand visual identity. Logo Detection 3 K dataset (LOGO DET-3K) is selected as the image graphic data, which is divided into 9 categories and 3,000 sub-categories, including 158,652 brand logo images and 200,000 labeled data. It is widely used in tasks such as brand logo detection and visual generation, and many related research studies in the industry have used this dataset to carry out experiments. The dataset is accessed at https://blog.51cto.com/u_16099190.

The color modal data is taken from the audio-visual cross-modal correlation dataset of the National Basic Science Public Science Data Center. The dataset is constructed based on the hue, saturation, and lightness color space, covering 8 hues, 32 standard color cards, and 50 groups of three-color color matching samples. It has complete color parameters and color scheme data, and can support color feature extraction, color semantic association analysis, and other work. The dataset can be accessed at https://www.nbsdc.cn/general/datalinks/16666.11.nbsdc.

The text style data adopts the Chinese text style classification test set of Magic Community. The dataset contains four typical text styles: news, science and technology, spoken language, and e-commerce, which can meet the model training needs of brand text semantic coding and style matching. The access address of the dataset is https://www.modelscope.cn/datasets/IIC/NLP_style_classification_Chinese_testset.

In the data usage stage, this study is based on the industry of the brand and describes the graphic samples, color parameters, and texts corresponding to the same brand. Binding and pairing to realize semantic homology of multimodal data. To solve the problems of class imbalance and data deviation in the dataset, this study uses the stratified resampling method to balance the number of samples, and optimizes the original images through image augmentation operations such as random cropping, horizontal flipping, brightness fine-tuning, and the median filtering algorithm to improve data quality. All data labels are uniformly marked by professionals, and two rounds of cross-checking are completed to ensure accurate and reliable labeling results. In Tables I to IV, the characteristics of the dataset, experimental hardware environment, experimental software environment, and model core parameters used in this study are shown in turn.

TABLE I. Statistics of Multimodal Experimental Datasets

Dataset Name	Data Type	Data Scale
LogoDet-3K	Graphic mode	9 categories, 3,000 subcategories, 158,652 images, and 200,000 labels.
Audio-visual cross-modal correlation dataset	Color mode	8 tones, 32 standard color blocks, 50 sets of three-color color matching.
Chinese text style classification test set	Text mode	Four styles: news, science and technology, spoken language and e-commerce

Data source: Compiled by the author.

TABLE II. Experimental Hardware Configuration

Hardware Type	Specific Configuration
CPU	Intel Xeon Gold 6248R 2.5GHz
GPU	NVIDIA Tesla V100 32GB
RAM	128GB DDR4 2933MHz
SSD	2TB SSD+10TB HDD
Graphics memory	A single card is 32GB, which supports multi-card collaborative training.

Data source: Compiled by the author.

TABLE III. Experimental Software Environment and Dependent Libraries

Software Category	Specific Version/Tool
Operating system	Ubuntu 20.04 LTS
Deep learning framework	PyTorch 1.12.1
Programming language	Python 3.8.16
Visual processing library	OpenCV 4.5.5

Data source: Compiled by the author.

TABLE IV. Dataset Partition and Repeated-Experiment Parameters

Parameter Category	Parameter Name	Value/ Configuration
Data partitioning	Training set proportion	80%
Data partitioning	Verification set proportion	10%
Data partitioning	Test set proportion	10%
Training parameters	Number of repeated experiments	10 rounds

Data source: Compiled by the author.

V. Evaluation of Multimodal Brand Identity Model

A. Comparative Evaluation of Core Performance Indicators

Based on the standard data division (80% of the training set, 10% of the verification set, and 10% of the test set), three core dimensions, namely, generation quality, semantic mapping accuracy, and style consistency, are selected and compared with mainstream models. After 10 rounds of repeated experiments, the random error is reduced, and the analysis results of the mean value, standard deviation, and significant differences between models are presented below. Fig. 2 shows the results of comparative evaluation of core performance indicators.

In Fig. 2, the lower Fréchet Inception Distance (FID) and Style Feature Distance (SFD) represent the higher quality of generated samples and the better style consistency. The higher Structural Similarity Index (SSIM) and Semantic Matching (SM) indicate that semantic mapping accuracy and visual structure similarity are better. The data show that the proposed model is significantly superior to the traditional GAN, DCGAN (Deep Convolutional Generative Adversarial Network), and mainstream multimodal generation models in all core indicators: the FID average of 16.9 is 24.9% lower than StyleGAN2, and the SFD average of 0.82 is 40.6% lower than MM-GAN. SSIM and SM are 0.92 and 0.89, respectively, which are 27.8% and 30.9% higher than the basic GAN. At the same time, the standard deviation of each index of the proposed model is the smallest, which shows that the training stability of the model is stronger. This verifies the effectiveness of the multimodal feature alignment mechanism and style consistency constraint. It can effectively eliminate the barriers of semantic-visual mapping and improve the accuracy and coordination of BVIS generation.

B. Quantitative Evaluation of Model Robustness and Generalization Abilities

Aiming at the heterogeneity of data and the complexity of scenes in practical applications, a multi-scenario quantitative test is designed. It includes three types of test scenarios: data noise interference (Gaussian noise, salt-and-pepper noise), cross-industry data adaptation (beauty, science and technology, catering), and modality missing adaptation (single-modal input, dual-modal input) to quantify the stable performance of the model under complex conditions. Fig. 3 shows the results of quantitative evaluation of model robustness and generalization ability.

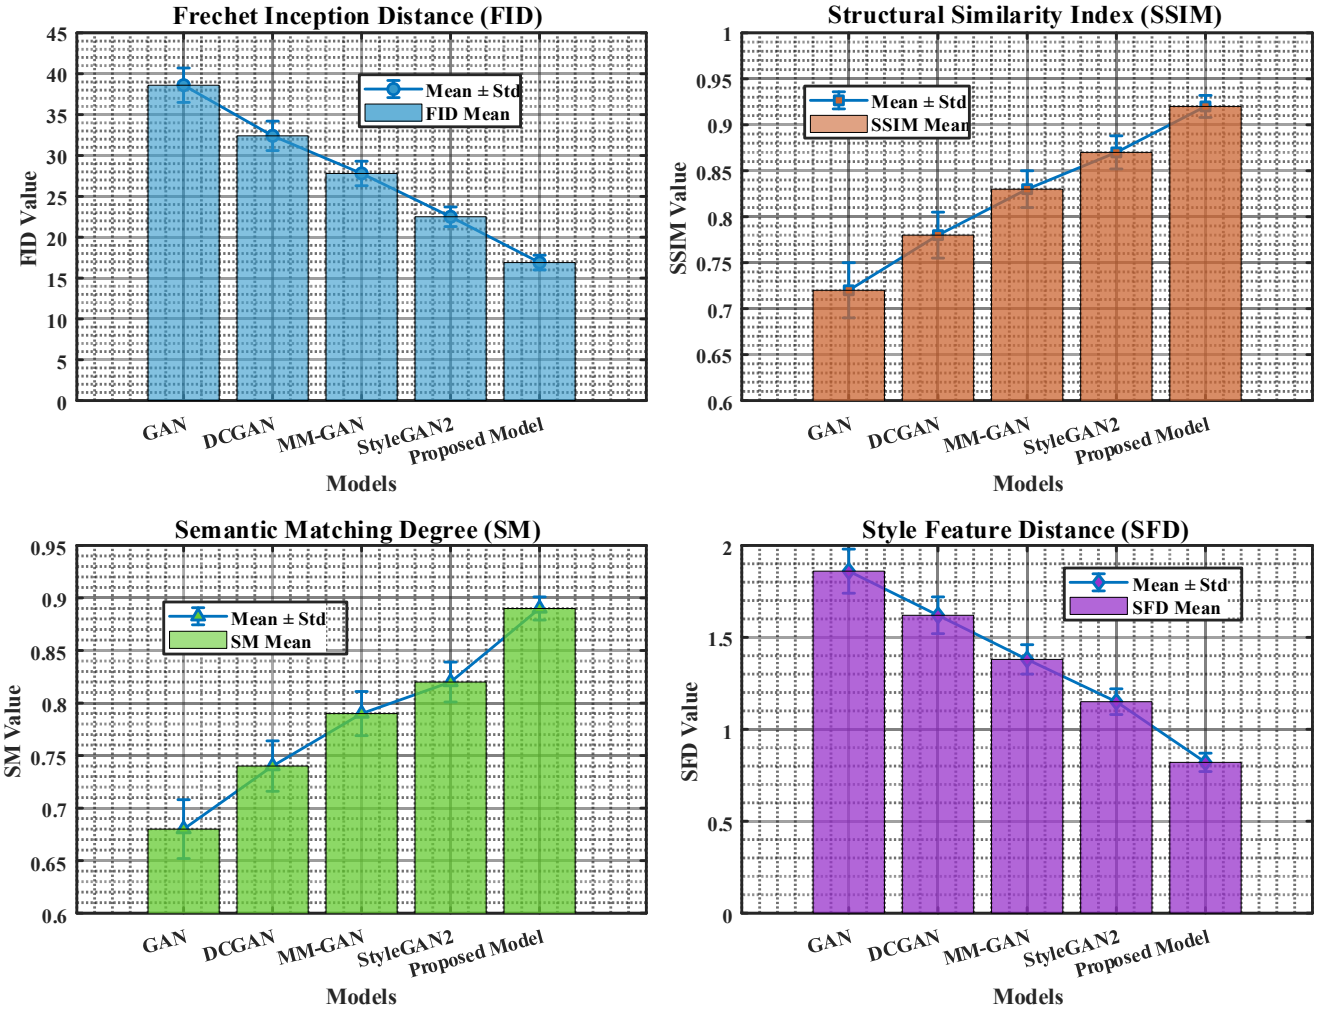

Fig. 2. Results of comparative evaluation of core performance indicators.

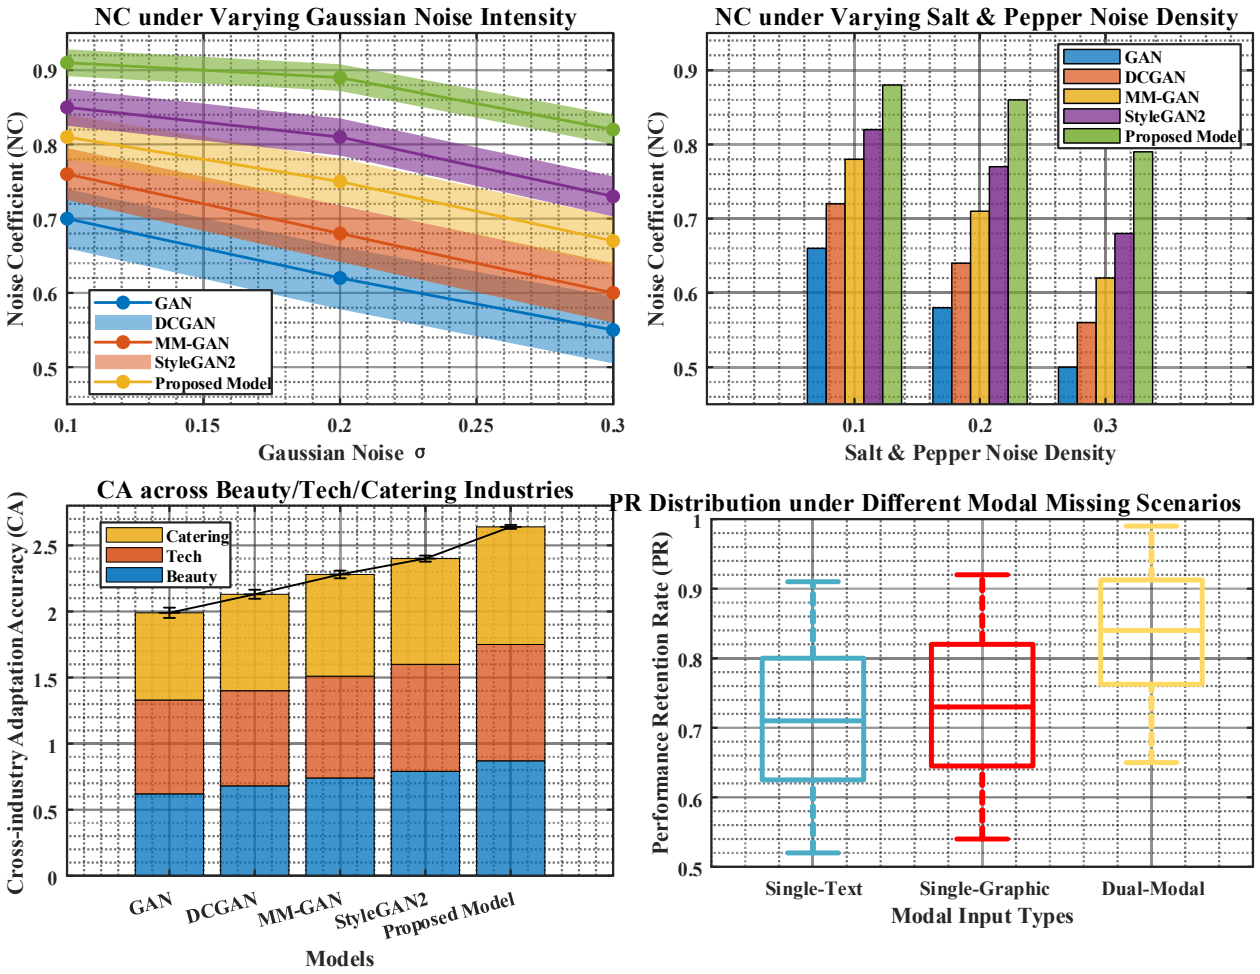

Fig. 3. Results of quantitative evaluation of model robustness and generalization ability.

In Fig. 3, the proposed model shows significant advantages in the noise-interference scene: the value of Noise Coefficient (NC) reaches 0.82 under σ=0.3 Gaussian noise, which is 12.3% higher than that of StyleGAN2. When the salt-and-pepper noise density is 0.3, the NC value is 0.79. It is 27.4% higher than that of MM-GAN, which verifies the strong anti-noise robustness. In cross-industry adaptation, the average value of total CA is 2.64, which is 32.7% higher than that of basic GAN. The beauty, technology, and catering industries all maintain high accuracy and outstanding generalization ability. In the scene of modal absence, the single-text-input Performance Retention (PR) reaches 0.84, and the dual-modal-input PR reaches 0.93. It is much higher than the contrast model, reflecting the effectiveness of the modal adaptation mechanism. On the whole, the proposed model is more stable under data heterogeneity and scene complexity. Its robustness and generalization ability can meet the practical application requirements of brand visual identification.

C. Evaluation of Ablation Experiment

To verify the independent contribution and synergistic effect of the core modules of the proposed model, an ablation experiment is designed to remove the multimodal feature alignment mechanism, style consistency constraints, and adaptive optimization modules one by one. The core performance indicators (FID, SSIM, SM, NC) are used as the evaluation basis to compare with the complete model. The experiment is based on the same dataset and training parameters. The effects of each module are isolated by the control variable method. The following is a quantitative analysis of the influence of each module on the model generation quality, robustness, and generalization ability, and the necessity of key technologies is clarified. Fig. 4 shows the results of the ablation experiment.

In Fig. 4, the ablation experimental results show that the complete model is the best in all core indicators: the lowest FID value (16.9) and the highest SSIM, SM, and NC values, which verifies the effectiveness of the synergy of each module. After removing the multimodal feature alignment mechanism, each index degrades most significantly, with FID rising by 69.8% and SM dropping by 19.1%, which shows that this module is the core to ensure semantic matching and generation quality. The lack of a style consistency constraint leads to a reduction in the structural similarity of generated content, while the adaptive optimization module mainly affects the anti-noise ability of the model (NC decreases by 7.9%). On the whole, the three modules are irreplaceable, and the contribution of the feature alignment mechanism is the most critical. Together, the three modules improve the generation quality, robustness, and semantic matching ability of the model.

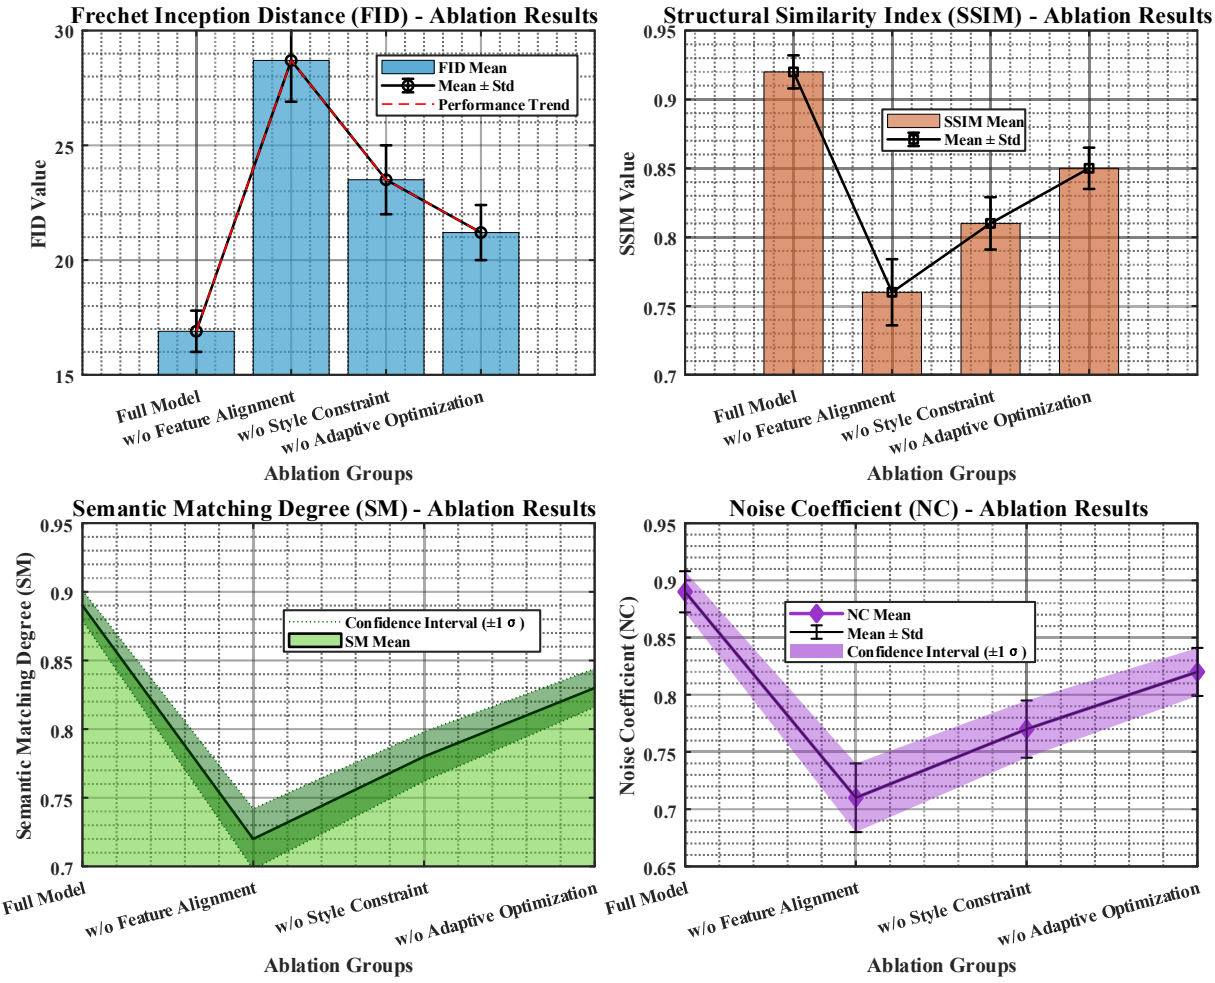

Fig. 4. Results of ablation experiment.

D. Comprehensive Evaluation Results

To highlight the comprehensive performance of this model, this study comprehensively analyzes the model through deeper comparative evaluation. Tables V-IX show the comprehensive evaluation results of the model.

In Tables V-IX, combined with the experimental data of each group, it shows that the comprehensive performance advantage of this model is remarkable. The data in Table V show that the FID value of this model is 16.9, which is the lowest among all comparison models, representing the best image generation quality. SSIM reaches 0.92. The semantic matching degree is 0.89, which is far superior to traditional models such as basic GAN and DCGAN, and superior to the CLIP guidance model and diffusion model. It proves that the multi-modal fusion scheme in this study can effectively improve the visual restoration degree and the text-visual semantic matching ability. The statistical results in Table VI show that the standard deviation of each index is small, the 95% confidence interval is narrow, and the p-values are all less than 0.05. This shows that the model performance is stable and the experimental results are statistically significant. The Kappa coefficients of all indicators in Table VII are higher than 0.8, which proves that the evaluation criteria of self-defined indicators such as semantic matching degree and communication effect score are scientific and the results are credible. From Table VIII, the parameters and reasoning time of this model are much lower than those of CLIP and diffusion models, which ensures the generation effect and gives consideration to the operation efficiency. In Table IX, in the cross-dataset test, the indicators of the model only drop slightly. There is no obvious performance decline, which shows excellent generalization ability. On the whole, this model is balanced in terms of generation quality, stability, operation efficiency, and cross-scene adaptability, and can adapt to the actual design requirements of a brand visual identification system.

TABLE V. COMPARATIVE RESULTS OF CORE PERFORMANCE INDICATORS FOR DIFFERENT GENERATION MODELS

Model	FID	SSIM	Semantic Matching Degree
Basic GAN	22.5	0.72	0.68
DCGAN	21.1	0.71	0.67
StyleGAN2	22.6	0.79	0.72
CLIP-guided generation model	19.3	0.83	0.77
Diffusion model	18.2	0.85	0.80
The proposed model	16.9	0.92	0.89

Data source: Compiled by the author.

TABLE VI. VERIFICATION RESULTS OF INDICATOR CONSISTENCY

Evaluation Indicator	Mean Value	Standard Deviation	95% Confidence Interval	Significance (p-Value)
FID	16.9	0.42	[16.48,17.32]	p<0.05
SSIM	0.92	0.018	[0.902,0.938]	p<0.05
Semantic matching degree	0.89	0.021	[0.869,0.911]	p<0.05
Noise figure	0.82	0.015	[0.805,0.835]	p<0.05
Cross-industry adaptation accuracy	2.64	0.033	[2.607,2.673]	p<0.05
Performance retention rate	0.84	0.024	[0.816,0.864]	p<0.05

Data source: Compiled by the author.

TABLE VII. CONSISTENCY VERIFICATION BETWEEN MANUAL SCORING AND ALGORITHM SCORING

Evaluation Indicator	Algorithm Average Score	Artificial Average Score	Kappa Coefficient
Semantic matching degree (SM)	0.89	0.87	0.86
Communication effect score	0.86	0.85	0.84
Performance retention rate (PR)	0.84	0.83	0.82

Data source: Compiled by the author.

TABLE VIII. PARAMETER SCALE AND INFERENCE EFFICIENCY COMPARISON OF VARIOUS MODELS

Model	Parameter Quantity (Ten Thousand)	Single Sample Inference Time (ms)
Basic GAN	426	28.6
DCGAN	512	32.1
StyleGAN2	1286	65.3
CLIP-guided generation model	2153	92.7
Diffusion model	1869	84.2
The proposed model	675	36.5

Data source: Compiled by the author.

TABLE IX. CROSS-DATASET GENERALIZATION PERFORMANCE TEST OF THE PROPOSED MODEL

Dataset	FID	SSIM	Semantic Matching Degree (SM)
Original dataset	16.9	0.92	0.89
Logo-2K+dataset	17.5	0.90	0.87

Data source: Compiled by the author.

VI. CONCLUSION

In the context of global brand digital transformation, traditional BVIS design heavily relies on the subjective experience of designers, resulting in problems such as long design cycles, style homogenization, and delayed market response. Multimodal generative adversarial networks offer a new approach to intelligent BVIS generation, but still face technical bottlenecks such as insufficient accuracy in multimodal semantic mapping, inconsistent visual element styles, and a lack of quantitative optimization mechanisms. This study uses MM-GAN as the basic architecture, integrating attention mechanisms and adaptive optimization strategies to complete multimodal data preprocessing alignment, feature fusion, generation constraints, and dynamic optimization, constructing an automatic BVIS generation and optimization algorithm. Experimental results show that the proposed model achieves a Fraser Inception distance of 16.9, significantly outperforming StyleGAN2. The structural similarity index and semantic matching (SM) reach 0.92 and 0.89, respectively. The model also demonstrates good anti-interference ability and generalization performance in scenarios with noise interference, cross-industry adaptation, and modality loss. Ablation experiments confirm that the multimodal feature alignment mechanism is the core module of the model, style consistency constraints ensure the internal coordination of the visual system, and adaptive optimization improves scene adaptability. These three elements synergistically enhance generation quality, semantic matching accuracy, and model robustness, providing technical support for BVIS intelligent design. Compared to diffusion and CLIP models, the proposed method has advantages in training efficiency and industry customization, but there is still room for improvement in detail generation capabilities. This study also discusses ethical application risks such as dataset bias, copyright of AI-generated content, and brand counterfeiting. Due to data limitations, the current dataset has limited industry coverage. Future research could expand the dataset with more perceptual modal information to extend the dynamic brand visual recognition system generation task, further enhancing the algorithm's engineering application value.

***Abstract*—Physical activity applications support monitoring, motivating, and sustaining healthy behavior, yet long-term engagement remains challenging. This study validates an integrated Health Belief Model and User Engagement Model for explaining behavior change among physical activity application users. Survey data from 423 users were analyzed using Partial Least Squares Structural Equation Modeling, followed by a four-week Strava study involving 17 participants and post-usage interviews. The results showed that Healthy Behavior Adoption and Health Technology Engagement significantly influenced behavior change, with technology engagement exerting the stronger effect. Perceived usability and reward factors were the strongest predictors of technology engagement, while self-efficacy and objective barriers were the strongest predictors of healthy behavior adoption. Focused attention and cues to action were not significant. Real-world usage and interview findings supported the model by showing that usability, meaningful feedback, and perceived progress were more influential than continuous attention or repeated reminders in supporting sustained physical activity behavior.**

Keywords*—Mobile health; physical activity applications; health belief model; user engagement model; behavior change; technology engagement

I. Introduction

Physical inactivity remains a public health challenge despite various campaigns and interventions being implemented. The prevalence of insufficient physical activity has been reported to increase from 26.4% in 2010 to 31.3% in 2022, indicating that awareness of the importance of physical activity has not necessarily led to sustained behavioral changes [1]. In this context, mobile health applications, or mHealth, are increasingly used to support activity monitoring, goal setting, performance feedback, and the formation of an active lifestyle.

Although mHealth applications have the potential to increase physical activity, their effectiveness is often limited by decreased engagement and discontinuation of use after the initial phase. Users may stop using the application due to time constraints, usability issues, decreased motivation, or the perception that the application is no longer needed [2], [3]. Additionally, frequent use of the application does not necessarily reflect meaningful engagement or actual behavior change. Therefore, the evaluation of mHealth applications should take into account not only user perceptions but also usage experiences and behavioral data in real contexts [4], [5].

Previous studies typically explain behavioral changes from the perspective of health psychology or technology engagement separately. The Health Belief Model (HBM) explains how perceptions of benefits, barriers, severity, self-efficacy, and cues to action influence individual health decisions [6], [7]. However, the HBM does not explain the user interaction experience with digital applications. On the other hand, the User Engagement Model (UEM) emphasizes focused attention, usability, aesthetic appeal, and reward factors in shaping the technology usage experience [8], [9], but it pays less attention to health beliefs that drive physical activity behavior.

To address this gap, this study integrates HBM and UEM into a single model of user behavior change for physical activity applications. This model proposes two parallel mechanisms: "Healthy Behavior Adoption," shaped by health beliefs, and "Health Technology Engagement," influenced by the experience of using the application. Both mechanisms are expected to drive changes in user behavior. This approach allows for an understanding of behavioral change through a combination of health motivation and technology experience, rather than relying on a single theoretical perspective.

This study aims to validate the integrated HBM-UEM model using PLS-SEM, based on data from 423 users of physical activity applications. The model was further evaluated in a real-world usage context through a four-week study of Strava usage involving 17 participants, followed by post-usage interviews. The study contributes to the fields of mHealth and human-computer interaction by combining statistical validation, real-world usage data, and user experience to explain how health beliefs and technology engagement jointly support behavioral changes regarding physical activity.

The theoretical contribution of this study indicates that behavioral change in physical activity applications stems from two complementary mechanisms, as it cannot be fully explained by a single perspective. While existing studies based on the Health Belief Model (HBM) are useful for explaining healthy behaviors in terms of perceived barriers and risks, they offer limited insight into how users evaluate and sustain engagement with digital applications. Conversely, engagement-based models account for factors such as interaction quality, usability, attention, aesthetic appeal, and rewards, yet they fail to consider the health-related beliefs that drive physical activity adequately. By integrating HBM and UEM, this study extends prior research by distinguishing between Healthy Behavior Adoption, which represents psychological readiness, and Health Technology Engagement, which represents users' digital experience. This dual-pathway structure enables a more comprehensive explanation of behavioral change in mobile health (mHealth) physical activity applications, highlighting that users require

both the psychological motivation to remain active and the technological support to sustain the app-driven behavior.

II. Related Work

A. mHealth Applications and Changes in Physical Activity Behavior

Mobile health (mHealth) applications are increasingly being used to support physical activity through features such as step and distance monitoring, goal setting, performance feedback, and progress tracking. Previous studies indicate that the use of mHealth applications can increase step counts and the duration of physical activity, particularly during short-term interventions [10]. However, these effects do not necessarily persist after the intervention ends. Users also frequently reduce or discontinue app usage after the initial phase due to usability issues, the need for manual input, time constraints, subscription costs, and declining motivation [11], [12].

User engagement in mHealth encompasses behavioral and psychological dimensions. The behavioral dimension refers to the frequency of use, number of sessions, and duration of interaction, while the psychological dimension involves motivation, attention, satisfaction, and perceived value from using the application [13]. Although higher engagement is often associated with increased physical activity, frequent use of the application does not necessarily result in behavioral change if the interaction does not hold meaning for the user [4]. Therefore, the evaluation of physical activity applications needs to consider user experience and actual behavior, not just intention or frequency of use.

B. Health Belief Model in the Context of mHealth

The Health Belief Model HBM explains that individual health actions are influenced by beliefs about health risks, the benefits of actions, barriers faced, self-efficacy, and cues to action [6], [7]. In physical activity studies, perceived benefits, perceived barriers, and self-efficacy are often identified as important factors influencing an individual's decision to initiate or maintain active behavior [14], [15].

Recent mHealth and digital health studies have continued to apply HBM to explain users' adoption of health applications, preventive health behavior, exercise participation, and technology-supported self-management. For example, Alharbi et al. [16] applied the HBM to examine health mobile app adoption and found that perceived benefits and self-efficacy were important predictors of behavioral intention, while perceived barriers and cues to action were not significant. Nasution et al. [17] also used HBM constructs to guide the development of a mobile health application for breast examination awareness, showing that the model remains relevant for structuring app-based health promotion content. In the context of physical activity, Faghih et al. [18] demonstrated the usefulness of HBM-based training and social support in promoting physical activity. However, studies on continuous mHealth use also indicate that sustained engagement is influenced by usability, feedback, personalization, and interaction experience [19]. Therefore, although HBM remains valuable for explaining health-related beliefs and readiness to act, it needs to be complemented by a technology engagement perspective when studying physical activity applications.

In the context of mHealth, HBM is used to explain how users assess the benefits of the application, usage barriers, and self-efficacy to engage in health behaviors. Applications that provide monitoring, goal setting, and progress visualization have the potential to enhance users' self-efficacy. However, users who understand the benefits of an application can still stop using it when the interaction experience is unsatisfactory, the content becomes repetitive, or the application no longer fits their daily routine [19]. This indicates that HBM is more effective in explaining health motivations and decisions, but less effective in explaining the continuous experience of technology use.

Additionally, HBM was originally developed to explain health behaviors that are more episodic in nature. Therefore, its ability to explain behaviors that require long-term commitment, such as physical activity and continuous app usage, still has limitations [18]. In a digital environment, health trust needs to be complemented by factors that explain how users experience and evaluate their interactions with the application.

III. Methodology

A. Study Design

This study employs a multi-phase mixed-methods design to validate the integration model of the Health Belief Model and the User Engagement Model. The quantitative component is used as the primary method to evaluate the measurement model and the structural model, while actual application usage data and user interviews are used to provide contextual validation and explanation for the statistical findings. This design allows the model to be evaluated through three forms of evidence, namely user perception, actual usage behavior, and user subjective experience.

Specifically, the study involves three stages. The first stage is the empirical validation of the model using a questionnaire and Partial Least Squares Structural Equation Modeling (PLS-SEM) analysis. The second stage involves a longitudinal study of the use of the Strava application over four weeks. The third stage involves post-usage interviews to explain the behavior patterns and experiences of the participants. The Strava study and interviews were not used to re-estimate the structural model, but as behavioral and contextual validation of the relationships identified through PLS-SEM.

B. Participants and Data Collection of the Questionnaire

The target population consists of adult users aged 18 and above who own a smartphone and have either used or are currently using at least one physical activity application. Purposive sampling was used to ensure that respondents had relevant experience to evaluate the app features and behavioral changes. From the responses received, 423 respondents who met the participation criteria were used in the final analysis.

The research instrument contains items that measure the constructs of HBM, UEM, Healthy Behavior Adoption (HBA), Health Technology Engagement (HTE), and behavior change. The HBM construct includes perceived benefits, objective barriers, subjective barriers, self-efficacy, perceived severity, and cues to action. The UEM construct, on the other hand, consists of focused attention, perceived usability, aesthetic appeal, and reward factors. All items were adapted from

instruments used in previous studies and measured using a five-point Likert scale.

The questionnaire was developed based on established measures of HBM, user engagement, technology engagement, and behavior change. Each construct was operationalized according to its theoretical meaning in the context of physical activity applications. Perceived benefits measured users' beliefs regarding the usefulness of physical activity applications in improving health and activity behavior. Objective barriers captured external constraints such as time, cost, access, and environmental limitations, while subjective barriers captured internal concerns such as lack of confidence, low motivation, and perceived difficulty. Self-efficacy measured users' perceived ability to engage in physical activity with the support of the application. Perceived severity assessed users' awareness of the consequences of physical inactivity, while cues to action measured prompts, reminders, notifications, and social triggers that may encourage activity.

For the UEM constructs, focused attention measured the extent to which users were absorbed in interacting with the application, perceived usability assessed ease of use and clarity of interaction, aesthetic appeal measured visual attractiveness and interface presentation, and reward factors captured the role of achievements, feedback, badges, and progress indicators. Healthy Behavior Adoption represented users' intention and readiness to adopt physical activity behavior, while Health Technology Engagement represented meaningful engagement with the application. Behavior change measured perceived changes in physical activity behavior after using the application. All items were measured using a five-point Likert scale ranging from strongly disagree to strongly agree. The adapted items were reviewed for contextual suitability before data collection.

C. PLS-SEM Analysis

Survey data were analyzed using SmartPLS through two main stages. The first stage involves the assessment of the measurement model. Internal reliability is assessed using Cronbach's alpha and composite reliability values, while convergent validity is evaluated through the Average Variance Extracted (AVE) value. Discriminant validity is assessed using the Fornell–Larcker criterion and the Heterotrait–Monotrait Ratio (HTMT).

The second stage involves the evaluation of the structural model to test the relationships between constructs. In addition to the assessment of path coefficients, the structural model was evaluated using collinearity statistics, model fit, and bootstrapping results. Variance inflation factor (VIF) values were examined to determine whether multicollinearity was present among predictor constructs. Bootstrapping was conducted to obtain t-values, p-values, and confidence intervals for each hypothesized relationship. These procedures were used to ensure that the structural paths were statistically reliable and that the model validation was not based solely on path coefficients. This analysis includes the examination of collinearity, path coefficients, t-values, and p-values through the bootstrapping procedure. The explanatory and predictive capabilities of the model are evaluated using the R^2 coefficient of determination, f^2 effect size, and Q^2 predictive value. PLS-SEM was chosen because it is suitable for models involving many latent constructs, is prediction-oriented, and does not require strict assumptions of data normality.

The health-belief pathway explains HBA through perceived benefits, objective barriers, subjective barriers, self-efficacy, perceived severity, and cue to action. The technology-engagement pathway explains HTE through focused attention, perceived usability, aesthetic appeal, and reward factors. The structural relationships are expressed as follows:

$$HBA = \beta_1 PB + \beta_2 POB + \beta_3 PSB + \beta_4 SE + \beta_5 PS + \beta_6 CTA + \zeta_1, \quad (1)$$

$$HTE = \beta_7 FA + \beta_8 PU + \beta_9 AE + \beta_{10} RW + \zeta_2$$

$$BC = \beta_{11} HBA + \beta_{12} HTE + \zeta_3$$

where, β represents the path coefficients and ζ represents the residual terms. These relationships were estimated using PLS-SEM.

D. Study of Actual Strava Usage

After the empirical validation of the model, a longitudinal case study was conducted to assess whether the behavioral change mechanisms in the model could be observed in actual app usage. This study involved 17 participants aged between 18 and 35 years who were physically inactive, owned a smartphone, and had never used the Strava application.

Before participating in the study, the participants underwent screening using the International Physical Activity Questionnaire–Short Form (IPAQ-SF), the Stages of Change Questionnaire, and the Physical Activity Readiness Questionnaire (PAR-Q+). This screening aims to identify the initial level of activity, readiness to change, and the suitability of participants to engage in physical activity.

Participants are asked to use Strava for four weeks and engage in at least three physical activity sessions per week, with a minimum duration of 30 minutes for each session. Strava was chosen because it provides an objective record related to the number of sessions, duration, distance, frequency, and consistency of activities. Participants' log data were analyzed to identify weekly usage patterns, adherence to targets, and early changes in physical behavior. This study aims to provide real-world validation rather than statistical generalization, given the small sample size.

The Strava substudy was not intended to statistically represent the larger survey sample or to re-estimate the structural model. Instead, it served as a contextual and behavioral validation component to examine whether selected mechanisms identified in the PLS-SEM model could be observed in actual application use. The smaller and more homogeneous sample allowed the study to monitor real-world app usage consistently over four weeks. Therefore, the triangulation was interpreted as convergent contextual evidence rather than direct sample equivalence between the survey and longitudinal components.

E. Post-Usage Interview

Semi-structured interviews were conducted after the four-week Strava usage period to understand participants' experiences with the application and to explain the quantitative findings. The interview questions focused on users' motivation

to be physically active, perceived benefits and barriers, experience with Strava features, perceived usefulness of feedback and rewards, attention during app use, reminders, and perceived behavior change. Each interview was conducted after the completion of the usage study and was guided by an interview protocol aligned with the HBM and UEM constructs.

The interview data were analyzed using thematic analysis. The analysis involved transcription of participants' responses, repeated reading to obtain familiarity with the data, initial coding based on meaningful statements, grouping of related codes into themes, and interpretation of themes in relation to the HBM-UEM constructs. A deductive approach was used because the coding was guided by the constructs in the integrated model, while inductive interpretation was applied to identify contextual explanations that emerged from participants' experiences. The themes were then compared with the PLS-SEM results and Strava usage patterns to determine whether the qualitative findings supported, contradicted, or extended the quantitative results.

F. Data Integration

To gain further insight into the quantitative data findings, data triangulation was conducted to deepen the understanding of the results. This process involved triangulating the quantitative data with qualitative data derived from actual usage patterns and interviews. This triangulation is crucial for understanding the actual situations and user behaviors regarding the use of physical activity applications.

IV. Results

A. Measurement Model Assessment

The assessment of the measurement model shows that all constructs meet the established levels of reliability and validity. The Cronbach's alpha and composite reliability values for all constructs exceed 0.70, while the Average Variance Extracted (AVE) values exceed 0.50. These findings indicate that the measurement items have satisfactory internal consistency and convergent validity. Table I presents the summary of the measurement model assessment, including indicator loading range, Cronbach's alpha, composite reliability, and AVE values for each construct.

The measurement model demonstrated acceptable reliability and convergent validity. Cronbach's alpha and composite reliability values exceeded the recommended threshold of 0.70 for all constructs, while AVE values were above 0.50. Most indicator loadings exceeded 0.70. Several items, including HBA8, PSB1, PU2, and SE1, recorded lower loadings; however, they were retained because the AVE and composite reliability values remained acceptable and the items were theoretically relevant to their respective constructs.

Discriminant validity was also confirmed through the Fornell–Larcker criterion and the Heterotrait–Monotrait Ratio (HTMT). All HTMT values are below the threshold of 0.90, with the highest value being 0.799 between Health Technology Engagement (HTE) and behavioral change. Therefore, each construct in the model can be empirically distinguished from the other constructs.

TABLE I. Measurement Model Assessment

Construct	Item	Loading Range	CA	CR	AVE
BC	BC1-BC7	0.607–0.877	0.904	0.910	0.638
HTE	HTE1-HTE6	0.713–0.933	0.940	0.950	0.775
HBA	HBA1-HBA8	0.313–0.849	0.891	0.915	0.590
EA	AE1-AE3	0.872–0.932	0.897	0.937	0.826
FA	FA1-FA3	0.834–0.917	0.843	0.940	0.752
PU	PU1-PU3	0.643–0.944	0.714	0.780	0.648
RW	RW1-RW3	0.900–0.933	0.903	0.906	0.837
CTA	CTA1-CTA3	0.751–0.912	0.788	0.841	0.701
PB	PB1-PB3	0.909–0.951	0.923	0.952	0.865
POB	POB1-POB4	0.924–0.979	0.965	0.967	0.905
PS	PS1-PS2	0.766–0.954	0.700	0.910	0.749
PSB	PSB1-PSB3	0.470–0.969	0.702	0.969	0.563
SE	SE1-SE3	0.691–0.879	0.713	0.755	0.636

[a.] Note: CA = Cronbach's Alpha, CR = Composite Reliability, AVE = Average Variance Extracted, BC = Behaviour Change; HTE = Health Technology Engagement; HBA = Healthy Behaviour Adoption; AE = Aesthetic Appeal; FA = Focused Attention; PU = Perceived Usability; RW = Reward Factor; CTA = Cue to Action; PB = Perceived Benefits; POB = Perceived Objective Barriers; PS = Perceived Severity; PSB = Perceived Subjective Barriers; SE = Self-Efficacy.

TABLE II. Discriminant Validity Summary

Criterion	Result	Interpretation
Fornell–Larcker criterion	The square root of AVE for each construct was higher than its correlations with other constructs.	Discriminant validity was established.
HTMT	All HTMT values were below 0.90; the highest HTMT value was 0.799 between HTE and BC.	Discriminant validity was established.
Cross-loading	All indicators loaded highest on their intended constructs compared with other constructs.	No critical cross-loading issue was detected.

Discriminant validity was confirmed using the Fornell–Larcker criterion, HTMT, and cross-loading assessment (Table II). The Fornell–Larcker results showed that each construct shared higher variance with its own indicators than with other constructs. All HTMT values were below 0.90, with the highest value of 0.799 between HTE and BC. The cross-loading assessment also showed that each indicator loaded highest on its assigned construct, indicating no critical overlap among indicators.

B. Model Evaluation: Structural Model Assessment

The results of the structural model analysis indicate that 10 out of the 12 tested relationships are significant. Table III summarizes the path coefficient results for the HBM–UEM integration model. Table III shows that 10 of the 12 hypothesized relationships were supported, with HTE exerting the strongest effect on behaviour change.

$$BC = 0.230(HBA) + 0.653(HTE) \quad (2)$$

TABLE III. STRUCTURAL MODEL PATH COEFFICIENTS AND HYPOTHESIS TESTING RESULTS

Relationship	β	t-Value	p-Value	f^2	Result
HTE → BC	0.653	18.447	<0.001	0.883	Supported
HBA → BC	0.230	4.890	<0.001	0.110	Supported
AE → HTE	0.114	3.154	0.002	0.005	Supported
FA → HTE	0.064	1.258	0.208	0.027	Not Supported
PU → HTE	0.438	10.991	<0.001	0.344	Supported
RW → HTE	0.358	8.193	<0.001	0.139	Supported
CTA → HBA	0.098	1.686	0.092	0.052	Not Supported
PB → HBA	0.200	5.717	<0.001	0.082	Supported
POB → HBA	0.315	10.399	<0.001	0.253	Supported
PS → HBA	0.235	7.002	<0.001	0.117	Supported
PSB → HBA	0.147	4.829	<0.001	0.028	Supported
SE → HBA	0.320	9.527	<0.001	0.270	Supported

[b.] Note: BC = Behavior Change; HTE = Health Technology Engagement; HBA = Healthy Behavior Adoption; AE = Esthetic Appeal; FA = Focused Attention; PU = Perceived Usability; RW = Reward Factor; CTA = Cue to Action; PB = Perceived Benefit; POB = Objective Barrier; PS = Perceived Severity; PSB = Subjective Barrier; SE = Self-Efficacy.

Based on the estimated path coefficients, the final behavior change equation is expressed in Eq. (2), indicating that technology engagement exerted a stronger effect than healthy behavior adoption.

HTE is the strongest predictor of behavior change with a β value of 0.653, while HBA also has a positive and significant influence with a β value of 0.230. In the technology pathway, perceived usability is the strongest predictor of HTE (β = 0.438), followed by reward factors (β = 0.358) and aesthetic appeal (β = 0.114). Focused attention does not show a significant relationship with HTE (β = 0.064, p = 0.208).

In the health belief pathway, self-efficacy is the strongest predictor of HBA (β = 0.320), followed by objective barriers (β = 0.315), perceived severity (β = 0.235), perceived benefits (β = 0.200), and subjective barriers (β = 0.147). The cue to action does not have a significant influence on HBA (β = 0.098, p = 0.092).

C. Model's Explanatory Power and Predictive Relevance

The model recorded an R^2 value of 0.665 for HBA, 0.538 for HTE, and 0.613 for behavioral change. This shows that the HBM construct explains 66.5% of the variation in HBA, the UEM construct explains 53.8% of the variation in HTE, while HBA and HTE together explain 61.3% of the variation in behavioral change.

Effect size analysis shows that HTE has a large effect on behavioral change, with $f^2 = 0.883$, while HBA has a small effect, with $f^2 = 0.110$. In the technology pathway, perceived ease of use has a moderate effect on HTE ($f^2 = 0.344$), followed by the reward factor ($f^2 = 0.139$). In the HBM path, self-efficacy ($f^2 = 0.270$) and objective barriers ($f^2 = 0.253$) show a moderate effect on HBA.

All endogenous constructs also recorded Q^2 values exceeding zero, namely 0.382 for HBA, 0.412 for HTE, and 0.375 for behavioral change. This result (Table IV) shows that the model has satisfactory predictive relevance.

TABLE IV. MODEL EXPLANATORY POWER, PREDICTIVE RELEVANCE AND COMMON METHOD BIAS

Assessment	Construct / Test	Value	Interpretation
R^2	BC	0.613	Substantial
R^2	HTE	0.538	Substantial
R^2	HBA	0.665	Substantial
Q^2	BC	0.375	High predictive relevance
Q^2	HTE	0.412	High predictive relevance
Q^2	HBA	0.382	High predictive relevance
Common method bias	Harman's single-factor test	30.61%	Below 50%; low risk of common method bias

The model demonstrated satisfactory explanatory and predictive capability. The R^2 values indicated substantial explanatory power for BC, HTE, and HBA, while Q^2 values above zero confirmed predictive relevance. Common method bias was assessed using Harman's single-factor test. The first factor explained 30.61% of the total variance, which is below the 50% threshold, indicating that common method bias was unlikely to be a serious concern.

D. Pattern of Strava Usage in Real Context

The real usage study involved 17 participants, consisting of eight men and nine women aged between 18 and 23 years. The majority of the participants were students. Throughout the four weeks, a total of 55 sessions were recorded in Week 1, 52 sessions in Week 2, 58 sessions in Week 3, and 48 sessions in Week 4. Table V shows that participants maintained approximately three activity sessions per week, with the highest activity recorded in Week 3.

TABLE V. WEEKLY STRAVA USAGE AND PHYSICAL ACTIVITY STATISTICS

Metric	Week 1	Week 2	Week 3	Week 4
Number of sessions/week	3.18 ± 1.01	2.76 ± 1.30	3.24 ± 1.75	2.82 ± 1.51
Active minutes/week	112.34 ± 75.92	99.52 ± 66.70	146.20 ± 106.65	105.11 ± 65.23
Average minutes/session	33.59 ± 16.86	35.08 ± 18.46	45.11 ± 22.81	39.43 ± 22.23

[c.] Note: Values are presented as mean ± standard deviation.

The average number of sessions remained nearly three sessions per week throughout the study. The highest activity level was recorded in Week 3, with an average of 3.24 sessions and 146.20 active minutes per week. However, activity decreased again in Week 4 to 2.82 sessions and 105.11 minutes. The percentage of participants who met the session and activity duration targets reached its highest level in Week 3, at 64.71%, and remained at 58.82% in Week 4. This pattern shows that behavioral changes do not occur linearly, but rather fluctuate according to time, commitment, and the daily circumstances of the participants.

E. Post-Usage Interview Findings

Post-usage interview findings revealed several themes aligned with the HBM and UEM constructs. Participants were aware of the dangers of physical inactivity and the benefits of an active lifestyle, which correspond to the constructs of perceived severity and perceived benefits.

However, participants also acknowledged that time constraints, commitments, weather conditions, and other factors served as major barriers to remaining active. Participants may have lacked confidence in their ability to engage in physical activity during unfavorable weather (such as rain or excessive heat) or were unaware that they could perform simple physical activities without disrupting their daily commitments. App-based recommendations and personalization are crucial to ensuring that participants do not allow these constraints to deter them from engaging in physical activity.

From the UEM perspective, participants generally found Strava easy to use, noting its organized and uncomplicated interface. Features such as maps, distance, duration, and progress tracking helped participants evaluate their performance and foster a sense of achievement. However, the impact of digital rewards varied; some participants valued medals and achievements, while others paid little attention to them.

Participants also explained that they did not need to constantly monitor the app while exercising. The app was simply activated before the activity and allowed to run in the background. This finding aligns with the non-significant relationship observed between focused attention and HTE. Some participants continued their physical activity even as their usage of Strava declined, indicating that reduced interaction with the app did not necessarily mean the behavioral change had ceased.

F. Integration of Findings

Overall, the PLS-SEM findings, Strava data, and interviews support the two-path structure in the HBM–UEM integration model. The HBM pathway shows that perceived benefits, barriers, severity, and self-efficacy shape HBA, while the UEM pathway shows that usability, rewards, and aesthetics shape HTE. Both paths influence behavior change, but the technology engagement path shows a stronger effect.

The findings of actual usage also provide an explanation for the two insignificant relationships. Focused attention is not required continuously because Strava operates passively during the activity. The cues to action are also insufficient to form HBA without internal motivation, perceived benefits, and self-efficacy. Therefore, the triangulation of findings indicates that behavioral changes in the application of physical activities are influenced by a combination of psychological readiness and practical, meaningful technological experience.

The qualitative findings did not merely confirm the statistical results but helped explain why certain relationships were stronger or weaker in actual use. For example, interviews clarified why perceived usability strongly influenced technology engagement: participants valued Strava because it required minimal effort during activity while still producing meaningful feedback after exercise. The interviews also explained why focused attention was not significant, as users did not need to continuously interact with the app during physical activity. Similarly, the weak role of cues to action was explained by participants' reliance on personal goals, confidence, and progress feedback rather than generic reminders. These insights suggest that sustained behaviour change in physical activity apps depends less on continuous screen-based attention and more on low-effort tracking, meaningful feedback, and alignment with users' daily routines.

V. Discussion

The findings from PLS-SEM, actual Strava usage, and interviews indicate that behavioral change occurs through two complementary pathways: psychological readiness and technological engagement. The HBM explains why users are prepared to change, whereas the UEM explains how the application facilitates the implementation of that change in daily life.

The most interesting finding is that Focused Attention and Cue to Action did not show a significant relationship. The non-significant effect of focused attention suggests that physical activity apps do not require users' continuous attention during exercise. Instead, users may need to focus more on physical activity itself, while the app operates passively in the background as a support tool. These findings indicate that focused attention may not be relevant within the scope of mHealth applications for physical activity.

The non-significant effect of cues to action on Healthy Behavior Adoption suggests that external triggers such as reminders, prompts, and notifications may be insufficient to initiate or sustain physical activity when users do not possess strong internal motivation, self-efficacy, or perceived personal relevance. In the HBM, cues to action are often conceptualized as triggers that activate behavior. However, in the context of physical activity applications, such cues may function only as prompts rather than as direct determinants of adoption. Physical activity requires time, effort, planning, and repeated commitment; therefore, reminders alone may not overcome objective barriers such as workload, weather, schedule constraints, or lack of routine. This finding indicates that cues to action may be more effective when they are personalized, timely, and aligned with users' goals and readiness to change, rather than delivered as generic app notifications. The interview findings support this interpretation, as participants reported that reminders or app prompts were less influential than usability, progress feedback, perceived benefits, and confidence in maintaining activity.

In contrast, perceived usability and reward factors aligned more consistently with actual usage experiences. Participants valued Strava for its ease of use and its ability to record activities without complex interactions. Feedback such as distance, duration, and progress logs helped users visualize their achievements. However, digital rewards like badges did not affect all participants equally, suggesting that rewards are more meaningful when linked to personal goals. Fluctuating patterns of Strava usage indicate that behavioral change does not occur linearly. Indeed, a decline in app usage does not necessarily signify failure, as some participants continued their physical activity even after usage dropped. Overall, these findings reinforce the HBM-UEM model by demonstrating that health

beliefs initiate change and technology facilitates it, while real-life context determines whether that change is sustained.

VI. Conclusion and Future Work

This study develops and validates an integrated HBM-UEM model to explain behavioral changes among physical activity app users through two primary directions: the psychological and the technological direction. Health belief factors such as perceived benefits, self-efficacy, perceived severity, and objective and subjective barriers influence Healthy Behavior Adoption, whereas usability and reward factors influence Health Technology Engagement. In contrast, cues to action and focused attention did not show a significant influence.

The findings from this study indicate that technology engagement has a stronger impact on behavioral change than the adoption of healthy behaviors. A study on actual Strava usage further reveals that behavioral change is dynamic, influenced by performance feedback, rewards, personal goals, and daily constraints. Overall, the HBM-UEM model offers a more comprehensive explanation by combining users' psychological readiness and user-centric technological support. Future studies should test the model with larger and more diverse groups, including older adults and individuals with chronic conditions. Longer study periods are also needed to examine real behavior changes.

Evaluating Government Website Readiness for Generative AI Search Engines: A Framework and Empirical Assessment

Hussein Ali Bahadi
Digital Government Authority, Saudi Arabia

***Abstract*—The rapid adoption of generative artificial intelligence (GenAI) search engines is changing how citizens obtain government information. Unlike conventional search engines, which return ranked links, GenAI systems synthesise answers directly from retrieved sources, positioning government websites as inputs to AI-mediated information ecosystems rather than as destinations. To our knowledge, no systematic framework currently exists for determining whether government websites are prepared for this form of access. This study develops and validates an AI Readiness Index for government websites through a three-phase sequential mixed-methods design. The framework is validated perceptually through a one-round Delphi-informed expert survey (n = 18) and a citizen survey (n = 85) analysed using partial least squares structural equation modelling. The framework is applied to government portals across 14 jurisdictions using a documented scoring protocol. The expert panel confirmed content validity for Data Foundation, Technical Optimisation, and Content Quality; Discoverability met the consensus threshold marginally, and Governance did not reach it (I-CVI = 0.67). The structural model identifies Technical Optimisation and Content Quality as significant predictors of perceived AI readiness, explaining 55 per cent of the variance, while Discoverability and Governance are non-significant. Portal assessment reveals wide disparities, with relative strength in data foundations and technical optimisation and consistent weakness in governance, ethics, and accountability. Because the index measures structural properties that condition AI retrieval rather than testing retrieval performance directly, its scores are proxy indicators of readiness rather than measures of realised AI output quality.**

Keywords*—Generative AI; government websites; AI readiness; E-government; retrieval-augmented generation; SmartPLS; digital transformation; evaluation framework

I. Introduction

Generative artificial intelligence (GenAI) search engines are displacing traditional web browsing, synthesizing answers from government websites without citizens ever visiting them. This shifts the role of a government portal from a curated destination for human readers to a critical, yet often invisible, data input for autonomous systems. In this emergent paradigm, the quality of a citizen's interaction with the state is no longer determined by a website's usability or visual design, but by its machine-readability and semantic coherence. Consequently, the prevailing frameworks for evaluating e-government - focused on human-centric metrics like navigation and accessibility - are rendered obsolete [1]. This study addresses the resulting lacuna by developing and validating a framework to assess whether government websites are structurally prepared to serve as reliable sources for GenAI-driven information retrieval.

The scale is not marginal: the United Kingdom's GOV.UK platform alone hosts over 700,000 pages [2], any of which may be retrieved, excerpted, and synthesised without human review. Yet the standards by which government websites are presently evaluated, such as usability, readability, accessibility, and visual design, all presuppose a human reader. This transformation introduces a new intermediary layer between citizens and government information [3]. Governments around the world are starting to appreciate the possibility and the difficulties of GenAI integration. Applications are being realized in jurisdictions. Recently, the Indiana Department of Transportation (INDOT) created an AI-based workflow that focuses on RAG in line with a 30-day executive order mandating government efficiency reporting. INDOT used Vertex AI Search with Gemini to create a searchable vector index of internal documents and generate draft reports with 98% fidelity across 9 divisions, estimated to save 360 hours of manual search time, and defined a template that 60 other state agencies have adopted [5]. And in the same vein, the UK Government has introduced GOV.UK Chat, a pilot service based on RAG to enable citizens to pose natural language questions through the GOV.UK estate. Initial testing with hundreds of users indicated high potential for enhancing access to government information and unveiled vital insights into the importance of automated quality assurance and how RAG surpasses fine-tuning based on frequent content updates [2].

At the strategic level, countries are formulating structures to evaluate and improve AI preparedness. To measure the institutional readiness of adopting AI technologies in government organizations, the Saudi Data and Artificial Intelligence Authority (SDAIA) has introduced a National AI Index in 2025, which is based on three pillars, seven dimensions, and 23 subcategories [6]. This project is indicative of an increasing awareness that systematic evaluation is a precondition to successful integration of AI. Although this has evolved, there is a gaping hole in the literature and practice. Current AI preparedness measures are done on two levels: national and organizational. On a national scale, national indices like the Government AI Readiness Index of Oxford Insights evaluate the general AI preparedness of a country in terms of policy, infrastructure, and human capital aspects [7]. On the organizational level, as recent studies suggest, dual-level models that integrate Technology-Organization-Environment (TOE)

theories with Unified Theory of Acceptance and Use of Technology (UTAUT) would help determine how the public sector is ready to adopt AI [8].

Nevertheless, the level of AI preparedness at a website level-how well a government's digital presence can be utilized by AI systems created by other parties-has not been studied. Whereas organizational readiness deals with whether an agency is capable of developing and implementing AI systems, website readiness deals with whether an agency is capable of effectively consuming AI systems created by commercial vendors. This difference is essential as citizens can more readily obtain government information via non-governmental AI interfaces that are out of governmental control. Recent research has started looking into related dimensions. Krauze-Maślankowska and Vrabie [9] studied 108 municipal websites in Poland and Romania, discovered the mention of GenAI, and found increasing awareness but at the initial stage of integration, mostly with visual content generation. Divides in e-government research have added a GenAI Gap dimension based on access, task uses, and competence, and have found evidence that GenAI may increase disparities in the short term by increasing a vulnerable group's exposure to higher levels of verification and ethics [10].

In information infrastructure research on AI, there is a focus on multi-actor information infrastructures with important variables in three categories: 1) information-sharing process, systems, and services, 2) information format, and 3) governance structures [11]. These variables should be taken into account early enough to reap the most and minimize the risk of failure. In the same way, the study of AI fusion with Open Government Data has determined eight perfect types of AI applications, such as AI as Portal Curator, Explorer, Linker, and Monitor [12], that offer conceptual bases for understanding how AI interacts with government information systems. However, these insights have not been combined in a systematic and empirically proven framework for assessing the preparedness of individual government websites for GenAI-mediated access. This gap leaves government agencies without guidance on how to prepare their online presence for the GenAI future and researchers without empirical baseline data against which to assess progress.

This study addresses this gap through the following research questions:

RQ1: What dimensions and metrics constitute a comprehensive framework for evaluating government website readiness for generative AI search engines?

RQ2: To what extent do experts agree on the relevance, clarity, and comprehensiveness of the proposed dimensions and metrics, as assessed through a one-round Delphi-informed survey?

RQ3: Which dimensions (Technical Optimisation, Content Quality, Discoverability, Governance) significantly influence citizens' perceived AI readiness of government websites, as tested through a PLS-SEM analysis of citizen survey responses?

RQ4: How do current government websites perform when evaluated against the framework using both an equal-weight index and a perception-weighted index that accounts for the empirical findings?

The remainder of this study is organised as follows. Section 2 reviews three literature streams, namely e-government evaluation, generative AI and information retrieval, and AI readiness assessment, and identifies the website-level gap this study addresses. Section 3 sets out the three-phase sequential mixed-methods design, covering framework development, perceptual validation through expert and citizen surveys, and the portal assessment protocol. Section 4 reports results across all three phases, including expert consensus outcomes, the structural model, and the cross-jurisdictional assessment under both equal and adjusted weighting. Section 5 discusses theoretical and practical implications. Section 6 concludes with limitations and directions for future research.

II. Literature Review

A. The Evolution of E-Government Evaluation

The evaluation of e-government over the last 20 years has changed considerably as a result of the maturity of technology as well as the academic knowledge of what successful digital government entails. The initial solutions revolved around the presence of websites and accessibility of online services. The four-stage model of e-government development proposed by Layne and Lee [13] - cataloguing, transaction, vertical integration, and horizontal integration - provided a framework that would help to determine the evolution of simple information provision to integrated service delivery. This four-phase methodology has impacted later assessment models by defining that e-government maturity is a multi-dimensional and progressive approach.

The model that has had a significant impact on e-government studies is the DeLone and McLean Information Systems Success Model [14]. This model recognizes six dimensions of success that are interrelated: system quality, information quality, service quality, user satisfaction, intention to use, and net benefits. What is strong about the model is that it acknowledges the fact that information systems success is multi-faceted and that these dimensions are not independent of each other but are dependent. This model was confirmed by Wang and Liao [15] in the e-government setting, where the authors discovered that system quality, information quality, and service quality play a significant role in generating user satisfaction and perceived net benefits.

Newer assessment frameworks have added new dimensions based on emerging knowledge of e-government success. Valdés et al. [16] proposed a multidimensional e-government maturity model incorporating technological, organizational, operational, and human-capability dimensions for evaluating public agencies. While this framework provides a comprehensive basis for assessing digital-government capability, it remains oriented toward human-operated service delivery rather than AI-mediated information consumption. Pather and Gomez [17] introduce the dimensions of functional suitability, reliability, and security to the ISO 25010 quality model used on e-government. This quality-driven method offers well-organized systems of assessing the quality of software products, and it can be directly applied to government sites as information systems. But these defined structures have one thing in common; they all assume that the final consumer of a government site is a human being. Usability, readability, and visual design metrics

presuppose human cognition and perception. Navigation structures presuppose human navigation. Patterns of human information processing are presupposed in content organization. This premise is growing less tenable with AI intermediaries being key entry points. The AI system, rather than the citizen, is the direct consumer of the content on the web when the citizen poses a question to ChatGPT regarding government services. The quality of information that the citizen gets depends on the accuracy of the interpretation, retrieval, and synthesis of that content by the AI. This alters the nature of evaluation requirements: now websites are required not just to be readable by humans, but by machines as well, and to be readable and synthesizable by machines.

B. Generative AI and Information Retrieval

Currently, genAI models are trained on large models of language (LLMs) that are trained on large text collections. These models have outstanding language understanding, language generation, and reasoning abilities. Nevertheless, they also have clear-cut constraints, such as the propensity towards hallucination- the production of plausible-sounding, but factually inaccurate information - and impairment of tasks that demand accurate, current, or specialized information [1]. They are particularly consequential in a governmental context, because the correctness of information is not only desirable, but a necessity to fulfill legal needs, to be eligible to obtain benefits, and to possess rights. Having an AI that hallucinates and believes that it requires a passport, or that it has to pay taxes, can actually be harmful. To alleviate these weaknesses, generative AI systems are increasingly adopting retrieval-augmented generation (RAG), a text generation model that combines information retrieval [4]. In RAG architecture, the user can pose a question, and the system will extract the documents or passages within a knowledge base - in this case, the indexed information on government websites. It then feeds these passages that have been retrieved into the LLM, which gives a coherent answer synthesizing the information. This approach will improve accuracy and reduce the amount of hallucinations because the responses are based on retrieved evidence.

RAG has successfully been implemented in government situations. The AI system of Indiana DOT consisted of Vertex AI Search, which generated a vector index of internal documents, and then gave retrieved snippets to Gemini to generate responses with 98 percent fidelity to original documents [5]. In the same way, GOV.UK Chat uses RAG on the 700,000+ pages of GOV.UK, developers observe that "and since GOV.UK content is constantly being updated, Retrieval-Augmented Generation (RAG) is more accurate and relevant in responses than fine-tuning" [2]. RAG architecture has far reaching implication on government website construction and testing. To be effective, RAG systems require the content of websites to meet a number of requirements. Content has to be readable by machines, and it should be indexed and available to crawlers. This requires technical infrastructure that facilitates automated access, including correctly set robots.txt, sitemaps, and not using formats (e.g., image-based PDFs) that are hard to extract text from (Van Donge et al., 2024). The content should be in such a way that retrieval algorithms can recognize the most relevant passages. This involves semantic markup, proper heading structures, and metadata that reflects content correctly [4]. The information must also be factual, as the LLM will merely combine retrieved information without any further verification. This puts the value of accurate content on a higher level than the human-facing scenario, where users may cross-reference a variety of sources. The contents must be recent, as there is no inherent priority of recent information in RAG systems in comparison to that provided by retrieval algorithms. Certain dates of publication and versions are crucial pointers.

C. AI Readiness: From National to Website Levels

The concept of AI readiness has been developed at the dissimilar levels of analysis and with diverse paradigms and measurement plans. On a macro level, Oxford Insights publishes an annual Government AI Readiness Index, which assesses 195 countries across 69 indicators grouped into fourteen dimensions and six pillars: government, technology sector, and data infrastructure [7]. The index takes into account a range of factors such as digital capacity, innovation capability, and availability of data, and provides comparative rankings, which inform policymaking and international benchmarking. Regarding the same, the National AI Index of the Saudi Data and Artificial Intelligence Authority assesses government organizations based on three pillars, seven dimensions, and 23 categories and reports the outcomes that indicate the level of maturity of AI adoption and inform capability improvement [6]. These national indices are similar in that they all revolve around systemic factors, which include policy frameworks, human capital, and infrastructure to enable AI development and deployment across government.

A recent study has employed factor and cluster analysis to assess the extent of AI readiness in the European Union member countries and has identified two focal dimensions: Digital Skills and Electronic Government Engagement, and Transparency and Electronic Government Service Availability [18]. It was observed that there were six unique profiles of preparedness of member states, with significant differences in both infrastructural and citizen-level preparedness, which signifies more general digital divides. A literature gap is a systematic emphasis on AI-readiness at a website level - how well individual government websites are prepared to be fed to third-party AI systems. Whereas organizational readiness contends with the issue of whether an agency can build AI, and infrastructure readiness with the information systems that underlie them, website readiness relates to the digital presence to the public that AI systems actually discover [19].

This is an important gap for a number of reasons. First, AI intermediaries are becoming more and more accessible to citizens who are already using AI to gain access to government information, irrespective of the official adoption of AI by the agencies. The readiness of websites directly affects the results for citizens, irrespective of the AI approach in its structure. Second, the characteristics of the site that are more likely to be involved in the intervention are not the organizational or national factors but the website features. Metadata, content structure, and governance processes can be enhanced using digital service teams, without requiring a policy change or infrastructure redesign. Third, web preparedness provides a similar unit of analysis, which can be empirically measured and compared to other similar units.

However, no existing framework integrates technical requirements of GenAI systems with e-government evaluation approaches to assess website-level readiness for AI-mediated access. Furthermore, no study has validated such a framework against stakeholder perceptions using advanced statistical methods. This gap is increasingly consequential as citizens adopt GenAI tools for government information seeking, regardless of whether government agencies have officially embraced AI technologies, as is evident from the UK public sector [20].

III. METHODOLOGY

This study used a sequential mixed-methods research design to create an operationalised, empirically validated AI Readiness Index of government websites. This design type is especially suitable in the emerging fields of research where the development of concepts should be followed by empirical validation. The study is carried out in three phases.

A. Phase 1: Framework Development

1) Theoretical foundations and literature integration: To create the AI Readiness Index, a structured, concept-centric literature review was conducted following the methodology of Webster and Watson [23]. This approach organises the review around concepts rather than around individual publications, and is appropriate where the objective is theory synthesis for construct development rather than exhaustive evidence aggregation.

The study framework incorporates multi-actor information infrastructure views [11], which focus on the significance of data formats, information-sharing mechanisms and governance organization. This allows the conceptualisation of AI readiness as a socio-technical entity instead of a technical capability. The framework also takes into consideration the latest international guidelines and policy standards to be relevant and aligned with the best practices in the world. According to the United Kingdom Government Digital Service [24], technical optimisation, data quality, organisational context and ethical compliance are identified as crucial pillars of AI-ready datasets. The Australian Government Technical Standard of AI [25] focuses on lifecycle governance, auditability and bias management. The Georgia Technology Authority has also published guidelines for the responsible use of AI in government, emphasising transparency and accountability [26]. Likewise, the Saudi Data and Artificial Intelligence Authority [6] suggests a multi-dimensional index of readiness, and it is important to note that systematic assessment is essential.

2) The AI readiness index: This study synthesizes the theoretical literature and new international frameworks to propose a five-dimensional AI Readiness Index for government websites.

Dimension 1: Data Foundation

This dimension deals with the quality, structure, and provenance of underlying data that drives the content of the websites.

DF1: Data Quality and Completeness – The extent to which data underlying website content is accurate, complete, and fit for purpose. This includes assessment of data gaps, inconsistencies, and errors that would propagate through AI systems.

DF2: Machine-Readable Formats – Content is available in formats that AI crawlers can easily parse, avoiding image-based PDFs and other non-machine-readable formats. This extends beyond basic HTML to structured data formats.

DF3: Data Provenance and Lineage – Clear documentation of data sources, collection methods, and transformation processes, enabling AI systems and users to assess reliability and potential biases.

DF4: Metadata Quality and Completeness – Comprehensive metadata that accurately describes content, including descriptive, structural, and administrative metadata that enables AI systems to understand content meaning and context.

Dimension 2: Technical Optimisation

This dimension addresses the technical infrastructure that enables AI systems to discover, access, and process website content effectively.

TO1: Structured Data Implementation – Use of schema.org or other structured data markup to provide explicit context and relationships, enhancing AI understanding of content meaning. This includes appropriate schema types for government services, organisations, events, and publications.

TO2: API Availability and Design – Programmatic access to data through well-documented APIs that enable direct machine-to-machine data exchange, following best practices for API design and documentation.

TO3: Crawlability and Indexability – Robots.txt and sitemap configurations that facilitate comprehensive AI crawling without blocking legitimate AI agents, including explicit allowances for AI crawlers where appropriate.

TO4: Performance and Reliability – Technical performance characteristics including page load speed, uptime, and response times that affect both human and AI access.

Dimension 3: Content Quality for AI Consumption

This dimension addresses the quality characteristics of website content that determine its utility for AI synthesis.

CQ1: Accuracy and Factual Correctness – Information is factually correct and verified. For AI-mediated access, accuracy is paramount as AI systems synthesise without independent verification, and errors can propagate with authoritative presentation.

CQ2: Currency and Timeliness – Content is regularly updated with clear publication and revision dates, enabling AI systems to prioritise current information.

CQ3: Completeness and Self-Containment – Information is comprehensive and self-contained, not requiring cross-referencing multiple pages to understand key concepts.

CQ4: Clarity and Unambiguity – Content uses plain language and avoids ambiguity that could lead to AI misinterpretation. This includes avoiding vague references, implicit assumptions, and culturally specific knowledge that AI

systems may lack.

Dimension 4: Discoverability and Context

This dimension addresses the extent to which content can be accurately retrieved and appropriately contextualised by AI systems.

DC1: Semantic Structure and Hierarchy – Use of heading tags (H1, H2, H3) and other structural elements that create logical content hierarchies, enabling AI to understand content organisation and relationships.

DC2: Contextual Independence – Individual content units are understandable when retrieved out of context, requiring self-contained explanations and minimal reliance on implicit knowledge from elsewhere on the site.

DC3: Internal Linking and Relationship Mapping – Clear relationships between related content through descriptive links that provide semantic information about the nature of relationships.

DC4: Metadata for Discovery – Descriptive metadata (titles, descriptions, keywords) that accurately represent page content and support accurate retrieval by AI systems.

Dimension 5: Governance, Ethics, and Accountability

This dimension addresses the organisational processes, ethical frameworks, and accountability mechanisms that support reliable AI interpretation and public trust.

GE1: Information Ownership and Accountability – Clear attribution of content to responsible agencies, teams, or individuals, enabling accountability and follow-up.

GE2: Quality Assurance Processes – Evidence of systematic review processes and quality controls, including documentation of reviews, approvals, and updates. This supports the Australian requirement for end-to-end auditability.

GE3: Transparency and Disclosure – Clear explanations of information sources, limitations, and any AI involvement in content creation or curation. This aligns with Georgia's requirement to label AI outputs and broader transparency principles.

GE4: Ethical Framework and Bias Management – Evidence of attention to ethical considerations including bias identification and mitigation, protection of privacy, and consideration of impacts on vulnerable groups.

GE5: Version Control and Audit Trail – Complete version history with change notes, enabling reconstruction of content evolution and supporting accountability.

All metrics are rated on a 3-0 scale that has specific behavioural anchors. The 0-3 scale offers just enough granularity to capture the meaningful difference in readiness and yet is reliable between evaluators. Per metric, the evaluators reviewed the page against the rubric anchors (Appendix A), giving a score according to the most appropriate description. Dimension scores were computed as the sum of metrics in each of the dimensions, and total readiness score as the sum of all metrics. Normalised percentages enabled comparison across websites and dimensions.

B. Phase 2: Index Validation Through Expert Panel and Causal Relationships

1) One-round Delphi-informed expert survey: To determine expert consensus on the significance, clarity, and completeness of the five dimensions and 20 measures of the AI Readiness Index, a single round (informed by the principles of the Delphi) was used. An international sample was purposively sampled to recruit 18 international experts who had a background in academia (n=8), government digital agencies (n=7), and international organisations (n=3) around the world. These were the inclusion criteria: 1) e-government, AI preparedness, or information systems research; 2) 3 years of professional experience in digital government or AI policy.

Experts received a briefing document summarising the theoretical foundations of the AI Readiness Index, the five dimensions, and the twenty metrics with their 0–3 behavioural anchors. For each metric, experts rated three aspects on 7-point Likert scales (1 = strongly disagree/unacceptable, 7 = strongly agree/excellent):

Relevance – How important is this metric for assessing government website AI readiness?

Clarity – Is the metric definition and behavioural anchor unambiguous and operationalisable?

Consensus was defined a priori as:

Median relevance ≥ 6.0 AND interquartile range (IQR) ≤ 1.0 on the 7-point scale.

Item-level Content Validity Index (I-CVI) ≥ 0.78 (proportion of experts rating relevance as 6 or 7).

A single structured round was used rather than the multiple iterative rounds of a classical Delphi. This design choice reflects the study's objective, which was content validation of a predefined framework rather than the generation of consensus from an open problem space. Descriptive statistics (median, IQR, mean, standard deviation) were calculated for each metric. Qualitative comments were analysed thematically to identify refinement suggestions.

Quantitative Perceptual Validation (PLS-SEM)

The expert survey provides content validity that the five dimensions are relevant, clear, and exhaustive to domain experts, so that the index measures what it aims to measure. Nonetheless, content validity by itself does not indicate the perception of the end users, who are citizens and who will eventually depend on AI-mediated access to government information, of the preparedness of these websites. The perceptual validation stage looks at how the site's objective characteristics and citizen perceptions are related. The following hypotheses were tested in the model.

H1: Technical Optimisation positively influences citizens' perceived AI readiness of government websites.

H2: Content Quality positively influences citizens' perceived AI readiness of government websites.

H3: Discoverability positively influences citizens' perceived

AI readiness of government websites.

H4: Governance positively influences citizens' perceived AI readiness of government websites.

H5: Digital Literacy moderates the relationship between Technical Optimisation and Perceived AI Readiness. Digital Literacy was incorporated not as a further determinant of perceived readiness but to test an additional mechanism that could plausibly matter: whether a citizen's own familiarity with AI-mediated retrieval shapes how strongly a website's technical quality translates into perceived readiness. Including this moderation allows the study to check whether the framework's perceptual relationships hold uniformly across users or depend on the respondent's level of digital sophistication, which is an important consideration for the generalisability of the findings.

2) Questionnaire design and measurement instrument: The survey instrument is developed using established guidelines for scale development [27], [28] (Table I). All constructs are modelled as reflective and measured using multiple items on a five-point Likert scale ranging from strongly disagree to strongly agree (Appendix B). To ensure that responses reflected perceptions of a concrete object rather than general attitudes, all respondents evaluated the same designated government website, which was provided to them before completing the survey. Four of the five framework dimensions were carried forward into the citizen perceptual model. Data Foundation was not, and the reason concerns observability rather than importance. This dimension addresses the quality, provenance, and machine-readability of the data underlying published content, properties that are largely invisible at the point of citizen interaction. A citizen can judge whether a page loaded reliably, whether its content appeared accurate and current, whether they could locate what they needed, and whether the responsible agency was identifiable; they are not positioned to assess dataset completeness, lineage documentation, or metadata schema conformance, and survey items asking them to do so would elicit inference rather than experience.

TABLE I. SOURCES FOR THE ESTABLISHMENT OF CONSTRUCTS

Construct	Items	Source
Technical Optimisation	3 items	Adapted from Wang & Liao [15] - validated in e-government context
Content Quality	4 items	Adapted from Wang & Liao [15] and DeLone & McLean [14]
Discoverability	3 items	Adapted from Venkatesh et al. [21], UTAUT (effort expectancy items)
Governance	3 items	Developed for this study based on Van Donge et al. [11] and international frameworks (UK, Australian, Saudi guidelines)
Digital Literacy	3 items	Adapted from Parasuraman & Colby [29] TRI 2.0
Perceived AI Readiness	3 items	Developed for this study based on constructs from Kelly et al. [22], a systematic review of AI acceptance factors

3) Sampling and data collection: The target population includes citizens who have accessed government websites in the last six months. A non-probability snowball purposive sampling method is used. The data collection is carried out in six weeks. Screening questions established the eligibility of respondents. Eighty-five valid responses were retained. The adequacy of this sample was assessed using the inverse-square-root method [31], which bases the minimum sample size on the smallest path coefficient the study aims to detect. At the conventional significance level (0.05) and statistical power (0.80), detecting the weakest hypothesised meaningful effect, corresponding to the smallest significant path in the model ($\beta = 0.437$), requires a minimum of approximately 33 observations, and detecting a path of $\beta = 0.30$ requires approximately 69. The retained sample of 85 therefore provides adequate power for the effect sizes hypothesised as substantively meaningful. It should be noted that the sample is less well powered to detect small effects ($\beta \approx 0.20$ would require approximately 155 observations); the non-significant paths reported below are interpreted with this in mind.

4) Data analysis using SmartPLS: SmartPLS 4.0 was used to conduct data analysis in accordance with the best practices of PLS-SEM [30]. The analysis was done in two phases. The measurement model was initially assessed. Outer loadings were used to evaluate indicator reliability, and a value greater than 0.70 is said to be acceptable. Cronbach's alpha and composite reliability were the two measures used to evaluate internal consistency. Average Variance Extracted (AVE) was considered to assess convergent validity, and a threshold of 0.50 was used. The Fornell-Larcker criterion and the HTMT ratio below 0.85 were used to measure discriminant validity. Second, the structural model was tested using bootstrapping of 5,000 resamples. Path coefficients and their importance were discussed. R^2 was used to determine model explanatory power and Q^2 to determine predictive relevance. The contribution of each construct is calculated by finding its effect size (f^2). Moderation analysis was conducted using the product indicator approach to examine the moderating effect of Digital Literacy.

C. Phase 3: Empirical Assessment of Government Websites

1) Sample selection: The framework was applied to a purposive sample of government websites from each country and policy artefacts from multiple jurisdictions, including Canada, the European Union, the United States, Singapore, New Zealand, Australia, India, Pakistan, Saudi Arabia, and the United Kingdom. The sample includes both operational portals and policy documents to capture variation in implementation and strategic guidance.

2) Evaluation procedure: Each website was evaluated using publicly available information, including website structure, metadata, API documentation, licensing policies, and governance documentation. Evaluators systematically assessed each metric using predefined criteria (as per dimensional criteria described above) and documented supporting evidence. A structured scoring protocol was used to ensure consistency. Where evidence was incomplete, conservative scoring was applied. Fractional scores (e.g., 2.5) were permitted where evidence suggested. Such fractional scoring was used very

conservatively and only in exceptional cases where qualitative assessment indicated that a website substantially met the higher criterion but retained minor limitations. Scores are aggregated to produce dimension-level and overall readiness measures, enabling cross-case comparison.

To support reproducibility, the assessment protocol is specified as follows. The unit of analysis was the national government web presence, operationalised as the primary central-government portal together with a consistent set of high-traffic service and information pages linked from it; where a single national portal did not exist, the principal equivalent gateway was used. Each metric was scored against publicly available evidence only, drawn from four source types: the rendered pages themselves, the underlying page source and structured-data markup, machine-access artefacts (robots.txt, XML sitemaps, and any published APIs and their documentation), and published governance material (data licences, editorial and quality-assurance policies, and accountability statements). Each metric carries a four-point behavioural rubric (0-3) with explicit anchors for each level; the full rubric is provided in the supplementary material (Appendix). Each of the five dimensions comprises several sub-metrics in the rubric (for example, Data Foundation covers data quality, machine-readable formats, provenance, and metadata); the dimension score reported in Table X is the rounded aggregate of its constituent sub-metric ratings, and the accompanying descriptor summarises the most salient factor supporting that score. Where evidence was absent or incomplete, the lower score was assigned, ensuring that unverifiable capability was never credited. Because portal content changes over time, all assessments were conducted within a single defined evaluation window, and the evidence basis was captured at the time of scoring so that scores can be re-verified against archived material. The assessment was performed by a single evaluator, which introduces a risk of subjective bias. To mitigate this, scoring followed the fixed behavioural rubric described above, applied conservatively and with a documented evidence basis for each metric.

The weighting scheme was also subjected to a sensitivity analysis to assess how far the results depend on the specific weights chosen. Because any weighting scheme embeds a judgment about relative importance, the index was tested for sensitivity to that judgment. Four schemes were compared: equal weighting across all five dimensions; the pragmatic scheme adopted here, assigning full weight to Data Foundation, Technical Optimisation and Content Quality and half weight to Discoverability and Governance; a scheme with weights proportional to the expert panel's I-CVI values; and a path-informed scheme downweighting the two dimensions that did not significantly predict perceived readiness in the structural model.

IV. Results

A. Expert Validation Results of the One-Round Delphi-informed Expert Survey

A total of eighteen experts rated the five dimensions of the AI Readiness Index on a seven-point scale for relevance, clarity, and comprehensiveness. Technical Optimisation achieved the strongest consensus, with a median of 7.0, an interquartile range of 0.0, 100 percent agreement (18 out of 18 experts rating 6 or 7), an item-level content validity index (I-CVI) of 1.00, and a mean clarity score of 6.9. Data Foundation also reached consensus, with a median of 7.0, an interquartile range of 0.5, 88.9 percent agreement (16 out of 18), an I-CVI of 0.89, and a mean clarity score of 6.4. Content Quality similarly achieved consensus, with a median of 7.0, an interquartile range of 1.0, 83.3 percent agreement (15 out of 18), an I-CVI of 0.83, and a mean clarity score of 6.6. Discoverability and Context met the consensus criteria but only borderline, with a median of 6.0, an interquartile range of 1.0, 77.8 percent agreement (14 out of 18), an I-CVI of 0.78 (exactly at the acceptable threshold), and a mean clarity score of 6.1. Governance, Ethics and Accountability did not reach consensus, with a median of 6.0, an interquartile range of 1.5, 66.7 percent agreement (12 out of 18), an I-CVI of 0.67 (below the 0.78 threshold), and a mean clarity score of 5.7. These results indicate strong expert support for data, technical, and content dimensions, borderline support for discoverability, and a lack of consensus on governance. Governance, Ethics and Accountability did not meet the a priori consensus threshold (I-CVI = 0.67, below the 0.78 criterion), yet the dimension was retained in the framework. This decision was deliberate and rests on three considerations. First, the dimension is strongly grounded in the reviewed literature and in current government AI policy instruments, several of which make accountability, transparency, and auditability explicit requirements; excluding it would leave the framework silent on properties that policy already treats as essential. Second, the sub-threshold result concerns expert agreement on citizen-facing relevance rather than the dimension's intrinsic importance, and the divergence itself is an informative finding: governance is genuinely harder to assess from public evidence than the more technical dimensions. However, the weighting scheme in the results accordingly assigns Governance a reduced rather than a full weight. Table II reports the expert consensus outcomes.

TABLE II. Expert Consensus on Five Dimensions (N=18)

Dimension	Median	IQR	% rating 6 or 7 (Agreement)	I-CVI	Clarity (mean)	Consensus reached?
Data Foundation	7.0	0.5	88.9%	0.89	6.4	Yes
Technical Optimisation	7.0	0.0	100%	1.00	6.9	Yes
Content Quality	7.0	1.0	83.3%	0.83	6.6	Yes
Discoverability & Context	6.0	1.0	77.8%	0.78	6.1	Yes (borderline)
Governance, Ethics & Accountability	6.0	1.5	66.7%	0.67	5.7	No

B. Data Analysis Using SmartPLS

The collected survey data was analysed using Partial Least Squares Structural Equation Modelling (PLS-SEM) with SmartPLS 4.0. PLS-SEM was selected due to its suitability for exploratory and prediction-oriented research, particularly in studies involving complex models, multiple constructs, and relatively non-normal data distributions [30]. Additionally, the method is appropriate for models that include moderation effects and aim to maximise explained variance in the dependent construct. The data analysis followed a two-stage approach comprising measurement model assessment and structural model evaluation, in accordance with established guidelines.

1) Measurement model assessment: The measurement model was evaluated to assess the reliability and validity of the constructs. As all constructs were modelled as reflective, the following criteria were applied:

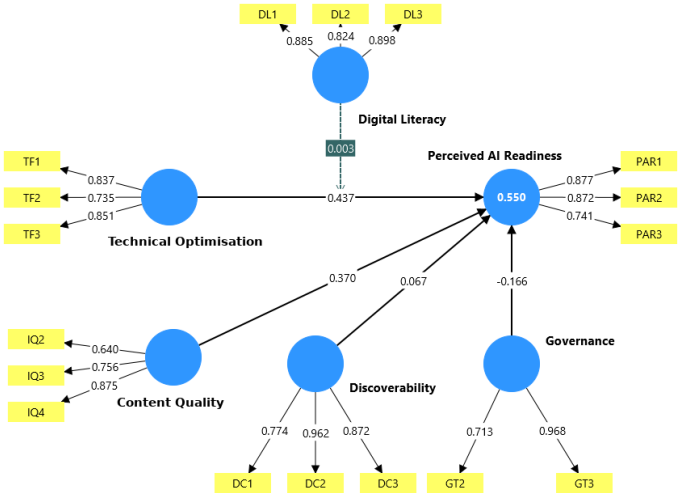

Fig. 1. Measurement model assessment.

Indicator reliability was assessed by examining outer loadings of each item on its respective construct. Loadings of 0.70 or higher were considered acceptable, indicating that the indicator explains at least 50% of the variance in the construct. Items with loadings between 0.60 and 0.70 were retained where theoretically justified. Two items were removed during measurement-model purification: IQ1 (Content Quality) and GT1 (Governance), whose outer loadings fell below the 0.60 threshold. Their removal improved the convergent validity and reliability of their respective constructs without altering the conceptual content of either, and both removals were made before structural-model estimation. The resulting outer loadings are shown in Table III.

Internal consistency was evaluated using both Cronbach's alpha and composite reliability (CR). Values above 0.70 were considered acceptable, indicating satisfactory reliability of the constructs. Convergent validity was assessed using Average Variance Extracted (AVE). An AVE value greater than 0.50 indicates that the construct explains more than half of the variance in its indicators, confirming adequate convergent validity. These reliability and validity statistics are reported in Table IV.

TABLE III. OUTER LOADINGS

Construct	Outer loadings		
DC1 <- Discoverability	0.774	IQ3 <- Content Quality	0.756
DC2 <- Discoverability	0.962	IQ4 <- Content Quality	0.875
DC3 <- Discoverability	0.872	PAR1 <- Perceived AI Readiness	0.877
DL1 <- Digital Literacy	0.885	PAR2 <- Perceived AI Readiness	0.872
DL2 <- Digital Literacy	0.824	PAR3 <- Perceived AI Readiness	0.741
DL3 <- Digital Literacy	0.898	TF1 <- Technical Optimisation	0.837
GT2 <- Governance	0.713	TF2 <- Technical Optimisation	0.735
GT3 <- Governance	0.968	TF3 <- Technical Optimisation	0.851
IQ2 <- Content Quality	0.640	IQ3 <- Content Quality	0.756

TABLE IV. INTERNAL CONSISTENCY RELIABILITY AND CONVERGENT VALIDITY

	Cron bach's alpha	Composite reliability (rho_a)	Composite reliability (rho_c)	Average variance extracted (AVE)
Digital Literacy	0.844	0.890	0.903	0.756
Discoverability	0.873	0.813	0.905	0.762
Governance	0.877	0.912	0.835	0.722
Content Quality	0.719	0.729	0.804	0.582
Perceived AI Readiness	0.777	0.801	0.871	0.693
Technical Optimisation	0.747	0.788	0.850	0.655

Discriminant validity, reported in Table V, was assessed using the Heterotrait–Monotrait (HTMT) ratio, where values below 0.85 indicate satisfactory discriminant validity.

TABLE V. DISCRIMINANT VALIDITY VALUES ASSESSED USING THE HETEROTRAIT-MONOTRAIT (HTMT) RATIO

	DL	DC	GT	CQ	PAR	TO	DL x TO
DL							
DC	0.124						
GT	0.341	0.189					
CQ	0.190	0.168	0.200				
PAR	0.386	0.132	0.206	0.598			
TO	0.077	0.107	0.329	0.258	0.644		
DL x TO	0.088	0.233	0.108	0.153	0.144	0.077	

Table VI reports the variance inflation factor (VIF) values for all predictor constructs, with all values well below the conservative threshold of 5, indicating that multicollinearity is not a concern in this model.

TABLE VI. COLLINEARITY AMONG PREDICTOR CONSTRUCTS WAS ASSESSED USING THE VARIANCE INFLATION FACTOR (VIF). VIF VALUES BELOW 5 INDICATED THAT MULTICOLLINEARITY WAS NOT A CONCERN

Construct	VIF		
DC1	2.298	IQ3	1.513
DC2	2.595	IQ4	1.462
DC3	2.212	PAR1	1.851
DL1	1.925	PAR2	1.913
DL2	2.035	PAR3	1.381
DL3	2.102	TF1	1.471
GT2	1.356	TF2	1.513
GT3	1.356	TF3	1.489
IQ2	1.130	Digital Literacy x Technical Optimisation	1.000

2) Structural model assessment: The structural model was evaluated using bootstrapping with 5,000 resamples to assess the significance of path coefficients. The full structural results are reported in Table VII and illustrated in Fig. 2. The results indicate that Technical Optimisation has the strongest positive effect on Perceived AI Readiness ($\beta = 0.437$, $t = 4.108$, $p < 0.001$). This suggests that the technical infrastructure and system capabilities of government websites are the most critical determinants of their readiness for generative AI. Content Quality also demonstrates a significant positive relationship with Perceived AI Readiness ($\beta = 0.370$, $t = 2.886$, $p = 0.004$). This finding highlights the importance of accurate, complete, and well-structured content in enabling effective AI-based information retrieval. Moreover, Discoverability does not exhibit a significant relationship with Perceived AI Readiness ($\beta = 0.067$, $t = 0.487$, $p = 0.626$). Although discoverability is theoretically important, its effect is not statistically supported in this model. Similarly, Governance shows a negative but non-significant relationship ($\beta = -0.166$, $t = 1.422$, $p = 0.155$). This suggests that governance mechanisms alone may not directly influence perceived AI readiness unless supported by strong technical and informational factors. The moderating effect of Digital Literacy on the relationship between Technical Optimisation and Perceived AI Readiness was also examined. Unexpectedly, the interaction term was found to be non-significant ($\beta = 0.003$, $t = 0.026$, $p = 0.980$), indicating that Digital Literacy does not strengthen or weaken the effect of Technical Optimisation. Although the model also returns a direct Digital Literacy path, this was treated as a control rather than a hypothesised effect; the study's interest in Digital Literacy is confined to its moderating role. Digital Literacy was included in the model specifically to examine whether respondents' own familiarity with AI-mediated retrieval conditions the way website attributes translate into perceived readiness, on the reasoning that more digitally literate citizens might weigh technical quality differently from less experienced users. The non-significant interaction indicates that this conditioning effect was not observed: the influence of Technical Optimisation on perceived readiness did not vary with respondents' digital literacy.

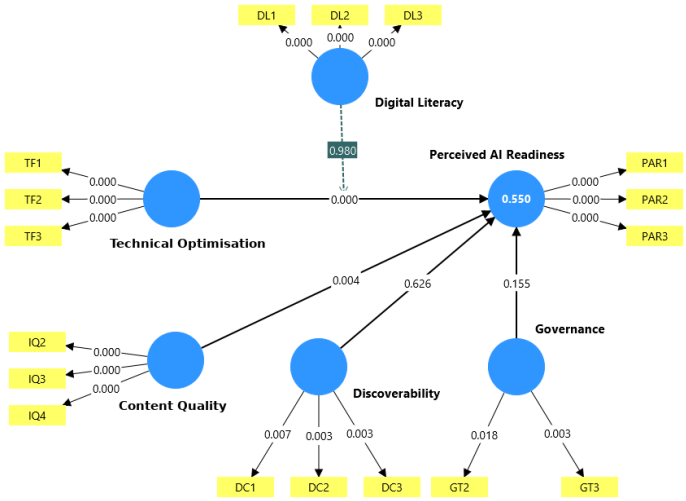

Fig. 2. Structural model.

TABLE VII. STRUCTURAL MODEL ASSESSMENT

	Original sample (O)	Sample mean (M)	Standard deviation (STDEV)	T statistics (|O/STDEV|)	P values
DL -> PAR	0.357	0.338	0.091	3.942	0.000
DL x TO -> PAR	0.003	-0.024	0.102	0.026	0.980
DC -> PAR	0.067	0.026	0.137	0.487	0.626
GO -> PAR	-0.166	-0.141	0.117	1.422	0.155
CQ -> PAR	0.370	0.360	0.128	2.886	0.004
TO -> PAR	0.437	0.443	0.106	4.108	0.000

C. Model Explanatory Power

The explanatory power of the model (Fig. 1) was assessed using the coefficient of determination (R^2). The results show that the model explains 55.0% of the variance in Perceived AI Readiness ($R^2 = 0.550$), with an adjusted R^2 value of 0.494. This indicates a moderate level of explanatory power, suggesting that the included constructs collectively provide a meaningful explanation of AI readiness perceptions. Table VIII presents the coefficient of determination.

TABLE VIII. COEFFICIENT OF DETERMINATION (R^2)

	Original sample (O)	Sample mean (M)	Standard deviation (STDEV)	T statistics (|O/STDEV|)	P values
PAR	0.550	0.616	0.084	6.563	0.000

D. Predictive Relevance

Predictive relevance, reported in Table IX, was evaluated using the Stone–Geisser Q^2 values obtained through the blindfolding procedure. All Q^2 values were positive (ranging from 0.149 to 0.338), indicating that the model has sufficient predictive relevance. Further assessment using Q^2predict compared the PLS-SEM model against the linear model (LM) benchmark at the indicator level. The PLS-SEM model produced lower RMSE and MAE values for PAR1 and PAR3, while for PAR2 the two approaches performed identically

(RMSE = 0.523 for both). Following Shmueli et al., this pattern, in which the majority but not all indicators favour the PLS-SEM model, indicates medium rather than strong predictive power. Because Q²predict was computed at the indicator level, construct-level predictive relevance is not reported here.

TABLE IX. PREDICTIVE RELEVANCE (Q²PREDICT) AT THE INDICATOR LEVEL

	Q²predict	PLS-SEM_RMSE	PLS-SEM_MAE	LM_RMSE	LM_MAE	IA_RMSE	IA_MAE
PAR1	0.338	0.533	0.424	0.562	0.456	0.656	0.539
PAR2	0.262	0.523	0.415	0.523	0.415	0.609	0.556
PAR3	0.149	0.586	0.443	0.686	0.499	0.636	0.563

The analysis confirms that Technical Optimisation and Content Quality are the primary drivers of perceived AI readiness. The model demonstrates moderate explanatory power and strong predictive capability, supporting the robustness of the proposed framework.

E. Weighting Adjustments for Index

Based on the combined findings of the expert consensus survey and the citizen SmartPLS perceptual validation, a pragmatic weighting scheme was adopted for the empirical website assessment. The expert survey confirmed that all five dimensions are relevant for assessing AI readiness, with Technical Optimisation, Data Foundation, and Content Quality receiving the strongest consensus (I-CVI ≥ 0.83). The SmartPLS analysis further showed that Governance and Discoverability did not significantly predict perceived AI readiness from a citizen perspective (H3 and H4 not supported, with $\beta = 0.067$ and $\beta = -0.166$ respectively, both $p > 0.05$). While these dimensions remain theoretically important, their direct influence on user perceptions is limited. Therefore, the index was modified to assign full weight (1.0) to Data Foundation, Technical Optimisation, and Content Quality, while Governance and Discoverability each received half weight (0.5). This adjustment preserves the comprehensiveness of the framework while reflecting the empirical finding that citizens and experts prioritise technical and content dimensions. The maximum possible weighted score becomes 12 (sum of 3+3+3+1.5+1.5), and each website's weighted score was calculated accordingly and normalised to a percentage.

F. Empirical Assessment of Government Websites

Fig. 3 presents the full matrix of dimension scores across all fourteen portals, and Fig. 4 summarises the cross-portal mean for each dimension. Data Foundation is uniformly the strongest dimension (mean 2.86 of 3.0), while Discoverability and Content Quality are the weakest, and the developing-economy portals show their steepest declines on these two dimensions.

Most of the evaluated sites perform reasonably well on data foundation. The United Kingdom, Canada, United States, Japan, Singapore, India, Pakistan, Kenya, New Zealand, Saudi Arabia, and Australia all provide datasets or policy guidance that emphasises machine-readable formats and high-quality data (Table X). For example, Canada's guidance explicitly recommends tagging content with machine-readable JSON-LD, and Japan's Digital Agency stresses that public data should be accessible under the Basic Act. These commitments reflect a growing recognition that data foundations underpin AI-driven public services. However, South Africa, Brazil, and Uruguay exhibit weaker foundations. Their portals often provide data only in PDF or HTML form, with sometimes restricted mention of machine-readable formats. Brazil's National Data Catalogue guide does call for open, structured data, but implementation across the broader domain appears inconsistent. AI systems depend on high-quality, well-structured data; without consistent machine-readable formats, generative AI will struggle to retrieve accurate information from government portals. Countries with stronger data foundations are better positioned to integrate AI into public services.

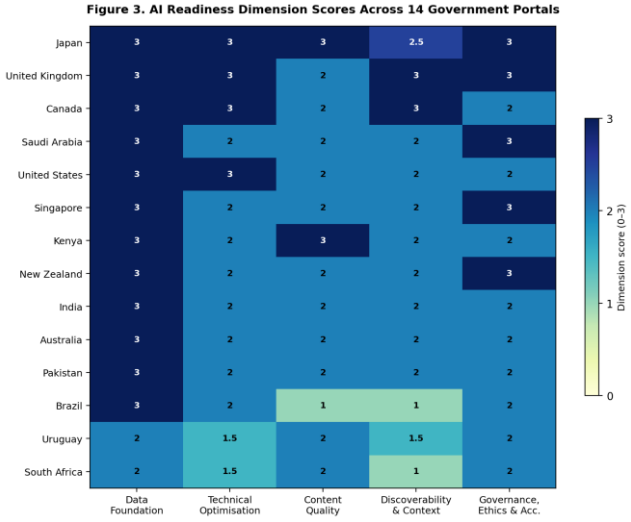

Fig. 3. AI readiness dimension scores across the fourteen assessed government portals.

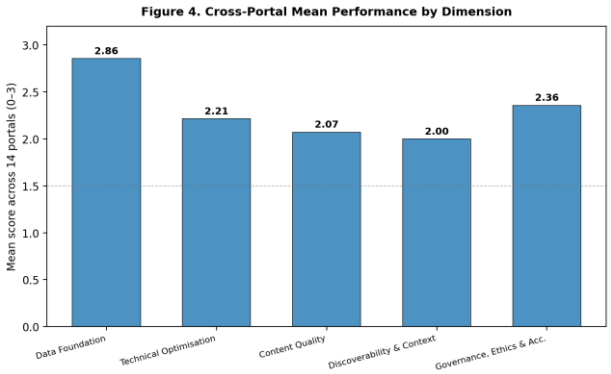

Fig. 4. Cross-portal mean performance by dimension.

High-performing sites not only provide data but also optimise for machine consumption. GOV.UK implements multiple schema.org templates via a shared metadata component, making its pages highly discoverable. Canada's guidance details how to select appropriate schemas and validate JSON-LD. The US federal government uses DCAT-US to standardise metadata for datasets and APIs, and Digital.gov highlights the use of schema.org for Special Announcements and FAQ pages during the pandemic. Japan's portal offers advanced search, visualisations and a communication function,

reflecting strong technical optimisation. In contrast, Singapore, India, Pakistan, Kenya, New Zealand, and Australia demonstrate moderate optimisation: they provide APIs and some metadata guidance but lack comprehensive schema implementation or uniform practices. For example, Singapore's licence permits widespread data reuse but doesn't prescribe technical standards, and Pakistan's playbook advocates APIs but notes that they're not substitutes for bulk data. The lowest scores occur in South Africa, Brazil, and Uruguay, where there is little evidence of structured metadata or standardised APIs. These portals appear to prioritise content publication over machine accessibility. Without structured metadata and standardised APIs, AI models must rely on scraping unstructured HTML, increasing the risk of hallucination and misinterpretation. Countries with strong technical optimisation are better prepared for future AI-driven service delivery.

The quality of content determines the accuracy of information, the up-to-date information, and the contextual independence of the information. High performers (e.g., Japan and the UK) will always keep information updated, and the pages are always meaningful when taken out of context. Canada and the US also have fairly high standards but depend on the individual agencies to be accurate, and hence the variability in departments. Middle tier nations (Singapore, India, Pakistan, Kenya, New Zealand, Australia, and Saudi Arabia) release valuable datasets but occasionally contain out-of-date data or make use of documents that are hard for AI to read (e.g., scanned PDFs). Saudi Arabia's my.gov.sa presents bilingual content (Arabic and English) that is regularly updated and organised by life events, yet content quality varies across 289 contributing agencies. Brazil and Uruguay have problems with context and outdated content.

Portals with high performance invest in search and navigation. Breadcrumb and FAQ templates in GOV.UK help users and crawlers navigate the site, whereas the portal provides cross-sectional search and visualisation in Japan. Canada promotes search engine optimisation using structured data. Interactive charts, maps, or catalogues are available in Kenya, Singapore, New Zealand, Australia, and Saudi Arabia, although navigation remains unreliable across some agencies in the latter. Saudi Arabia's my.gov.sa employs life-event-based navigation and a dedicated FAQ section to aid discovery, but cross-agency metadata consistency varies. Low scores in South Africa, Brazil, Uruguay, and, to a lesser degree, India and Pakistan are a manifestation of portals with some limitations in search functionality, metadata, and not well-developed contextual indicators (breadcrumbs or prominent headings). In the absence of these signals, humans and AI have difficulties in locating and interpreting information.

The governance aspect shows sharp differences. Nations that have developed open data licensing and ethics - including the Open Government Licence in the UK, usage policies (implicit) in Canada, the Public Data Licence in Japan, and the open data licence in Singapore - have high scores due to their definition of reuse rights and focus on transparency. Licences and privacy considerations are also outlined in Kenya, New Zealand and Australia. Saudi Arabia stands out as having a comprehensive AI governance ecosystem: SDAIA's AI Ethics Principles (2023), the Generative AI Guidelines for Government (2024), a Personal Data Protection Law enforced since September 2023, and ISO 42001 AI management systems certification achieved in July 2024, together with the National AI Index measuring government AI readiness. This multi-layered framework earns Saudi Arabia a maximum governance score. On the other hand, South Africa, Brazil and Uruguay have more lax governance structures. The US and Pakistan have moderate results: there are national open licences, yet the ethical control and management of bias with AI are in the early stages. The assessment of Saudi Arabia's Unified National Platform (my.gov.sa) included in Table X and Table XI of this study was conducted using publicly available sources. During the evaluation period, the portal at times returned HTTP 403 (access denied) errors, which prevented complete direct access and analysis of certain technical aspects of the live website.

TABLE X. AI READINESS ASSESSMENT OF VERIFIED GOVERNMENT WEBSITES

Country (Region)	Data Foundation	Technical Optimisation	Content Quality	Discoverability & Context	Governance, Ethics & Accountability	Total (0–15)	%
Japan (Asia) https://www.digital.go.jp	3	3	3	2.5	3	15	97

G. Recalculated AI Readiness Index (Expert-Weighted)

Applying the Delphi-derived importance weights to the normalised dimension scores obtained in Phase 2, a weighted readiness percentage was computed for each government website. Table XI presents a comparison between the original equal-weight index (each dimension contributing equally) and the perception-weighted index based on expert consensus. The two schemes produce closely aligned rankings (Spearman $\rho = 0.982$, $p < 0.001$), with no website shifting by more than two rank positions. Re-weighting therefore adjusts absolute scores only modestly and leaves the overall ordering essentially unchanged, which supports the robustness of the index to reasonable variation in dimension importance.

High-performing websites such as Japan, the United Kingdom, and Canada retain their leading positions, with weighted scores of 98 %, 92 %, and 88 %, respectively. Their consistent strength across Data Foundation, Technical Optimisation, and Content Quality keeps them at the top under either weighting. Saudi Arabia (my.gov.sa) records a weighted score of 79 %, remaining within the closely grouped mid-tier of portals; its strong governance and data foundation offset comparatively lower discoverability. The mid-tier group, including the United States, Kenya, Singapore, New Zealand, India, Pakistan, and Australia, shifts only slightly under re-weighting, with changes of a few percentage points in either direction and at most a two-position rank movement.

TABLE XI. COMPARISON OF ORIGINAL EQUAL-WEIGHT AND DELPHI-WEIGHTED AI READINESS INDEX SCORES, WITH ABSOLUTE CHANGE (PERCENTAGE POINTS) AND RANK CHANGE FOR EACH GOVERNMENT WEBSITE

Government Website	Original equal-weight score (%)	Delphi-weighted score (%)	Change (p.p.)	Rank change
Japan	97	98	+1	0
United Kingdom	93	92	–1	0
Canada	87	88	+1	0
United States	80	83	+3	0
Singapore	80	79	–1	–2
Saudi Arabia (my.gov.sa)	80	79	–1	–2
Kenya	80	83	+3	0
New Zealand	80	79	–1	–2
India	73	75	+2	0
Pakistan	73	75	+2	0
Australia	73	75	+2	0
Brazil	60	62	+2	0
Uruguay	60	60	0	–1
South Africa	57	58	+1	0

The lower-scoring portals move in the same modest fashion: Brazil, Uruguay, and South Africa remain at the foot of the ranking under both schemes, with weighted scores of 62 %, 60 %, and 58 %, respectively. The absence of large re-orderings indicates that overall AI readiness is driven by broadly consistent quality differences across dimensions rather than by any single heavily weighted component. The expert-weighted index thus offers a citizen-centric emphasis on the dimensions experts consider most important, while yielding an ordering that is substantively consistent with the equal-weight baseline for reliable AI-mediated information access.

V. DISCUSSION

This research aimed to analyze government website preparedness to consume generative AI through the incorporation of a multidimensional assessment framework with the experts' agreement, citizen perception validation based on PLS-SEM, and objective assessment of the websites. The results can bring a number of valuable theoretical and practical insights into the position of governments in a new information ecosystem mediated by AI.

The initial significant contribution is that it helps to change the notion of AI readiness at the organisational and national levels to the level of the website, where the government information is actually read by AI systems and citizens. The single-round Delphi-informed expert survey demonstrated content validity of all five dimensions, but Governance, Ethics and Accountability had only borderline consensus (I-CVI = 0.67, which falls below the 0.78 criterion), and Discoverability only marginally met the criteria (I-CVI = 0.78). Such a shortage of good expert consensus on governance implies that although governance is theoretically significant, experts disagree on how to operationalize it based on publicly accessible features of the websites. Nevertheless, it is because of this that governance was retained, as it is eminent in international policy structures despite the divergence being realized.

The PLS-SEM results of citizen perceptions offered solid empirical evidence of the key role of Technical Optimisation and Content Quality in the process of perceived AI readiness. Technical Optimisation became the most significant predictor, followed by Content Quality. In contrast, Discoverability and Governance did not significantly influence citizens' perceptions. The citizens seem to emphasize the material, technical, and content qualities, and the governance processes are not seen by the citizens unless they are made known.

The analysis of the cross-country websites provides insights that although open data principles have been embraced by many governments, it does not necessarily equate to AI readiness. Examples of countries that do perform well, like Japan, the United Kingdom, and Canada, show that preparation needs not just the availability of data but also standardized metadata, regular content design, and transparent governance structures. On the contrary, weaker countries tend to have a lack of alignment between policy intent and technical execution, so their websites are human-friendly and not machine-friendly.

According to these empirical results, a pragmatic weighting scheme was used on the index. Governance and Discoverability were not important predictors of perceived AI readiness, so they were given half the weight (0.5 each), whereas Data Foundation, Technical Optimisation, and Content Quality were given the full weight (1.0 each). This change maintains the wholeness of the framework and makes the index consistent with the views of citizens. The weighted scores did not cause significant changes in rankings in comparison to the equal-weight index, which

verifies the strength of the original rankings. The websites that remain at the lower end of the ranking under both schemes (e.g. South Africa, Brazil, Uruguay) score consistently lower across Content Quality and Technical Optimisation, supporting the view that these dimensions are the principal drivers of readiness.

A sensitivity analysis comparing the four weighting schemes showed that the portal rankings are highly stable. Spearman rank correlations against the equal-weight baseline were 0.982 for the pragmatic scheme, 0.981 for the I-CVI-proportional scheme, and 0.981 for the path-informed scheme (all $p < 0.001$), and no portal moved more than two positions under any scheme. Absolute scores shifted modestly, most within three percentage points of the equal-weight value, but the ordering of jurisdictions was essentially invariant. Because Data Foundation scores are uniformly high and portals that perform well on one dimension tend to perform well on others, the composite is dominated by consistent cross-dimensional quality differences rather than by any single weighted component. The rankings can therefore be read as robust to reasonable disagreement about dimension importance.

The comparative analysis reveals that there are major differences in AI preparedness by country and region. The developed digital governments are more integrated in terms of technical, informational, and governance elements, which leads to higher readiness scores. Conversely, partial readiness is seen in most developing countries, where the quality of available data is high, but poorly optimised in technical terms and with irregular governance. This implies that an AI readiness gap is developing, with similar traits akin to the traditional digital divides but with novel aspects concerning machine intelligibility and structured information.

The relevance of content quality also points to the relevance of correct, up-to-date, and context-neutral content. Generative AI systems are also very dependent on source data to generate a response, and any lack of content quality can cause misinformation or incomplete results. Thus, it is important to note that governments should not only focus on the availability of information, but on its semantic clarity and reliability. A further and less visible challenge concerns the unevenness of quality within portals rather than merely between them. Even governments that score highly overall show marked variation across their contributing agencies, so that accuracy, currency, and structure can differ from one department to the next. This intra-portal variability means that readiness must be secured at the level of the individual page, since a retrieval system draws on whichever source it locates.

VI. Conclusion

This study contributes to the growing literature on digital government and generative AI by developing and validating a comprehensive framework for assessing the AI readiness of government websites. A one-round Delphi-informed expert survey confirmed content validity for all five dimensions, though governance did not reach the consensus threshold (I-CVI = 0.67, below the 0.78 criterion). A citizen PLS-SEM study revealed that Technical Optimisation and Content Quality are the strongest positive predictors of perceived AI readiness, while Discoverability and Governance are not significant. Based on these findings, a pragmatic weighting scheme was applied to the website assessment, giving half weight to the non-significant dimensions. The weighted index produced rankings largely consistent with the equal-weight version, confirming robustness. The study highlights substantial global disparities in readiness, suggesting the emergence of an AI readiness divide between advanced and developing digital governments. Addressing this divide will require coordinated efforts to improve technical capacity, standardise data practices, and strengthen governance frameworks. Overall, the study underscores that AI readiness is not simply a matter of adopting new technologies, but of restructuring digital information ecosystems to support machine interpretation and interaction. Because the index measures structural properties that condition AI retrieval rather than testing retrieval performance directly, its scores should be read as proxy indicators of readiness rather than as measures of realised generative-AI output. Governments that restructure their information ecosystems accordingly are, on this evidence, better positioned to benefit from AI-mediated access, though realised gains in service delivery and transparency remain to be demonstrated empirically. This study is subject to several limitations. First, the website evaluation is based on a purposive sample and may not fully capture the diversity of government websites globally. Second, the scoring process involves a degree of subjective judgment, although efforts were made to standardise evaluation criteria.

Third, the citizen perceptual model was validated on a modest sample ($n = 85$); while sufficient for PLS-SEM estimation, a larger and more diverse respondent pool would strengthen generalisability.

A. Future Research Directions

Several directions follow from this work. First, the framework could be operationalised as an automated auditing instrument, using crawlers and structured-data validators to score machine-readability, metadata completeness, and content structure at scale, reducing reliance on manual evaluation. Second, longitudinal application would allow the AI readiness divide identified here to be tracked over time, testing whether it widens or narrows as governments respond to generative-AI adoption. Third, as autonomous AI agents increasingly access public services on behalf of citizens, the framework could be extended to assess readiness for agentic interaction, including programmatic authentication, transaction completion, and machine-actionable service interfaces.

APPENDIX A. WEBSITE ASSESSMENT RUBRIC

Each metric was scored on a four-point scale (0-3) against the behavioural anchors below, using publicly available evidence only. Where evidence was absent or incomplete, the lower score was assigned. Fractional scores (e.g., 2.5) were permitted only in exceptional cases where a portal substantially met the higher anchor but retained a minor limitation.

TABLE XII. WEBSITE ASSESSMENT RUBRIC

Dimension	Code	Metric	Score 0	Score 1	Score 2	Score 3
Data Foundation	**DF1**	**Data Quality and Completeness**	No usable data published, or significant errors/gaps throughout.	Some data available but with visible gaps, inconsistencies, or no disclosed quality process.	Data generally accurate and complete; minor gaps in some areas.	Strong, documented data quality with comprehensive coverage and minimal gaps.
Data Foundation	**DF2**	**Machine-Readable Formats**	Content only in non-machine-readable formats (e.g. scanned/image PDFs).	Some machine-readable formats (CSV/JSON) available but inconsistent or limited.	Machine-readable formats available for most key datasets/content.	Machine-readable formats mandated/standard across the portal (CSV, JSON, XML, etc.).
Data Foundation	**DF3**	**Data Provenance and Lineage**	No documentation of data sources or collection methods.	Minimal or inconsistent provenance information.	Provenance documented for some datasets.	Clear, consistent documentation of sources, methods, and transformations.
Data Foundation	**DF4**	**Metadata Quality and Completeness**	No descriptive metadata.	Sparse or inconsistent metadata.	Reasonable metadata coverage with some gaps.	Comprehensive, standardised metadata (descriptive, structural, administrative).

Technical Optimisation	**TO1**	**Structured Data Implementation**	No schema.org or structured markup.	Isolated or inconsistent use of structured markup.	Structured markup present on some page types.	Comprehensive schema.org implementation across page types (e.g. via a shared component).
Technical Optimisation	**TO2**	**API Availability and Design**	No public API.	Limited or undocumented API.	APIs available with some documentation.	Well-documented APIs following best practice, with broad coverage.
Technical Optimisation	**TO3**	**Crawlability and Indexability**	robots.txt blocks crawling, or no sitemap exists.	Crawlable but with significant gaps or issues.	Generally crawlable, with a sitemap present.	Fully crawlable; explicit sitemaps; no unnecessary blocking of legitimate crawlers.
Technical Optimisation	**TO4**	**Performance and Reliability**	Frequent outages or very slow load times.	Noticeable performance or uptime issues.	Generally reliable, with occasional issues.	Consistently fast and high-uptime.
Content Quality for AI Consumption	**CQ1**	**Accuracy and Factual Correctness**	Significant factual errors found, or no verification process evident.	Some inaccuracies, or an unclear verification process.	Generally accurate, with minor lapses.	High accuracy, with evident verification processes.
Content Quality for AI Consumption	**CQ2**	**Currency and Timeliness**	Content is stale, with no dates shown.	Dates shown but content is significantly outdated.	Mostly current, with some lag.	Regularly updated, with clear publish/revision dates.
Content Quality for AI Consumption	**CQ3**	**Completeness and Self-Containment**	Requires extensive cross-referencing to understand.	Limited self-containment.	Mostly self-contained.	Comprehensive, self-contained content.
Content Quality for AI Consumption	**CQ4**	**Clarity and Unambiguity**	Highly ambiguous or jargon-heavy.	Some ambiguity present.	Generally clear.	Plain language, unambiguous throughout.
Discoverability and Context	**DC1**	**Semantic Structure and Hierarchy**	No heading structure.	Inconsistent use of headings.	Generally good heading hierarchy.	Consistent, logical heading hierarchy site-wide.
Discoverability and Context	**DC2**	**Contextual Independence**	Content is incomprehensible out of context.	Significant reliance on external context.	Mostly understandable independently.	Fully self-contained, context-independent content.
Discoverability and Context	**DC3**	**Internal Linking and Relationship Mapping**	No internal linking or breadcrumbs.	Sparse or inconsistent linking.	Reasonable internal linking.	Comprehensive breadcrumb/related-content linking.
Discoverability and Context	**DC4**	**Metadata for Discovery**	No descriptive metadata (titles/descriptions).	Minimal or inconsistent metadata.	Present but inconsistent.	Comprehensive, accurate discovery metadata.
Governance, Ethics and Accountability	**GE1**	**Information Ownership and Accountability**	No attribution of content to an agency/owner.	Inconsistent attribution.	Generally attributed.	Clear, consistent attribution and accountability.
Governance, Ethics and Accountability	**GE2**	**Quality Assurance Processes**	No evidence of a review process.	Minimal evidence of review.	Some documented review process.	Systematic, documented QA process.
Governance, Ethics and Accountability	**GE3**	**Transparency and Disclosure**	No disclosure of sources or limitations.	Minimal disclosure.	Reasonable disclosure.	Clear disclosure of sources, limitations, and any AI involvement.
Governance, Ethics and Accountability	**GE4**	**Ethical Framework and Bias Management**	No ethical framework.	Minimal or aspirational mention only.	Documented framework, partially implemented.	Comprehensive ethics framework with active bias management.
Governance, Ethics and Accountability	**GE5**	**Version Control and Audit Trail**	No version history.	Minimal or inconsistent version information.	Some version control evident.	Complete version history and audit trail.

Dimension-level application. In practice, the metric anchors informed a holistic 0–3 judgment at the dimension level, which is the level reported in the cross-country assessment. A dimension scored 3 where practice was comprehensive and consistent across its metrics, 2 where practice was reasonable with some gaps, 1 where practice was minimal or inconsistent, and 0 where the relevant capability was absent.

APPENDIX B. SURVEY INSTRUMENT

The instrument administered to citizen respondents comprised nineteen items across six constructs, each measured on a five-point Likert scale ranging from strongly disagree (1) to strongly agree (5).

TABLE XIII. SURVEY INSTRUMENT

Section / Construct	Code	Item (measured on a five-point Likert scale)
A. Technical Optimisation	**TF1**	This website loaded quickly and worked reliably when I used it.
	TF2	This website performed smoothly across the pages and functions I needed.
	TF3	This website was technically well-built and worked well on my device.
B. Content Quality	**IQ1**	The information on this website was accurate.
	IQ2	The information on this website was current and up to date.
	IQ3	The information on this website was complete enough for my needs.
	IQ4	The information on this website was clearly presented and easy to understand.
C. Discoverability	**DC1**	I could easily find the specific information I was looking for on this website.
	DC2	The content on this website was logically structured.
	DC3	The information on this website was easy to navigate to and retrieve.
D. Governance	**GT1**	It was clear which government body was responsible for this website's content.
	GT2	The content on this website appeared to be regularly reviewed and maintained.
	GT3	This website was transparent about how its information is sourced or produced.
E. Digital Literacy	**DL1**	I understand how AI systems retrieve information from websites.
	DL2	I am confident using AI-powered search tools.
	DL3	I can generally tell when online information is well-structured for AI tools to use.
F. Perceived AI Readiness	**PAR1**	This website is well prepared for AI tools to read and use its information accurately.
	PAR2	This website is structured in a way that would let AI tools represent its content faithfully.
	PAR3	Overall, this website is ready to be used effectively by AI-powered search and assistant tools.

A Hybrid Econometric and Machine Learning Framework for Identifying Nonlinear Dynamics Between Digital Economy and Carbon Emissions

Jinghan Li
Lincoln University College, 47301 Petaling Jaya, Selangor, Malaysia

***Abstract*—The rapid expansion of the digital economy has reshaped global production systems and energy consumption patterns, yet its environmental consequences remain theoretically ambiguous. This study investigates the nonlinear relationship between digital economy development and carbon emissions using a cross-country panel dataset covering 45 countries during 2012–2024. A hybrid econometric and machine learning framework is developed to identify the structural dynamics underlying the digital economy–carbon emissions nexus. The empirical analysis combines fixed-effects estimation, System Generalized Method of Moments, instrumental variable estimation, and threshold regression with Gradient Boosting Decision Trees and SHAP-based interpretation. The results reveal a robust inverted-U relationship between digital economy development and carbon emissions, with the quadratic specification yielding a turning point of approximately 0.71 and the panel threshold model indicating a significant threshold value of 0.742. This indicates that digital transformation initially increases emissions through infrastructure expansion and energy demand, but subsequently contributes to emission mitigation through technological progress, energy efficiency improvement, and industrial restructuring. The nonlinear transition pattern is consistently validated across multiple identification strategies, with machine learning evidence further confirming the heterogeneous marginal effects of digital development across different development stages. Mechanism analysis shows that energy efficiency enhancement, technological innovation, and industrial upgrading are key channels through which digitalization promotes low-carbon transformation. These findings highlight that the environmental impacts of the digital economy are not inherently positive or negative but evolve dynamically with technological maturity and economic structure. Policy strategies should therefore emphasize the quality-oriented development of digital infrastructure and strengthen complementary innovation capabilities to maximize the emission-reduction potential of digital transformation.**

Keywords*—Digital economy; carbon emissions; nonlinear relationship; system GMM; machine learning; energy efficiency; industrial upgrading

I. Introduction

In the context of accelerating digital transformation and global carbon neutrality initiatives, understanding the environmental consequences of digital economy development has become increasingly important. Digital technologies, including big data, artificial intelligence, and cloud computing, enhance resource allocation efficiency and facilitate industrial upgrading; however, they may also generate additional energy demand through the expansion of digital infrastructure, such as data centers and communication networks. Therefore, the net environmental impact of digitalization remains theoretically and empirically uncertain.

Previous studies have documented both emission-reducing and emission-increasing effects of digitalization. On the one hand, digital technologies promote energy efficiency improvement, technological innovation, and structural transformation, thereby reducing carbon emissions [1,2]. On the other hand, the expansion of digital infrastructure and increased electricity consumption may generate additional emission pressures [3,4]. However, many existing studies still rely primarily on linear or quadratic specifications and treat the digital economy as a static explanatory factor, limiting the understanding of its evolving environmental effects.

More importantly, the existing literature provides limited evidence on whether digitalization represents a stage-dependent structural transition process, in which its environmental effects shift as digital development advances. This perspective suggests that the digital economy–carbon emission nexus may exhibit nonlinear and regime-dependent dynamics rather than a constant marginal effect.

To address this gap, this study develops a structural transition perspective by conceptualizing digitalization as a regime-shifting force that alters the balance between emission-enhancing scale effects and emission-reducing efficiency effects. Using a cross-country panel dataset covering 45 countries during 2012–2024, this study combines econometric identification and machine learning-based nonlinear validation to investigate the dynamic evolution of the digital economy–carbon emission nexus.

The results reveal a robust inverted-U relationship between digital economy development and carbon emissions. Specifically, digitalization initially increases emissions due to infrastructure expansion and energy demand, but beyond a critical development stage, its effects shift toward emission reduction through improvements in energy efficiency, technological innovation, and industrial upgrading. Machine learning analysis provides independent evidence supporting the identified nonlinear transition pattern.

This study contributes to the literature by establishing a regime transition framework for understanding the digital economy–carbon nexus and demonstrating that the environmental effects of digitalization evolve dynamically across development stages. The findings provide new insights

for designing differentiated digital transformation and low-carbon development strategies.

The remainder of this study is organized as follows. Section II reviews the related literature, while Section III discusses the research gap and the positioning of the present study. Section IV describes the measurement of the main variables, and Section V presents the computational methodology. Section VI reports the empirical results, followed by framework validation, nonlinear regime transition analysis, and robustness analysis. Section VII concludes the study and discusses the implications and limitations.

II. Literature Review

The relationship between the digital economy and carbon emissions has attracted increasing attention in recent years, and the existing literature can generally be classified into three main strands. Despite substantial progress, current studies have yet to establish a unified structural framework explaining how digital transformation reshapes environmental outcomes across different stages of development [1,4,5,6].

First, a large body of literature investigates the environmental effects of digital economy development. Many studies suggest that digital technologies contribute to carbon emission reduction by improving energy efficiency, optimizing production processes, facilitating technological innovation, and enhancing resource allocation efficiency [1,5-9]. In contrast, other scholars argue that rapid expansion of digital infrastructure, including data centers and communication networks, may increase electricity consumption and generate additional carbon emissions, producing a "digital expansion effect" [4,12,13]. Although these studies acknowledge the dual environmental effects of digitalization, most empirical analyses rely on linear or quadratic econometric models and treat digital economy development as a static explanatory variable [5,7,10-11].

Second, another stream of research explores the determinants of carbon emissions from a broader macroeconomic perspective, emphasizing factors such as economic growth, industrial upgrading, technological progress, and global value chains [5,6,8,12,14]. These studies provide important evidence regarding the drivers of carbon emissions and the broader economic effects of digital transformation [15]; however, their analytical frameworks generally assume smooth and continuous relationships among variables, making it difficult to capture structural changes and nonlinear transitions during digital transformation [5,6,8].

Third, recent studies have increasingly introduced machine learning and nonlinear analytical methods into environmental and digital economy research [16,17,18,19]. Compared with conventional econometric approaches, machine learning techniques exhibit superior predictive performance and greater flexibility in modeling complex nonlinear relationships [20,21,22]. Nevertheless, these methods are primarily employed to improve prediction accuracy or estimation robustness, rather than to explain the structural mechanisms underlying the relationship between digital economy development and carbon emissions [19,23].

Overall, three major research gaps remain. First, existing studies generally regard the digital economy as a static explanatory variable instead of a dynamic process of structural transformation. Second, insufficient attention has been paid to regime-dependent changes in the digital economy–carbon emissions relationship across different stages of digital development. Third, econometric identification and machine learning validation have rarely been integrated into a unified analytical framework for explaining the nonlinear transition mechanism.

Motivated by these limitations, this study adopts a structural transition perspective and investigates the relationship between the digital economy and carbon emissions as a nonlinear and regime-dependent process that evolves across different stages of digital development.

III. Research Gap

Despite extensive literature examining the relationship between the digital economy and carbon emissions, existing studies remain fragmented in three important aspects (Table I):

First, most existing research relies on linear or quadratic specifications within the Environmental Kuznets Curve (EKC) framework, implicitly assuming a stable functional relationship between digital development and environmental outcomes. However, such an assumption neglects the possibility that digital transformation operates as a structural and stage-dependent process, in which its environmental effects evolve dynamically rather than following a fixed parametric form.

Second, although recent studies acknowledge the dual effects of digitalization on emissions—through both efficiency improvement and energy demand expansion—they often fail to systematically model the transmission structure underlying this duality. In particular, limited attention has been paid to how digital trade integration, industrial restructuring, and technological diffusion jointly shape the carbon impact of the digital economy as an interconnected system.

Third, empirical strategies in existing literature are predominantly econometric and rely on predefined functional forms, which restrict their ability to capture high-dimensional nonlinearities and interaction effects. As a result, the structural heterogeneity and latent nonlinear patterns embedded in the digital economy–environment nexus remain insufficiently explored.

In addition, while machine learning methods have recently been introduced into environmental economics, they are still rarely integrated with causal econometric frameworks in a complementary manner. This creates a gap between predictive accuracy and causal interpretability in the analysis of digital economy–carbon relationships.

Therefore, a comprehensive framework that integrates nonlinear econometric identification with machine learning-based structural validation is still lacking in the current literature.

This study makes three main contributions to the existing literature.

First, it extends the traditional EKC-based framework by conceptualizing the digital economy as a structural transition system rather than a single explanatory variable. By incorporating digital trade and mechanism-based channels, this study provides a more comprehensive representation of how digital transformation reshapes carbon emission dynamics across different stages of development.

TABLE I. STYLIZED CHARACTERISTICS OF DIGITAL ECONOMY DEVELOPMENT AND CARBON EMISSION PATTERNS ACROSS COUNTRY GROUPS

Country Group	Typical Digital Economy Development	Typical Carbon Emission Pattern	Expected Relationship
Developed economies	High	Moderate to low	Digitalization primarily contributes to carbon reduction through efficiency gains and industrial upgrading
Upper-middle-income economies	Medium	Relatively high	Digital expansion coexists with industrialization, leading to both efficiency gains and increased energy demand
Lower-middle-income economies	Low	High	Infrastructure construction dominates, resulting in higher energy consumption and carbon emissions
Low-income economies	Very low	Low but unstable	Limited digitalization leads to a relatively weak digital–carbon linkage

Second, this study develops a multi-layer identification strategy that combines System GMM and instrumental variable estimation with machine learning-based nonlinear validation. Unlike prior studies that treat machine learning as purely predictive, this study positions it as a complementary tool for uncovering latent structural patterns and validating nonlinear functional relationships, thereby bridging the gap between causal inference and data-driven pattern recognition.

Third, the study identifies and confirms a robust nonlinear inverted-U relationship between the digital economy and carbon emissions across countries, while further demonstrating significant heterogeneity in the turning point across development levels. This finding enriches the understanding of digital-environment interactions by highlighting the stage-dependent nature of digital transformation and its environmental consequences.

Overall, this study contributes to the literature by offering a unified analytical framework that integrates structural economics, nonlinear econometrics, and machine learning methods to better understand the complex relationship between digital development and environmental sustainability.

IV. MEASUREMENT ANALYSIS

A. Measurement of the Digital Economy

The digital economy is a multidimensional concept that represents the integration of digital technologies into traditional economic activities, including production, exchange, and service processes. Due to its heterogeneous characteristics and the lack of a universally accepted cross-country measurement framework, digital economic development cannot be fully represented by a single indicator.

Drawing on the conceptual framework of the Bureau of Economic Analysis (BEA) digital economy measurement approach and related structural decomposition methods, this study constructs a composite Digital Economy Index by integrating sectoral value-added structures with digital intensity coefficients. This approach captures both the structural characteristics of economic activities and the degree of digital technology penetration across sectors, providing a more comprehensive measure of digital transformation.

Specifically, the value-added share of each sub-sector within industry j is calculated as:

$$S_{ijt} = \frac{VA_{ijt}}{\sum_{j=1}^{n} VA_{ijt}}$$

where, VA_{ijt} denotes the value-added of sub-sector j in country i at time t, and S_{ijt} represents its relative contribution within the industry structure.

To capture cross-industry differences in digital transformation, a digital intensity coefficient is introduced. This coefficient represents the relative degree of digital technology penetration across sectors. Following the structural accounting logic of the BEA digital economy framework, the digital intensity coefficients are derived from ICT infrastructure penetration, digital service availability, and technology adoption indicators. The indicators are normalized to a common scale before aggregation to improve cross-country comparability.

The final digital economy index is constructed as:

$$DE_{it} = \sum_{j=1}^{n} S_{ijt} \cdot \delta_{jt}$$

This formulation implies that the digital economy is not only determined by the industrial structure of an economy, but also by the intensity of digital technology embedded within each sector. Compared with single-dimensional proxies such as internet penetration or ICT trade, this structural composite index provides a more comprehensive and less biased measurement of digital economic development.

In addition, this approach is consistent with recent empirical literature emphasizing structural accounting methods for measuring digital transformation and is particularly suitable for nonlinear econometric frameworks such as the Environmental Kuznets Curve (EKC).

We further construct alternative indices using PCA and entropy weighting to ensure robustness, and all results remain qualitatively unchanged.

B. Measurement of Carbon Emissions

Carbon emissions are used as the dependent variable to measure environmental performance across countries. In line with EDGAR (Emissions Database for Global Atmospheric Research) standards, this study adopts carbon dioxide (CO_2) emissions as the proxy for total carbon emissions.

Compared with total greenhouse gas emissions, CO_2 emissions provide a more consistent and comparable indicator across countries and over time. Therefore, it is widely used in empirical studies on economic growth and environmental sustainability.

To reduce heteroscedasticity and improve estimation efficiency, carbon emissions are transformed using the natural logarithm form:

$$lnCO_{2,\ it} = \ln(nCO_{2,\ it})$$

All data are harmonized across countries and years to ensure comparability in the panel dataset.

C. Mechanism Variables

To investigate the transmission mechanism through which digital economy development affects carbon emissions, this study focuses on the energy efficiency channel. Digital transformation can influence environmental performance by improving resource utilization efficiency, optimizing production processes, and reducing energy intensity.

Energy efficiency (EE) is selected as the mediating variable to capture the resource utilization improvement induced by digital transformation. It is measured as the ratio of economic output to energy consumption, representing the amount of economic output generated per unit of energy input. A higher value indicates higher energy efficiency, reflecting the capability of an economy to achieve greater economic output with fewer energy resources.

The mediation mechanism is based on the assumption that digital technologies, including intelligent manufacturing, digital management systems, and data-driven optimization, enhance energy utilization efficiency and consequently contribute to carbon emission reduction.

V. Computational Methodology

A. Variable Definition and Data Description

This study investigates the nonlinear relationship between digital economy development and carbon emissions using a global panel dataset. The dependent variable is carbon emissions, while the key explanatory variable is digital economy development. Several control variables are incorporated to mitigate omitted variable bias. In addition, energy efficiency is considered as a potential transmission mechanism, while environmental regulation is introduced as a moderating factor.

The definitions and measurements of all variables are presented in Table II.

The empirical sample consists of 45 countries covering different development stages and geographical regions over the period 2012–2024. The sample was selected based on data availability and cross-country comparability over the study period. The resulting panel dataset provides sufficient cross-country and temporal variation to examine heterogeneous digital transformation pathways and carbon emission dynamics across countries.

Missing observations are addressed using interpolation methods to maintain panel continuity for empirical estimation.

B. Baseline Econometric Model

To examine the relationship between digital economy development and carbon emissions, this study first establishes a baseline panel regression framework. Considering country-specific characteristics and common time shocks, country fixed effects and year fixed effects are included.

The baseline specification is formulated as follows:

$$lnCO_{2,it} = \alpha + \beta_1 DE_{it} + \beta_2 DE_{it}^2 + \gamma' X_{it} + \mu_i + \lambda_t + \varepsilon_{it}$$

where, $lnCO_{2,it}$ denotes the natural logarithm of carbon emissions for country i in year t;

DE_{it} represents the Digital Economy Index,

DE_{it}^2 captures the nonlinear effect of digital economy development;

X_{it} is a vector of control variables, including economic development, population density, and trade openness;

μ_i denotes country fixed effects;

λ_t denotes time fixed effects;

ε_{it} is the random disturbance term.

The expected inverted-U relationship implies that:

$\beta_1 > 0$, and $\beta_2 < 0$, indicating that digital economy development initially increases carbon emissions but eventually contributes to emission reduction after exceeding a certain development stage.

TABLE II. Variable Definition and Construction

Variable Type	Variable	Symbol	Measurement and Definition
Dependent variable	Carbon emissions	$lnCO_2$	Natural logarithm of CO_2 emissions (metric tons), obtained from the EDGAR database
Core explanatory variable	Digital economy development	DE	Digital Economy Index constructed using a BEA-style value-added decomposition framework combined with digital intensity adjustment coefficients
Control variable	Economic development level	ED	Logarithm of GDP per capita, representing economic development conditions
Control variable	Population density	PD	Population divided by land area (people/km²), reflecting demographic pressure
Control variable	Trade openness	TO	Ratio of total imports and exports to GDP, representing economic globalization
Mediating variable	Energy efficiency	EE	GDP divided by total energy consumption, representing economic output generated per unit of energy input
Moderating variable	Environmental regulation	ER	Composite index measuring environmental policy intensity and regulatory strength

C. System GMM Estimation

Although fixed-effects estimation controls for unobserved heterogeneity, potential endogeneity may still exist because carbon emissions can influence digital transformation through policy adjustment and technological investment. Furthermore, carbon emissions usually exhibit strong persistence over time.

Therefore, following Arellano and Bover (1995) and Blundell and Bond (1998), the System Generalized Method of Moments (System GMM) approach is employed.

The dynamic panel specification is expressed as:

$$lnCO_{2,it} = \alpha + \rho lnCO_{2,i,t-1} + \beta_1 DE_{it} + \beta_2 DE_{it}^2 + \gamma' X_{it} + \mu_i + \lambda_t + \varepsilon_{it}$$

where, $lnCO_{2,i,t-1}$ represents the lagged carbon emission level capturing emission persistence.

System GMM uses lagged variables as internal instruments to address potential endogeneity. The validity of the estimation is assessed using the Arellano–Bond serial correlation test and the Hansen test of over-identifying restrictions.

D. Instrumental Variable Estimation

To further strengthen causal identification, an instrumental variable (IV) approach is employed.

This study uses:

- Lagged internet penetration rate.
- Submarine optical cable density.

These instruments are intended to capture variation in digital connectivity infrastructure. Their relevance is based on their association with digital economy development, while their exogeneity is assessed through the instrumental variable estimation framework.

The two-stage least squares (2SLS) estimation is specified as:

First stage:

$$DE_{it} = \beta_0 + \beta_1 IV_{it} + \beta_2 X_{it} + \mu_i + \lambda_t + u_{it}$$

Second stage:

$$lnCO2_{it} = \theta_0 + \theta_1 \widehat{DE}_{it} + \theta_2 \widehat{DE}_{it}^2 + \gamma X_{it} + \mu_i + \lambda_t + v_{it}$$

The first-stage F-statistic is examined to assess instrument strength, while consistency between IV estimates and baseline results provides additional evidence of robustness.

E. Mechanism Analysis Model

To further examine the transmission mechanism through which digital economy development affects carbon emissions, this study focuses on the energy efficiency improvement channel.

Specifically, energy efficiency (EE) is introduced as the mediating variable, reflecting the extent to which digital transformation improves resource utilization and reduces energy intensity.

Following the mediation framework, the first-stage model is specified as:

$$M_{it} = \delta + \theta DE_{it} + \eta' X_{it} + \mu_i + \lambda_t + \varepsilon_{it}$$

where, M_{it} denotes energy efficiency for country i at year t.

The second-stage model incorporates both digital economy development and the mediating variable:

$$lnCO_{2,it} = \alpha + \beta_1 DE_{it} + \beta_2 DE_{it}^2 + \phi M_{it} + \gamma' X_{it} + \mu_i + \lambda_t + \varepsilon_{it}$$

A significant coefficient of M_{it} indicates that energy efficiency serves as an important transmission channel through which digital economy development influences carbon emissions.

F. Moderating Effect Model

Environmental regulation may influence the effectiveness of digital transformation by affecting technological adoption, industrial adjustment, and environmental governance efficiency.

To examine this moderating role, the following interaction model is constructed:

$$lnCO_{2,it} = \alpha + \beta_1 DE_{it} + \beta_2 DE_{it}^2 + \beta_3 ER_{it} + \beta_4 (DE_{it} \times ER_{it}) + \gamma' X_{it} + \mu_i + \lambda_t + \varepsilon_{it}$$

where, ER_{it} represents environmental regulation intensity, and $DE_{it} \times ER_{it}$ denotes the interaction between digital economy development and environmental regulation.

A statistically significant interaction coefficient indicates that environmental regulation changes the marginal environmental effect of digital economy development.

G. Threshold Regression Model

Although the quadratic model captures nonlinear characteristics, it assumes a smooth transition process. To further identify potential structural changes during digital transformation, this study applies Hansen's (1999) panel threshold regression model.

The single-threshold specification is:

$$lnCO_{2,it} = \mu_i + \lambda_t + \beta_1 DE_{it} I(DE_{it} \le \gamma) + \beta_2 DE_{it} I(DE_{it} > \gamma) + \theta' X_{it} + \varepsilon_{it}$$

where, γ represents the threshold parameter and I(·) is the indicator function.

To capture multiple development stages, a double-threshold model is further estimated:

$$lnCO_{2,it} = \mu_i + \lambda_t + \beta_1 DE_{it} I(DE_{it} \le \gamma_1) + \beta_2 DE_{it} I(\gamma_1 < DE_{it} \le \gamma_2) + \beta_3 DE_{it} I(DE_{it} > \gamma_2) + \theta' X_{it} + \varepsilon_{it}$$

where, γ1 and γ2 represent the first and second threshold values, respectively.

The threshold values are estimated by minimizing the residual sum of squares:

$$\hat{\gamma} = argmin_{\gamma} RSS(\gamma)$$

The significance of threshold effects is evaluated through bootstrap procedures following Hansen (1999).

H. Machine Learning Validation Framework

To complement the econometric analysis, this study employs a Gradient Boosting Decision Tree (GBDT) model to capture nonlinear relationships and potential interaction effects among variables. Unlike the econometric models, the GBDT approach is not intended for causal inference but is employed as a predictive validation framework. The input variables include the Digital Economy Index (DE), Economic Development (ED), Population Density (PD), Trade Openness (TO), Energy Efficiency (EE), and Environmental Regulation (ER). The predictive performance of the model is evaluated using commonly adopted prediction accuracy metrics. Furthermore, SHAP (SHapley Additive exPlanations) analysis is employed to quantify the contribution of each variable to carbon emissions, while partial dependence analysis is conducted to visualize the nonlinear effect of digital economy development. The consistency between the nonlinear patterns identified by the GBDT model and the econometric results provides additional evidence supporting the inverted-U relationship between digital economy development and carbon emissions.

VI. Results

A. Baseline Regression Results

Table III reports the estimation results of the baseline regression model. Columns (1)–(5) present the regression results with progressively added control variables. Throughout all specifications, the coefficient of Digital Economy (DE) remains significantly positive, whereas the coefficient of Digital Economy Squared (DE^2) remains significantly negative. The estimation results are highly consistent across different specifications, providing strong empirical evidence of an inverted-U relationship between digital economy development and carbon emissions.

TABLE III. Baseline Regression Results

Variables	(1)	(2)	(3)	(4)	(5)
Digital Economy (DE)	1.285*** (4.76)	1.177*** (4.91)	1.352*** (4.68)	1.219*** (4.54)	1.243*** (4.62)
Digital Economy² (DE²)	−0.863*** (−3.72)	−0.795*** (−3.54)	−0.914*** (−3.88)	−0.846*** (−3.67)	−0.871*** (−3.75)
Economic Development (ED)		0.386*** (6.32)	0.403*** (6.45)	0.396*** (6.51)	0.385*** (6.37)
Population Density (PD)			−2.165** (−2.18)	−2.328** (−2.26)	−2.452** (−2.31)

Country FE	Yes	Yes	Yes	Yes	Yes
Year FE	Yes	Yes	Yes	Yes	Yes
Observations	579	579	579	579	579
R^2	0.512	0.566	0.638	0.612	0.605

[a.] Notes: t-statistics are reported in parentheses. *** p < 0.01; ** p < 0.05; * p < 0.10.

As shown in Table III, the coefficient of Digital Economy (DE) is consistently positive and statistically significant at the 1% level, whereas the coefficient of Digital Economy² (DE^2) is significantly negative across all model specifications. These findings confirm the existence of a nonlinear inverted-U relationship between digital economy development and carbon emissions, thereby supporting Hypothesis H1.

The results indicate that, during the initial stage of digital transformation, large-scale investment in digital infrastructure, communication networks, and data centers increases energy demand and electricity consumption, resulting in higher carbon emissions. As digitalization continues to advance, however, improvements in production efficiency, industrial upgrading, intelligent resource allocation, and technological innovation gradually outweigh the initial expansion effect. Consequently, the marginal impact of digital economy development on carbon emissions becomes negative after a certain level of digitalization is achieved.

Among the control variables, Economic Development (ED) exhibits a significantly positive coefficient, suggesting that economic growth remains associated with increased energy consumption and carbon emissions. Population Density (PD) shows a significantly negative effect, indicating that agglomeration economies and improved resource allocation contribute to emission reduction. Trade Openness (TO) generally presents a negative coefficient, implying a potential carbon-reduction effect through international trade and technological diffusion, although its statistical significance varies across specifications.

Overall, the baseline regression results demonstrate that the environmental impact of digital economy development evolves dynamically rather than remaining constant. The empirical evidence strongly supports the nonlinear structural transition proposed in this study and provides the basis for the subsequent analyses of transmission mechanisms and moderating effects.

B. Mechanism Analysis

To further explore how digital economy development affects carbon emissions, this study examines whether Energy Efficiency (EE) serves as an intermediate transmission channel. Following the mediation analysis framework described in Section V- E, the estimation results are presented in Table IV.

The mechanism analysis provides evidence that Energy Efficiency (EE) serves as an important transmission channel linking digital economy development and carbon emissions.

As shown in Column (2), Digital Economy (DE) has a positive and statistically significant effect on Energy Efficiency (EE), suggesting that digital transformation improves energy productivity through intelligent production systems, digital management, and more efficient resource allocation.

Column (3) further shows that Energy Efficiency is significantly negatively associated with carbon emissions, indicating that improvements in energy productivity contribute to emission mitigation. After introducing Energy Efficiency into the carbon emission model, the coefficient of Digital Economy (DE) decreases in absolute value from −0.568 to −0.512 while remaining statistically significant. This decline suggests that part

of the emission-reduction effect of digital economy development is transmitted through improvements in energy efficiency.

TABLE IV. MECHANISM ANALYSIS RESULTS

Variables	Carbon Emissions	Energy Efficiency	Carbon Emissions
Digital Economy (DE)	−0.568*** (−4.82)	1.236*** (3.45)	−0.512*** (−4.16)
Energy Efficiency (EE)			−0.021*** (−5.92)
Economic Development (ED)	0.422*** (6.41)	0.821** (2.51)	0.346*** (7.12)
Population Density (PD)	−1.862** (−2.36)	2.351** (2.14)	−1.648** (−2.11)
Trade Openness (TO)	−0.013 (−0.61)	0.584 (0.73)	−0.009 (−0.48)
Constant	3.185***	2.964***	2.158***
Country FE	Yes	Yes	Yes
Year FE	Yes	Yes	Yes
R^2	0.591	0.405	0.706

[b.] Notes: t-statistics are reported in parentheses. *** p < 0.01; ** p < 0.05; * p < 0.10.

These findings highlight that energy efficiency improvement represents one of the key pathways through which digital economy development contributes to carbon reduction, particularly when digital transformation enters a more mature stage.

The empirical evidence therefore supports Hypothesis H2, suggesting that digital transformation contributes to carbon reduction not only through direct effects but also indirectly by improving energy efficiency. Digital technologies enable real-time monitoring of energy consumption, optimize production processes, and enhance resource allocation efficiency, thereby reducing energy intensity and facilitating sustainable low-carbon development.

Overall, the mechanism analysis demonstrates that improvements in energy efficiency represent an important transmission pathway through which digital economy development promotes carbon emission reduction. This finding provides empirical support for the proposed theoretical framework and highlights the role of energy efficiency enhancement in facilitating a digital-driven low-carbon transition.

C. Moderating Effect Analysis

To further investigate whether environmental regulation strengthens the carbon-reduction effect of the digital economy, the moderating effect model specified in Section V- F is estimated. Following the Porter Hypothesis, stronger environmental regulation is expected to enhance the environmental benefits generated by digital transformation through encouraging green innovation, improving resource allocation, and accelerating industrial upgrading.

The estimation results are presented in Table V.

Table V reports the estimation results of the moderating effect model. The coefficient of Environmental Regulation (ER) is negative and statistically significant, indicating that stronger environmental regulation is directly associated with lower carbon emissions.

TABLE V. MODERATING EFFECT OF ENVIRONMENTAL REGULATION

Variables	Carbon Emissions ($lnCO_2$)
Digital Economy (DE)	−0.842***(-3.28)
Environmental Regulation (ER)	−0.386*(-1.72)
DE × ER	−0.418** (-2.41)
Economic Development (ED)	0.392*** (6.24)
Population Density (PD)	−2.438**(-2.32)
Trade Openness (TO)	−0.012 (-0.56)
Constant	2.206***(3.15)
Country Fixed Effects	Yes
Year Fixed Effects	Yes
R^2	0.718

[c.] Notes: t-statistics are reported in parentheses. *** p < 0.01, ** p < 0.05, * p < 0.10.

More importantly, the interaction term between Digital Economy (DE) and Environmental Regulation (ER) is significantly negative. This finding suggests that environmental regulation strengthens the carbon-reduction effect of digital economy development. As environmental regulation becomes more stringent, digital technologies are more effectively translated into improvements in energy efficiency, cleaner production processes, and green technological innovation, thereby generating greater environmental benefits.

These findings are consistent with the Porter Hypothesis, which argues that appropriately designed environmental regulation can stimulate innovation and improve environmental performance rather than merely increasing compliance costs. Under stricter regulatory conditions, firms are more likely to adopt digital technologies to optimize production, reduce energy consumption, and improve resource allocation efficiency, ultimately accelerating the low-carbon transition.

The moderating effect also implies that digital transformation alone may not be sufficient to maximize carbon-reduction performance. Instead, supportive institutional arrangements and effective environmental governance play an important complementary role in converting digital investment into sustainable environmental outcomes. Consequently, countries with stronger environmental regulatory frameworks are more likely to achieve larger emission reductions through digital economy development.

Overall, the empirical evidence confirms Hypothesis H3, indicating that environmental regulation positively moderates the relationship between digital economy development and carbon emissions by reinforcing the environmental benefits of digitalization.

D. Threshold Effect Analysis

To further investigate whether the environmental effect of digital economy development varies across different stages of digitalization, a panel threshold regression model is estimated following the methodology proposed in Section V-G. Compared with the quadratic specification, the threshold model allows the marginal impact of the digital economy on carbon emissions to change discretely once the Digital Economy Index exceeds an estimated threshold value.

The bootstrap procedure confirms the existence of a statistically significant threshold effect. The estimated threshold value of the Digital Economy Index is reported in Table VI. The likelihood ratio (LR) statistic rejects the null hypothesis of no threshold effect at the 5% significance level, indicating that the relationship between digital economy development and carbon emissions differs across development regimes.

TABLE VI. THRESHOLD REGRESSION RESULTS

Variables	DE ≤ γ	DE > γ
Digital Economy (DE)	0.842*** (4.26)	-0.956*** (-3.84)
Economic Development (ED)	0.403*** (6.31)	0.397*** (6.08)
Population Density (PD)	-2.684** (-2.34)	-4.926** (-2.37)
Trade Openness (TO)	-0.015 (-0.71)	-0.021* (-1.82)
Threshold Value (γ)	0.742	
Bootstrap F-statistic	18.640	
Bootstrap p-value	0.018	
Country Fixed Effects	Yes	Yes
Year Fixed Effects	Yes	Yes
R^2	0.714	

[d.] Notes: t-statistics are reported in parentheses. *** p < 0.01, ** p < 0.05, * p < 0.10.

The threshold regression results, reported in Table VI, provide further evidence that the environmental impact of digital economy development differs across stages of digital transformation. The estimated threshold value ($\gamma = 0.742$) is statistically significant, indicating the existence of a nonlinear regime transition in the relationship between the digital economy and carbon emissions.

When the Digital Economy Index is below the estimated threshold ($DE \leq \gamma$), the coefficient of Digital Economy (DE) is positive and statistically significant, suggesting that the expansion of digital infrastructure and digital industries initially increases carbon emissions. At this stage, large-scale investment in communication networks, data centers, and digital equipment increases electricity demand and energy consumption, causing the scale effect to dominate the environmental impact.

In contrast, when the Digital Economy Index exceeds the estimated threshold ($DE > \gamma$), the coefficient of Digital Economy becomes significantly negative. This result indicates that the efficiency-enhancing and technology-driven benefits of digital transformation gradually outweigh the initial expansion effect. As digital technologies become more mature and are more widely integrated into industrial production, intelligent manufacturing, digital resource allocation, and optimized energy management improve energy efficiency, facilitate green technological innovation, and ultimately contribute to carbon emission reduction.

Compared with the quadratic regression presented in Section V-A, the threshold model provides a more flexible representation of nonlinear structural changes by explicitly identifying different development regimes. Rather than assuming a continuous nonlinear relationship, the threshold regression demonstrates that the marginal environmental effect of digital economy development changes after the digital economy reaches a critical development stage.

Overall, the threshold regression results provide additional empirical evidence supporting the existence of a structural transition in the relationship between digital economy development and carbon emissions. The findings indicate that digital economy development does not generate uniform environmental effects throughout the development process; instead, its contribution to carbon reduction becomes substantially stronger after surpassing the critical threshold.

E. Machine Learning Interpretation

To further explore the nonlinear characteristics of the digital economy–carbon emission relationship beyond parametric econometric specifications, this study employs a Gradient Boosting Decision Tree (GBDT) model. Unlike traditional regression models that impose predefined functional forms, the GBDT approach captures complex nonlinear interactions among explanatory variables and provides a data-driven representation of the underlying relationship.

The GBDT model uses carbon emissions as the dependent variable and incorporates the Digital Economy Index (DE), Economic Development (ED), Population Density (PD), Trade Openness (TO), Energy Efficiency (EE), and Environmental Regulation (ER) as explanatory variables. Model interpretability is further enhanced through the SHapley Additive exPlanations (SHAP) framework, which quantifies the marginal contribution of each variable to the predicted carbon emission outcomes.

The GBDT model demonstrates satisfactory predictive performance and effectively captures the complex nonlinear relationship underlying cross-country variations in carbon emissions. Compared with conventional parametric regression models, the machine learning approach identifies nonlinear interactions among explanatory variables without imposing a predefined functional form, thereby providing additional support for the nonlinear findings obtained from the econometric analysis Fig. 1, SHAP feature importance.

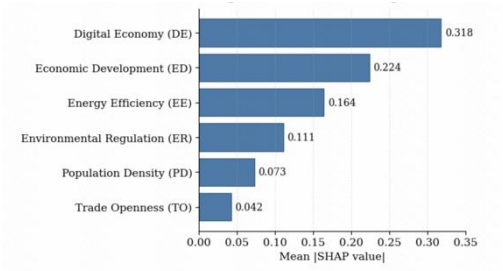

Fig. 1. SHAP Feature importance of carbon emission drivers.

The SHAP feature importance results indicate that the Digital Economy (DE) is one of the most influential determinants of carbon emissions. Among the explanatory variables, the digital economy exhibits the highest contribution to the model predictions. Energy Efficiency (EE) and Environmental Regulation (ER) also demonstrate substantial explanatory power, highlighting the important roles of technological efficiency improvement and institutional governance in shaping carbon emission dynamics.

The ranking of feature importance is broadly consistent with the econometric findings presented in Sections VI-A to VI-D, where digital economy development, energy efficiency improvement, and environmental regulation were identified as key factors influencing carbon outcomes. These results suggest that digital transformation affects carbon emissions not only through direct effects but also through efficiency enhancement and governance mechanisms.

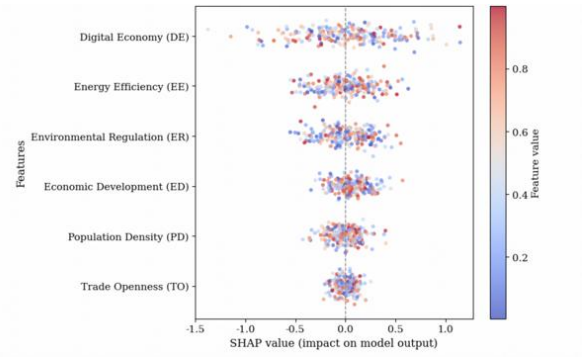

Fig. 2. SHAP summary plot.

The SHAP summary plot (Fig. 2) provides further evidence regarding the nonlinear influence of digital economy development on carbon emissions. At relatively low levels of digitalization, higher Digital Economy Index values are generally associated with positive SHAP contributions, indicating that early-stage digital expansion tends to increase carbon emissions.

This phenomenon reflects the dominance of the scale effect during the initial phase of digital transformation, where infrastructure deployment, data center expansion, and increased electricity demand generate additional energy consumption pressures.

However, as digitalization advances, the SHAP contributions gradually decline and become negative, suggesting that the marginal environmental effect of digital development shifts from emission promotion toward emission reduction. This transition indicates that efficiency-enhancing mechanisms, including intelligent resource allocation, industrial digitalization, and technological innovation, gradually outweigh the initial expansion effect.

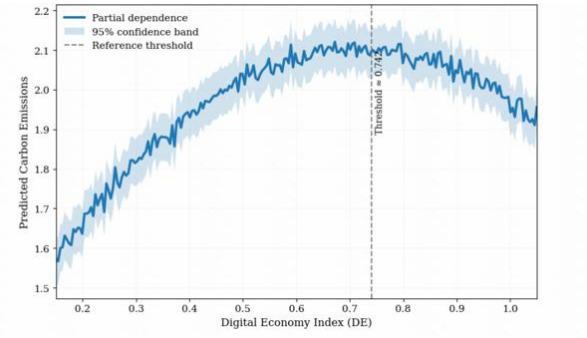

Fig. 3. Partial dependence plot of digital economy.

The partial dependence plot (Fig. 3) further illustrates the nonlinear marginal effect of digital economy development on predicted carbon emissions. The relationship exhibits a clear inverted-U pattern: carbon emissions initially increase with digital economy expansion but decline after reaching a critical development level.

The nonlinear transition identified by the GBDT model is broadly consistent with the turning point estimated from the quadratic regression model and the threshold value obtained from the panel threshold regression. This consistency suggests that the nonlinear relationship between digital economy development and carbon emissions is robust across different analytical approaches and reflects an underlying structural transition rather than a model-specific artifact.

Overall, the GBDT–SHAP analysis provides a non-parametric interpretation of the nonlinear relationship between digital economy development and carbon emissions. The results demonstrate that digitalization produces heterogeneous environmental effects across development stages: it initially increases emissions through infrastructure expansion but eventually contributes to carbon reduction through efficiency improvements, technological upgrading, and enhanced resource optimization.

F. Heterogeneity Analysis: Developed and Developing Economies

To examine whether the nonlinear relationship between digital economy development and carbon emissions varies across different development stages, this study conducts a heterogeneity analysis by dividing the sample into developed and developing economies.

The estimation results indicate that the inverted-U relationship remains valid in both groups, confirming the robustness of the nonlinear effect. However, substantial differences are observed in the turning points and marginal effects between the two groups. Developed economies exhibit a relatively lower turning point, suggesting that digital transformation reaches the emission-reduction stage earlier. This pattern may be attributed to their more mature digital infrastructure, higher energy efficiency, and stronger environmental governance capacity.

In contrast, developing economies present a higher turning point, implying that digital expansion requires a longer transition period before generating significant carbon reduction benefits. During the early stage of digitalization, infrastructure deployment, electricity demand growth, and digital capital accumulation may offset the potential environmental benefits.

These findings demonstrate that the environmental impact of digital economy development is not homogeneous across countries but depends on technological maturity, energy structure, and institutional conditions. Therefore, the effectiveness of digitalization as a carbon-reduction pathway is strongly associated with the development stage of individual economies. Fig. 4 illustrates the hybrid framework for identifying nonlinear digital economy–carbon emission dynamics, highlighting the transmission mechanisms, hybrid identification strategy, nonlinear transition, and regime evolution underlying the digital economy–carbon emission nexus.

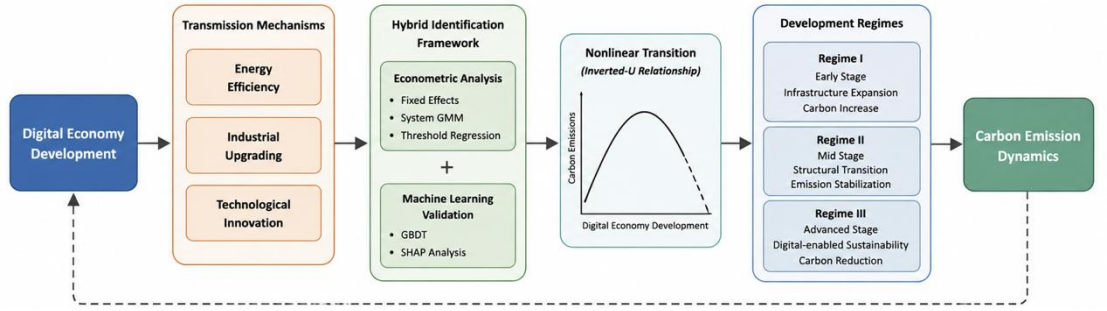

Fig. 4. Hybrid framework for identifying nonlinear digital economy–carbon emission dynamics.

G. Cross-Method Validation of Nonlinear Effects

To verify the robustness of the nonlinear relationship between the digital economy and carbon emissions, this study compares three complementary approaches: quadratic regression based on the EKC specification, panel threshold regression, and GBDT-based nonlinear estimation with SHAP interpretation.

The three approaches provide complementary evidence for the nonlinear relationship. The quadratic model identifies a turning point of approximately 0.71, while the panel threshold model identifies a regime transition at $\gamma = 0.742$. The GBDT–SHAP analysis provides an independent non-parametric assessment of the changing marginal contribution of digital economy development. The close correspondence across these approaches strengthens the interpretation of the nonlinear transition without relying on a single model specification.

VII. Framework Validation

A. Validation Strategy

To improve the reliability of nonlinear relationship identification, the proposed computational framework integrates econometric estimation with machine learning interpretation. The validation process combines four complementary modules: quadratic fixed-effects estimation, System GMM, instrumental variable estimation, and GBDT–SHAP analysis. Each module examines the digital economy–carbon emission relationship from a different analytical perspective, providing complementary evidence for framework validation.

B. Cross-Method Validation

The proposed framework is supported by complementary evidence from econometric estimation, threshold regression, and machine learning interpretation. The econometric models provide statistical identification, the threshold model identifies the regime transition, and the GBDT–SHAP analysis provides a flexible non-parametric assessment of nonlinear patterns. The consistency among these components strengthens the internal validity of the proposed analytical framework.

The threshold regression further identifies a significant threshold value ($\gamma = 0.742$), which is broadly consistent with the nonlinear transition pattern revealed by the GBDT partial dependence analysis. Moreover, the SHAP interpretation indicates that the contribution of digital economy development varies across different levels of digital development, providing additional evidence of its nonlinear effect.

The consistency across econometric estimation, threshold regression, and machine learning interpretation suggests that the identified nonlinear relationship is not driven by a specific modeling approach but reflects a robust structural relationship between digital economy development and carbon emissions.

C. Framework Validation Summary

The proposed framework demonstrates consistency from three complementary perspectives. Statistical consistency is confirmed by the agreement among econometric estimators. Structural consistency is supported by the close correspondence between the threshold regression and machine learning results. Interpretability consistency is established through SHAP analysis, which explains the stage-dependent contribution of digital economy development to carbon emissions.

Collectively, these results validate the proposed computational framework and strengthen the reliability of the identified nonlinear transition mechanism (Table VII).

TABLE VII. Validation Results of the Computational Framework

Validation Component	Method	Main Evidence
Econometric Estimation	Fixed Effects	Significant inverted-U relationship
Endogeneity Test	System GMM and IV	Consistent estimation results
Structural Identification	Threshold Regression	Estimated threshold ($\gamma = 0.742$)
Machine Learning	GBDT + SHAP	Consistent nonlinear pattern
Overall Validation	Integrated Framework	Strong cross-method consistency

VIII. Nonlinear Regime Transition Analysis

A. Regime Interpretation of the Nonlinear Relationship

Building on the empirical evidence presented above, this section interprets the nonlinear relationship from a regime transition perspective. Instead of assuming a constant marginal effect of digitalization, this study interprets the observed nonlinear pattern from a regime transition perspective (Table VIII).

A regime represents a relatively stable development state characterized by the combined effects of digital infrastructure, energy systems, industrial structure, and technological capability. Under different regimes, the environmental impacts of digitalization vary.

TABLE VIII. CROSS-METHOD VALIDATION OF NONLINEAR EFFECTS

Method	Framework	Nonlinear Evidence	Turning Point / Threshold	Result
Quadratic EKC model	Econometric regression	Significant inverted-U relationship	Turning point ($\tau \approx 0.71$)	Marginal effect reversal
Panel threshold model	Threshold regression	Significant regime change	Threshold value ($\gamma = 0.742$)	Nonlinear stage transition
GBDT + SHAP	Machine learning	Data-driven inverted-U pattern	Broadly consistent with econometric estimates	Consistent nonlinear evidence

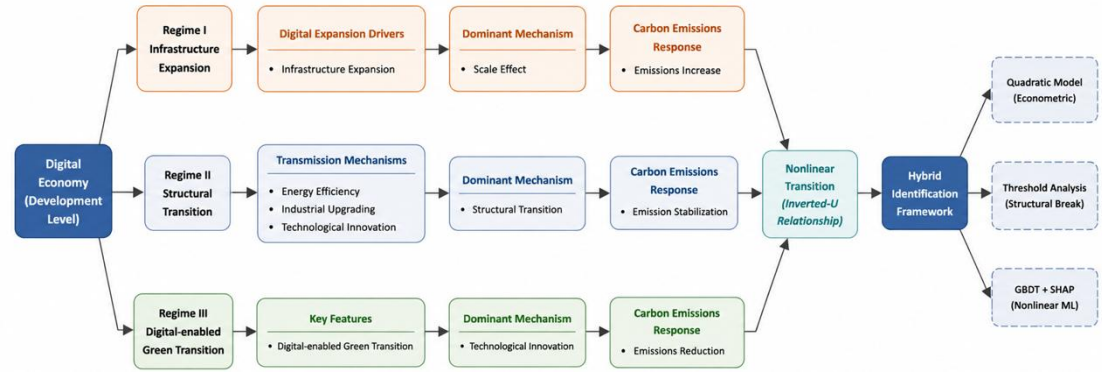

Fig. 5. Digital economy–carbon emission transition framework across development regimes.

The dominant mechanisms affecting carbon emissions evolve with the level of digital economy development. During the initial stage, digital expansion is primarily characterized by infrastructure expansion and scale effects, resulting in higher carbon emissions. As digital development advances, structural transformation, energy efficiency improvement, and technological innovation gradually become the dominant drivers, weakening the carbon-intensive effects of early-stage digitalization and promoting emission reduction. Consequently, the relationship between the digital economy and carbon emissions evolves through distinct nonlinear transition regimes rather than following a linear pathway.

The proposed framework (Fig. 5) illustrates the hybrid identification process of nonlinear digital economy–carbon emission dynamics. Different development regimes are characterized by changing dominant mechanisms, including scale effects, structural transition, and technological innovation, while the nonlinear transition is jointly identified through econometric estimation and validated using machine learning methods.

B. Three Development Regimes of Digitalization and Carbon Emissions

Based on the nonlinear response pattern identified by the econometric and machine learning models, the digital economy–carbon emission relationship can be interpreted through three representative development regimes.

Regime I: Digital Expansion Regime

In the initial stage of digital transformation, the expansion of digital infrastructure dominates the environmental outcome.

The deployment of communication networks, computing facilities, and digital equipment requires substantial energy inputs, leading to additional carbon emissions. In this regime, the scale effect exceeds the efficiency effect, and digitalization may increase environmental pressure.

Regime II: Transition Regime

As digital development progresses, emission-increasing and emission-reducing mechanisms coexist.

Digital infrastructure continues to generate energy demand, while digital technologies simultaneously improve production efficiency, optimize resource allocation, and promote industrial restructuring. The interaction between these opposing effects results in a gradual reduction of the marginal emission impact of digitalization.

This regime represents the transition process from energy-intensive digital expansion toward efficiency-oriented digital development.

Regime III: Digital Decoupling Regime

At a higher level of digital maturity, the efficiency and structural effects become dominant.

Advanced digital technologies enable intelligent energy management, process optimization, and low-carbon innovation, thereby reducing carbon intensity and improving resource utilization efficiency.

In this regime, digitalization contributes to the decoupling between economic development and carbon emissions.

C. Empirical Evidence for Regime Transition

The transition characteristics are supported by both econometric estimation and machine learning interpretation.

The quadratic specification provides evidence of a nonlinear turning point in the digital economy–carbon emission relationship. The estimated critical value indicates the development level at which the marginal effect of digitalization changes from emission-increasing to emission-reducing.

Furthermore, the Gradient Boosting Decision Tree (GBDT) model and SHAP-based interpretation reveal nonlinear variations in the contribution of digitalization across different

development levels. The partial dependence patterns demonstrate that the environmental effect of digitalization is not uniform but changes along the digital development trajectory.

These results jointly support the existence of different digital economy–carbon emission regimes and indicate that countries may occupy different positions along the transition pathway.

D. Evolution of Driving Mechanisms Across Regimes

The transition among different regimes is associated with the changing dominance of three major mechanisms: scale effect, structural effect, and technological effect.

In the Digital Expansion Regime, the scale effect dominates because digital infrastructure deployment increases energy demand.

During the Transition Regime, structural adjustment and efficiency improvement gradually compensate for the additional energy consumption associated with digital expansion.

In the Digital Decoupling Regime, technological advancement becomes the primary driver by improving energy efficiency, facilitating low-carbon innovation, and supporting sustainable production systems.

The evolution of these mechanisms provides an integrated explanation for the observed inverted-U relationship between digital economy development and carbon emissions.

E. Engineering Implications for Digital Low-Carbon Transition

The regime transition analysis provides practical implications for designing digital-driven low-carbon development strategies.

For regions in the Digital Expansion Regime, improving the energy efficiency of digital infrastructure and increasing renewable energy utilization should be prioritized.

For regions in the Transition Regime, the focus should shift toward accelerating industrial digital transformation, enhancing technological integration, and improving resource utilization efficiency.

For regions in the Digital Decoupling Regime, advanced digital technologies can be further integrated with energy systems and industrial processes to achieve continuous emission reduction.

Therefore, the environmental benefits of digitalization depend not only on the scale of digital development but also on the degree of technological integration and energy system transformation.

IX. Robustness and Validation

A. Alternative Econometric Specifications

To examine the reliability of the estimated nonlinear relationship between the digital economy and carbon emissions, alternative econometric specifications are employed, including fixed-effects models, dynamic System Generalized Method of Moments (System GMM), and instrumental variable (IV) estimations.

The results obtained from different estimation approaches consistently support the baseline findings. Specifically, the coefficient of the digital economy remains positive, while the coefficient of its quadratic term remains negative and statistically significant, indicating the persistence of the inverted-U relationship.

The dynamic panel estimation further considers potential adjustment effects and temporal dependence of carbon emissions. The consistency of the key coefficients across different model specifications suggests that the identified nonlinear relationship is not sensitive to econometric assumptions.

Overall, the robustness analysis confirms the stability of the baseline estimation results under alternative identification strategies.

B. Alternative Measurements of the Digital Economy

To evaluate whether the findings depend on the specific measurement approach of the digital economy, alternative indicators are introduced for robustness verification.

The estimation results based on alternative digital economy measurements preserve the same nonlinear pattern as the baseline model. The digital economy coefficient remains positive, while the squared term maintains a negative relationship with carbon emissions.

These results indicate that the observed inverted-U relationship is not driven by a particular index construction method, but reflects a consistent association between digital development and carbon emission dynamics.

C. Machine Learning-Based Nonlinear Validation

To further examine the nonlinear characteristics without imposing a predefined functional form, a Gradient Boosting Decision Tree (GBDT) model is employed as a complementary validation approach.

The GBDT results provide additional support for the econometric findings. Feature importance analysis identifies the digital economy as a major explanatory factor in carbon emission prediction. Furthermore, SHAP analysis and partial dependence plots reveal a nonlinear response pattern consistent with the inverted-U relationship obtained from the quadratic specification.

The turning point identified by the machine learning model is close to the value estimated from the econometric approach, indicating consistency between parametric and non-parametric methods.

Therefore, the nonlinear relationship between digital development and carbon emissions is supported by multiple analytical approaches rather than relying solely on a specific functional form.

D. Stability Across Country Groups

To assess whether the nonlinear relationship remains stable under different sample compositions, additional analyses are conducted across alternative country groups.

The results show that the inverted-U relationship persists across different subsamples, although the estimated coefficients vary in magnitude. Such variations reflect differences in digital development levels, energy structures, and industrial characteristics among countries.

Importantly, the direction and nonlinear pattern of the relationship remain unchanged, suggesting that the identified digital economy–carbon emission nexus represents a relatively stable empirical relationship rather than a sample-specific outcome.

E. Summary of Robustness and Validation Evidence

The robustness checks and additional validation collectively demonstrate the reliability of the main findings.

The inverted-U relationship between the digital economy and carbon emissions remains consistent under alternative econometric specifications, alternative measurements, subsample analyses, and machine learning-based nonlinear validation.

The agreement between econometric estimation and GBDT-based interpretation confirms the stability of the identified nonlinear pattern and provides complementary evidence for the proposed regime transition analysis.

X. Conclusion

This study investigates the nonlinear relationship between the digital economy and carbon emissions using a global cross-country panel dataset by integrating econometric models with machine learning-based validation. A regime transition perspective is proposed to interpret the structural evolution of the digital economy–carbon emission nexus beyond the traditional linear assumption.

The results consistently reveal an inverted-U relationship between digital economy development and carbon emissions. This nonlinear pattern remains stable under alternative econometric specifications, including System GMM and instrumental variable estimations. The GBDT model with SHAP interpretation further confirms the nonlinear characteristics, demonstrating consistency between parametric and non-parametric approaches.

The findings indicate that the environmental impact of digitalization varies across development stages. Digital expansion may initially increase emissions due to infrastructure-related energy demand. With increasing digital maturity, efficiency improvement, industrial restructuring, and technological integration gradually become dominant, enabling digitalization to contribute to carbon reduction.

The estimated turning point represents a transition boundary between emission-increasing and emission-reducing stages. Cross-country differences in digital development, energy structures, and technological capabilities lead to heterogeneous positions along this transition pathway.

This study contributes by providing a nonlinear interpretation of the digital economy–carbon emission relationship and by combining econometric identification with machine learning-based validation. The findings highlight that digital transformation should be accompanied by improvements in energy efficiency, technological integration, and low-carbon development strategies.

Future research can further explore sector-level mechanisms and micro-scale digital applications to better understand the heterogeneous environmental effects of digital transformation.

This study has several limitations. First, interpolation of some missing observations may introduce measurement uncertainty. Second, differences in cross-country data availability may affect the precision of the Digital Economy Index. Third, the machine learning analysis provides complementary nonlinear validation rather than independent causal identification. Future research may further examine these issues using more granular data and independent samples.

A Multi-Layer Hyper-Personalization Pipeline for Predicting Next User Actions Across Web, App, Email, and Social Channels

A Simulation-Based Feasibility Study

Kohei Arai
Saga University, 1 Honjo, Saga 840-8502 Japan

***Abstract*—Hyper-personalization systems that unify customer behavior across Web, App, Email, and social channels are increasingly central to digital business strategy, yet published evaluations rarely isolate which modeling component—collaborative filtering, sequential prediction, or behavioral clustering—actually drives predictive value, and rarely validate a full pipeline end-to-end before committing to production data collection. This study presents a complete hyper-personalization pipeline spanning unified behavior aggregation, recency/frequency/content feature engineering, item-based collaborative filtering, sequential next-action modeling (first-order Markov chains and LSTM networks), and K-means behavioral clustering, validated on a simulated multi-channel dataset (80,997 events, 600 users, 90 days) constructed with five known latent personas so that recovered structure could be checked against ground truth. The LSTM next-action model reached 34.5% validation accuracy against a 10.0% uniform-chance baseline and a 16.0% majority-class baseline, and outperformed the order-1 Markov chain by approximately 6 percentage points once evaluated on a matched held-out split. An ablation study further shows that 1) LSTM accuracy is insensitive to capacity across a 50-fold parameter range, suggesting that the bottleneck is behavioral signal rather than model size; 2) collaborative-filtering hit-rate@2 is strong despite weak absolute cosine similarities, indicating that relative ranking survives even when category-level content granularity limits similarity magnitude; and 3) clustering quality is substantially higher on a reduced recency/frequency/channel-mix feature set than on the full feature set including content preferences, implying that content preferences are better used downstream in recommendation than as clustering inputs. I report these findings, together with the pipeline's limitations on simulated versus real data, as a feasibility baseline for practitioners designing multi-channel personalization systems.**

Keywords*—Hyper-personalization; collaborative filtering; sequential recommendation; LSTM; Markov chain; customer segmentation; multi-channel analytics; ablation study

I. Introduction

Businesses increasingly engage customers across four or more digital channels simultaneously—a corporate website, a mobile application, email marketing, and social media—each generating its own behavioral signal in its own format and cadence. A customer who browses a product on the web, opens a follow-up email two days later, and comments on a related social post is, from the business's perspective, a single evolving intent; from the data's perspective, these are three disconnected event streams unless deliberately unified. Hyper-personalization—the practice of predicting what an individual user will want next from their full cross-channel behavioral history—depends on solving this unification problem before any predictive model can be trained at all.

A second, less discussed problem is architectural: personalization systems are typically built from one dominant technique—collaborative filtering for product recommendation, sequential models for session-based prediction, or clustering for segmentation—rather than as a combined pipeline whose components are individually validated and compared. Practitioners choosing between these approaches rarely have a controlled feasibility study to draw on, particularly one that isolates whether a more complex model such as an LSTM earns its complexity over simpler baselines such as a Markov chain or a majority-class predictor on their specific data shape.

This study addresses both problems directly. I construct a unified multi-channel behavioral pipeline and validate it on a simulated dataset engineered with known latent structure—five distinct user personas with different channel-activity rates and content preferences—so that every stage of the pipeline can be checked against a ground truth that real-world data never provides. My contributions are threefold.

A complete, reproducible hyper-personalization pipeline covering behavior aggregation, feature engineering, collaborative filtering, sequential modeling, and clustering, implemented and validated end-to-end.

A controlled comparison of majority-class, Markov-chain, and LSTM baselines for next-action prediction on matched held-out data, resolving an apparent parity that informal per-user inspection suggested but rigorous evaluation did not support.

An ablation study isolating the effect of the collaborative-filtering weighting scheme, LSTM capacity, and clustering feature composition, surfacing a counter-intuitive finding that a reduced feature set produces substantially better-separated clusters than the full engineered feature set.

The remainder of this study is organized as follows. Section II reviews related work in collaborative filtering, sequential recommendation, and customer segmentation. Section III describes the simulated dataset and the full pipeline architecture.

Section IV details the experimental setup and evaluation metrics. Section V reports the main results. Section VI presents the ablation study. Section VII discusses limitations, Section VIII discusses implications, and Section IX concludes.

II. Related Work

A. Collaborative Filtering

Collaborative filtering (CF) recommends items to a user based on patterns of co-engagement across a population, rather than content attributes of the items themselves. Sarwar et al. [1] introduced item-based CF, computing similarity between items from the co-rating patterns of users, which scales more favorably than user-based CF for large catalogs. Koren et al. [2] later formalized matrix-factorization approaches to CF, learning latent factors for users and items jointly, which became the dominant paradigm following the Netflix Prize. My collaborative-filtering component follows the item-based tradition of [1], computing cosine similarity between content categories from a user x content-type engagement matrix, chosen for interpretability and its established track record for the category-level granularity used here.

B. Sequential and Session-Based Recommendation

Markov-chain models capture the probability of a user's next action conditional on their most recent action(s), and remain a strong, fully interpretable baseline for next-item prediction; Rendle et al. [3] combined Markov chains with factorization in their factorized personalized Markov chain (FPMC) model for next-basket recommendation, demonstrating that sequential and latent-factor signals are complementary rather than substitutable. The introduction of recurrent architectures shifted sequential recommendation toward models capable of learning longer-range dependencies: Hidasi et al. [4] proposed GRU4Rec, applying gated recurrent units to session-based recommendation, and LSTM networks -- introduced by Hochreiter and Schmidhuber [5] as a solution to the vanishing-gradient problem in standard recurrent networks -- have since been widely adopted for the same task family. This study directly compares a first-order Markov chain [3] against an LSTM [5] on the same next-action prediction task, which is a comparison the sequential-recommendation literature [3,4,5] more often assumes than measures on a specific dataset.

C. Customer Segmentation and RFM Analysis

Recency-Frequency-Monetary (RFM) analysis has been a standard customer-segmentation technique in direct marketing since Hughes' [6] foundational treatment of database marketing, and Bult and Wansbeek [7] formalized its use for optimal target selection. K-means clustering, dating to MacQueen [8], remains the most widely used unsupervised method for operationalizing RFM-style segments into discrete, actionable customer groups. My feature engineering extends the classical RFM formulation of [6,7] with channel-mix and content-preference features, and my ablation study (Section VI-C) directly tests whether this extension improves or degrades cluster separability relative to RFM alone -- a question the classical RFM literature [6,7] does not address, since it predates multi-channel behavioral data of this kind.

D. Research Gap and Original Contributions

Each stream of prior work reviewed above is evaluated within its own paradigm: collaborative filtering studies [1,2] benchmark recommendation quality without reference to sequential or segmentation structure; sequential-recommendation studies [3,4,5] typically introduce a new architecture and compare it against other sequential models rather than against a combined pipeline; and the RFM/clustering literature [6,7,8] predates, and does not address, multi-channel behavioral features of the kind generated by modern Web, App, Email, and Social platforms jointly. To the best of my knowledge, no prior study combines all three paradigms into a single validated pipeline, evaluates that pipeline on data with deliberately injected ground-truth structure, and subjects each component to a controlled ablation. This study's originality rests on three specific points of departure from [1]-[8]:

- Ground-truth-validated evaluation: unlike [1]-[8], which evaluate models on production or benchmark data where the true underlying user-behavior structure is unobservable, this study injects five known latent personas into the simulated data specifically so that every pipeline stage -- clustering, CF, and sequential modeling -- can be checked against a ground truth that real-world evaluation cannot provide;
- Cross-paradigm integration with controlled comparison: rather than proposing a new sequential architecture in the tradition of [4,5] or a new CF formulation in the tradition of [1,2] in isolation, this study integrates collaborative filtering, sequential modeling, and clustering into one pipeline and directly measures where each component's predictive value comes from, including a matched-validation-set comparison between Markov chains [3] and LSTMs [5] that the literature more often assumes than tests;
- Feature-attribution ablation for clustering: this study is, to my knowledge, the first to test whether extending classical RFM features [6,7] with modern multi-channel behavioral features (content preference, channel mix) improves or degrades cluster separability, rather than assuming -- as [6,7,8] implicitly do -- that a richer feature set is a strictly better one for unsupervised segmentation.

This combination of ground-truth validation, cross-paradigm integration, and feature-attribution ablation constitutes the study's original contribution relative to prior work, and is what allows Sections V and VI to report not only that the pipeline works, but why each component works to the degree that it does.

III. Materials and Methods

A. Simulated Multi-Channel Dataset

A synthetic event log was generated for 600 users over 90 days across four channels, using a single unified schema (user_id, timestamp, channel, event_type, content_type, value) so that no channel required special-case handling in downstream code. Table I shows the unified event schema across the four simulated channels.

TABLE I. UNIFIED EVENT SCHEMA ACROSS THE FOUR SIMULATED CHANNELS

Channel	Event Types	Value Field Semantics
Web	page_view, product_click	Dwell time (seconds), gamma-distributed
App	feature_usage, session	Session length (minutes), gamma-distributed
Email	open, click, conversion	Binary engagement flag
Social	like, comment, referral_click	Binary engagement flag

Five latent personas were assigned to users with fixed mixture weights, each defined by a distinct vector of per-channel Poisson event rates and a Dirichlet-sampled content-type preference distribution: multi-channel power users, app power users, email lurkers, social browsers, and dormant/churning users whose activity terminates partway through the observation window. This persona structure was known by construction and used exclusively to validate whether unsupervised clustering could recover it without being told it existed.

Fig. 1 shows simulated event volume by channel (n = 80,997 total events).

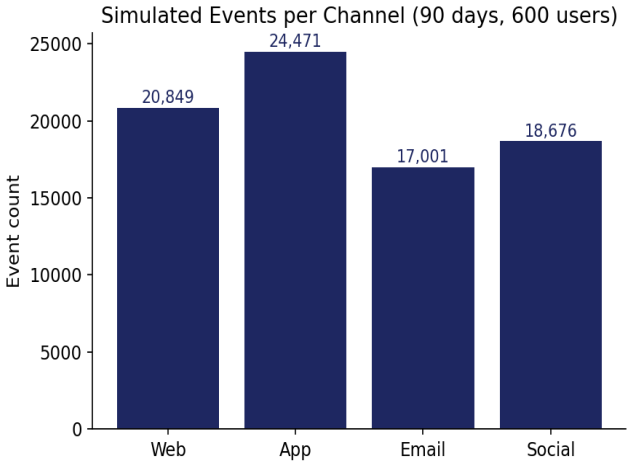

Fig. 1. Simulated event volume by channel (n = 80,997 total events).

B. Unified Behavior Aggregation

Raw events were aggregated into a single behavior matrix, one row per user. Of 600 simulated users, 581 generated at least one event; the remainder (entirely from the dormant/churning persona) produced zero events and were retained as realistic cold-start cases rather than removed, since a production system must handle such users gracefully. Fig. 2 shows the distribution of recency (days since last interaction) across all users.

C. Feature Engineering

Five feature groups were computed per user from the aggregated behavior matrix.

Recency: days since last interaction, computed overall and separately per channel.

Frequency: interaction counts, overall and per channel.

Time spent per channel: summed dwell time (Web), session length (App), or engagement-event count (Email, Social).

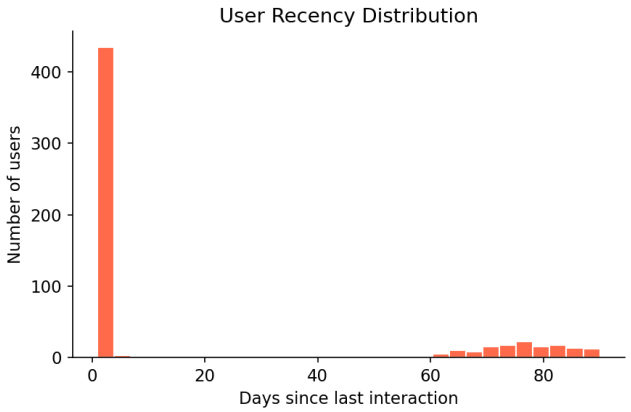

Fig. 2. Distribution of recency (days since last interaction) across all users.

Content-type preference shares: normalized interaction share across six content categories (Electronics, Fashion, Home, Beauty, Sports, Books).

Channel-mix shares: fraction of each user's total activity occurring on each of the four channels.

These 25 features were selected to balance interpretability and coverage across recency, frequency, channel intensity, and content preference. This design supports both clustering and recommendation while remaining compact enough for ablation analysis; practitioners can extend the feature set by adding domain-specific variables such as device type, geography, campaign exposure, or product-category depth.

D. Modeling Architecture

1) Collaborative filtering baseline: An item-based CF model was constructed from a user x content-type interaction matrix. Two weighting schemes were compared (Section VI-B): raw interaction counts and engagement-value weighting (summed dwell time/session length/engagement flags). Cosine similarity was computed between content-type columns, and recommendations for a given user were generated by projecting their engagement vector through the similarity matrix, down-weighting (rather than excluding) categories already heavily consumed so that adjacent, complementary categories could still surface.

2) Sequential models markov chain and LSTM: Each user's chronological action sequence (channel concatenated with event type, yielding 10 distinct actions) was modeled two ways. A first-order Markov chain estimated transition probabilities directly from observed action-to-action transitions across all users. An LSTM network (embedding layer, single LSTM layer, linear output over the action vocabulary) was trained to predict the next action from a padded window of up to 12 preceding actions, using cross-entropy loss and the Adam optimizer. Both models were evaluated on an identical held-out validation split (Section IV-A), which is what permits the direct comparison in Section V-C and Section VI-A.

3) Behavioral clustering: K-means clustering was applied to the standardized 25-column feature table. The number of clusters k was selected by silhouette score over a candidate

range of 3 to 7 (Section VI-C), and cluster profiles were subsequently interpreted in terms of dominant channel and recency to assign business-readable labels (e.g., "App power users", "Dormant / at-risk").

IV. Experiments

A. Experimental Setup

The LSTM and its ablation variants were trained with an 85/15 train/validation split at the level of individual (input-window, target-action) samples, using a fixed random seed for split reproducibility. The Markov chain was fit on the full transition dataset (as is standard for frequency-table estimators) and evaluated on the same validation targets as the LSTM, using only the single preceding action visible in each validation sample's input window, so that both models are compared on identical held-out predictions. All experiments used a fixed random seed (42) for the data simulation, model initialization, and train/validation splitting, to ensure the reported numbers are reproducible from the accompanying code.

B. Evaluation Metrics

- Next-action prediction: top-1 validation accuracy, benchmarked against both a uniform-chance baseline (1 / number of actions) and an empirical majority-class baseline (always predicting the single most frequent action in the training data);
- Collaborative filtering: hit-rate@2, a leave-one-out metric in which each user's single most-engaged content category is held out, and a hit is recorded if item-based CF (fit on the remaining categories) ranks the held-out category in its top 2 recommendations, benchmarked against random-selection chance (2 of 6 categories ≈ 33.3%);
- Clustering: silhouette score, computed over standardized features for candidate k in {3, ..., 7} and for four feature-subset configurations at fixed k = 4.

V. Results

A. Data Characteristics

The simulated dataset comprised 80,997 events: 20,849 Web, 24,471 App, 17,001 Email, and 18,676 Social events. Recency was strongly bimodal (Fig. 2): the majority of users were active within the preceding day, while a persona-driven dormant subgroup showed recency exceeding 60-90 days, a direct artifact of the churn mechanism built into the simulation.

B. Collaborative Filtering Results

Cosine similarities among the six content-type categories were uniformly weak (mean = 0.1898, off-diagonal), reflecting the coarse category-level granularity of the simulated content taxonomy and the persona-driven spread of users across categories rather than tight product-level affinities. Fig. 3 shows the content-type similarity matrix from item-based collaborative filtering.

C. Sequential Model Results

The LSTM reached 34.5% validation accuracy, more than three times the 10% uniform-chance baseline (Fig. 4). Section VI-A reports the controlled comparison against the Markov chain and majority-class baselines on identical validation targets.

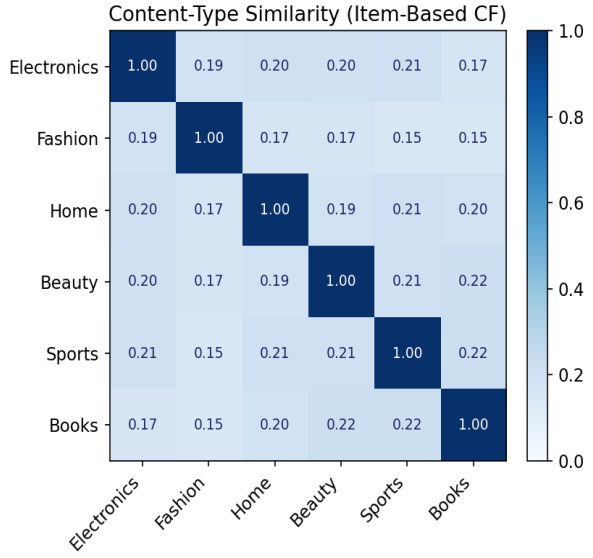

Fig. 3. Content-type similarity matrix from item-based collaborative filtering.

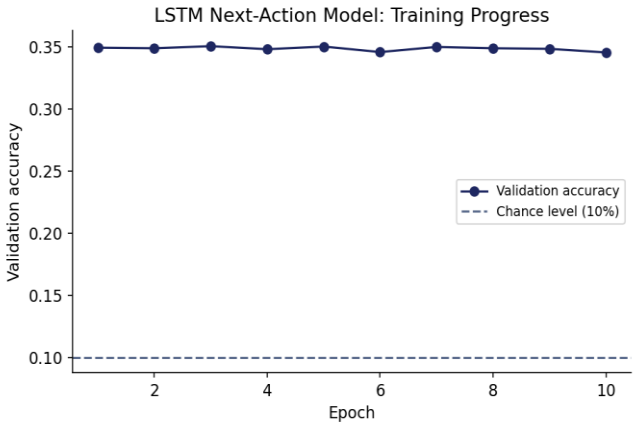

Fig. 4. LSTM validation accuracy across training epochs.

D. Clustering Results

K-means with k = 4 (selected by silhouette score) produced clusters that mapped cleanly onto the personas built into the simulation, without cluster labels ever being informed by the ground-truth persona assignment: Table II shows cluster sizes and business-readable labels assigned by profile inspection. Fig. 5 shows average channel mix by behavioral cluster.

TABLE II. Cluster Sizes and Business-Readable Labels Assigned by Profile Inspection

Cluster	Size	Interpreted Label
Cluster 0	140	Email-first, low cross-channel
Cluster 1	210	App power users
Cluster 2	108	Dormant / at-risk
Cluster 3	123	Social-driven browsers

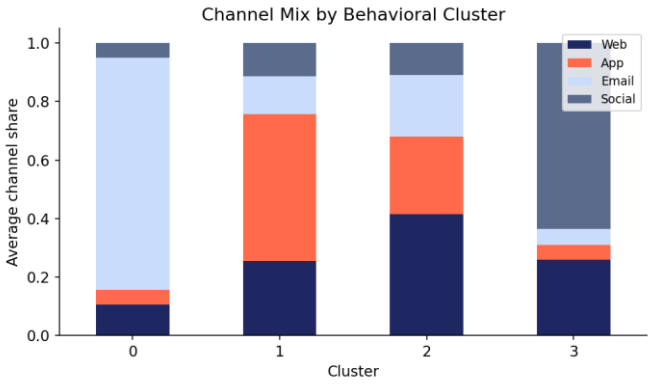

Fig. 5. Average channel mix by behavioral cluster.

E. End-to-End Combined Predictions

Combining all three modeling layers, the pipeline produces one row per user with a cluster assignment, a content-type recommendation, and next-action predictions from both sequential models (Table III).

TABLE III. SAMPLE OF COMBINED PER-USER PREDICTIONS FROM THE FULL PIPELINE

User	Cluster	Recency (d)	Content recs	Markov next	LSTM next
0	0	1	Home, Electronics	email_open (0.356)	email_open (0.481)
2	3	1	Books, Home	social_like (0.25)	social_like (0.298)
3	3	1	Books, Beauty	web_page_view (0.181)	social_like (0.308)
4	1	1	Home, Beauty	app_feature_usage (0.324)	app_feature_usage (0.407)
5	1	1	Sports, Home	app_feature_usage (0.311)	app_feature_usage (0.456)
6	1	1	Home, Electronics	app_feature_usage (0.324)	web_page_view (0.238)
8	3	1	Books, Electronics	social_like (0.25)	social_like (0.314)
9	3	1	Fashion, Electronics	social_like (0.25)	social_like (0.294)
10	1	2	Sports, Electronics	social_like (0.267)	web_page_view (0.206)
12	2	76	Beauty, Sports	app_feature_usage (0.324)	web_page_view (0.226)

VI. ABLATION STUDY

A. Sequential Model Ablation

To determine whether the LSTM's advantage over simpler baselines is real, and whether its accuracy is limited by model capacity, five predictors were evaluated on identical held-out validation targets: a majority-class baseline, a first-order Markov chain, and LSTMs at three parameter scales. Table IV shows sequential model ablation. Uniform chance level = 0.1 (1/10 actions) (Fig. 6).

TABLE IV. SEQUENTIAL MODEL ABLATION. UNIFORM CHANCE LEVEL = 0.1 (1/10 ACTIONS)

Model	Val. Accuracy	Parameters
Majority-class baseline	0.1604	—
Markov chain (order-1)	0.2819	—
LSTM-small (emb=8, hidden=16)	0.3498	1,939
LSTM-base (emb=32, hidden=64)	0.3407	26,155
LSTM-large (emb=64, hidden=128)	0.3498	101,451

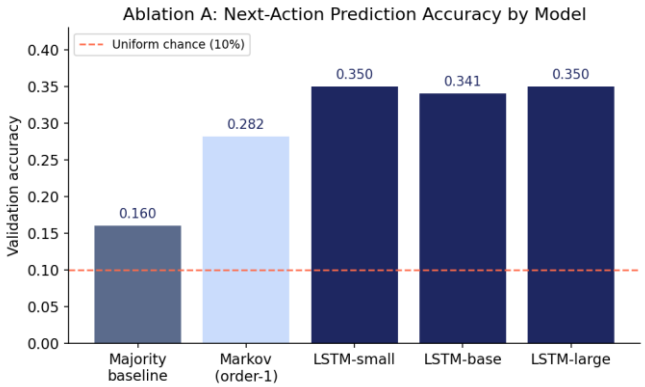

Fig. 6. Next-action prediction accuracy across baseline and LSTM-capacity variants.

The Markov chain (28.2%) clearly outperforms the majority-class baseline (16.0%), confirming genuine one-step sequential signal in the data. All three LSTM variants converge to a narrow band (34.1–35.0%) despite a roughly 50-fold difference in parameter count between the smallest and largest variants, indicating that the LSTM's accuracy ceiling here is set by the available behavioral signal rather than model capacity -- additional parameters do not buy additional accuracy on this dataset.

All three LSTM variants outperform the order-1 Markov chain by approximately 6 percentage points, a gap that a prior informal inspection of individual users' predictions (comparing Markov and LSTM outputs qualitatively, user by user) did not clearly reveal, since both models tend to agree on the single most probable next action for any given user even when their overall accuracy differs. This distinction matters methodologically: qualitative, per-user comparison and quantitative, held-out evaluation can lead to different conclusions about the same pair of models, and the latter should be trusted when the two disagree.

B. Collaborative Filtering Weighting Ablation

Two interaction-matrix weighting schemes were compared using leave-one-out hit-rate@2: raw interaction counts and engagement-value weighting (dwell time, session length, or engagement flags, as used in the main pipeline). Table V shows collaborative filtering weighting ablation. Chance level (random 2-of-6 categories) = 0.3333.

TABLE V. COLLABORATIVE FILTERING WEIGHTING ABLATION. CHANCE LEVEL (RANDOM 2-OF-6 CATEGORIES) = 0.3333

Weighting Scheme	Hit-rate@2	n Users Evaluated
Raw interaction count	0.7447	517
Engagement-value weighted	0.7505	517

Both weighting schemes performed far above chance (33.3%), reaching 74.5% and 75.0% hit-rate@2 respectively -- a result that appears to sit in tension with the weak absolute similarity values reported in Section V-B (mean cosine similarity 0.19). The two findings are in fact compatible: hit-rate@2 depends only on the relative ranking of categories for a given user, not on the absolute magnitude of similarity scores, so even uniformly weak similarities can still rank a user's true held-out preference correctly if that ranking is directionally consistent across the population. Engagement-value weighting provided a small, consistent improvement over raw counts (+0.6 percentage points), suggesting that how long or how often a user engages carries modestly more signal than whether they engaged at all, though the effect at this scale is not large.

C. Clustering Feature-Subset and k-Selection Ablation

Silhouette score was evaluated across candidate k (full feature set) and across four feature-subset configurations at fixed k = 4.

Table VI shows silhouette score by number of clusters (full 25-feature set). Also, Table VII shows silhouette score by feature-subset composition, fixed k = 4. On the other hand, Fig. 7 shows clustering quality (silhouette score) by feature-subset composition.

TABLE VI. SILHOUETTE SCORE BY NUMBER OF CLUSTERS (FULL 25-FEATURE SET)

k	Silhouette Score
k = 3	0.1982
k = 4	0.1995
k = 5	0.1881
k = 6	0.1909
k = 7	0.1884

TABLE VII. SILHOUETTE SCORE BY FEATURE-SUBSET COMPOSITION, FIXED K = 4

Feature Subset	Silhouette Score (k=4)
RFM only	0.7362
Content preference only	0.318
Channel mix only	0.654
Full feature set	0.1995

The k sweep shows only modest sensitivity to k (silhouette range 0.188–0.200), with k = 4 marginally the best choice among the candidates tested -- consistent with a real but weak natural clustering structure in the full feature set. The feature-subset ablation, however, reveals a substantially larger effect: clustering on recency/frequency features alone achieves silhouette = 0.7362, and channel-mix features alone achieve silhouette = 0.654, both far exceeding the full 25-feature set's silhouette = 0.1995. Content-preference features alone sit in between (silhouette = 0.318).

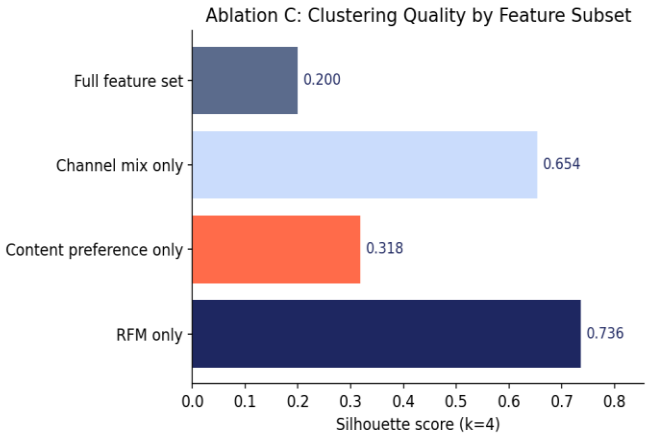

Fig. 7. Clustering quality (silhouette score) by feature-subset composition.

This indicates that recency, frequency, and channel-mix features drive the great majority of separable cluster structure in this dataset, and that adding content-preference features to the clustering input dilutes rather than sharpens cluster separation -- likely because content preferences vary more continuously across users (via the Dirichlet sampling in the simulation) than channel behavior does (via discrete per-persona rate differences), adding within-cluster variance without adding between-cluster separation. The practical implication is that content-preference features are better reserved for the collaborative-filtering and sequential components, where they are used directly, than included as clustering inputs, where they appear to add noise relative to signal.

VII. LIMITATIONS

All results are derived from simulated data with five deliberately injected personas; real customer behavior is likely more heterogeneous and less cleanly separable, and the strong cluster-recovery and hit-rate results reported here should be treated as an upper bound on what the same pipeline would achieve on production data.

Collaborative filtering operates at the level of six broad content categories rather than individual products (SKUs); the weak absolute similarity values in Section V-B are partly an artifact of this coarse granularity and would likely improve with product-level content.

The train/validation split for sequential modeling is random over (input, target) samples rather than a temporal holdout; this evaluates the models' ability to interpolate within the observed period, not their ability to forecast genuinely future behavior, which is the more demanding and practically relevant test.

The Markov chain was fit on the full dataset (standard practice for frequency-table estimators) while the LSTM was fit only on the training split; this gives the Markov chain a marginal data advantage that, if anything, understates the LSTM's relative improvement reported in Section VI-A.

The LSTM architecture tested is intentionally simple (single recurrent layer, three capacity variants); no Transformer-based sequential model was evaluated in this study, though one would be a natural extension once real, larger-scale behavioral data is available.

No live A/B testing or production deployment was conducted; all reported metrics are offline validation metrics computed on held-out simulated data.

VIII. Discussion

Three findings from this study carry implications beyond the specific simulated dataset used here. First, the divergence between qualitative and quantitative model comparison (Section VI-A) is a methodological caution relevant to any personalization system: informally inspecting a handful of per-user predictions can suggest that a complex model (the LSTM) offers little over a simple one (the Markov chain), when a properly controlled, matched-validation-set comparison reveals a real, consistent advantage. Personalization teams evaluating whether a deep sequential model is worth its added engineering and serving cost should insist on the latter kind of comparison before concluding the former.

Second, the LSTM capacity ablation (Section VI-A) suggests that, at least at this data scale, the limiting factor for next-action prediction accuracy is the information content of the behavioral signal itself rather than model expressiveness. This has a direct practical corollary: teams facing a ceiling in next-action prediction accuracy should first investigate whether additional behavioral features or longer observation windows are available, rather than reflexively scaling up model size, which this ablation suggests would not help.

Third, the clustering feature-subset ablation (Section VI-C) is, to my knowledge, a finding not previously highlighted in the RFM/clustering literature [6,7,8]: engineered features that are individually reasonable additions to a customer feature table (content preferences, in this case) can measurably degrade the very clustering they were added to support. This argues for treating clustering feature selection as its own tunable step, evaluated via silhouette score or an equivalent internal validity measure, rather than assuming that a richer feature set is always a better one for unsupervised segmentation, as the classical RFM formulation [6,7] implicitly does -- even when that same richer feature set is valuable elsewhere in the pipeline, as content preferences are for collaborative filtering [1,2].

Collectively, the three modeling layers appear to serve complementary rather than redundant roles: clustering is most effective as a coarse, business-facing segmentation layer built primarily from recency/frequency/channel behavior; collaborative filtering is most effective as a content-recommendation layer that benefits from exactly the preference features clustering does not need; and sequential modeling is most effective as a fine-grained, real-time next-action layer where model capacity is not yet the binding constraint. A production system would likely deploy all three concurrently rather than choosing among them.

A production system would likely deploy all three modeling layers concurrently rather than choosing among them. Clustering is most effective as a course, business-facing segmentation layer built primarily from recency, frequency, and channel behavior; collaborative filtering is most effective as a content-recommendation layer that benefits from preference features; and sequential modeling is most effective as a fine-grained, real-time next-action layer where model capacity is not yet the binding constraint.

For real-world deployment, the pipeline should next be validated on heterogeneous behavioral data, using a temporal train-test split so that test targets occur after the training window. Practical implementation would also need to address privacy, schema drift, missingness, channel imbalance, and the fact that real customers do not separate into personas as cleanly as the synthetic data used here.

IX. Conclusion

This study presented a complete hyper-personalization pipeline -- unified multi-channel behavior aggregation, recency/frequency/content feature engineering, item-based collaborative filtering, Markov-chain and LSTM sequential modeling, and K-means behavioral clustering -- validated end-to-end on a simulated dataset with known ground-truth persona structure. The pipeline recovered the injected persona structure through clustering, achieved LSTM next-action accuracy well above both chance and majority-class baselines, and achieved strong collaborative-filtering hit-rate despite weak absolute similarity values.

A controlled ablation study further showed that LSTM accuracy is capacity-insensitive at this data scale, that engagement-value weighting offers a modest edge over raw interaction counts for collaborative filtering, and that clustering quality depends heavily on feature-subset composition, with a reduced recency/frequency/channel-mix feature set substantially outperforming the full engineered feature set.

Taken together, these results provide a feasibility baseline and a set of concrete, testable hypotheses—particularly around feature selection for clustering and the value of capacity versus data scale for sequential models—that can guide the transition from this simulated study to a production deployment on real multi-channel customer data. The next step is to re-run the same pipeline on a real behavioral dataset, verify the results under a temporal holdout, and then evaluate operational impact with an A/B test.

Acknowledgment

The author would like to thank Prof. Dr. Hiroshi Okumura of Saga University for his valuable comments and suggestions throughout this research.

Abstract*—Apple diseases cause great losses in fruit yield and quality, while manual diagnosis is time-consuming, subjective, and difficult to scale across orchards. Deep learning has thus become a staple in image-based disease recognition, but evidence remains scattered across classification and object-detection paradigms, heterogeneous datasets, and inconsistent evaluation protocols. This systematic literature review integrates 30 peer-reviewed studies published between 2020 and 2026, selected from 180 database records using a PRISMA 2020-aligned protocol. The final corpus includes 22 image-classification studies and eight object-detection studies. One non-peer-reviewed preprint was kept as contextual evidence only and was excluded from all corpus counts and comparative analyses. Architectures, datasets, preprocessing and augmentation strategies, training configurations, evaluation metrics, evidence of generalization, and deployment characteristics are discussed separately for the two task paradigms. Reported classification accuracies vary from 91.0% to 99.99%, whereas detection studies report mAP@0.5 values from 82.1% to 99.99%; these ranges are descriptive and are not pooled estimates. These values are heavily dependent on dataset composition and evaluation design: controlled-background datasets often yield near-perfect scores, while field transfer can lead to a drop of almost 30 percentage points. CNNs still dominate the field, but hybrid transformer-based attention mechanisms, multi-scale feature fusion, class-imbalance-aware training, and lightweight YOLO variants are gaining traction. Long-standing limitations are the lack of reporting of hyperparameters, an over-reliance on accuracy, the lack of external validation, heterogeneity in annotation, the lack of uncertainty analysis, and limited reporting of latency, memory, and energy consumption. Accordingly, the research agenda emphasizes standardized real-orchard benchmarks, cross-dataset validation, calibrated and explainable predictions, reproducible experimental protocols, and deployment-aware model design.

Keywords*—Apple disease recognition; deep learning; convolutional neural networks; object detection; PRISMA 2020; systematic literature review; precision agriculture

I. Introduction

Apple (Malus domestica) is a high-value fruit crop, and its productivity is constrained by various fungal, bacterial, and viral diseases such as apple scab, powdery mildew, Alternaria leaf spot, Marssonina blotch, fire blight, and postharvest blue mold. Disease pressure reduces the marketable yield, accelerates defoliation, and may result in greater chemical use when diagnosis is late or inaccurate [1], [8]– [11]. Insect pests and mites such as codling moth, aphids, spider mites, and San Jose scale also affect orchard health and further complicate visual assessment and crop-management decisions [12]–[17]. Traditional diagnosis is based on field scouting and visual interpretation by farmers, agronomists, or plant pathologists. Expert inspection is still required but is labour-intensive and sensitive to symptom similarity, disease stage, illumination, occlusion, and observer experience. Image-based AI offers a non-destructive alternative that can learn discriminative patterns directly from leaf or fruit images. Therefore, convolutional neural networks (CNNs), vision transformers, hybrid CNN-transformer models, and object detectors have been used in precision-agriculture applications [6], [7].

The fast development of the field has created an evaluation problem. In classification studies, the objective is to assign one label to an image. Accuracy, precision, recall, and F1-score are the most common metrics reported in these studies. Detection studies also localize lesions, or diseased leaves, and are mostly evaluated in terms of mean average precision. Mixing these task types in one ranking is methodologically unsound because the outputs, annotation requirements, and error structures differ. In this review, recognition is used as an umbrella term for image classification and object detection rather than as a third task category. Dataset conditions may also be very different: sample counts are between a few hundred and over 200,000 images, and images can be taken in front of uniform laboratory backgrounds or in complex orchards with shadows, overlapping foliage, and different cameras [2], [18]–[29], [31]–[48]. Existing reviews give useful summaries on the development of apple disease recognition and bibliometrics [4], [5]. Nevertheless, the interaction between task paradigm, dataset realism, class balance, augmentation, training configuration, evaluation completeness, and deployment constraints has received little attention. A review is needed that is replicable for purposes of comparison.

The main contributions can be summarized as follows:

- A PRISMA 2020-aligned synthesis of 30 peer-reviewed studies published between 2020 and 2026 is presented,

with explicit separation of 22 classification and eight detection studies. Five research questions address architecture families, datasets and augmentation, performance evaluation, reproducibility, and deployment evidence.

- Dataset scale, training hyperparameters, acquisition settings, validation design, and reported metrics are compiled to reduce misleading cross-study interpretation.
- The gap between controlled benchmarks and real-orchard performance is examined together with class imbalance, annotation quality, explainability, and edge deployment.
- An evidence-based research roadmap is derived for standardized datasets, external validation, calibrated predictions, reproducible pipelines, and deployment-aware model design.

The rest of the study is organized as follows. Section II discusses apple disease imaging and its associated deep learning architecture families. The review protocol, research questions, search strategy, selection criteria, quality assessment, and data-extraction process are presented in Section III. Results by research question are presented in Section IV. Section V examines cross-study implications, unresolved gaps, and threats to validity. The review ends with Section VI.

II. Background and Related Reviews

A. Apple Disease Imaging and Diagnostic Complexity

Visible symptoms are often expressed as lesions, discolouration, powdery growth, necrotic areas, deformation, or premature defoliation. Apple scab is characterized by olive green or dark lesions on leaves and fruits. Powdery mildew causes pale or powder-like growth. Alternaria and Marssonina diseases cause spots whose appearance varies with severity. Fire blight can attack leaves, shoots, blossoms, and fruit [1], [8]-[11]. Similar patterns of color and texture across diseases create a fine-grained classification problem, while small overlapping lesions introduce an additional localization problem for object detectors. Representative disease manifestations considered in this review are illustrated in Fig. 1, showing the visual overlap in lesion color, texture, and morphology that complicates image-based diagnosis.

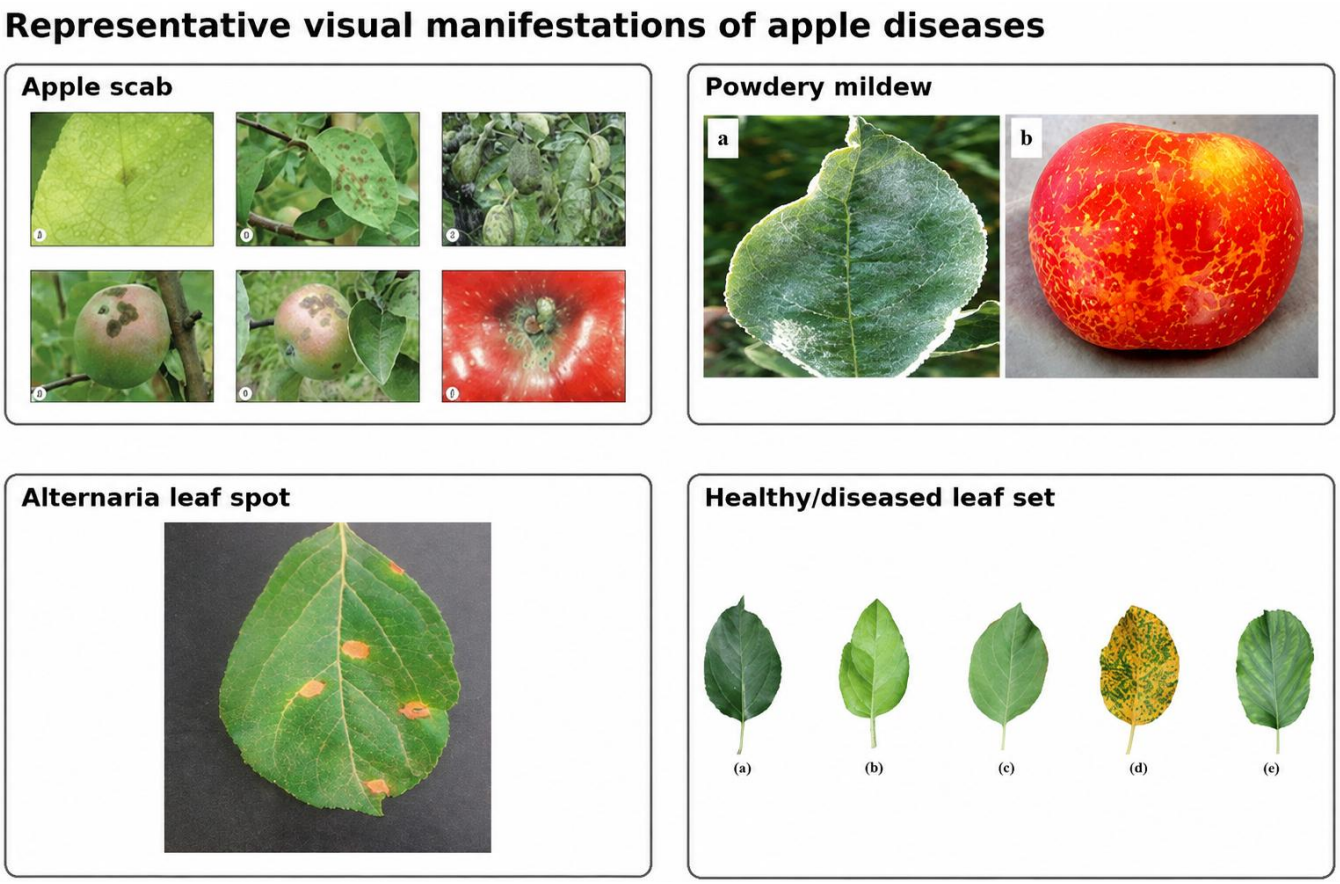

Fig. 1. Representative apple-disease symptoms illustrating scab, powdery mildew, Alternaria leaf spot, and healthy/diseased leaf conditions; disease descriptions are supported by [1], [8], and [10].

These visual ambiguities make dataset acquisition conditions crucial. Centered leaves and homogeneous backgrounds simplify segmentation in controlled datasets, but can cause models to learn background shortcuts. Natural-scene datasets have branches, fruits, soil, sky, mixed illumination, occlusion, and multiple symptoms, which makes the evaluation more difficult but operationally meaningful. Expert-annotated field imagery has been made significantly more accessible by

datasets such as Plant Pathology 2020 and 2021 [2], while self-collected datasets like MSALDD have enabled more research on real-time detection [48].

B. Deep-Learning Architecture Families

Convolution, non-linear activation, pooling, and classification layers enable a CNN to learn hierarchical image features. The early layers are sensitive to edges and local texture, and the deeper layers learn disease-specific shape and semantic patterns [6], [7]. Residual connections, dense feature reuse, depthwise separable convolution, squeeze-and-excitation attention, and feature pyramids are employed to enhance gradient flow, parameter efficiency, and multi-scale recognition. The hierarchical feature-extraction sequence underlying CNN-based image classification is illustrated in Fig. 2, from convolutional feature learning to the final class prediction.

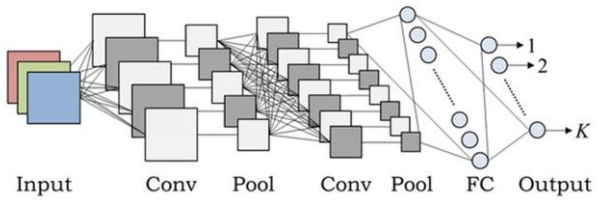

Fig. 2. Conceptual CNN processing pipeline for image classification; the architectural principles are discussed in [7].

The reviewed corpus adopted the classification architectures of ResNet, DenseNet, EfficientNet, Inception, RegNet, Xception, lightweight bilinear CNNs, vision transformers, and hybrid CNN-transformer architectures [18]–[29], [31]– [40]. Improved Faster R-CNN and several YOLO derivatives are detection architectures with feature pyramids, attention modules, lightweight convolution, normalized Wasserstein distance, or auxiliary detection heads [41]–[48]. Transformer-based models provide long-range context, whereas CNN branches retain local texture sensitivity. DBCoST and CTPlantNet are hybrid systems trying to combine both properties [23], [24].

C. Limitations of Earlier Reviews

Doutoum and Tugrul [4] have provided a systematic review, which proposed a comprehensive taxonomy of apple leaf disease classification and detection. Bonkra et al. [5] performed a bibliometric analysis to quantify publication and collaboration trends. These works show the maturity of the field but leave three issues open. First, the results of classification and detection are not always consistently separated. Second, the relationship between dataset realism, hyperparameter reporting, and reported performance is underexplored. Third, deployment evidence (model size, memory, inference latency, power consumption and field validation) is rarely synthesized as a unified dimension. The present review addresses these limitations using a multidimensional extraction framework.

III. Materials and Methods

A. Review Design and Research Questions

The systematic literature review was designed and reported in alignment with the PRISMA 2020 statement [3]. The protocol comprised six stages: identification, deduplication, title/abstract screening, full-text eligibility assessment, methodological-evidence appraisal, and structured qualitative synthesis. Research questions, eligibility criteria, appraisal domains, and data-extraction variables were defined before full-text extraction. No prospective registration or standalone protocol was available.

Study screening and data extraction were conducted by one lead reviewer and subsequently checked by a second author. Disagreements were resolved through discussion and consensus. This procedure is considered a potential source of selection bias and is addressed explicitly in the threats-to-validity analysis. The five research questions and analytical purposes are summarized in Table I.

TABLE I. Research Questions

ID	Research question	Analytical purpose
RQ1	Which deep-learning architectures and task paradigms are used for apple disease recognition?	Establish the taxonomy of classification, detection, hybrid, lightweight, and transformer-based models.
RQ2	Which datasets, acquisition conditions, preprocessing methods, and augmentation strategies are used?	Assess data realism, class balance, sample scale, and the role of preprocessing or synthetic data.
RQ3	How are models evaluated, and what performance patterns are reported?	Interpret accuracy, precision, recall, F1-score, and mAP within comparable experimental contexts.
RQ4	How completely are training settings and reproducibility information reported?	Examine optimizers, learning rates, batch sizes, epochs, validation protocols, and missing details.
RQ5	How close are current models to reliable field deployment, and which research gaps remain?	Evaluate robustness, external validation, interpretability, efficiency, latency, memory, energy, and future priorities.

B. Information Sources and Search Strategy

Scopus, Web of Science Core Collection, and IEEE Xplore were selected for their cross-disciplinary coverage of peer-reviewed research in artificial intelligence, computer vision, agriculture, and engineering. The final searches were conducted on 30 June 2026 and covered January 2020-June 2026. Only English-language peer-reviewed journal and conference articles were eligible as primary studies; the exact executed search expressions are reported in Table II. Specialized agricultural databases such as CAB Abstracts and AGRICOLA were not searched, and this restriction is addressed in Section V-C.

TABLE II. DATABASE SEARCH STRATEGY

Database	Field	Complete search expression	Limits
Scopus	TITLE-ABS-KEY	("apple" OR "Malus domestica") AND ("leaf disease" OR "fruit disease" OR "apple disease") AND ("deep learning" OR CNN OR transformer OR YOLO OR "Faster R-CNN") AND (classification OR detection OR recognition)	Jan. 2020-Jun. 2026; English; journal/conference
Web of Science	TS=	(("apple" OR "Malus domestica") AND ("leaf disease" OR "fruit disease" OR "apple disease") AND ("deep learning" OR CNN OR transformer OR YOLO OR "Faster R-CNN") AND (classification OR detection OR recognition))	Jan. 2020-Jun. 2026; English; article/proceedings
IEEE Xplore	All Metadata	(("apple disease" OR "apple leaf disease") AND ("deep learning" OR CNN OR "object detection" OR YOLO OR "Faster R-CNN"))	Jan. 2020-Jun. 2026; English; journals/conferences

Backward citation screening was performed using the reference lists of included studies and relevant reviews; no additional eligible peer-reviewed report was added. Full texts were retrieved from publisher repositories, institutional subscriptions, and open-access archives. Database exports, deduplication decisions, screening decisions, full-text decisions, and the extraction form constituted the audit record. The executed database strings relied mainly on generic apple-disease terms; disease-specific and segmentation terminology was not exhaustively represented and is therefore treated as a search-sensitivity limitation in Section V-C.

C. Eligibility Criteria

Eligibility criteria were applied at the title/abstract and full-text stages. A study was required to report an apple-specific deep-learning experiment and quantitative model evaluation. General plant-disease papers were included only when apple-specific results could be separated. Non-peer-reviewed sources were excluded from the primary synthesis. The D-KAP preprint [30] was retained only as contextual evidence and was excluded from corpus counts, performance ranges, figures, methodological appraisal, and comparative tables. The eligibility criteria are summarized in Table III.

TABLE III. INCLUSION AND EXCLUSION CRITERIA

Type	ID	Dimension	Criterion
Inclusion	IC1	Domain	Apple leaf, fruit, or apple-plant disease classification/detection.
Inclusion	IC2	Method	CNN, transformer, hybrid deep network, transfer learning, or deep object detector.
Inclusion	IC3	Evidence	Quantitative experimental evaluation using accuracy, precision, recall, F1-score, AUC, mAP, or deployment metrics.
Inclusion	IC4	Publication	Peer-reviewed journal or conference article in English, 2020–2026.
Inclusion	IC5	Accessibility	Full text available for methodological and numerical extraction.
Exclusion	EC1	Scope	General agriculture or plant disease research without separable apple experiments.
Exclusion	EC2	Method	Handcrafted image processing or shallow machine learning without a deep-learning component.
Exclusion	EC3	Evidence	No experimental validation or no quantitative results.
Exclusion	EC4	Publication	Editorials, tutorials, theses, non-English papers, and non-peer-reviewed items were excluded from the primary synthesis. The D-KAP preprint [30] was retained only as contextual evidence.
Exclusion	EC5	Redundancy	Duplicate database records or duplicate versions of the same study.

D. Quality Assessment and Data Extraction

The former binary quality score was replaced by a domain-based methodological-evidence appraisal because reporting completeness and risk of bias are not equivalent. Eight domains were considered: dataset provenance and label validity, evaluation independence and leakage control, class imbalance, generalization strength, metric adequacy and uncertainty, reproducibility, agronomic context, and transparency of limitations. Each domain was interpreted on a three-level basis (0 = insufficient/unclear, 1 = partial, 2 = strong evidence) when information was available. No aggregate study score or numerical weighting was used; the domains informed qualitative sensitivity interpretation. The appraisal domains are defined in Table IV, and the extraction variables are summarized in Table V.

TABLE IV. QUALITY ASSESSMENT CRITERIA

ID	Assessment domain	Purpose
Q1	Dataset provenance and diagnostic-label validity	Assess traceable data sources, labels, and expert/validated diagnosis.
Q2	Evaluation independence and leakage control	Assess train-test separation, source grouping, and augmentation-lineage leakage.
Q3	Class distribution and imbalance management	Assess class counts, balancing strategy, and minority-class evaluation.
Q4	Generalization and external validation	Distinguish holdout/CV from cross-dataset, orchard, or field validation.
Q5	Metric adequacy and statistical uncertainty	Assess task-appropriate, classwise, and uncertainty reporting when available.
Q6	Experimental reproducibility	Assess optimizer, learning rate, batch size, epochs, resolution, seeds/code, and validation details.
Q7	Biological and agronomic context	Assess cultivar, season, severity, acquisition conditions, expert diagnosis, and disease co-occurrence.
Q8	Transparency, limitations, and failure modes	Assess explicit threats, implementation constraints, and acknowledged failure modes.

TABLE V. DATA EXTRACTION FRAMEWORK

Attribute	Extracted information	Analytical use
Bibliographic profile	Authors, year, venue	Publication trend and traceability.
Task paradigm	Classification, detection, hybrid	Avoid invalid cross-task comparison.
Dataset	Source dataset size, experimental subset, augmented count, classes, acquisition environment, label provenance	Assess scale, biological independence, class balance, realism, and label validity.
Preprocessing	Resize, enhancement, segmentation, normalization	Identify data-pipeline variation.
Augmentation	Geometric, photometric, GAN, class-aware	Assess robustness and synthetic-data use.
Architecture	Backbone, attention, transformer, feature fusion	Build the model taxonomy.
Training settings	Optimizer, learning rate, batch size, epochs, split/CV design, seeds when reported	Assess reproducibility and evaluation independence.
Metrics	Accuracy, precision, recall, F1, AUC, mAP, test size, fold variability/CI when reported	Compare evidence within task while avoiding unsupported uncertainty reconstruction.
Deployment	Parameters, FLOPs, model size, FPS/latency, memory, power, target hardware, field evidence	Assign qualitative deployment-evidence level (D0-D3).
Limitations	Generalization, annotation, imbalance, interpretability	Derive research gaps.
Agronomic context	Organ, cultivar, season, severity/stage, location, device, annotation authority, disease co-occurrence	Assess biological validity and orchard transferability.

E. Study Selection and Synthesis

The database search yielded 180 records: 90 from Scopus, 50 from Web of Science, and 40 from IEEE Xplore. After 18 duplicates were removed, 162 unique records underwent title/abstract screening, and 88 were excluded. All 74 reports sought for full-text review were retrieved. Forty-four full-text reports were excluded because apple-specific results could not be separated (n = 12), no deep-learning architecture was evaluated (n = 9), quantitative results were absent (n = 11), the publication was not peer-reviewed (n = 8), or the paper was not in English (n = 4). The final corpus comprised 30 peer-reviewed studies: 22 classification and eight detection studies. These correspond to 16.7% of all identified records, 18.5% of unique records after deduplication, and 40.5% of full-text reports assessed. The screening pathway is shown in Fig. 3.

Full-text exclusion categories are summarized in Table VI. The item-level full-text exclusion list is not reproduced because it is no longer available in a form that can be independently verified. To avoid retrospective reconstruction and possible misclassification, only the contemporaneously retained aggregate exclusion counts and primary reason categories are reported. Reason-level counts for the 88 title/abstract exclusions were not retrospectively reconstructed when they had not been recorded as quantitative categories. The D-KAP preprint [30] remained contextual evidence only.

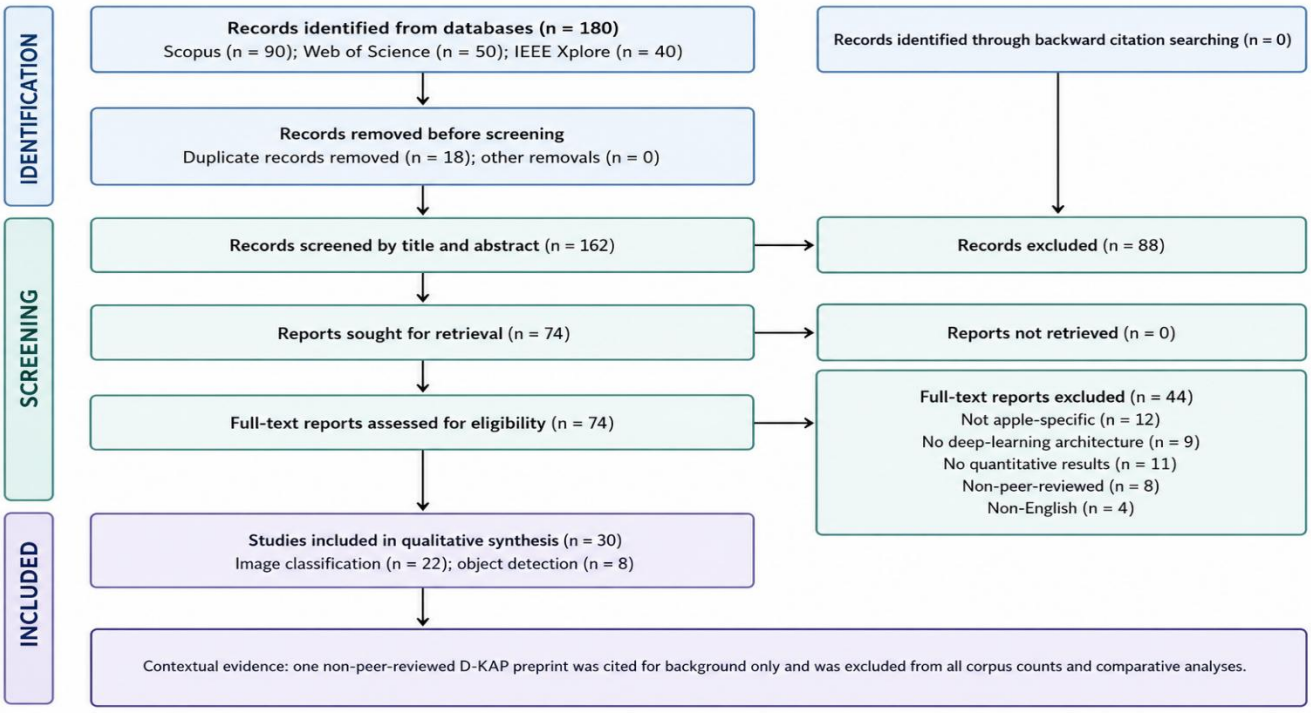

Fig. 3. PRISMA 2020 flow diagram for identification, screening, eligibility assessment, and inclusion.

TABLE VI. FULL-TEXT EXCLUSION SUMMARY

Code	Primary reason for exclusion	Reports (n)	Interpretive note
FT1	Apple-specific experimental results could not be separated	12	Aggregate exclusion category retained from screening
FT2	No deep-learning architecture was evaluated	9	Aggregate exclusion category retained from screening
FT3	No quantitative experimental results were reported	11	Aggregate exclusion category retained from screening
FT4	Non-peer-reviewed publication	8	Includes D-KAP [30] as contextual evidence only
FT5	Non-English publication	4	Aggregate exclusion category retained from screening
Total	Full-text reports excluded	44	Aggregate count retained

A statistical meta-analysis was not performed due to large differences between included studies in dataset composition, class definitions, acquisition environments, training-validation-test splits, augmentation procedures, model implementations, and evaluation metrics. Classification accuracy and detection mAP were therefore not combined in a single effect-size model. A structured qualitative synthesis was conducted, and the numerical results were discussed in the framework of the original experimental settings.

IV. RESULTS

A. Descriptive Profile of the Included Corpus

Subsections IV-B to IV-F answer RQ1-RQ5 sequentially. The selected literature increased markedly after 2021: one included study was published in 2020, four in 2021, seven in 2022, four in 2023, six in 2024, six in 2025, and two in 2026. Classification accounts for 73.3% of the corpus (22/30), whereas detection accounts for 26.7% (8/30). The annual distribution is shown in Fig. 4.

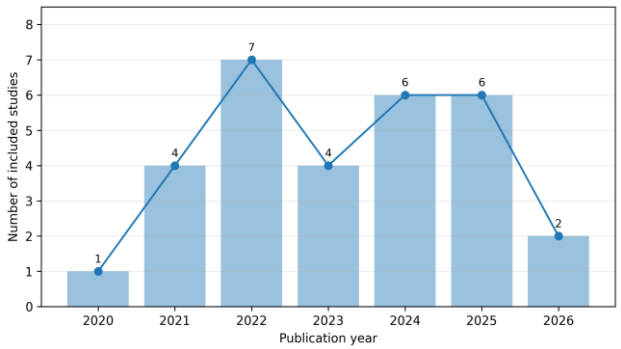

Fig. 4. Annual distribution of the 30 included peer-reviewed primary studies.

The corpus contains controlled PlantVillage images, datasets from the Plant Pathology competition, AppleLeaf9, special national or regional collections, self-constructed natural-scene datasets, and mixed datasets. The number of images varies over more than three orders of magnitude. Such heterogeneity rules out a simple model leaderboard and needs to be interpreted in the context of data conditions.

B. RQ1: Architectures and Task Paradigms

CNN-based classification remains dominant. EfficientNet, ResNet, DenseNet, Inception, RegNet, and Xception are commonly used because transfer learning can provide strong performance with limited training data [20]-[29], [31]-[40]. Dense and residual connections improve feature reuse and gradient propagation, whereas EfficientNet- and MobileNet-inspired designs reduce computational cost. RegNet-based studies also report strong performance across multiple disease classes. BLSENet [25] uses bilinear fusion and squeeze-and-excitation attention for fine-grained recognition.

A second major family comprises hybrid and transformer-based architectures. DBCoST utilizes local features from CNN and global context from Swin-Transformer [23]. CTPlantNet combines the outputs of SEResNeXt, EfficientNet-V2S, and Swin-Large [24]. To improve long-range representation, AppViT uses a lightweight transformer formulation [26]. Such models can improve the discrimination of diseases in complex backgrounds, but the computational burden is larger than that of compact CNNs.

Detection research is dominated by the YOLO family. YOLOX-ASSA-Nano replaces YOLOX-Nano with asymmetric ShuffleBlocks, attention, and separable convolution [48], Apple-Net improves YOLOv5 [47], and YOLOv5-Res adds multiscale residual blocks and lightweight feature fusion [45]. Recent detectors include auxiliary feature pyramids [41], RT-DETR components [42], attention modules [42], normalized Wasserstein distance [43], and specific small-object heads [43]. Improved Faster R-CNN is still relevant when two-stage localization is tolerable [44]. Fidan et al. [18] set up YOLOv11x for image-level classification, reporting classification metrics, but YOLO architectures are usually linked to detection; this is classified by experimental results, not architectural heritage. To summarize, the findings of RQ1 show that CNN classifiers are still the mainstream. However, hybrid transformer models and lightweight YOLO-based models are the two main emerging trends. Fig. 5 summarizes the task taxonomy.

C. RQ2: Datasets, Preprocessing, and Augmentation

Publicly available datasets dominate model development. PlantVillage provides a large, controlled benchmark, and Plant Pathology 2020/2021 provides expert-labeled field imagery with more variation in the illumination and background [2]. Specialized collections like AppleLeaf9 contain disease categories and imbalance patterns, while MSALDD was developed for lightweight detection in diverse natural scenes [48].

Image resizing and normalization are almost universal. Further pre-processing includes histogram equalization, contrast-limited adaptive histogram equalization, bilateral filtering, multi-scale retinex, edge enhancement, background suppression, and lesion segmentation [28], [29]. BAM-Net employs BF-MSRCR to highlight color and texture before classification [29]. Preprocessing can improve the contrast, but over-enhancement may mislead the natural distributions of color and reduce the transferability.

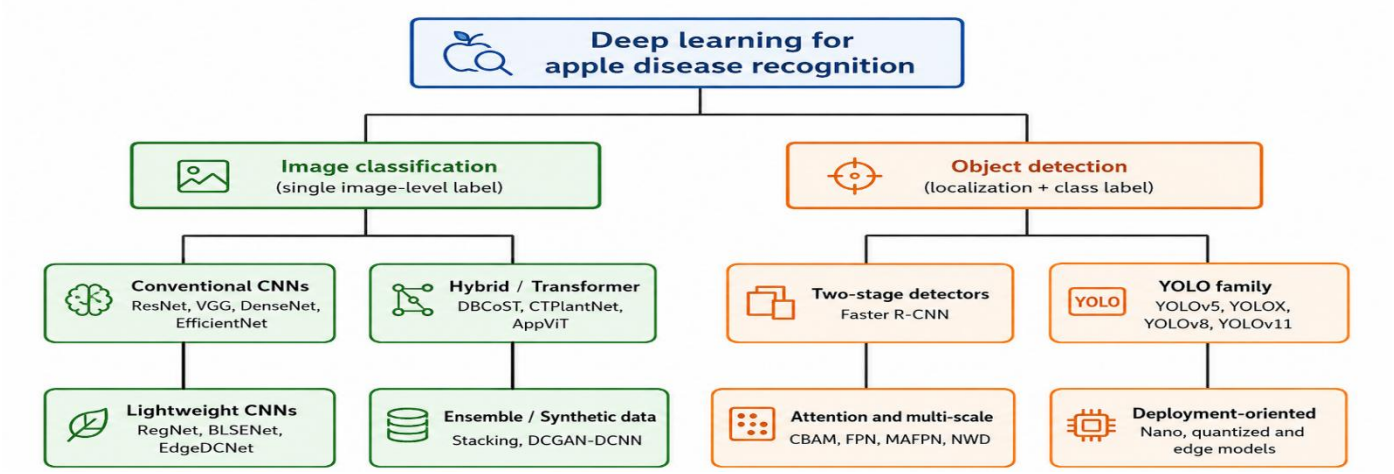

Fig. 5. Taxonomy of deep-learning approaches represented in the selected corpus.

Augmentation is widely used to address limited data and class imbalance through rotation, flipping, translation, scaling, cropping, photometric variation, blur, and noise. Tian et al. used CycleGAN to synthesize anthracnose and ring-rot symptoms [36], while Ayaz et al. combined DCGAN-generated samples with a deep CNN [35]. Fidan et al. showed that balancing effects are architecture-dependent: physically inspired augmentation benefited YOLOv11x, whereas EfficientNet-B1 performed best without the same intervention [18]. Augmented sample counts were not treated as equivalent to independent biological observations because lineage overlap can increase leakage risk.

The largest performance threat is the mismatch between development data and deployment conditions. Lin et al. reported a decline from 95.74% under controlled conditions to 66.18% in a real-field setting [32], a 29.56-point reduction that precludes treating benchmark accuracy as evidence of orchard readiness. Agronomic reporting is also uneven: optimized RegNet experiments include multiple diseases on the same leaf and complex acquisition conditions [27], whereas cultivar, season, disease severity, diagnostic authority, and co-occurrence are not consistently documented across the corpus. RQ2 therefore shows that dataset realism, biological annotation, class balance, and augmentation design are central determinants of transferability.

D. RQ3: Reported Performance and Evaluation Practice

Classification studies report accuracy values from 91.0% to 99.99%, whereas detection studies report mAP@0.5 values from 82.1% to 99.99%. These ranges are descriptive extrema from heterogeneous experimental settings and are not pooled estimates or confidence intervals. Differences in dataset realism, evaluation-set size, split design, and class composition preclude a universal architecture ranking. Validation design, test-set size, fold variability, and confidence intervals were considered when reported by the primary studies; unavailable uncertainty information was not reconstructed. Fig. 6 visualizes the reported distributions, while detailed classification and detection settings are summarized in Tables VII and VIII.

Accuracy is reported by 21 out of the 22 classification studies, but precision, recall, and F1-score are reported less consistently. Fig. 7 summarizes: All detection studies provide mAP@0.5. Only two studies provide an F1-score. This pattern is problematic for imbalanced data sets, because the overall accuracy can hide the minority-class failure. Besides the overall accuracy, the macro-averaged precision, recall, F1-score, per-class confusion matrices, balanced accuracy, AUC, and calibration measures should be reported. Detection studies should also report performance on small objects, classwise average precision, false-positive analysis, and mAP at multiple IoU thresholds. RQ3 therefore indicates that high point estimates are common, but metric completeness and evaluation context remain insufficient for direct cross-study ranking.

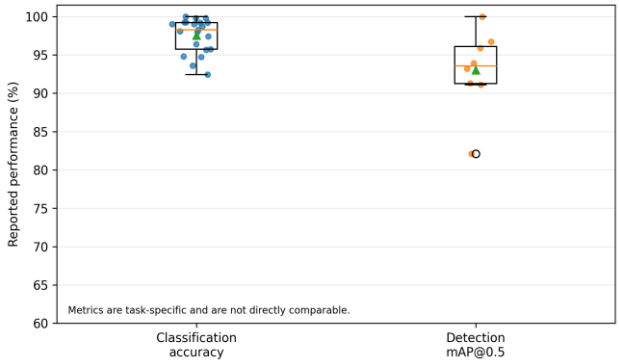

Fig. 6. Distribution of reported classification accuracy and detection mAP@0.5. Values are descriptive and not directly comparable across tasks or datasets.

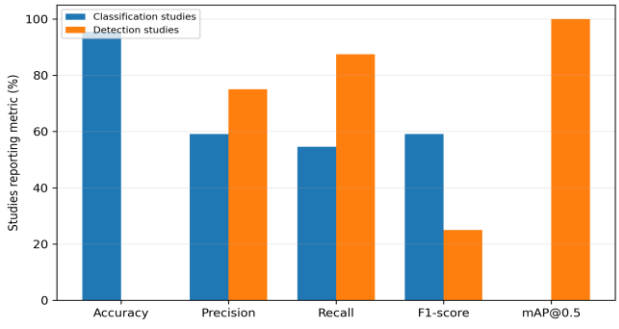

Fig. 7. Completeness of metric reporting across the 22 classification and eight detection studies.

TABLE VII. CLASSIFICATION STUDIES AND REPORTED EXPERIMENTAL SETTINGS

Ref.	Year	Model	Dataset/images	Training configuration	Main result (%)	Key observation
[18]	2026	YOLOv11x	AppleLeaf9; 14,582	SGD; LR 0.01; batch 64; 100 epochs; Momentum=0.9; WD=0.01	Acc 99.18; P 99.17;F1 99.17;R 99.18	Class-imbalance scenarios and physical augmentation.
[19]	2026	EdgeDCNet	PP2020/2021-derived set	Adam; 500 epochs; 10-fold CV	Acc 94.80	36.2 KB model; 162.2 KB RAM; 463.8 ms; 14 mW; edge quantization evaluated.
[20]	2025	Fine-tuned EfficientNet-B0	PlantVillage; 54,448	AdaMax; LR 0.001; batch 32; 20 epochs	Acc/F1/R 99.78; P 99.79	High accuracy with compact transfer learning.
[21]	2025	ResNet-9	TPD; 4,447	Adam; LR 0.011; batch 32; 100 epochs; WD=0.00018; Momentum = 0.4	Acc 97.41; P 96.40; F1 95.70; R 97.09	SHAP explanation and significance testing.
[22]	2025	Xception	Apple leaf subset; 12,000	Adam; LR 4×10^{-5}; batch 32	Acc/P/F1/R 99.0	Web application and visual explanations.
[23]	2024	DBCoST	PP2021; 18,632	AdamW; LR 10^{-4}; batch 128; 100 epochs ; WD=0.05	Acc 97.32; P 97.33; F1 97.36; R 97.40	Primary PP2021 result; additional AppleLeaf9/mixed-disease experiment reached Acc 98.06.
[24]	2024	CTPlantNet	PP2020/2021; 3,526/18,632	RectifiedAdam; LR 0.0007; batch 64	Acc 98.28 / 95.96 P 98.67/ 97.55	CNN-transformer ensemble; 5-fold validation.
[25]	2024	BLSENet	Apple leaf set; 14,582	Adam; LR 10^{-4}; batch 16; 200 epochs	Acc 93.58	Lightweight bilinear fusion and SE attention.
[26]	2024	AppViT	PP2021; 16,093	AdamW; LR 0.002→0.000125; batch 32; Epochs=65	Acc 96.40; P 96.70; F1 96.30; R 95.90	Lightweight vision transformer.
[27]	2024	Optimized RegNet	2,609 / 13,752	Ranger or Adam; batch 16; 50 epochs	Acc 99.23	Multiple diseases and complex backgrounds.
[28]	2023	InceptionV3 / VGG-16	PlantVillage; >18,000	Not completely reported	Acc 92.42 / 91.53	Comparison of pretrained CNNs.
[29]	2023	BAM-Net	Complex-background set; 3,500	AdamW; LR 10^{-3}; batch 64; 50 epochs	Acc 95.64; P 95.62 ; F1 95.25; R 95.89	BF-MSRCR, coordinate attention, multiscale refinement.
[31]	2023	Conv-3 DCNN	3,171	Adam; LR 10^{-4}; batch 50; 1,000 epochs	Acc 98.0; P 98.0 ;F1 97.0; R 97.0	Apple disease CNN with transfer comparison.
[32]	2022	BM + CMSFF + CA	PlantVillage and real-field AFD	SGD; LR 0.1→0.01; batch 128; Epochs=150	Acc 95.74 / 66.18	Strong controlled-to-field degradation.
[33]	2022	AFD-Net	PP2020	Adam; LR 5×10^{-6}→5×10^{-3}; 5-fold CV; Epochs=140	Acc 98.70; P 97.0; F1 89.0	Multiclass foliar disease classification.
[34]	2021	Stacking ensemble	10,000	Not fully reported	F1 98.05	Ensemble learning; incomplete training details.
[35]	2021	DCGAN-DCNN	319 expanded to 4,000	Adam-family; LR 0.001–0.002; batch 55; epochs 10 to 35	Acc 99.99	Synthetic-data benefit; redundancy risk.
[36]	2021	Multi-scale Dense Inception-ResNet-V2	12,714	LR 10^{-4}; batch 16; 4,000 epochs	Acc 94.74; P 94.71; F1 94.86; R 95.03	CycleGAN and multiscale dense features.
[37]	2022	Lightweight RegNet	8,510	Adam; LR 10^{-4}; batch 16; 50 epochs	Acc 99.23; P 99.24; R 99.16	Small and imbalanced dataset.
[38]	2022	CNN-C	200,000 augmented samples	16 epochs; dropout 0.25–0.5	Acc 99.20; R 99.70	Augmented sample count; not equivalent to 200,000 independent biological observations.
[39]	2021	EfficientNet-B7 / DenseNet	10,000 augmented samples	40 epochs	Acc 99.80 / 99.75	Edge/blur augmentation; augmented samples are not independent biological observations.
[40]	2020	ResNet-18/34/50	PlantVillage	Adam/SGD; LR=0.0001 to 0.01; Epochs=30 to 100; Momentum=0.9	Acc 99.0	Limited-data comparison across residual networks.

TABLE VIII. DETECTION STUDIES AND REPORTED EXPERIMENTAL SETTINGS

Ref.	Year	Model	Dataset/images	Training configuration	Main result (%)	Key observation
[41]	2025	DMN-YOLO	6,301	AdamW; LR 0.1; batch 16; 300 epochs; Momentum=0.937; WD=0.0005	mAP50 93.2; P 88.8;F1 88.3; R 87.9	MAFPN, RT-DETR decoder, P2 head, NWD loss.
[42]	2025	ELM-YOLOv8n	13,218	SGD; LR 0.01; batch 16; 100 epochs	mAP50 96.7; P 94.5; F1 94.0; R 93.6	44.8% fewer parameters and 39.5% lower computation.
[43]	2025	E-YOLOv8	6,986	SGD; LR 0.01; batch 32; 300 epochs	mAP50 93.9; P 90.1; R 89.6	GhostConv, C3 fusion, CBAM, FPN; 1.8 M parameters.
[44]	2023	Improved Faster R-CNN	4,182	LR 0.0025; Soft-NMS	mAP50 91.3	Two-stage high-precision detection.
[45]	2024	YOLOv5-Res	4,863	Adam; LR 0.01; batch 2; 150 epochs	mAP50 82.1; P 81.4; R 76.9	Residual multiscale block; small batch may limit stability.
[46]	2022	DF-Tiny-YOLO	1,404	LR 0.001; batch 64; momentum 0.9; WD=0.0005	mAP50 99.99; R 100	Outlying result on a small, specific dataset.
[47]	2022	Apple-Net	12,500	Adam; LR 0.01; batch 4; 100 epochs	mAP50 95.9; P 93.1; R 94.4	Improved YOLOv5 with efficient feature fusion.
[48]	2022	YOLOX-ASSANano	MSALDD; 3,209	CIoU loss; incomplete hyperparameter report	mAP50 91.08; P 89.75 R 83.63	0.83 MB lightweight natural-scene detector.

E. RQ4: Hyperparameters, Validation, and Reproducibility

Training conditions vary substantially: learning rates range from approximately 10^-6 to 10^-1, batch sizes from 2 to 128, and training duration from 16 to 4,000 epochs. Adam, AdamW, AdaMax, Ranger, RectifiedAdam, and SGD are reported. Six studies (20.0%) omit at least one central setting such as optimizer, learning rate, batch size, or epoch count. Validation ranges from single holdout splits to five- or ten-fold cross-validation, and several studies do not clarify whether images from the same source tree or augmentation lineage were separated. Random image-level splits may therefore permit leakage when near-duplicate augmented samples occur in both training and testing. Orchard- or acquisition-session-level splitting, together with random seeds, software versions, pretrained weights, image resolution, early-stopping rules, augmentation probabilities, hardware, and code/data identifiers, would improve reproducibility. RQ4 therefore identifies incomplete configuration reporting and heterogeneous validation as persistent barriers to replication.

F. RQ5: Deployment Evidence and Operational Constraints

Deployment evidence was operationalized on four qualitative levels: D0, benchmark performance only; D1, efficiency-aware reporting such as parameters, FLOPs, model size, or theoretical speed; D2, prototype execution in a web, mobile, embedded, or hardware-relevant environment with at least one operational metric; and D3, target/resource-constrained hardware evaluation under natural or operational conditions with practical efficiency metrics and field validation. EdgeDCNet provides D3-level evidence through a 36.2 KB model, 162.2 KB runtime memory, 463.8 ms inference, and 14 mW power consumption [19]. YOLOX-ASSANano reports 122 FPS and a 0.83 MB model [48], while ELM-YOLOv8n and E-YOLOv8 provide strong D1-D2 efficiency evidence [42], [43].

Most classification studies do not evaluate field latency, battery consumption, network dependency, sensor variability, or failure modes. Web-based deployment [22] improves accessibility but may depend on connectivity and server resources. On-device inference can reduce latency and data transmission, yet quantization, pruning, and compression may disproportionately reduce minority-class sensitivity; classwise degradation should therefore accompany global metrics.

Similarly, evidence of explainability is limited. SHAP-based analysis is presented in [21] and visual explanations in a web system in [22] by Shafik et al. and Aksoy et al., respectively. “Saliency maps are not causally reliable per se. Scores should be given for localization, robustness and relevance to plant pathology. Calibrated confidence and uncertainty estimates should aid expert referral of ambiguous cases. RQ5 thus suggests that practical readiness is driven by hardware efficiency, field robustness, uncertainty handling, and clinically/agronomically meaningful explanations, not solely by predictive accuracy.

V. DISCUSSION

A. Cross-Study Interpretation

The results show that architectural innovation can help improve apple disease recognition, but the performance is determined by the complete experimental system, not by the network itself. Dataset curation, image acquisition, class balance, split design, augmentation, resolution, annotation, optimization, and metric selection. Thus, near-perfect performance on controlled datasets does not suffice to demonstrate field reliability. Classification as a benchmark task is mature, but limited in operation when multiple diseases or lesion locations need identification. Detection is more informative for targeted treatment because it localizes the symptoms, but it requires expensive bounding-box annotation and is still sensitive to small lesions and background clutter. Instead of treating them separately, a practical pipeline may combine fast detection, fine-grained classification, severity estimation, and temporal monitoring. The synthesis also indicates that, in general, larger datasets stabilize training, but size alone is not a decisive factor. A small data set can achieve a high score if the task is visually simple or the split is favorable, while a larger field data set can lead to lower but more credible performance. Sample count of the test set is less important than its diversity and independence. Similarly, synthetic

augmentation can also improve minority-class representation, but may inflate the results if the generated images are highly redundant or if the generator is trained on the same images that are subsequently used for evaluation.

B. Research Gaps and Future Directions

The principal evidence gaps and required validation steps are summarized in Table IX, and Fig. 8 links these gaps to a staged data-model-evaluation-deployment roadmap.

TABLE IX. RESEARCH GAPS AND RECOMMENDED DIRECTIONS

Gap	Current limitation	Recommended direction	Required validation
Real-world data	Controlled backgrounds and limited environmental diversity	Multi-orchard, multi-season, multi-device datasets with cultivar, severity, weather, and location metadata.	Cross-orchard testing and external validation.
Evaluation	Accuracy-dominated reporting and incomparable splits	Task-specific minimum metric sets, calibration, confidence intervals, classwise results, and robustness testing.	Standard benchmark protocol and public leaderboards.
Generalization	Large controlled-to-field performance decline	Domain adaptation, self-supervised pretraining, few-shot learning, and style-robust augmentation.	Unseen orchard, season, and device evaluation.
Reproducibility	Missing hyperparameters, seeds, code, and split details	Complete experimental checklists, public code, fixed dataset versions, and leakage-resistant splitting.	Independent reproduction studies.
Interpretability	Unvalidated saliency maps and overconfident predictions	Pathologist-informed explanations, uncertainty quantification, calibration, and reject options.	Human-in-the-loop diagnostic evaluation.
Deployment	Limited latency, memory, and energy reporting	Quantization-aware training, pruning, edge accelerators, offline inference, and energy benchmarking.	Accuracy-efficiency Pareto analysis on target hardware.
Disease scope	Single-label disease categories and weak severity modeling	Multi-label recognition, lesion segmentation, severity estimation, and progression tracking.	Decision support linked to treatment thresholds.
Data governance	Inconsistent annotations and unclear reuse conditions	Annotation guidelines, provenance, licensing, privacy, and FAIR dataset documentation.	Auditable data and model cards.

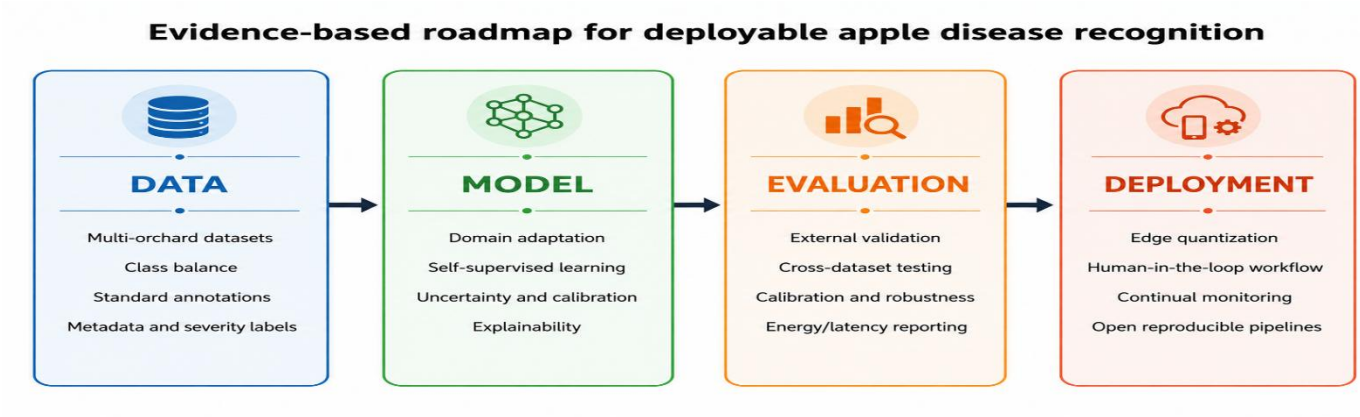

Fig. 8. Evidence-based roadmap for robust and deployable apple disease recognition.

C. Threats to Validity

There are still some threats to validity. The search was limited to English-language publications and generic apple-disease terminology and was conducted in Scopus, Web of Science Core Collection, and IEEE Xplore. Thus, CAB Abstracts, AGRICOLA, and exhaustive disease-specific or segmentation terms were not included, and relevant regional or otherwise indexed studies may have been missed. The review was not prospectively registered, which limits the ability to independently verify that there was no protocol drift during the development of the review. Screening and extraction were undertaken by a single lead reviewer and checked by a second author rather than by two independent teams. Results were extracted, not re-implemented, and dataset names, number of samples, definitions of splits, and reporting of uncertainty were inconsistent across studies. These risks were mitigated through the application of explicit eligibility criteria, separation of classification and detection, an audit record, domain-based methodological appraisal, and explicit documentation of missing information. The lack of a common benchmark, however, and the reporting of complete uncertainty preclude formal meta-analysis and causal claims of architectural superiority. In addition, the item-level list of full-text exclusions was no longer available in an independently verifiable form during revision; it was therefore not reconstructed retrospectively, and only the retained aggregate exclusion categories are reported.

VI. CONCLUSION

This systematic literature review synthesizes 30 peer-reviewed deep learning studies on apple disease recognition published between 2020 and 2026: 22 studies on image classification and eight studies on object detection. One preprint was included as contextual evidence only. The classification accuracy reported is in the range of 91.0% to 99.99%, and detection mAP@0.5 is in the range of 82.1% to 99.99%; these are descriptive and still depend on the realism of the dataset and the evaluation design. CNNs are still dominant, but the methodological landscape is enriched by transformer hybrids,

attention, multiscale fusion, class-imbalance-aware training, synthetic augmentation, and lightweight YOLO variants.

The primary takeaway is that good benchmark performance does not mean orchard reliability. Controlled background datasets can produce nearly ideal numbers, but there can be substantial degradation due to field transfer. Barriers to reproducibility and practical adoption remain in the form of partial hyperparameter reporting, heterogeneous validation, absence of uncertainty analysis, limited external testing, and scarce evidence of hardware-level deployment.

Future work should focus on standardized multi-orchard datasets, leakage-protected splits, complete experimental reporting, calibrated and interpretable outputs, cross-dataset evaluation, agronomic metadata, and efficiency metrics on target hardware. Robust, interpretable, and resource-aware decision support is more informative for real orchards than optimization of a single benchmark score.

When Calibrated Detectors Meet New Attacks: Per-Category Reliability of Machine-Learning Intrusion Detection Under Distribution Shift

Khalid Alalawi
College of Computer Science and Engineering (CCSE), Taibah University, Medina 42353, Saudi Arabia

***Abstract*—Machine-learning intrusion detectors are usually reported with accuracy or F1 on a single train and test split, and their confidence scores are often read operationally as probabilities without an explicit calibration check. We test that assumption. We measure the reliability of the predicted probabilities of three classifiers, logistic regression, random forest, and XGBoost, on two benchmarks, NSL-KDD and UNSW-NB15, in two settings: when training and test data share a distribution, and under the shift each benchmark's official split already contains. In distribution, all three detectors are well calibrated, with top-label expected calibration error at most 0.03. Under shift, the outcome depends on its content. On NSL-KDD, whose test set contains attack types absent from training, top-label calibration error rises from at most 0.007 in distribution to between 0.170 and 0.209, and the error is largest on the benign and Remote-to-Local classes, so unfamiliar attacks are labeled normal with high confidence. On UNSW-NB15, whose split keeps the same attack categories, the error stays far smaller, between 0.025 and 0.068, even though a domain classifier detects a clear shift on both benchmarks. Recalibrating on training-distribution data does not reliably transfer to the shifted test set. Supervised target-domain recalibration on a held-out labeled sample from the shifted distribution substantially reduces the calibration error and recovers much of the minority-class recall on NSL-KDD. Most of the aggregate top-label ECE reduction is obtained with about one hundred labeled target samples. This remedy requires labeled observations from the shifted environment and therefore describes reliability after target labels become available, not reliability against attacks that remain entirely unseen. A decision-curve analysis and expected-cost comparison show that an uncalibrated score used at its nominal cost threshold is very costly, and that both recalibration and a target-tuned threshold reduce operating cost, with recalibration additionally improving the multiclass probabilities. A leave-one-attack-out study reproduces the failure and indicates that the attack family for which performance degrades substantially is the one least separable from benign traffic, not the one most distinct from the other attacks.**

Keywords*—Intrusion detection; probability calibration; distribution shift; expected calibration error; decision curve analysis; class imbalance; network security

I. Introduction

Network intrusion detection is now built mostly on supervised machine learning. Detectors trained on flow records reach high accuracy on the public benchmarks, and reported accuracy above ninety-five percent is common [1], [2], [3]. Accuracy is rarely the property that decides whether a detector can be deployed. A detector returns a label and a score, and an analyst has to decide which alerts to act on and in what order. That decision uses the score as a probability. If the score reads 0.9, the operator treats the flow as very likely to be an attack. If it reads 0.5, the operator treats it as uncertain. A probability that does not mean what it says leads to wrong triage, to thresholds set in the wrong place, and to alert volumes that do not reflect real risk.

The property that makes a probability mean what it says is calibration. A detector is calibrated when, among the events it assigns probability 0.8, about eighty percent are attacks. Calibration is separate from accuracy. A model can rank cases well, and so score high on the area under the receiver operating characteristic curve, while its probabilities are systematically too high or too low [4], [5]. Calibration and predictive uncertainty have been studied at length for modern deep networks [4], [6], [7], [8], and calibration is known to degrade when test-time data differ from training data [9]. In intrusion detection, this has begun to receive attention, including work on uncertainty and out-of-distribution behavior [10], calibrated cost-sensitive alerting [11], and concept drift [12], but it is still far less standard than accuracy reporting, and where probabilities are reported, they are seldom checked per class or under shift.

Two facts make this gap matter. First, intrusion detection datasets are heavily imbalanced [13], so aggregate figures are dominated by the common classes and hide the behavior of the rare ones [14], [15]. Second, and more importantly here, deployment is not the setting in which these detectors are usually evaluated. A model in production meets traffic and attacks that were not in its training data, which is a distribution shift. The standard benchmark protocol trains and tests on a single split of one dataset, so it reports the behavior of a detector on data that resemble its training data. Whether the calibration measured that way survives the shift a real deployment faces is the question this study reviews.

We study it directly, training three standard classifiers on two benchmarks and measuring their calibration in two regimes. The first is in-distribution: a held-out split of the training file serves as the test set. The second is shifted: the benchmark's official test file is used instead. Calibration is reported per attack category, not in aggregate alone. Two further questions follow: whether standard recalibration repairs any failure we find, and what that failure costs the decisions an operator makes.

The results are as follows. In distribution, all three detectors are already well calibrated, so the calibration problem is invisible under the usual protocol. Under shift, the outcome

depends on the kind of shift. When the shifted test set contains attack types absent from training, calibration degrades sharply, and the error concentrates on the benign class, so novel attacks are confidently passed as normal. When the shift keeps the same attack categories, calibration degrades only mildly, even though a domain classifier detects a clear shift in both cases. Recalibrating on training-distribution data does not fix the failure. Recalibrating on a held-out labeled sample from the shifted distribution does, and it recovers minority-class recall.

This study makes four contributions. The first is to show that the good calibration of machine-learning intrusion detectors is a property of same-distribution testing and does not carry over to the shift introduced by deployment. The second contrasts two kinds of shift and finds that the kind involving unfamiliar attacks, rather than measured distance between distributions, is associated with failure, and supports this with a controlled leave-one-attack-out study. The third evaluates supervised target-domain recalibration on a held-out labeled sample from the target environment and measures how calibration changes as the labeled sample is reduced. The fourth uses decision-curve analysis and an expected-cost comparison to separate the operating benefit of calibration from that of threshold placement. The remainder reviews related work in Section II, describes data and methods in Section III, reports results in Section IV, discusses them in Section V, and concludes in Section VI.

II. Related Work

A. Machine Learning for Network Intrusion Detection

Supervised classification of network flows has been the dominant approach to intrusion detection for two decades, and several surveys map the methods and datasets in use [1], [2], [16]. Recent systematic reviews and a meta-analysis extend this to current machine- and deep-learning methods, datasets, and validation practice [15], [17], [18]. NSL-KDD [19] and UNSW-NB15 [20], [21] are among the most used benchmarks, and CIC-IDS2017 [22] is a common alternative. Ring et al. [13] review the available datasets and their properties. On tabular flow features, tree ensembles lead most comparisons, with random forests [23] and gradient-boosted trees such as XGBoost [24] as the usual strong baselines, and logistic regression a common linear reference, using scikit-learn [25]. Class imbalance recurs across these datasets and is handled with resampling, for example, the synthetic oversampling of Chawla et al. [14], or with cost-sensitive training [26], [27]. This body of work reports detection quality with accuracy, F1, or the area under the receiver operating characteristic curve. The trustworthiness of the predicted probabilities is not usually part of the evaluation, and robustness concerns such as adversarial evasion are treated separately again [28].

B. Confidence Calibration and Predictive Uncertainty

A predicted probability is calibrated when it matches the observed frequency of the event. Platt scaling fits a logistic function to a classifier's scores [29], and isotonic regression fits a monotone step function without a parametric form [30]. Niculescu-Mizil and Caruana [5] found that maximum-margin methods such as boosted trees and support vector machines push their predicted probabilities away from 0 and 1, giving a characteristic sigmoid distortion, while naive Bayes has the opposite bias and pushes them toward 0 and 1. Guo et al. [4] showed that modern neural networks are badly miscalibrated and that a single temperature on the logits restores calibration cheaply. Minderer et al. [7] revisited this for newer architectures and found that several recent models, in particular non-convolutional ones, can be both accurate and well calibrated, which tempers that trend, and Kull et al. [6] extended parametric calibration to the multiclass case. The quality of a probability is measured with the expected calibration error [31], for which debiased estimators exist [32], and the Brier score [33], [34]. These calibration tools sit within a wider effort to quantify predictive uncertainty in deep networks, which [8] surveys. These tools were developed and are mostly applied to fixed models on same-distribution test data.

C. Distribution Shift and Out-of-Distribution Behavior

A model deployed in the field meets data drawn from a different distribution than its training data, a situation studied under dataset shift and concept drift [12], [35], [36], [37]. Ovadia et al. [9] measured predictive uncertainty under shift and found that accuracy and calibration both degrade as the shift grows, and that methods calibrated in distribution do not stay calibrated once the data move. Minderer et al. [7] later reported the same decay for recent image classifiers, though some architectures resisted it and in-distribution calibration tended to track out-of-distribution calibration. Detecting that a shift has occurred is itself a task. Rabanser et al. [38] evaluated methods for it, one of which trains a classifier to separate source from target samples, a device grounded in the domain-divergence theory of Ben-David et al. [39]. Hendrycks and Gimpel [40] studied flagging inputs a model should not be confident about. In intrusion detection, the shift is concrete, because new attacks and new traffic appear after a detector is trained. Recent work addresses this directly: Talpini et al. [10] study uncertainty quantification and out-of-distribution detection for ML-based intrusion detection and show conventional networks assign high confidence to unknown-class inputs, and Shyaa et al. [12] survey concept- and feature-drift-aware detection. The guidance of Arp et al. [41] on evaluation pitfalls in security machine learning is still often not followed.

D. Decision-Analytic Evaluation

Whether a probability is useful depends on the decision it informs and on the relative cost of the two kinds of error. Cost-sensitive learning weights errors by their cost [27]. Decision curve analysis, introduced by Vickers and Elkin [42] and set out further by Vickers et al. [43], evaluates a model by its net benefit across the operating thresholds an operator might use, and needs no external cost figure specified in advance. It is standard in clinical prediction. Closest to our operating-cost analysis, Youssef [11] presents a streaming intrusion detector that maps a change-point posterior through isotonic calibration to a calibrated conditional attack probability and derives its alerting threshold from operator-specified costs and budgets, reporting isotonic-calibration Brier-score reductions across several benchmarks. That work targets a single binary alerting decision on streaming data. We complement it with a per-category multiclass calibration analysis under an official unseen-attack split, and use decision-curve analysis to separate the operating value of calibration from that of threshold placement. Most

directly, Ganesh et al. [44] build a two-stage generative-AI detector for cloud security and evaluate its calibration on NSL-KDD and UNSW-NB15, comparing Platt, isotonic, Beta, and temperature scaling by expected calibration error and reporting per-class calibration curves and decision-curve analysis, the closest prior application of these tools to intrusion detection on these benchmarks.

E. Positioning

These lines of work are converging but remain partial. Intrusion-detection studies report detection quality and, increasingly, uncertainty, but rarely the per-class reliability of the probabilities under an official unseen-attack split. The most closely related work [44] compares these calibration methods and reports decision-curve analysis on the same benchmarks, but it fits its calibrators on a training-derived validation set and reports test-set calibration as one part of evaluating a proposed detector. It does not contrast in-distribution against shifted calibration, compare recalibration fitted on the source against recalibration fitted on a target sample, or report per-category reliability under the shift. The calibration literature measures reliability on fixed same-distribution data. The shift literature shows calibration is fragile under shift, largely on image and text models, without separating the kinds of shift a security setting produces. This study measures the calibration of intrusion detectors per attack category, in distribution and under the shift the benchmarks encode, distinguishes shift that introduces new attacks from shift that does not, tests supervised target-domain recalibration and measures how its results change as the labeled target sample is reduced, and expresses the result as an operating cost, separating the contribution of calibration from that of threshold adaptation. Post-hoc calibration also rests on assumptions that matter under shift. A calibrator fitted on source-domain validation data depends on the score-label relationship transferring to the target domain, an assumption that can fail when the distribution changes [9]. Target-domain fitting avoids that source-to-target transfer assumption but requires labeled observations from the shifted environment. Class-wise isotonic regression can also have little data from which to estimate a mapping for very rare classes. Threshold tuning can lower binary operating cost without correcting the multiclass probability vector, so calibration and threshold adaptation are evaluated separately here.

III. Materials and Methods

A. Datasets and Shift Protocol

We use two public benchmarks. NSL-KDD [19] is the cleaned successor to KDD Cup 1999. Its training file holds 125,973 records and its official test file holds 22,544 records, each with forty-one features. Three of these features, the protocol, service, and flag fields, are categorical. Attack labels are grouped into the four standard categories: Denial-of-Service, Probe, Remote-to-Local, and User-to-Root, which, with normal traffic, gives five classes. UNSW-NB15 [20] provides forty-nine flow and packet features. We use the partitioned release analyzed by Moustafa and Slay [21], which holds 175,341 training and 82,332 test records over forty-two analysis features, three of them categorical (the protocol, service, and state fields), across ten classes, one benign and nine attack families. Both are heavily imbalanced. In NSL-KDD, the rarest class, User-to-Root, has sixty-seven test instances by our count of the official test file. In UNSW-NB15, the rarest, Worms, has forty-four.

The official train and test partitions of these benchmarks are not two samples of one distribution. NSL-KDD places attack types in the test set that do not occur in training, so its split contains a shift by construction, and we refer to this as an unseen-attack shift. UNSW-NB15 keeps the same attack categories on both sides but re-partitions the traffic, a milder shared-taxonomy shift. Moustafa and Slay [21] report that these official partitions share the same distribution, non-linear and non-normal, on a Kolmogorov-Smirnov, skewness, and kurtosis analysis, so the separability our domain classifier finds on UNSW-NB15 reflects feature-space distance within a split its designers describe as matched, and it is against that baseline that the mild calibration change we observe on this benchmark should be read. We use both splits to create two regimes. For the in-distribution regime, we ignore the official test file and split the training file into three stratified parts: sixty percent for training, twenty percent for a calibration set, and twenty percent for an in-distribution test set. For the shifted regime, we train on the sixty-percent portion and test on the official test file. To study supervised target-domain recalibration, we set aside a stratified twenty-five percent slice of the official test file as a labeled calibration sample and evaluate on the remaining seventy-five percent. This is a supervised adaptation protocol. The calibrator has access to labels from the shifted distribution, while the remaining seventy-five percent is kept separate for evaluation.

B. Classifiers and Preprocessing

We compare three classifiers spanning the families common in intrusion detection: logistic regression as a linear reference, a random forest of one hundred trees with a maximum depth of fifteen, and XGBoost with one hundred trees of maximum depth six and a learning rate of 0.1, using the histogram method. The settings are fixed rather than tuned, so the comparison reflects the effect of shift and recalibration rather than a hyperparameter search. Numeric features are standardized, and the three categorical fields are one-hot encoded, with categories seen fewer than twenty times folded into an infrequent group to keep the feature count bounded. The scaler and encoder are fitted on the training portion alone and applied without refitting to every other split, so no information from the calibration or test data reaches the model. This split-first order is the standard guard against the leakage that Arp et al. [41] identify as a frequent error.

C. Calibration Methods

We apply three post-hoc calibrators, each fitted on a held-out calibration set and applied to a separate evaluation set. Temperature scaling divides the logits by a single positive scalar chosen to minimize the negative log-likelihood on the calibration set [4], which softens or sharpens every probability without changing the ranking. Platt scaling fits a logistic function to each class score [29], applied here in a one-versus-rest decomposition [30]. Isotonic regression fits a monotone step function to each class score in the same scheme [30]. For the one-versus-rest calibrators, the per-class outputs are renormalized to sum to one. All three are fit on the whole calibration set without an internal cross-validation loop, which

makes the results deterministic given the data and the software versions we report. Temperature scaling operates on logits, which we take as the decision scores for logistic regression, the native margins for XGBoost, and the log of the clipped class probabilities for the random forest, which has no native logits.

D. Reliability Metrics

We measure calibration with the expected calibration error and the Brier score. The expected calibration error bins predictions and averages the absolute gap between mean confidence and accuracy within each bin [31], using fifteen equal-mass bins. The reliability diagrams are drawn with twelve bins. We report two forms. The top-label form uses the predicted class and its confidence, the usual multiclass definition. The class-wise form averages, over classes, the one-versus-rest error for each class, exposing miscalibration in a class even when that class is rarely the top prediction [6], [32]. The tabulated values use fifteen equal-mass bins, so each bin holds the same number of predictions. We also report the per-category one-versus-rest error. The Brier score we report is the total multiclass score: for each example, the sum over classes of the squared differences between the predicted probabilities and the one-hot label, averaged over examples [33]. Unlike ECE, it does not depend on confidence bins, so it provides a binning-independent check on overall probability quality. Because it reflects both calibration and refinement [34], it is read alongside ECE and macro-F1 rather than as a pure calibration measure.

E. Shift Severity

To measure how far the shifted test set stands from the training distribution, independently of any detector, we train a domain classifier to separate in-distribution samples from shifted samples and report the area under its receiver operating characteristic curve from three-fold cross-validation. A value near 0.5 means the two are indistinguishable, and a value near one means they are fully separable [38], [39]. This gives a single detector-independent number for the size of each shift. It measures how far apart the two distributions are, not which features differ or whether the conditional label distribution changes, and we treat values across datasets as indicative rather than directly comparable. Table I summarizes the two datasets and the measured severity of each shift. The domain classifier is a random forest with 100 trees and a maximum depth of 12. Its inputs use the training-fitted scaler and one-hot encoder described in Section III-B. For each seed, 5,000 observations are sampled without replacement from each domain to form a balanced 10,000-record dataset. AUROC is averaged over three stratified folds with shuffling, with the same seed used for sampling, the classifier, and cross-validation.

F. Decision-Curve Analysis and Expected Cost

To express calibration in operational terms, we reduce the problem to attack versus benign and vary the operating threshold. For a threshold t, a flow is flagged when its attack probability is at least t, and the net benefit is TP/N minus (FP/N) times the odds t/(1-t), where N is the number of evaluated records [42], [43]. We plot net benefit against t for the uncalibrated and the recalibrated detector, alongside the reference policy of flagging every flow. We also report an expected cost. Missing an attack is treated as r times as costly as a false alarm. The expected cost is (r times the false negatives plus the false positives) divided by N. To separate the value of calibration from that of threshold placement, we report four operating conditions at each r: the uncalibrated score at a fixed threshold of 0.5, the uncalibrated score at the decision-theoretic threshold 1/(1+r) [27], the uncalibrated score at a threshold tuned to minimize cost on the same labeled target sample used for recalibration, and the target-recalibrated probability at the decision-theoretic threshold. We report r equal to five, ten, and twenty.

G. Leave-One-Attack-Out Protocol

To test whether unfamiliar attacks are associated with calibration degradation, we build a controlled shift on UNSW-NB15. We remove one attack family from the training data so it is absent at training time and present, as a novel family, in the test set, and we measure the binary attack-versus-benign detector's recall on that family and the mean confidence with which it assigns the family to the benign class, on a held-out evaluation subset, using XGBoost with two hundred trees as the binary detector. We repeat this for several families. To characterize each family, we compute two feature-space separability scores, each the area under a random-forest classifier's curve under three-fold cross-validation with preprocessing fitted inside each fold: how separable the family is from the other attack families, and how separable it is from benign traffic. A low family-versus-benign score means the family resembles normal traffic.

H. Reproducibility

The core calibration metrics and the per-category results are reported as mean ± standard deviation (SD) over three seeds, 42, 7, and 123, which re-partition the training data and so give genuine seed variability. The target-sample-size sweep draws ten stratified labeled subsamples at each of the three seeds, thirty draws per size, and is reported as the mean with a ninety-five percent confidence interval. The uncalibrated baseline has no calibration subset to resample and is summarized as the mean and standard deviation over the three seeds. The reliability diagram and the per-category and decision-curve figures use seed 42 as an illustrative run. In the leave-one-attack-out study, the withheld and full models are fitted deterministically on the full training data, so the three seeds vary only the evaluation partition, giving the small spread reported. The calibrators are deterministic given the data. Both datasets are public [19], [20]. The experiments were run under scikit-learn 1.8.0 [25] and XGBoost 3.3.0 [24] with fixed data partitions and software versions.

TABLE I. DATASETS AND MEASURED SHIFT SEVERITY

Dataset	Classes	Train / Test	Shift AUROC
NSL-KDD	5	126.0k / 22.5k	0.87
UNSW-NB15	10	175.3k / 82.3k	0.81

IV. RESULTS

A. In Distribution, the Detectors are Already Calibrated

When the calibration and test sets are drawn from the training distribution, all three detectors are well calibrated on both benchmarks. On NSL-KDD, the top-label expected calibration error is 0.000 for XGBoost, 0.006 for the random

forest, and 0.007 for logistic regression. On UNSW-NB15, it is 0.011, 0.030, and 0.012 for the same three. These values are small, and they are what a study that trains and tests on one split would report. Under the usual protocol, there is no calibration problem to see.

B. *New-Attack Shift Substantially Degrades Calibration, While Same-Category Shift Degrades it Far Less*

The shift the official splits contain changes this, and not in the same way for the two benchmarks. Table II reports the shifted regime. On NSL-KDD, the top-label error rises to between 0.170 and 0.209 for every model, about thirty times the in-distribution value for logistic regression and the random forest, and from a value near zero for XGBoost. On UNSW-NB15, it stays far smaller, between 0.025 and 0.068, and the change is model-dependent, decreasing slightly for the random forest while rising modestly for the other two. A domain classifier separates in-distribution from shifted samples with an area under the curve of 0.87 on NSL-KDD and 0.81 on UNSW-NB15. The score is somewhat higher for NSL-KDD, but because the two values arise from different feature spaces, they describe source-target separability rather than giving directly comparable shift magnitudes. The difference in calibration degradation between the two benchmarks is far larger than the difference between these separability scores. What differs is the content of the shift: the NSL-KDD test set contains attack types absent from training, whereas the UNSW-NB15 split keeps the same attack categories.

The failure on NSL-KDD is not spread evenly across the classes. Table III gives the per-category error and recall for XGBoost. The error is largest on the benign class, at 0.203, and on Remote-to-Local, at 0.116, while the other categories stay low. This is the security concern in the result: under a shift that brings unfamiliar attacks, the detector hands many of them to the benign class with high confidence, and its recall on Remote-to-Local is only 0.08. A reliability diagram makes the over-confidence visible. In Fig. 1, the in-distribution points lie on the diagonal, and the shifted uncalibrated points fall well below it, meaning the accuracy in each confidence bin is far lower than the confidence. Fig. 2 places the two benchmarks side by side.

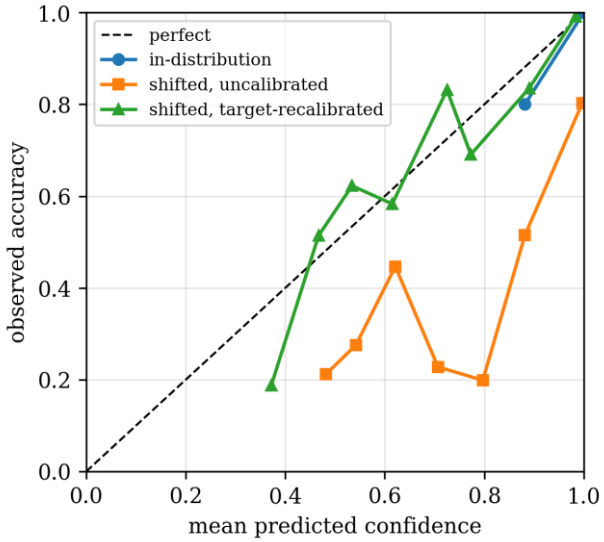

Fig. 1. Reliability of XGBoost on NSL-KDD (illustrative seed-42 result). In-distribution points lie on the diagonal; the shifted, uncalibrated points fall below it, indicating over-confidence; target-domain recalibration returns them toward the diagonal.

TABLE II. RELIABILITY AND DETECTION ON THE SHIFTED (OUT-OF-DISTRIBUTION) TEST SET, MEAN ± SD OVER THREE SEEDS

Data	Model	ECE in-dist	ECE OOD uncal.	ECE OOD temp (in-dist)	ECE OOD iso (target)	Brier OOD uncal.	Brier OOD iso (target)	F1 OOD uncal.	F1 OOD iso (target)

UNSW	XGB	0.011±0.001	0.043±0.001	0.053±0.002	0.009±0.002	0.280±0.001	0.216±0.001	0.497±0.020	0.519±0.005

LR, logistic regression; RF, random forest; XGB, XGBoost; ECE, top-label expected calibration error; OOD, shifted official-test evaluation; temp, temperature scaling; iso, isotonic regression; F1, macro-averaged F1. Values are mean ± SD over three seeds. An SD shown as 0.000 is smaller than 0.0005 at the displayed precision. Calibrators fit on in-distribution data do not repair the shifted failure; calibrators fit on a labeled target-domain sample do.

TABLE III. PER-CATEGORY ECE AND RECALL FOR XGBOOST ON THE SHIFTED NSL-KDD TEST SET, MEAN ± SD OVER THREE SEEDS

Category	ECE uncal.	ECE iso (target)	Recall unc./cal.
Normal	0.203±0.002	0.031±0.001	0.97±0.00/0.95±0.00
DoS	0.065±0.003	0.020±0.004	0.83±0.02/0.86±0.01
Probe	0.034±0.003	0.020±0.003	0.64±0.02/0.77±0.02
R2L	0.116±0.002	0.043±0.020	0.08±0.02/0.55±0.01
U2R	0.002±0.000	0.001±0.000	0.10±0.03/0.18±0.17

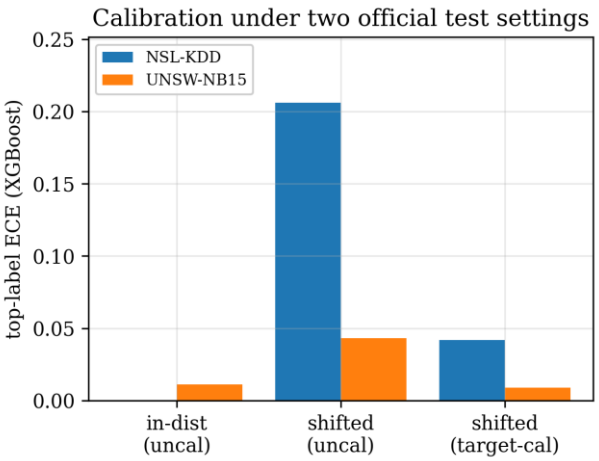

Fig. 2. Top-label ECE for XGBoost in three settings on the two benchmarks (three-seed means). The unseen-attack shift (NSL-KDD) degrades calibration far more than the shared-taxonomy shift (UNSW-NB15), even though a domain classifier finds the source and target readily separable in both.

C. A Controlled Study Points to Benign-Resembling Families

The contrast between the two benchmarks suggests that greater calibration degradation is associated with unfamiliar attacks rather than with measured source-target separability alone. The leave-one-attack-out study on UNSW-NB15 examines this, and its results are in Table IV. Removing most attack families from training barely changes the detector's ability to flag them: with the family absent from training, recall on Denial-of-Service, Reconnaissance, Backdoor, Shellcode, and Worms stays at or above 0.98, because these families still trip the binary detector. Fuzzers are the exception. With Fuzzers removed from training, its recall falls from 0.90 to 0.40, and the detector assigns Fuzzers to the benign class with a mean confidence of 0.59. The two separability scores help characterize this pattern. Generic feature-distinctness from the other attacks does not explain it: Shellcode (0.99) and Worms (0.99) are more distinct from the other attacks than Fuzzers (0.98), yet do not collapse. What sets Fuzzers apart is that it is the family least separable from benign traffic, with a family-versus-benign area under the curve of 0.94 against 0.997 or above for every other family, and it is the only family the detector confidently labels benign. The pattern is consistent with the NSL-KDD result, where the failing categories, Remote-to-Local and User-to-Root, are those that most resemble normal connections [3]. The margin is modest, and we read the effect as an association between resemblance to benign traffic and confident misclassification rather than a demonstrated mechanism. Ganesh et al. [44] likewise attribute part of the NSL-KDD minority-class difficulty to overlap between these classes and normal traffic. This control is binary and limited to UNSW-NB15, whereas the main NSL-KDD result is multiclass. It supports the observed association but does not establish the mechanism behind the NSL-KDD calibration failure.

TABLE IV. LEAVE-ONE-ATTACK-OUT ON UNSW-NB15 (BINARY ATTACK VS BENIGN), MEAN OVER THREE EVALUATION PARTITIONS

Withheld family	Rec. in train	Rec. novel	Benign conf.	AUROC vs attacks	AUROC vs benign
Exploits	0.99	0.98	0.07	0.93	0.998
Fuzzers	0.90	0.40	0.59	0.98	0.942
DoS	1.00	1.00	0.02	0.89	0.999
Reconnaissance	1.00	1.00	0.12	0.97	0.999
Backdoor	1.00	1.00	0.01	0.84	0.999
Shellcode	0.99	0.99	0.08	0.99	0.998
Worms	1.00	1.00	0.03	0.99	0.999

Recall on the withheld family when present in training, when novel, and the mean confidence with which the novel family is labeled benign. The last two columns give feature-space separability (leak-free cross-validated AUROC): the novel family versus the other attacks, and versus benign traffic. Only Fuzzers collapse, and it is the least separable from benign traffic rather than the most distinct from other attacks.

D. Supervised Target-Domain Recalibration Reduces Shifted Calibration Error

A natural response to miscalibration is to fit a calibrator on held-out data and apply it. Table II shows that fitting the calibrator on data from the training distribution does not repair the shifted failure. On NSL-KDD, temperature scaling fitted in distribution leaves the XGBoost error at 0.208 and raises the random-forest error from 0.170 to 0.205, because it sharpens the probabilities in the wrong direction. Supervised target-domain recalibration, fitted on a held-out labeled sample from the shifted distribution, behaves differently. These results describe performance after labeled target observations become available. They do not describe a detector facing new attacks with no labeled target data. Temperature scaling on the target sample reduces the error by roughly one third to one half across the three models, and isotonic regression on the target sample lowers it much further, to 0.042 for XGBoost, 0.064 for the random forest, and 0.058 for logistic regression, while the Brier score falls from about 0.42 to about 0.21. Isotonic regression gives the lowest error in five of the six model-dataset combinations. For the NSL-KDD random forest, Platt scaling on the target sample is slightly lower, at 0.048. Target-fitted calibrators change the area under the curve only marginally or improve it, so ranking is not traded away for calibration. Source-fitted isotonic regression, in contrast, lowers it substantially for the NSL-KDD random forest and XGBoost, further evidence that source-domain calibration does not transfer reliably.

Target-domain isotonic recalibration does more than lower the calibration error. On NSL-KDD, it recovers much of the rare-class detection. For XGBoost, the macro-averaged F1 rises from 0.545 to 0.681, the recall on Remote-to-Local rises from 0.08 to 0.55, and the recall on Probe rises from 0.64 to 0.77, as reported in Table III. The change for User-to-Root is smaller and much less stable, from 0.10 ± 0.03 to 0.18 ± 0.17 across the three partitions. The full official test file contains only sixty-seven

User-to-Root records, with about fifty in each evaluation slice. The small U2R ECE should be read cautiously at this support. Concretely, the shift makes the benign class overconfident, so many attack flows are given to benign at the argmax. Deflating the benign probability lets the attack classes win, which raises their recall. Because the one-versus-rest isotonic mappings are fitted separately and then renormalized, they can change the relative class probabilities and the argmax prediction. The recall increase reflects this change in the multiclass decision rather than a probability adjustment that preserves class ranking. On UNSW-NB15, where miscalibration was mild, the same recalibration lowers the already-small error further, from 0.043 to 0.009 for XGBoost, with a small gain in F1. Fig. 3 shows the per-category error before and after recalibration on NSL-KDD, concentrated on the classes that were most miscalibrated.

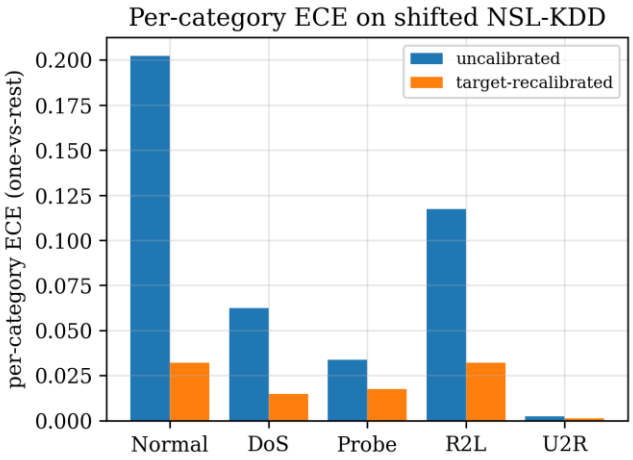

Fig. 3. Per-category ECE on the shifted NSL-KDD test set, before and after target-domain recalibration (illustrative seed-42 result). The reduction is concentrated on the classes that were most miscalibrated.

E. Effect of Labeled Target Sample Size

Because supervised target-domain recalibration requires labeled data from the shifted distribution, its cost depends on how many such samples are available. Table V reports the top-label error as the labeled sample grows. For each seed, ten stratified subsamples at each size are drawn from the twenty-five percent target-calibration pool, while the remaining seventy-five percent stays fixed for evaluation. Stratification uses the five mapped NSL-KDD classes, not raw attack subtype. At 100 samples, every draw has 43 Normal, 33 DoS, 11 Probe, and 13 R2L records, with no U2R record. Each 100-record draw includes 4 to 8 of the 17 test-only attack types, so none covers every unseen subtype. The thirty resamples and ninety-five percent confidence intervals reflect this composition variation. One hundred labeled samples cut the error from 0.206 to 0.047, a reduction of about three quarters, and lift the macro-averaged F1 from 0.545 to 0.639. Most of the reduction is achieved by one hundred samples. Beyond about five hundred, the error shows no further systematic decrease, varying between 0.032 and 0.040, and the F1 plateaus near 0.68. For aggregate top-label ECE, the 100-sample condition captures most of the observed reduction in this benchmark. It should not be read as reliable per-class calibration at that size because U2R and many unseen subtypes are not represented. The twenty-five percent slice used for the main experiment is not itself small. Only the smaller sample sizes in this sweep are, and we report their values explicitly. For NSL-KDD, this slice contains 5,636 labeled records and represents an optimistic adaptation condition with a large labeled sample rather than a low-label deployment setting.

TABLE V. TARGET-DOMAIN ISOTONIC RECALIBRATION ON NSL-KDD (XGBOOST) VS LABELED TARGET SAMPLE SIZE. NONZERO ROWS: MEAN ± 95% CI OVER THIRTY DRAWS; UNCALIBRATED BASELINE: MEAN ± SD OVER THREE SEEDS

Labeled target	Top-label ECE	Macro-F1
0 (uncal.)	0.206 ± 0.003	0.545 ± 0.018
100	0.047 ± 0.006	0.639 ± 0.007
250	0.037 ± 0.004	0.654 ± 0.013
500	0.035 ± 0.003	0.669 ± 0.013
1000	0.032 ± 0.003	0.668 ± 0.013
2500	0.033 ± 0.004	0.681 ± 0.012
5000	0.040 ± 0.004	0.677 ± 0.010

F. The Operating Cost, and What Calibration Contributes to it

The final question is what the miscalibration costs an operator, and how much of any benefit comes from calibration rather than from moving the threshold. Table VI reports the expected cost on NSL-KDD for XGBoost and the random forest. Using an uncalibrated score at its nominal decision-theoretic threshold is very costly: for XGBoost at a ratio of ten to one, the expected cost is 1.65, against 0.13 for the target-recalibrated detector at the same threshold, a reduction of 92 percent. That comparison, however, conflates calibration with threshold placement. When the uncalibrated score is instead used with a threshold tuned on the same labeled target sample, its cost falls to 0.13 as well, close to the cost from recalibration. For the random forest, the tuned uncalibrated threshold is lower still. The reading is that most of the operating benefit comes from placing the threshold correctly, which the raw score at its nominal threshold does not, rather than from calibration itself. Calibration's distinct value is twofold: it makes the principled cost-derived threshold usable directly, because the probabilities then mean what they say, and it repairs the multiclass probabilities, recovering the rare-class recall that tuning a single binary threshold does not. The decision curve in Fig. 4 shows the recalibrated detector at or above the uncalibrated one across the evaluated thresholds. On UNSW-NB15, where the shift was mild, all of these differences are small.

TABLE VI. EXPECTED OPERATING COST ON SHIFTED NSL-KDD (ATTACK VS BENIGN), MEAN OVER THREE SEEDS.

Model	r	uncal. (0.5)	uncal. (pt*)	uncal. (tuned)	cal. (pt*)
XGB	5:1	0.99	0.88	0.12	0.12
XGB	10:1	1.97	1.65	0.13	0.13
XGB	20:1	3.93	3.09	0.13	0.14
RF	5:1	1.07	0.66	0.11	0.14
RF	10:1	2.12	0.82	0.11	0.18
RF	20:1	4.23	0.99	0.12	0.35

Miss costs r times a false alarm. pt* is the decision-theoretic threshold 1/(1+r). The uncalibrated score at pt* is very costly; a threshold tuned on the target sample (uncal. (tuned)) matches or beats target-domain calibration at pt* (cal. (pt*)). Most of the operating benefit is threshold placement, not calibration.

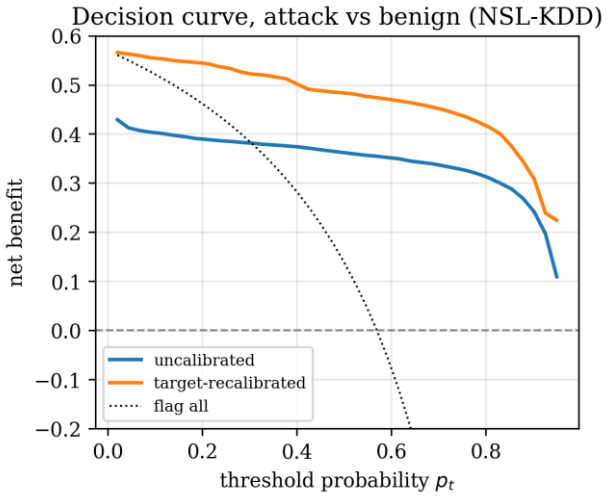

Fig. 4. Decision curve for attack versus benign on NSL-KDD (illustrative seed-42 result). The target-recalibrated detector has net benefit at or above the uncalibrated one across the evaluated operating thresholds.

V. DISCUSSION

The central finding is that good calibration measured on a same-distribution split did not carry over to the unseen-attack shift represented by NSL-KDD. In distribution, the three detectors were well calibrated, and a study that stopped there would report trustworthy probabilities. Under the shift the benchmarks contain, the probabilities on NSL-KDD were substantially miscalibrated. This is a caution about how intrusion detectors are evaluated. A reliability figure computed on a held-out split of the training distribution can overstate reliability when the evaluation distribution changes, and the evaluation protocol should include unseen attacks.

The second finding refines the first. The domain-classifier score alone does not predict the calibration failure. The observed degradation is more closely associated with the content of the shift. When the shift brought attacks whose behavior was unlike the training attacks, calibration degraded, and the calibration error was concentrated in the benign class. When the shift kept the same attack families, calibration degraded far less, and the change was model-dependent. The leave-one-attack-out study made this concrete: among the withheld families, only Fuzzers collapsed, and it was distinguished not by being the most feature-distinct from other attacks, which it was not, but by being the family least separable from benign traffic. Recalibrating on a labeled target sample did not restore this family: with Fuzzers present in the recalibration sample, its binary recall at the default threshold was 0.34 after recalibration against 0.40 before it, so improving the calibration of the probabilities did not by itself recover detection of the withheld family. Within these benchmark experiments, the observed harm takes a specific form. New attack traffic that is less separable from normal traffic receives confident benign labels. We state this as an association rather than a demonstrated mechanism, since the separability margin is modest and the analysis does not control for every confound.

The results also show what target-domain recalibration can and cannot improve. Recalibrating on training-distribution data did not reliably help and sometimes hurt, so it is not a safe default. Recalibrating on a held-out labeled sample from the target environment did help, with isotonic regression most effective in most cases, and in the severe case it recovered much of the rare-class detection as well as reliability, with about one hundred labeled samples enough for most of the gain. The decision-analytic view adds a caution of its own: most of the reduction in expected operating cost comes from placing the decision threshold correctly, and an uncalibrated score with a threshold tuned on the same target sample matches recalibration on the binary cost. This is consistent with Minderer et al. [7], who report that for practical rejection rates a model's accuracy advantage can outweigh its calibration advantage in a selective-prediction cost analysis. What calibration adds beyond threshold tuning is that the principled cost-derived threshold becomes usable without a search, and that the multiclass probabilities are repaired, recovering rare-class recall. Within the studied benchmark shifts, this supports recalibrating and setting the operating threshold on labeled target data rather than relying on source-domain calibration.

Several limits bound these conclusions. Both benchmarks are built from simulated traffic in a single testbed, so the exact numbers may not carry over to live networks with other traffic mixes and attack tools. The rarest classes are small enough that their per-class figures are noisy, and the calibration of a class with sixty-seven instances in the official test file, such as User-to-Root, cannot be estimated with confidence, a limit we state rather than resolve. The remedy assumes a labeled sample from the target environment can be obtained, which has an operational cost. The hyperparameters were fixed rather than tuned, so the numbers describe untuned defaults. The shift-severity score measures distributional distance, not the direction of the shift, and the family-level separability analysis is descriptive. Finally, we studied two datasets and three model families, and while the pattern was consistent across them, wider replication would strengthen it.

VI. Conclusion

We measured the reliability of the probabilities produced by three machine-learning intrusion detectors, in distribution and under the shift two standard benchmarks contain, per attack category. In distribution, the detectors were well calibrated. Under a shift that introduced unfamiliar attacks, calibration degraded by a large factor, and the calibration error was concentrated in the benign class, so novel attacks were labeled normal with confidence, while a shift that kept the same attack families left calibration much less affected, even though a domain classifier detects the shift in both cases. Recalibrating on training-distribution data did not repair the failure. Once labeled target observations were available, supervised target-domain recalibration reduced the error, with isotonic regression giving the lowest error in most model-dataset combinations, and it recovered much of the rare-class detection. About one hundred labeled samples captured most of the aggregate top-label ECE gain. A decision-analytic analysis showed that most of the reduction in operating cost comes from correct threshold placement, with calibration contributing a usable principled threshold and repaired multiclass probabilities. The benchmark results support measuring calibration under protocols that include novel attacks, not only on a same-distribution split. Once labeled target observations are available, supervised target-domain recalibration can substantially reduce calibration error and provide data for threshold setting. Whether the same effect sizes hold in live networks remains an open question. A multiclass leave-one-attack-out study on NSL-KDD would test whether the benign-resemblance association persists in the setting where calibration degradation is largest. Future work should also test the protocol on live network traffic and additional IDS benchmarks, compare further model families, and evaluate online recalibration as labeled target observations arrive. The evaluation should account for label delay and annotation cost and test whether selective labeling can reduce the amount of target data needed for recalibration and threshold setting.

Funding and Conflicts of Interest

***Abstract*—Cardiovascular disease remains a major public health burden and is associated with demographic, behavioral, and chronic-health characteristics. This study evaluates explainable machine learning for cross-sectional classification of self-reported cardiovascular disease status using the 2020 CDC Behavioral Risk Factor Surveillance System (BRFSS)-derived Personal Key Indicators of Heart Disease dataset. After removing 18,078 exact duplicate feature-target rows, 301,717 records and 17 predictor variables were retained. The target variable, HeartDisease (Yes/No), indicates whether a respondent had ever been diagnosed with cardiovascular disease or had experienced a heart attack; therefore, the task is classification of prevalent disease status rather than longitudinal prediction of future disease incidence. Six machine learning families were compared using stratified train-test splitting, 5-fold cross-validation, cost-sensitive learning, and hyperparameter tuning. The tuned XGBoost model achieved the highest test-set F1-score of 0.3939 (approximate 95% CI: 0.384–0.403) and a ROC-AUC of 0.8362 (approximate 95% CI: 0.829–0.843). SHAP analysis showed that age category, self-rated general health, sex, smoking status, and body mass index contributed most strongly to the model outputs. These SHAP values describe model dependence and should not be interpreted as causal effects or as novel epidemiological risk-factor discoveries. A prototype business intelligence dashboard was developed for research-oriented communication of model performance and feature contributions. The results support transparent classification of self-reported cardiovascular disease status for analytical and preliminary screening contexts, not future-risk forecasting or direct clinical diagnosis.**

Keywords*—Cardiovascular disease; machine learning; explainable artificial intelligence; cardiovascular disease status classification; behavioral risk factor surveillance system; cross-industry standard process for data mining (CRISP-DM)

I. Introduction

Cardiovascular disease (CVD) remains the leading cause of death worldwide, accounting for approximately 17.9 million deaths annually [1]. Established determinants include age, sex, smoking, hypertension, hyperlipidemia, obesity, diabetes, physical inactivity, and other chronic conditions. In the present work, these characteristics are used to distinguish respondents who report an existing history of cardiovascular disease from those who do not. Because the outcome records prior disease status rather than incident events observed during follow-up, the analysis is framed as cross-sectional disease-status classification rather than future-risk prediction.

Large-scale population health surveys provide useful information for population-health analytics because they capture demographic, behavioral, and self-reported health characteristics at scale. The U.S. Centers for Disease Control and Prevention (CDC) Behavioral Risk Factor Surveillance System (BRFSS) [2] collects annual health-related information from hundreds of thousands of respondents. Variables such as body mass index (BMI), smoking behavior, self-rated general health, and histories of chronic conditions can therefore support machine-learning classification of self-reported cardiovascular disease status [3]. Machine learning is particularly useful for examining nonlinear relationships and interactions among such indicators [4]–[6].

This study compares six machine learning families—logistic regression, decision tree, random forest, gradient boosting, XGBoost [7], and support vector machine (SVM)—for classifying self-reported cardiovascular disease status in the BRFSS 2020-derived dataset [8]. The workflow follows CRISP-DM [9], uses cost-sensitive learning to address class imbalance [10], and applies SHAP (SHapley Additive exPlanations) [11] to quantify the extent to which individual features influence the fitted model. The intended contribution is not the discovery of previously unknown epidemiological risk factors; rather, it is a transparent comparison of class-imbalance strategies and interpretable machine-learning behavior on a large survey-derived dataset. A prototype business intelligence dashboard is included only as a research communication layer and not as a clinical decision-support system.

II. Background and Related Work

A. Cardiovascular Disease and Risk Factors

Cardiovascular disease (CVD) refers to a broad group of disorders affecting the heart and blood vessels and remains a leading cause of global mortality [1]. These conditions include coronary heart disease, cerebrovascular disease, peripheral arterial disease, and heart failure. Although many demographic, behavioral, and comorbidity-related variables are associated with cardiovascular outcomes, the present dataset does not observe future disease incidence. Accordingly, this study uses survey indicators to classify respondents according to reported

* Corresponding author

existing cardiovascular disease status rather than to estimate prospective clinical risk.

B. Dataset Description

This study uses the personal key indicators of heart disease dataset [8], compiled by Kamil Pytlak and made available through Kaggle. The dataset is derived from the 2020 CDC BRFSS [2], a large-scale annual telephone-based health survey conducted in the United States. The BRFSS collects health-related information from more than 400,000 respondents each year. The dataset originally contained 319,795 records and 18 columns, including the target variable. After removing 18,078 exact duplicate feature-target rows, 301,717 records remained for analysis. The target variable, HeartDisease (Yes/No), indicates whether a respondent had ever been diagnosed with cardiovascular disease or had experienced a heart attack. The positive class accounted for 9.04% of the dataset, indicating substantial class imbalance. As presented in Table I, the 17 predictor variables, excluding the target variable, are grouped into several categories according to their characteristics.

TABLE I. DESCRIPTION OF VARIABLES IN THE BRFSS 2020 HEART DISEASE DATASET

No.	Variable	Description	Type
1	BMI	Body Mass Index (kg/m²)	Numeric
2	Smoking	Smoked >100 cigarettes	Binary
3	AlcoholDrinking	Heavy alcohol use	Binary
4	Stroke	Had stroke	Binary
5	PhysicalHealth	Poor phys. health days (30d)	Numeric
6	MentalHealth	Poor mental health days (30d)	Numeric
7	DiffWalking	Difficulty walking/stairs	Binary
8	Sex	Gender	Categorical
9	AgeCategory	Age group (5-yr intervals)	Ordinal
10	Race	Race/ethnicity	Categorical
11	Diabetic	Diabetes status	Categorical
12	PhysicalActivity	Exercise in past 30 days	Binary
13	GenHealth	Self-rated general health	Ordinal
14	SleepTime	Avg hours of sleep/day	Numeric
15	Asthma	Has asthma	Binary
16	KidneyDisease	Has kidney disease	Binary
17	SkinCancer	Has skin cancer	Binary
—	HeartDisease	Target: cardiovascular disease (9.04%)	Binary

Table I summarizes the 17 predictor variables from the CDC BRFSS 2020 dataset [2], excluding the target variable. Following preprocessing and exact-row filtering, the final dataset used in this study comprised 301,717 records.

The dataset was selected because its large sample size supports model development and evaluation, while its BRFSS origin provides a transparent survey-data provenance. The variables are also readily interpretable, allowing model behavior to be examined using SHAP. However, these advantages apply to classification performance on the processed dataset and do not imply that the fitted model yields nationally representative prevalence estimates or individualized future-risk probabilities.

Important limitations arise from measurement, preprocessing, and survey design. The variables are self-reported rather than physician-confirmed and may therefore be affected by recall and response bias [32]. The released Kaggle file contains no respondent identifier; therefore, identical feature-target rows removed during preprocessing cannot be confirmed as repeated respondents, and the reported results are conditional on this exact-row filtering rule. The file also omits the original BRFSS survey-weight, stratum, and primary sampling-unit variables; consequently, the analysis treats observations as independent records and does not perform design-based population inference. The data are restricted to U.S. respondents and omit detailed clinical measurements such as laboratory tests, electrocardiography, and cardiac imaging. Results should therefore be interpreted as model performance on this processed BRFSS-derived dataset, not as survey-weighted national estimates or prospective clinical risk estimates.

C. Machine Learning for Cardiovascular Disease Status Classification

Artificial intelligence (AI) and machine learning are increasingly used in health analytics to identify complex patterns in large datasets [4]–[6]. For cross-sectional health data, the appropriate interpretation depends on the outcome definition: a model may classify an existing disease state without predicting a future event. This distinction is especially important for the BRFSS-derived HeartDisease variable, which represents a respondent's reported history of disease.

AI-based data analysis includes supervised, unsupervised, semi-supervised, and reinforcement-learning approaches [12]. This study uses supervised binary classification to distinguish self-reported cardiovascular disease status from 17 personal health indicators. Six algorithm families are evaluated: logistic regression, decision tree [13], [14], random forest [15], gradient boosting [16], XGBoost [7], and SVM [17]. The comparison emphasizes class-imbalance handling and interpretable model behavior rather than claims of prospective disease forecasting.

The decision tree algorithm is an important baseline because it forms the basis of several ensemble methods [18], including random forest and XGBoost. It partitions data at each node using criteria such as information gain or Gini impurity [13], [14], producing interpretable if-then decision rules. However, single decision trees are susceptible to overfitting when model complexity is not properly controlled. Ensemble methods such as random forest [15] and XGBoost [7] reduce this limitation by combining multiple trees, often improving predictive performance and stability on large-scale datasets.

D. Business Intelligence for Analytical Reporting

Business Intelligence (BI) refers to the use of information technology to collect, manage, analyze, and present data for decision-making support [19]. Common BI processes include data source identification, data quality management, extract-transform-load operations, data warehousing, reporting, online analytical processing, and data mining.

In this study, BI serves only as a reporting and communication layer. The dashboard summarizes model performance, algorithm comparisons, and SHAP-based predictive-feature contributions. It is not intended to estimate an individual's future cardiovascular risk, to provide treatment recommendations, or to substitute for clinical assessment.

E. Data Visualization for Model Evaluation and Interpretation

Data visualization supports interpretation at both exploratory and evaluation stages [20]. Exploratory graphics are used to examine variable distributions, class imbalance, and patterns across disease-status groups. During model evaluation, confusion matrices and ROC curves [21] summarize threshold-dependent outcomes and discrimination, while SHAP plots [11] display feature contributions. Average Precision (AP) is retained as a scalar supplementary metric for imbalanced classification and is reported numerically in the results table; the manuscript does not treat a Precision–Recall curve as part of the model-selection procedure.

F. Structured Comparison with Prior Studies

Chen et al. [36] analyzed the BRFSS 2020 Kaggle derivative (319,795 records) using a stacking ensemble, reporting 86.69% accuracy, 86.91% weighted F1-score, and SHAP-based interpretation. Imani et al. [37] used BRFSS 2022 data (221,643 participants) with several machine learning models and SMOTE, with XGBoost achieving 94.2% accuracy, 85.3% F1-score, and ROC-AUC of 0.94. This study uses 301,717 BRFSS 2020 records after exact-row filtering, six algorithm families, cost-sensitive learning without synthetic oversampling, and F1-score for model selection. Due to differences in outcome construction, preprocessing, sampling year, and imbalance handling, results are compared contextually rather than directly.

III. Methodology

The analytical workflow follows the CRISP-DM framework [9], comprising business understanding, data understanding, data preparation, modeling, evaluation, and deployment-as-communication. All analyses were implemented in Python 3.10 using pandas, NumPy, scikit-learn [22], XGBoost [7], SHAP [11], Matplotlib, and joblib. A fixed random seed of 42 was used throughout the experimental workflow to support reproducibility.

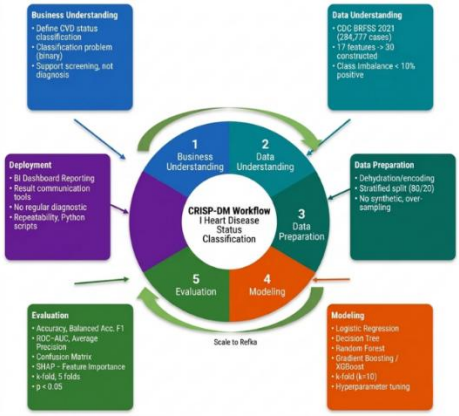

Fig. 1. Workflow of the CRISP-DM process for CVD status classification.

Fig. 1 illustrates the CRISP-DM workflow used in this study, covering six phases from business understanding to deployment. For this research, these phases are organized into three main methodological stages.

A. Problem Definition and Data Understanding

This study formulates the task as binary classification of self-reported cardiovascular disease status from personal health indicators. The research questions are: 1) which model provides the best F1-score under substantial class imbalance; 2) which features contribute most strongly to the fitted model outputs; and 3) how does class-sensitive training affect model performance? Because the target reflects prior diagnosis or heart-attack history, the analysis does not estimate future disease incidence. The intended use is research-oriented screening support and population-health analytics rather than clinical diagnosis or prospective risk forecasting.

The analysis uses the Personal Key Indicators of Heart Disease dataset [8], derived from CDC BRFSS 2020 [2]. The source file contained 319,795 records and 18 columns, including 17 predictors and the HeartDisease (Yes/No) target. Exact-row filtering removed 18,078 rows that were identical across all predictors and the target, leaving 301,717 records. The predictors comprise numerical, binary, ordinal, and nominal variables. The processed file contains no missing values, but it also does not retain the original BRFSS complex-survey design variables; therefore, model evaluation is performed at the record level rather than using survey-weighted inference.

B. Data Preparation and Model Development

Data preparation was conducted in Python. As a preprocessing rule, 18,078 rows identical across all 17 predictors and the target were removed, reducing the dataset from 319,795 to 301,717 records. Because the released file contains no respondent identifier, this operation is treated as exact-row filtering rather than confirmation of duplicate respondents. The target variable, HeartDisease, was converted from Yes/No labels into binary values, with 1 representing the positive class and 0 representing the negative class. Ordinal encoding was applied to variables with a natural order, including AgeCategory and GenHealth. For instance, AgeCategory was encoded from 18–24 = 0 to 80 or older = 12. Other categorical variables, including Sex, Race, Diabetic, and Smoking, were transformed using one-hot encoding. This process resulted in 34 encoded features for model development.

The dataset was divided into training and test sets using a stratified 80/20 split to preserve the class distribution in both subsets, yielding 241,373 training records and 60,344 test records. A fixed random_state of 42 was applied throughout the experimental workflow to support reproducibility. Feature scaling was conducted using StandardScaler, which was fitted only on the training set and subsequently applied to both the training and test sets to prevent data leakage [23]. To address class imbalance, cost-sensitive learning [10] was used instead of oversampling or undersampling. Specifically, class_weight='balanced' was applied to scikit-learn models [22], whereas scale_pos_weight was used for XGBoost [7]. This strategy enabled the models to place greater emphasis on the minority positive class while preserving the original data distribution.

Model development was conducted in Python using scikit-learn [22] and XGBoost [7]. A total of 11 model configurations from six algorithm families were implemented and evaluated, as summarized in Table II.

TABLE II. MACHINE LEARNING MODEL CONFIGURATIONS AND MAIN HYPERPARAMETERS

Model	Variant	Hyperparameters
Logistic Regression [24], [25]	default + balanced	max_iter=1000, solver=liblinear
Decision Tree	default + balanced	max_depth=10, min_samples_split=20, min_samples_leaf=10
Random Forest [15]	default + balanced + tuned	n_estimators=200, max_depth=15
Gradient Boosting [16]	default	n_estimators=200, max_depth=5, lr=0.1
XGBoost [7]	default + balanced + tuned	n_estimators=200, max_depth=5, lr=0.1
SVM [17]	balanced (CV only)	kernel=rbf, class_weight=balanced

Table II summarizes the six model families and 11 model configurations evaluated in this study, together with their main hyperparameters. The configurations include default, class-balanced, and tuned variants, allowing comparison of both algorithm choice and class-imbalance handling. Model performance was assessed using 5-fold stratified cross-validation [26] on the training set. To reduce computational cost, cross-validation for computationally intensive models, namely SVM, gradient boosting, and XGBoost, was conducted using a stratified subsample of 50,000 training instances. The same preprocessing and evaluation criteria were applied across configurations to support a consistent comparison of model performance.

C. Model Evaluation and Result Communication

Model performance was evaluated using accuracy, balanced accuracy, precision, recall, F1-score, ROC-AUC [21], and Average Precision (AP). F1-score was prespecified as the primary model-selection criterion because it balances precision and recall in the presence of substantial class imbalance. ROC-AUC was used as a threshold-independent measure of discrimination, while AP was retained as a supplementary scalar summary of precision-recall performance rather than as the basis for a separate graphical selection procedure. The best model was selected from cross-validation and then evaluated once on the unseen hold-out test set of 60,344 records. To quantify uncertainty for the final XGBoost model, an approximate 95% confidence interval for F1-score was obtained by multinomial bootstrap resampling of the four observed confusion-matrix cells (10,000 resamples), and the ROC-AUC interval was estimated using the large-sample variance approximation of Hanley and McNeil [38]. The classification threshold was fixed before final test-set evaluation to avoid post hoc optimization on the hold-out data. Confidence intervals were reported alongside point estimates to provide a clearer indication of statistical uncertainty. These procedures support a more transparent assessment of model performance under substantial class imbalance.

Deployment in CRISP-DM was operationalized only as a prototype BI dashboard [19] for communicating the analytical results. The dashboard presents model-performance indicators, algorithm comparisons, and SHAP-based feature contributions. It is a non-functional research mock-up and is not a calibrated clinical risk calculator or decision-support tool.

IV. RESULTS

A. Exploratory Data Analysis

After exact-row filtering, 301,717 records remained from the original 319,795 records, and feature encoding produced 34 model inputs. HeartDisease = Yes represented 9.04% of observations, creating an approximate 10:1 negative-to-positive class ratio. A classifier that always predicts the negative class would therefore achieve 90.96% accuracy while identifying no positive cases. This imbalance motivated the use of F1-score as the primary selection metric and discouraged interpretation of accuracy in isolation.

The exploratory analysis showed clear differences in cardiovascular disease prevalence across demographic and health-related groups. Individuals aged 65 years and older had a substantially higher prevalence than those younger than 45 years, and males showed a higher proportion of positive cases than females. Respondents who reported poor general health also had a markedly higher prevalence of cardiovascular disease than those who reported excellent general health.

The target variable showed substantial class imbalance: HeartDisease = Yes accounted for 27,373 cases (9.04%), while HeartDisease = No accounted for 274,344 cases (90.96%), corresponding to an approximate 10:1 ratio. This imbalance strongly influenced the modeling strategy and the selection of evaluation metrics.

B. Performance Comparison of Machine Learning Models

The revised analysis evaluated 11 model configurations from six algorithm families on the exact-row-filtered dataset (n = 301,717; positive class = 9.04%). A stratified 80/20 train-test split was applied to preserve the target class distribution, yielding 241,373 training instances and 60,344 test instances. A fixed random_state of 42 was used throughout the experiment to support reproducibility.

As shown in Table III, 5-fold stratified cross-validation [26] demonstrated a clear effect of class-sensitive training. Weighted configurations achieved CV F1-scores of approximately 0.33–0.37, whereas non-weighted configurations remained near 0.12–0.18 despite accuracies above 0.90. The latter accuracies were dominated by correct classification of the majority negative class, confirming that class imbalance handling materially changes the threshold-dependent behavior of the models. Among the weighted configurations, XGBoost and random forest produced the strongest overall CV performance, while logistic regression remained competitive in terms of discrimination. The relatively small differences in ROC-AUC across several models indicate that model selection depended more strongly on the balance between precision and recall than on discrimination alone. These results support the use of F1-score as the primary criterion for selecting the final model.

Hyperparameter tuning was performed using GridSearchCV with 3-fold cross-validation. Among the evaluated configurations, the tuned XGBoost model achieved the highest

validation F1-score of 0.3752. The selected hyperparameter values were max_depth = 5, learning_rate = 0.1, scale_pos_weight = 5, and n_estimators = 200.

The top five models identified during cross-validation were further evaluated on the hold-out test set (n = 60,344) to assess generalization performance. Table IV compares their predictive performance across multiple metrics, including accuracy, balanced accuracy, precision, recall, F1-score, ROC-AUC, and AP. This comparison provides a clearer assessment of the trade-offs among models, especially in relation to the substantial class imbalance in the dataset.

TABLE III. FIVE-FOLD CROSS-VALIDATION PERFORMANCE OF MODEL CONFIGURATIONS

Model	CV Accuracy	CV F1	CV ROC-AUC	Class Weight
xgboost_tuned	0.8352 ± 0.0019	0.3708 ± 0.0057	0.8367 ± 0.0016	balanced

TABLE IV. HOLD-OUT TEST PERFORMANCE OF THE TOP FIVE MODELS

Model	Accuracy	Balanced Accuracy	Precision	Recall	F1	ROC-AUC	AP
xgboost_tuned	0.8335	0.7278	0.2934	0.5989	0.3939	0.8362	0.3472
random_forest_balanced	0.7756	0.7414	0.2427	0.6997	0.3604	0.8250	0.3143
logistic_regression_balanced	0.7429	0.7550	0.2274	0.7698	0.3511	0.8324	0.3450
xgboost_ balanced	0.7351	0.7592	0.2247	0.7885	0.3498	0.8359	0.3476
decision_tree_balanced	0.7201	0.7462	0.2130	0.7781	0.3344	0.8136	0.3147

As shown in Table IV, the tuned XGBoost model [7] achieved the highest hold-out F1-score (0.3939; approximate 95% CI: 0.384–0.403) and a ROC-AUC of 0.8362 (approximate 95% CI: 0.829–0.843). These intervals indicate good discrimination while reflecting uncertainty in the point estimates. AP is reported in Table IV as a complementary precision-recall metric rather than a model-selection criterion.

Compared with balanced logistic regression, XGBoost achieved higher F1-score and precision, while ROC-AUC and AP differed only slightly. Logistic regression achieved higher recall and balanced accuracy. Accordingly, XGBoost was retained based on the prespecified F1 criterion rather than a universal performance advantage. Calibration was not evaluated, so no claim of superior probability calibration or clinical utility is made.

The tuned XGBoost model had lower accuracy than the default configuration (0.8335 vs. 0.9055) but substantially higher recall (0.5989 vs. approximately 0.11), illustrating the limitations of accuracy under class imbalance. ROC curves in Fig. 2 further compare discrimination across thresholds and complement the F1 and AP results reported in Table IV.

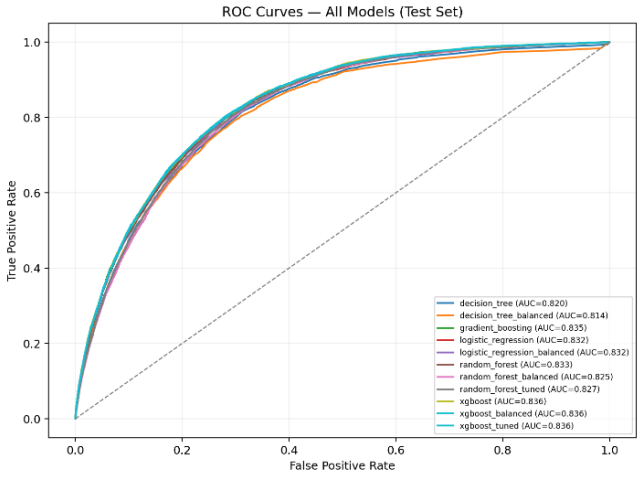

Fig. 2. ROC curves of the compared machine learning models.

Fig. 2 presents the ROC curves for all model configurations evaluated on the test set (n = 60,344). The tuned XGBoost model achieved a ROC-AUC of 0.8362, indicating good discriminative ability between positive and negative cases.

Although most models obtained similar ROC-AUC values, approximately 0.81 to 0.84, their operating points differed considerably depending on the use of class weighting.

C. Model Interpretability Analysis

1) Confusion matrix evaluation: As shown in Fig. 3, the tuned XGBoost model correctly detected 3,265 of 5,452 cardiovascular disease cases on the hold-out test set, giving a recall of 59.89%, while 2,187 positive cases were missed. Of the 11,127 instances predicted as positive, 3,265 were true positives, resulting in a precision of 29.34%. The false positive rate was 14.32%, calculated from 7,862 false positives among 54,892 actual negative cases.

In the context of preliminary health screening, a recall of approximately 60% means that the model identified about six out of ten individuals with cardiovascular disease for further examination. The false positive cases represent the cost of improving sensitivity. Although false positives may increase the burden of follow-up assessment, false negatives are more critical because affected individuals may be missed entirely. This trade-off is illustrated in Fig. 3.

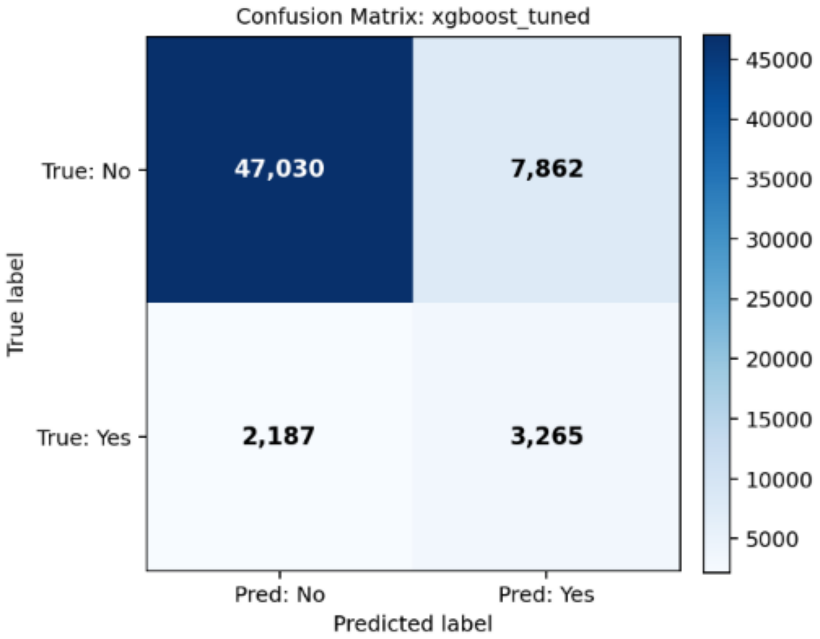

Fig. 3. Confusion matrix of the tuned XGBoost model.

Fig. 3 presents the confusion matrix of the tuned XGBoost model on the test set (n = 60,344). The heatmap shows the distribution of true positives, true negatives, false positives, and false negatives, providing a clear visual summary of the model's classification outcomes.

2) SHAP-based feature importance analysis: To interpret the tuned XGBoost model, SHAP analysis [11], [27] was used to identify the predictors that contributed most strongly to the model's outputs.

As shown in Fig. 4, the 20 most influential encoded features were ranked by mean absolute SHAP value. AgeCategory had the largest contribution (mean absolute SHAP = 0.1155; 36.8% of total importance), followed by GenHealth and Sex. Together, these three features accounted for 68.7% of the reported global importance. These values quantify how strongly the fitted XGBoost model depends on the features; they do not establish causality, effect size in the population, or a new epidemiological relationship.

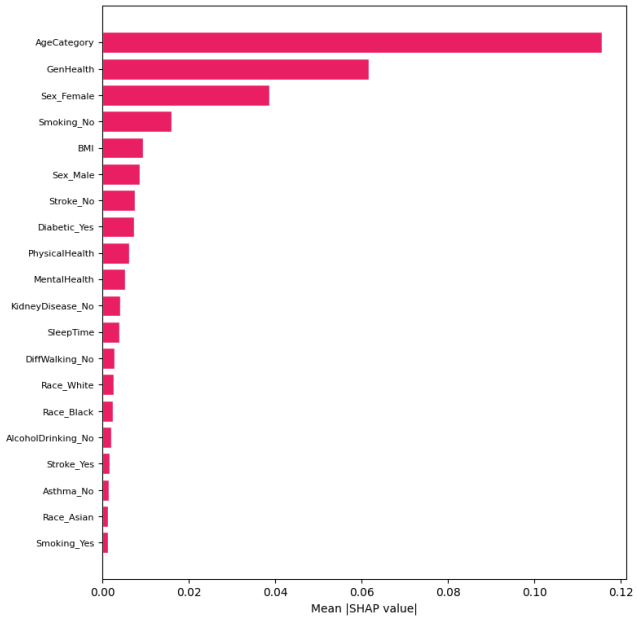

Fig. 4. SHAP feature importance of the tuned XGBoost model.

Behavior-related features such as Smoking, BMI, and PhysicalActivity and comorbidity indicators such as Diabetic, Stroke, and KidneyDisease contributed less global SHAP importance than AgeCategory, GenHealth, and Sex. In particular, GenHealth should be interpreted cautiously because self-rated general health may partly proxy underlying disease burden, comorbidity, or consequences of already-existing cardiovascular disease. This concern is especially relevant in a cross-sectional status-classification setting and reinforces that SHAP importance should not be presented as evidence of a prospective causal risk factor.

3) Dashboard-based result communication: A BI dashboard [19] was developed as a non-functional web mock-up to communicate the classification results, as shown in Fig. 5. The interface is intended for research visualization only and should not be interpreted as a clinical risk calculator.

Fig. 5. Business intelligence dashboard for CVD status classification results.

The dashboard includes summary metrics, model comparison, and SHAP-based predictive-feature visualization. The summary area reports F1-score = 0.3939, ROC-AUC = 0.8362, and the analyzed sample size of 301,717 records. The feature panel displays the strongest model contributors, including age category, general health, sex, smoking, and BMI. These displays communicate model outputs and feature dependence rather than causal risk estimates or individualized future-disease probabilities.

V. Discussion and Conclusion

This study compared six machine-learning families across 11 configurations for cross-sectional classification of self-reported cardiovascular disease status in a CDC BRFSS 2020-derived dataset. After preprocessing, 301,717 records were analyzed. The tuned XGBoost model achieved the highest prespecified F1-score (0.3939; approximate 95% CI 0.384–0.403) and ROC-AUC of 0.8362 (approximate 95% CI 0.829–0.843). These findings support the feasibility of classifying prevalent self-reported disease status from large-scale survey indicators, but they do not demonstrate prospective prediction of future cardiovascular events.

Class imbalance materially affected model behavior. Non-weighted models produced accuracies near 91% but very low positive-class recall, whereas class-sensitive configurations increased recall substantially at the cost of lower precision. The selected XGBoost configuration achieved the highest F1-score, but the balanced logistic regression baseline achieved higher recall and balanced accuracy. The small differences in ROC-AUC and AP between these two models indicate that the practical benefit of XGBoost lies mainly in the chosen operating trade-off rather than in a large improvement in overall discrimination.

Comparison with prior work must be made cautiously because BRFSS-based studies use different survey years, target definitions, preprocessing pipelines, and imbalance strategies. Chen et al. [36] used the same 2020 Kaggle derivative with a stacking ensemble and SHAP, whereas Imani et al. [37] analyzed BRFSS 2022 data with SMOTE and four model families. Broader cardiovascular machine-learning studies [28]–[31] also vary substantially in clinical context and outcome construction. The structured comparison in Section II therefore contextualizes the present results without treating cross-study metric differences as direct evidence that one modeling approach is superior.

Several methodological limitations remain. First, exact-row filtering removed identical feature-target patterns, but the released file has no respondent identifier; these rows therefore cannot be verified as repeated respondents, and the results are conditional on this preprocessing choice. Second, the file does not retain BRFSS sampling weights, strata, or primary sampling units, so the analysis does not support survey-weighted national inference. Third, the outcome and predictors are self-reported, and the cross-sectional design does not establish temporality. Confidence intervals for F1 and ROC-AUC quantify uncertainty only approximately and do not replace external validation. Calibration was not evaluated, so output scores should not be interpreted as individualized clinical probabilities. Finally, subgroup findings are descriptive and require dedicated validation before deployment-oriented threshold adjustment.

SHAP analysis [11], [33] identified AgeCategory, GenHealth, Sex, Smoking, and BMI as the strongest contributors to XGBoost outputs. This pattern largely agrees with established epidemiological knowledge and should not be claimed as a new scientific discovery. The interpretability contribution is instead the transparent quantification of model dependence. GenHealth deserves particular caution because self-rated health can encode broad underlying morbidity and

may act as a proxy for existing disease burden; therefore, its SHAP importance cannot be interpreted as a causal or prospective risk effect.

Implementation in Python with a fixed random seed of 42 supports computational reproducibility. The subgroup analysis [34] indicated ROC-AUC values above 0.82 across demographic groups, while recall varied by sex and age group. These differences suggest that a single operating threshold may not perform equally across subpopulations. Because subgroup calibration and prospective outcomes were not assessed, these observations should be treated as diagnostic checks on model behavior rather than evidence for subgroup-specific clinical decision rules.

Overall, machine learning can support transparent classification and analytical summarization of self-reported cardiovascular disease status in a large survey-derived dataset under substantial class imbalance. The present model is not a longitudinal risk-prediction model, a calibrated clinical risk score, or a diagnostic device. Future work should evaluate external datasets with incident outcomes, incorporate appropriate survey-design variables when population inference is intended, assess calibration and decision utility, test models without broad proxy variables such as GenHealth, and validate subgroup performance before considering practical deployment [35].

***Abstract*—Transformer health index (THI) prediction supports condition-based maintenance by mapping dissolved-gas, oil-quality, and furan indicators to an interpretable asset-condition score. This study develops a supervised benchmarking framework using 3,392 transformer oil diagnostic records from 510 transformers. Thirteen diagnostic features from dissolved gas analysis, oil quality analysis, and furan analysis are evaluated across three modelling groups: static machine learning, static deep learning, and variable-length temporal deep learning. Transformer-level splitting is applied to reduce data leakage from repeated transformer histories. Static gradient-boosted tree models achieved the strongest results. XGBoost obtained the lowest test root mean square error of 3.4254 with a coefficient of determination of 0.9780 and health-index class accuracy of 88.20 percent. The best temporal model, the liquid time-constant neural network (LTC-LNN), achieved a test root mean square error of 4.8691 and a coefficient of determination of 0.9567. Permutation feature importance identified 2FAL, C2H2, and dielectric breakdown as the most influential predictors. For the present dataset, static gradient-boosted tree models produced the strongest observed point-estimate performance, while LTC-LNN remained a promising temporal-learning alternative for repeated diagnostic histories. However, the uncertainty analysis indicates that small numerical differences among the leading static models should not be interpreted as definitive evidence of model superiority.**

Keywords*—Transformer health index; machine learning; deep learning; liquid neural networks; oil diagnostic data; condition-based maintenance; smart grid asset management

I. Introduction

Oil-immersed power and distribution transformers are among the most critical assets in electrical networks. Their failure can cause supply interruption, long replacement lead times, safety hazards, and high operational costs. For this reason, transformer condition assessment has shifted from age-based replacement to condition-based and risk-informed asset management. Oil diagnostic testing is central to this transition because dissolved gas analysis (DGA), oil quality analysis (OQA), and furan analysis provide non-invasive evidence of thermal faults, electrical faults, oil degradation, and paper-insulation ageing [1-7].

The transformer health index (THI) is widely used to consolidate multiple diagnostic indicators into a single condition score. Weighted-score-sum approaches, including Kinectrics-type and other utility-oriented health-index methods, remain attractive because they are transparent and interpretable for engineers [8-15]. However, these methods usually apply fixed scoring thresholds and fixed weights. As a result, they may not fully capture nonlinear dependencies among DGA gases, oil-quality parameters, and furan compounds, especially when the same transformer has repeated oil-test histories.

Machine learning (ML) and deep learning (DL) provide a data-driven route to learn the relationship between diagnostic measurements and a supervised THI target. Ensemble tree models such as random forest, gradient boosting, XGBoost, LightGBM, and CatBoost are especially relevant for tabular engineering data because they can model nonlinear feature interactions and threshold-like behaviour [16-23]. Neural models provide another route for static and sequential learning, including multilayer perceptrons and other deep feed-forward architectures [24-26], recurrent models such as long short-term memory (LSTM) and gated recurrent units (GRUs) [27], [28], attention-based Transformers [29], temporal convolutional networks (TCNs) [30], and continuous-time liquid neural networks [31-35].

Despite the growing interest in intelligent transformer diagnostics, two methodological gaps remain. First, many studies evaluate either classical ML or a single neural model, without distinguishing between static tabular learning and temporal history learning. Second, repeated oil-test records from the same transformer are often treated as independent samples, which can lead to leakage if samples from the same transformer appear in both the training and testing sets. This study addresses these issues by using transformer-level data splitting and by separating the evaluation into three modelling groups: static ML, static DL, and variable-length sequence DL.

The main contributions of this study are as follows: 1) a leakage-aware benchmarking framework for THI prediction using 3,392 oil diagnostic records; 2) a three-level experimental comparison between static ML, static DL, and variable-length sequence DL; 3) a liquid time-constant neural network (LTC-LNN) implementation for repeated transformer oil-test histories; and 4) a feature-importance analysis identifying the diagnostic variables most responsible for THI prediction.

II. Related Work

DGA is one of the most established diagnostic tools for mineral-oil-filled transformers. IEEE and IEC guides define gas interpretation procedures and support the identification of thermal, partial discharge, and arcing faults [1], [2]. OQA parameters such as breakdown voltage, moisture, neutralization value (NV), interfacial tension, and colour provide complementary information about insulation-fluid degradation [3], [4]. Furan analysis, especially 2-furfural, is commonly associated with paper-insulation ageing [5].

Health-index methods integrate these diagnostic channels into an asset-level condition indicator. Early approaches combined condition factors, scores, and weights derived from expert knowledge and operational practice [8-13]. These methods are useful because they preserve physical interpretability. However, their rule-based scoring structure can become restrictive when diagnostic indicators interact nonlinearly or when different assets exhibit different ageing trajectories.

ML methods have been increasingly used for asset condition assessment because they can learn nonlinear functions from data. Random forests and gradient boosting provide robust baselines for tabular prediction [16], [17] while AdaBoost, support vector regression, and k-nearest-neighbour models provide complementary comparisons [18], [19], [23]. Modern boosting frameworks such as XGBoost, LightGBM, and CatBoost are particularly suitable for mixed-scale engineering diagnostics because they handle nonlinear feature interactions efficiently [20-22]. DL methods can model more complex functions, but they typically require careful optimization and regularization [24-26], [36-38]. Sequence models such as LSTM, GRU, Transformers, and TCNs are designed for ordered data, although their usefulness depends on sufficiently long and informative temporal histories [27-30].

Liquid time-constant networks (LTCs) are continuous-time recurrent neural models that adapt their hidden-state dynamics through input-dependent time constants [31], [32]. Neural circuit policies and closed-form continuous-time models further demonstrate the relevance of liquid and continuous-time neural models for dynamic systems [33], [34]. For transformer condition monitoring, liquid neural networks based on liquid time-constant dynamics (LTC-LNNs) are attractive because oil diagnostic records are irregularly sampled and may contain short histories. This motivates the sequence-learning experiment in this study.

III. Materials and Methods

The study used a model-ready transformer oil diagnostic dataset containing 3,392 actual records, excluding the Excel header row. The diagnostic inputs consisted of 13 parameters: H2, CH4, CO, CO2, C2H4, C2H6, C2H2, dielectric breakdown, moisture, neutralization value (NV), interfacial tension (IFT), colour, and 2FAL. The supervised output was Real_HI%, the reference health index (HI), calculated using a conventional weighted health-index procedure. For maintenance-oriented evaluation, continuous HI values were mapped into five condition classes: Good ($80 < HI \leq 100$), Acceptable ($60 < HI \leq 80$), Need Caution ($40 < HI \leq 60$), Poor ($20 < HI \leq 40$), and Critical ($0 \leq HI \leq 20$). Identifier fields were not used as prediction features; Serial No. was used only to define transformer-level splits and repeated histories.

Three experiments were implemented. Experiment 1 evaluated static ML models using single oil-test records. Experiment 2 evaluated static DL models using the same single-record structure. Experiment 3 evaluated variable-length sequence DL models using transformers with at least two repeated oil-test samples. For a transformer with n chronological records, $n-1$ sequences were generated, beginning with the second record. Each sequence used all records from the first sample to the current sample and predicted the current Real_HI%. The time interval between consecutive oil-test records was included as an additional temporal feature for sequence modelling.

All experiments used transformer-level splitting so that records from the same transformer were not shared across training, validation, and test partitions. This design is important because repeated samples from one transformer are statistically dependent and may otherwise inflate the apparent predictive performance. Feature scaling was fitted on the training set only. Missing diagnostic feature values in the prepared dataset were handled using median imputation where required. The overall experimental workflow is illustrated in Fig. 1. The diagnostic variables and their roles are summarized in Table I, while the dataset composition and transformer-level splits are presented in Table II. The supervised THI target distribution and the distribution of repeated oil-test records per transformer are shown in Fig. 2 and 3, respectively.

TABLE I. Diagnostic Variables used in the Study

Group	Variables	Purpose
DGA gases	H2, CH4, CO, CO2, C2H4, C2H6, C2H2	Internal electrical and thermal fault indicators
Oil quality	Dielectric breakdown, moisture, neutralization value, interfacial tension, colour	Insulating-oil degradation and dielectric condition
Paper insulation	2FAL	Cellulose ageing indicator
Target	Real_HI%	Supervised transformer health index output
Identifier for split	Serial No. / Transformer_ID	Used only for leakage-safe grouping; not used as a feature

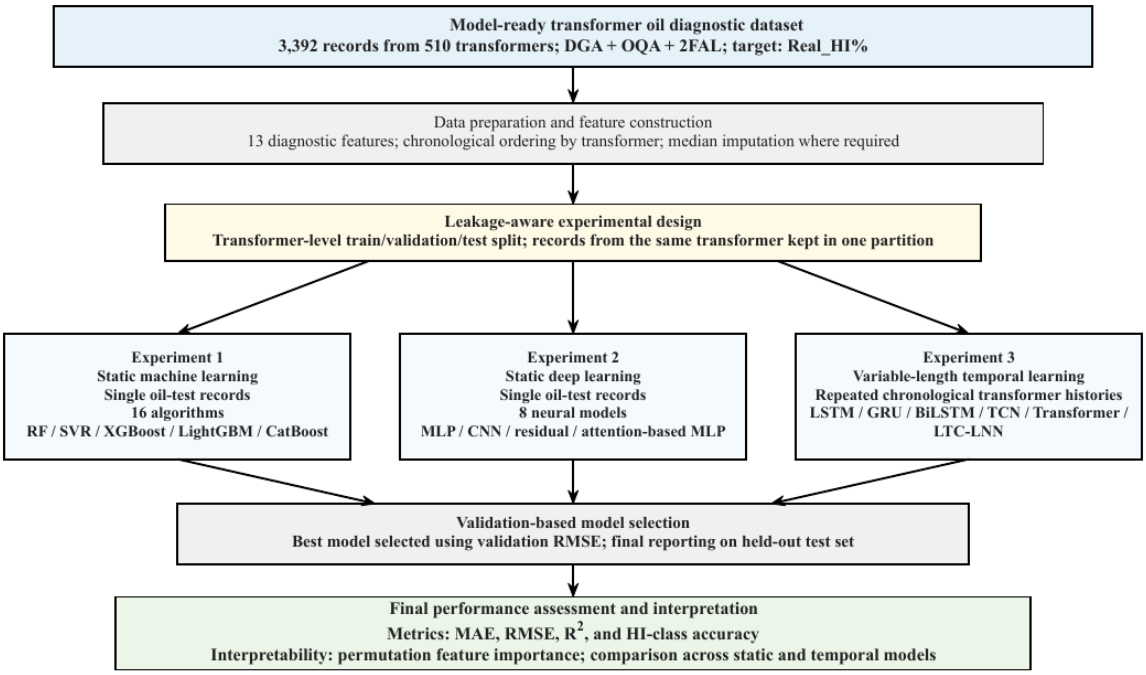

Fig. 1. Overall framework of the three-level benchmarking design.

TABLE II. DATASET AND SPLIT SUMMARY

Component	Unit	Value	Description
Static ML and Static DL	Records	3392	510 transformers; 13 diagnostic features; 3,392 records retained
Static train split	Records/transformers	2352 / 357	Transformer-level split
Static validation split	Records/transformers	489 / 76	Transformer-level split

IV. Modeling Framework

Experiment 1 trained 16 static ML regressors: dummy mean baseline, linear regression, ridge, lasso, elastic net, k-nearest neighbours, support vector regression, decision tree, random forest, extra trees, gradient boosting, AdaBoost, histogram gradient boosting, XGBoost, LightGBM, and CatBoost. The model set was designed to cover classical linear baselines, kernel learning, tree ensembles, and modern gradient-boosting frameworks [16-23]. The best model was selected using validation RMSE, and all models were also evaluated on the held-out test set.

Experiment 2 trained eight static DL models: MLP-ANN, deep MLP, regularized MLP, residual MLP, wide-deep MLP, feature-attention MLP, 1D-CNN, and CNN-MLP hybrid. The feed-forward architectures were motivated by standard back-propagation and deep-learning principles [24-26], while the residual and regularized designs used skip connections, dropout, and batch normalization to improve trainability and reduce overfitting [39], [36], [38]. Inputs were scaled using statistics from the training set only, the target was scaled to [0, 1], and Adam-based optimization with early stopping and learning-rate reduction was used for neural training [36].

Experiment 3 trained variable-length sequence models on repeated transformer histories: LSTM, GRU, BiLSTM, Transformer encoder, temporal convolutional network (TCN), and liquid time-constant neural network (LTC-LNN) variants U32 and U64. LSTM and GRU were included as recurrent baselines for ordered diagnostic histories [27], [28], the Transformer encoder represented attention-based sequence modelling [29], and TCN represented convolutional temporal modelling [30]. The time gap between consecutive samples was added as an additional sequence feature, increasing the sequence input size from 13 to 14. The LTC-LNN models used the ncps.torch implementation and were motivated by liquid time-constant, neural circuit policy, closed-form continuous-time, and neural ordinary differential equation concepts [31-35, 40].

A. Deep Learning Hyperparameter Configuration

To improve reproducibility, the architectural and training configurations used in the static and sequence deep learning experiments are summarized below. For the static deep learning experiment, the input features were scaled using statistics fitted on the training set only, the target was scaled to [0, 1], and Adam optimization with early stopping and learning-rate reduction was used. The principal architecture and training settings are summarized in Table III.

TABLE III. Static Deep Learning Model Configurations

Model	Architecture	Dropout	Initial LR
MLP-ANN	Dense 64-32-16-1	None	0.001
Deep MLP	Dense 128-64-32-16-1	None	0.001
Regularized MLP	Dense 128-64-32-1 + BatchNorm	0.25	0.001
Residual MLP	64-unit residual blocks -> Dense 32-1	None	0.001
Wide-Deep MLP	Deep 128-64-32 + linear wide branch	0.20	0.001
Feature-Attention MLP	13-unit attention gate -> 128-64-32-1	0.20	0.001
1D-CNN	Conv1D 32 -> Conv1D 64 -> GAP -> Dense 32-1	None	0.001
CNN-MLP Hybrid	Conv1D 32 -> Conv1D 64 -> Dense 64-32-1	0.20	0.001

All static deep learning architectures used ReLU activation in the hidden layers and a linear output layer for regression. The saved training histories confirm an initial learning rate of 0.001 for all eight static DL models, with adaptive learning-rate reduction according to validation performance.

For the variable-length sequence experiment, each time step contained 14 input features consisting of the 13 diagnostic variables and Time_Gap_Days. The principal sequence architectures, dropout rates, initial learning rates, and validation-selected training epochs are summarized in Table IV.

TABLE IV. SEQUENCE DEEP LEARNING MODEL CONFIGURATIONS

Model	Architecture	Dropout	Initial LR	Best epoch
LSTM	1-layer LSTM, hidden 64 -> Dense 32-1	0.10	0.001	78
GRU	1-layer GRU, hidden 64 -> Dense 32-1	0.10	0.001	117
BiLSTM	1-layer BiLSTM, 32/dir -> Dense 32-1	0.10	0.001	106
Transformer	2 layers; d_model 64; 4 heads; FFN 128 -> Dense 32-1	0.10	0.001	114
TCN	2 x 64 channels; k=3; dilations 1,2 -> Dense 32-1	0.10	0.001	52
LTC-LNN U32	32 liquid -> Dense 32-1; 6 ODE unfolds	0.10	0.001	276
LTC-LNN U64	64 liquid -> Dense 32-1; 6 ODE unfolds	0.10	0.0005	282

The recurrent baselines used one recurrent layer followed by a 32-unit dense regression head. The Transformer Encoder used two encoder layers (d_model = 64, four attention heads, and a feed-forward dimension of 128), whereas the TCN used two 64-channel temporal blocks with kernel size 3 and dilations of 1 and 2. All sequence configurations used a dropout rate of 0.10. The LTC-LNN U32 and U64 used six ODE unfolding steps. Model selection was based on the lowest validation RMSE, and the corresponding best validation checkpoint was retained for final evaluation.

B. Additional Evaluation Protocols

To quantify uncertainty in the comparison between the leading static ML models, a paired transformer-level bootstrap analysis with 10,000 resamples was performed on the held-out test set. Transformers, rather than individual records, were resampled with replacement to preserve the dependence among repeated measurements from the same transformer. The bootstrap distributions were used to derive 95% confidence intervals (CIs) for the RMSE values of XGBoost and CatBoost and for their paired RMSE difference. Statistical distinguishability was assessed at the 0.05 significance level based on whether the 95% CI of the paired RMSE difference excluded zero.

Computational efficiency was also evaluated for four representative models: XGBoost, CatBoost, MLP-ANN, and LTC-LNN U32. XGBoost represented the static ML model with the lowest test RMSE, CatBoost represented the validation-selected static ML model, MLP-ANN represented the best static DL model, and LTC-LNN U32 represented the best variable-length sequence DL model. All runtime measurements were obtained in the same CPU-only environment using an Intel Xeon processor at 2.20 GHz with 12.67 GB RAM. Wall-clock training time, average inference latency, peak additional resident memory above the process baseline, and serialized model-plus-preprocessing storage size were recorded. Neural-network trainable parameters were counted directly from the implemented architectures. A fixed FLOP count was reported only where it was technically meaningful; for tree ensembles, computation depends on tree traversal, while for LTC-LNN it depends on variable sequence length and the number of ODE unfolding steps. Consequently, structural complexity is reported for these models instead of a potentially misleading fixed FLOP estimate.

Residual analysis was also performed for representative models from the three experimental groups. Residuals were defined as the actual HI minus the predicted HI. For each model, the mean residual was used to assess systematic prediction bias, while the residual standard deviation and variance were used to characterize error dispersion. Tail and worst-case behavior were quantified using the 95th percentile of the absolute error and the maximum absolute error. Because the evaluated models generate deterministic point predictions at inference, a per-sample predictive variance is not intrinsically available; therefore, residual variance across held-out observations was used as an empirical measure of prediction variability. Condition-class-specific errors were also examined to identify whether performance degraded across different HI operating ranges.

To examine dependence among the diagnostic predictors, Pearson correlation analysis and variance inflation factor (VIF) diagnostics were performed on the 13 model inputs. Pairwise correlation coefficients were used to identify strongly related diagnostic variables, while VIF quantified the extent to which each predictor could be linearly explained by the remaining inputs. VIF values above 5 were treated as indicating elevated multicollinearity and values above 10 as indicating severe multicollinearity. Because the benchmarking framework intentionally retained the complete set of physically meaningful DGA, oil-quality, and furan indicators, correlated variables were not removed solely based on these diagnostics; instead, the resulting dependence was considered when interpreting feature-importance rankings.

To assess prediction confidence for the validation-selected static ML model, a post-hoc prediction-interval calibration analysis was performed using the validation and test partitions. Absolute prediction errors from the 489-record validation set were used to determine finite-sample residual quantiles for nominal 90% and 95% prediction intervals. For a test prediction, the corresponding calibrated residual quantile was added to and subtracted from the point prediction, with interval limits restricted to the valid HI range of 0-100%. The resulting intervals were evaluated on the held-out 551-record test set by comparing their nominal coverage levels with the empirical proportion of true HI values contained within the intervals. Because the validation partition was also used for model selection, these intervals are

interpreted as an empirical post-hoc uncertainty assessment rather than a formal deployment guarantee.

V. RESULTS

The test performance of the leading static ML models is summarized in Table V.

TABLE V. TOP STATIC ML MODELS RANKED BY TEST RMSE

Model	MAE	RMSE	R^2	HI acc.
XGBoost	2.5759	3.4254	0.9780	88.20%
LightGBM	2.5813	3.5213	0.9767	87.48%
CatBoost	2.6569	3.6017	0.9757	86.39%
Hist. Gradient Boosting	2.7084	3.6870	0.9745	86.21%
Gradient Boosting	3.1522	4.1146	0.9683	84.21%
Random Forest	3.6697	5.0080	0.9530	82.58%
Extra Trees	4.1695	5.6000	0.9412	80.04%
SVR-RBF	5.1564	6.8787	0.9113	75.50%
Decision Tree	5.0136	7.9868	0.8804	78.22%
AdaBoost	6.6450	8.0613	0.8781	71.14%

The static ML experiment produced the strongest observed point-estimate results. CatBoost was selected by validation RMSE, achieving validation RMSE of 3.7092 and validation R^2 of 0.9706. On the held-out test set, the validation-selected CatBoost model achieved MAE of 2.6569, RMSE of 3.6017, R^2 of 0.9757, and HI-class accuracy of 86.39%. XGBoost achieved the lowest observed test RMSE among all ML models at 3.4254, with R^2 of 0.9780 and HI-class accuracy of 88.20%.

To determine whether the observed difference between XGBoost and CatBoost reflected a statistically meaningful performance improvement, a paired transformer-level bootstrap analysis with 10,000 resamples was conducted on the held-out test set. XGBoost achieved a test RMSE of 3.4254 with a 95% bootstrap CI of 3.1391-3.7030, whereas CatBoost achieved an RMSE of 3.6017 with a 95% CI of 3.1828-4.0522. The paired RMSE difference (XGBoost - CatBoost) was -0.1763, with a 95% CI of -0.5723 to 0.1423 and a two-sided bootstrap p-value of 0.3816. Because the confidence interval for the paired difference included zero and $p > 0.05$, the lower point-estimate RMSE obtained by XGBoost was not statistically distinguishable from that of CatBoost at the 95% confidence level. Therefore, XGBoost should be interpreted as having the lowest observed test RMSE rather than demonstrating statistically significant superiority over CatBoost. The corresponding confidence intervals are summarized in Table X.

The strong performance of gradient-boosted tree models is consistent with the structure of the problem. The supervised THI target was derived from diagnostic factors with nonlinear thresholds, weighted combinations, and class boundaries. Tree boosting can represent such piecewise relationships efficiently, which explains why CatBoost, XGBoost, and LightGBM achieved lower errors than linear models, SVR, KNN, and standalone neural models. The static ML test RMSE comparison is shown in Fig. 4, while the agreement between the actual and predicted THI values for the validation-selected static ML model is illustrated in Fig. 5.

The test performance of the evaluated static DL models is presented in Table VI.

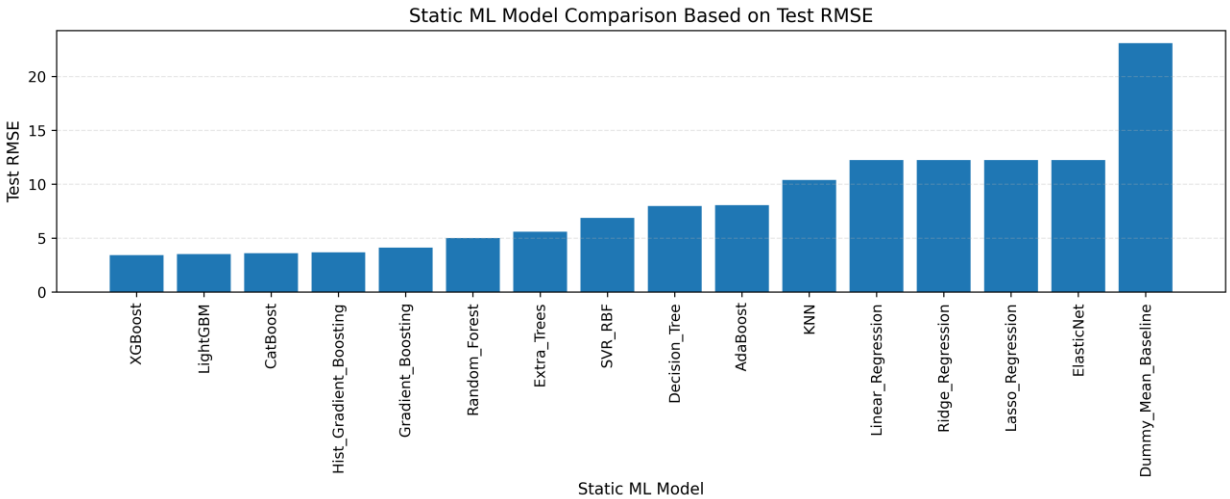

Fig. 4. Static ML model comparison based on test RMSE.

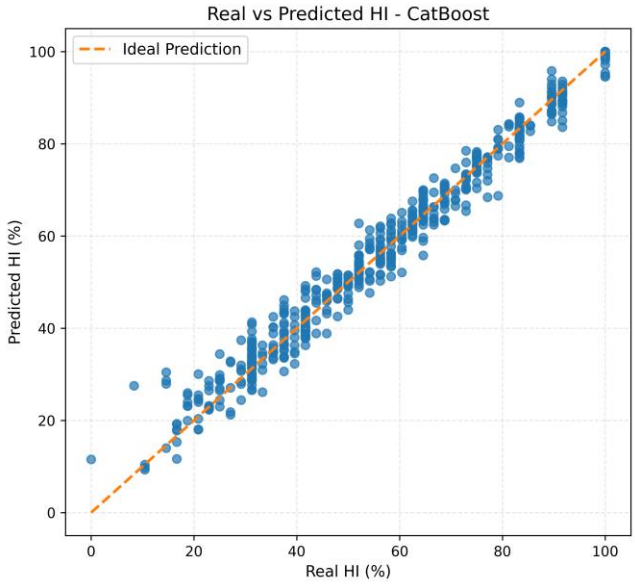

Fig. 5. Real versus predicted THI for the validation-selected static ML model.

TABLE VI. STATIC DL MODELS RANKED BY TEST RMSE

Model	MAE	RMSE	R^2	HI acc.
MLP-ANN	4.7676	6.4480	0.9220	79.49%
Deep MLP	8.7559	10.9349	0.7758	59.35%
Feature-Attention MLP	8.4871	11.0802	0.7698	60.62%
Residual MLP	11.5511	15.1814	0.5678	50.82%
1D-CNN	12.6159	15.7276	0.5362	43.01%
Wide-Deep MLP	13.3638	17.3844	0.4333	46.28%
Regularized MLP	33.6164	39.2058	-1.8824	12.34%
CNN-MLP Hybrid	47.0373	51.3838	-3.9511	3.81%

The best static DL model was MLP-ANN, with a test MAE of 4.7676, RMSE of 6.4480, R^2 of 0.9220, and HI-class accuracy of 79.49%. Although this result confirms that neural networks can learn the THI mapping, static DL did not outperform the boosted tree models. In contrast, the Regularized MLP and CNN-MLP Hybrid produced negative R^2 values of -1.8824 and -3.9511, respectively, indicating that these architectures performed worse than a mean-target baseline on the held-out test set and failed to generalize effectively. This suggests that the additional architectural complexity and regularization were not beneficial for the present tabular THI prediction task. These models were retained for benchmarking completeness but were not considered suitable candidates for final model selection. Overall, deeper and more complex neural structures degraded performance, indicating that the available tabular dataset favors regularized, shallow nonlinear models over high-capacity neural architectures. The static DL test RMSE comparison is shown in Fig. 6, and the training and validation loss of the best static DL model is presented in Fig. 7.

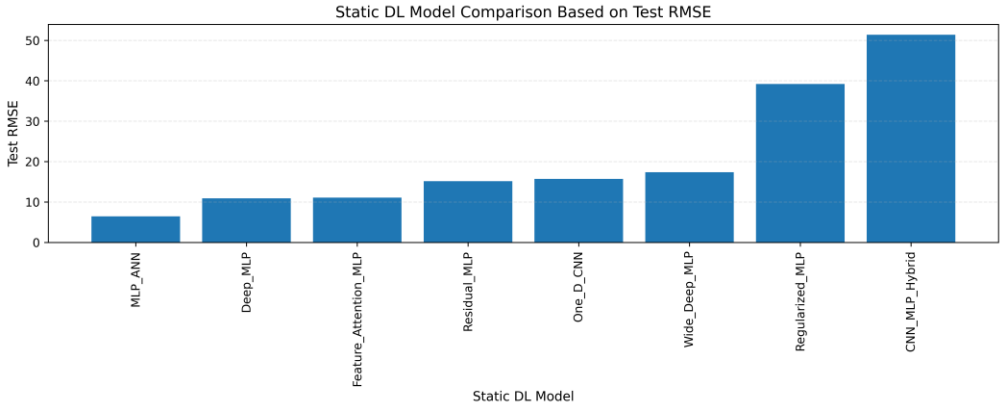

Fig. 6. Static DL model comparison based on test RMSE.

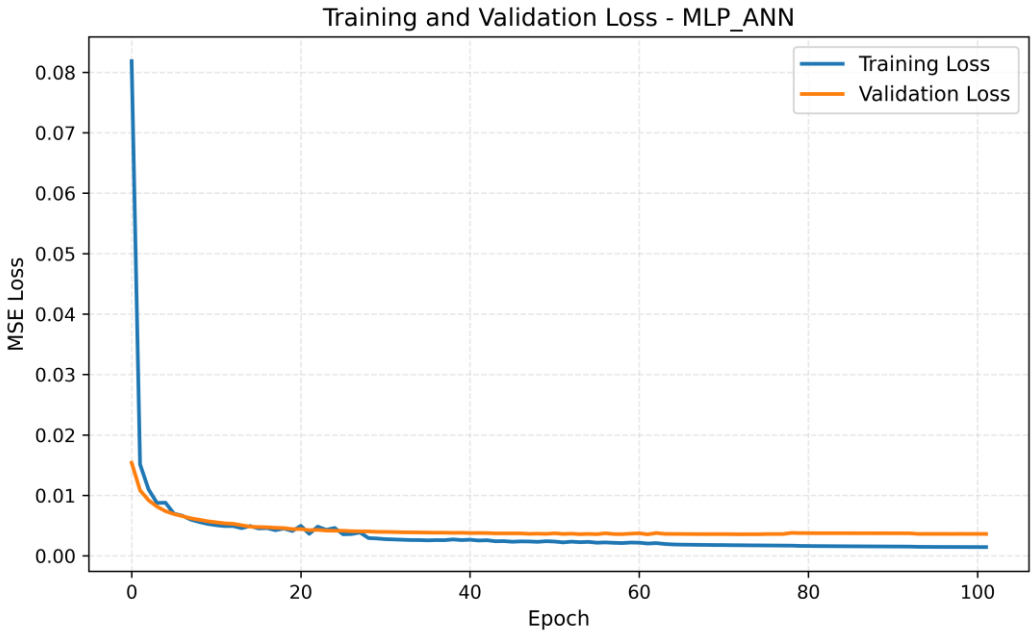

Fig. 7. Training and validation loss of the best static DL model.

The validation performance and best training epoch of each variable-length sequence model are summarized in Table VII.

Among the variable-length sequence DL models, LTC-LNN U32 achieved the best validation performance, with validation MAE of 3.8029, RMSE of 4.8595, R^2 of 0.9519, and HI-class accuracy of 82.18%. On the test set, the same model achieved MAE of 3.7766, RMSE of 4.8691, R^2 of 0.9567, and HI-class accuracy of 79.49%. These results show that LTC-LNN outperformed the LSTM, GRU, BiLSTM, TCN, and Transformer sequence baselines on the repeated-history subset.

TABLE VII. VARIABLE-LENGTH SEQUENCE DL MODELS RANKED BY VALIDATION RMSE

Model	Val. MAE	Val. RMSE	Val. R^2	Val. HI acc.	Epoch
LTC-LNN U32	3.8029	4.8595	0.9519	82.18%	276
LTC-LNN U64	4.0200	5.0791	0.9475	79.63%	282
Transformer	4.4164	5.5786	0.9367	74.77%	114
BiLSTM	5.3077	6.7855	0.9063	71.53%	106
GRU	5.1330	6.7932	0.9061	73.15%	117
TCN	5.3005	6.8272	0.9051	72.69%	52
LSTM	5.1759	6.8807	0.9036	73.15%	78

The sequence models were trained on a repeated-history subset containing 425 of the 510 transformers used in the static experiments, corresponding to a 16.7% reduction in the number of transformers. This restriction was necessary because temporal sequence construction requires at least two diagnostic records per transformer. Nevertheless, the repeated-history subset retained 3,305 of the original 3,392 records (97.4%). Thus, although 85 transformers were excluded from the sequence experiment, they accounted for only 87 records (2.6% of the complete dataset). The effect of this subset restriction on predictive performance cannot be isolated from the present experiments because the static and sequence models use different sample structures; a matched evaluation of all model groups on the same 425-transformer subset would be required to quantify this effect directly. Because the static and sequence experiments use different sample structures and held-out test sets, their performance metrics should be interpreted as descriptive cross-group comparisons rather than strictly paired comparisons. The sequence experiment therefore primarily evaluates the relative performance of temporal models under the same repeated-history setting. The validation RMSE comparison of the variable-length sequence models is shown in Fig. 8, while the actual and predicted THI values for the best sequence model are illustrated in Fig. 9. The overall comparison across the three modelling groups is summarized in Table VIII.

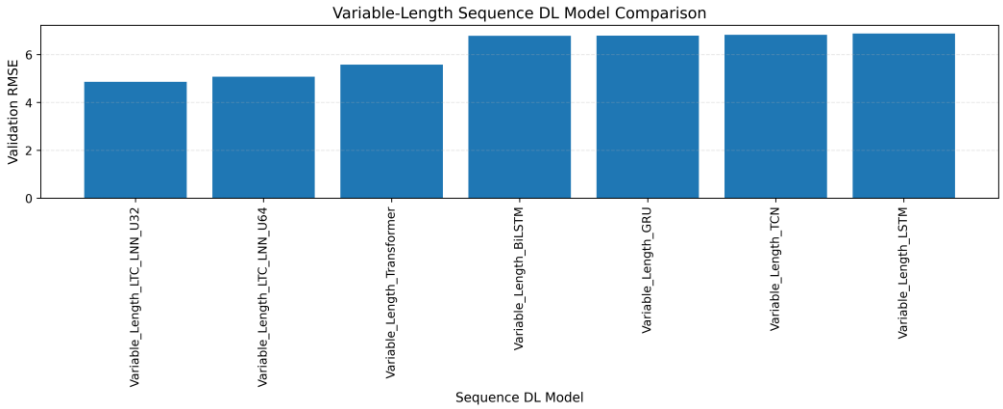

Fig. 8. Variable-length sequence DL model comparison based on validation RMSE.

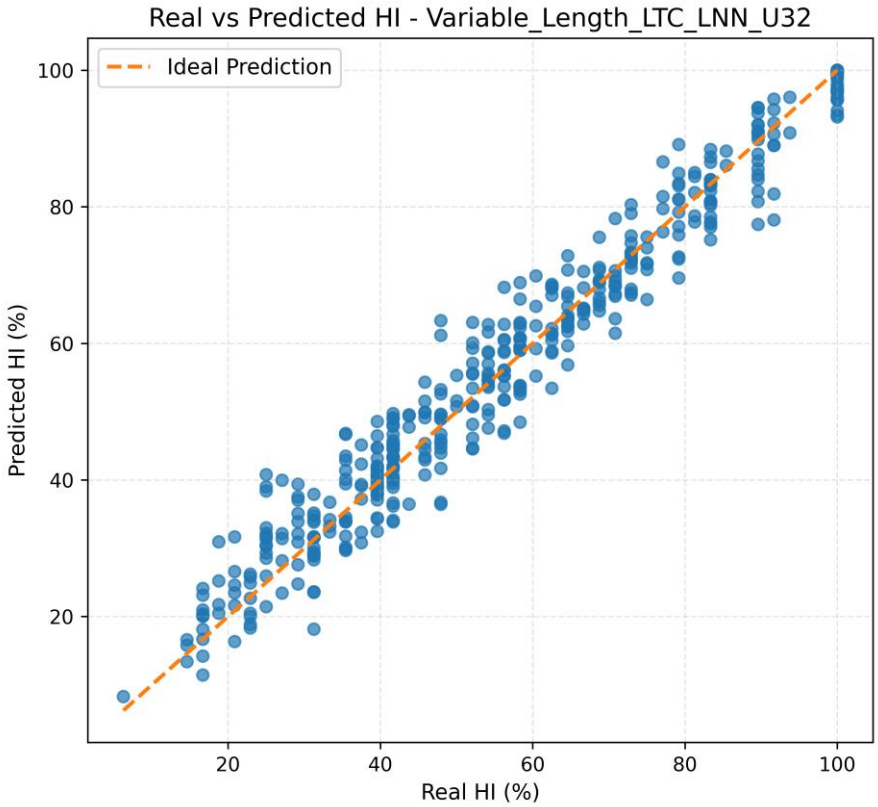

Fig. 9. Real versus predicted THI for the best variable-length sequence model.

TABLE VIII. OVERALL COMPARISON ACROSS MODELLING GROUPS

Model group	Test RMSE	Test R^2	Test HI acc.
Static ML (CatBoost, validation-selected)	3.6017	0.9757	86.39%
Static ML (XGBoost, lowest test RMSE)	3.4254	0.9780	88.20%
Static DL (MLP-ANN)	6.4480	0.9220	79.49%
Sequence DL (LTC-LNN U32)	4.8691	0.9567	79.49%

The test RMSE values of the representative models from each experimental group are compared in Fig. 10. The ten most influential diagnostic variables identified by permutation feature importance are summarized in Table IX, and the corresponding feature-importance ranking is illustrated in Fig. 11.

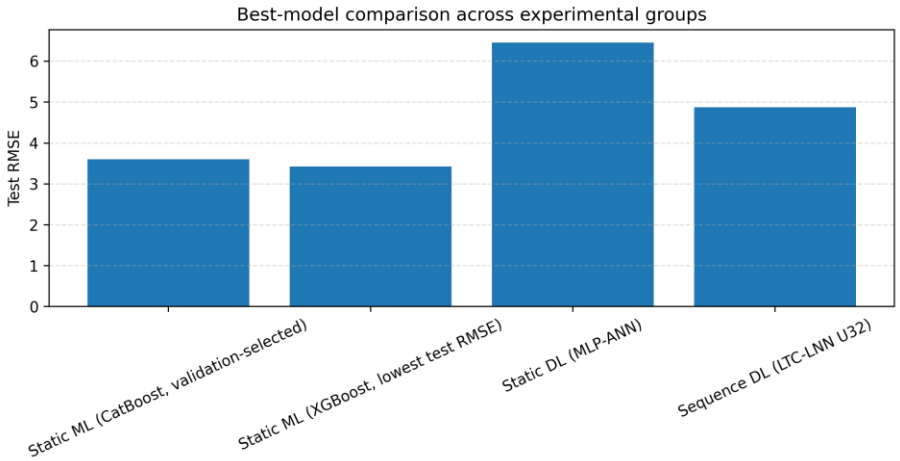

Fig. 10. Test RMSE comparison across best modelling groups.

TABLE IX. TOP 10 PERMUTATION FEATURE IMPORTANCE RESULTS FOR THE VALIDATION-SELECTED STATIC ML MODEL

Feature	Importance Mean	Importance SD
2FAL	0.2620	0.0111
C2H2	0.1681	0.0096
Dielectric Breakdown	0.0961	0.0040
C2H6	0.0676	0.0043
C2H4	0.0597	0.0038
Colour	0.0464	0.0037
Moisture	0.0378	0.0029
CO2	0.0355	0.0022
CH4	0.0305	0.0023
IFT	0.0246	0.0019

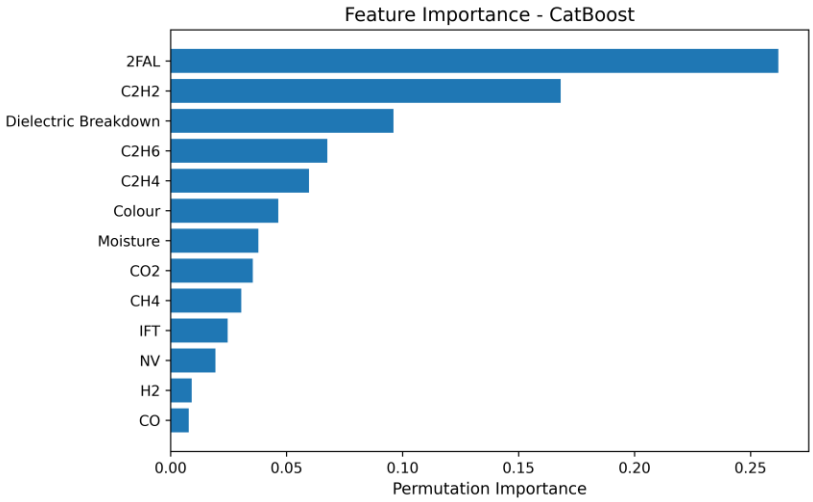

Fig. 11. Permutation feature importance for the validation-selected static ML model.

TABLE X. STATISTICAL UNCERTAINTY OF THE LEADING STATIC ML MODELS

Model	Test RMSE	95% CI
XGBoost	3.4254	3.1391-3.7030
CatBoost	3.6017	3.1828-4.0522

The paired RMSE difference (XGBoost - CatBoost) was -0.1763 (95% CI: -0.5723 to 0.1423; p = 0.3816).

The computational benchmark showed substantial differences among the representative models. XGBoost required 2.8939 s for training and 0.0352 ms per static record for inference, whereas CatBoost required 4.6119 s for training but

achieved the lowest inference latency at 0.0104 ms per record. MLP-ANN required 36.7382 s for training and 0.0126 ms per record for inference, with 3,521 trainable parameters and an approximate dense-layer cost of 6,816 FLOPs per input. In contrast, LTC-LNN U32 required 3625.3234 s for training and 1.6859 ms per variable-length sequence for inference, reflecting the higher computational cost of continuous-time sequence modelling with repeated ODE unfolding. Peak additional training RAM was 1.9297 MB for XGBoost, 3.1367 MB for CatBoost, 28.6406 MB for MLP-ANN, and 94.9414 MB for LTC-LNN U32. The corresponding serialized model-plus-preprocessing sizes were 0.9734, 0.6465, 0.0733, and 0.0423 MB, respectively. Thus, the static models provided substantially lower runtime requirements, while LTC-LNN incurred greater computational cost to model variable-length temporal histories. The computational-efficiency results are summarized in Table XI.

TABLE XI. COMPUTATIONAL EFFICIENCY OF REPRESENTATIVE MODELS

Model	Train time (s)	Inference (ms/input)	Peak add. train RAM (MB)	Model + prep. size (MB)	Complexity
XGBoost	2.8939	0.0352	1.9297	0.9734	600 trees; max depth 4
CatBoost	4.6119	0.0104	3.1367	0.6465	600 trees; depth 6
MLP-ANN	36.7382	0.0126	28.6406	0.0733	3,521 params; ~6,816 FLOPs/input
LTC-LNN U32	3625.3234	1.6859	94.9414	0.0423	7,165 params; 6 ODE unfolds; FLOPs sequence-dependent

Note: For XGBoost, CatBoost, and MLP-ANN, one input denotes one static diagnostic record; for LTC-LNN U32, one input denotes one variable-length diagnostic sequence. Peak additional inference RAM was 0.0039 MB for XGBoost and CatBoost and 0.0078 MB for MLP-ANN and LTC-LNN U32. Serialized storage values are framework-specific and should be interpreted as approximate deployment footprints. The MLP FLOP estimate covers dense-layer multiply-add operations; a single fixed FLOP value is not reported for the tree ensembles or variable-length LTC-LNN.

The residual analysis provided additional information beyond MAE, RMSE, and R^2. XGBoost showed the smallest overall systematic bias, with a mean residual of -0.1040, together with the lowest residual standard deviation (3.4269) and residual variance (11.7439) among the representative models. Its 95th-percentile absolute error was 7.3013, and its maximum absolute error was 11.6427. CatBoost also exhibited low average bias (-0.2885) and a residual standard deviation of 3.5933, although its maximum absolute error increased to 19.1718. MLP-ANN showed substantially greater error dispersion, with a residual standard deviation of 6.4523, residual variance of 41.6316, and maximum absolute error of 33.3333. LTC-LNN U32 produced an intermediate error spread, with a residual standard deviation of 4.8554 and maximum absolute error of 15.7975 on the repeated-history test subset. The leading gradient-boosted models had lower average errors, lower residual dispersion, and smaller extreme errors than the representative static neural model. The residual robustness metrics are summarized in Table XII.

TABLE XII. RESIDUAL ROBUSTNESS ANALYSIS OF REPRESENTATIVE MODELS

Model	Test n	Mean residual (bias)	Residual SD	Residual variance	95th pct. abs. error	Maximum abs. error
XGBoost	551	-0.1040	3.4269	11.7439	7.3013	11.6427
CatBoost	551	-0.2885	3.5933	12.9122	7.1036	19.1718
MLP-ANN	551	0.1455	6.4523	41.6316	11.8886	33.3333
LTC-LNN U32	429	-0.4344	4.8554	23.5745	9.7010	15.7975

Note: Residual = actual HI - predicted HI. A negative mean residual denotes a tendency to overestimate HI, whereas a positive mean residual denotes a tendency to underestimate HI. The sequence model was evaluated on the repeated-history test subset and therefore has a different test-sample count from the static models.

TABLE XIII. MULTICOLLINEARITY DIAGNOSTICS FOR THE 13 PREDICTOR VARIABLES

Predictor	VIF
C2H2	9.350
H2	9.049
NV	2.414
C2H4	2.301
Colour	2.176
CH4	1.958
IFT	1.823
CO2	1.635
Moisture	1.535
CO	1.516
Dielectric Breakdown	1.439
C2H6	1.396
2FAL	1.237

The correlation analysis identified several related diagnostic variables. The strongest Pearson correlation occurred between H2 and C2H2 (r = 0.9402). Other notable relationships included NV and Colour (r = 0.6711), CH4 and C2H4 (r = 0.6466), NV and IFT (r = -0.6072), IFT and Colour (r = -0.5414), CO and CO2 (r = 0.5150), and dielectric breakdown and moisture (r = -0.5048). The VIF analysis further showed elevated values for C2H2 (9.350) and H2 (9.049), whereas the remaining 11 predictors had VIF values between 1.237 and 2.414. These findings indicate that multicollinearity is concentrated mainly in the H2-C2H2 relationship rather than being widespread across the complete diagnostic feature set. No predictor exceeded a VIF of 10. The VIF results are summarized in Table XIII, while the corresponding Pearson correlation heatmap is shown in Fig. 12.

Prediction-confidence analysis was performed for the validation-selected CatBoost model using residual quantiles obtained from the validation set. The nominal 90% interval used a calibrated half-width of 6.2764 HI points and achieved an empirical test coverage of 92.92%, with a mean interval width of

12.2081 HI points. The nominal 95% interval used a half-width of 7.4494 HI points and achieved 95.83% empirical coverage, with a mean width of 14.4744 HI points. The observed test-set coverage was close to the nominal levels, showing that the residual-based intervals reasonably represented prediction uncertainty for the selected static model. However, condition-specific inspection showed that the 95% interval covered 76.19% of the 21 Critical-class test records, compared with 93.44-99.14% coverage across the other condition classes. This lower coverage in the small Critical-class subset indicates that prediction confidence is less uniform in the most severe condition region and should be considered when using model outputs for maintenance decisions. The prediction-interval calibration results are summarized in Table XIV.

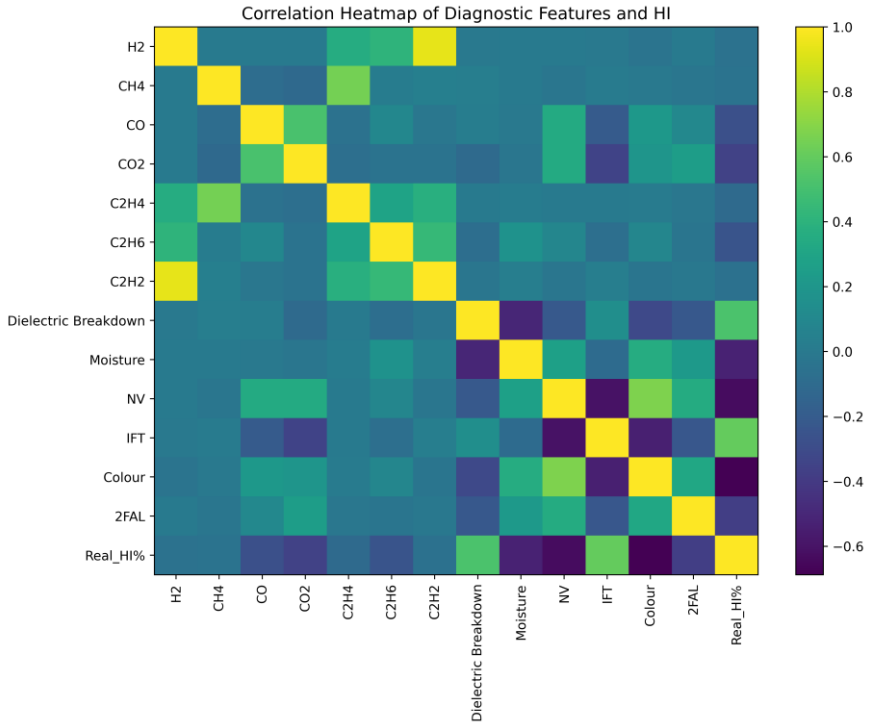

Fig. 12. Pearson correlation heatmap of the diagnostic features and transformer health index.

TABLE XIV. PREDICTION-INTERVAL CALIBRATION OF THE VALIDATION-SELECTED CATBOOST MODEL

Nominal interval	Calibrated half-width (HI points)	Empirical test coverage	Mean interval width (HI points)
90%	±6.2764	92.92%	12.2081
95%	±7.4494	95.83%	14.4744

VI. DISCUSSION

The main result of this study is that static gradient-boosting models provided the highest observed predictive performance for the available THI dataset. This does not mean that neural models are unsuitable for transformer health assessment; rather, it indicates that the target and input structure are mainly tabular and threshold-driven. The Real_HI% target is derived from conventional diagnostic scoring, and boosting models are well matched to this type of nonlinear but structured mapping. These findings identify gradient-boosted tree models as strong candidates for static THI prediction on the present dataset; however, broader deployment suitability should also consider statistical uncertainty, prediction confidence, computational requirements, and external validation.

Although XGBoost produced the lowest point-estimate test RMSE, the bootstrap analysis showed that its performance was not statistically distinguishable from that of CatBoost. This finding indicates that small differences among the leading gradient-boosted models should not be interpreted as definitive evidence of model superiority. The results instead support the broader conclusion that gradient-boosted tree models constitute a strong-performing model family for the present THI dataset, while the relative ranking of XGBoost and CatBoost remains subject to sampling uncertainty.

The negative R^2 values obtained by the Regularized MLP and CNN-MLP Hybrid indicate that these models failed to generalize effectively on the held-out test set. Their additional architectural complexity and regularization did not provide an advantage for the relatively low-dimensional tabular THI inputs and likely contributed to poorer generalization compared with the simpler MLP-ANN architecture. Consequently, both models performed worse than the mean-target baseline and were retained only for benchmarking completeness rather than final model selection. Although these results indicate architecture-specific generalization limitations, a dedicated ablation analysis would be required to isolate the individual contribution of each architectural component.

The feature-importance results are physically meaningful. 2FAL was the strongest predictor, reflecting the importance of paper-insulation ageing in the health-index target and the diagnostic role of furan compounds. C2H2 was also highly influential, which is consistent with the role of acetylene in severe electrical fault interpretation using gas-in-oil analysis. Dielectric breakdown ranked third, showing that insulation-oil dielectric strength remains a major driver of the overall THI. The appearance of moisture, colour, interfacial tension (IFT), and DGA gases among the influential predictors confirms that the model did not rely on a single diagnostic channel.

The correlation and VIF analyses show that the predictor set contains localized dependence, particularly between H2 and C2H2. This dependence does not invalidate the predictive comparison because the leading models are nonlinear tree-based ensembles rather than coefficient-based linear regressors. However, correlated predictors can share or redistribute model-based importance, and the importance assigned to an individual variable should therefore not be interpreted as an independent causal contribution. The complete diagnostic set was retained because the correlated variables represent distinct physical fault indicators and because most predictors exhibited low VIF values. Future studies could additionally evaluate grouped feature importance, dimensionality reduction, or correlation-aware feature selection when larger multi-utility datasets become available.

The variable-length liquid time-constant neural network (LTC-LNN) result is important because it demonstrates a temporal-learning route for repeated oil-test histories. Unlike fixed-window modelling, the variable-length design allows each transformer to use its available historical depth. For transformers with sparse histories, this design avoids discarding samples or over-padding long sequences. The strong validation and test performance of LTC-LNN suggests that continuous-time recurrent modelling is promising for irregularly sampled asset-condition data.

The computational results also highlight differences in the practical requirements of the models. XGBoost and CatBoost required only a few seconds of CPU training time and sub-0.04-ms inference per static record, indicating a favorable computational profile for single-record THI estimation. MLP-ANN also provided low inference latency and a compact parameterization, although its predictive accuracy was lower than that of the boosted tree models. LTC-LNN U32 had a small serialized model footprint but required substantially longer training time, higher peak training memory, and higher per-sequence inference latency because it processes variable-length histories through continuous-time recurrent dynamics and repeated ODE unfolding. Considering both predictive accuracy and computational cost, the boosted tree models therefore provide the strongest observed accuracy-efficiency trade-off for static THI prediction in the present CPU benchmark, whereas LTC-LNN remains a temporal alternative when repeated histories are available, and the additional computational cost is acceptable. Absolute timing values remain hardware- and software-dependent and should therefore be re-evaluated on the intended deployment platform.

Model performance also varied across the HI condition classes. The Critical class was particularly challenging for the static models: the mean residual was -2.7919 for XGBoost, -4.8594 for CatBoost, and -7.5747 for MLP-ANN, indicating a tendency to predict a healthier condition than the observed HI in this class. The corresponding Critical-class MAEs were 3.7153, 5.6887, and 8.9841, respectively. LTC-LNN U32 showed a Critical-class mean residual of -2.7867 and an MAE of 3.7690. This class-dependent behavior is important for maintenance applications because optimistic errors in severely degraded transformers may be more consequential than errors in healthier classes. Therefore, aggregate metrics should be interpreted together with residual and condition-specific analyses, particularly when considering safety-critical deployment.

The prediction intervals provide additional information about the uncertainty of the point predictions. For the validation-selected CatBoost model, the empirical coverage of the 90% and 95% intervals was 92.92% and 95.83%, respectively, suggesting that the calibrated residual bands broadly reflected the observed test uncertainty. Nevertheless, interval coverage was not uniform across health-condition classes. In particular, the Critical class showed lower 95% coverage, although this estimate was based on only 21 test records. This finding is important for safety-critical use because the most severe transformer conditions are precisely those for which overconfident predictions should be avoided. Accordingly, the reported prediction intervals should be treated as decision-support information rather than as a substitute for diagnostic testing, expert assessment, or utility-specific maintenance rules. Future work should evaluate dedicated calibration sets, class-conditional or transformer-level conformal methods, and external calibration on independent utility datasets.

A limitation of the present sequence experiment is that repeated histories were still relatively short for many transformers, and only transformers with at least two records could be used. Consequently, the sequence subset is smaller than the full static dataset. Future work should evaluate the framework on longer longitudinal histories, include load and maintenance information, and conduct external validation across different utilities or voltage classes.

Another methodological issue is that MAPE was not used as a primary discussion metric because some HI values were close to or equal to zero, making percentage errors unstable. Therefore, RMSE, MAE, R^2, and HI-class accuracy were emphasized as the main evaluation metrics. This is more appropriate for the present target distribution. A further limitation is that all experiments were conducted using a proprietary dataset from a single Malaysian utility. Consequently, the reported performance may reflect utility-specific transformer populations, operating practices, diagnostic procedures, and voltage classes. External validation using independent datasets from other utilities and transformer populations is therefore required before the findings can be generalized more broadly.

The uncertainty analysis also shows that the numerical ranking of the models should be interpreted with caution. Although XGBoost achieved the lowest point-estimate test RMSE, its paired RMSE difference relative to the validation-selected CatBoost model was -0.1763, with a 95% bootstrap confidence interval of -0.5723 to 0.1423 and a two-sided bootstrap p-value of 0.3816. Because the confidence interval included zero and $p > 0.05$, the observed difference was not statistically

distinguishable at the 95% confidence level. In addition, prediction-interval analysis for CatBoost produced overall empirical coverages of 92.92% and 95.83% for the nominal 90% and 95% intervals, respectively, while coverage for the Critical condition subgroup was lower. These findings indicate that aggregate accuracy alone is insufficient to justify a definitive deployment ranking and that uncertainty, condition-specific reliability, computational cost, and external validation should be considered together when selecting models for operational use.

VII. Conclusion

This study presented a comprehensive benchmarking framework for transformer health index prediction using dissolved gas analysis, oil-quality, and furan diagnostic records. Three experimental groups were evaluated: static machine learning, static deep learning, and variable-length sequence deep learning. For the present single-record tabular dataset, gradient-boosted tree models achieved the strongest observed predictive performance among the evaluated model families. XGBoost obtained the lowest point-estimate test RMSE of 3.4254, while CatBoost was selected based on validation RMSE. However, the paired transformer-level bootstrap analysis showed that the XGBoost-CatBoost RMSE difference was not statistically significant (difference = -0.1763, 95% CI: -0.5723 to 0.1423; p = 0.3816). Therefore, the small numerical difference between these models should not be interpreted as definitive evidence that one is universally superior to the other.

Among the static deep learning models, MLP-ANN achieved the strongest performance, whereas LTC-LNN U32 provided the best result among the variable-length sequence models and demonstrated the potential of continuous-time learning for irregularly sampled repeated transformer histories. Prediction-confidence analysis of the validation-selected CatBoost model further showed empirical test coverages of 92.92% and 95.83% for nominal 90% and 95% prediction intervals, respectively. Nevertheless, lower coverage in the Critical condition subgroup highlights the need for caution when model outputs are used in high-consequence maintenance decisions.

Overall, the results support gradient-boosted tree models as strong candidates for static THI prediction within the evaluated dataset rather than establishing a universally preferred deployment model. Model selection for operational use should consider predictive accuracy together with statistical uncertainty, prediction confidence, computational requirements, and the consequences of errors in critical condition classes. External validation using independent utilities, transformer populations, and voltage classes, together with richer longitudinal histories and additional operating and maintenance information, is required before broader deployment recommendations can be made.

Acknowledgment

The authors gratefully acknowledge the utility company in Malaysia for providing the diagnostic dataset and Universiti Teknikal Malaysia Melaka (UTeM) for its support. This research was funded by the Ministry of Higher Education (MOHE), Malaysia, through the Fundamental Research Grant Scheme (FRGS), FRGS/1/2024/TK07/UTEM/02/24 (MOHE grant code) and FRGS/1/2024/FTKE/F00579 (UTeM grant code).

ROMBandAR: Development of an AR-Based Wrist ROM Assessment Prototype for Rehabilitation

Nurul Aimi Johan, Wan Rizhan, Normala Rahim
Faculty of Informatics and Computing, Universiti Sultan Zainal Abidin, Besut, Malaysia

***Abstract*—Wrist range of motion (ROM) assessment is important in rehabilitation because wrist movement supports hand positioning and functional hand use. Limited wrist movement can be caused by a variety of conditions, including neurological conditions such as stroke and musculoskeletal or orthopedic injuries such as distal radius fractures or tendon repairs. In current practice, wrist ROM is commonly assessed using a goniometer. Although the tool is widely used, the reading still depends on correct positioning, therapist handling, and visual judgment. Augmented reality has the potential to support this process because it can show digital feedback together with the real wrist movement. However, AR is still not widely explored for wrist-specific ROM assessment compared with virtual reality, robotics, and wearable or sensor-based systems. This study presents the development of ROMBandAR, an AR-based wrist ROM assessment prototype for rehabilitation. The prototype uses a wrist armband as a model target for AR tracking. The armband was first scanned using KIRI Engine software, then trained using Vuforia Model Target Generator, and lastly imported into Unity for AR integration. MediaPipeUnityPlugin was also integrated to show hand landmarks on the detected hand via the smartphone camera. After that, custom C# scripts were developed to display wrist ROM readings, classify movement, show real-time feedback, save assessment readings, and support report submission for therapist review. This study follows the Design Science Research Methodology and, at this stage, focuses on development-level testing. Three test cases were carried out: device compatibility testing, application functionality testing, and screenshot-based ROM reading consistency testing. The results show that ROMBandAR can run on different Android devices, successfully detect the wrist armband, display hand landmarks, show ROM readings, and save assessment results. These findings provide an early foundation for future evaluation of the proposed framework, especially the extrinsic feedback provided during wrist ROM assessment. Repeated trials, inter-rater reliability, direct goniometer measurement of the wrist, and further evaluation of the feedback were not part of this development stage and are planned as future work.**

Keywords*—ROMBandAR; augmented reality; wrist range of motion; rehabilitation; pose estimation; MediaPipe; vuforia; extrinsic feedback

I. INTRODUCTION

Rehabilitation helps people recover movement and regain the ability to carry out daily activities after an injury, illness, or medical condition. For the upper limb, recovery depends on how well the shoulder, elbow, wrist, and hand work together. Wrist movement can become limited in different rehabilitation cases. For example, in neurological rehabilitation, stroke can reduce upper limb motor control and affect simple daily activities such as holding, grasping, and object manipulation [1]-[3]. On the other hand, in musculoskeletal or orthopaedic rehabilitation, wrist stiffness and loss of motion can also follow distal radius fracture and tendon injury or repair [4]-[6]. So, although the causes are different, therapists still need to observe wrist movement and monitor recovery of their patients over time.

Wrist range of motion (ROM) is commonly measured using a goniometer [7]. A goniometer is an angle-measuring protractor that has extending ruler-like arms, and it comes in different varieties for different body parts. This method is simple and widely used in rehabilitation practice and is still the gold standard today. However, the accuracy and reliability still depend on correct wrist positioning and therapist handling. This is because wrist assessment can also be sensitive and less reliable because sometimes the joint is small, so the hand position can change easily during measurement. When the assessment is repeated across sessions, small differences in goniometer placement or wrist posture may then affect the final reading.

Therefore, different technologies have been introduced to support upper limb rehabilitation. This includes technologies like virtual reality, robotic and haptic devices, wearable or sensor-based systems, telerehabilitation, and augmented reality [8]-[21]. Virtual reality and robotic systems often focus on repeated exercise or physical assistance, while wearable and sensor-based systems collect movement data. AR takes a different approach because it functions by combining the real world with the virtual overlay. This ensures the real limb is always visible, and it's possible to place digital information in the same view. So, for wrist ROM assessment, the user can see the actual wrist together with the angle and movement feedback.

In this study, AR refers to the digital labels and information that appear over the smartphone camera view. ROMBandAR uses model-based AR, which means that the system recognises a physical object from a trained three-dimensional model. In this case, the wrist armband acts as the model target. Once Vuforia detects it, the application uses the armband as a reference for placing the AR content around the wrist [22], [23], [24]. MediaPipe performs a separate task by detecting the hand landmarks needed for the wrist angle calculation [25]-[27].

Besides model-based AR, pose estimation is the part of the prototype that identifies key points from the camera image and follows how those points change during movement. For the hand, MediaPipe estimates 21 landmarks at the wrist, palm, and finger joints [25], [26]. ROMBandAR uses these landmarks as movement references, but the landmark display alone does not provide a clinical ROM value. Hence, custom calculation is

needed; with the armband reference, the selected assessment plane, and the neutral reset to reset the hands' position, patients' hands can be detected; thus, the angle is shown to the user accurately in the form of feedback.

ROMBandAR also applies the feedback theory. There are two types of feedback, intrinsic and extrinsic. Extrinsic feedback is information provided by an external source to help the user understand a movement or its result [28]-[30]. The angle reading provides knowledge of results because it shows the measured outcome. The movement label, guidance panel, and AR labels provide knowledge of performance because they show how the wrist is moving. The feedback appears during the assessment, so the user can view it while performing the movement.

This study presents ROMBandAR, an AR-based prototype for wrist ROM assessment in rehabilitation. The intended scope includes neurological and musculoskeletal or orthopaedic rehabilitation, with stroke, distal radius fracture, and tendon injury or repair as possible future case groups. The prototype is not tied to one diagnosis because it measures wrist movement rather than the cause of the impairment.

The prototype uses a wrist armband as the model target for AR tracking. The armband is scanned using KIRI Engine, trained using Vuforia Model Target Generator, and imported into Unity. MediaPipeUnityPlugin is then integrated into Unity to display the hand landmarks and support the wrist movement output. From there, ROMBandAR provides real-time extrinsic feedback in the form of angle output, movement labels, ROM guide popups, and necessary AR labels.

This study aims to report the development phase of ROMBandAR and its early functional evaluation. At this stage, the study does not claim clinical effectiveness or full measurement validation.

The main contribution of this study is a simple development workflow for an AR-based wrist ROM assessment prototype that can later be examined in different real rehabilitation settings. The study also reports the early testing of the user interface, core AR and MediaPipe functions, screenshot-based ROM reading consistency, and an assessment library with a therapist submission function.

The rest of this study is organized as follows. Section II compares existing rehabilitation technologies and explains the gap found for this project. Section III describes the research design, proposed framework, system development, and evaluation procedure. Section IV presents the prototype implementation and test results. Section V discusses the findings, significance, and limitations, while Section VI presents the conclusion and future work.

II. Related Works

This section compares the main technologies that have been used in upper limb rehabilitation. The comparison looks at how each technology presents the rehabilitation task, how it obtains movement information, and what hardware it requires. Their suitability for wrist ROM assessment is also considered.

A. Virtual Reality-Based Rehabilitation

Virtual reality usually conducts rehabilitation activities in a simulated environment. This setup allows patients to easily repeat movements, interact with different tasks, and progress through several levels of difficulty [8]-[10]. However, most VR studies use these activities for training and motor recovery rather than for directly measuring an assessment. Fully immersive VR can also hide the user's own body from their view; thus, it is difficult to feel the real objects during rehab. This also becomes a limitation when the therapist needs to observe the actual joint position of their patients during the assessment and to control what the patient sees.

B. Robotic, Haptic, Wearable, and Sensor-Based Systems

Robotic and haptic systems are commonly used when the upper limb movement needs to be assisted, resisted, or guided, as not every patient can do active rehab. Orthoses and wearable robots may also support the wrist and hand during training [11]-[14]. Sensor-based and telerehabilitation systems take a different approach by recording kinematic data and allowing movement to be monitored outside the clinic [15]. These technologies can provide useful and objective information. Even so, the setup often involves additional hardware, calibration, or equipment attached to the limb, which causes discomfort and is difficult to set up. For a simple wrist ROM check, this type of setup may be too bulky and more than what is needed and is not accessible to all.

C. Augmented Reality Systems

Augmented reality keeps the real environment visible and adds digital information to it. Existing studies have used AR for rehabilitation, hand motor training, real-time upper limb kinematic feedback, and clinical data visualisation [16]-[21]. This gives AR an advantage for wrist assessment because the user and therapist can still see the real wrist while viewing movement information. However, most existing AR systems focus on exercise guidance, general upper limb movement, or data visualisation. Few studies examine a mobile wrist-specific assessment that combines a physical model target, hand landmarks, real-time angle feedback, saved results, and therapist submission.

D. Camera-Based Pose Estimation and Hand Landmark Tracking

Camera-based pose estimation provides another way to obtain movement information without attaching a separate sensor to the limb. MediaPipe first locates the hand and then estimates 21 landmark points from the camera image [25], [26]. These points can be followed from frame to frame and used in a separate angle calculation. However, hand landmarks are not the same as a clinical ROM measurement. Even so, the detected landmark positions are not always stable. They may shift when part of the hand is covered, when the camera angle changes, or when the tracking briefly loses confidence.

Besides, MediaPipeUnityPlugin makes it possible to run this landmark pipeline inside Unity [27]. This provides a practical way to extend the hand landmark pipeline for use in a wrist ROM assessment application. For the current prototype, MediaPipeUnityPlugin was customized and integrated with the

model-based AR components to support the wrist ROM assessment functions.

E. Comparative Synthesis and Research Gap

Hence, AR offers a different approach from the other rehabilitation technologies discussed earlier. Unlike VR, it allows the real wrist to remain visible throughout the assessment. It can also provide visual guidance without using the mechanical support required by many robotic and haptic systems. Wearable and sensor-based systems can produce detailed movement data, but AR can display the information directly beside the wrist being observed in real time, although this still depends on clear camera visibility and stable tracking. Based on this comparison, a gap remains for a mobile model-based AR system developed specifically for wrist ROM assessment across rehabilitation settings. ROMBandAR was developed as an early prototype to examine this possibility.

III. Materials and Methods

This section explains the steps used to design, develop, and test ROMBandAR. It begins with the research design and the proposed framework. The development process and evaluation procedure are then described in the following subsections. The main materials and software include the prototype wrist armband, Android smartphones, KIRI Engine, Vuforia Model Target Generator, Unity, MediaPipeUnityPlugin, and C# scripts.

A. Research Design

This study follows Design Science Research Methodology because the main focus is to develop and test a digital artifact [31]. The artifact in this study is ROMBandAR. The development process includes problem identification, objective setting, design and development, demonstration, evaluation, and communication.

The problem identified in this study is the need for a simple AR-based prototype to support wrist ROM assessment across rehabilitation settings. The intended clinical scope includes neurological rehabilitation, such as stroke, and musculoskeletal or orthopaedic rehabilitation, such as distal radius fracture and tendon injury or repair. ROMBandAR was therefore developed to detect a wrist armband, display AR labels, show hand landmarks, provide wrist movement output, save the assessment reading in the application library, and allow the reading to be submitted to a therapist.

B. Proposed Framework of ROMBandAR

Fig. 1 shows the proposed framework of ROMBandAR. The framework starts with the user, which includes people who require wrist rehabilitation and therapists. Possible future user groups include people recovering from stroke, distal radius fracture, or tendon injury and repair. The user performs the wrist assessment using the application, while the therapist is the intended reviewer of the submitted assessment.

The wrist armband is used as the model target for AR tracking. The armband is first scanned using KIRI Engine [32]. Then, the three-dimensional model of the armband is trained using Vuforia Model Target Generator [24]. After the model target database is exported, it is imported into Unity for AR development. In Unity, Vuforia detects the wrist armband and keeps the AR labels aligned with the model target. MediaPipe and MediaPipeUnityPlugin perform a separate task by displaying hand landmarks from the smartphone camera input [25]-[27]. Additional C# scripts use the reference information to calculate the angle, classify the movement, display feedback, save the assessment reading, and control the report submission function.

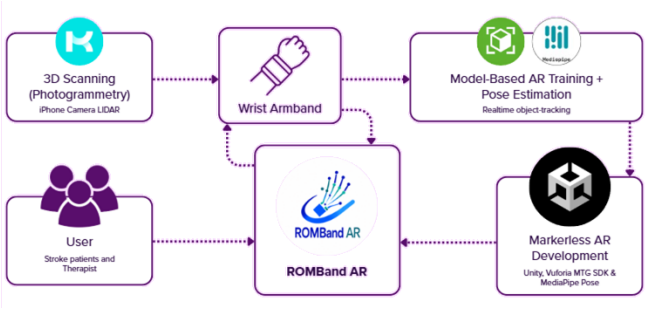

Fig. 1. Proposed ROMBandAR development framework.

C. System Development

The development started with the preparation of the prototype wrist armband. The armband was used as the physical reference for AR tracking. A textured surface was added because a plain surface did not provide enough visual features for scanning and model target detection.

The armband was scanned using KIRI Engine. The scanning process used photogrammetry, where images of the armband were captured from different angles and processed into a 3D model [32]. The model was then imported into Vuforia Model Target Generator. In Vuforia MTG, the model orientation, scale, and guide views were set before the model target database was exported [24].

After that, the Vuforia database was imported into Unity. The AR Camera and Model Target object were configured in the Unity scene. AR labels were placed around the wrist armband so that they would appear when the armband was detected by the camera.

Before the angle output could be produced, the hand pose first had to be represented using landmark points from the camera image. In ROMBandAR, this pose-estimation step is handled through Google MediaPipe hand landmark detection.

MediaPipeUnityPlugin was then integrated into the Unity project [27]. The plugin was used to display hand landmarks from the camera input based on the MediaPipe hand tracking pipeline [25], [26]. Since the plugin does not directly provide wrist ROM output, additional C# scripts were developed. These scripts read the landmark positions, use the model target and wrist landmark as reference points, calculate the wrist angle output, classify the movement label, and update the feedback display.

From Fig. 2, MediaPipe Landmark 0 (WRIST) is used as the main hand reference. A fixed reference at the centre of the rigid armband is aligned with the forearm, and the current wrist position is stored when Reset is pressed as the neutral baseline. The neutral position is treated as 0°. The wrist movement is then compared with this baseline in the selected assessment plane to update the displayed angle and movement direction. The angle represents the angular opening from the fixed armband and

forearm reference to the moving wrist reference, similar to reading an angle from the fixed arm of a protractor.

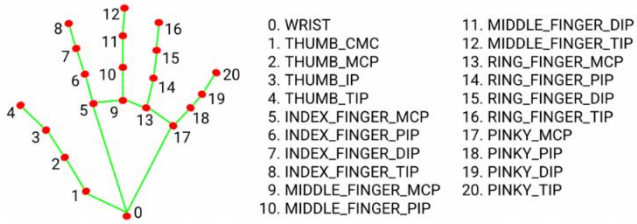

Fig. 2. Google MediaPipe hand landmarker model.

For example, as the wrist moves farther from the 0° neutral anchor, the displayed value increases according to the measured position, such as 30°, 60°, or 90°. Vuforia is used to detect and track the armband and maintain the AR registration, while the wrist movement output is produced by the custom MediaPipe-based calculation. The selected assessment plane follows the movement option chosen on the Assessment Setup Page, namely flexion, extension, ulnar or radial deviation, and pronation or supination.

The prototype also includes a Neutral output, a guide popup, an assessment library, and an assessment submission button for therapist review.

Fig. 3. Prototype wrist armband built as the model target.

Fig. 3 shows the prototype wrist armband prepared as the physical model target. The rigid body provides the textured surface needed for tracking, while the strap keeps the device positioned around the wrist. Fig. 4 shows the 3D model obtained from the KIRI Engine scan. The same model is then exported as an FBX file and imported into Vuforia MTG to be trained in Fig. 5, where the scale, orientation, and guide view for the model target were selected. Fig. 6 shows the Unity scene where the model target and MediaPipe are combined and integrated to produce an AR app for wrist ROM assessment with a clean, sleek UI design.

Fig. 4. 3D Scanning of the wrist armband using the KIRI engine.

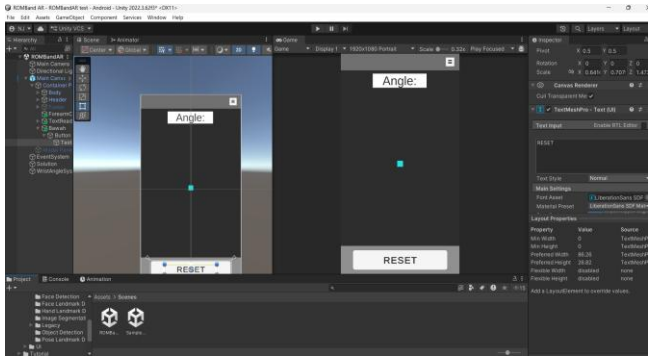

Fig. 6. ROMBandAR development in Unity.

D. Evaluation Procedure

At this stage, the evaluation only covered development testing. Patient testing and clinical validation were not included in this study and are planned for the next stage of this project. Three test cases were used to check device compatibility, application functionality, and the consistency of the preliminary screenshot-based readings. The present testing did not involve repeated measurements, comparison between raters, or direct goniometer readings taken from the wrist.

Test Case 1 examined device compatibility. The purpose was to check whether ROMBandAR could be installed, opened, and run on the selected Android devices.

Test Case 2 examined the application functions. Each main function was tested to confirm that it responded as expected. These functions include page navigation, camera view, UI interaction, armband detection, hand landmark display, ROM reading, movement label, guide popup, assessment library, and submission function.

Test Case 3 was screenshot-based ROM reading consistency testing. For this test, the wrist was placed in a selected movement position and captured from the ROMBandAR assessment screen. The ROMBandAR reading shown on the screen was recorded. The ROMBandAR screenshot or static image was then measured using a goniometer by aligning the goniometer with the visible wrist posture in the image. Similar AR-based ROM research has compared software-generated joint measurements with manual goniometry [33]. In this study, the recorded ROMBandAR reading and the goniometer reading from the screenshot were compared using the absolute error, and the overall error was summarised using mean absolute error (MAE).

The absolute error for each movement was calculated using Eq. (1), while the overall MAE was calculated using Eq. (2):

$$e_i = |R_i - G_i| \quad (1)$$

$$MAE = (1/n)\ \Sigma_{i=1}^{n} |R_i - G_i| \quad (2)$$

where, R_i is the ROMBandAR reading, G_i is the goniometer reading taken from the same screenshot, and n is the number of movement positions.

This test was used only as an early development check and does not represent clinical validation. Its purpose was to observe whether the ROMBandAR reading followed the visible wrist posture and remained close to a manual goniometer reading taken from the same screenshot.

Fig. 7 shows how the preliminary screenshot comparison was carried out. The ROMBandAR reading remained visible on the captured image, and the goniometer was aligned with the wrist posture shown in the same image. This allowed both readings to be compared without treating the screenshot measurement as direct clinical goniometry.

Fig. 8 shows an example of the standard goniometer positioning used to measure wrist ROM directly on the hand. The figure is included only to illustrate how conventional wrist ROM measurement is normally carried out and was not used as part of the evaluation reported in this study.

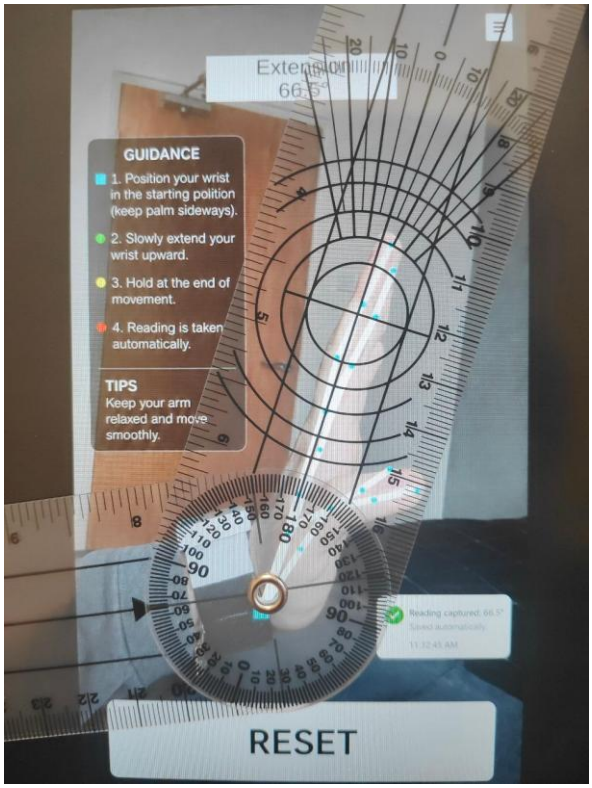

Fig. 7. Screenshot-based AR ROM reading consistency check with goniometer reference.

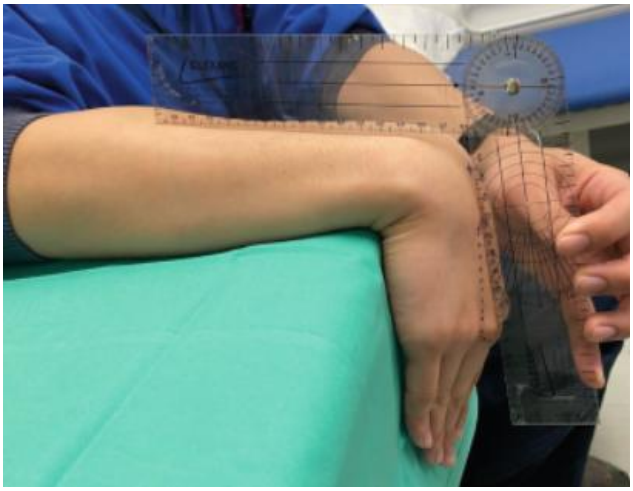

Fig. 8. Direct Wrist ROM measurement on an actual hand using a goniometer.

IV. Analysis and Results

This section presents the implementation and development-level test results of ROMBandAR. It first describes the development environment, deployment configuration, and application interfaces. It then reports the results of device compatibility testing, application functionality testing, and screenshot-based ROM reading consistency testing. The results in this section therefore reflect prototype-level testing only. Repeated measurements, inter-rater analysis, and direct wrist measurement with a goniometer were not carried out in this study.

A. Prototype Implementation

ROMBandAR was developed as an Android prototype with eight main pages: the splash page, start page, home page, notes page, assessment setup page, AR ROM reading page, assessment library, and submission page. During the assessment, the main AR page shows the live camera view together with the AR overlay, detected hand landmarks, angle reading, and movement label in real time.

Once the prototype was ready, it was installed on selected devices and tested under the intended conditions, which is by checking two basic points: whether the application could run properly and whether its main functions responded correctly and smoothly. The following subsections describe the development environment, device setup, application interfaces, and the results obtained.

Table I summarizes the main development environment, tools, platform, physical reference, and prototype outputs used in ROMBandAR.

TABLE I. DEVELOPMENT ENVIRONMENT

ITEM	SPECIFICATION
Development engine	Unity
Programming language	C#
AR tracking	Vuforia Engine and Vuforia MTG
3D scanning	KIRI Engine
Hand landmark detection	MediaPipeUnityPlugin
Target platform	Android
Physical reference	Prototype wrist armband
Main output	AR labels, hand landmarks, angle output, movement label, saved ROM reading, and report submission

1) Deployment and configuration: ROMBandAR was developed as a mobile Android application using Unity, Vuforia Engine, and C#. The application was developed on an ASUS TUF Gaming A15 laptop with an AMD Ryzen 5 processor, NVIDIA GeForce graphics card, 15.6-inch display, and Windows 11 operating system. For device testing, the application was installed on a Realme C35 running Android 11, a Xiaomi Redmi Note 12 running Android 13, and a Samsung Galaxy A25 5G running Android 14.

The wrist armband serves as the physical model target for Vuforia detection. When the camera recognises the rigid armband body, the application places the AR labels around the wrist reference. MediaPipe separately detects the hand landmarks, while the custom scripts use the reference data to update the movement type, angle reading, and guidance in real time.

2) Interfaces: The outputs of the proposed framework can be seen through the application interfaces. ROMBandAR has eight main pages.

As shown in Fig. 9, the Splash Page appears when the application is launched. After the loading process is completed, the user is directed to the Start Page shown in Fig. 10. The page displays the ROMBandAR logo, a Start button, and a How to use? option. Clicking the Start button then opens the Home Page shown in Fig. 11.

Fig. 9. Splash page.

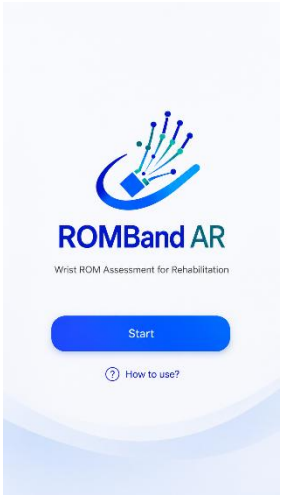

Fig. 10. Start page.

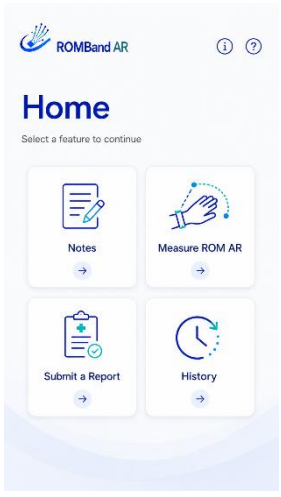

Fig. 11. Home page.

The Home Page contains the main navigation buttons, which are Notes, Measure ROM AR, Submit a Report, and History. It also includes the About and Help buttons for additional information. As shown in Fig. 12, the Notes Page provides simple information about wrist ROM, how to measure wrist movement, and the basic steps for using ROMBandAR.

Fig. 12. Notes page.

When the user clicks Measure ROM AR, the Assessment Setup Page is displayed as shown in Fig. 13. On this page, the user can choose the right or left wrist and select the assessment type, such as flexion and extension, ulnar and radial deviation, or pronation and supination. The user can then start the AR assessment.

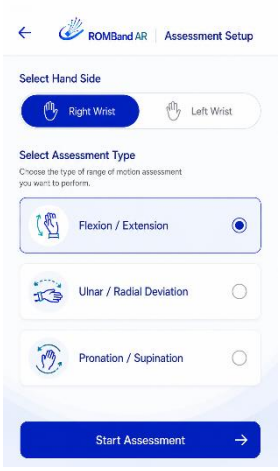

Fig. 13. Assessment setup page.

As shown in Fig. 14, the Measure ROM AR Page opens the smartphone camera to detect the wrist armband. When the armband is detected, the application displays the ROM reading, movement label, hand landmark overlay, and guidance panel. A Reset button is provided so the user can set the current arm position as the neutral reference before taking another reading. This step is needed because the arm and camera position can change between assessments.

The Submit a Report Page, shown in Fig. 15, allows the user to prepare the latest ROM assessment for therapist review through email. This page contains the selected reading, basic patient details, therapist information, and additional notes. Lastly, the History Page in Fig. 16 displays the saved ROM readings with their dates, movement types, wrist side, and reading values in one library. The user can open any saved result to view more details.

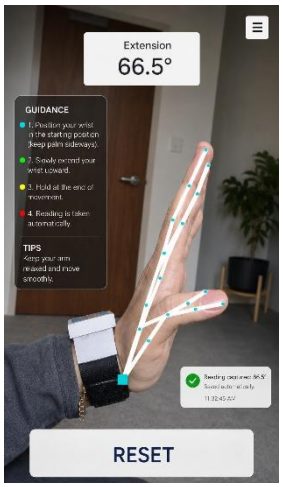

Fig. 14. AR ROM reading.

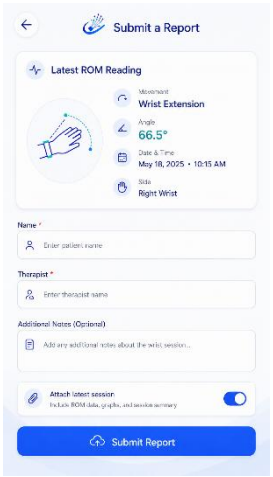

Fig. 15. Submit page.

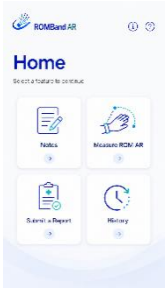
Fig. 16. History page.

B. Test Case 1: Device Compatibility Testing

Device compatibility testing was conducted to check whether ROMBandAR could be installed and opened on different Android devices, access the camera, and display the user interface correctly. Armband detection and assessment output were evaluated under Test Case 2 because they are application functions rather than device specifications.

All three devices installed and opened ROMBandAR successfully. Camera access and the main user interface also worked on each device. The results in Table II report device compatibility only. The armband detection, hand landmarks, movement output, saving function, and submission function are reported separately in Table III.



C. Test Case 2: Application Functionality Testing

Application functionality testing was conducted to check whether the main functions worked as expected. This test includes the user interface functions, AR model target detection, MediaPipe landmark display, ROM reading, movement label, guide popup, assessment library, and submission function.

TABLE II. TEST CASE 1: DEVICE COMPATIBILITY TESTING

TEST ITEM	EXPECTED OUTPUT	DEVICE #1	DEVICE #2	DEVICE #3
Device Name		Realme C35	Xiaomi Redmi Note 12	Samsung Galaxy A25 5G
Android Version		11	13	14
Processor		Unisoc T616 Octa-core	Qualcomm Snapdragon 685 Octa-core	Samsung Exynos 1280 Octa-core
RAM		4.00 GB	6.00 GB	8.00 GB
Storage		128 GB	128 GB	256 GB
Application installation	Application installs successfully	Success	Success	Success
Application launch and basic display	Application opens, accesses the camera, and displays the user interface correctly	Success	Success	Success

TABLE III. TEST CASE 2: APPLICATION FUNCTIONALITY TESTING

PAGE	PROCEDURES	EXPECTATION	RESULTS		
			DEVICE #1	DEVICE #2	DEVICE #3
 Splash page	Launch the ROMBandAR application	Splash screen with ROMBandAR logo is displayed	Success	Success	Success
	Wait for the loading process	Application goes to the Start page automatically			
 Start page	Click on the Start button	Go to the Home Page	Success	Success	Success
	Click on the How to Use text	Help or guideline popup/page is displayed	Success	Success	Success
	Close the How to Use? popup/page	Return to the Start page	Success	Success	Success
 Home page	Click on the Notes button	Go to the Notes page	Success	Success	Success
	Click on the Measure ROM AR button	Go to the assessment setup page	Success	Success	Success
	Click on the Submit a Report button	Go to the submit report page	Success	Success	Success
	Click on the History button	Go to the history page	Success	Success	Success
	Click on the 'i' button	Open about popup	Success	Success	Success
	Click on the '?' button	Open Help page	Success	Success	Success

 Notes page	Display notes content Click on each note Click the back button	Notes about wrist ROM, how to measure ROM, and a step-by-step guide are displayed Note details will pop up Go to the Home page	Success Success Success	Success Success Success	Success Success Success
 Assessment Setup page	Click the left or right wrist button Click assessment type Click Start Assessment button Click back button	Side of hand is selected Assessment type is selected Go to Measure ROM page Go to Home page	Success Success Success Success	Success Success Success Success	Success Success Success Success
 Measure ROM page	Click the reset button Click the 3-bar option in the top-right corner Detect wrist armband model target Move wrist based on selected assessment	ROM reading is reset to neutral position Home, Settings, and Quick Action options are displayed Wrist armband is detected by the application ROM reading and movement label are updated	Success Success Success Success	Success Success Success Success	Success Success Success Success
 Submit a Report page	Display the latest ROM reading Enter patient and therapist details Enter additional notes Click the Submit Report button	Latest reading details are displayed correctly User details can be entered Notes can be added before submission Report is submitted successfully	Success Success Success Success	Success Success Success Success	Success Success Success Success
 History page	Display saved ROM readings Display selected result detail Click selected reading Scroll history list Click back button	Saved ROM readings are shown in the list Result detail is displayed Date, side, movement type, reading, and notes are displayed User can view more saved readings Go back to the Home page	Success Success Success Success Success	Success Success Success Success Success	Success Success Success Success Success

The result shows that the main functions of ROMBandAR worked as intended at the prototype level. The armband was detected, the hand landmarks and movement output were displayed, and the assessment reading could be saved in the library and prepared for therapist review through the submission function.

D. Test Case 3: Screenshot-Based ROM Reading Consistency Testing

Screenshot-based ROM reading consistency testing was conducted to compare the ROMBandAR reading with a goniometer measurement taken from the wrist screenshot. The wrist movement screen was captured from ROMBandAR with the wrist in a selected movement position. The ROMBandAR reading shown on the screen was recorded. Then, the same screenshot was measured manually using a goniometer as the reference. Table IV presents the ROMBandAR readings, the goniometer readings measured from the captured wrist screenshots, and the absolute error for each movement tested.

The screenshot-based test showed that the ROMBandAR readings were close to the manual goniometer readings taken from the ROMBandAR wrist screenshots. Based on Eq. (1), the absolute errors ranged from 0.8° to 1.5°. Based on Eq. (2), the overall MAE was 1.19°, showing only a small average difference between the ROMBandAR readings and the screenshot-based goniometer measurements. This error is below the approximately 5° measurement error that has been reported as acceptable for wrist goniometry [34]. Therefore, the result gives an encouraging indication that the prototype readings were close to the reference measurements and showed good consistency at this early stage, although it should not yet be interpreted as clinical accuracy or reliability.

TABLE IV. TEST CASE 3: SCREENSHOT-BASED ROM READING CONSISTENCY TESTING

WRIST/FOREARM MOVEMENT	ROMBANDAR READING	GONIOMETER READING FROM SCREENSHOT	ABSOLUTE ERROR	OBSERVATION
Neutral	0.8°	0.0°	0.8°	Consistent
Flexion	74.0°	73.0°	1.0°	Consistent
Extension	66.5°	65.0°	1.5°	Consistent
Radial Deviation	23.5°	22.5°	1.0°	Consistent
Ulnar Deviation	28.5°	29.5°	1.0°	Consistent
Pronation	79.0°	80.5°	1.5°	Consistent
Supination	82.5°	81.0°	1.5°	Consistent

V. DISCUSSION

This section discusses what the development results mean, how ROMBandAR differs from the existing rehabilitation technologies, the significance of the prototype, and the limitations that must be addressed before clinical evaluation.

The development of ROMBandAR shows that the rigid body of a wrist armband can be used as a model target for AR-based wrist ROM assessment. The flexible strap is more difficult to track because its shape changes according to the user's wrist size. For this reason, the current model target focuses on the rigid armband body. The textured surface also helped the armband become more suitable for scanning and detection because the plain surface did not provide enough visual features.

The development pipeline also demonstrates that KIRI Engine, Vuforia MTG, Unity, and MediaPipeUnityPlugin can be combined in one prototype. KIRI Engine was used to scan and prepare the three-dimensional model, Vuforia was used for model target training and armband detection, and MediaPipeUnityPlugin was used to display hand landmarks. The custom C# scripts then connected these components with the angle reading, movement label, guide popup, saving function, and report submission function.

At the prototype stage, the main functions worked during testing. ROMBandAR could be installed and opened on the three selected Android devices. The page navigation, armband detection, hand landmark display, ROM output, assessment saving, and report submission functions also operated as expected. For the preliminary screenshot check, the ROMBandAR readings remained close to the goniometer readings taken from the same images. The calculated MAE was 1.19°.

Although ROMBandAR was initially considered for stroke rehabilitation, its measurement function is not limited to stroke. Wrist or forearm movement is also assessed after conditions such as distal radius fracture and tendon injury or repair. The reason for the movement limitation may be different, but therapists still need to observe and record the available movement. Since the basic measurement task remains similar, the prototype can later be tested with more than one rehabilitation group without changing its main function.

At this stage, the main value or significance of ROMBandAR is that several assessment functions are brought together in one mobile application. The system combines model-based AR tracking with hand landmark display, live angle output, movement guidance, assessment saving, and therapist submission. Unlike VR, ROMBandAR allows the real wrist to remain visible during the assessment. It also does not require the mechanical equipment or separate sensor packages used in many robotic and wearable systems. This approach may later support supervised assessment or home-based follow-up. However, usability, validity, and reliability still need to be examined before the prototype can be considered for clinical use.

Also, these results still need to be interpreted as an early development check. No patient or clinical evaluation was carried out, so this study cannot show that ROMBandAR is clinically

accurate or better than a goniometer. The screenshot comparison was only used to check the consistency, whether the displayed reading feedback followed and was close to the goniometer measurement or not. The result may still be influenced by the image used, camera angle, wrist posture, and the way the goniometer was aligned. Therefore, the next stage should involve a controlled study with repeated measurements.

Some practical limitations also appeared during this development stage, such as the current armband is still an early prototype and needs a more stable, neat, and comfortable design. Furthermore, tracking performance may also change when the lighting is poor, the camera is too near or too far, the viewing angle changes, or part of the armband is hidden. The hand landmarks may also become unstable when the hand is partly covered or moved too quickly. Besides, the guidance provided by the application is also still general and does not yet consider the movement limits of different rehabilitation conditions.

Taken together, the prototype shows potential for different rehabilitation cases, but the next evaluation should not treat all users in the same way. Stroke, distal radius fracture, and tendon repair involve different movement limitations, so each group will need its own testing protocol before the accuracy and reliability of ROMBandAR can be properly established. Following this development stage, future work will evaluate the proposed framework through its ROM measurement performance and the extrinsic feedback provided during wrist ROM assessment.

VI. Conclusion and Future Work

This study presents the development of ROMBandAR, an AR-based prototype for wrist ROM assessment in rehabilitation. The project was first considered for stroke rehabilitation, but the system is not limited to stroke only. It may also be used in musculoskeletal and orthopaedic rehabilitation, where wrist movement still needs to be measured and monitored. For the AR tracking, a wrist armband was used as the model target. The armband was scanned using KIRI Engine, trained in Vuforia MTG, and later imported into Unity. MediaPipeUnityPlugin was then added to display the hand landmarks from the camera view. Several C# scripts were also written to handle the angle reading, movement label, feedback, guide popup, saving function, and therapist submission.

At this point, the prototype was tested with three test cases at the development level. These were tests of device compatibility, application functionality, and the consistency of ROM reading based on screenshots. ROMBandAR runs successfully on all selected Android devices. It also detected the wrist armband, displayed the AR overlay and hand landmarks, updated the movement reading, saved the result, and opened the submit page successfully. For the screenshot-based comparison, ROMBandAR produced an MAE of 1.19°, which was below the approximately 5° measurement error reported as acceptable for wrist goniometry [35]. This provides an encouraging preliminary result, although clinical accuracy and reliability still need to be established through controlled testing.

So, future work will mainly focus on improving the armband design so that it is more stable and comfortable to wear. There are some parts of the application that still need some refinement, particularly the tracking performance, the interface layout, the angle calculation, and movement guidance. After these improvements, the prototype will be tested in a more controlled setting by comparing its readings with a standard goniometer. ROMBandAR will also be used together with a newly developed ROM assessment form during selected rehabilitation assessments. This evaluation will help determine whether the system can provide consistent readings and support wrist ROM assessment in practice. These findings will support the next stage of framework evaluation, including the extrinsic feedback provided during selected wrist ROM assessments.

Acknowledgment and Funding

The authors would like to acknowledge the Ministry of Higher Education (MoHE) and Center for Research Excellence and Incubation Management (CREIM) as well as Center for Management of Academic Excellence and Innovation, Universiti Zainal Abidin for their financial support through the Scholarship of Teaching and Learning (SoTL) Grant. We also want to thank the Sultan Zainal Abidin Hospital (HoSZA), Faculty of Medicine UniSZA, and Besut District Health Center.

Conflict of Interest

The authors declare that they have no conflict of interest.

***Abstract*—Rapid urbanization and increasing pressure on natural resources demand efficient, transparent, and sustainable management systems. However, existing booking systems in government agencies often operate in silos and lack integration with geospatial data. This study conducts a Systematic Literature Review (SLR) to identify essential components of intelligent booking systems (IBS) and research gaps in the context of Natural Resources and Urban Development with geospatial data integration. The SLR follows a three-phase protocol (Planning, Execution, Reporting). The literature was searched in IEEE Xplore, SpringerLink, ScienceDirect, and ACM Digital Library for 2021–2025. From an initial pool of 40 articles, 16 were selected for in-depth analysis after eligibility and quality assessment (scoring ≥ 3 out of 5). The analysis reveals six main component categories, with Resource Management (n=12) and Booking Management (n=11) as the foundational layers, whereas Geospatial Integration was addressed in only 4 of the 16 studies. Critically, no existing system integrates Sentinel satellite data (Sentinel-1/2), and no optimisation model combines Multi-Criteria Decision Making (MCDM) with GIS for this specific domain. This SLR provides a comprehensive component framework and systematically maps four key research gaps, laying a foundation for developing geospatially-integrated intelligent booking systems for smarter natural resource and urban facility allocation.**

Keywords*—Intelligent booking systems; natural resource management; Geographic Information Systems (GIS); satellite remote sensing; data mining; Multi-Criteria Decision Making (MCDM)

I. Introduction

With rising population and urbanization, efficient public service delivery and organizational resource utilization have become critical. Many government agencies still rely on outdated, fragmented, or partially digitized booking procedures that fail to meet modern requirements.

For this research, we focused on Sarawak, Malaysia. Reservations are typically handled through paper forms, emails, phone calls, or stand-alone spreadsheets [1], [2]. Such ways do not work consistently across departments because there is no common platform to manage available resources. Besides the lack of integration with geospatial data, the current methods also cause double-bookings, scheduling conflicts, delays, and inefficient allocation. There is also poor visibility of resource availability and a lack of historical records. Although these issues may seem minor administratively, together they create a significant burden, reducing productivity and the efficiency of public service delivery.

Malaysia launched its Public Sector Digitalisation Strategy to address these operational hurdles. While significant investments have been made in enterprise systems such as electronic document management, HR, and financial systems. Little attention has been paid to booking and reservation processes. Current systems function mainly as electronic calendars without intelligent decision support, making them transactional rather than adaptive or predictive.

Advances in AI, data analytics, optimization, and decision support have enabled the creation of Intelligent Booking Systems (IBS). IBS go beyond traditional reservation tools by offering features such as conflict detection, resource optimization, recommendations, demand forecasting, priority-based scheduling, and real-time decision support [3], [4]. Previous studies have demonstrated IBS applications across transportation (e.g., EV charging, parking prediction) and hospitality (e.g., tourism marketing, personalized travel) [5], [6], [7], [8], [9], [10], [11], [12], [13], [14], [15], [16], [17], [18]. IBS adoption in government remains limited.

A major weakness in booking systems is the absence of geospatial integration. Sentinel-1 and Sentinel-2 satellite data provide crucial information on location, land cover, environmental changes, and zoning. All highly relevant for resource management [19], [20]. Practical experience at Spectral Imaging Services and the Ministry of Natural Resources and Urban Development Sarawak demonstrates the potential of Sentinel data to improve booking decisions. Although GIS and remote sensing technologies are mature, integration into booking systems for natural resource and urban domains remains scarce [21], [22].

Government organizations face unique challenges compared to commercial ones. They operate under governance policies, regulatory constraints, hierarchical decision-making, security standards, and interdepartmental resource sharing. Booking decisions often follow organizational priorities rather than "first come – first served." Thus, systems must ensure auditability, policy enforcement, transparency, fairness, and compatibility with other government information systems.

Most IBS studies focus on narrow areas such as healthcare, laboratories, transportation, hotels, and libraries. Most previous research does not address government-specific needs [23].

*Corresponding author.

While systems provide features like predictive analysis, automated allocation, adaptive scheduling, conflict resolution, workflow automation, decision support, and performance analysis. These are implemented separately, resulting in poor integration for administrative decision-making. No existing system combines Sentinel satellite data with IBS or integrates Multi-Criteria Decision Making (MCDM) with GIS for resource and urban facility management [24], [25].

Developers lack a structured framework for IBS design in government, leading to ad hoc development, inconsistent functionality, poor interoperability, low scalability, and varied implementation quality.

To address these gaps, this research will conduct a Systematic Literature Review (SLR). This study identifies, synthesizes, and categorizes IBS components from contemporary literature. Following the established SLR protocol by Lane and Richardson [26], the SLR includes planning, execution, and reporting phases. The research questions are:

- What are the core IBS components recognized in literature?
- How should these components be adapted for natural resource and urban development domains?
- What components and interfaces are required to integrate geospatial data (GIS and satellite imagery)?
- What research gaps remain, and how can they inform future studies?

The review will cover peer-reviewed journal articles and conference proceedings published between 2021–2025 in IEEE Xplore, SpringerLink, ScienceDirect, and ACM Digital Library. The 2021–2025 timeframe was deliberately chosen to capture recent breakthroughs in AI, optimization algorithms, and GIS technologies, which have evolved substantially in the post-pandemic period, making earlier literature less representative of current system capabilities. Scopus was excluded as coverage from the four databases was deemed sufficient. Books, chapters, editorials, dissertations, and grey literature will be excluded to maintain methodological consistency.

The article follows the IMRaD structure. Starting from methodology (SLR protocol and paper selection), findings (IBS component classification and gap identification), discussion (linking findings to government requirements), and conclusion (contributions, limitations, and future directions).

II. METHODOLOGY

This Systematic Literature Review (SLR) follows the three-phase protocol by Lane & Richardson [26]. This study follows the planning, execution, and reporting phases as defined in the protocol. The focus of this research is to identify, synthesize, and categorize IBS components and research gaps, particularly for natural resource and urban domains with geospatial integration.

A. Search Strategy

We searched four significant databases (IEEE Xplore, SpringerLink, ScienceDirect, ACM Digital Library). We selected peer-reviewed articles published 2021–2025. Scopus was excluded as these four databases provided sufficient coverage. Scoping searches conducted before the main search confirmed that the four selected databases already covered the core computer science, information systems, and engineering journals relevant to this topic, and no additional eligible records were uniquely found in Scopus. Table I details the Boolean search strings and initial results.

TABLE I. SEARCH STRATEGY AND KEYWORDS

Database	Keywords / Search String	Initial Results
IEEE Xplore	("intelligent booking" OR "smart reservation") AND ("GIS" OR "geospatial") AND ("natural resource" OR "urban")	3
SpringerLink	("intelligent booking system" AND ("GIS" OR "geospatial") AND ("resource" OR "urban"))	16
ScienceDirect	("intelligent booking" OR "smart reservation") AND ("GIS" OR "geospatial")	17
ACM Digital Library	("intelligent booking" OR "smart reservation") AND ("GIS" OR "geospatial")	4
Total		40

To quantitatively validate the adequacy of the selected databases, a supplementary scoping search was conducted in Scopus on 15 August 2026 using the identical Boolean string applied to the primary databases: ("intelligent booking" OR "smart reservation") AND ("GIS" OR "geospatial"). Unlike the primary searches, which targeted full-text content across IEEE Xplore, SpringerLink, ScienceDirect, and ACM Digital Library, this validation search was executed across all fields in Scopus to maximise recall. The Scopus search returned only 5 records. A manual title and abstract screening of these 5 records revealed that none met the eligibility criteria: four were focused on tourism, cybersecurity, or metaverse applications without any booking system component, and one was a survey of parking solutions that did not present an intelligent booking system or geospatial integration for natural resource or urban development domains. Consequently, no unique eligible records were identified in Scopus beyond those already captured by the four primary databases. Table II summarises the comparative coverage validation, confirming that the selected databases provide comprehensive and representative coverage for this systematic literature review.

TABLE II. VALIDATION OF DATABASE COVERAGE

Source	Initial	Unique	Relevant
IEEE Xplore	3	3	2
SpringerLink	16	16	8
ScienceDirect	17	17	5
ACM Digital Library	4	4	1
Scopus (Validation)	5	5	0

Notes: Initial = total records retrieved from the database; Unique = records remaining after deduplication against the four primary databases (or within the pooled corpus); Relevant = records that passed the title/abstract screening and eligibility criteria (quality score ≥ 3). The Scopus validation search returned 5 records, all of which were excluded after screening as they did not address intelligent booking systems with geospatial integration for natural resource or urban development domains.

B. Inclusion and Exclusion Criteria

In this research, we included English-language, full-text, peer-reviewed journal articles and conference proceedings. The

focus of article content that discuss booking/reservation systems employing intelligent technologies (AI, optimization, or ML). We also consider GIS/geospatial discussion as an added value but not mandatory for RQ1. Excluded were books, book chapters, editorials, non-English articles, studies lacking intelligent/optimization elements, and those without GIS relevance (unless highly relevant to core booking components).

C. Study Selection Process

Selection followed the PRISMA 2020 flow [29]. We identified database searches and deduplication. Besides screening (title/abstract review), eligibility (full-text assessment against criteria), and inclusion (final dataset). Results of our article selection are presented in Fig. 1.

Each article was evaluated with a quality score (0–5). The scoring criteria included clarity of objectives, methodological depth, completeness of system description, discussion of intelligent aspects, and relevance to GIS. Studies scoring <3 were excluded. The scoring rubric was as follows: clarity of objectives (0–1), methodological depth (0–1), completeness of system description (0–1), discussion of intelligent aspects (0–1), and relevance to GIS (0–1), for a maximum total score of 5.

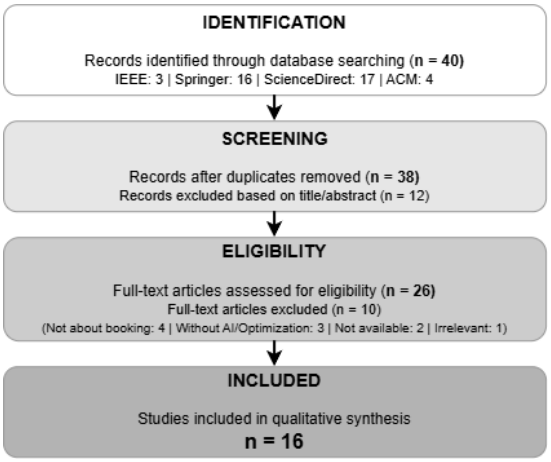

Fig. 1. PRISMA 2020 study selection process flow diagram (modified from[27]).

D. Quality Assessment

From each eligible study, we extracted bibliographic data, research objectives, methodologies, system components, intelligent techniques, GIS relevance, application domain, key findings, and identified gaps. Data were analyzed thematically [27] through coding, categorization, theme identification, and narrative synthesis to map IBS components and integration requirements.

E. Data Extraction, Analysis, and Study Management

From each eligible article, we extracted data on bibliographic details, research objectives, and methodology. We also recorded system components, intelligent techniques such as AI and optimization, and GIS relevance. In addition, application domains, key findings, and research gaps were documented using a standardized form.

Data synthesis was conducted using thematic analysis. This process involved iterative coding, which grouped components by function, such as scheduling, optimization, and GIS. The coding was followed by categorization and narrative synthesis to ensure a structured mapping of IBS architectures and integration needs.

The review process was managed using Mendeley for reference storage. Excel spreadsheets were used for selection, quality assessment, and extraction tracking. Each study was assigned a unique identifier (S1, S2, …). This ensured traceability throughout the review.

III. Results

A. Search Results and Study Selection

The literature search was conducted across four academic databases. We used IEEE Xplore, SpringerLink, ScienceDirect, and the ACM Digital Library, as described in the search strategy in Section II. The initial search yielded a total of 40 articles. Specifically, 3 articles were from IEEE Xplore, 16 from SpringerLink, 17 from ScienceDirect, and 4 from the ACM Digital Library.

The study selection process followed the PRISMA 2020 flow diagram, which is recommended for SLR reporting [27]. The flow diagram is shown in Fig. 1. It maps the number of articles identified, included, and excluded at each stage. It also presents the reasons for exclusion.

TABLE III. Mapping of Included Studies to IBS Component Categories

ID	Author & Year	Domain	Primary Category(ies)
S1	Sun & Song (2021) [28]	Timetabling	Booking, Intelligence
S2	Sadreddini et al. (2021) [29]	EV Parking	Resource, Booking, Intelligence
S3	Al-Khatib et al. (2022) [30]	Vehicular	Resource, Booking, Intelligence
S4	Muzzini et al. (2023) [31]	Smart Parking	Resource, Intelligence
S5	Ting et al. (2024) [32]	EV Charging	Resource, Geospatial, Intelligence
S6	Wang (2023) [33]	Laboratory	Resource, Booking, Intelligence
S7	Zhou (2025) [34]	Stadium	Resource, System, Intelligence
S8	Channamallu et al. (2026) [35]	Urban Parking	Resource
S9	Yadav et al. (2026) [36]	EV Charging	Booking, Intelligence
S10	Lv et al. (2026) [37]	Parking	Resource, Intelligence
S11	Han & Wang (2025) [38]	EV Charging	Booking, Intelligence
S12	Navpreet et al. (2025) [39]	Parking	Resource, Intelligence
S13	Fatema et al. (2026) [40]	Tourism	Booking, Intelligence
S14	(X. (Simon) Zhou et al., 2025) [41]	Transportation	Geospatial, Intelligence
S15	Zayat et al. (2023) [42]	Industry 4.0	Intelligence
S16	Gurung et al. (2025) [43]	Transportation	System

The selection process was conducted in four stages. The Identification stage produced 40 articles from four databases.

The Screening stage removed 2 duplicates, leaving 38 articles. After screening titles and abstracts, 12 articles were excluded because they were not relevant to the research topic. This left 26 articles. The Eligibility stage involved full-text reading of these 26 articles. At this stage, 10 articles were excluded. The reasons were: 1) did not substantially discuss intelligent booking systems (n=4), 2) did not include intelligent or optimization aspects (n=3), 3) full-text was not available (n=2), and 4) not relevant to natural resource or urban domains (n=1). Examples of excluded studies include a sports teaching application without intelligent booking components, a study on recreational prawn fishing focused only on consumer behavior [18], and a grounded theory study on voluntary blood donation outside the scope of booking systems [44]. The Inclusion stage resulted in 16 final articles that met all quality criteria for further analysis.

Based on the analysis of 16 articles, the publication distribution shows an increasing trend in recent years. The growth is especially visible since 2020. This indicates a rising research interest in intelligent booking systems. The focus is particularly on systems that integrate artificial intelligence and optimization technologies. Most of the articles come from journals and conference proceedings. They are mainly in the fields of computer science, information systems, and engineering.

B. Characteristics of Included Studies

From the 16 articles that passed the selection, data extraction was conducted to identify the characteristics of each study. Table III presents a summary of the characteristics of each reviewed article.

C. Classification of Intelligent Booking System Components

Based on thematic analysis of the 16 reviewed articles [45], the components of intelligent booking systems can be classified into six main categories. Table IV presents a summary of the component classification along with the number of studies addressing each category.

TABLE IV. CLASSIFICATION OF INTELLIGENT BOOKING SYSTEM COMPONENTS

Category	Components Identified	Studies (n)
Resource Management	Resource inventory, availability status, geospatial location, resource categorization, charging/parking space management	12
Booking Management	New booking, modification, cancellation, recurring booking, approval workflow, reservation algorithms	11
Intelligence (AI/Optimization)	Smart scheduling, conflict detection, recommendation engine, resource optimization, predictive booking, MADM, heuristic optimization, multi-agent RL	10
Geospatial Integration	GIS interface, satellite data integration, interactive mapping, zoning analysis, location verification, spatial placement	4
System Integration	IoT integration, Outlook/Google Calendar, HR system, facility management, digital workplace, cloud connectivity	8
Security & Compliance	Access control, Single Sign-On (SSO), audit trail, data protection, privacy, regulatory compliance	5

First is Resource Management. It includes bookable resources such as inventory, availability, location, categorization, etc. Most of the articles covered this element. It shows that any booking system is built on resource management.

The second category is Booking Management. It manages the booking lifecycle: new bookings, modifications, cancellations, recurring bookings, and approvals. This component was consistent across the literature. This is the heart of what a booking system does.

The third category is Intelligence. It is the most diverse and distinguishes the conventional from the intelligent systems. Features include smart scheduling, conflict detection, recommendations, optimization, and predictive booking. Compared with tourism and service industries, research on the application of MCDM to booking systems is still limited [42].

The fourth category is Geospatial Integration. It is the least common we find in the literature. Components. GIS interfaces, satellite data, mapping, zoning, location validation. This suggests that geospatial integration remains an under-explored area. Studies [32] and [41] did not use remote sensing but only simple location data or IoT.

The fifth category is System Integration. It links booking systems to calendars, HR, and facility management. Its importance is mentioned in the literature from other domains. These include IoT-enabled facility management and AI-powered web architectures in e-commerce and healthcare [46]. Other studies such as IoT-based transport frameworks [47] and digital transformation in railways [48] illustrate how interoperability can be achieved in public sector environments.

The sixth category is Security and Compliance. This protects data and ensures regulatory compliance. It provides access control, single sign-on, audit trails, and data protection.

TABLE V. SUMMARY OF RESEARCH GAPS IDENTIFIED FROM THE LITERATURE

Gap ID	Research Gap	Supporting Evidence from Included Studies
G1	No intelligent booking system integrating satellite data (Sentinel)	Out of 40 reviewed articles, none utilized satellite imagery (Sentinel-1/Sentinel-2) for location verification or environmental analysis. Studies such as Ting et al. (2024) and X. (Simon) Zhou et al. (2025) only employed basic location data or IoT, not remote sensing data.
G2	No optimization model combining MCDM with GIS for natural resource domains	Zayat et al. (2023) discussed MADM in general for Industry 4.0, but no study integrated it with GIS-based spatial analysis for natural or urban resource allocation.
G3	No comprehensive guideline on booking system components for natural resource and urban domains	Most studies (e.g., Sadreddini et al., 2021; X. Wang, 2025; S. A. Zhou, 2025) focused on specific domains (laboratories, stadiums, parking) without providing an integrated component framework that could be replicated for natural resources.
G4	Government booking systems still operate in silos	None of the 16 included articles addressed cross-system interoperability or inter-agency integration. All solutions were single-domain or single-organization.

D. Research Gaps Identified

Based on the analysis of the reviewed literature, several significant research gaps were identified. Table V summarizes the identified gaps along with supporting evidence from the literature.

Gap 1: Satellite Data Integration. The most significant finding of this SLR is the absence of intelligent booking systems that integrate satellite data (such as Sentinel-1 and Sentinel-2) into the booking process. Satellite data provides critical information about location, land cover, and environmental changes that is highly relevant for decision-making in natural resource management and urban planning.

Gap 2: MCDM + GIS Optimization Model. Although MCDM has been used in various fields such as tourism and education, its application to booking systems for natural resource and urban domains integrated with GIS remains very limited. No optimization model comprehensively combines these two approaches.

Gap 3: Domain-Specific Component Guidance. Existing literature on booking system components is mostly generic or developed for specific domains such as libraries or laboratories. No guidance or component framework has been specifically designed for natural resource and urban development domains.

Gap 4: Siloed Systems in Government Agencies. Most research on booking systems focuses on solutions for a single domain or specific organization. There is limited research addressing integration across systems in government agencies that still operate in silos.

E. Initial Conceptual Map

Based on the component classification findings in Table IV, an initial conceptual map can be drawn showing the relationships between components in an intelligent booking system. This map is synthesized from the literature. It serves as the basis for the framework proposed in the Discussion section.

The conceptual map shows that the components of an intelligent booking system are interconnected and interdependent. Resource Management and Booking Management form the core of the system. Intelligence and Geospatial Integration add extra layers that provide value. System Integration and Security and Compliance act as supporting layers. They ensure the system can operate within a broader ecosystem and meet security standards.

IV. Discussions

This section discusses the findings presented in Section III. The discussion answers the four research questions (RQs) that have been formulated. It also analyzes the implications of the findings from the 16 reviewed articles. In addition, the section identifies the research limitations. The structure of the discussion follows the logical flow from RQ1 to RQ4. It concludes with a synthesis that connects the findings to the research contributions.

A. Core Components of Intelligent Booking Systems (RQ1)

Six main categories of intelligent booking system components were identified, extending the earlier five-component framework by Owonibi et al. [49]

Resource Management and Booking Management are the foundational elements, present in nearly all studies, covering inventory, recording, modification, cancellation, and approval workflows [28], [29], [33].

Intelligence is the key differentiator from conventional systems, enabling optimization, conflict detection, and recommendations. Research on MCDM in booking systems is still limited, leaving room for further exploration [50], [42].

The most important new finding is Geospatial Integration. The use of GIS and remote sensing technologies in booking systems is underexplored despite mature technologies and is one of the major contributions of this SLR. Supporting layers are System Integration and Security and Compliance. They provide interoperability with other organizational systems (e.g., calendars, HR) and security and regulatory compliance [51].

B. Component Modifications for Natural Resource and Urban Domains (RQ2)

The SLR results show that the generic components identified in RQ1 should be adapted and extended to address the specific needs of the natural resource and urban development domains. These changes concern three main aspects.

The first step is to require geospatial data to be a property of every resource managed by the system. In conventional reservation systems, resources are usually identified by name, code, or category only. However, in the natural resource and urban domains, each resource (e.g., land plots, forest areas, public facilities) needs to be accurately described by location attributes, including geographic coordinates and boundary areas. This is consistent with the literature on spatial data infrastructure that identifies the importance of location as a key attribute in all resource management decisions [52].

Second, the addition of zoning protection and eligibility rules as constraints in the booking system is required. Unlike booking lecture rooms or laboratories, which are relatively simple, booking natural resources involves more complex rules, such as utilization quota limits, environmental protection zoning, and user eligibility requirements. This finding aligns with research on natural resource management that emphasizes the importance of zoning and utilization rules in maintaining environmental sustainability [1], [2].

Third, the system must be equipped with automatic location verification capabilities based on geospatial data. This capability enables the system to automatically verify whether the requested location is within an allowed zone, whether there are conflicts with existing land use, and whether it complies with applicable spatial plans.

C. Components for Geospatial Data Integration (RQ3)

Based on the SLR findings and domain requirements analysis, the components required to integrate geospatial data into intelligent booking systems can be identified. Fig. 2 presents the proposed component framework for geospatial integration in intelligent booking systems.

The proposed framework (Fig 2) shows that geospatial integration requires four main components:

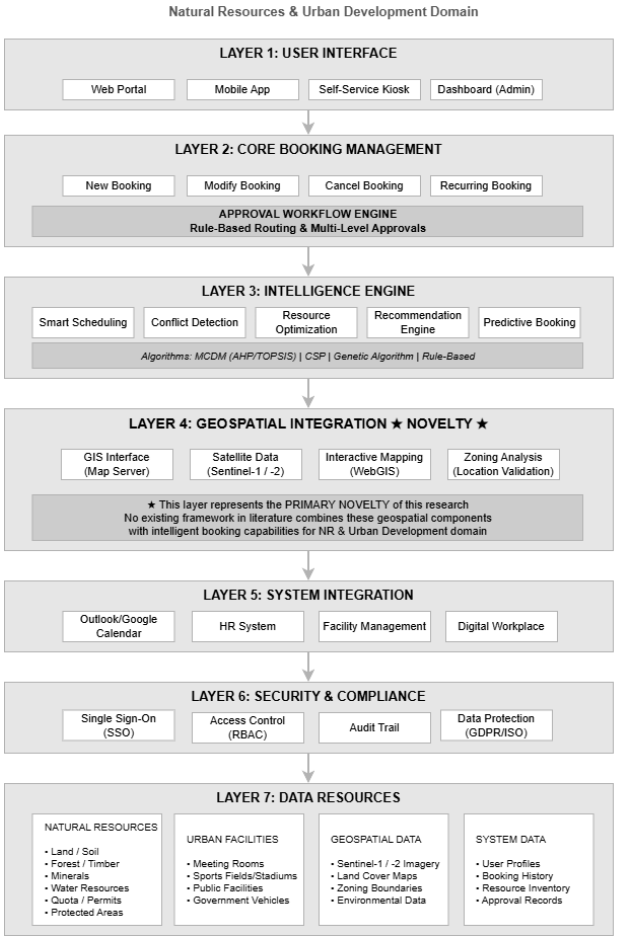

Fig. 2. Proposed component framework for intelligent booking system in natural resources and urban development.

1) GIS interface: A layer that connects the booking system to a map server to display spatial data interactively. This interface enables users to view resource locations on a map, select resources based on location, and visualize spatial conflicts. This finding aligns with research on web-based geographic information systems that emphasize the importance of intuitive interfaces for user adoption [53].[53]

2) Satellite data integration: The capability to consume and process satellite imagery data (such as Sentinel-1 and Sentinel-2) to obtain information about land cover, environmental changes, and resource conditions. For natural resource booking, Sentinel-2's 10-meter resolution optical bands enable the verification of land cover classes (e.g., forest, water, agricultural) to ensure that a requested site complies with its designated zoning category. Simultaneously, Sentinel-1's C-band SAR imagery provides all-weather change detection, allowing the system to flag recent illegal encroachments or flood-affected areas before approving a booking. Unlike static GIS layers, these satellite products offer near-real-time ground truthing, which is essential for enforcing environmental compliance in resource allocation. Studies such as Zhou et al. (2024) and Zhou et al. (2025) [54], [55] only used basic location data or IoT, not remote sensing data. The authors have direct experience in managing Sentinel satellite data at Spectral Imaging Services, which provides an advantage in designing this component.[54], [55]

3) Interactive mapping: The capability to display resources on an interactive map that enables users to view availability, zoom, and click on resources for further information.

4) Zoning and location analysis: The capability to analyze resource locations based on zoning rules, spatial regulations, and environmental data to determine eligibility and booking optimization.

D. Main Research Gaps and Future Research Directions (RQ4)

Based on the analysis of the 16 reviewed articles, four main research gaps have been identified (Table V). These gaps not only indicate what remains under-researched but also open opportunities for future research. Of the four gaps, Gap 1 (satellite data integration) and Gap 2 (MCDM+GIS optimization model) are the most significant gaps that have not been addressed at all by the existing literature. However, merely listing these gaps is insufficient; understanding their underlying causes is critical for charting meaningful future work. The persistence of these gaps can be attributed to disciplinary silos—researchers in optimization, GIScience, and public administration rarely collaborate—as well as the technical complexity of operationalizing satellite imagery (which requires preprocessing pipelines) within transactional booking databases. The following analysis reframes each gap not as a simple omission, but as a multi-faceted design challenge involving data integration, algorithmic adaptation, and institutional readiness. These gaps are not mere omissions but reflect deeper challenges: disciplinary silos between optimization, GIScience, and public administration researchers, as well as the technical complexity of integrating satellite imagery preprocessing pipelines with transactional booking databases.

Gap 1: Satellite Data Integration. The most significant gap is the absence of intelligent booking systems that integrate satellite data (such as Sentinel-1 and Sentinel-2) into the decision-making process. This finding aligns with the research by Turner et al. [56], [57], which emphasizes that satellite data has great potential to support natural resource management, yet its integration into operational systems remains very limited. Future research can focus on developing architectures that enable booking systems to consume and process satellite data in real-time to improve decision accuracy.

Gap 2: MCDM + GIS Optimization Model. Although MCDM has been used in various fields such as tourism and education, its application to booking systems for natural resource and urban domains integrated with GIS remains very limited. Future research can focus on developing new optimization models that combine MCDM with GIS-based spatial analysis to solve complex resource allocation problems [58], [59].

Gap 3: Domain-Specific Component Guidance. Existing literature on booking system components is mostly generic or developed for other specific domains. Future research can develop a comprehensive and validated component framework for natural resource and urban development domains, which can

serve as a guide for system developers in government agencies [60], [61].

Gap 4: Siloed Systems in Government Agencies. Most research on booking systems focuses on solutions for a single domain or specific organization. Future research can address integration across systems in government agencies, including data interoperability and business processes.

E. Research Implications

This SLR yields several important theoretical and practical implications. Theoretically, it bridges critical gaps in the existing body of knowledge by presenting an updated six-category classification framework for intelligent booking systems (IBS) components, highlighting geospatial integration as a notably absent architectural element, and delivering a systematic map of research voids. These contributions extend Babafemi et al.'s [62] foundational framework with contemporary categories driven by AI, optimization, and spatial technologies.

Practically, the proposed framework (Fig. 2) acts as a blueprint for developers at Malaysia's Ministry of Natural Resources and Urban Development, Sarawak, and other government agencies. It clarifies not only the necessary modules and their interconnections but also how geospatial data can be operationalized. However, technical architecture alone is insufficient; success depends on organizational readiness, digital-intelligent transformation [63], and generative AI adoption [64]. Furthermore, frameworks for AI social responsibility [65] and sustainable governance (e.g., CICC, 2022 [66]) offer essential benchmarks for designing systems that are efficient, socially responsible, and transparent, aligning with public sector values and the digitalization mandates for resource management [1], [2].

F. Research Limitations

This review is limited to English articles, excluding non-English research. The search, confined to IEEE Xplore, SpringerLink, ScienceDirect, and ACM Digital Library (representing core CS/IS/engineering outlets), may miss relevant works in Web of Science, Google Scholar, or regional databases; Scopus was deliberately excluded after scoping searches confirmed no additional eligible records. The 2021–2025 timeframe, justified by recent AI/GIS progress, excludes earlier foundational literature, though key advancements remain recent. Finally, despite a systematic protocol, subjectivity in screening and quality assessment was unavoidable, but minimized through documented traceability.

V. Conclusion

This section presents the conclusion of the research, the contributions made, as well as suggestions for future research. The conclusion is formulated based on the findings and discussion elaborated in the previous sections, while still referring to the research questions that have been established.

A. Conclusion

Guided by the established research questions, a comprehensive Systematic Literature Review (SLR) was conducted across four major databases—IEEE Xplore, SpringerLink, ScienceDirect, and ACM Digital Library—covering the 2021–2025 period. This rigorous process initially retrieved 40 articles, which were subsequently filtered through a strict eligibility and quality assessment protocol, resulting in 16 final articles selected for in-depth synthesis. Based on this analysis, four principal conclusions have been formulated.

First, the core components of intelligent booking systems (IBS) can be systematically classified into six distinct categories. These comprise Resource Management (identified in 12 articles), Booking Management (11 articles), Intelligence and AI/Optimization (10 articles), Geospatial Integration (4 articles), System Integration (8 articles), and Security and Compliance (5 articles). While the Resource and Booking Management categories constitute the essential functional foundation consistently found across the literature, the Intelligence and Geospatial Integration categories serve as the primary differentiators, elevating these systems from conventional transactional calendars to truly adaptive and predictive platforms.

Second, to effectively meet the specific requirements of natural resource and urban development domains, these generic IBS components require three critical modifications. Geospatial data must be treated as a mandatory attribute for every resource within the system. Additionally, zoning protection and eligibility rules must be embedded as core constraints in the scheduling logic. Finally, automatic location verification capabilities, based on geospatial datasets, must be enabled. These modifications are non-negotiable given the distinct spatial characteristics and stringent regulatory frameworks governing natural resources and urban facilities, which are absent in conventional domains like libraries or laboratories.

Third, successful integration of geospatial data into intelligent booking systems requires four essential architectural elements. These include a GIS interface to connect the system to map servers for spatial data rendering, integration of Sentinel-1 and Sentinel-2 satellite data to provide up-to-date land cover and environmental change information, interactive mapping features enabling users to view and select resources based on location, and comprehensive zoning/location analysis to verify eligibility against spatial and environmental regulations. The proposed component framework (Fig. 2) presents a holistic architecture that cohesively integrates these four elements.

Fourth, the review identifies four significant research gaps currently unaddressed in the literature:

- None of the studies use Sentinel-1/2 imagery for location verification or environmental monitoring, leaving a complete void.
- No models combine Multi-Criteria Decision Making with GIS-based spatial analysis for resource and urban facility allocation; existing studies treat them separately.
- Most articles are generic or narrowly focused (e.g., parking, EV charging), lacking frameworks tailored to natural resources and urban planning.
- Current research ignores interoperability and inter-departmental collaboration, focusing only on isolated organizational environments.

Among these four gaps, Gaps 1 and 2 are the most critical, as they remain entirely unexplored in the existing literature. Consequently, they offer the most substantial opportunities for future applied research, particularly for advancing sustainable and efficient natural resource management practices in Sarawak.

B. Implications and Contributions of the Research

Theoretically, this research delivers the first Systematic Literature Review (SLR) mapping the intersection of Intelligent Booking Systems (IBS), GIS, and natural resource/urban management. This study also produces a six-category classification framework, highlighting geospatial integration as a missing architectural element. This study also provides a systematic map of research gaps.

Practically, the proposed framework (Fig. 2) in this research serves as a blueprint for system developers at the Ministry of Natural Resources and Urban Development Sarawak and other Malaysian agencies. This study offers guidance on component relationships and geospatial implementation. Policy recommendations include digitizing manual booking systems, investing in spatial data and satellite integration, and building HR capacity in geospatial AI.

Methodologically, the SLR protocol, classification framework, and geospatial integration approach are replicable for IBS studies in other domains and public sector systems.

C. Limitations and Future Research Agenda

This review has several limitations that should be acknowledged. First, it is confined to English-language articles from IEEE Xplore, SpringerLink, ScienceDirect, and the ACM Digital Library. While these databases represent the core outlets in computer science, information systems, and engineering, relevant works published exclusively in Web of Science, Google Scholar, or regional/non-English journals may have been omitted. Scopus was deliberately excluded after scoping searches confirmed no additional unique eligible records beyond those already covered. Second, the 2021–2025 timeframe was chosen to capture recent advancements in AI, GIS, and optimization technologies; however, this decision intentionally excludes foundational pre-2021 literature that may provide relevant historical context. Third, despite the implementation of a systematic and documented protocol, inherent subjectivity in title/abstract screening and quality assessment scoring was unavoidable, though it was minimized through consensus-based decision-making and traceable records.

To address the identified gaps and advance the field, future research should pursue the following directions:

- Develop MCDM+GIS optimization models – Design and validate novel optimization frameworks that integrate Multi-Criteria Decision Making with GIS-based spatial analysis specifically for natural resource and urban facility allocation, addressing the complete void identified in Gap 2.
- Integrate Sentinel-1/2 satellite data – Operationalize near-real-time Sentinel-1 (SAR) and Sentinel-2 (optical) imagery within booking workflows to enable automated location verification, land cover classification, and environmental change detection, directly tackling Gap 1.
- Validate the proposed framework via case studies – Apply the component framework (Fig. 2) in real-world settings at the Ministry of Natural Resources and Urban Development Sarawak using Design Science Research (DSR) methodologies to assess its practicality, usability, and effectiveness.
- Prototype and test the integrated system – Build functional prototypes of the geospatially-enabled intelligent booking system and conduct empirical evaluations in live government environments to measure performance improvements in decision accuracy, resource utilization, and operational efficiency.
- Engage multi-stakeholder perspectives – Incorporate viewpoints from public agencies, private sector operators, NGOs, and local communities to ensure the resulting system is equitable, transparent, inclusive, and aligned with the Sustainable Development Goals (SDGs).

By systematically bridging these gaps—particularly satellite data integration and MCDM+GIS optimization—this research provides a solid foundation for developing smarter, more transparent, and sustainable resource governance systems in Sarawak, Malaysia, and other regions facing similar urbanization and natural resource management challenges.

A Smart Transformer-Based Model to Classify Extremist Behavior on Social Media

Tamer Salah*, Hazem M. El-Bakry, Amira Rezk
Information Systems Department-Faculty of Computers and Information, Mansoura University, Mansoura, Egypt

***Abstract*—In recent years, social media has been used as a fertile environment for spreading radical ideologies through extremist organizations and groups to recruit new individuals capable of implementing their schemes. This has led to an enormous amount of extremist data that can be used by research agencies to analyze and understand the behavioral and linguistic characteristics associated with extremist language, thereby contributing to the development of policies and laws that help to protect societies from this threat. This study proposes a smart transformer-based model for collecting and analyzing data on extremism from social media to be classified based on whether or not it relates to extremism. The proposed framework begins by collecting data from Twitter by using keywords related to extremism and then filtering and reprocessing the data to implement the word embedding process that relies on a bi-directional LSTM network to provide the best representation vector for each word in the input sentence that can provide the true meaning of each word based on its position in the input sentence. Here comes the importance of extracting linguistic and semantic features of the text by building a matrix of features that can be extracted from the text, divided into three categories related to surface features, polar features, and specific domain features. Finally, after effectively preparing data and extracting features, the vector representing each sentence is inserted into the proposed smart transformer-based model to carry out the classification task, as the development steps focus on increasing the model's ability to raise the standard weight of words related to extremism in the inserted sentence, thereby contributing to increasing the accuracy of the model to classify the text. The results demonstrated the ability of the proposed model to achieve a high accuracy rate on the F1-score benchmark of 91.6% as well as 96.7% on the accuracy standard. The proposed model was able to outperform the accuracy of 5 models of other algorithms that achieved high results in the classification task, exceeding the closest competition of SVM-Linear by 0.7% at the F1-score benchmark and 0.5% at the overall rating accuracy level.**

***Keywords*—Social media; transformer-based model; word embedding; Bi-LSTM network; additive attention**

I. Introduction

In recent years, technology has evolved significantly, helping the data sector grow exponentially. With so much data, especially on social media, there is a need to develop models, algorithms, and methods to analyse these data and discover hidden relationships between them, which helps exploit these data to help decision makers in many sectors of business and medicine, as well as political decisions for the benefit of the beneficiaries.

The spread of extremist ideology in recent years in many countries of the world has led many researchers to try to understand how extremists think [12] to try to deal with them more efficiently and provide safety for societies. The rebels' use of technology has led to greater sympathy and the dissemination of their thinking, resulting in increased availability of extremist data on social media sites, a dynamic that has also been linked to the fund-raising and disruption strategies used by extremist organisations [13].

The sheer volume of available data has increased the need to develop models and algorithms for data analysis, especially text data, a need that a systematic review of the online extremism detection literature has traced across datasets, classification techniques, and validation methods [11]. The development of these algorithms aims to help the machine to understand texts like humans through natural language processing techniques (NLP). Deep learning models have evolved to achieve excellent results in terms of model performance of models, especially for text classification tasks.

A new model based on a pre-trained transformer-based learning model is designed to analyse extremism data collected from the Twitter platform, where the dataset was collected using several keywords associated with extreme behaviour. The dataset has been reprocessed to help extract semantic and linguistic features, helping to provide the best possible representation vector for the input text by using a bidirectional LSTM network to pay more attention to the meaning of the context of each word in the text. Ultimately, after discovering and expressing the features of the text well, each word's representation vector was introduced into the deep learning network based on smart transformers to provide the best classification of the text in terms of extremism into three main classes: extremist, non-extremist, and neutral.

The contribution of the proposed model is to provide the best possible representation vector for each word in the input text, which reflects the best meaning of each word based on its order in the sentence. This process begins with the effective filtering and reprocessing of the text, then extracts the extremists' behaviours by analysing the linguistic and semantic characteristics of the input text based on many algorithms that extract the surface and polar features as well as specific features of the domain. The second contribution is architectural: rather than computing full pairwise self-attention across all token pairs as in standard transformer architectures, the proposed model compresses the query, key, and value representations into single global vectors via additive attention weighting, reducing the attention computation from the standard quadratic complexity to a linear one while retaining the ability to prioritize words most relevant to extremism. This global-vector additive-attention design is combined with a three-category engineered feature

*Corresponding author.

representation — surface, polarity, and domain-specific features, the latter derived from the HertLex extremism lexicon — that is extracted independently of the transformer's learned attention weights. This combination of an efficiency-oriented additive-attention mechanism with an explicit, domain-lexicon-grounded feature representation distinguishes the proposed architecture from prior transformer-based approaches to extremism and hate-speech detection ([6], [7], [10]), which rely on the transformer's learned representations alone without an explicit domain-lexicon feature layer.

This study is organized as follows. Section II presents an overview of previous work on dealing with the detection and classification of extremist text. Section III describes the materials and methods used to analyse extremist text classification tasks. Section IV presents our results, and Section V discusses them. Section VI outlines the limitations of the present study. Finally, Section VII offers our conclusions.

II. Related Work

A dynamic matrix has been proposed in [2] to classify extremism and terrorism (DMET) that is capable of analysing and classifying extremist data on social media based on identifying user behavior and cognitive signals and determining the level of extremism based on the dissemination of their ideologies and ideas. DMET is designed to help platform decision-makers who deal with extremist content in terms of preventing or disseminating it according to its degree and risks. The machine learning (ML) model was also proposed in [3] to analyze text content on social media platforms to discover the psychological and behavioral characteristics of the text. This model relies on adding improvements to the word embedding process to ensure a good representative vector to represent the input text that contributes to building a highly efficient ML model; the experimental results show that the proposed model has achieved high performance after being applied on the Twitter platform to detect extremist activities.

In [1], a calendar-correlation analysis (CCA) hybrid algorithm based on analysis of online communities was proposed to detect far-right communities by defining distinctive changes in the activities of these communities based on key dates associated with these communities. This hybrid algorithm was applied to the Russian social network VKontakte, and the results demonstrated the algorithm's ability to accurately identify far-right societies up to 84.3% compared to other models that performed less well in identifying these communities. The Ontology Framework to Facilitate Early Detection of 'Radicalization' (OFEDR) was developed in [4] for the early detection of extremist persons by detecting the link between the political extremism of persons and its compatibility with known criminal files. The framework was applied to five deep learning models and tested on the Protégé program designed by the University of Stanford for this purpose. The results demonstrated the ability of these models to achieve outstanding results with accuracy ranging from 86.3% to 91.2%. The results also demonstrated this framework's high ability to detect early signs of extremism using probability estimates for extremely rare events.

A broader survey of extremism analysis using natural language processing [5] has documented the range of methodological approaches applied to this problem, from qualitative ontology-building efforts drawing on populations of data collected across multiple social networking platforms such as Twitter, Facebook, and YouTube, to fully automated deep learning classification pipelines, and highlights persistent challenges around dataset scarcity, label disagreement, and the rapidly evolving vocabulary of extremist discourse, along with the corresponding trends toward data augmentation strategies designed to alleviate these limitations.

More recent work has continued to push transformer-based extremism and hate-speech detection forward. RADAR#, an ensemble approach combining a hybrid CNN-Bi-LSTM framework with the AraBERT transformer through a weighted strategy, achieved 98% accuracy and a 97% F1-score on a dataset of 89,816 Arabic tweets, and additionally reported ablation studies and attention visualizations to support interpretability [6]. A related hybrid deep learning study compared Bi-LSTM and DistilBERT-based transformer architectures for extremism classification, reporting binary classification accuracy of 97.33% and multiclass transformer accuracy of 91.07% [7]. Other recent studies have advanced the representation side of the problem, proposing multi-dimensional information representations for offensive language detection [8] and deep active learning strategies for identifying hate and offensive content across multilingual social media posts [9]. Closest in spirit to the attention-based contribution of the present study, an ontology-guided attention mechanism integrating RoBERTa embeddings with graph convolutional networks was shown to outperform baseline RoBERTa implementations on multiclass hate speech detection, with particularly strong gains on demographically challenging categories [10]. Collectively, these studies confirm that hybridizing transformer embeddings with either structured domain knowledge or additional attention mechanisms, as proposed in this study, remains an active and productive direction for extremist and hateful content classification.

III. Materials and Methods

A. Methodology

This study presents the proposed methodology for building a new framework based on transformer-based models to extract and analyse several text features to identify extreme views on social media platforms. This framework is based on the use of a bi-directional network of LSTM to provide a well-represented vector for input data capable of reflecting the best meaning of each of the listed sentence's words. The proposed architecture follows a two-stage pipeline: the Bi-LSTM layer first produces a context-aware embedding for each input word, and this embedding matrix then serves as the input to the transformer block, in which standard scaled dot-product self-attention is replaced by the additive-attention formulation described in detail below. On the other hand, the process of extracting features from text depends on three main axes: the extraction of surface features, the features of polarity, as well as the specific features of the domain.

As for the process of extracting surface features of the input text, it depends on identifying the existence of specific punctuation marks, especially the exclamation mark, or not in the text, as well as URLs. Polarity feature extraction is also

aimed at identifying and classifying texts into three main categories: positive, negative, and neutral. On the other hand, extracting the specific features of the domain depends on comparing the text of the input to the HertLex dictionary and determining whether or not it is identical to the text.

The proposed framework begins with the collection of data on extremist behaviour from Twitter using many words related to extremism. The data collected is then subject to a reprocessing step to filter the data by going through many steps such as removing punctuation, removing stop words, lowering the text, tokenizing words, stemming text, and lemmatization. The overall structure of the proposed framework is clearly explained in Fig. 1.

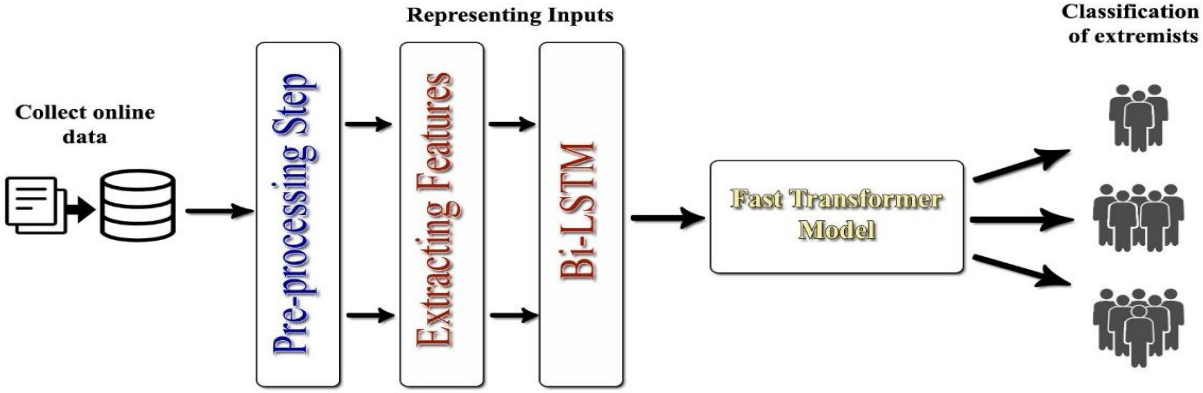

Fig. 1. General architecture for classifying extremist content.

This follows the process of representing the input text by relying on a bi-directional LSTM network that processes in both directions at the same time to focus more on the meaning of each of the entry words to provide a suitable vector that clarifies the relationship between each word and the surrounding words in the sentence. After the completion of the adequate text representation process comes the role of extracting features from the text discussed above. This process is done by relying on several algorithms capable of implementing them skilfully. The Linguistic Inquiry and Word Count (LIWC) algorithm was used to extract various additional features related to linguistic and semantic features of the input data. These features included 93 linguistic features that varied from simple word counts to complex features associated with emotional analysis of text.

Also, the Levenshtein algorithm was applied to compare input words to the HertLex dictionary by using a distance metric that measures the difference between two words. This algorithm is based on measuring the distance between two words by calculating the minimum required adjustments (delete - add - replace) on one word to reach the other, and this is done at the level of the character instead of the level of the word, where the distance between similar words decreases and vice versa.

In the end, the data that has been filtered, reprocessed, and extracted surface features from enters the last phase, which aims to extract the data polarity and also deal with punctuation, as this is done through the design of a pre-trained deep learning network based on smart transformers to classify texts into three classes (positive, negative, and neutral) and detect extreme users. The pre-trained Smart Transformer Network is based on paying more attention to the important words in the input text, which is the cornerstone of determining whether the text is extreme or not through the use of the additive transformation model that has proved highly efficient in dealing with long texts.

This model is based on converting the input word vector into three main matrices representing query, key, and value. Through the interaction between these matrices, the query weights attention(αi) is calculated to adjust the value of attention for each entry word to calculate the global query vector. It is done by calculating the appropriate attention weights based on the query matrix and the learnable parameter. The global key vector is also calculated by adjusting the key matrix weights (βi) as well as relying on the global query vector. The global value vector is also calculated by adjusting the appropriate weights and relying on the interaction between the global key vector and the adjusted weights to calculate global key vector. finally, the query, key and value global vectors are assembled using a single transformation layer suitable for representing the interactions and then passed to a dense layer based on the activation function of sigmoid to exit the appropriate classification in terms of extremes (positive, negative, and neutral) of the input text.

More formally, given the input word embedding matrix X produced by the Bi-LSTM representation layer, the query, key, and value matrices are obtained through learned projection matrices such that $Q = XW_Q$, $K = XW_K$, and $V = XW_V$. The additive attention weight for the query of the i-th word is computed as $\alpha_i = softmax\left(v^{\mathrm{T}} tanh(W_a Q_i + b_a)\right)$, where v and W_a are learnable parameters, giving the global query vector as the attention-weighted sum $q = \Sigma_i \alpha_i Q_i$. The global key vector is obtained analogously, with the key weight $\beta_i = softmax(v^{\mathrm{T}} tanh(W_b K_i + b_b)$ conditioned on q), giving $k = \Sigma_i \beta_i K_i$, while the global value $vector v_g = \Sigma_i \gamma_i V_i$ is computed using an analogous learnable weighting γ_i conditioned on k. The three global vectors q, k, and v_g are concatenated and passed through a single transformation layer, $W_o[q; k; v_g] + b_o$, before the final sigmoid-activated dense layer produces the classification output.

B. Data

The data were aggregated from Twitter by using the Twitter API tool during the period from September 2022 to February 2023 by relying on several right-wing extremism-related

keywords such as ("White Pride", "Ethnonationalism", "Anti-Globalism", "National Sovereignty", "Red Pill", and "Western Civilization"), where the dataset consists of 17,392 tweets. The dataset consists of TweetID, Username, timestamp for Tweets, and Tweets. Based on a team of three language professionals, the data was divided into three main categories: positive to extremism, negative to extremism, and neutral. Table I shows the composition of the dataset and the number of tweets in each category.

TABLE I. DETAILED DESCRIPTION OF THE DATASET

Class Name	No. of Tweets	Percentage %
Positive (Extremist)	9,451	54.3%
Negative (Non-Extremist)	5,287	30.4%
Neutral	2,654	15.3%

C. Data Preprocessing

Based on the nature of the data collected from Twitter, as it is irregular and unstructured data, it needs several steps to be processed so that it can be analysed in a good way to get out with high accuracy results in the classification task. Data processing begins with the deletion of detailed data that we do not need, such as removing non-alphabetical characters, hashtags, links, and whitespaces (tabs, newlines), converting text to lowercase, tokenizing text, using an emoji library in Python to replace emojis with short text, and finally normalizing numbers.

The data processing process is based on several tools from Python, where the Scikit-learn Library was used to implement the reprocessing steps; also, TensorFlow and Keras 2.4 tools were used to build the proposed deep learning model. The proposed deep learning model was implemented in an operational environment based on an eight-core CPU due to the small volume of data. The model's hyperparameter metrics are defined as follows: the aggregated data is divided into 80% training data and 20% test data, and the proposed model is also trained for 5 epochs using a 3e-4 learning rate, with Adam identified as the optimizer of the proposed model. On the other hand, the data is divided into 64-size batches, with a maximum sequence size of 128 and a 0.5 threshold for classification tasks.

On the other hand, the hyperparameters of the Bi-LSTM network are as follows: the hidden state of the network is set to 200, divided into 100 hidden states forward as well as 100 backward, also set 0.4 as a dropout rate in the LSTM layers; and stochastic gradient descent (SGD) is also used to handle the loss function through the back-propagation step. Finally, a sigmoid activation function in the pretrained steps for the multilabel classification tasks.

IV. RESULTS

The proposed framework was applied, and the classification function was evaluated on the basis of accuracy of results using precision, recall, and the F1-score of the positive data class. The results were also compared with several pre-trained models. Table II includes a comparison of the results of the proposed model assessment with a set of 5 algorithms, all implemented on the same collected data, as these algorithms have achieved promising results in the data classification task. The evaluation results of our model were compared with the results of several Machine learning algorithms, such as Support Vector Machine (SVM-linear) [14], Support Vector Machine with Radial Basis Function (SVM-RBF), Random Forest, Logistic Regression, and Decision Tree (DT).

TABLE II. COMPARISON OF THE PROPOSED MODEL WITH FIVE LEADING ALGORITHMS

Model	Precision	Recall	F1-score
SVM-Linear	0.934	0.886	0.909
SVM-RBF	0.951	0.835	0.889
Random Forest	0.976	0.801	0.880
Logistic regression	0.934	0.855	0.892
Decision Tree(DT)	0.896	0.912	0.904
Our Model	0.922	0.916	0.916

There are many hyperparameters set up for machine learning algorithms; for the SVM algorithm relied on a linear kernel, adjusted the penalty parameter to 1, and set the stopping criteria to 0.001. As for the logistic regression algorithm, the stopping criteria were set to 0.01 with reliance on L2 penalty. On the other hand, the random forest algorithm used the entropy standard with 200 estimators. In addition, the decision tree algorithm used default settings. Table III explains the percentage accuracy rate in the implementation of the classification task based on the confusion matrix.

TABLE III. TEXT CLASSIFICATION ACCURACY RESULTS OF COMPARING THE PROPOSED MODEL WITH 5 MACHINE LEARNING ALGORITHMS

Model	Accuracy %
SVM-Linear	96.2%
SVM-RBF	95.5%
Random Forest	95.3%
Logistic regression	95.6%
Decision Tree (DT)	95.8%
Our Model	96.7%

V. DISCUSSION

The experimental results in Table II showed that there was strong competition between our model and machine learning algorithm models in the implementation of the classification task, as the lowest rate of F1-score was achieved by the Random Forest algorithm at 88% while the highest rate achieved by our model is 91.6%, up to 3.6%, although Random Forest's algorithms are capable of achieving the highest correct positive predictions rate for extreme tweets(Precision) by 97.6%, while the Recall ratio was the lowest on all models at 80.1%, reflecting the overall inaccuracy of the model.

This reflects the low accuracy rate of the Random Forest algorithm, shown in Table III at a rate of 95.3%. The other models while our model was able to achieve the highest accuracy rate of 96.7%. This is because the superiority of our model over other machine learning algorithms in the standard F1- score has led to another outperformance in the overall rating accuracy level, leading to an increase in the accuracy of the model up to 1.4% from the lowest model, the Random Forest

algorithm, while the increase in accuracy is up to 0.5% from the nearest competing model, SVM-Linear.

Experimental results in Table II show that the proposed model has produced promising results in the text classification task, where it can outperform all machine learning models that have managed to achieve high results in this task before. In more detail, our model achieved 91.6% on the F1-score benchmark, outperforming the strongest classical machine-learning baseline evaluated in this study, the SVM-Linear algorithm, by 0.7%; although the SVM-Linear algorithm outperformed the correct positive prediction rate for extreme tweets by 1.2%, it failed in sensitivity ratio (Recall) by 3%. This close competition between deep learning and classical machine learning approaches echoes findings from comparative classification studies conducted on extremist content in other languages [16], suggesting that the margin of improvement achievable through architectural changes alone may be inherently limited without complementary gains in feature representation or data quality.

VI. LIMITATIONS

Although the proposed model has achieved promising results, several limitations of the present study should be acknowledged. On the dataset side, the aggregated data was collected using keywords associated with a single ideological strand of extremism, right-wing extremism, over six months, and from a single platform, Twitter, so the ability of the proposed model to generalise to other forms of extremism, other platforms, or other time periods has not yet been tested. On the other hand, the three classes are notably imbalanced (54.3%, 30.4%, and 15.3% of the dataset, respectively), and the effect of this imbalance on the model's ability to correctly classify the minority neutral class has not been separately analysed. As for the labelling process, although a team of three language professionals was relied on to annotate the dataset, a formal inter-annotator agreement score was not computed, so the reliability of the ground-truth labels cannot yet be quantified. In terms of evaluation, the proposed model was assessed using a single 80%/20% train-test split rather than k-fold cross-validation, and the reported improvements over the closest competing algorithm, SVM-Linear, are relatively small (0.7% at the F1-score benchmark and 0.5% at the accuracy level), so statistical significance testing would be needed to confirm that these gains are not attributable to chance. A paired test such as McNemar's test, applied to the per-instance predictions of the two models on the shared test set, would be a natural next step to establish this formally. Finally, the comparison in this study was restricted to classical machine learning algorithms and did not extend to other pre-trained transformer architectures such as BERT or RoBERTa, although prior work applying transformer-based approaches to related extremism and hate-speech classification tasks has reported F1-scores in the 91–97% range [6,7], broadly consistent with the 91.6% F1-score achieved here; nor did it include an ablation study capable of isolating the individual contribution of the feature-extraction step from that of the attention-weight modification.

VII. CONCLUSION

A new framework has been developed in this study based on the extraction of the text's connotative and linguistic features by paying attention to several steps that directly help to improve the representation of the data entered, including attention to the process of preparing and reprocessing the data collected to extract important features from the text. Relying on the LIWC extraction algorithm to extract many language features, as well as those associated with word counts and repeated words in the input text, contributes to the introduction of the text representation vector capable of reflecting as many text features as possible.

The process of extracting these linguistic features contributed to the presentation of a well-equipped text for the process of embedding words, in which a Bi-LSTM network was used to increase attention to the importance of the order of words in the input sentences, thereby contributing to further clarification of the meaning of each word in the input sentence. On the other hand, after paying attention to the good representation of the data, the data enters a pre-trained deep learning model based on smart transformers. The power of the smart transformer is to use matrices of global queries, keys, and values by calculating the required adjustments to the attention weights that are assembled in one transformation layer to interact with each other and then using a suitable dense layer with a sigmoid activation function to classify the input text into three categories: extremist, non-extremist, and neutral.

After the proposed model was trained on 80% of the aggregated data and tested on 20% of the same data, the results of the performance evaluation of the proposed model appeared in Table II and Table III, where Table II showed the results of the evaluation of the accuracy of the proposed model compared to 5 machine learning models that had previously achieved promising results in the data classification task. In addition, Table III shows the accuracy of each model in general in the data classification task.

The proposed model clearly outperformed all algorithms in comparison based on the F1-Score benchmark by an estimated 3.6% increase over the lowest competitors and Random Forest and 0.7% higher than the nearest competing algorithm, SVM-Linear. At the level of accuracy of the models as a whole, our model was able to achieve the highest accuracy with an estimated 1.4% increase from the lowest accuracy achieved by the Random Forest algorithm and an estimated 0.5% increase from the nearest rival's SVM-Linear algorithm.

As future work, the proposed framework could be extended beyond text-only inputs to incorporate multimodal feature extraction techniques, such as those developed for meme and image-based sentiment classification [15], in order to capture the full range of multimedia content through which extremist material is shared on social media.

Abstract*—The multi-objective nature of task scheduling for novel latency-sensitive applications in IoT-Fog-Cloud hierarchies presents persistent challenges, where optimizing one QoS metric often degrades another. Although bio-inspired algorithms provide adaptive solutions, existing comparative studies are constrained by narrow algorithmic scopes, limited evaluation metrics, and a notable absence of statistical validation. To bridge this gap, we introduce a novel unified benchmarking framework that systematically evaluates five prominent metaheuristics — Particle Swarm Optimization (PSO), Genetic Algorithm (GA), Bacterial Foraging Optimization (BFO), Ant Colony Optimization (ACO), and Artificial Bee Colony (ABC) — for load balancing within a three-tier architecture using the iFogSim simulator. We evaluate performance across three QoS dimensions (response time, makespan, and load imbalance degree) under three escalating workload intensities on heterogeneous infrastructure, with all experiments repeated over 10 independent runs. Statistical significance is assessed via the Wilcoxon signed-rank test against GA, selected as a widely established and computationally stable baseline. Our findings reveal no universally optimal algorithm. GA consistently maintains mean response times below 30.5 ms across all workloads, while PSO and BFO remain statistically indistinguishable from GA on makespan, highlighting their interchangeability under specific conditions. Conversely, ABC uniquely excels in distribution equity, reducing load imbalance from 2.64% to 1.32% as task density increases. ACO, however, incurs statistically significant penalties across all metrics, suffering from a pronounced cloud-bias that elevates load imbalance to 11.0% —up to eight times higher than its counterparts. Collectively, these results confirm the inherent trade-offs between latency, efficiency, and fairness. This reference benchmark delivers a reproducible, statistically validated performance baseline, offering system architects a clear empirical foundation for adaptive algorithm selection in heterogeneous Fog-Cloud environments.

Keywords*—Load balancing; IoT-Fog-cloud; metaheuristic algorithms; iFogSim; QoS optimization; wilcoxon signed-rank test; task scheduling; edge computing

I. Introduction

Billions of connected devices across healthcare systems, smart cities, industrial automation, and transportation are now pumping out data faster than ever, and most of it needs to be processed right away. Cloud computing can certainly handle the volume; computational power was never really the issue. The problem is latency: when an application needs a response in milliseconds, the round trip to a distant data center simply takes too long. This gap is exactly what fog computing was built to close. By placing processing nodes between the IoT devices and the cloud, it gives rise to a three-tier IoT-Fog-Cloud architecture that keeps time-sensitive workloads closer to where the data is actually generated. Fog computing essentially solves the capacity-latency trade-off by moving computation closer to where the data originates, which cuts down on bandwidth usage and makes real-time processing at the network edge actually possible. The catch is that fog nodes are nowhere near as powerful as cloud servers, so resource management becomes a real challenge. Tasks coming from a mix of heterogeneous IoT devices need to be spread across fog and cloud tiers in a way that balances several competing QoS goals at once, namely response time, makespan, and load distribution, none of which can be optimized in isolation. And this task assignment problem happens to be NP-hard: as the number of tasks and resources grows, the search space explodes exponentially, so finding the exact optimal solution simply isn't feasible at any meaningful scale.

Given this complexity, it's no surprise that load balancing in IoT-Fog-Cloud environments remains particularly hard to get right, as fog nodes vary widely in capability, IoT workloads fluctuate unpredictably, and edge applications often come with strict QoS constraints that leave little margin for error. Deterministic methods like Round Robin sidestep the complexity by spreading tasks evenly across nodes, but that simplicity comes at a cost: it ignores resource heterogeneity entirely, which inevitably hurts performance. Metaheuristic algorithms inspired by nature — PSO, ACO, GA, BFO, ABC — have emerged as a more adaptive answer, designed to navigate large, complex solution spaces and converge on near-optimal task assignments across the fog-cloud hierarchy. Yet despite a fair amount of research exploring these algorithms individually, very few studies have actually tested them side by side under the same conditions, using the same metrics, with results backed by rigorous statistical analysis. Most existing studies evaluate only a limited number of algorithms at a time, each under its own topology, metrics, and experimental conditions, which makes meaningful cross-study comparison difficult. Furthermore, many comparative works rely on a single QoS metric, overlooking the multi-dimensional trade-offs that characterize real fog deployments. Because statistical validation across multiple independent runs is rarely part of the picture, the reliability of reported results suffers further, leaving practitioners with little solid, evidence-based guidance for

choosing an algorithm in heterogeneous fog environments. This work sets out to address these gaps not by proposing a new load balancing algorithm, but by conducting a comprehensive, rigorous comparison of five existing algorithms, evaluated under a unified experimental framework using the iFogSim simulator.

The main contributions of this study are as follows:

- A unified experimental framework: all five algorithms are tested under the same conditions; the same three-tier topology, same task distribution, same simulation parameters, so the comparisons actually mean something and can be reproduced.
- Multi-metric evaluation: rather than focusing on a single number, three QoS metrics are tracked at once, namely response time, makespan, and load imbalance degree, to capture the trade-offs that really shape fog deployments in practice.
- Statistical rigor: each algorithm is run 10 times independently, with results reported as mean and standard deviation, giving a much more reliable picture of performance than what a single run could ever show.
- BFO in an IoT-Fog-Cloud setting: Bacterial Foraging Optimization is tested here within a three-tier IoT-Fog-Cloud architecture, a pairing that only a handful of existing studies have actually looked into.

The remainder of this study is structured as follows. Section II reviews related work on load balancing and task scheduling in fog and cloud environments. Section III presents the system model and the experimental framework adopted in this study. Section IV reports the experimental results along with the corresponding statistical analysis, and discusses the main findings and their practical implications. Section V concludes the study and outlines directions for future research.

II. Related Work

Load balancing in IoT-Fog-Cloud environments has attracted considerable research attention, driven by the need to handle latency-sensitive workloads across heterogeneous and resource-constrained fog nodes. Researchers have approached the problem from many angles, ranging from simple deterministic strategies to nature-inspired metaheuristic algorithms, each striking a different balance between response time, resource utilization, and scalability. The literature reviewed below is organized into several categories: survey studies, deterministic approaches, PSO-based methods, ACO-based methods, GA-based methods, BFO-based methods, and comparative evaluations, before closing with the research gaps that motivate the present work.

A. Survey Studies on Load Balancing in Fog Computing

Several systematic survey works have contributed to mapping the state of the art in load balancing for fog environments and identifying where the open research questions still lie. Kaur and Aron [1] conducted one of the most comprehensive studies in this space, covering approaches ranging from simple static policies to fairly sophisticated nature-inspired optimization algorithms. Their proposed taxonomy sorts existing methods along several dimensions, including algorithm type, optimization objective, deployment architecture, and evaluation methodology. A key finding of their analysis is that nature-inspired metaheuristics generally outperform deterministic methods once fog deployments become heterogeneous, particularly under dynamic and unpredictable IoT workloads where resource availability and task arrival patterns fluctuate over time. Their work also flags a problem that recurs throughout the literature: the absence of standardized evaluation frameworks, which makes it difficult to trust comparisons drawn across different studies. This observation directly motivates the unified experimental design adopted in the present study, where all five algorithms are evaluated under strictly identical conditions. Aldossary et al. [2] extended this analysis through a more recent systematic literature review specifically focused on load balancing techniques in fog computing, covering architectures, strategies, and emerging trends across a large corpus of studies. Their review systematically categorizes existing approaches and reveals that the vast majority of published works optimize a single QoS metric, most commonly either latency or energy consumption, while neglecting the multi-dimensional trade-offs that characterize real-world fog deployments. Their analysis further highlights that most simulation-based evaluations rely on single runs without statistical validation, which is insufficient to characterize the behavior of stochastic optimization algorithms that can exhibit significant run-to-run variability. These findings strongly support the multi-metric, statistically validated evaluation methodology adopted in the present work.

At a broader architectural scope, Isong and Mamidza [3] surveyed computational task scheduling across the full IoT-Edge-Fog-Cloud continuum, examining scheduling algorithms, their adaptability to dynamic environments, and the research gaps that persist across deployment layers. Their survey points out that while substantial progress has been made on cloud-specific scheduling, fog-specific challenges remain systematically underaddressed, particularly around multi-tier task coordination, node heterogeneity management, and real-time responsiveness under fluctuating workloads. They further note that most existing fog scheduling algorithms are evaluated under simplified topologies that fail to capture the complexity of real-world three-tier IoT-Fog-Cloud deployments, which limits how far the reported results can actually be trusted in practice. From a broader algorithmic perspective, Sinha and Parewa [4] conducted a systematic review of bio-inspired and machine learning-based multi-task scheduling techniques in cloud computing environments, covering a wide range of nature-inspired algorithms including GA, PSO, ACO, BFO, and their hybrid variants. Their analysis confirms that bio-inspired approaches consistently outperform classical heuristics across multiple QoS dimensions and identifies BFO as a relatively underexplored algorithm in scheduling contexts compared to the more widely studied PSO, ACO, and GA families.

B. Deterministic Approaches and Classical Load Balancing

Among deterministic load balancing strategies, Round Robin remains one of the most widely deployed methods in both cloud and fog environments due to its simplicity, predictability, and negligible computational overhead. By distributing incoming tasks uniformly across available resources in a cyclic

fashion, Round Robin requires no prior knowledge of task characteristics or resource capabilities, making it straightforward to implement in any deployment scenario. However, its fundamental limitation lies precisely in this uniformity: fog nodes vary significantly in processing capacity, memory, communication bandwidth, and current load, and assigning equal numbers of tasks to unequal resources inevitably produces severe load imbalance, increased response times, and degraded QoS under heterogeneous workload conditions. This well-documented limitation has driven the transition toward optimization-based scheduling strategies in the fog computing literature. Azmi et al. [5] compared task scheduling approaches in multi-tier fog-cloud computing, from classical methods such as Round Robin and First Come First Served to greedy multi-objective optimization strategies. Testing these under a unified multi-tier topology, they found that classical deterministic methods struggle with workload heterogeneity, producing higher response times and makespan than optimization-based alternatives. They also point out a complication specific to multi-tier setups: decisions made at the fog level ripple downstream and affect cloud-tier resource utilization, which is part of why multi-metric evaluation matters. What their comparison leaves out, though, is any nature-inspired metaheuristic, PSO, ACO, GA, or BFO, so it remains unclear how classical approaches actually stack up against these more sophisticated methods under the same experimental conditions. Singh et al. [6] proposed a fog-cluster based load balancing technique, organizing fog nodes into hierarchical clusters with cluster heads handling local task distribution. The hierarchy pays off in two ways: less inter-node communication overhead and better scalability than a fully centralized approach. Their results back this up, showing better resource utilization and response time than flat Round Robin. What's missing is any comparison against metaheuristic algorithms, and the metrics covered are fairly narrow, so it's hard to say how well their conclusions would hold up in more complex, heterogeneous fog deployments.

C. PSO-Based Approaches for Load Balancing

Particle Swarm Optimization has emerged as one of the most widely investigated metaheuristic algorithms for load balancing and task scheduling in fog and cloud environments. Drawing on the collective behavior of bird flocks and fish schools, PSO models candidate solutions as particles that move through the search space by combining their own best-known position with the swarm's global best. This lets the algorithm explore large, complex solution spaces without needing gradient information, which fits well with the NP-hard task assignment problems typical of fog computing. Goel et al. [7] compared PSO and ACO for workflow scheduling in fog computing using the iFogSim simulator, evaluating both algorithms on makespan and cost within a three-tier IoT-Fog-Cloud topology. Their setup shares our simulation environment and three-layer architecture, but the focus stays on workflow scheduling rather than load balancing itself, leaving a gap our work sets out to fill. The comparison also stops at two algorithms and two metrics, with no statistical validation across multiple runs. Shaik et al. [8] pair PSO with simulated annealing for resource allocation in fog-cloud environments, a sensible match since simulated annealing's probabilistic acceptance of worse solutions gives PSO exactly what it lacks: a way out of local optima, PSO's main weakness. The payoff: more uniform load distribution and faster response times than standalone PSO. Along similar lines, Kumar et al. [9] pair PSO with Bacterial Colony Optimization for fog load balancing instead, reporting makespan reductions of up to 35% over an adaptive inertia-weight PSO variant under heavy workloads. Neither study, however, benchmarks their PSO variant against GA, BFO, ACO, or ABC, so it's unclear how these hybrids would fare against the other algorithms under the same conditions; this is a gap the present comparison addresses directly.

D. ACO-Based Approaches for Load Balancing

Ant colony optimization brings a different metaphor to the table: pheromone trails left by foraging ants, reinforced over time, gradually steering the colony toward better paths. That mechanism translates naturally into task scheduling and load balancing for fog environments, and it is explored extensively. Yakubu and Murali [10] built on this with a resource allocation framework that pairs ACO with priority-based scheduling across IoT-Fog-Cloud tiers, assigning priority levels by deadline sensitivity and computational demand, then letting ACO's pheromone-guided search construct task-to-resource mappings that minimize response time without violating those priorities. Their comparison, however, stays within the ACO family, with no systematic look at other metaheuristics. Load imbalance never shows up in their evaluation at all, even though it's one of the three metrics, alongside response time and makespan, that we track here. Rafique et al. [11] went a step further with NBIHA, a bio-inspired hybrid that folds together multiple swarm-based operators: ACO-style pheromone updates alongside PSO-style velocity-based position updates. NBIHA consistently outperformed standalone ACO and PSO across several QoS metrics, though their evaluation targets a cloud-centric environment without a fog tier and does not provide a systematic comparison across a broader set of bio-inspired algorithms under unified conditions.

E. GA-Based Approaches for Load Balancing

Genetic algorithms form another well-established branch of metaheuristics applied to fog and cloud scheduling, borrowing from natural selection and genetic inheritance to evolve populations of candidate solutions across generations of selection, crossover, and mutation. Saad et al. [12] built a hybrid GA-PSO algorithm for multi-objective task scheduling in fog environments, aimed at big data applications where high volumes of concurrent tasks come with heterogeneous computational demands and tight latency constraints. The hybrid consistently outperformed both standalone GA and standalone PSO across all three QoS metrics in their tests, though ACO and BFO never entered the comparison. Shakir et al. [13] took a different route, presenting a multi-objective genetic algorithm grounded in SPEA2 for load balancing in large-scale IoT-Fog-Cloud health monitoring systems. Their iFogSim simulations show notable drops in latency and network congestion against classical Round Robin and First Fit policies, but the analysis stops at those classical baselines, leaving PSO, ACO, and BFO outside the comparison.

F. BFO-Based Approaches for Load Balancing

Bacterial Foraging Optimization, originally proposed by Passino and inspired by the foraging behavior of Escherichia

coli bacteria, is characterized by four core biological mechanisms: chemotaxis, reproduction, and elimination-dispersal, which collectively provide a distinctive balance between local exploitation and global exploration. Hosseinlou et al. [14] proposed BFO-HH, a hyper-heuristic framework that employs BFO as a high-level controller to dynamically select and combine four low-level scheduling heuristics in cloud data centers. Their experimental evaluation demonstrates consistent and statistically significant outperformance over GA, PSO, ACO, and ABC across all evaluated metrics, with statistical validation over 25 independent runs using paired t-tests. However, their evaluation is conducted in a cloud-only setting without a fog processing layer. Reffad et al. [15] proposed a dynamic adaptive bio-inspired multi-agent system for healthcare task deployment in fog computing environments, combining BFO-inspired adaptive behavioral mechanisms with a distributed multi-agent coordination framework. While their work confirms BFO's adaptability in dynamic fog environments, their evaluation is application-specific and does not include a systematic comparison with other metaheuristic families.

G. ABC-Based Approaches for Cloud and Fog Scheduling

Several recent studies have explored bee-colony-inspired strategies for resource scheduling in fog and cloud environments. Liu et al. [16] proposed a hybrid particle swarm genetic artificial bee colony algorithm (PGABC) combined with PSO-based load balancing (PGABC-PSO) for fog computing resource scheduling, embedding chromosome-crossover operators from the genetic algorithm into the employed-bee and scout-bee phases of the artificial bee colony (ABC) algorithm to address its tendency to fall into local optima. Their two-level architecture used PSO to balance load within a single fog cluster and PGABC to schedule tasks across clusters, reporting delay reductions of up to 28.5% and energy consumption reductions of up to 12.6% compared to standard ABC and PSO. Similarly, Wang [17] introduced a Modified Artificial Bee Colony (MABC) algorithm for dynamic load balancing across virtual machines in cloud computing, integrating genetic crossover and mutation operators to counteract the rapid loss of population diversity that limits the standard ABC algorithm's ability to propagate knowledge of the best solution across generations. Their results showed improvements in cost, energy, and resource utilization relative to existing approaches. While these studies demonstrate the effectiveness of bee-colony and hybrid bee-colony/genetic strategies for fog and cloud resource scheduling, none provides a systematic comparison across multiple bio-inspired metaheuristic families within a unified three-tier IoT-Fog-Cloud framework. This gap is precisely what the present study addresses by evaluating PSO, GA, BFO, ACO, and ABC under identical experimental conditions.

H. Comparative Evaluations and Identified Limitations

Subramoney and Nyirenda [18] carried out a comparative evaluation of population-based optimization algorithms for workflow scheduling in cloud-fog environments. Their work centers on workflow scheduling rather than load balancing proper, and while it marks a useful step toward systematic benchmarking, the comparison covers only a limited number of algorithms and leaves BFO out entirely. The results also rest on single runs, with no statistical validation across repeated trials. Vispute and Vashisht [19] took a different angle with LETSO, a scheduling algorithm built around energy efficiency for task scheduling in fog computing, benchmarked against the Bee Life Algorithm and Modified PSO. Here too, the scope stays narrow, with a single primary QoS objective and only two competing algorithms in the mix.

I. Research Gap and Motivation

Taken together, the literature reviewed above points to four gaps that this work sets out to close. Comparative studies tend to stop at a handful of algorithms, tested under different topologies, metrics, and simulation setups, which makes any comparison across studies shaky at best. Most published work also looks at just one QoS metric, missing the multi-dimensional trade-offs that actually play out between response time, makespan, and load distribution. BFO, meanwhile, has received far less attention than PSO, ACO, or GA in three-tier IoT-Fog-Cloud settings specifically, with most BFO-based studies confined to cloud-only or application-specific environments. And statistical validation across multiple independent runs is largely absent, which undercuts how much confidence one can place in reported performance numbers. This study takes on all four gaps at once, comparing five load balancing algorithms — PSO, GA, BFO, ACO, and ABC — within a single unified iFogSim framework [20], across three QoS metrics simultaneously, over 10 independent runs, with Wilcoxon signed-rank tests for statistical validation.

III. Experimental Framework

A. System Model and Architecture

The simulation environment models a three-tier IoT-Fog-Cloud architecture consistent with real-world heterogeneous deployments. The architecture comprises three interconnected layers as illustrated in Fig.1.

To evaluate the behavior of the five load balancing algorithms under increasing task load conditions, three workload configurations of increasing density are considered, denoted T1-Small, T2-Normal, and T3-Heavy. Each configuration preserves an identical architectural structure and infrastructure size while varying only the total number of tasks assigned to the system, as summarized in Table I. The tasks-per-device ratio reflects the average number of tasks generated per IoT device in each configuration, computed as the total number of tasks divided by the number of IoT devices, and serves as an indicator of the per-device workload intensity. The total resource count $|R|$ denotes the number of processing resources available for task allocation, namely the 10 fog nodes and 32 cloud cores ($|R| = 42$), and remains constant across all configurations since only the task volume varies, while IoT devices are excluded from $|R|$ as they act as task sources rather than processing resources.

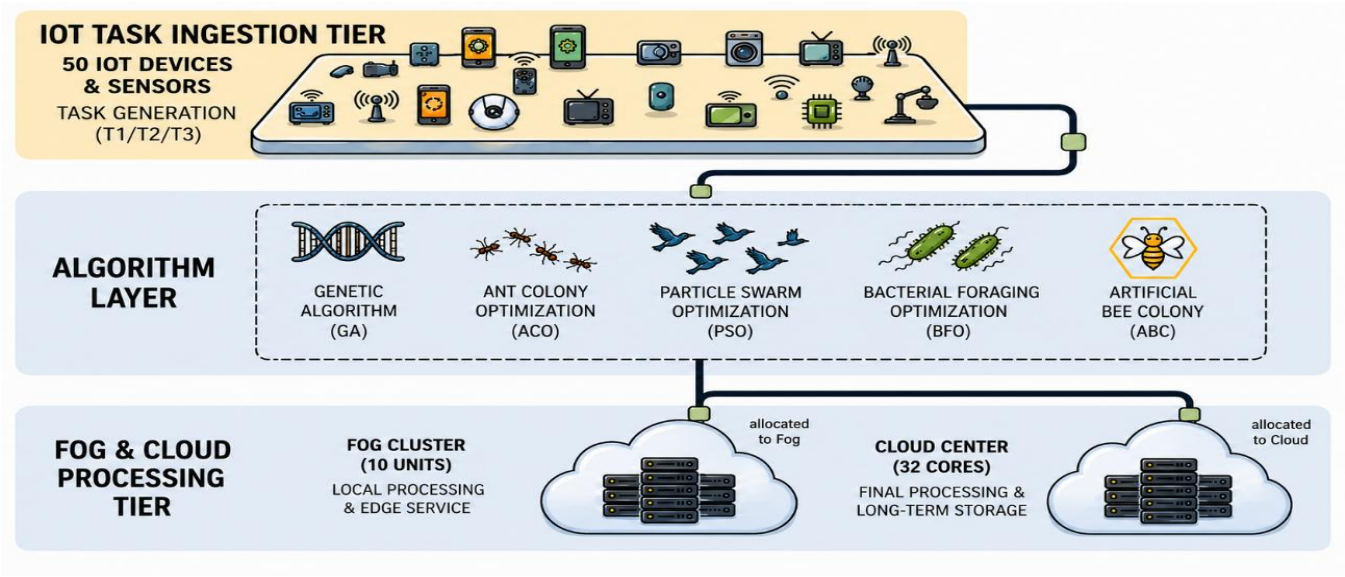

Fig. 1. Three-tier IoT-Fog-Cloud architecture and load balancing.

TABLE I. WORKLOAD CONFIGURATIONS (NUMBER OF DEVICES, NODES, AND TASKS PER SCENARIO)

Parameter	T1-Small	T2-Normal	T3-Heavy
IoT devices	50	50	50
Fog nodes	10	10	10
Cloud cores	32	32	32
Total tasks	500	1000	2000
Type 1 tasks	170	340	680
Type 2 tasks	165	330	660
Type 3 tasks	165	330	660
Tasks/device ratio	10	20	40
Resources |R|	42	42	42

The edge layer comprises fifty heterogeneous IoT devices, configured with varying task generation profiles in terms of rate, size, and computational demand, in order to simulate a realistic and heterogeneous workload. Tasks are generated continuously and deterministically, at a rate that scales with the workload configuration, before being forwarded to the fog layer. Ten heterogeneous fog nodes make up the fog layer, and their configuration does not change across the three workload scenarios. The fog and cloud layers communicate through links defined by latency and bandwidth parameters, mirroring the wide-area network (WAN) conditions one would expect between edge infrastructure and a centralized cloud. Fog nodes were deliberately given varying processing capacities and memory sizes, a choice meant to mirror the kind of resource variability found in real deployments — smart city infrastructure and industrial IoT systems being two common examples.

The cloud layer consists of one cloud server, fixed across all configurations, equipped with 32 high-capacity processing cores that provide substantially greater computational power than the fog nodes. Resource specifications for all three layers are summarized in Table II.

TABLE II. RESOURCE SPECIFICATIONS PER LAYER

Parameter	IoT Devices	Fog Nodes	Cloud Server
MIPS	[50, 100]	[200, 6500]	[50000, 100000]
RAM (MB)	[128, 512]	[512, 8192]	[131072, 262144]
BW (Mbps)	[500, 1000]	[1000, 10000]	100000
Latency (ms)	[5, 10]	[10, 50]	[10, 50]

Tasks are classified into three types with heterogeneous computational requirements, as described in Table III. For illustrative purposes, Type 1 tasks correspond to lightweight operations (e.g., sensing, monitoring), Type 2 tasks to intermediate processing workloads (e.g., data aggregation and filtering), and Type 3 tasks to computationally intensive operations (e.g., video analytics, machine learning inference). The total number of tasks scales from 500 in T1-Small to 1000 in T2-Normal and 2000 in T3-Heavy, maintaining a constant tasks-per-device ratio of 10, 20, and 40, respectively, as detailed in Table I.

TABLE III. TASK TYPE SPECIFICATIONS

Task Type	Length (MI)	Bandwidth (Mbps)	Deadline (ms)
Type 1	[100, 500]	[50, 200]	[10, 50]
Type 2	[501, 1000]	[500, 1000]	[51, 100]
Type 3	[1001, 2000]	[2000, 5000]	[101, 150]

B. Problem Formulation

1) System notation: To formally characterize the load balancing problem, an allocation function $\varphi : T \rightarrow R$ is defined, mapping each task t_i to a resource $R_j \in R$. Three QoS metrics are introduced to quantify the performance of φ in terms of latency, resource utilization balance, and overall completion time, which the allocation function seeks to jointly optimize.

a) Metric 1: Response Time (RT): Response time is the total latency that a task experiences from submission to

completion. It accounts for both network transmission time and execution latency on the assigned resource. For this reason, response time serves as the primary metric for user-facing quality of service (QoS) in latency-sensitive IoT applications [21]. The response time for task t_i assigned to resource R_j is defined as:

$$RT_{\{i,j\}} = lat_j + \frac{len_i.(MIPS_j + BW_j)}{MIPS_j \times BW_j} \quad (1)$$

where, lat_j is the network latency to resource Rj, len_i is the task length in MI, $MIPS_j$ is the processing capacity, and BW_j is the available bandwidth. The average response time over all K tasks is:

$$RT = \frac{1}{K} \sum_{i=1}^{K} RT_{i,\varphi(i)} \times 1000\ (ms) \quad (2)$$

b) Metric 2: Load Imbalance Degree (LID): The Load Imbalance Degree (LID) metric measures how evenly computational load is distributed across the available computing resources. A high LID value indicates that load is unevenly distributed, leading to resource waste and increased queuing delays for tasks assigned to overloaded resources [8]. In this study, LID is computed across all schedulable resources, including both fog nodes and the cloud server, following Shaik et al. [8] [Eq. (18)], as follows:

$$LID = \left(\left(max_{j\in R}(load_j) - min_{j\in R}(load_j)\right) \times 100\ (\%)\right) \quad (3)$$

where, $load_j$ represents the normalized computational load of a resource R_j , defined as the fraction of total work assigned to that resource. A value of LID = 0% indicates perfect load balance.

c) Metric 3: Makespan (MS): Makespan represents the total elapsed time required to complete all tasks in the system, defined as the finishing time of the last task across all resources. It reflects the efficiency of parallel resource utilization — a lower makespan indicates that tasks are well distributed across available resources, minimizing idle time and maximizing throughput [22]. It is defined as:

$$MS = max_{j\in R}\left(\sum_{i:\varphi(i)=j} \frac{len_i}{MIPS_j}\right) \times 1000\ (ms) \quad (4)$$

d) Objective function: The three metrics are combined into a unified scalar fitness function through weighted min-max normalization, allowing simultaneous optimization of all QoS objectives [8]:

$$F(\varphi) = W_{RT}.\widehat{RT} + W_{LID}.\widehat{LID} + W_{MS}.\widehat{MS} \quad (5)$$

where, $\hat{\cdot}$ denotes min-max normalization applied to each metric over the observed value range, ensuring that RT, LID, and MS are scaled to a comparable unit interval before aggregation. The weights are set to W_{RT} =0.40, W_{LID} = 0.30 and W_{MS}=0.30, reflecting the higher priority assigned to response time in latency-sensitive IoT applications, while maintaining balanced consideration of load distribution and completion efficiency.

2) Algorithm configurations and simulation environment: Five bio-inspired load balancing algorithms are evaluated in this study: PSO, GA, BFO, ACO, and ABC. All algorithms are implemented in their standard canonical forms without domain-specific hybridization or parameter tuning, ensuring a fair and unbiased comparison. Parameter values for each algorithm — population/colony/swarm size, iteration count, and algorithm-specific coefficients such as PSO's inertia weight or ACO's evaporation rate — were adopted from their most widely used canonical settings in the metaheuristic optimization literature rather than tuned specifically for this fog-cloud environment; this choice was made deliberately to isolate intrinsic algorithmic behavior from the confounding effect of per-algorithm tuning effort, at the cost of not reflecting the potentially improved performance each algorithm could achieve under a dedicated sensitivity analysis, a trade-off revisited in the Limitations section. Critically, all five algorithms share the same fitness function F(φ), the same task set T, the same resource configuration R, and the same iFogSim simulation environment. Performance differences observed in the results are therefore solely attributable to the intrinsic algorithmic behavior of each method. The complete parameter settings are summarized in Table IV.

TABLE IV. ALGORITHM PARAMETER SETTINGS

Algorithm	Parameter	Value
ABC	Colony size / Iterations	40 / 100
	Abandonment limit (LIMIT)	20
PSO	Particles / Iterations	40 / 100
	Inertia W	0.7
	Coefficients C1, C2	1.5, 1.5
ACO	Ants / Iterations	40 / 100
	α, β	1.0, 2.0
	Evaporation ρ	0.1
	Deposit Q	1.0
GA	Population / Iterations	40 / 100
	Crossover rate	0.8
	Mutation rate	0.1
BFO	Bacteria S	40
	Chemotaxis Nc	100
	Swim length Ns	4
	Reproduction Nre	4
	Elimination Ned	2
	Dispersion prob. Ped	0.25
All algorithms	Fitness function	F(φ) — shared
	Resources |R|	42

All experiments are conducted using iFogSim [20], a Java-based simulator widely used for modeling and evaluating IoT-Fog-Cloud environments. Each algorithm is run 10 times with different random seeds, and results are reported as mean ± standard deviation to account for the stochastic nature of the evaluated algorithms and ensure statistically reliable comparisons.

IV. Results and Discussion

A. T1-Small Topology Results (10 Fog Nodes, 500 Tasks)

Table V presents the comparative performance of the five bio-inspired load balancing algorithms under the T1-Small topology, reporting mean and standard deviation values across 10 independent runs for each of the three QoS metrics.

TABLE V. Performance Results — T1-Small (10 Fog Nodes, 500 Tasks)

Algorithm	Response Time (ms)	Load Imbalance (%)	Makespan (ms)
PSO	30.26 ± 0.95	3.283 ± 0.599	33.76 ± 1.00
GA	30.30 ± 1.25	2.876 ± 0.280	34.27 ± 0.46
BFO	30.14 ± 1.15	2.615 ± 0.376	34.12 ± 0.75
ACO	30.90 ± 1.97	9.701 ± 3.337	39.17 ± 4.61
ABC	30.42 ± 1.52	2.641 ± 0.264	34.80 ± 0.42

1) Response time analysis: Under the T1-Small configuration, response times are consistent across four of the five algorithms, ranging from 30.14 ms for BFO to 30.42 ms for ABC, a difference of only 0.28 ms. BFO achieves the lowest mean response time, marginally outperforming PSO (30.26 ms), GA (30.30 ms), and ABC (30.42 ms), a result attributable to its chemotaxis mechanism, which alternates between local tumble-and-swim exploitation and periodic elimination-dispersal to reliably identify low-latency task-to-resource mappings at this scale. ACO records a mean response time of 30.90 ms, 2.5% higher than BFO, with a standard deviation of 1.97 ms, nearly double BFO's 1.15 ms. In 3 of the 10 runs, ACO's pheromone trails concentrated exclusively on cloud resources, leaving all fog nodes unassigned. This collapse behavior is driven by the cloud's substantially higher MIPS values, which ACO's heuristic interprets as systematically more attractive targets regardless of load distribution.

2) Load imbalance degree analysis: The load imbalance degree results reveal the most pronounced performance divergence among the five algorithms, with ACO standing apart from a tightly clustered group of the remaining four. BFO achieves the lowest mean LID at 2.615%, closely followed by ABC (2.641%) and GA (2.876%), with PSO trailing at 3.283%. These four algorithms differ by less than 0.7 percentage points, indicating broadly comparable load-balancing quality among bacterial foraging, bee colony, genetic, and swarm-based strategies at this scale.

ACO is again the clear outlier, with a mean LID of 9.701%, between 3.3× and 3.7× higher than the other four algorithms, and by far the largest standard deviation observed (3.337%). This instability is directly attributable to the same pheromone-collapse phenomenon identified in the response time analysis: when the colony converges prematurely onto a single resource, load concentrates heavily on that node, while in better-distributed runs the imbalance approaches the level of the other algorithms. ABC's relatively tight standard deviation (0.264%, the lowest of the five) suggests that its food-source/onlooker/scout structure produces more consistent load distribution across independent runs than the other swarm- and evolution-based approaches.

3) Makespan analysis: Makespan results follow a pattern similar to response time, with four algorithms clustered within a narrow range and ACO as a significant outlier. PSO achieves the lowest makespan at 33.76 ms, followed by BFO (34.12 ms), GA (34.27 ms), and ABC (34.80 ms) — a span of just 1.04 ms across the four. Standard deviations for these four range from 0.42 ms for ABC to 1.00 ms for PSO, indicating that ABC produces the most run-to-run stable makespan despite not achieving the lowest mean. ACO records a mean makespan of 39.17 ms with a standard deviation of 4.61 ms, the highest variability observed across all algorithms and metrics in this topology. As with response time and load imbalance, this large spread traces back to the intermittent fog-collapse behavior: runs in which the colony defaults to a single fog node show substantially inflated makespan (up to 44.14 ms), while better-distributed runs remain close to the 33–34 ms range achieved by the other four algorithms.

4) Summary of T1-small findings: Fig. 2 presents a radar chart summarizing the relative performance of the five algorithms across all three QoS metrics at the T1-Small configuration, normalized to [0,1] relative to the best- and worst-performing algorithm on each metric at this scale. The chart shows BFO and ABC forming the largest polygons, reflecting their balanced performance across response time, load imbalance, and makespan even at this Smallest task scale, while ACO already shows a visibly compressed profile driven by its elevated load imbalance (9.701%, roughly 3.7× higher than the next-worst algorithm). PSO and GA occupy an intermediate position, with comparable response time and makespan to BFO and ABC but moderately higher load imbalance. These results establish that no single algorithm dominates uniformly even at the Smallest tested scale, setting the baseline against which the T2-Normal and T3-Heavy configurations are compared.

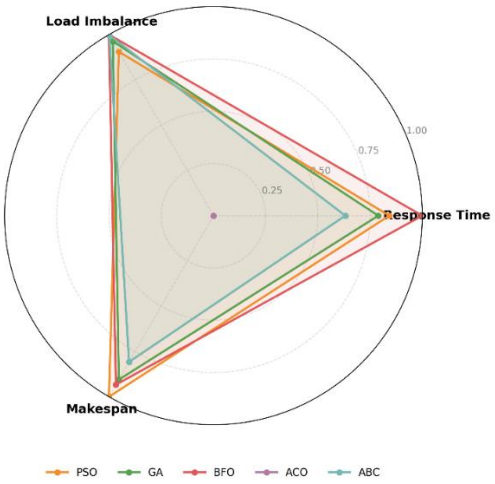

Fig. 2. Normalized radar comparison of bio-inspired load balancing algorithms across QoS metrics — T1-Small (500 tasks).

B. T2-Normal Workload Results (10 Fog Nodes, 1000 Tasks)

Table VI presents the comparative performance of the five bio-inspired load balancing algorithms under the T2-Normal workload configuration, reporting mean and standard deviation values across 10 independent runs for each of the three QoS metrics.

TABLE VI. PERFORMANCE RESULTS — T2-NORMAL (10 FOG NODES, 1000 TASKS)

Algorithm	Response Time (ms)	Load Imbalance (%)	Makespan (ms)
PSO	30.32 ± 1.29	2.758 ± 0.818	34.47 ± 0.57
GA	30.23 ± 1.34	2.234 ± 0.225	34.42 ± 0.47
BFO	30.25 ± 1.14	2.108 ± 0.287	34.15 ± 0.73
ACO	30.04 ± 1.89	9.885 ± 3.429	35.33 ± 1.75
ABC	30.61 ± 1.39	1.956 ± 0.283	34.72 ± 0.28

1) Response time analysis: Under the T2-Normal configuration, response times remain tightly clustered across all five algorithms, ranging from 30.04 ms for ACO to 30.61 ms for ABC, a spread of only 0.57 ms. ACO records the lowest mean response time at this scale, improving slightly over its T1-Small value of 30.90 ms, though this improvement comes with the largest standard deviation among the five algorithms (1.89 ms), reflecting the same convergence instability seen in the T1-Small configuration. GA and BFO remain close to each other at 30.23 ms and 30.25 ms, respectively, both showing marginal gains relative to T1-Small. ABC records the highest mean response time at 30.61 ms, a slight increase from its T1-Small value of 30.42 ms.

2) Load imbalance degree analysis: The load imbalance degree results under T2-Normal preserve the same overall ranking observed at T1-Small, with ABC achieving the best balance among the four closely clustered algorithms and ACO remaining the clear outlier. ABC improves from 2.641% at T1-Small to 1.956% at T2-Normal, the best result among all five algorithms at this scale, and also records the lowest standard deviation (0.283%), reinforcing the consistency advantage noted previously. BFO follows closely at 2.108%, also improving from its T1-Small value of 2.615%, while GA improves modestly from 2.876% to 2.234%. PSO records the highest LID among the four clustered algorithms at 2.758%, alongside the largest standard deviation in that group (0.818%), consistent with its T1-Small behavior of greater run-to-run variability. ACO again stands apart with a mean LID of 9.885%, only marginally higher than its T1-Small value of 9.701%, and continues to exhibit the largest standard deviation of any algorithm-metric combination (3.429%). As observed in the simulation logs, two of the ten runs triggered the " No fog used, defaulting to fog-0" warning, confirming that the pheromone-collapse phenomenon identified at T1-Small persists at higher task densities and continues to drive both the elevated mean and the high variance on this metric.

3) Makespan analysis: Makespan results under T2-Normal show all five algorithms within a relatively narrow band, with BFO achieving the lowest mean at 34.15 ms, followed by GA (34.42 ms), PSO (34.47 ms), and ABC (34.72 ms) — a span of just 0.57 ms across these four. ABC again records the lowest standard deviation (0.28 ms), the most stable makespan of any algorithm at this scale, consistent with its T1-Small behavior. ACO records the highest mean makespan at 35.33 ms, with a standard deviation of 1.75 ms. Notably, this represents a substantial normalization relative to its T1-Small makespan of 39.17 ms (± 4.61 ms): both the mean and the variability decrease considerably at the larger task scale, suggesting that the additional tasks provide more opportunities for the colony to distribute load across fog resources even when individual runs experience partial pheromone collapse, partially offsetting the impact of resource concentration on completion time.

4) Summary of T2-normal findings: The radar chart in Fig. 3 covers the T2-Normal workload, normalizing each algorithm's scores to [0,1] across the three QoS metrics. ABC stands out with a load imbalance of 1.956%, the best figure recorded at this scale, and its polygon is noticeably wider than at T1-Small. ACO manages its lowest response time across all three workloads here, yet its polygon stays narrow because its load imbalance remains at 9.885%. BFO and GA show similar, well-rounded profiles with no particular weakness across the three metrics. PSO's polygon shrinks slightly on the load imbalance side, which matches the higher variability seen in its individual runs. Taken together, the chart shows that the gap separating ACO from the other four algorithms seen at T1-Small has not closed at this intermediate scale.

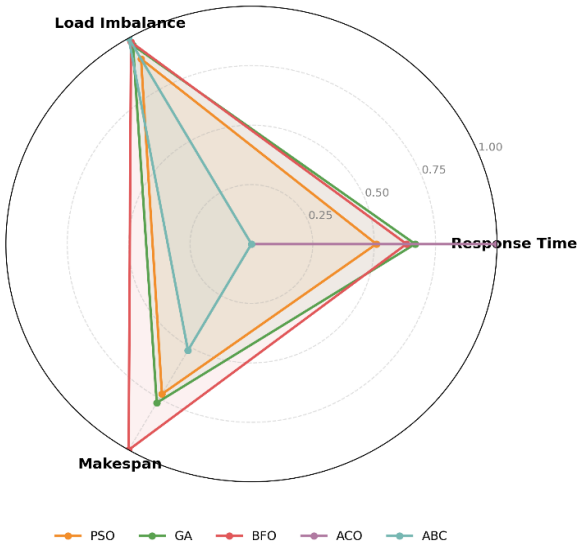

Fig. 3. Normalized radar comparison of bio-inspired load balancing algorithms across QoS metrics — T2-Normal (1000 tasks).

C. T3-Heavy Workload Results (10 Fog Nodes, 2000 Tasks)

Table VII presents the comparative performance of the five bio-inspired load balancing algorithms under the T3-Heavy workload configuration, reporting mean and standard deviation values across 10 independent runs for each of the three QoS metrics.

TABLE VII. PERFORMANCE RESULTS — T3-HEAVY (10 FOG NODES, 2000 TASKS)

Algorithm	Response Time (ms)	Load Imbalance (%)	Makespan (ms)
PSO	30.18 ± 1.10	2.079 ± 1.060	34.38 ± 1.17
GA	30.33 ± 1.21	1.465 ± 0.151	34.51 ± 0.94
BFO	30.40 ± 1.27	1.396 ± 0.144	34.44 ± 0.73
ACO	31.34 ± 2.37	11.019 ± 5.295	38.71 ± 0.75
ABC	30.68 ± 1.28	1.322 ± 0.113	35.12 ± 0.80

1) Response time analysis: Under the T3-Heavy workload configuration, response time results confirm the instability pattern observed for ACO at Smaller scales, now substantially amplified. ACO records the worst mean response time of 31.34 ms, 3.8% higher than PSO (30.18 ms), the best performer at this scale, and its standard deviation of 2.37 ms remains the largest of any algorithm-metric combination across all three topologies. This degradation is consistent with the cloud-bias phenomenon identified at T1-Small and T2-Normal: two of the ten runs at T3-Heavy triggered the " No fog used, defaulting to fog-0" warning, confirming that pheromone trails continue to saturate toward high-MIPS cloud resources at maximum task density, introducing WAN latency overhead that the other four algorithms do not experience.

PSO, GA, BFO, and ABC cluster within a narrow band of 30.18 to 30.68 ms, a spread of only 0.50 ms, indicating that response time converges across fog-dominant strategies regardless of the underlying optimization mechanism once task density reaches 2000. This convergence suggests that the task-to-resource mapping space becomes sufficiently constrained by fixed fog capacity at this scale that algorithm-specific search dynamics exert a diminishing influence on latency outcomes.

2) Load imbalance degree analysis: Load imbalance results under T3-Heavy continue the convergence trend observed across workload configurations for the four non-ACO algorithms, with ABC achieving the best result at this scale. ABC records a mean LID of 1.322%, improving from 1.956% at T2-Normal and 2.641% at T1-Small, and also recording the lowest standard deviation of any algorithm at this scale (0.113%), extending the stability advantage observed at the two Smaller configurations. BFO follows at 1.396%, also improving steadily across configurations (2.615% → 2.108% → 1.396%), while GA records 1.465%, similarly improving from 2.876% and 2.234% at the Smaller scales. PSO records the highest LID among the four clustered algorithms at 2.079%, with by far the largest standard deviation in that group (1.060%) — individual runs ranged from a low of approximately 1.21% to a high exceeding 4.1%, indicating that PSO's particle convergence remains highly sensitive to the random seed even at maximum task density.

ACO records a mean LID of 11.019%, its highest value across all three configurations (9.701% at T1-Small, 9.885% at T2-Normal), with a standard deviation of 5.295%, the largest observed for any metric in this study. Two runs recorded LID values above 16%, directly attributable to the fog-collapse phenomenon, while the better-converged runs remained closer to 6–9%, illustrating the wide behavioral range produced by the heuristic's cloud bias at this task density.

3) Makespan analysis: Makespan results under T3-Heavy show PSO, GA, BFO, and ABC within a comparatively narrow band, with BFO and PSO recording the lowest means at 34.44 ms and 34.38 ms, respectively, followed by GA at 34.51 ms and ABC at 35.12 ms. PSO's standard deviation of 1.17 ms is the highest among these four, while ABC's 0.80 ms remains competitive despite its mean being modestly higher than the other three — consistent with the stability-over-optimality pattern observed for ABC across the load imbalance metric at this and the previous two configurations. ACO again stands as a clear outlier, recording a mean makespan of 38.71 ms with a standard deviation of 0.75 ms. This is 12.0% higher than the next-worst algorithm (ABC, 35.12 ms) and 3.8 percentage points higher in relative terms than ACO's own T2-Normal makespan of 35.33 ms, confirming that the cloud-bias phenomenon's impact on completion time intensifies rather than stabilizes as task density reaches its maximum tested level. Unlike at T1-Small, where ACO's makespan variability was the largest observed (± 4.61 ms), the standard deviation at T3-Heavy is comparatively low, suggesting that at this task density the cloud-routing behavior has become a consistent rather than intermittent feature of the colony's convergence pattern.

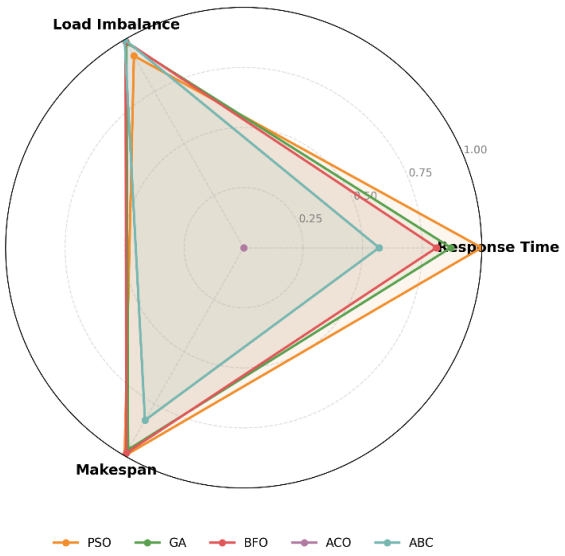

Fig. 4. Normalized radar comparison of bio-inspired load balancing algorithms across QoS metrics — T3-Heavy (2000 tasks).

4) Summary of T3-heavy findings: Fig. 4 presents a radar chart summarizing the relative performance of the five algorithms across all three QoS metrics at the T3-Heavy configuration, normalized to [0,1] relative to the best- and worst-performing algorithm on each metric at this scale. The chart visually confirms ACO's compressed polygon area, driven primarily by its substantially elevated load imbalance and makespan relative to the other four algorithms, while BFO, ABC, GA, and PSO form comparably sized polygons reflecting

their convergence on response time and the progressively tightening gap on load imbalance. Taken together with the T1-Small and T2-Normal results, this final configuration confirms a consistent and widening performance gap between ACO and the other four bio-inspired algorithms as task density increases, while BFO and ABC emerge as the most consistently well-rounded performers across all three tested scales.

D. Cross-Configuration Comparative Analysis

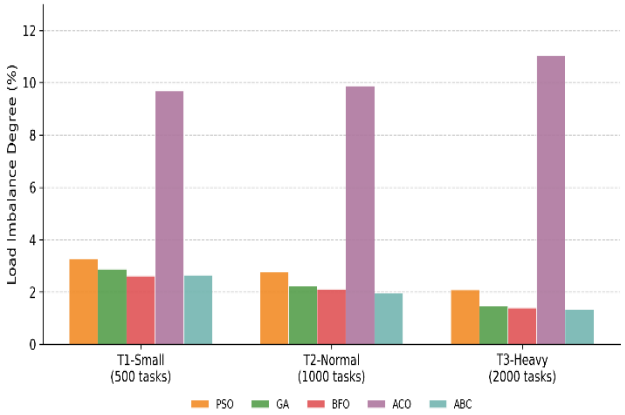

Fig. 5. Load across workload configurations.

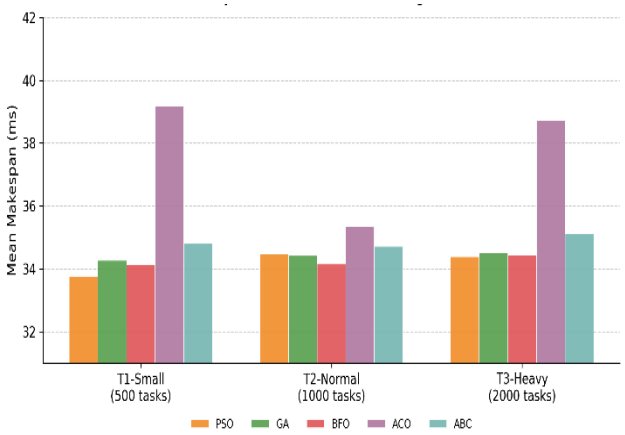

Fig. 6. Makespan across workload configurations.

Fig. 5, 6, and 7 summarize the evolution of the three QoS metrics across the three workload configurations for all five bio-inspired algorithms. Several consistent trends emerge. ABC demonstrates the most stable scalability profile among the five algorithms, recording progressively improving and increasingly stable load imbalance as task density increases (2.641% → 1.956% → 1.322%), while maintaining a moderate and consistent makespan throughout. BFO closely tracks this pattern, achieving comparable or slightly better load imbalance at each configuration alongside competitive response time and makespan, making it the strongest overall performer on response time and makespan jointly. GA shows steady, well-balanced performance across all three configurations without standing out as either a leader or an outlier on any single metric. ACO exhibits consistently degrading and highly variable behavior driven by its cloud-bias phenomenon, with both its load imbalance and makespan worsening as task density increases, and its standard deviations remaining the largest observed for any algorithm throughout the study. PSO shows comparatively higher variability in load imbalance at every configuration, indicating greater sensitivity to random seed and task density than the other four algorithms. Overall, no single algorithm dominates across all metrics and configurations, confirming the inherent multi-objective trade-off nature of the load balancing problem in heterogeneous IoT-Fog-Cloud environments, though ABC and BFO emerge as the most consistently competitive choices across the tested scales. This conclusion holds under the fixed, static fog infrastructure and deterministic task inter-arrival pattern evaluated in this study, and should be revisited under the dynamic, mobile, and larger-scale deployment conditions discussed in the Limitations section.

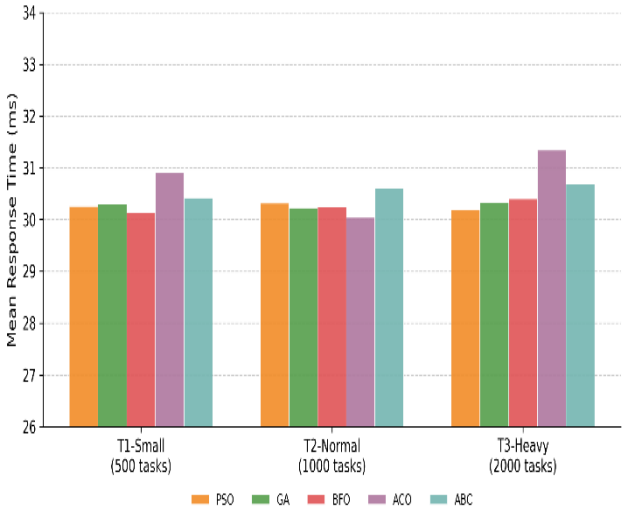

Fig. 7. Response time across workload configurations.

E. Statistical Significance Analysis

To validate the statistical significance of the observed performance differences, a Wilcoxon signed-rank test [23] was applied to compare each algorithm (PSO, BFO, ACO, ABC) against GA across all metrics and workload configurations, using a significance threshold of $\alpha = 0.05$. GA was selected as the reference algorithm for this comparison due to its consistently median performance profile across all nine metric-configuration combinations, neither dominating nor underperforming on any single metric, making it a representative midpoint against which the relative behavior of the remaining four algorithms can be assessed. This non-parametric test was selected due to the Small sample size of 10 independent runs per configuration, which does not justify the normality assumption required by parametric alternatives such as the t-test.

The results reveal several statistically significant patterns. Regarding response time, BFO shows a significant divergence from GA only at T1-Small ($p = 0.002$, lower; Fig. 8), with no significant difference at T2-Normal or T3-Heavy, indicating that its early latency advantage fades as task density increases. ACO and ABC display the opposite pattern, becoming significantly slower than GA at higher task density: ACO at T3-Heavy only ($p = 0.010$, higher; Fig. 10), and ABC at both T2-Normal and T3-Heavy ($p = 0.002$ in both cases, higher; Fig. 9 and 10). PSO

is statistically indistinguishable from GA at T1-Small (p = 0.432; Fig. 8) but becomes significantly different at T2-Normal and T3-Heavy (p = 0.027 and p = 0.010, respectively; Fig. 9 and 10), although the direction of this difference is inconsistent (higher at T2-Normal, lower at T3-Heavy), suggesting the observed differences may not reflect a systematic algorithmic effect.

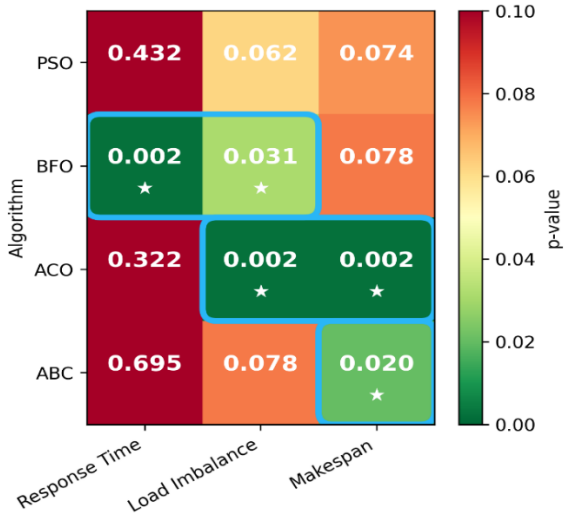

Fig. 8. Heatmap of Wilcoxon signed-rank p-values vs GA for T1-Small workload (500 tasks). Blue borders and ★ denote statistically significant differences ($p < 0.05$).

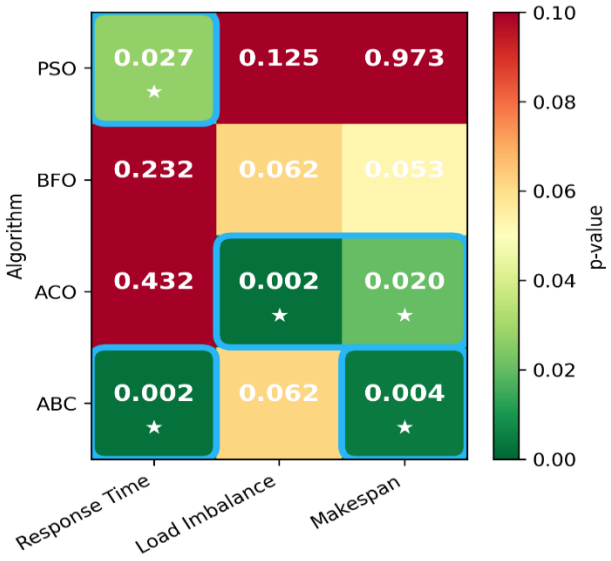

Fig. 9. Heatmap of Wilcoxon signed-rank p-values vs GA for T2-Normal workload (1000 tasks). Blue borders and ★ denote statistically significant differences ($p < 0.05$).

Regarding load imbalance, the pattern is clearly visible across Fig. 8-10. ACO produces significantly higher load imbalance than GA in all three configurations (p = 0.002 in each case), confirming the cloud-bias behavior identified in the qualitative analysis. BFO differs significantly from GA only at T1-Small (p = 0.031, lower; Fig. 8), indicating a brief balance advantage at low task density that does not persist at higher loads (Fig. 9-10). PSO shows no significant load imbalance difference from GA at any configuration (Fig. 8-10), while ABC is statistically indistinguishable from GA at T1-Small and T2-Normal but achieves significantly lower load imbalance at T3-Heavy (p = 0.016; Fig. 10).

Regarding makespan, statistical significance is more selective, as shown in Fig. 8-10. ACO produces a significantly higher makespan than GA across all three configurations ($p \leq 0.020$), and ABC follows the same pattern ($p \leq 0.023$), indicating that GA achieves a measurably lower completion time than both algorithms regardless of task density. PSO and BFO remain statistically equivalent to GA on makespan at every configuration (Fig. 8-10), confirming that GA's makespan performance is indistinguishable from these two algorithms throughout the tested range.

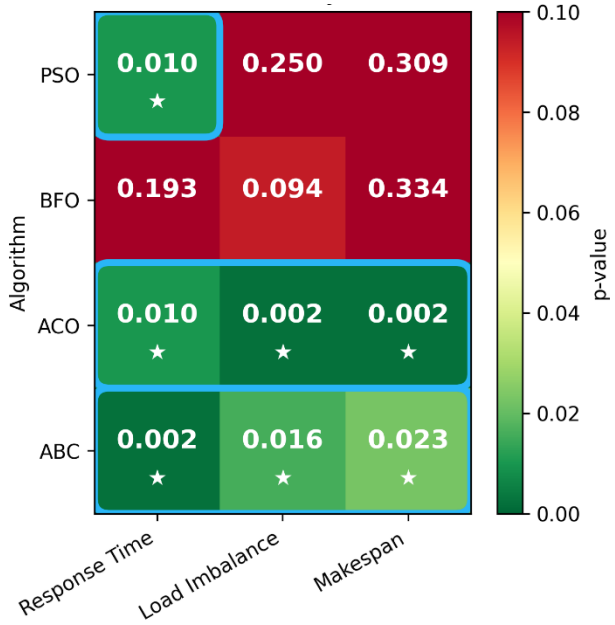

Fig. 10. Heatmap of Wilcoxon signed-rank p-values vs GA for T3-Heavy workload (2000 tasks). Blue borders and ★ denote statistically significant differences ($p < 0.05$).

Overall, these statistical results, summarized across Fig. 8-10, confirm that GA represents a robust and balanced reference point: PSO and BFO remain statistically comparable to GA on makespan throughout, while ACO shows a statistically validated cost relative to GA on all three fronts -significantly higher load imbalance across all configurations, higher response time at high task density (Fig. 10), and higher makespan across all configurations - and ABC trades a modest, significant makespan penalty for load-imbalance performance that is statistically indistinguishable from GA except at the highest task density, where it significantly improves on GA (Fig. 10).

V. Conclusion and Future Work

This study presented a comprehensive comparative evaluation of five bio-inspired load balancing algorithms — PSO, GA, BFO, ACO, and ABC — in a three-tier IoT-Fog-Cloud architecture simulated using iFogSim. The evaluation was conducted across three workload configurations of increasing task density (T1-Small: 500 tasks, T2-Normal: 1000 tasks, T3-Heavy: 2000 tasks) on a fixed infrastructure

comprising 50 IoT devices, 10 fog nodes, and 32 cloud cores, using three QoS metrics: response time, load imbalance degree, and makespan. Statistical significance was assessed through the Wilcoxon signed-rank test against GA as the reference algorithm, across 10 independent runs per configuration.

The results reveal several important findings. First, GA emerges as a robust, balanced reference point across all three configurations, consistently keeping mean response time under 30.5 ms while maintaining moderate, stable load imbalance, with PSO and BFO remaining statistically indistinguishable from GA on makespan throughout the tested range. Second, ABC demonstrates the most stable load distribution among all five algorithms, with load imbalance improving steadily from 2.64% at T1-Small to 1.32% at T3-Heavy, and achieving a statistically significant improvement over GA on this metric at the highest task density, albeit at the cost of a modest but consistent makespan penalty. Third, ACO exhibits a markedly unfavorable profile relative to the other four algorithms, with load imbalance ranging from 9.7% to 11.0% across all configurations, three to eight times higher than its counterparts, alongside a statistically significant cost on response time at high task density and on makespan across all three configurations, driven by a recurring cloud-bias phenomenon in which pheromone-guided search occasionally collapses onto a single resource. Fourth, PSO shows the highest run-to-run variability in load imbalance among the four non-ACO algorithms, suggesting that its velocity-based update mechanism is comparatively more sensitive to task density than the chemotaxis-, evolution-, or bee-colony-based alternatives. Fifth, no single algorithm dominates uniformly across all three QoS dimensions and all three workload scales, confirming the inherent multi-objective trade-off nature of the load balancing problem in heterogeneous IoT-Fog-Cloud environments.

These findings provide actionable guidance for practitioners: GA is recommended as a reliable default choice when response time and makespan are the primary objectives, ABC is preferable when load balance stability is the critical QoS requirement, particularly at higher task densities, and ACO should be approached with caution given its consistent underperformance across all three metrics in this experimental setting, despite the theoretical appeal of pheromone-guided search.

VI. Limitations

Several limitations of this study should be acknowledged.

- The evaluation was conducted on a fixed, static fog infrastructure with deterministic task inter-arrival times and no modeling of node failures, dynamic resource availability, task priorities, or deadline constraints — conditions that may not reflect the variability of real-world IoT deployments; prior work in related wireless sensor network contexts has shown that mobility models can significantly affect the performance of clustering and resource-organization approaches [24], suggesting this is a relevant direction for future investigation.
- Algorithms were evaluated using standard canonical parameter settings without domain-specific tuning or sensitivity analysis, and the computational overhead of the optimization process itself (e.g., per-iteration runtime) was not profiled, which may limit the generalizability of the results to real-time settings.
- The evaluation is limited to response time, load imbalance, and makespan; energy consumption, resource utilization, and throughput were not assessed despite their practical relevance for battery-powered IoT environments.
- Statistical validation used GA as a single reference algorithm rather than exhaustive pairwise comparisons among all five algorithms, which keeps the number of tests interpretable but limits the confirmatory strength of the reported differences.
- The evaluated infrastructure (10 fog nodes, 32 cloud cores) represents a small-to-medium deployment; how algorithm performance and overhead scale at substantially larger infrastructure sizes was not tested.

VII. Future Work

A number of directions are identified for future investigation. Extending the evaluation to heterogeneous and dynamic workload scenarios, with variable task inter-arrival rates, priorities, and deadline constraints, would give a more realistic picture of how each algorithm behaves under practical conditions. Adding energy consumption as a fourth QoS metric would round out the evaluation and bring it closer to the green computing requirements that matter in real IoT-Fog-Cloud deployments. Testing the algorithms under dynamic infrastructure conditions, including fog node failures, resource contention, and device mobility, would shed light on their robustness beyond the controlled simulation setting used here. Applying deep reinforcement learning as an adaptive load balancing strategy and benchmarking it against the five bio-inspired approaches within the same framework is a natural next step toward intelligent and self-adaptive resource management. Finally, the complementary profiles of BFO and ABC suggest that a hybrid BFO-ABC algorithm is worth exploring, with BFO contributing its chemotaxis-based local exploitation and ABC its load balancing stability. A PSO-BFO hybrid, combining PSO's global exploration with BFO's local chemotaxis, represents another promising direction toward better latency and load balancing trade-offs in IoT-Fog-Cloud architectures.

Emerging Technologies and Cybersecurity in Critical Information Infrastructure and Industrial Control Systems: An Integrated Cyber Risk Pathway Model

Jennita Rao Appanah Appayya, Sandhya Armoogum, Kaleem Ahmed Usmani
University of Technology, Mauritius, Republic of Mauritius

***Abstract*—The digital transformation of Critical Information Infrastructure (CII) and Industrial Control Systems (ICS) through Industry 4.0 technologies introduces significant cybersecurity challenges. While existing research examines technologies individually, little attention has been given to how their combined adoption reshapes the overall threat landscape. This study presents a Multivocal Literature Review, synthesising evidence from 41 academic and industry sources (January 2010–June 2026) and proposes an Integrated Cyber Risk Pathway Model that traces how technology adoption introduces interconnected vulnerabilities, expands threat actor capabilities, produces cyber-physical impacts, and ultimately defines resilience requirements. Three findings emerge: 1) emerging technologies play a dual role, enhancing operational capability while expanding the attack surface; 2) cyber-attacks have evolved from specialist ICS operations to ecosystem-level compromises exploiting supply chains and shared platforms; 3) the resulting vulnerabilities are systemically interconnected, creating risks that prevention-focused cybersecurity alone cannot fully address. The study argues that protecting modern critical infrastructure requires a shift to resilience-centred strategies supported by governance, secure system design and cross-sector collaboration.**

Keywords*—Critical Information Infrastructure (CII); Industrial Control Systems (ICS); emerging technologies; industry 4.0; IT/OT convergence; cyber resilience; cyber-physical systems; multivocal literature review; integrated cyber risk pathway model

I. Introduction

Critical Information Infrastructure (CII) is the foundation of many services on which modern societies depend. These include energy, water, healthcare, transportation, finance and telecommunications. These sectors rely heavily on Industrial Control Systems (ICS), such as Supervisory Control and Data Acquisition (SCADA) systems, Distributed Control Systems (DCS) and Programmable Logic Controllers (PLCs), to monitor and control physical processes. As these systems support critical services, cyber incidents affecting them can have consequences far beyond financial losses, disrupting public services, endangering safety and, in some cases, threatening national security [1][2].

Over the past decade, CII and ICS environments have undergone rapid digital transformation. Emerging technologies are increasingly being deployed to improve operational efficiency, enable predictive maintenance and support real-time decision-making. At the same time, organisations are integrating Information Technology (IT) and Operational Technology (OT) systems to improve visibility across operations and enable data-driven services. Although these developments deliver significant operational benefits, they also increase connectivity, introduce new dependencies, and expand the potential attack surface available to cyber adversaries [1][3].

Recent cyber incidents demonstrate that the threat landscape has evolved considerably. Earlier attacks, such as Stuxnet [15] and Triton [16], were highly specialised operations that required extensive knowledge of industrial processes and proprietary control systems. Modern attacks, however, increasingly exploit software supply chains, cloud platforms, Internet-facing devices and interconnected digital ecosystems. Consequently, adversaries are able to compromise multiple organisations without directly targeting industrial technologies themselves. This evolution indicates a wider trend - from attacks at the level of individual systems to attacks on interconnected infrastructure, in which vulnerabilities in one part of the digital ecosystem can quickly spread to several critical sectors [2][4].

A growing body of research has examined the cybersecurity implications of emerging technologies in CII and ICS environments. Previous studies have investigated areas such as Artificial Intelligence (AI) enabled systems, Industrial Internet of Things (IIoT) devices, cloud computing, digital twins, 5G networks, and industrial cybersecurity more generally [5][6][7]. These studies provide valuable insights on the security challenges of individual technologies. However, the cybersecurity landscape of modern critical infrastructure is becoming increasingly interconnected. CII operators are no longer adopting these technologies in isolation. Instead, multiple technologies are being integrated across IT and OT environments, creating new technical dependencies, external connections and shared attack surfaces.

This raises an important research problem. When emerging technologies are examined separately, it becomes difficult to understand how their combined adoption changes the overall cyber risk environment of CII and ICS. A vulnerability introduced through one technology may interact with weaknesses in another system, create new opportunities for threat actors, or allow an incident to propagate across interconnected operational environments. These relationships can ultimately result in operational disruption, physical consequences and cascading effects across critical services. There is therefore a need for an integrated perspective that connects technology adoption with vulnerability creation, threat actor capabilities, cyber-physical impacts and the resilience requirements needed to address these risks.

This study therefore addresses this gap by adopting a Multivocal Literature Review (MLR) [8], synthesising evidence from academic publications, government reports, international standards and industry threat intelligence. Rather than reviewing emerging technologies individually, the study examines how they collectively redefine cybersecurity risks within CII and ICS environments. Drawing on this synthesis, this study makes three main contributions. First, it synthesises current evidence on seven emerging technologies, namely AI, IIoT, cloud computing, edge computing, 5G, digital twins and quantum computing, to provide a unified view of how they are reshaping cybersecurity threats in CII and ICS. Second, it introduces an Integrated Cyber Risk Pathway Model that links technology adoption, emerging vulnerabilities, threat actor capabilities, cyber-physical impacts and resilience requirements into a single conceptual framework. Unlike previous research that focuses on particular technologies or isolated threats, the model shows how these interact within the wider digital ecosystem. Third, the study identifies resilience priorities that extend beyond traditional prevention-based cybersecurity, emphasising governance, secure system design, supply chain security and cross-sector collaboration as essential components of protecting modern critical infrastructure. The remainder of this study is organised around five research questions:

- RQ1: What are the main cyber threats affecting CII and ICS?
- RQ2: How are emerging technologies reshaping the cybersecurity landscape?
- RQ3: What new vulnerabilities and attack pathways are being introduced?
- RQ4: What operational, economic, physical and societal impacts arise from these threats?
- RQ5: What resilience strategies are needed to address these emerging challenges?

The findings derived from these questions are then incorporated through the proposed Integrated Cyber Risk Pathway Model, providing a conceptual foundation for understanding how digital transformation is reshaping cybersecurity and resilience in critical infrastructure.

II. Methodology

This study adopts a Multivocal Literature Review (MLR) to investigate the impact of emerging technologies on the cybersecurity landscape of CII and ICS. An MLR combines evidence from both peer-reviewed research and grey literature, making it particularly suitable for cybersecurity research, where emerging threats, vulnerabilities, and defensive practices are frequently documented in government advisories, technical standards, and industry threat intelligence before appearing in academic publications [8]. Fig. 1 summarises the overall methodology adopted in this study.

The review focused on publications from January 2010 to June 2026, covering the period during which Industry 4.0 technologies became increasingly integrated into CII and ICS environments. The literature search was last updated on 30 June 2026; therefore, publications from 2026 represent evidence available up to the search cut-off date rather than the complete publication year.

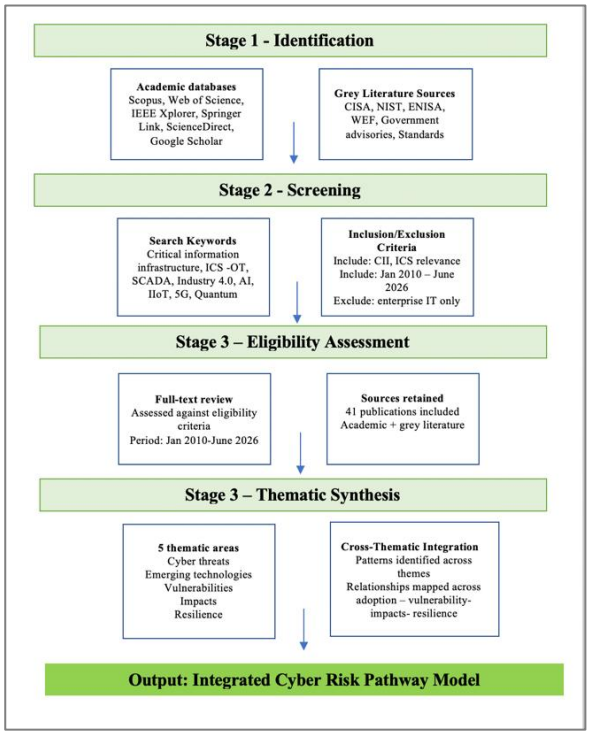

Fig. 1. Multivocal literature review process.

Academic literature was retrieved from Scopus, Web of Science, IEEE Xplore, SpringerLink, ScienceDirect and Google Scholar using a combination of keywords. Examples include Critical Information Infrastructure, Industrial Control Systems, Operational Technology, SCADA security, cyber resilience, Industry 4.0, AI, IIoT, cloud computing, edge computing, 5G, digital twins and quantum computing.

The review focuses on seven emerging technologies: AI, IIoT, cloud computing, edge computing, 5G, digital twins and quantum computing. These technologies were selected to provide coverage of major technological developments influencing connectivity, automation, data-driven operations, distributed computing and long-term cryptographic security within CII and ICS environments. The scope was intentionally limited to allow these technologies and their cybersecurity implications to be examined within a common analytical framework. Other relevant developments, including blockchain, distributed ledger technologies and autonomous industrial systems, were not examined in detail and therefore fall outside the scope of this review. Their exclusion does not mean that they are unimportant to CII and ICS cybersecurity, but that they are additional areas that could be incorporated in future extensions of the analysis.

To complement the academic literature, grey literature was collected from internationally recognised organisations, such as the Cybersecurity and Infrastructure Security Agency (CISA) [9], National Institute of Standards and Technology (NIST) [10], European Union Agency for Cybersecurity (ENISA) [11], International Society of Automation (ISA) [12] and the World Economic Forum (WEF) [13]. These sources were selected

because they provide current threat intelligence, technical guidance and policy recommendations that are highly relevant to the rapidly evolving cybersecurity landscape of critical infrastructure [8].

Given the inclusion of grey literature, the quality and credibility of non-peer-reviewed sources were also considered. These sources were assessed based on the authority of the issuing organisation, relevance to CII and ICS cybersecurity, timeliness of the information, transparency of the evidence presented, and consistency with other available sources. Priority was given to publications from recognised government agencies, standards bodies, international organisations and established cybersecurity organisations involved in critical infrastructure security or threat analysis. Industry sources were mainly used to provide information on recent cyber incidents, emerging threat activity and operational developments that may not yet be widely covered in academic literature. Peer-reviewed studies were used more comprehensively to support theoretical and conceptual arguments. The use of grey literature was, where possible, considered in the light of evidence from other independent sources. This approach helped to balance the timeliness of grey literature and the methodological rigour of academic research.

The literature selection followed four stages: identification, screening, eligibility and inclusion. Publications were included if they addressed cybersecurity issues relating to CII or ICS, examined one or more of the selected emerging technologies, or discussed cyber threats, vulnerabilities, resilience or significant cyber incidents affecting critical infrastructure. Studies focusing exclusively on conventional enterprise IT environments and that are not relevant to CII or ICS were excluded. Following the screening process, 41 publications were retained for detailed analysis. The characteristics of these publications are summarised in Table I.

TABLE I. CHARACTERISTICS OF PUBLICATIONS INCLUDED IN THE MULTIVOCAL LITERATURE REVIEW

No.	Author / Organisation, Year	Main Focus	Technology / Theme	Main RQ	Contribution to Pathway Model
1	Asghar, Hu & Zeadally, 2019 [1]	Security issues and challenges in ICS	ICS, IT/OT	RQ1, RQ2, RQ3	Determines the baseline risks, weaknesses, and increasing exposure of ICS due to digitalisation.
2	Hemsley & Fisher, 2018 [2]	Historical evolution of ICS cyber incidents	ICS threats	RQ1, RQ4	Establishes the relationship between an attack and the operational and physical consequences.
3	Katsikas et al.(2020) [3]	Computer security concepts and emerging environments	Digital transformation	RQ2	Affirms the connection between evolving security needs and technology adoption.
4	CISA, 2021 [4]	SolarWinds supply-chain compromise	Supply chain	RQ1, RQ3, RQ4	Demonstrates how trusted third-party dependencies can compromise an ecosystem.
5	Axon et al.(2022) [5]	Cybersecurity capability gaps in IIoT	IIoT	RQ2, RQ3	Demonstrates how connected industrial devices increase the attack surfaces
6	Raval et al., 2024 [6]	Critical infrastructure attacks and AI security	AI, CII	RQ1–RQ3	Connects the use of AI to new dangers, weaknesses, and defensive needs
7	Abraham et al., 2025 [7]	ICS cybersecurity using modelling, digital twins and ML	AI, digital twins	RQ2, RQ3, RQ5	Supports the advantages and security dependencies of intelligent industrial technologies
8	Langner, 2011 [14]	Analysis of Stuxnet	ICS malware	RQ1, RQ4	Demonstrates how direct physical harm can be caused by cyber manipulation
9	Cherepanov & Lipovsky, 2017 [15]	Industroyer attack	ICS malware, energy	RQ1, RQ4	Demonstrates how specialised malware is directly interfering with electrical infrastructure.
10	Pinto, Dragoni & Carcano, 2018 [16]	TRITON attack on Safety Instrumented Systems	ICS/ Safety Instrumented Systems (SIS)	RQ1, RQ4	Shows how industrial safety devices can be compromised digitally.
11	ESET Research, 2022 [17]	Industroyer2 attack	ICS malware, energy	RQ1, RQ4	Demonstrates how threats against operational technologies are still evolving.
12	Hunter, 2020 [18]	EKANS ransomware targeting ICS/OT	OT ransomware	RQ1, RQ3	Shows how ransomware is migrating from traditional IT to operational settings.
13	FBI/CISA/HHS, 2024 [19]	ALPHV/BlackCat ransomware	Ransomware	RQ1, RQ4	Demonstrates how ransomware is causing disruption across critical sectors.
14	CISA, 2016 [20]	Mirai and IoT botnets	IoT/IIoT	RQ1–RQ3	Illustrates how insecure connected devices become distributed attack infrastructure.
15	Easterly & Fanning, 2023 [21]	Colonial Pipeline ransomware	IT/OT convergence	RQ1, RQ4	Illustrates how physical operations can be shut down due to an IT compromise.
16	HHS, 2023 [22]	KillNet DDoS attacks	DDoS, multi-sector CII	RQ1, RQ4	Demonstrates a coordinated disruption that has an impact on different critical sectors.
17	FBI/CISA/NSA/EPA/INCD, 2023 [23]	Exploitation of PLCs in water systems	PLC, ICS	RQ1, RQ3, RQ4	Demonstrates the use of default login credentials and operational assets exposed to the internet.
18	CISA, 2024 [24]	Threats against communications infrastructure	Telecom, Advanced Persistent Threat (APT)	RQ1, RQ3	Demonstrates state-linked exploitation of interconnected communications infrastructure.

19	Dragos, 2026 [25]	Attack against Polish distributed energy infrastructure	Energy/OT	RQ1, RQ4	Shows how cyber risks extend to distributed and interconnected energy assets.
20	FBI/CISA, 2024 [26]	BlackSuit/Royal ransomware	Ransomware	RQ1, RQ4	Demonstrates the dangers of ransomware in the manufacturing, medical, and utility industries.
21	CYFIRMA, 2025 [27]	Jaguar Land Rover cyberattack	Manufacturing	RQ1, RQ4	Demonstrates how interconnected IT systems can create significant operational interruption.
22	Itron/SEC, 2026 [28]	Cyber compromise involving CII technology supplier	Supply chain	RQ1, RQ3	Illustrates third parties and the supply chain access to CII operators.
23	Cilluffo, 2025 [29]	Chinese Typhoon cyber campaigns	Nation-state threats, CII	RQ1, RQ3	Demonstrates state-sponsored exploitation of connected infrastructure.
24	NIST NCCoE, 2023 [31]	5G cybersecurity	5G	RQ2, RQ3, RQ5	Demonstrates new security considerations arising from virtualised and highly connected networks.
25	Kravchik, Biggio & Shabtai, 2021 [32]	Poisoning attacks against cyberattack detectors	AI/ML	RQ2, RQ3	Demonstrates manipulation of training data and loss of trust in AI-enabled monitoring.
26	Gokkaya, Aniello & Halak, 2025 [33]	Software supply-chain attacks and mitigations	Supply chain	RQ3, RQ5	Indicate how third-party dependency acts as a major pathway for systemic compromise.
27	Sharma, 2025 [34]	Cloud misconfiguration and breaches	Cloud computing	RQ2, RQ3	Demonstrates how configuration and privilege-related exposure are caused by cloud adoption.
28	ENISA, 2021 [35]	Growth of supply-chain attacks	Supply chain	RQ1, RQ3	Supports the transition from attacks targeting individual organisations to ecosystem compromise.
29	Waterfall Security Solutions, 2025 [36]	OT attacks producing physical consequences	OT, IT/OT	RQ1, RQ4, RQ5	Connects operational and physical repercussions to attacks originating from IT.
30	DHS, 2021 [37]	Preparation for post-quantum cryptography	Quantum computing	RQ2, RQ3, RQ5	Identifies long-term cryptographic exposure and the need for migration planning.
31	NIST, 2024 [38]	Post-quantum cryptography standards	Quantum computing	RQ2, RQ5	Supports post-quantum readiness as a present resilience requirement.
32	Obasuyi, 2023 [39]	Convergence of edge, 5G and cloud security	Edge, 5G, cloud	RQ2, RQ3	Illustrates how the adoption of many technologies results in interconnected attack surfaces.
33	Palleti et al., 2021 [40]	Cascading effects of cyberattacks on interconnected CI	Interdependencies	RQ4, RQ5	Provides direct evidence for the cascading and systemic impact stage of the model.
34	Erukude, Marella & Veluru, 2026 [41]	AI-driven cybersecurity threats	AI	RQ1, RQ3	Demonstrates new offensive threats connected to threat capabilities enabled by AI.
35	Center for Security and Emerging Technology, 2024 [42]	AI security in critical infrastructure	AI, CII	RQ2, RQ3, RQ5	Connects the need for resilience and CI risk management with the adoption of AI.
36	Järveläinen et al., 2025 [43]	Cybersecurity resilience of critical infrastructure	Cyber resilience	RQ5	Enhances the capacity for organisational and dynamic resilience.
37	Kott & Linkov, 2019 [44]	Cyber resilience of systems and networks	Cyber resilience	RQ5	Gives a theoretical foundation for anticipating, enduring, reacting, and recovering.
38	Claroty, 2024 [47]	Business impact of CPS security incidents	CPS/OT	RQ4	Demonstrates the operational and financial effects of cyber-physical incidents.
39	EuRepoC [49]	NotPetya cyber incident	Supply chain/systemic risk	RQ1, RQ4	Illustrates how an attack can widely propagate beyond the initially compromised organisation.
40	World Bank, 2025 [50]	Economic costs of cyber incidents	Economic impact	RQ4	Supports the evaluation of both direct and indirect economic effects.
41	DNI, 2024 [51]	Nation-state cyber threats	Geopolitical/CII threats	RQ1, RQ4	Supports national-security and societal dimensions of CII cyber risk

Rather than analysing each publication independently, the selected literature was examined through thematic and conceptual synthesis. The evidence was first organised around the five research questions that guided this study. The results were then compared across publications to identify recurrent patterns and relationships between these themes.

To strengthen the consistency of the synthesis, evidence from the selected sources was examined in relation to the five research questions and grouped according to recurring concepts identified across the literature. These included cyber threats, emerging technologies, vulnerabilities and attack pathways, cyber-physical impacts, and resilience requirements. Relationships identified across the reviewed sources were then compared to determine how developments in one area influenced another. Particular attention was given to the progression from technology adoption to vulnerability creation, the exploitation of these vulnerabilities by threat actors, the resulting operational and cyber-physical consequences, and the resilience measures proposed in response. Findings were supported through comparison across peer-reviewed studies, government publications and industry evidence rather than relying on individual sources. This iterative synthesis provided the analytical basis for consolidating the recurring relationships into the five stages of the Integrated Cyber Risk Pathway Model.

The final stage of the review involved integrating these recurring relationships into a single conceptual representation. Instead of creating another taxonomy of technologies or threats, the aim was to develop a broader understanding of how digital transformation is changing the nature of cyber risk in interconnected CII and ICS environments. This process resulted

in the development of the Integrated Cyber Risk Pathway Model, which connects technology adoption, vulnerability creation, threat actor exploitation, cyber-physical impacts, and resilience requirements.

III. The Evolving Cyber Threat Landscape

A. From Attacks on Individual Systems to Exploiting Ecosystems

The cyber threat landscape for CII and ICS has evolved significantly over the last fifteen years. Earlier attacks mainly targeted specific industrial processes by exploiting vulnerabilities in proprietary control systems. But with time, the nature and scope of these attacks have changed. Cyber threat actors are now targeting the entire digital ecosystem around critical infrastructure, including software supply chains, cloud platforms, Internet-facing devices, and third-party service providers. This is due to the convergence of IT and OT, where vulnerabilities outside traditional industrial environments can affect physical assets through ICS [2][4]. Several key incidents illustrate how these threats have evolved. For example, the 2010 Stuxnet attack [14] was a milestone in industrial cybersecurity, demonstrating that malicious programs could be tailored to affect physical equipment in ICS environments. Subsequent attacks, such as Industroyer [15], Triton [16], and attacks on the Ukrainian power grid [17], revealed that sophisticated adversaries with an understanding of industrial protocols and engineering processes could effectively target OT systems [2],[16]. These incidents indicated that cyber-attacks could cause physical disruption, not just affect digital assets.

From around 2020 onwards, this evolution entered a new phase. Rather than directly attacking industrial systems, threat actors increasingly exploited vulnerabilities in the wider digital ecosystem that supports critical infrastructure operations. The SolarWinds [4] compromise exemplifies this shift by demonstrating how a single software supply chain attack could simultaneously provide access to thousands of organisations, including operators of critical infrastructure. Likewise, ransomware campaigns such as EKANS [18] and BlackCat [19], together with attacks targeting Internet-facing operational assets, demonstrate that adversaries no longer require detailed knowledge of ICS environments to disrupt critical services. Instead, they exploit trusted software, cloud services, remote access solutions and poorly secured IT infrastructure as entry points into operational environments [4][18].

This evolution reflects an important change in attacker strategy. Earlier attacks were mainly focused on compromising individual industrial assets through direct manipulation of operational technologies, whereas contemporary attacks tend to exploit the interconnected relationships between organisations, software platforms and supply chains. With the acceleration of digital transformation, cybersecurity of CII can no longer be viewed in isolation from an individual organisation. Instead, the resilience of critical infrastructure is increasingly dependent on the security of the wider digital ecosystem in which it is embedded.

Table II provides a summary of major cyber incidents between January 2010 and June 2026, illustrating the evolution of cyber threats affecting CII and ICS. The table does not list isolated events, but instead highlights the transition from highly specialised attacks on ICS to broader ecosystem compromises that exploit shared digital platforms, interconnected technologies, and third-party dependencies.

TABLE II. Major Cyber Incidents Illustrating the Evolution of the CII/ICS Threat Landscape (2010–2026)

Year	Threat Name	Targeted Sector	Type of Attack	Impact
2010	Stuxnet [14]	Nuclear, energy	ICS Malware	Physical damage to centrifuges
2016	Industroyer [15]	Energy	ICS Malware	Electricity disruption
2016	Mirai [20]	Telecom	IIOT DDOS	Domain Name System (DNS) disrupted
2017	Triton/Trisis/Hatman [16]	Energy – Oil, gas	ICS Malware	Safety Instrumented Systems (SIS) compromised
2020	SolarWinds [4]	Energy, Utilities, Telecom	Supply chain Malware	Over 18,000 organisations affected
2021	Colonial Pipeline [21]	Energy – Oil	Ransomware	Fuel disruption across 17 states
2022	Sandworm /Industroyer 2 [17]	Energy – electrical	Malware	Power outages and supply disruptions across several areas in Ukraine.
2022	KillNet [22]	Health, energy, defense	DDOS malware	Disruptions to health, energy, and defense sectors across NATO countries
2023	Cyber Av3ngers [23]	Water	Intrusion and malware attack	Aliquippa water authority booster station disabled via default credentials.
2024	Blackcat/ALPHV [19]	Health	Intrusion attack and ransomware	Healthcare services were disrupted
2024	Salt Typhoon [24]	Telecom	APT	Major U.S and global telecom operators compromised.
2025	Electrum [25]	Energy – Power grid	Ransomware	Distributed renewable energy sites and combined heat and power (CHP) plants across Poland compromised.
2025	BlackSuit (Royal) [26]	Manufacturing, Health, Utilities	Malware	Telecontrol and protection functions disrupted
2025	Scattered Spider and HellCat [27]	Manufacturing	Ransomware	Shutting down of global IT infrastructure at Jaguar Land Rover
2026	Itron [28]	Energy, Water	Supply chain Malware	The attack allowed cyber threat actors to gain access to the networks of CII operators.

B. Emerging Vulnerabilities in Digitally Connected CII

The growing adoption of emerging technologies has introduced new categories of vulnerability that differ from those traditionally associated with isolated ICS. Rather than existing independently, these vulnerabilities reinforce one another, creating multiple pathways through which attackers can move from digital systems into operational environments. Five recurring vulnerability categories were identified through the literature review.

1) Growing attack surfaces from connected devices: The rapid adoption of IIoT devices, edge computing platforms and 5G-enabled sensors has led to an exponential increase in the number of connected assets in CII. While these technologies help to improve operational visibility and provide real-time monitoring, many devices still use default credentials, run obsolete firmware, or have limited security features. As a result, each new connected device becomes a potential attack vector. Large botnets such as Mirai [20] and Flax Typhoon [29] have shown how insecure connected devices can be used to attack critical infrastructure without directly targeting ICS [30][31].

2) Risks to data integrity in intelligent systems: As AI and digital twins increasingly enable operational monitoring, predictive maintenance and decision-making within CII, they pose new challenges for data integrity. Unlike traditional cyber-attacks, which aim to disrupt a system's availability, AI-enabled environments are often targeted for data integrity compromises. Techniques such as data poisoning can manipulate the information used to train or operate AI models, reducing their ability to detect malicious activity or leading operators to make incorrect decisions [32]. As organisations become more dependent on intelligent systems, maintaining trustworthy data becomes as important as protecting the systems themselves.

3) Cloud and supply chain dependencies: Cloud computing has become a vital component of digital transformation, allowing organisations to better manage geographically distributed infrastructure. However, greater reliance on cloud platforms and third-party software also creates new dependencies that extend beyond organisational boundaries. Misconfigurations, excessive privileges and software supply chain compromises have become common attack vectors, as demonstrated by the SolarWinds incident and numerous cloud security breaches [33][34]. These dependencies indicate that the security of critical infrastructure increasingly relies on organisations outside the operator's direct control.

4) Weak IT-OT segmentation: Historically, OT systems were physically separated from enterprise IT systems. Today, however, increasing integration between these environments allows cyber incidents originating in IT networks to affect physical operations. According to the OT Cyber Threat Report 2025, by Waterfalls Security Solutions [36], most recent cyber incidents resulting in physical consequences have originated from compromised IT environments rather than direct attacks on industrial control systems. Strengthening IT–OT segmentation therefore remains one of the most effective measures for reducing cyber-physical risk.

5) Preparing for the post-quantum era: Although practical quantum attacks have not yet materialised, the transition towards quantum computing presents a long-term cybersecurity challenge for CII. Current cryptographic algorithms used to secure communications may eventually become vulnerable, enabling adversaries to exploit a "harvest now, decrypt later" strategy. Consequently, planning for post-quantum cryptography should be viewed as a present resilience priority rather than a distant technical concern [37][38].

Although these vulnerability categories are discussed separately, they rarely occur in isolation. Connected devices increase the number of possible entry points, cloud platforms create external dependencies, AI systems rely on trusted data, and IT-OT convergence enables attacks to propagate beyond operational boundaries. These vulnerabilities combine to create a growing, interconnected risk environment in which weaknesses in one component can increase risks in others. Understanding these relationships is key to investigating how emerging technologies collectively are transforming cybersecurity in CII and ICS, as discussed in the next section.

IV. Emerging Technologies and Cyber Risk Dynamics

The adoption of emerging technologies is significantly changing the operational makeup of CII and ICS environments in ways that are more than just increasing efficiency. While these technologies enable automation, real-time monitoring and data-driven decision-making, they also change the nature of cyber risk by introducing new dependencies, expanding connectivity and increasing the complexity of digital ecosystems. They do not necessarily introduce new threats, but rather alter how existing threats emerge, propagate, and impact critical infrastructure. This review has identified three broad technological shifts that collectively revolutionise the cybersecurity environment: increased connectivity, the proliferation of operational intelligence, and long-term uncertainty surrounding cryptography.

A. Connectivity Technologies: Expanding the Attack Surface

The first transformation is enabled by technologies that improve connectivity between operational environments. IIoT, 5G, and edge computing allow industrial assets, sensors, controllers and enterprise systems to be continuously connected with each other. These technologies enable better operational visibility, predictive maintenance and decentralised decision-making, which are all the hallmarks of Industry 4.0 initiatives [5][39].

But more connectivity also means a larger attack surface for cyber intrusion. With each connected sensor, gateway, or edge device, there is an increased attack surface available to adversaries. Unlike traditional industrial environments that were largely isolated from external networks, modern CII increasingly relies on distributed devices that often operate outside secure network boundaries.

Many of these devices have limited computational resources, infrequent software updates and inconsistent security controls, making them attractive targets for attackers.

The expanding deployment of wireless communication and virtualised network services further complicates security. For example, vulnerabilities in 5G network slicing or edge nodes may allow attackers to move laterally across interconnected environments and impact multiple operational systems. Therefore, the cybersecurity challenge is no longer limited to protecting individual devices but extends to securing a highly connected digital ecosystem.

B. Intelligent Technologies: Shifting the Focus from Availability to Trust

The second transformation is driven by technologies that increasingly support operational decision-making. AI, digital twins and cloud computing enable operators to process large volumes of operational data, optimise industrial processes and detect anomalies more efficiently than traditional approaches [7]. These technologies also introduce a different category of cyber risk. Traditionally, cybersecurity in industrial environments focused primarily on maintaining system availability and protecting systems from unauthorised access. As organisations become more dependent on these technologies, the integrity and reliability of data become equally important. If attackers manipulate sensor readings, poison AI training data, or compromise digital models, operational decisions may become unreliable even when the underlying systems continue to function normally [6].

Cloud computing reinforces this challenge by creating additional dependencies on external service providers. Cloud platforms improve scalability and operational flexibility. However, they also centralise critical services and increase the dependency on third-party software, making supply chain security one of the major components of cyber resilience [41][42]. These technologies, together, are transforming cybersecurity by not only protecting system availability, but also ensuring the trustworthiness of operational data, algorithms and digital services.

C. Quantum Computing: a Future Threat with Present-Day Implications

Unlike the technologies discussed above, quantum computing is not yet impacting day-to-day industrial operations. Its significance lies in its capacity to compromise the cryptographic foundations that protect digital communications in CII and ICS environments. Current public-key cryptographic algorithms, including Rivest-Shamir-Adleman (RSA) and Elliptic Curve Cryptography (ECC), are expected to become vulnerable to sufficiently powerful quantum computers [38].

Although practical quantum attacks remain some years away, adversaries may already be collecting encrypted information for future decryption using a “harvest now, decrypt later” strategy [37][38]. Given that many industrial systems remain operational for decades, preparing for post-quantum cryptography has become a strategic resilience issue rather than simply a future technical challenge.

D. A Common Pattern Across Emerging Technologies

While the seven technologies examined in this review differ in purpose and maturity, they exhibit a common pattern. Each technology provides significant operational benefits, but also introduces new types of cyber exposure. Connectivity technologies expand the attack surface, intelligent technologies increase dependence on trusted data and digital services, while quantum computing challenges the long-term security of existing cryptographic mechanisms. These technologies therefore do not create isolated cybersecurity problems. Rather, they collectively reshape how cyber risks emerge and propagate across interconnected CII and ICS environments.

V. Cyber-Physical Impacts of Emerging Technologies on CII and ICS

A. Operational and Economic Impacts

The increasing digitalisation of CII and ICS has significantly increased the operational and financial consequences of cyber incidents. Unlike traditional enterprise IT environments, disruptions to critical infrastructure can interrupt essential services such as electricity generation, water treatment, healthcare delivery and transportation. Even when OT systems is not directly compromised, attacks on supporting IT systems can force operators to suspend critical processes as a precautionary measure, leading to substantial operational disruption.

The Colonial Pipeline [21] ransomware incident demonstrated that a cyberattack targeting enterprise IT systems could trigger the shutdown of operational infrastructure because of concerns over the safe management of pipeline operations. Similarly, attacks against manufacturing facilities, healthcare organisations and utility providers have resulted in prolonged service interruptions, delayed production and significant financial losses.

The 2025 OT Cyber Threat Report [36] states that multiple cyber incidents per year have quantifiable physical operational impacts, with some cases resulting in losses of several million to hundreds of millions of dollars. Another study found that nearly half of the critical infrastructure organisations surveyed had experienced cyber-physical incidents resulting in financial losses exceeding US$500,000, indicating that economic impacts of cyberattacks are beyond system recovery costs [47]. Furthermore, studies of major incidents such as NotPetya [49] demonstrate that indirect supply chain disruption often exceeds the direct cost of the original attack, thereby increasing economic losses across interconnected organisations [50].

These examples indicate that cyber incidents impacting CII are no longer limited to technical failures. Rather, they increasingly disrupt operational continuity, interrupt essential services and cause economic consequences that propagate across interdependent supply chains.

B. Physical, Safety and Societal Impacts

A significant characteristic of cyber incidents affecting CII and ICS is their ability to produce physical consequences.

Incidents targeting industrial environments may affect equipment, industrial processes and public safety, as compared to cyber-attacks against traditional IT systems. Consequently, cybersecurity within critical infrastructure is closely linked to operational resilience and the protection of human life.

Historical incidents illustrate this distinction clearly. Stuxnet demonstrated that malware could manipulate industrial equipment to cause physical damage, while Triton specifically targeted Safety Instrumented Systems (SIS), highlighting that cyber-attacks can deliberately compromise mechanisms designed to protect people and industrial facilities. More recently, attacks on water treatment facilities and energy operators have demonstrated that relatively simple vulnerabilities, such as exposed remote access services or default credentials, may create opportunities for attackers to interfere with critical processes [16][23].

The societal impact of these events extends beyond the organisations concerned. Interruptions to electricity, healthcare, telecommunications or water supply can rapidly affect businesses, government services and the daily lives of citizens. Furthermore, the increasing involvement of nation-state actors in targeting critical infrastructure introduces geopolitical dimensions that encompass cybersecurity beyond organisational risk management and into national security and economic stability [51].

C. Cascading and Systemic Impacts

Perhaps the most significant consequence of digital transformation is the increasing potential for cyber incidents to cascade across interconnected infrastructures. Modern CII sectors are no longer isolated systems but form part of a wider ecosystem connected through shared communication networks, cloud platforms, software suppliers and operational dependencies. Consequently, a disruption affecting one organisation or sector may trigger secondary effects across multiple critical services.

Research on interconnected critical infrastructure consistently demonstrates that cyber incidents can produce cascading failures, in which disruption spreads through technical, organisational, and supply-chain dependencies rather than remaining confined to the original target [40]. For example, failures within the electricity sector may affect telecommunications, transportation, healthcare and financial services, while compromises of widely used software platforms or cloud service providers can simultaneously expose thousands of organisations, as demonstrated during the SolarWinds incident.

These systemic effects challenge many traditional cybersecurity approaches, which primarily focus on protecting individual organisations. As digital transformation deepens inter-sectoral interconnections, cyber resilience must increasingly consider the wider ecosystem in which critical infrastructure operates. Protecting one organisation is no longer sufficient if vulnerabilities in trusted suppliers, cloud providers, or interconnected services can cause widespread disruption.

VI. An Integrated Pathway Model for Understanding Cyber Risk Transformation in CII and ICS

The literature reviewed in this study reveals a consistent pattern beyond individual technologies or isolated cyber incidents. While emerging technologies, cyber threats, vulnerabilities, and resilience have been examined independently in previous studies, little attention has been paid to how these elements interact to reshape cyber risks in CII and ICS. Bringing these relationships together reveals that digital transformation does not simply introduce new technologies; it changes the pathways through which cyber risks emerge, propagate and ultimately affect critical services.

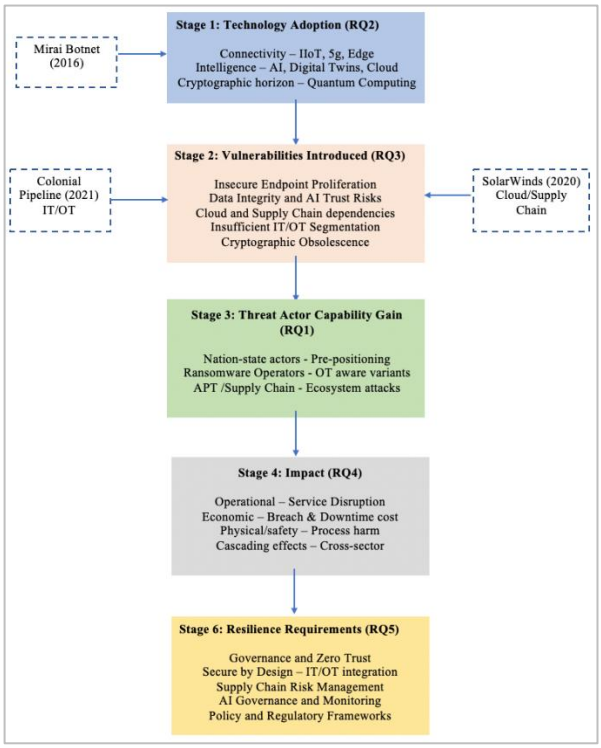

Fig. 2. Integrated cyber risk pathway model illustrating the relationship between the different stages.

Fig. 2 presents an Integrated Cyber Risk Pathway Model that synthesises these relationships. The model illustrates cyber risk as a progressive process that begins with technology adoption, creates new forms of exposure, expands opportunities for cyber threat actors and results in operational, physical and societal consequences. These consequences, in turn, redefine the resilience capabilities required to protect modern critical infrastructure.

A. Stage 1: Technology Adoption

The pathway starts with the growing adoption of Industry 4.0 technologies. These technologies are being deployed to improve operational efficiency, enable predictive maintenance, improve situational awareness and allow for more autonomous industrial processes [1][3].

All technologies provide significant operational benefits, but the combined adoption fundamentally alters the architecture of CII and ICS. Industrial environments are becoming increasingly connected, data-driven, and dependent on external digital services. As a result, the nature of cybersecurity challenges has evolved from securing individual systems to managing risks in an interconnected digital ecosystem.

B. Stage 2: Vulnerability Creation

Digital transformation inevitably introduces new forms of exposure. The literature reviewed in this study identified five recurring vulnerability categories: expanding attack surfaces, data integrity risks, cloud and third-party dependencies, weak IT–OT segmentation and emerging cryptographic challenges. Importantly, these vulnerabilities should not be viewed as independent security issues. They reinforce one another. For example, IIoT devices increase the number of internet-connected assets, cloud computing introduces external dependencies, AI systems rely on trustworthy data, while IT–OT convergence creates pathways through which attacks originating in enterprise networks can affect physical operations. Together, these vulnerabilities create a highly interconnected risk environment in which weaknesses in one domain can amplify risks elsewhere [32][36].

C. Stage 3:Threat Actor Exploitation

These vulnerabilities provide cyber threat actors with new opportunities to compromise critical infrastructure. The review shows that attacker behaviour has evolved alongside digital transformation. Earlier attacks generally required specialist knowledge of industrial processes and proprietary control systems. More recent attacks increasingly exploit software supply chains, cloud services, internet-facing assets and trusted third-party relationships to gain access to operational environments [4][18].

Consequently, the capabilities of threat actors are no longer determined solely by their understanding of industrial systems. Increasingly, attackers exploit weaknesses created by digital integration, allowing them to compromise critical infrastructure without directly attacking industrial technologies themselves. This explains the growing prevalence of ransomware, supply chain compromises and attacks targeting interconnected digital services.

D. Stage 4: Cyber-Physical Impacts

When vulnerabilities are successfully exploited, the consequences surpass the loss of information. Unlike traditional enterprise environments, cyber incidents affecting CII and ICS can disrupt physical processes, interfere with the delivery of essential services and cause cascading effects across interconnected sectors.

The review identified four general types of impacts: operational disruption, economic loss, physical and safety consequences, and systemic or cascading failures. These impacts are closely related. For example, a compromise of an enterprise IT network may disrupt industrial operations, leading to financial losses, interruption of public services, and wider societal consequences. As digital interdependencies increase, the likelihood that failures will propagate across multiple sectors also increases [40][36].

E. Stage 5: Resilience Requirements

The final stage of the pathway recognises that preventing every cyber-attack is unrealistic. Instead, resilience therefore involves the ability to anticipate, withstand, respond to and recover from cyber incidents while maintaining essential services.

The literature consistently highlights governance, secure-by-design principles, IT-OT integration, supply chain security, continuous monitoring and cross-sector collaboration as key resilience capabilities. Importantly, these capabilities address different stages of the pathway rather than functioning as isolated security controls. Resilience should be viewed as a system-wide capability that reflects the interconnected nature of modern CII and ICS.

VII. Discussion

A. Advancing an Integrated Perspective of Cyber Risk

The findings of this review suggest that the cybersecurity of CII and ICS can no longer be understood by examining individual technologies or isolated cyber incidents. While previous studies have made important contributions by investigating the security implications of AI, IIoT, cloud computing, digital twins, 5G and other emerging technologies, they have generally addressed these technologies separately. In practice, however, CII operators are adopting several of these technologies simultaneously, creating an increasingly interconnected digital ecosystem in which vulnerabilities, threats and impacts are closely related [6][43]. The Integrated Cyber Risk Pathway Model developed in this study brings these relationships together into a single conceptual framework. Instead of viewing cyber-attacks as isolated technical events, the model demonstrates how digital transformation progressively reshapes cyber risk. The adoption of emerging technologies creates new forms of exposure; these vulnerabilities provide opportunities for cyber threat actors, successful attacks produce cyber-physical and societal impacts, and those impacts redefine the resilience capabilities required to protect essential services. This perspective is consistent with studies showing that cyber incidents increasingly propagate across interconnected infrastructures rather than remaining confined to individual organisations [40].

The model also reinforces a broader shift in cybersecurity research. Traditional approaches have largely focused on preventing unauthorised access and protecting individual assets. While these objectives remain important, they are no longer sufficient for digitally connected critical infrastructure. Modern CII environments operate as complex socio-technical systems in which cloud platforms, software supply chains, operational technologies and external service providers are tightly interconnected. As a result, resilience depends not only on protecting individual components but also on understanding how disruptions propagate across the wider ecosystem. This systemic perspective aligns with the growing body of cyber resilience literature, which argues that resilience should be viewed as an organisational and system-level capability rather than simply a collection of technical security controls [43][44].

B. Implications for Research and Practice

This review has implications for both researchers and practitioners. From a research perspective, the Integrated Cyber Risk Pathway Model provides a conceptual foundation for future empirical studies examining the relationships between technology adoption, emerging vulnerabilities and cyber resilience. Most existing studies investigate these topics independently, making it difficult to explain how digital transformation influences the overall cybersecurity posture of CII and ICS. The proposed model offers a structured framework that can be validated using longitudinal cyber incident data, sector-specific case studies, or quantitative resilience assessments.

From a practical perspective, the model encourages organisations to move beyond technology-specific security measures towards a more integrated understanding of cyber risk. Decisions relating to AI adoption, cloud migration, IIoT deployment or IT–OT integration should not be evaluated independently. This is because each decision can influence vulnerabilities in other parts of the digital ecosystem. Consequently, resilience planning should incorporate governance, secure system design, supply chain risk management and cross-sector collaboration as complementary rather than independent activities.

Although the pathway model is intended to provide a cross-sector perspective, its individual stages should be interpreted in the context of the sector in which it is applied. CII sectors differ in their operational environments, technology dependencies, threat exposure and potential consequences of disruption. For example, energy infrastructure may focus on availability and integrity of operational technologies and prevention of cascading disruptions. Healthcare settings must consider continuity of clinical services, protection of sensitive information and the increasing reliance on interconnected medical systems. Water infrastructure might be especially vulnerable to risks of remote-access control systems, legacy operational technologies and physical process manipulation. Therefore, the route from technology adoption to vulnerability, exploitation, impact and resilience applies across CII sectors, but the importance of individual vulnerabilities, threat scenarios and resilience measures may vary according to sector-specific characteristics. The model should therefore be viewed as a common analytical structure that can be adapted to the operational and risk context of individual CII sectors.

The model also has relevance for policymakers and regulators. As governments continue to promote digital transformation across critical sectors, cybersecurity policies should increasingly recognise the interconnected nature of modern infrastructure. Regulatory initiatives such as the NIS2 Directive [45], the Critical Entities Resilience Directive (CER) [46] and the Cyber Resilience Act (CRA) [48] represent significant progress by promoting stronger governance and supply chain security. However, the findings of this review suggest that future policy development should place greater emphasis on systemic risk, cross-sector dependencies and coordinated resilience planning.

C. Limitations of the Study

This Study Has Certain Limitations that Should Be Acknowledged. First, the Findings Are Based on a Multivocal Literature Review, Which Combines Peer-reviewed Research with Grey Literature. Although This Approach Is Well Suited to Cybersecurity Research Because Many Emerging Threats Are First Reported by Government Agencies and Industry Organisations, the Quality and Level of Evidence Across Sources Are Not Always Consistent [8].

Second, the Integrated Cyber Risk Pathway Model is a conceptual framework derived from evidence synthesis and has not yet been empirically validated. While the relationships represented in the model are supported by the literature reviewed, future research should examine whether these relationships are consistently observable in real-world CII and ICS environments. One approach would be to analyse documented cyber incidents and map the available evidence against the five stages of the model: technology adoption, vulnerability creation, threat actor exploitation, cyber-physical impacts and resilience requirements. Sector-specific case studies in areas such as energy, healthcare and water could then be used to examine whether the nature and strength of these relationships vary across different operational environments. As the evidence base develops, quantitative indicators could also be defined for individual stages of the pathway to support more systematic assessment of the relationships between technology adoption, cyber exposure, incident impacts and resilience outcomes. These approaches would provide a basis for progressively testing and refining the proposed model.

Third, the review examines seven emerging technologies. Other developments that may have cybersecurity implications for CII and ICS, such as blockchain, distributed ledger technologies and autonomous industrial systems, are not examined. As the integration of these technologies into critical infrastructure evolves, they should be considered in future extensions of the review.

Finally, the study adopts a cross-sector perspective and therefore does not provide a detailed comparative analysis of individual CII sectors. Differences in operational environments, technology dependencies, threat exposure and resilience priorities across sectors such as energy, healthcare, water, telecommunications and manufacturing may influence how individual stages of the proposed pathway manifest in practice. Future sector-specific studies could therefore apply and validate the model within individual CII domains to determine how these relationships vary across operational contexts. Despite these limitations, the study provides an integrated perspective on how emerging technologies collectively reshape cyber risk and resilience within critical infrastructure, while providing a foundation for future empirical and theoretical research.

VIII. Conclusion

The rise of emerging technologies is transforming the cybersecurity landscape of CII and ICS in ways that go beyond the introduction of new technologies or attack vectors. The fast pace of digital transformation is resulting in increasingly complex cybersecurity challenges, with vulnerabilities emerging not only from individual systems but also from

interactions among technologies, organisational processes, and digital dependencies. This shift calls for a broader understanding of cyber risk, considering the complexity of modern critical infrastructure.

This study addresses this challenge by synthesising evidence from academic research, government publications and industry threat intelligence to examine how emerging technologies collectively influence cybersecurity in CII and ICS. Instead of analysing technologies, vulnerabilities, threat actors and resilience as separate topics, the study combined these perspectives into an Integrated Cyber Risk Pathway Model that explains how cyber risk develops from technology adoption through to cyber-physical impacts and resilience needs. By bringing these relationships together, the framework provides a comprehensive view that complements existing technology-specific and threat-specific research.

Results also indicate that securing critical infrastructure requires a shift from siloed security measures to resilience strategies that recognise the interconnected nature of today's digital ecosystem. As organisations increasingly integrate AI, cloud computing, IIoT, edge computing and other Industry 4.0 technologies into operational environments, cybersecurity cannot be addressed solely through technical controls. Effective protection increasingly depends on governance, secure system design, supply chain assurance and collaboration across organisations and sectors. Building resilience, therefore, requires understanding not only where vulnerabilities exist but also how they interact and propagate across interconnected systems.

However, the present study has some limitations. The Integrated Cyber Risk Pathway Model presented is a synthesis of existing evidence and has not been empirically tested. In addition, the review adopts a cross-sector perspective and focuses on seven emerging technologies. Sector-specific differences and other technological developments are not examined in detail.

Future research should therefore focus on the empirical validation and further refinement of the proposed model. Documented cyber incidents could be mapped against its five stages to examine whether the relationships identified through the literature are consistently observable in practice. Sector-specific case studies across areas such as energy, healthcare and water could further determine how vulnerability profiles, threat actor behaviour, cyber-physical impacts and resilience priorities vary across different operational environments. Future extensions of the review could also consider other emerging developments, including blockchain and distributed ledger technologies and increasingly autonomous industrial systems. Also, as the model matures, quantitative indicators may be developed for its individual stages to support a more systematic assessment of cyber risk transformation and resilience in CII and ICS environments.

The Integrated Cyber Risk Pathway Model provides a basis for understanding how cyber risk is changing in critical infrastructure through technological transformation and increasing interconnectedness. The model connects the adoption of technology, vulnerabilities, exploitation by threat actors, cyber-physical consequences, and resilience needs. It provides a foundation for future empirical research and offers practitioners and policymakers a systematic perspective to ponder cybersecurity risks within the framework of ongoing digital transformation.

IX. Declaration of Generative AI

The authors declare that Generative AI was not used for the preparation and writing of this research study.

MalBERT-Temporal: Transformer-Based Zero-Day Malware Detection in Windows Executable Binaries Under Strict Temporal Isolation

Manar Alanazi, Israa Alsiyat
Department of Computer Science, Northern Border University, Arar, Saudi Arabia

***Abstract*—In current malware detection benchmarks, random train/test splits are commonly used, allowing temporal leakage to occur and obscuring performance degradation caused by concept drift. Moreover, traditional classifiers that operate on a one-dimensional PE feature vector do not explicitly model long-range interactions between structurally distant feature groups. This study introduces a Transformer-based malware detection approach named MalBERT-Temporal that reshapes the 2,381-dimensional BODMAS PE feature vector into 16 contiguous feature-group tokens and then processes these tokens with Transformer encoder layers employing multi-head self-attention to model interactions among all tokens. The proposed approach is evaluated using a strict temporal protocol in which the training data comprise only pre-2020 samples, and the test data span the complete 2020 evaluation timeline. Each model is independently calibrated using a fixed validation set with a false-positive-rate budget of 0.1% and is evaluated monthly and on malware families unseen during training. At the calibrated security threshold, MalBERT-Temporal achieves an F1-score of 97.84% with a false-positive rate of 0.138%, outperforming a 1-D CNN baseline, which achieves an F1-score of 92.01% and a false-positive rate of 3.388%, and a Random Forest baseline, which achieves an F1-score of 67.29%. Welch's t-tests confirm statistically significant differences in monthly F1-scores between the proposed approach and both baselines. Moreover, MalBERT-Temporal maintains monthly F1-scores within a 2.2-point band throughout the nine-month evaluation period, indicating improved robustness to temporal distribution shift. A component-wise ablation traces the improvement to the tokenized self-attention mechanism itself: substituting a token-wise feed-forward block for self-attention while keeping every other component costs 2.73 F1 points, and removing the tokenization costs 1.85 points, while positional embeddings, the CLS token, multi-scale pooling, encoder depth, and nonlinearity are each worth 0.47 points or less. A matched random-split control that leaves the model, the preprocessing, the training budget, and the calibration procedure unchanged gives an F1-score of 98.86%, which confirms that chronological evaluation is the stricter protocol.**

Keywords*—Zero-day malware detection; transformer; self-attention; portable executable; temporal isolation; concept drift; BODMAS; structural feature modeling

I. Introduction

Malicious software remains one of the major threats to digital infrastructure as it can facilitate data theft, surveillance, and compromise of systems in both commercial and public-sector environments [1]. Signature-based detection systems remain the dominant approach in operational malware detection and work by matching executables against databases of known patterns; consequently, they cannot detect polymorphic, obfuscated, or previously unseen zero-day malware [1, 2]. Since adversaries frequently develop mutation and obfuscation toolkits that can bypass static fingerprinting, the inadequacy of signature-centric methods for emerging threats is well established in the security literature.

This major weakness has motivated the use of machine-learning and deep-learning methods that are capable of classifying executables based on structural, statistical, and behavioral evidence rather than relying on libraries of curated rules [1]. Windows Portable Executable (PE) static analysis is particularly suitable as a source for large-scale analysis of binary files: information such as file headers, section tables, import directories, exported symbols, string statistics, and byte-entropy profiles can be gathered without executing any computer program, resulting in high-dimensional feature vectors that reflect a binary's design intent, dependency structure, and payload characteristics [3]. These features render structured PE feature analysis a practical foundation for large-scale automated malware classification.

Transformer-based deep-learning models are well suited to operate in such highly structured, high-dimensional environments. Self-attention computes the relationships between all positions in the input sequence simultaneously. This allows the model to capture long-range structural dependencies that are difficult to model explicitly using local methods [2]. In malware analysis, malicious intent is often spread among different attributes that are spatially separated, such as an entropy anomaly in one section and suspicious import patterns in another, rather than being found entirely in a single local region. Traditional machine-learning classifiers treat PE feature vectors as unordered feature sets, while convolutional models mainly focus on local neighboring patterns. As a result, both approaches are limited in their ability to capture interactions between distant feature elements [2].

Another less frequently acknowledged difficulty is the issue of evaluation realism. Malware is non-stationary in nature: new malware families are continually discovered, existing variants undergo change, and even benign software evolves, causing the feature distribution to drift away from any fixed training dataset [4]. The use of random train-test splitting permits samples belonging to a future period to appear within the training data, and thereby gives rise to temporal data leakage [4, 5]. Such temporal data leakage artificially inflates the reported

performance relative to that which would be observed under real-world deployment [4, 5]. This phenomenon, in which the distribution shifts as a consequence of changes in the environment, is termed concept drift. Within only a few months of deployment, concept drift of this kind may degrade detection performance to a considerable degree. Notwithstanding this, the majority of existing studies neither implement chronological partitioning nor evaluate performance over subsequent time windows [5].

Taken together, the literature review reveals two gaps that are closely interlinked. First, PE feature vectors are typically regarded as flat, order-agnostic arrays, with the consequence that models may overlook the long-range relational patterns that attention mechanisms are specifically designed to capture. Second, most evaluations are carried out through random splits and ignore temporal drift monitoring. This makes it difficult to evaluate long-term robustness reliably. Only a limited number of studies have combined both aspects in a single framework focused on Windows PE malware detection.

To bridge these gaps, this study proposes MalBERT-Temporal, a Transformer-based framework for detecting zero-day malware in Windows executables. The framework transforms structured PE feature vectors into sequences of semantically meaningful tokens, captures long-range dependencies using Transformer encoder layers with multi-head self-attention, and relies on an evaluation protocol that strictly separates the training and testing periods chronologically. MalBERT-Temporal is built using the timestamped BODMAS dataset [6], which consists of 134,435 PE samples spanning fourteen years. The model is trained exclusively on pre-2020 data and tested on 2020 data. The framework's performance is then compared with that of CNN and Random Forest baselines under exactly the same temporal conditions to distinguish the impact of architectural design from that of the evaluation protocol. This design addresses the following research questions: 1) to what extent does strict chronological splitting expose performance degradation hidden by conventional random splitting (RQ1); and 2) can a Transformer-based architecture capture long-range structural relationships within PE feature vectors well enough to outperform the CNN and Random Forest baselines under identical temporal conditions (RQ2)?

The primary contributions of this study are the following:

- A rigorous chronological evaluation methodology using the timestamped BODMAS dataset, which enforces temporal isolation and reduces data leakage in zero-day malware detection.
- MalBERT-Temporal, a Transformer-based architecture in which the structured PE feature vector is encoded as a token sequence and multi-head self-attention models long-range structural dependencies in the data.
- A controlled comparison against CNN and Random Forest baselines using identical temporal splits for training and evaluation, isolating the effect of architectural decisions.
- A systematic study of generalization to future and previously unseen malware families under realistic chronological conditions.
- Monthly temporal drift monitoring that tracks detection performance across successive time windows and evaluates temporal stability using statistical testing.
- A set of controlled ablation and control experiments that isolate the source of the reported gains, covering component and group-granularity ablations, a matched random-split control, retraining schedules, bootstrapped zero-day confidence intervals, and feature-level drift analysis.

The rest of the study is structured in the following way. Section II reviews the literature concerning Transformer-based malware detection, alternative representations, and temporal evaluation methodologies. Section III describes the dataset, the preprocessing pipeline, the model designs, and the experimental design. Section IV presents the comparative and temporal-drift results. Section V interprets these results in the light of the research questions, and Section VI concludes the study and outlines directions for future research.

II. Related Work

A. Transformer and Sequence-Based Executable Malware Detection

Numerous researchers have examined the application of attention-based and Transformer models to the analysis of malware. Wang et al., for example, proposed TTDAT, a dual-attention Transformer founded upon API call sequences. The method fuses global multi-head attention with a local attention mechanism to capture dependencies across various scales effectively. This model yielded an average F1-score of 0.90 on a dynamic API dataset [7]. Qian and Cong, along the same lines, enhanced the Transformer encoder by inserting a one-dimensional channel attention module (CAFTrans) to better capture correlations among features within API vectors. They reported state-of-the-art performance on the mal-api-2019 benchmark [8]. The two publications cited above rely on dynamically extracted API sequences, which entail different extraction costs and scalability constraints from those of structured static PE feature vectors.

Lu et al. tested two self-attention Transformer classifiers directly on subsets of BODMAS by means of a two-stage pipeline. SeqConvAttn processed raw bytes, whereas ImgConvAttn used binary image representations [9]. The two-stage pipeline achieved 96.96% accuracy on BODMAS-11, showing that Transformers outperform CNN baselines on PE binary data. However, the input consisted of raw bytes rather than structured PE attributes, and random data partitioning was applied; temporal generalization therefore remains uncharacterized. Labied et al. combined disassembly, assembly-level tokenization, DLL import extraction, and a Transformer encoder to achieve 96.88% accuracy on 11,000 VirusTotal PE samples [10]. The results indicate that attention-based models can be successful for PE analysis, but their approach focuses on assembly-level semantics rather than structured multi-group PE feature vectors. In addition, no chronological evaluation was

presented. Kim et al. adopted a Transformer encoder for pre-training with new masking strategies and finally fine-tuned it for malware detection tasks across different binary formats. Their work indicates that pre-training on raw bytes yields generalizable representations [11]. Tallane et al. used a byte-embedding Transformer encoder to process the first 1,024 bytes of each binary. Their model also used stochastic weight averaging and Mixup. They reached 99% accuracy on one benchmark and 92–94% on two others [12]. Both works show that byte-level Transformers are effective malware detectors. However, they also forgo the semantic structure contained in PE headers, section descriptors, and import tables.

B. Alternative Representations and Hybrid Architectures

Binary visualization techniques convert malware into grayscale images and utilize vision models for classification. Alshomrani et al. combined ConvNeXt-Tiny's local feature extraction with Swin Transformer's global context modeling through adaptive gating, resulting in 94.04% average validation accuracy across three malware image benchmarks and 98% on external validation [13]. Despite the intuitive nature of the image approach, it loses the hierarchical semantic structure of PE files. Alzahrani et al. developed RansomFormer, a cross-modal Transformer that integrates PE byte data with API import features using cross-attention to detect ransomware, demonstrating that merging static bytes with behavioral metadata enhances specificity [14]. Miraoui and Belgacem compared classical machine-learning classifiers and CNN-based models on structured Windows PE feature vectors, finding that both methods achieved high detection accuracy, though neither explicitly captures long-range interactions among distant PE attributes [15]. Dhanya et al. proposed a zero-day IoT malware defense using an anomaly-driven approach that blends attention-enhanced autoencoders, cosine similarity in latent space, Isolation Forest scoring, and a Transformer encoder, achieving 99.38% accuracy on Mirai network traffic [16]. However, the study targeted IoT network traffic rather than Windows PE files, which limited its applicability, and no temporally structured evaluation was performed.

C. Temporal Evaluation, Concept Drift, and Long-Term Robustness

Concept drift and temporal robustness are two issues of increasing concern in malware research. Chen et al. discovered that Android malware classifiers can lose significant detection capability within several months of the training cutoff date and thus developed contrastive learning methods for maintaining classifier reliability under an active-learning budget [4]. Li et al. noted that retraining techniques for Windows PE malware underperform when drift-invariant representations obtained through adversarial domain adaptation are not used [5]. Through the evaluation of timestamping and feature selection methods over a seven-year Android detection period, Guerra-Manzanares and Bahsi demonstrated the significance of labeling budget allocation and temporal placement for achieving long-term performance stability [17]. Maniriho et al. developed MeMalDet, a memory-analysis framework containing explicit temporal attributes and chronological data splits, which achieved an accuracy of 98.82% under concept-drift evaluation conditions, thereby showing that incorporating timestamps into dataset design yields fundamentally more informative benchmarks [18].

D. Synthesis and Identified Research Gap

The reviewed literature consistently validates Transformer architectures for learning contextual relationships in executable data. In addition, concept drift is acknowledged as a practically significant phenomenon. However, a clear yet underexplored combination emerges. Works that depend on raw bytes, assembly tokens, or binary images sacrifice the semantically organized structure of structured PE feature vectors; at the same time, works using structured PE metadata mostly rely on flat-feature classifiers or CNN models that are incapable of modeling long-range attribute interactions; furthermore, the large majority of published evaluations across all representation types employ random train-test splits and omit systematic temporal drift monitoring. Few studies have jointly examined: 1) Transformer-based sequential modeling of structured PE feature vectors, 2) strictly chronological separation of training and test data, 3) evaluation on future and previously unseen malware families, and 4) month-by-month performance monitoring. MalBERT-Temporal is positioned to address this combined gap by integrating attention-based sequence modeling of the full 2,381-dimensional BODMAS feature space, strict temporal isolation, explicit zero-day family generalization testing, and temporal drift analysis with statistical significance testing under controlled baseline comparisons.

III. Methodology

The MalBERT-Temporal framework represents a Transformer-based approach to malware detection. The key idea behind the architecture is to replace the standard flat, order-agnostic representation of Portable Executable (PE) data with a structured token-based representation. Instead of feeding a 2,381-dimensional feature vector to the classifier as a flat array of features, the framework transforms it into a token-based representation, allowing multi-head self-attention to model interactions between semantically related feature groups. To study the effectiveness of this approach independently of other factors, the framework was evaluated against two established structured PE detection approaches: a tree-based ensemble [15], [19] and a one-dimensional convolutional network [9], under the same chronological partitioning. A key methodological principle maintained throughout all experiments is that the chronological order of the data is preserved and all operating thresholds are determined using only a held-out subset of the pre-2020 training data.

A. System Overview

There are four distinct stages in the pipeline, as illustrated in Fig. 1. The first stage involves Data Preparation, in which the timestamp metadata is merged with the feature matrix, malformed instances are removed, the samples are sorted by time, and a strict temporal split is performed. In the second stage, Feature Enhancement, the attributes are preprocessed through signed-logarithmic transformation and robust scaling to make attributes of vastly different orders of magnitude comparable for modeling purposes. The third stage entails the use of a Comparative Modeling Framework, where three models, namely MalBERT-Temporal, a Random Forest model, and a CNN model, are trained on exactly the same data using identical

preprocessing. Therefore, any observed performance difference can be attributed to the modeling strategy rather than differences in data preparation or evaluation. The fourth stage, in turn, involves the Comprehensive Performance and Temporal Stability Analysis, in which the models are assessed based on two dimensions: 1) multi-scenario evaluation of F1-score, accuracy, precision, recall, and zero-day generalization, and 2) temporal drift assessment that tracks monthly performance and evaluates the statistical significance and temporal consistency of the observed differences using Welch's t-test.

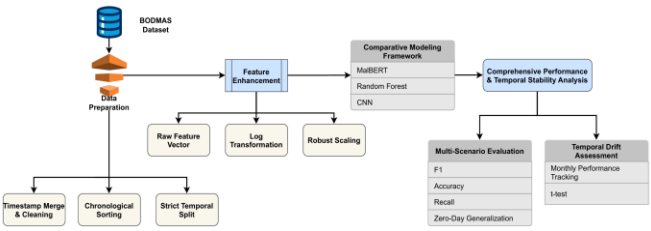

Fig. 1. End-to-end MalBERT-temporal pipeline.

B. Model Architectures

Three model architectures are trained and evaluated under identical temporal partitioning, preprocessing, and training data to provide representative implementations of three commonly used approaches to structured PE malware detection: order-agnostic tree ensembles, local convolutional modeling, and Transformer-based self-attention [2]. This fixes the input pipeline throughout the experiments, making the comparison primarily a test of each model's inductive bias and ensuring that observed performance differences are attributable to the modeling strategy rather than to preprocessing or evaluation.

1) Random forest baseline: The first baseline employs an ensemble of decision trees trained directly on the entire structured PE feature vector, without making any assumptions about sequential information or performing an architecture search [19]. Random Forest models handle heterogeneous tabular features of diverse scales robustly and have long been used as order-agnostic baselines in PE malware detection [15], [19]. The main drawback of the model is architectural in nature, in that feature interactions are encoded only through hierarchical decision paths, making complex relationships between distant attributes less explicit than in attention-based models. Consequently, interactions between feature groups that rarely co-occur along the same decision paths may be more difficult to model effectively.

2) 1-D Convolutional Network (CNN): The second architecture treats the feature vector as a one-dimensional signal and applies a series of convolutional filters aimed at capturing local patterns from neighboring feature indices [9]. This type of architecture has demonstrated strong performance on PE and byte-level representations by exploiting local structural patterns that conventional tabular models may overlook [9]. One of the main disadvantages of such an approach is locality, since the receptive field of a filter contains only neighboring feature indices. Therefore, interactions between widely separated feature groups typically require several convolution and pooling stages before they can be integrated. For example, an entropy anomaly in one section and a suspicious import pattern in another may be combined only after several such stages. As a result, modeling very long-range feature relationships may be less effective than with architectures that explicitly support global interactions.

3) Transformer-based MalBERT-temporal architecture: The architecture proposed herein transforms the flat PE feature vector into a short sequence of tokens and uses multi-head self-attention to model relationships between groups of features. The 2,381 features are divided into 16 contiguous groups, each of which is projected through its own learnable linear transformation, layer-normalized [20], and passed through a GELU activation function [21], leading to one token per feature group. The group boundaries come from an equal-width partition of the ordered index range F1-F2381 and not from any feature-selection or clustering procedure. Since 2,381 is not an integer multiple of 16, three groups hold 148 features and the other thirteen hold 149. Section IV-H examines the choice of sixteen groups empirically. A learnable classification (CLS) token, following the BERT architecture [22], is prepended to aggregate global information, whereas learnable positional embeddings preserve the ordering within the sequence. The resulting 17-token sequence is processed by a stack of pre-normalized Transformer encoder layers [23], based on multi-head self-attention:

$$\text{Attention}(Q,K,V) = softmax\left(\frac{QK^{\top}}{\sqrt{d_k}}\right)V \quad (1)$$

where, Q, K, and V denote the query, key, and value projections of the token sequence, respectively, while d_k denotes the dimensionality of each attention head [24]. As self-attention allows each token to attend directly to every other token, interactions between distant feature groups, such as an entropy anomaly encoded in one group and a suspicious import pattern encoded in another, can be modeled within a single Transformer encoder layer. This global interaction mechanism facilitates learning long-range structural dependencies that are difficult to model using convolutional or tree-based methods. Therefore, the novelty of this research lies not in the introduction of a new Transformer architecture but in the reorganization of structured PE features into a tokenized representation that enables attention-based modeling under a temporally rigorous evaluation framework.

C. Pooling and Threshold Calibration

Each architecture is evaluated independently without being incorporated into an ensemble system. As such, each model generates its own continuous output score, which is then converted into a binary decision using an independently calibrated threshold. This ensures that performance differences between the models are attributable to the individual architectures rather than ensemble effects.

MalBERT-Temporal summarizes the encoder output via three different pooling operations: the CLS token embedding, the mean of the feature-token embeddings, and their element-wise maximum. The concatenated outputs are fed into a classification head regularized with dropout [25]. Combining a

learned global representation with mean and maximum pooling provides complementary global and distributional information before final classification. The CNN and Random Forest models are baseline methods that produce a single output logit or probability directly from their respective classification layers. Therefore, they do not require explicit pooling operations.

Rather than using the standard probability threshold of 0.5, each architecture is calibrated independently using its corresponding validation receiver operating characteristic (ROC) curve. The operating threshold is then determined as the probability level for which the validation set false-positive rate (FPR) is closest to a fixed budget of 0.1%. This approach aligns with the evaluation method of the original BODMAS work [6], which considers maintaining a very low false-positive rate an important operational constraint. Since the three architectures result in different score distributions, the calibrated thresholds also vary, although the target validation FPR budget remains the same. For completeness, all models were additionally evaluated using the standard decision threshold of 0.5, which permits an assessment of the trade-off between false positives and false negatives.

All operating thresholds were determined solely from the pre-2020 validation subset, prior to the observation of any 2020 samples. No recalibration was carried out during the temporal evaluation period, and strict chronological isolation between the development of the model and its testing was thereby maintained. Consequently, changes in the underlying data distribution during 2020 may influence the realized false-positive rate relative to its validation estimate. In order to quantify this effect, the false-positive rates for each month within the evaluation period were reported together with the corresponding performance measures.

D. Dataset and Temporal Integration

This study makes use of the BODMAS dataset introduced by Yang et al. [6]. The dataset provides pre-extracted static features for Windows Portable Executable (PE) files, together with curated malware family labels and first-seen timestamps for each sample. The two principal components of the dataset, namely the main feature table and the timestamp metadata, were merged by means of the SHA-256 file hash. Each record comprises 2,381 numerical features (F1-F2381), which describe PE header information, section properties, import and export tables, string statistics, and byte-entropy histograms. Following the parsing of the timestamps and the removal of the small number of records for which timestamp information could not be recovered, 130,716 samples remained, spanning the period from January 2007 to September 2020. Samples are sorted in chronological order with respect to the year, month, and precise timestamp. Feature columns are kept in their original indexing order (F1–F2381), providing a consistent ordering for the subsequent tokenization process.

The binary class label is directly derived from the Label field of the dataset, where samples belonging to any malware family are labeled as malicious (y = 1), and all others are labeled as benign (y = 0):

$$y = 1 \; if \; Lable > 0, \; otherwise \; y = 0 \tag{2}$$

Consequently, the dataset contains 73,426 benign samples (56.17%) and 57,290 malicious samples (43.83%), resulting in a moderate class imbalance that is intentionally preserved so that the reported operating metrics reflect the natural class distribution. As benign files do not have any malware family or category details, the corresponding metadata fields are assigned the values "non-malicious" and "benign," respectively, which eliminates missing values in the dataset. Fig. 2 depicts the temporal distribution of the samples throughout the fourteen-year collection period. There is an evident clustering of samples in 2019 and 2020, which provides a sufficiently dense and recent time window for creating a temporally separated training set and future test set.

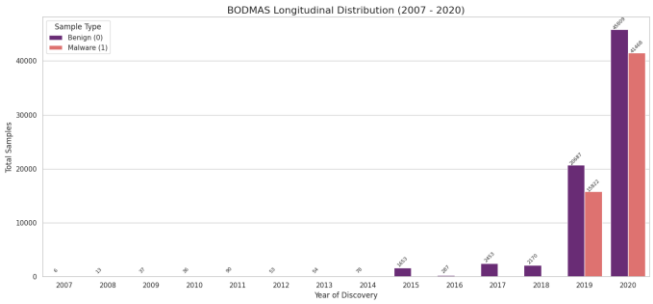

Fig. 2. Longitudinal distribution of benign and malicious BODMAS samples by year of discovery.

E. Signed-Log Transform and Robust Scaling

The raw PE attributes span several orders of magnitude because counts, sizes, and entropy-related measurements are defined on substantially different numerical scales. Consequently, conventional standardization may be disproportionately influenced by a small number of large-valued features. The effect of extreme values that can result from the parsing process is reduced by clipping the magnitudes of the attributes to $\pm 1 \times 10^{10}$. The sign of each attribute is then preserved through a signed logarithmic transformation:

$$\tilde{x} = sign(x) \cdot Ln(1 + |x|) \tag{3}$$

The transformed features are then scaled using the RobustScaler implementation provided by scikit-learn [26], which replaces the mean and standard deviation with the median and interquartile range (IQR), making the transformation more robust to the heavy-tailed distributions commonly observed in PE feature statistics:

$$x' = \frac{\tilde{x} - Q_2}{Q_3 - Q_1} \tag{4}$$

where, Q_1, Q_2, and Q_3 denote the first quartile, median, and third quartile, respectively, estimated exclusively from the training partition. The scaler is fitted only on the training data and is subsequently applied unchanged to the validation and test sets. This approach prevents information from future samples from influencing feature normalization. Any remaining non-finite values are set to zero, while the normalized values are clipped to ±5 to decrease the influence of rare extreme values. Identical preprocessing steps were applied to all three architectures, thereby ensuring that the observed differences in performance arise primarily from the modeling approach rather than from differences in feature preprocessing.

F. Strict Temporal Partitioning and Zero-Day Isolation

All samples collected prior to 2020 were employed for the development of the models, whereas all samples dated within 2020 were reserved exclusively for evaluation. This strict chronological division yielded 43,439 pre-2020 samples for model development and 87,277 temporally subsequent samples for evaluation. Within the pre-2020 group, a stratified 20% subset (8,688 samples) was set aside for validation, leaving 34,751 samples for the training of the models. The validation subset was used solely for threshold calibration and early stopping, and was never used during the test period.

The 2020 test set was further subdivided according to the degree of malware-family exposure encountered during training. If the malware family of a sample was present in the pre-2020 training data, the sample was classified as belonging to a known family; otherwise, it was regarded as a zero-day family. On the basis of this categorization, the test set contained 85,705 known-family samples and 1,572 zero-day samples, the latter representing malware families that had not been observed during training. Table I summarizes the resulting data partition. Since genuinely new malware families occur far less frequently than new variants of existing families, the zero-day subset is comparatively small. This subset nevertheless affords the most direct evaluation of the ability of the model to generalize to previously unseen malware families.

TABLE I. STRICT CHRONOLOGICAL DATA PARTITION OF THE BODMAS DATASET

Partition	Samples	Description
Training (pre-2020)	43,439	All samples dated 2007–2019
• Pure training	34,751	used for model fitting
• Validation	8,688	threshold calibration, early stopping
Test (2020)	87,277	strictly later than training
• Known families	85,705	family seen during training
• Zero-day families	1,572	previously unseen families

G. Training, Calibration, and Evaluation

MalBERT-Temporal was optimized by means of the AdamW optimizer [27]. A cosine-annealing learning-rate schedule with warm restarts was adopted [28], and, in conjunction with this strategy, gradient clipping at 1.0 was applied in order to stabilize the optimization process. The model was trained using binary cross-entropy loss. The checkpoint corresponding to the highest validation F1-score was retained and used for final evaluation on the test set.

Rather than adopting the conventional decision threshold of 0.5, each architecture was calibrated independently on the basis of its validation receiver operating characteristic (ROC) curve. The operating threshold was chosen as the probability cutoff whose validation false-positive rate (FPR) lay closest to a fixed budget of 0.1%. This is consistent with the evaluation protocol used in the original BODMAS study [6], where maintaining a very low false-positive rate is treated as an operational deployment requirement. The resulting calibrated thresholds are 0.4358 for the CNN, 0.9052 for the Random Forest, and 0.9795 for MalBERT-Temporal. For completeness, every model was evaluated using both its calibrated security threshold and the conventional 0.5 decision threshold, allowing the trade-off between false positives and false negatives to be assessed.

Performance is evaluated using accuracy, precision, recall, F1-score, and the false-positive rate,

$$FPR = \frac{FP}{FP+\mathrm{TN}} \tag{5}$$

Computed both over the complete 2020 evaluation period and separately for each month. Generalization to previously unseen malware families is evaluated using the zero-day subset and further analyzed on a per-family basis. Welch's two-sample t-test [29] is used to determine whether the observed performance differences between model pairs are statistically significant based on their monthly F1-score series:

$$t = \frac{\bar{x}_A - \bar{x}_B}{\sqrt{s_A^2/n + s_B^2/n}} \tag{6}$$

where, each calendar month is treated as an independent observation. Welch's test is suitable because it does not assume equal variances between groups and is therefore appropriate for comparing monthly performance series with different levels of variability.

IV. RESULTS AND ANALYSIS

The study's testing horizon comprises nine monthly evaluation periods spanning January to September 2020. Unless otherwise explicitly stated, all comparative results are presented with reference to the calibrated security threshold that corresponds to a validation false-positive rate of 0.1%. The model-specific diagnostic panels, which display the validation ROC curve, the monthly F1-score, the monthly false-positive rate, and the overall confusion matrix, are presented in Fig. 3 for the CNN and in Fig. 4 for the Random Forest. The analysis proceeds from aggregate performance to temporal behavior across successive months, followed by zero-day generalization, statistical significance analysis, and per-family performance.

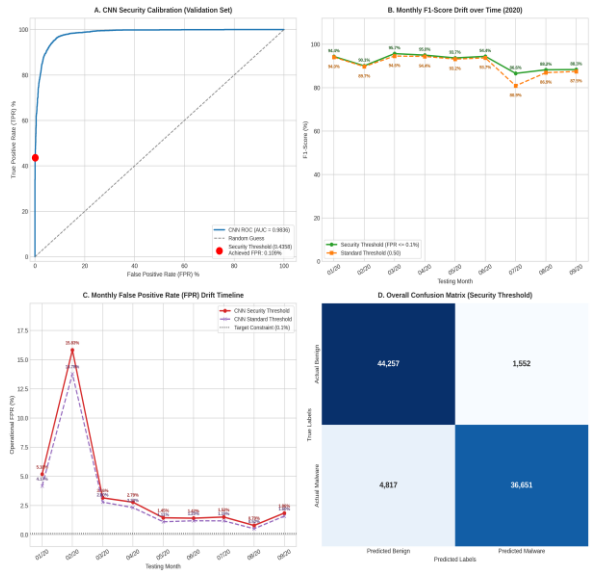

Fig. 3. CNN baseline diagnostics: (a) ROC and security calibration on the validation set, (b) monthly F1 drift, (c) monthly false-positive-rate timeline, and (d) overall confusion matrix at the security threshold.

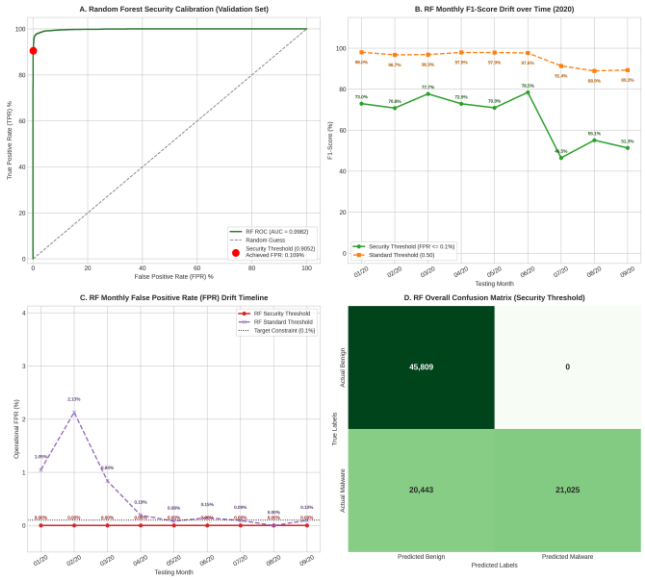

Fig. 4. Random-forest baseline diagnostics: (a) ROC and security calibration, (b) monthly F1 drift, (c) monthly false-positive-rate timeline, and (d) overall confusion matrix at the security threshold.

A. Overall Comparative Performance

Table II summarizes the aggregate performance achieved over the complete 2020 evaluation period and indicates the effect of the proposed attention-based representation under identical temporal evaluation conditions. At its calibrated security threshold, MalBERT-Temporal attains an F1-score of 97.84% while maintaining a false-positive rate of 0.138%. At the conventional 0.5 threshold, the model achieves an F1-score of 98.63%. At the calibrated operating point, the CNN achieves an F1-score of 92.01% but has a substantially higher false-positive rate of 3.39%. The Random Forest has a false-positive rate of 0.000% at its calibrated security threshold; however, this operating point reduces recall to 50.70% and the F1-score to 67.29%, showing that reducing false positives comes at the expense of detecting a considerable proportion of malicious samples. At the conventional 0.5 threshold, the F1-score of the Random Forest increases to 95.21%, although it remains below the performance achieved by MalBERT-Temporal at its stricter calibrated operating point.

TABLE II. OVERALL COMPARATIVE PERFORMANCE ON THE 2020 TEST HORIZON

Model (operating point)	Thr.	FPR%	Acc%	Prec%	Rec%	F1%
MalBERT – Security	0.9795	0.138	97.98	99.84	95.91	97.84
MalBERT – Standard	0.5000	0.362	98.71	99.59	97.69	98.63
CNN – Security	0.4358	3.388	92.70	95.94	88.38	92.01
CNN – Standard	0.5000	2.840	91.73	96.47	85.73	90.78
Random Forest – Security	0.9052	0.000	76.58	100.0	50.70	67.29
Random Forest – Standard	0.5000	0.454	95.64	99.45	91.32	95.21

Fig. 5 represents the model-specific diagnostic panels, which display the validation ROC curve, the monthly F1-score, the monthly false-positive rate, and the overall confusion matrix for MalBERT-Temporal. MalBERT-Temporal achieves an area under the ROC curve (AUC) of 0.9989 (see Fig. 5a). Its confusion matrix at the calibrated security threshold (see Fig. 5d) contains 45,746 true negatives and 63 false positives while correctly identifying 39,772 of the 41,468 malicious samples. These results indicate that the proposed Transformer-based representation maintains a favorable balance between malware detection and false-positive control.

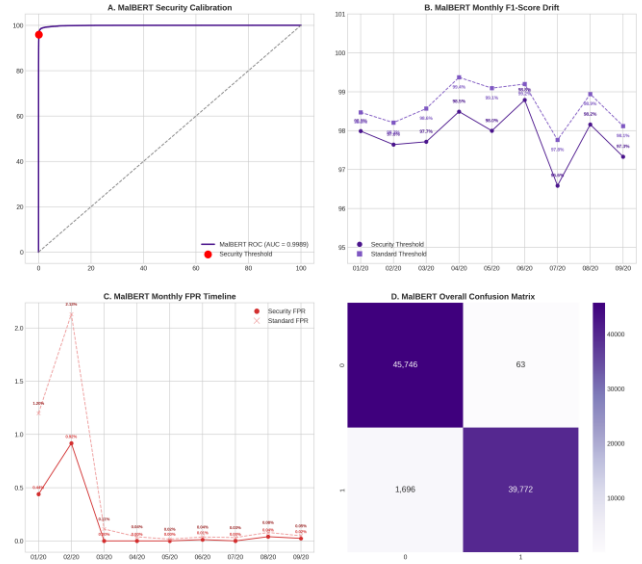

Fig. 5. MalBERT-Temporal diagnostics: (a) ROC curve, (b) monthly F1 drift, (c) monthly false-positive-rate timeline, and (d) overall confusion matrix.

B. Temporal Drift Across the 2020 Horizon

The aggregate results do not reflect the temporal behavior across the evaluation period, which is one of the main elements of the study methodology. Table III provides an analysis of the monthly performance of MalBERT-Temporal at the calibrated security threshold. The F1-score remains within a narrow range, from 96.59% to 98.79%, across all nine months. The false-positive rate is below or equal to 0.1% from March onward, following higher values of 0.44% in January and 0.92% in February. No monotonic degradation is observed as the temporal distance from the training cutoff increases. Performance in August (98.16%) and September (97.33%) remains comparable to that observed in the earlier months, which indicates consistent behavior across the full 2020 horizon. These results point to temporal stability under the proposed evaluation protocol, rather than to performance concentrated within a specific subset of months.

The baseline comparison, presented in Fig. 6, illustrates markedly different behavior. The Random Forest model exhibits a pronounced decline during the second half of the evaluation period, falling from F1-scores in the high 70% range to 46.51% in July, followed by a partial recovery to the low 50% range in August and September. The CNN displays more moderate variation but nevertheless shows a downward trend, reaching the high-80% range in the final months. By contrast, MalBERT-Temporal sustains relatively stable performance throughout the entire period. The monthly F1 and FPR trajectories displayed in

Fig. 5b and Fig. 5c, respectively, confirm that this stability extends to both metrics and is not an artifact of aggregation. Operationally, such temporal stability is relevant in deployment scenarios where retraining is not performed frequently, and models are expected to maintain performance under distribution shift.

TABLE III. MALBERT-TEMPORAL MONTHLY PERFORMANCE IN 2020 (SECURITY THRESHOLD)

Month	#Ben.	#Mal.	FPR%	Acc%	Prec%	Rec%	F1%
01/20	5,921	4,515	0.44	98.28	99.41	96.61	97.99
02/20	3,708	4,264	0.92	97.52	99.18	96.15	97.64
03/20	3,577	4,990	0.00	97.40	100.0	95.53	97.71
04/20	5,201	4,640	0.00	98.60	100.0	97.03	98.49
05/20	6,121	5,449	0.00	98.15	100.0	96.07	98.00
06/20	8,182	4,217	0.01	99.19	99.98	97.63	98.79
07/20	6,387	5,000	0.00	97.10	100.0	93.40	96.59
08/20	2,521	3,816	0.04	97.82	99.97	96.41	98.16
09/20	4,191	4,577	0.02	97.29	99.98	94.82	97.33

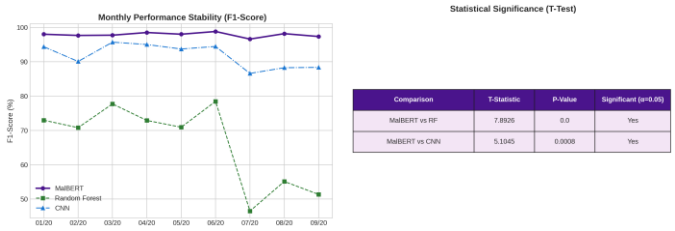

Fig. 6. Monthly F1 stability of the three models across the 2020 horizon (left) and the corresponding Welch t-test results (right).

C. Zero-Day Family Generalization

The zero-day set comprises 1,572 samples belonging to malware families that were not observed during training and therefore provides an evaluation of MalBERT-Temporal's generalization under strict family-level separation. MalBERT-Temporal accurately classifies the majority of these zero-day samples, with only a small number of malware families exhibiting low recall. In several months, at most one zero-day family contributes to misclassifications.

The per-family analysis compares the F1-scores of all malware families present in the test dataset. Substantial improvements are observed for several zero-day-dominated families, such as agentb, aupa, wannacry, waledac, and zenpak, where the F1-score increases from near zero for the Random Forest classifier to perfect or near-perfect classification for MalBERT-Temporal. Improvements over the CNN are also observed for the majority of families. Cases where MalBERT-Temporal underperforms are primarily associated with families containing very few samples, where individual misclassifications have a disproportionate effect on the computed F1-score. Overall, the performance differences are driven by consistent gains on larger and more stable families, with limited and isolated degradations on low-support classes. Several of these families have fewer than ten test samples, so bootstrapped confidence intervals for the per-family zero-day estimates are given in Section IV-K and should be read alongside the point estimates below.

D. Statistical Significance

To assess whether the observed performance differences are statistically significant, Welch's two-sample t-test [29] is applied to the monthly F1-score series for each model pair, as reported in Table IV and Fig. 6. At the security threshold, the improvements in performance for MalBERT-Temporal compared with the Random Forest ($t = 7.89$, $p < 0.001$) and the CNN ($t = 5.10$, $p = 0.0008$) are found to be statistically significant. Similar results are obtained at the conventional 0.5 threshold, where the performance of MalBERT-Temporal is significantly higher than that of the Random Forest ($t = 2.80$, $p = 0.022$) and the CNN ($t = 5.13$, $p = 0.0008$). All comparisons satisfy the significance level of $\alpha = 0.05$, which indicates that the observed differences in performance are unlikely to have arisen from random variation across the monthly evaluation windows.

TABLE IV. WELCH'S T-TEST ON MONTHLY F1 SCORES

Comparison	t-stat	p-value	Sig. (α=0.05)
MalBERT vs RF (Security)	7.8926	< 0.001	Yes
MalBERT vs CNN (Security)	5.1045	0.0008	Yes
MalBERT vs RF (0.50)	2.8011	0.0223	Yes
MalBERT vs CNN (0.50)	5.1272	0.0008	Yes

E. Per-Family Comparative Detection Analysis

Table V presents a representative subset of twenty malware families chosen from the complete per-family evaluation, showing how the overall results presented in Table II are distributed among the individual classes. Across these malware families, the proposed model either matches or exceeds the Random Forest baseline at both operating points and outperforms the CNN in the majority of cases. Specifically, the proposed model achieves a mean security-threshold F1-score of 97.81%, compared with 96.90% for the CNN and 67.22% for the Random Forest.

These differences are largest in comparison with the Random Forest baseline, especially within the agen and agentb family categories, where the Random Forest has an F1-score equal to or near zero, whereas MalBERT-Temporal successfully detects all instances. However, the differences from the CNN model are relatively smaller, with a mean improvement of approximately +0.9 percentage points. This reflects closer parity between the two models for well-represented families. Moreover, decreased performance for some selected families, such as alinaos and aitinject, is associated with limited sample sizes in the test partition, where individual misclassifications have a disproportionate effect on the F1-score. Section IV-K quantifies this effect with confidence intervals, which show that the negative differences reported for these low-support families cannot be statistically distinguished from zero.

TABLE V. COMPARATIVE PER-FAMILY F1-SCORE (%) ACROSS MALBERT-TEMPORAL, CNN, AND RANDOM FOREST AT SECURITY AND STANDARD (0.5) THRESHOLDS FOR TWENTY REPRESENTATIVE MALWARE FAMILIES

Family	MalBERT (Sec)	MalBERT (0.5)	CNN (Sec)	CNN (0.5)	RF (Sec)	RF (0.5)	Imp. vs RF (Sec)	Imp. vs CNN (Sec)
Unknown	100.00	100.00	100.00	100.00	66.67	100.00	33.33	0.00
adload	100.00	100.00	100.00	100.00	100.00	100.00	0.00	0.00

agqr	100.00	100.00	100.00	100.00	57.14	100.00	42.86	0.00
ainslot	96.97	96.97	90.32	90.32	52.17	90.32	44.80	6.65
aitinject	91.89	97.44	97.44	97.44	40.00	94.74	51.89	-5.54
alinaos	88.89	88.89	100.00	100.00	57.14	88.89	31.75	-11.11
almanahe	100.00	100.00	100.00	100.00	66.67	100.00	33.33	0.00
alureon	100.00	100.00	100.00	100.00	100.00	100.00	0.00	0.00
androm	100.00	100.00	94.74	88.89	66.67	94.74	33.33	5.26
androme	100.00	100.00	100.00	100.00	100.00	100.00	0.00	0.00
andromeda	100.00	100.00	100.00	100.00	100.00	100.00	0.00	0.00
asacky	92.31	92.31	100.00	92.31	72.73	92.31	19.58	-7.69

The comparison of the security and standard (0.5) thresholds also highlights that MalBERT-Temporal exhibits relatively stable performance across operating points, while the Random Forest model is more sensitive to threshold selection, especially under strict false-positive constraints. Generally, the family-level results show that the observed aggregate improvements are broadly distributed across various malware families and are not concentrated in only a limited number of them.

F. Explicit Definition of the Feature-Token Groups

Table VI gives the full specification of the tokenization stage. The 2,381 ordered features F1-F2381 are split into 16 contiguous groups using a boundary set b(i), which is the integer part of $i \times 2381/16$ for $i = 0, 1, ..., 16$. Group Gi then covers features F(b(i−1) + 1) to F(b(i)). Since 2381/16 = 148.8125, 2,381 is not an integer multiple of 16, and the groups cannot all have the same width. The extra dimensions are spread along the sequence rather than collected into one over-long token: G1, G6, and G11 hold 148 features each, and the other thirteen groups hold 149 each, which gives $3 \times 148 + 13 \times 149 = 2{,}381$. Every feature belongs to one group only, none appears twice, and nothing is padded or truncated.

Groups of different widths are acceptable because each group has its own linear projection layer whose input size is set to the width of that group. The sixteen projections therefore map 148- or 149-dimensional inputs to the common model dimension of 256. No tuning was applied to the boundaries, and they do not come from any feature-selection, clustering, or attribution procedure. They simply follow the native ordering of the published BODMAS feature extractor, in which related descriptors already occupy contiguous index blocks. The tokenization thus inherits whatever grouping that ordering provides and adds no further prior knowledge. Section IV-H measures separately how sensitive the results are to the number of groups.

TABLE VI. EXPLICIT DEFINITION OF THE SIXTEEN FEATURE-TOKEN GROUPS

Group	First	Last	Dim.	Group	First	Last	Dim.
G1	F1	F148	148	G9	F1191	F1339	149
G2	F149	F297	149	G10	F1340	F1488	149
G3	F298	F446	149	G11	F1489	F1636	148
G4	F447	F595	149	G12	F1637	F1785	149

G8	F1042	F1190	149	G16	F2233	F2381	149

G. Component-Wise Ablation Study

The architecture in Section III-B combines several elements: grouped feature tokens, independent per-group projections, positional embeddings, a CLS token, a four-layer Transformer

encoder, three-way pooling, and nonlinear activations. The aggregate results in Table II do not show which of these elements produces the observed improvement. A component-wise ablation was therefore run, removing or simplifying one element per configuration while keeping everything else fixed: the same pre-2020 training partition, the same validation partition, the same signed-logarithmic and robust-scaling pipeline, the same optimizer and learning-rate schedule, the same 2020 test set, and the same calibration rule, which selects the threshold whose validation false-positive rate is closest to 0.1%. The results are given in Table VII and Fig. 7.

TABLE VII. COMPONENT-WISE ABLATION OF MALBERT-TEMPORAL ON THE 2020 TEST HORIZON

Variant	F1%	ΔF1	FPR%	Acc%	Par. (M)	Min
− Positional embeddings	98.19	+0.02	0.207	98.31	4.00	1.14
Full model	98.17	—	0.279	98.29	4.01	1.23
− Nonlinearity (GELU)	97.95	−0.22	0.266	98.08	4.01	1.13
Mean pooling only	97.93	−0.24	0.124	98.07	3.87	1.13
− CLS token	97.76	−0.41	0.203	97.91	3.87	0.96
Single encoder layer	97.70	−0.47	0.074	97.86	1.64	0.41
− Tokenization (flat)	96.32	−1.85	0.085	96.62	2.03	0.29
− Self-attention	95.44	−2.73	0.090	95.85	1.37	0.37

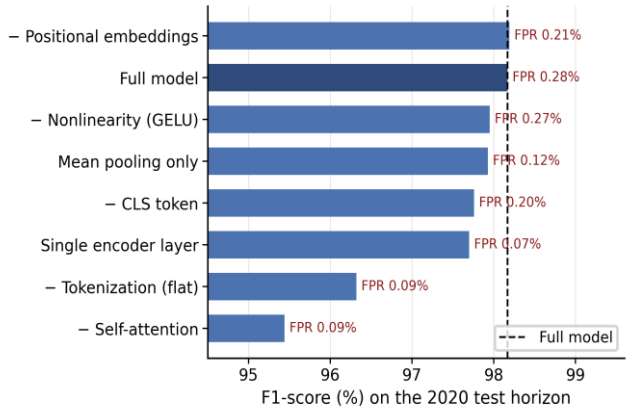

Fig. 7. Component-wise ablation of MalBERT-temporal.

Eight configurations were tested. The full model keeps all components. The "− tokenization" variant drops the grouping completely and feeds the 2,381-dimensional vector to a feed-forward network of similar width; this is the flat-vector control. The "− self-attention" variant keeps the tokenization, the per-group projections, the CLS token, the positional embeddings, and the pooling stage, and replaces only the Transformer encoder with a position-wise feed-forward block applied to each token separately, which separates the effect of self-attention from the effect of the surrounding components. The five remaining variants each make one change: the positional embeddings are removed; the CLS token is removed, and pooling uses the token mean only; mean pooling alone replaces the CLS/mean/max concatenation; identity mappings replace the GELU activations; and the encoder is reduced from four layers to one.

The two variants that change the tokenized-attention mechanism have by far the largest effect. Removing self-attention costs 2.73 F1 points, 95.44% compared with 98.17%, even though all auxiliary components are kept, and removing the tokenization costs 1.85 points, giving 96.32%. Each auxiliary component accounts for at most 0.47 points: a single-layer encoder costs 0.47 points, removing the CLS token costs 0.41 points, mean-only pooling costs 0.24 points, and removing the nonlinearity costs 0.22 points. Removing the positional embeddings changes the F1-score by +0.02 points, which is within run-to-run variation and shows that the order of the feature groups carries little usable positional information. The improvement reported in this study therefore comes from grouped tokenization combined with self-attention over those tokens, and not from the sum of the additional components.

H. Group-Granularity Ablation

The number of feature-token groups G is the design parameter that separates MalBERT-Temporal from a flat-vector Transformer, so the choice G = 16 needs empirical support. Four settings, $G \in \{4, 8, 16, 32\}$, were trained with the protocol used for the component ablation. The group boundaries were produced by the equal-width rule of Section IV-F, and all other hyperparameters were left unchanged. Table VIII repeats the untokenized flat-vector control from Table VII as a reference point, and Fig. 8 plots F1-score against training cost.

TABLE VIII. GROUP-GRANULARITY ABLATION: EFFECT OF THE NUMBER OF FEATURE-TOKEN GROUPS

Tokenization	F1%	FPR%	Acc%	Par. (M)	Min
Flat vector (none)	96.32	0.085	96.62	2.03	0.29
G = 4	97.92	0.124	98.06	3.99	0.48
G = 8	98.24	0.114	98.35	4.00	0.68
G = 16 (adopted)	98.17	0.279	98.29	4.01	1.10
G = 32	98.62	0.262	98.70	4.02	1.99

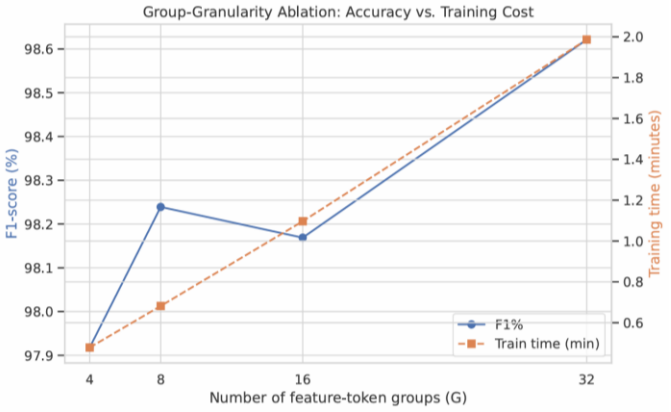

Fig. 8. Group-granularity ablation. F1-score (left axis) and training time (right axis) as a function of the number of feature-token groups G.

All tokenized configurations outperform the flat vector by a large margin. The weakest setting, G = 4, gives 97.92% against

96.32% for the untokenized control, a gap of 1.60 points, and all other settings perform better. The differences between the tokenized settings are small: G = 8 gives 98.24%, G = 16 gives 98.17%, and G = 32 gives 98.62%, a range of 0.45 points. Training time increases monotonically from 0.48 min at G = 4 to 1.99 min at G = 32, because both the number of independent projection layers and the length of the attention sequence increase with G. The gain from finer tokenization therefore saturates. The step from a flat vector to G = 4 already recovers 1.60 of the 2.30 points that separate the flat control from the best configuration, and the remaining 0.70 points require an eightfold increase in G and a fourfold increase in training time. G = 32 gives the highest F1-score in this single-seed comparison, and G = 16 is not claimed to be optimal: the differences between $G \in \{8, 16, 32\}$ are of the same size as the variation between nominally equivalent variants in Table VII. G = 16 is kept for three reasons. It sits in the flat part of the accuracy-cost curve, it keeps the token width close to the size of the contiguous descriptor blocks in the BODMAS feature layout, and it is the setting used for every other result in this study. A deployment that prioritizes accuracy could use G = 32 at about 1.8 times the training cost, and one that prioritizes cost could use G = 8 at about 0.6 times.

I. Random Versus Chronological Splitting

RQ1 asks how much performance loss chronological evaluation reveals that random splitting hides. Answering it requires a control in which only the rule for assigning samples to partitions changes. The control used here keeps the same architecture and hyperparameters, the same signed-logarithmic and robust-scaling pipeline with the scaler refitted on the new training partition, the same training budget, the same partition sizes of 34,751 training, 8,688 validation, and 87,277 test samples, the same calibration rule at a 0.1% validation false-positive-rate budget, and the same metrics. The only change is that the partitions are drawn by stratified random sampling over the full 2007-2020 corpus instead of by date, so 2020 samples can appear in training and pre-2020 samples can appear in the test set.

TABLE IX. RQ1 CONTROL EXPERIMENT: THE SAME MODEL UNDER RANDOM AND CHRONOLOGICAL SPLITTING

Protocol and operating point	Thr.	FPR%	Acc%	Prec%	Rec%	F1%
Random – Security	0.9740	0.116	99.01	99.85	97.89	98.86
Random – Standard	0.5000	0.251	99.41	99.68	98.98	99.33
Chronological – Security	0.9795	0.138	97.98	99.84	95.91	97.84
Chronological – Standard	0.5000	0.362	98.71	99.59	97.69	98.63
Inflation (Security)	—	−0.022	+1.03	+0.01	+1.98	+1.02

The two protocols are compared in Table IX, and Fig. 9 presents the same comparison as a figure. At the security operating point, the random protocol gives an F1-score of 98.86% against 97.84% for the chronological protocol, an inflation of 1.02 points. Recall increases from 95.91% to 97.89%, an inflation of 1.98 points, and precision is essentially unchanged. Measured as error instead of score, the random protocol removes 47% of the residual error at the security threshold, 1.14 points against 2.16 points. At the conventional 0.5 threshold, the inflation is smaller, 0.70 F1 points, but has the same sign.

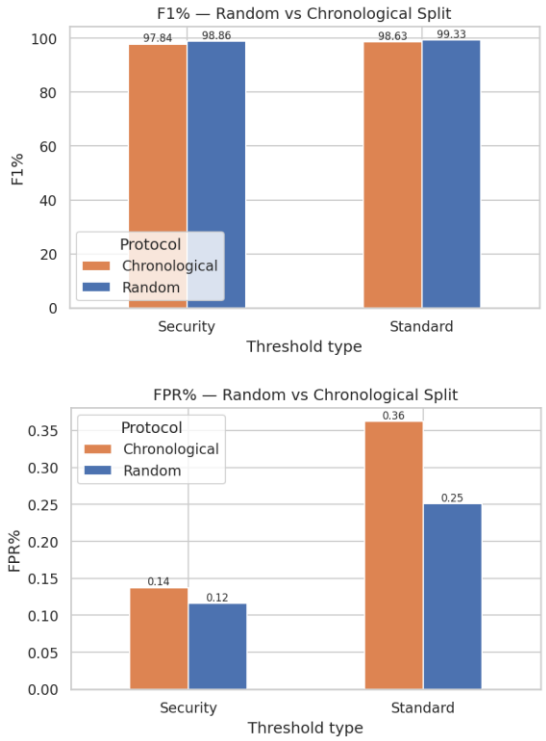

Fig. 9. F1-score and false-positive rate for the same MalBERT-Temporal under random-split vs. chronological-split protocols.

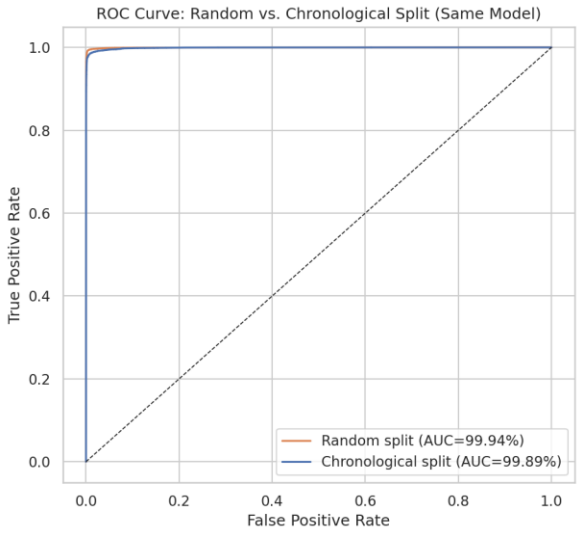

Fig. 10. ROC curves for MalBERT-Temporal under the random and the chronological protocols.

The threshold-free comparison behaves differently. Fig. 10 shows the two ROC curves, and their areas differ by only 0.044 points: 99.939% for random splitting and 99.895% for chronological splitting. Temporal leakage therefore has almost no effect on the ranking quality of the score function, but it does have a measurable effect on the calibrated operating point, which lies far out in the tail of the benign score distribution. This

matters for evaluation practice. Reporting only the area under the ROC curve would have hidden almost all of the effect that RQ1 asks about, since the effect appears only in metrics computed at a fixed low-false-positive operating point.

J. Retraining-Schedule Analysis

The claim that a temporally robust representation reduces the need for frequent retraining cannot be tested on a single fixed model; it requires a comparison of retraining schedules. Three schedules were compared over the nine months of the 2020 horizon. The static schedule is the one used elsewhere in this study: the pre-2020 model is frozen and scores all nine months with no update. The quarterly schedule fine-tunes the model at a learning rate of 1×10^{-4} at the end of March, June, and September, using the labeled samples of the quarter that has just ended. The monthly schedule applies the same fine-tuning step at the end of each month. In every schedule, a month is scored before any update that uses data from that month, so chronological order is preserved, and no prediction uses future information. The schedules do assume that ground-truth labels for a period are available as soon as that period ends. This is optimistic compared with operational labeling latency, so the comparison gives an upper bound on what retraining can achieve.

TABLE X. MONTHLY F1-SCORE (%) UNDER THREE RETRAINING SCHEDULES

Test month	Static	Quarterly	Monthly
01/20	97.99	97.99	97.99
02/20	97.64	97.64	98.60
03/20	97.71	97.71	98.13
04/20	98.49	99.03	99.45
05/20	98.00	98.43	97.75
06/20	98.79	99.09	99.54
07/20	96.59	95.77	94.03
08/20	98.16	95.99	99.50
09/20	97.33	92.91	99.50
Mean	97.86	97.18	98.28

Monthly F1-scores are given in Table X and Fig. 11. The static model averages 97.86% over the nine months, monthly retraining averages 98.28%, and quarterly retraining averages 97.18%. Monthly retraining therefore gains 0.42 F1 points on average over no retraining at all, and quarterly retraining is 0.68 points worse than no retraining.

The month-by-month results explain these averages. Monthly fine-tuning gives the largest gains in the last two months, raising August from 98.16% to 99.50% and September from 97.33% to 99.50%, which is where the drift literature expects a static model to be weakest. The gain is not uniform: in July the F1-score falls from 96.59% to 94.03%, because the update at the end of June adapts the model to a month whose composition differs from that of July. Quarterly fine-tuning is the least stable of the three schedules. After the update at the end of June, its scores fall to 95.77% in July, 95.99% in August, and 92.91% in September, which is consistent with over-adaptation to a narrow and recent labeled window at the expense of the wider pre-2020 evidence.

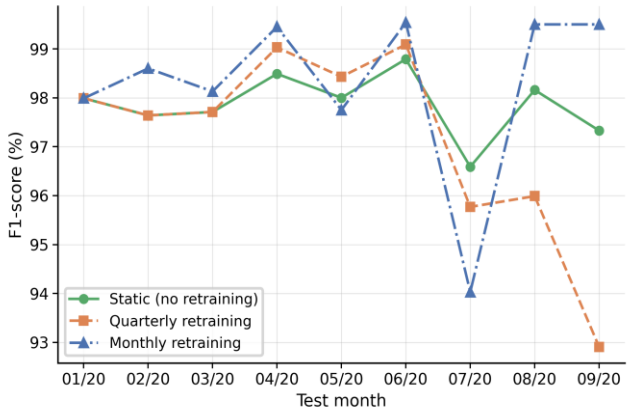

Fig. 11. Monthly F1-score of MalBERT-Temporal under three retraining schedules across the 2020 evaluation horizon.

Two conclusions follow, and the claim in the manuscript is narrowed accordingly. Over a nine-month horizon, the static model stays within 0.42 F1 points of the best schedule tested, so frequent retraining is not needed to maintain performance in this window. Quarterly fine-tuning is worse than no retraining at all, which indicates that periodic updates should be validated on a held-out window rather than adopted without checking.

K. Statistical Reliability of the Zero-Day Per-Family Estimates

The zero-day subset contains 1,572 of the 87,277 test samples, or 1.80% of the test horizon, and it is very unevenly distributed across families. One family, mintluks, provides 670 of these samples, and no other zero-day family provides more than 57. On supports of this size, per-family F1-scores are dominated by single misclassifications, so a point estimate alone overstates how precise the measurement is. A percentile bootstrap was applied to each family to quantify this. The family's test samples were resampled with replacement 1,000 times; the F1-score was recomputed on each resample at the fixed calibrated threshold of 0.9795, and the 2.5th and 97.5th percentiles of the resulting distribution were used as a 95% confidence interval. The threshold is held fixed throughout, so the intervals measure sampling uncertainty in the test set and not uncertainty in the calibration.

Table XI gives the intervals for the largest zero-day families and for the singleton families, and Fig. 12 covers all families with non-trivial uncertainty in their estimates. Interval width follows support closely. For mintluks (n = 670), the interval is 0.55 points wide, so the reported F1-score of 99.76% is reliable. For families with about forty to sixty samples, the intervals are 2.9 to 6.3 points wide, which still supports the qualitative conclusion that these families are detected well. Below about ten samples, the intervals are uninformative: families with two to eight samples routinely span 30 to 60 points, and several of them, including hynamer and foreign with three samples each, run from 0% to 100%. Families with a single sample give degenerate intervals of [100, 100] or [0, 0], which carry no statistical information at all.

TABLE XI. BOOTSTRAPPED 95% CONFIDENCE INTERVALS FOR PER-FAMILY ZERO-DAY F1-SCORES

Zero-day family	n	F1%	95% CI	Width
mintluks	670	99.76	[99.45, 100.00]	0.55
cosmicduke	57	99.10	[97.14, 100.00]	2.86
sillywnse	47	98.88	[96.29, 100.00]	3.71
qakbot	42	97.56	[93.67, 100.00]	6.33
kwbot	41	98.73	[96.00, 100.00]	4.00
Singletons (wannacry, worgtop, zonidel, …)	1	100.00	[100.00, 100.00]	0.00

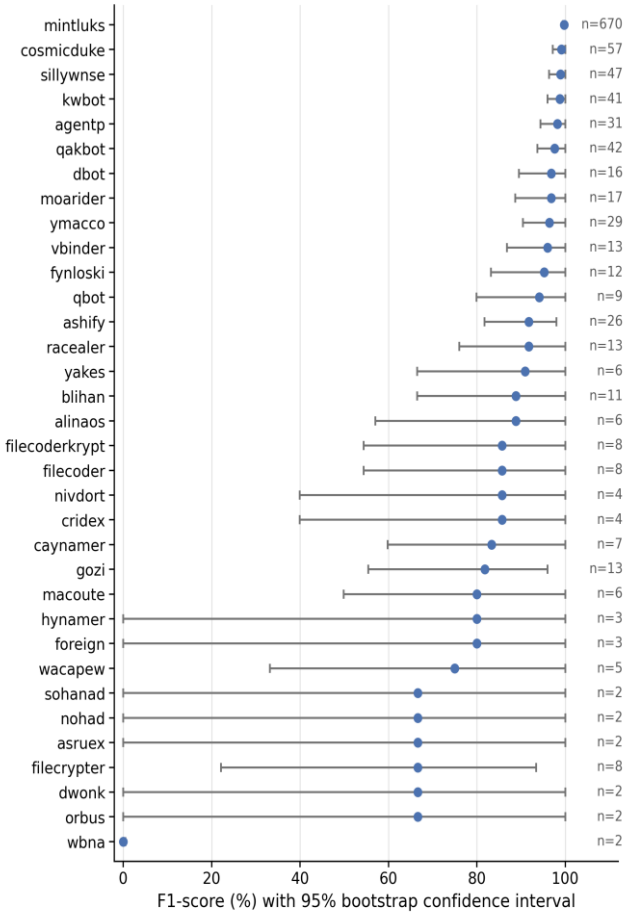

Fig. 12. Bootstrapped 95% CI for zero-day per-family F1-score.

This affects how Table V should be read. The families in that table where MalBERT-Temporal is reported to underperform the CNN all have small test supports.

For example, alinaos is a zero-day family with six test samples and a 95% interval that extends below 60 points (Fig. 12), so the difference of −11.11 points reported for it in Table V cannot be distinguished from zero. The aggregate zero-day conclusion is not affected, because it is dominated by the well-supported families, but per-family entries with small n should be read as indicative only. Future evaluations of zero-day generalization would benefit from a larger zero-day sample, or from reporting intervals together with point estimates as standard practice.

L. Feature-Level Drift and the Early-2020 False-Positive Excess

Table III shows that the realized false-positive rate exceeds its 0.1% validation budget in the first two months of the evaluation horizon, at 0.44% in January and 0.92% in February, and stays at or below 0.04% from March onwards. The absolute counts show the concentration even more clearly than the rates do: of the 63 false positives produced over the whole 2020 horizon, 26 occur in January and 34 in February, so 95% of all false alarms fall in the first two months and the remaining seven months produce three in total. The deviation is confined to a specific period and does not grow with temporal distance, so it is more likely a property of the early-2020 sample population than a progressive failure of the model. This section tests that explanation directly.

All 2,381 features were tested for a change between the pre-2020 training partition and the January and February test samples. Two measures were used: a two-sample Kolmogorov-Smirnov test, for which the training side was subsampled to 2,000 observations to keep the computation tractable, and a standardized mean shift expressed in units of the training standard deviation. The five features with the strongest shift in each month are listed in Table XII, and Fig. 13 shows the fifteen strongest.

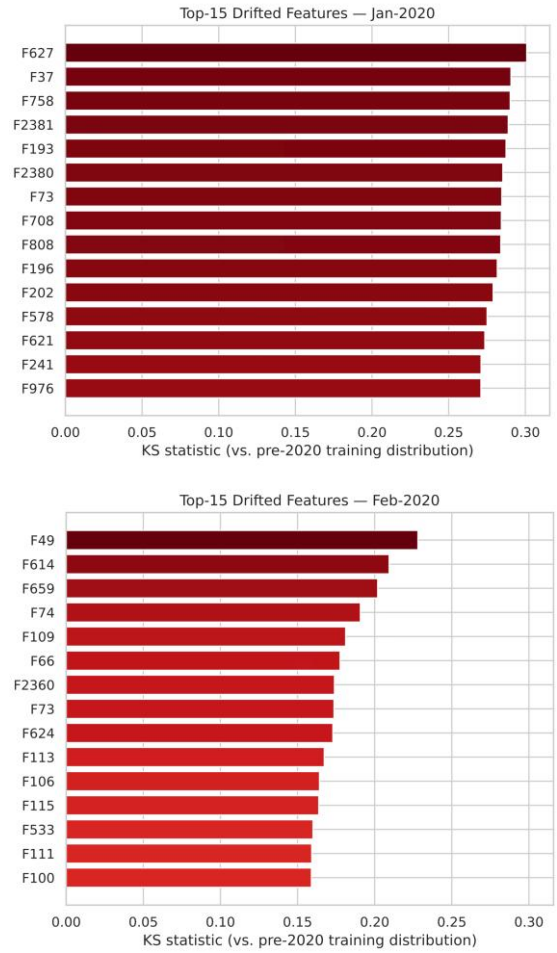

Fig. 13. Feature-level distributional drift between the pre-2020 training partition and the January and February 2020 test months.

TABLE XII. FIVE MOST STRONGLY DRIFTED FEATURES IN JANUARY AND FEBRUARY 2020 RELATIVE TO THE PRE-2020 TRAINING DISTRIBUTION

Period	Feature	KS	p-value	Mean shift
Jan-2020	F627	0.3009	2.9×10^{-135}	−0.124
Jan-2020	F37	0.2906	5.0×10^{-126}	−0.220
Jan-2020	F758	0.2902	1.3×10^{-125}	−0.473
Jan-2020	F2381	0.2889	1.8×10^{-124}	−0.000
Jan-2020	F193	0.2874	3.3×10^{-123}	−0.325
Feb-2020	F49	0.2281	1.9×10^{-73}	−0.234
Feb-2020	F614	0.2094	7.0×10^{-62}	+0.015
Feb-2020	F659	0.2020	1.4×10^{-57}	+0.346
Feb-2020	F74	0.1907	2.3×10^{-51}	−0.245
Feb-2020	F109	0.1812	2.4×10^{-46}	−0.237

Both months differ from the training distribution far beyond sampling variation. In January, the largest KS statistic is 0.301, for F627, and the fifteen most affected features lie between 0.271 and 0.301, with p-values below 10^{-108}. In February, the largest is 0.228 for F49, with the top fifteen between 0.159 and 0.228 and p-values below 10^{-35}. The affected features are not randomly scattered. They cluster in three regions: the low-index header and section-property block (F37, F49, F66, F73, F74, F100-F115, F193-F241), the mid-range import and string block (F533-F808, F976), and the tail of the byte-entropy histogram (F2360, F2380, F2381). The largest standardized shifts in these regions are +1.06 for F976, −0.47 for F758, and −0.46 for F202.

The fixed calibration is what turns this shift into a false-positive excess. The operating threshold of 0.9795 is the 0.1% false-positive quantile of the pre-2020 validation score distribution, so it lies far into the upper tail of the benign score distribution, where the density is low and the cumulative probability changes quickly for small displacements. A shift that moves even a small fraction of benign scores upwards therefore causes a disproportionate change in the realized false-positive rate while leaving accuracy, precision, and recall almost unchanged. This is the pattern seen in Table III: in February the false-positive rate is 9.2 times its budget, but the F1-score for that month is 97.64%, which is inside the band observed across the whole horizon. February also has the third-smallest benign population of the horizon, 3,708 samples, so the same number of tail crossings produces a higher rate than it would in a larger month.

The data-side explanation is also supported by independent evidence. All three systems evaluated in this study have their highest false-positive rate of the whole horizon in February 2020 and their second-highest in January: MalBERT-Temporal at 0.92% and 0.44% (Table III), the CNN baseline at 15.83% and 5.18% (Fig. 3c), the Random Forest baseline at 2.13% and 1.05% at its standard threshold (Fig. 4c). These systems cover the Transformer, convolutional and tree-ensemble families, and they share only the preprocessing pipeline and the calibration rule. A false-positive peak that appears in all of them in the same month, and in no other month, is therefore explained much more consistently by the benign population of January and February 2020 than by any single architecture.

For deployment, this limits the concern rather than removing it. The budget is met in seven of the nine months with no intervention, and the two months that exceed it are the two closest to the training cut-off, so the excess does not grow with temporal distance and does not indicate a progressive drift failure. It does show that a threshold calibrated once on historical data cannot be assumed to keep its nominal false-positive rate on incoming data. A practical deployment could recalibrate the threshold periodically on a small recent sample of confirmed benign files, which requires no retraining of the model, or monitor the KS statistics of the drift-prone features listed in Table XII and trigger recalibration when they exceed a preset bound. Neither option is evaluated in this study; both are given as recommendations, not as results.

V. DISCUSSION

These results are closely related to the concept drift problem that prompted the creation of the BODMAS dataset. Yang et al. [6] introduced BODMAS as a temporal stress-testing benchmark in which gradient-boosted decision trees and deep neural networks were trained on earlier temporal partitions and evaluated on subsequent time periods, revealing a decrease in monthly F1-score as the evaluation progressed. In their analysis, the greatest performance deterioration occurred in August and September 2020, when false-negative rates reached up to 43% for previously unseen malware families. These findings highlighted the sensitivity of static classifiers to temporal distribution shift and the need for periodic retraining.

In the current research, the same evaluation horizon is examined under identical chronological constraints, with a particular focus on the impact of architectural choices on temporal robustness. The results suggest measurable differences among the models under the same temporal evaluation setting.

Table XIII compares the performance of MalBERT-Temporal with the binary classifiers reported in the BODMAS paper over the overlapping evaluation period from January to September 2020 under comparable low-false-positive operating conditions.

TABLE XIII. MONTHLY F1 (%) VS. BODMAS BINARY CLASSIFIERS OF YANG ET AL. [6], 2020 TEST MONTHS (FPR ≈ 0.1%)

Test month	Ember-GBDT	SOREL-DNN	SOREL-GBDT	MalBERT
01/20	93.69	95.41	96.31	97.99
02/20	93.43	93.23	95.73	97.64
03/20	95.75	95.98	98.14	97.71
04/20	96.98	97.30	98.90	98.49
05/20	97.50	96.03	98.64	98.00
06/20	97.76	96.74	98.94	98.79
07/20	96.38	93.86	98.68	96.59
08/20	92.93	85.85	95.99	98.16
09/20	92.14	82.88	95.70	97.33
Mean	95.17	93.03	97.45	97.86

There are two key findings. First, MalBERT-Temporal achieves a mean monthly F1-score of 97.86%, which is slightly higher than that of the best-performing classifier in the BODMAS paper, SOREL-GBDT (97.45%), despite being trained on a substantially smaller dataset (43,439 pre-2020 samples compared with approximately twenty million samples used in SOREL-GBDT). This indicates that improved representation learning may partially offset differences in training data scale in this setting.

Second, differences in temporal behavior are observed in the later evaluation months. The performance of the classifiers in the original BODMAS paper decreases in August and September 2020, consistent with the drift behavior discussed in [6]. Specifically, SOREL-GBDT decreases to 95.99% and 95.70%, SOREL-DNN to 85.85% and 82.88%, and Ember-GBDT to 92.93% and 92.14%, respectively. In contrast, MalBERT-Temporal displays relatively stable performance, achieving 98.16% and 97.33% during the same period.

Three factors may contribute to the observed differences: representational capacity, evaluation protocol, and calibration strategy. From a representational perspective, MalBERT-Temporal models structured PE features as grouped token embeddings and applies self-attention to capture interactions between non-adjacent feature groups. This design allows the model to learn interactions among heterogeneous feature groups, such as section-level statistics and import-table characteristics. In contrast, the Random Forest baseline relies on axis-aligned decision boundaries over individual features, while the CNN baseline primarily captures local feature interactions constrained by its receptive field. The ablation results in Section IV-G provide direct evidence for this representational argument instead of simply asserting it. Removing self-attention while keeping the tokenization, the projections, the CLS token, and the pooling stage lowers the F1-score by 2.73 points, and removing the tokenization lowers it by 1.85 points, while no other component of the architecture is worth more than 0.47 points. The advantage over the baselines therefore comes from the mechanism the paper attributes it to, and not from the additional components that surround that mechanism.

All models were evaluated under a strict chronological partition, in which training was confined to pre-2020 samples, and testing was conducted on temporally subsequent data. This procedure eliminates temporal leakage and provides an evaluation setting that is aligned with deployment conditions.

Furthermore, all models were assessed by means of a unified thresholding strategy based on a fixed validation false-positive-rate budget of 0.1%. This approach ensures consistent operating conditions across the architectures and reflects the practical constraints of malware detection applications, in which false positives must be strictly controlled. The calibration strategy also has a limitation that the monthly results make visible. The threshold is fixed once on pre-2020 data, so the realized false-positive rate can exceed its budget whenever the incoming benign population shifts, and this is what happens in January and February 2020. Section IV-L shows three things about these two months: their feature distributions are the ones that differ most from the training partition, they contain 60 of the 63 false positives recorded across the whole horizon, and three structurally unrelated models calibrated by the same rule all exceed the budget in the same two months. The deployability claim made here should therefore be understood as conditional on periodic recalibration of the operating threshold, an operation that needs only a small sample of recent confirmed benign files and no retraining of the model.

Further limitations should also be noted. The evaluation spans a nine-month horizon, and Section IV-J shows that quarterly fine-tuning can perform worse than no retraining, so update schedules should be validated on a held-out window before adoption rather than applied on a fixed calendar. The method also relies exclusively on static PE features, so packed or obfuscated binaries attenuate the structural signal on which the tokenized representation depends; combining it with lightweight dynamic or byte-level features is the natural mitigation. Per-family zero-day estimates below roughly ten samples likewise carry confidence intervals too wide to support conclusions, as quantified in Section IV-K, which a larger zero-day sample or the routine reporting of intervals would remedy.

Tables II and IV present the results obtained under identical preprocessing, temporal partitioning, and evaluation procedures. Under these controlled conditions, MalBERT-Temporal achieves higher overall performance and statistically significant improvements in monthly F1-score over both baselines.

VI. Conclusion

This study has investigated whether the representation of structured PE features as a token sequence within a Transformer network is capable of improving zero-day Windows malware detection, relative to conventional baseline methods, under a temporally consistent evaluation protocol. Using a strict chronological split of the BODMAS dataset, where the training data include samples prior to 2020 and evaluation is conducted exclusively on 2020 data, MalBERT-Temporal achieved an F1-score of 97.84% with a false-positive rate of 0.138%. The model maintained relatively stable performance over the nine-month testing period, with its monthly F1-scores varying within a narrow range, including periods when the baseline models exhibited noticeable degradation. Furthermore, MalBERT-Temporal outperformed a 1-D CNN and a Random Forest model trained and tested under the same conditions, with statistical significance confirmed using Welch's t-test, and achieved performance comparable to or exceeding that of strong baselines reported in the BODMAS paper, despite being trained under a more constrained data regime.

The key findings of this study are as follows. First, representing structured PE features as a token sequence and applying self-attention enables the modeling of long-range feature interactions, which contributes to improved generalization to previously unseen malware families. Second, Transformer-based representations demonstrate greater robustness under temporal distribution shift. Across the nine-month horizon examined, a model that is never retrained stays within 0.42 F1 points of the best of the three retraining schedules tested, so performance in this window can be maintained without frequent retraining. The quarterly schedule nevertheless shows that periodic fine-tuning can also reduce performance, and no claim is made about horizons longer than nine months. These findings address Research Question 1 (RQ1) by showing

that strict chronological evaluation reveals performance degradation that is not observable under random splitting, while also indicating that MalBERT-Temporal maintains comparatively stable performance under such conditions. A matched control experiment in which only the partition rule changes quantifies degradation of 1.02 F1 points and 1.98 recall points at the calibrated security threshold, whereas the area under the ROC curve differs by only 0.044 points. The effect is thus visible at a fixed low-false-positive operating point and almost invisible in threshold-free metrics. They also address Research Question 2 (RQ2) by demonstrating consistent improvements over the CNN and Random Forest baselines under identical temporal constraints. Therefore, the novelty of this study does not lie in the development of a new learning paradigm but in a representation-level redesign of structured PE analysis that improves robustness under temporal drift.

Potential directions for future research include extending the study by evaluating longer temporal horizons beyond 2020, performing multi-seed experiments to quantify variance, integrating static PE features with lightweight dynamic or byte-level representations, and analyzing the attention patterns in greater detail to improve interpretability. Further evaluation of the method's robustness under adversarial evasion scenarios would also strengthen the practical applicability of the approach. Overall, the findings provide evidence that attention-based modeling of structured PE features is a promising direction for temporally robust malware detection.

Next-Generation Explainable Sensor-Fusion-Based Artificial Intelligence Framework for In-Home Diabetic Foot Ulcer Risk Prediction

Jayashree J, Vijayashree J*, Vijayarajan V, Saravanan S
School of Computer Science and Engineering, Vellore Institute of Technology, VIT, Vellore, 632014, India

***Abstract*—Diabetic Foot Ulcers (DFUs) are one of the most serious but preventable complications of diabetes mellitus that often develop without clinical signs until the late stages. This means that neuropathic and vascular abnormalities should be diagnosed in time to be effectively prevented. This study presents the design and development of a home-based smart monitoring system that can be used to identify DFU risk in its early stage by non-invasive sensor-fusion-based monitoring. A baseline version of the system with a plantar pressure sensor and a vibration-based tactile sensitivity evaluation was developed to detect early neuropathic changes in foot health with the use of a composite learning model. Building on this baseline, the proposed framework extends the sensor array with force-sensing resistors (FSRs) to map abnormal plantar pressure regions, vibration motors to evaluate tactile sensitivity, DS18B20 temperature sensors to evaluate dermal thermal variation, and a pulse sensor to evaluate the plantar blood flow. SHAP (SHapley Additive exPlanations) guided RFE (Recursive Feature Elimination) is used to process sensor signals to identify physiologically salient features. One of these is a hybrid Multi-Layer Perceptron-Bidirectional Long Short-Term Memory (MLP-BiLSTM) model with a fuzzy inference layer that then categorizes DFU risk into Low, Medium, and High. Explainable Artificial Intelligence (XAI) methods, such as SHAP and LIME (Local Interpretable Model-agnostic Explanations), are incorporated to increase clinical understandability. Experimental results indicate that the proposed model improves both predictive performance and explainability relative to the baseline methods evaluated, supporting consistent, clinician-interpretable home-based screening of diabetic foot risk within the studied population; broader external validation across additional sites remains necessary before wider clinical generalization can be claimed.**

Keywords*—DFU risk assessment; sensor-fusion-based monitoring system; Explainable Artificial Intelligence (XAI); MLP-BiLSTM hybrid model; home-based healthcare monitoring

I. Introduction

Diabetes mellitus is one of the most widespread metabolic disorders worldwide, and as of 2021, the prevalence of this disease was about 537 million adults in the world, whereas this number is estimated to be approximately 783 million in 2045. The increasing prevalence highlights its burden on general health and the need for more effective preventive and management measures [1]. DFU is one of the most debilitating chronic complications of diabetes that can quickly turn into an infection, gangrene, and, in the most severe cases, amputation of lower limbs [2]. Primary evidence indicates that 15-25% of diabetic patients will experience DFUs at some point in their life, with about 85 percent of all amputations relating to diabetes coming after the development of the ulcers [3]. DFUs have become a major source of hospitalization, morbidity, and disability in India, especially among the elderly and rural population, with a prevalence of diabetes in over 77 million adults in India [4]. The mortality rate from DFUs was estimated to be 30-40 years, which is similar to the number of malignancies, which, in turn, observes the first cases of DFU infection and constant risk monitoring extremely important [5]. However, it is difficult to diagnose in time, particularly in those places where clinics are inaccessible, subjective assessment is among the possible ones, and the instruments of continuous monitoring are not affordable [6].

II. Background

Traditional approaches like monofilament tests and thermography require clinical knowledge and do not provide real-time quantitative data on ulcer progression. In turn, studies have paid more attention to wearable and home-based smart systems that combine sensor technologies with artificial intelligence in order to enable continuous monitoring and the detection of early risk [7].

Late diagnosis continues to worsen ulcers, infection, and result in amputation, especially in semi-urban and rural areas where podiatrist follow-ups are infrequent. As part of the attempt to overcome these challenges, recent studies have examined various methods, such as thermal imaging, plantar pressure mapping, and vibration-based neuropathy assessment, among others. As an example, Early signs of DFUs were found by Eldin et al. [8] through thermal asymmetry indices, whereas Tang et al. [9] and Castro-Martins et al. [10] suggested in-shoe pressure monitoring systems to measure the local plantar load changes. Although these research studies were important towards understanding plantar biomechanics, most of them were based on a single-modality sensing; they lacked vascular analysis and did not use explainable or clinician-oriented frameworks to interpret them.

Remote monitoring and reliance on face-to-face clinical visits are decreasing as new platforms for diabetic care through telemedicine have gained widespread traction following the COVID-19 pandemic [11]. The majority of current methods rely on documenting ulcers via images or patients' subjective responses, rather than on automated, sensor-based

measurements. Equally, wound images and thermal datasets have been used to generate deep learning models [12] [13], but at this point, the subject of focus is visual classification, rather than physical risk prognosis. These models are often black boxes and thus not very interpretable, hence restricting clinical acceptance. The recent explainable AI (XAI) projects in the field of diabetes care, including those by Al-Hudaibi et al. [14] and Islam et al. [15], underline the importance of model transparency, but the application is focused on electronic health records and structured tabular data, rather than continuous multi-sensor data on wearable platforms. Few studies have combined both neuropathic predictors (loss of sensation) and ischemic markers (vascular perfusion) in one predictive system in diabetic foot monitoring. The current smart systems are mainly centered on analyzing plantar pressure and do not involve circulation assessment, and localized vascular profiling at the foot level is not studied much. Moreover, a lot of AI-based models follow the paradigm of single-stage deep learning, which ignores the temporal changes in physiological data, thus missing more subtle progressive changes that can help to identify early ulcer risks.

Based on [16] previous experiment, which used vibration, temperature, and plantar pressure and included a CatBoost-Deep Neuro-Fuzzy Network (DN-FN) model, this study suggests a more refined prototype of the home-based prototype with an added heart rate pulse sensor to measure the plantar venous blood flow, a vital parameter in the assessment of vascular health and predicting ischemic ulcer. The constructed sensor-fusion-based dataset includes vibration sensitivity, plantar pressure, temperature, and pulse, which are processed through SHAP-RFE to obtain interpretable features and subsequently classified with a hybrid MLP-Bi-LSTM model with a fuzzy inference layer. The last system will categorize the DFU risk into low risk, medium risk, and high risk. Moreover, there is the integration of explainable AI (XAI) frameworks like SHAP and LIME, which allow global and local interpretability so that clinicians can interpret the sensor-level factors impacting the model predictions. The developed mobile application, optimized with TensorFlow Lite, performs real-time inference and automatically sends high-risk data to clinicians, providing timely feedback and treatment suggestions. It is a clinician-in-the-loop design that transforms the system into a smart, interpretable, and interrelated healthcare solution that fosters patient awareness and allows expert-based intervention to enable proper management of diabetic foot. The principal contributions of this work can be summarized as follows. First, to the authors' knowledge, this is among the first home-deployable frameworks to combine neuropathic indicators (vibration and pressure) with an ischemic/vascular indicator (pulse-derived plantar blood flow) alongside thermal data within a single edge-inference system; earlier single-modality studies [8]–[10], as well as the authors' own prior baseline [16], did not include this vascular channel. Second, SHAP-RFE is used here not simply to reduce dimensionality but to constrain the retained feature subset to physiologically interpretable variables, which are then passed to a temporally-aware Bi-LSTM branch; pairing clinically grounded feature selection with sequence modelling in this way differs from the static, tree-based feature scoring used in [16]. Third, the fuzzy inference output layer converts model outputs into clinician-legible Low/Medium/High categories that feed directly into a clinician-in-the-loop mobile application, automatically escalating high-risk cases to a physician dashboard - a deployment pathway not present in the cited XAI-for-diabetes literature [14], [15], which is largely confined to retrospective analysis of electronic health records.

III. Dataset Specification

The samples analysed in this study constitute 316 individuals who were enrolled at the healthcare centers that were located in the Vellore District in Tamil Nadu, India. These included 192 patients who were clinically diagnosed with diabetes and 124 healthy volunteers. The sample, which was produced by this cohort, was heterogeneous, thus making it easier to study the risk of DFU between diabetic and non-diabetic groups.

The data are represented by 40 attributes, separated into 16 demographic, physiological, and lifestyle variables and 24 sensor-derived measurements, as detailed in Table I. The demographic and clinical variables include age, body mass index (BMI) level, a blood level of glycated haemoglobin (HbA1c), blood pressure, family history of diabetes, eating habits, physical activity, smoking, or alcoholism. Together, these parameters provide the contextual health data, which is relevant to DFU risk assessment.

TABLE I. Clinical and Sensor Data Features with Corresponding System Identifiers

Data Category	Parameters	Identifiers
Demographics	Age, Gender, BMI, Height, Weight	D-2, D-3, D-4, D-15, D-16
Clinical Markers	Diabetic Status, HbA1c, Blood Pressure, Early DFU Signs	D-1, D-5, D-6, D-14
Lifestyle Factors	Diet, Physical Activity, Smoking, Alcohol	D-8, D-9, D-10, D-11
Social Determinants	Education, Profession, Family History	D-7, D-12, D-13
Sensor Data	Vibration (16 points), Pressure (4 points), Temperature (2 points), Pulse (2 points)	RV-1-8, LV-1-8, RP-1/2, LP-1/2, RT, LT, PR, PL

IV. Methodology

A. Baseline Model: LightGBM-E-ANFIS Framework

The experimental platform was designed to acquire biomechanical and sensory information that was relevant to early diabetic neuropathy. An in-shoe prototype was fabricated, including a force-sensing resistor (FSR) and coin-type vibrators. The 4 FSRs were positioned on anatomically significant plantar locations: the forefoot, the midfoot, and the heel, to record pressure-distribution profiles. Plantar-pressure loading variations were acquired in analog form and digitised through an Arduino Mega 2560 microcontroller, thus enabling aberrant loading asymmetries associated with ulcer-prone areas to be identified.

Sensory impairment was determined based on a series of 16 micro-vibration motors (8 motors per foot) that were placed at physiologically relevant plantar sites, such as the hallux, metatarsal heads, midfoot, and heel. In the assessment

protocol, subjects were asked to self-report their perceptual thresholds through a mobile interface based on the controlled vibratory stimulus (motors). The integrated sensing system simultaneously analyses biomechanical load patterns and neurosensory losses. Both the pressure-loading and vibratory motor metrics were wirelessly transmitted via an HC-05 Bluetooth module to an Android app for further clinical analyses. After data collection, the entire dataset was rescaled via normalised pre-processing, where continuous variables were normalised using the min-max method and one-hot encoding (categorical variables). The features were refined through an Enhanced Adaptive Neuro-Fuzzy Inference System (E-ANFIS) optimised with the help of Ant Lion Optimizer (ALO) [17] [18] [19]. This process removed redundant features and reduced the feature space, which increased model stability and alleviated overfitting.

Light Gradient Boosting Machine (LightGBM) [20] was utilized to classify the risks of DFU due to its computational efficiency and suitability for tabular biomedical data. To ensure high generalisation, the model was trained using stratified five-fold cross-validation. LightGBM produced probabilistic outputs, which were further narrowed by the E -ANFIS model that combined rule-based fuzzy reasoning with neural learning to learn nonlinear associations between physiological variables.

Formally, let $X \in \mathbb{R}^{n\times d}$ denotes the preprocessed dataset represented as a real-valued matrix, where X (preprocessed dataset) consists of n samples (rows) and d selected attributes (columns). Here, $\mathbb{R}$ indicates that all elements of the matrix are real numbers, corresponding to continuous numerical values obtained after the data pre-processing stages. The LightGBM classifier estimates a confidence score $s_i = f_{LGB}(x_i)$ for each sample. This score, together with auxiliary physiological indicators, forms the input vector u for the E-ANFIS system. The model follows the Takagi-Sugeno fuzzy inference model [21], in which the fuzzy antecedents are modeled using the Gaussian membership functions and the terminal risk score is estimated using the linear consequents. The membership function for each input variable is defined as in Eq. (1).

$$\mu_{j,p}(u_p) = \exp\ \left(-\frac{(u_p - c_{j,p})^2}{2\sigma_{j,p}^2}\right), \tag{1}$$

where, $c_{j,p}$ and $\sigma_{j,p}$ denote the center and width of the membership function. The firing strength of rule $j$is determined using the product t-norm [Eq. (2)],

$$w_j = \prod_p\ \mu_{j,p}(u_p), \tag{2}$$

followed by normalization [Eq. (3)],

$$\bar{w}_j = \frac{w_j}{\sum_{k=1}^{m} w_k}. \tag{3}$$

Each rule computes a linear consequent of the form [Eq. (4)]

$$z_j = \mathrm{r}_j^{\top}\mathrm{u} + t_j, \tag{4}$$

and the final E-ANFIS output is obtained by weighted aggregation [Eq. (5)].

$$z = \sum_{j=1}^{m}\ \bar{w}_j z_j. \tag{5}$$

The output z is converted into one of the three diagnostic categories using two calibrated thresholds [Eq. (6)],

$$\hat{y} = \begin{cases} 0 & z < \theta_1, \\ 1 & \theta_1 \le z < \theta_2, \\ 2 & z \ge \theta_2. \end{cases} \tag{6}$$

The aggregated output is then mapped into three diagnostic categories representing normal, at-risk, and early DFU conditions. Therefore, the hybrid LightGBM-E-ANFIS framework will combine the strong predictive power of gradient-boosted decision trees with the interpretability of neuro-fuzzy reasoning, enabling reliable, clinically transparent assessment of DFU risk.

B. *Proposed Sensor-Fusion-Based Explainable AI Framework*

This study aims to improve DFU risk prediction by incorporating vascular, sensory, and thermal modalities into a home-based diagnostic architecture. Building on a previously reported baseline system [16], which incorporated vibration, temperature, and plantar-pressure measurements, the present framework adds a vascular dimension with heartbeat pulse monitoring, which measures the peripheral circulation via the plantar vein. This multimodal sensing scheme allows for a more exhaustive assessment of neuropathic and ischemic signals, which contributes to the timely occurrence of DFU-related complications. The general workflow of the proposed model is defined in Fig. 1.

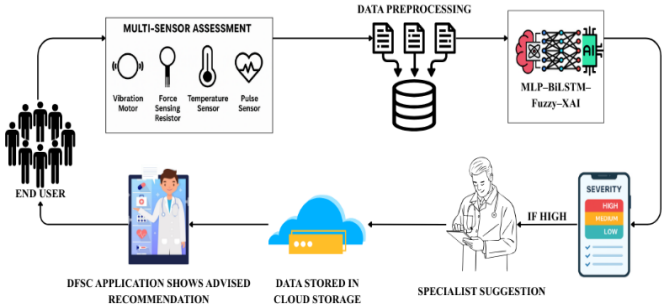

Fig. 1. Workflow cycle of the proposed model.

1) Data acquisition and sensor integration: Building on the baseline hardware described in Section IV-A, the sensor array was extended with DS18B20 temperature sensors at the midfoot for localized thermal data and a heart-rate pulse sensor for plantar venous blood flow, in addition to the existing plantar-pressure and vibration channels. All sensors were connected to an Arduino Mega 2560 acquisition unit and transmitted synchronized readings wirelessly via an ESP32 Wi-Fi module to a smartphone application for processing and visualization.

Data pre-processing and feature engineering: Technically, defined pre-processing steps were incorporated to ensure the integrity of the data and the consistency of the analysis. The non-captured numerical values (e.g., BMI, HbA1c, blood pressure) were substituted with the means of existing datasets, and categorical attributes (i.e., diet, smoking, alcohol consumption) with the mode value to retain the population-

level trends. Categorical variables were encoded through a hybrid strategy, wherein binary and ordinal features were transformed via label encoding. To eliminate the artificial ordinal relationships, the nominal variables were represented using one-hot encoding, and continuous variables were normalized using min-max scaling to reduce the influence of inter-subject variance. Pulse signals were divided into short, predetermined windows to extract time- and frequency-domain features for detecting hidden vascular anomalies, which indicate ischemic stress. Vibration responses were processed into sensitivity indices that indicated the number of detectable vibration points per foot, and this denotes neuropathic degradation. The multimodal data, which is formed as a combination of clinical, sensory, and vascular data, becomes a solid basis for the extended refinement of features and classification (Fig. 2).

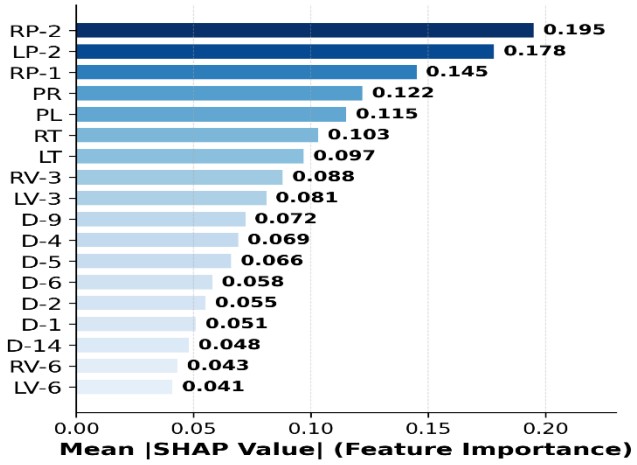

Fig. 2. Feature importance graph of the SHAP-RFE selected features.

2) SHAP-guided recursive elimination feature selection: SHAP-RFE [22] was utilized to refine the features for enhancing the interpretability of the model and computational efficiency. SHAP values were used to measure the individual contribution of each attribute to the model performance, and attributes with smaller SHAP values were repeatedly removed through recursive elimination. This process provided an 18-variable subset of the original 40-feature dataset, with each retained variable carrying high clinical and discriminative significance. The subset is dominated by pressure and pulse variables - heel and forefoot pressure at both feet (RP-1, RP-2, LP-2), plantar pulse readings (PR, PL), and bilateral plantar temperature (RT, LT) together with vibration sensitivity at specific plantar sites (RV-3, LV-3, RV-6, LV-6) and a set of clinical and demographic variables (BMI, HbA1c, blood pressure, age, diabetic status, early DFU signs, and physical activity). These retained features are consistent with the neuropathic and vascular mechanisms underlying DFU risk. In comparison to traditional ranking-based approaches, SHAP-RFE combines both statistical robustness and physiological interpretability, so that the refined subset is composed of medically meaningful risk factors of DFU. The output 18-feature input space offers a consistent and interpretable training base for hybrid models.

3) Hybrid MLP-Bi-LSTM-Fuzzy classification model: A hybrid architecture of MLP-Bi-LSTM refined dataset was modelled with a fuzzy inference output layer [23] [24]. The MLP module models all the variables that are not organized in time, e.g., clinical parameters and vibration responses; the Bi-LSTM branch models the sequential correlations in the time series of pressure, temperature, and pulse sensors. The bi-directional structure of the Bi-LSTM allows both antecedent and subsequent temporal contexts to be used in learning, thus enhancing the ability to detect small dynamic changes that may be precursors to DFU occurrence. Fig. 3 depicts the general description of the workflow of the proposed methodology.

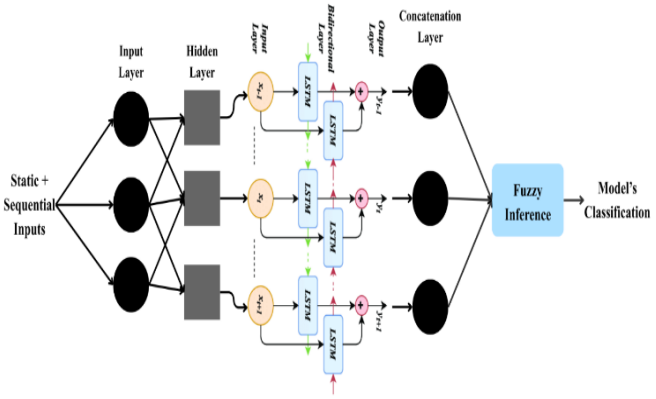

Fig. 3. Hybrid MLP-Bi-LSTM-Fuzzy classification model.

The results of the MLP and the Bi-LSTM branches are merged in a fusion layer, and a single feature vector will be formed, which will then be fed to the fuzzy inference module. This module classifies DFU risk into three linguistic levels: Low, Medium, and High, whereby a smooth transition is achieved between boundary regions with the use of Gaussian membership functions. The fuzzy mapping is a method that converts the numerical results of the deep network into clinically interpretable extremes of severity and thus reconciles model results with the clinical practitioner.

4) Training the MLP-Bi-LSTM-Fuzzy model and validation: Categorical cross-entropy loss with adaptive regularisation is implemented to train the hybrid model to maintain a trade-off between sensitivity and specificity of classification. Bayesian optimisation was used to perform hyperparameter tuning and was implemented with the help of the Optuna framework [25] [26], which progressively searched the hyperparameter space of learning rates, neuronal configurations, and regularisation weights. The data were split into 80% training and 20% testing (balanced class distribution), and five-fold cross-validation was utilized to improve generalisation and reduce overfitting.

5) Algorithm of the MLP-Bi-LSTM-Fuzzy model:

The pre-processed input vector is determined as being $x_i \in \mathbb{R}^{40}$. The MLP branch computes hierarchical feature representations as given in Eq. (7).

$$h_1 = \sigma(W_1 x_i + b_1), h_2 = \sigma(W_2 h_1 + b_2) \quad (7)$$

as the BiLSTM operates on time-series lengthy sequences $\{s_t\}_{t=1}^{T}$ of pressure, temperature, and pulse measurements, as described in Eq. (8):

$$h_t = \text{LSTM}_f(s_t), \overleftarrow{h}_t = \text{LSTM}_b(s_t), \quad (8)$$

Resulting in a concatenated sequence representation as shown in Eq. (9):

$$h_{seq} = [h_T; \overleftarrow{h}_1]. \quad (9)$$

The fusion layer combines the two representations as in Eq. (10)

$$z = \tanh(W_f[h_2; h_{seq}] + b_f) \quad (10)$$

and the fuzzy membership of each of the classes $c \in \{L, M, H\}$ is stated as [Eq. (11)]

$$\mu_c(z) = \exp(-\frac{||z-\eta_c||^2}{2\sigma_c^2}). \quad (11)$$

The risk is assessed as predicted risk [Eq. (12)].

$$\hat{y}_i = \arg\max_c \frac{\mu_c(z)}{\sum_k \mu_k(z)}. \quad (12)$$

This method combines profound time-based learning and fuzzy reasoning to generate an interpretable probabilistic answer regarding the probability of DFU risk severity. The framework is an adaptive, transparent, and clinician-monitored diagnostic system during deployment. The model provides context-aware predictions to be interpreted and acted upon as clinically necessary by merging vibration, plantar pressure, temperature, and pulse measurements with clinical parameters. Its mobile integration and explainable design provide the ability to monitor constantly, at home, to provide patients with real-time insights and assist in data-driven clinical feedback. In general, the system provides a comprehensive solution for scalable, intelligent, and patient-centred diabetic foot management.

V. Model Outcomes and Interferences

The clinical trials demonstrate that the proposed system achieves a substantial improvement in predictive accuracy compared with existing frameworks. The addition of the temperature sensor and pulse sensor, which have the potential to monitor abnormal differences in the plantar temperature and peripheral blood flow and circulatory dynamics of the plantar vein, significantly increases the ability of the model to differentiate cases of high-risk diabetic foot ulcer (DFU) that are related to ischemic or vascular dysfunction. This addition significantly decreases the number of false negative identifications of severe conditions that had been hard to identify with the use of vibration motor response and plantar pressure sensor alone.

To achieve this, the quantitative analysis of performance (Fig. 4) indicates that the proposed model positively impacts the estimation of various metrics by 2-3% relative to the CatBoost-DN-FN. This methodology outperforms the other tested architectures, such as CNN-SVM. [27], LSTM-Fuzzy [28]and LightGBM-EANFIS (Baseline), which highlights its strength and capacity to generalise in DFU risk profiling. The high values of area under the receiver operating characteristic curve (AUC-ROC) and Matthews correlation coefficient (MCC) are also consistent and show that the model is stable and reliable when it is used in multi-class classification.

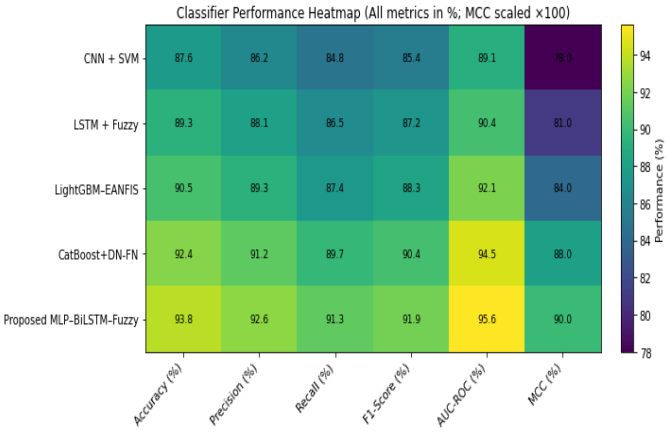

Fig. 4. Heatmap indicating the performance comparison of classifiers.

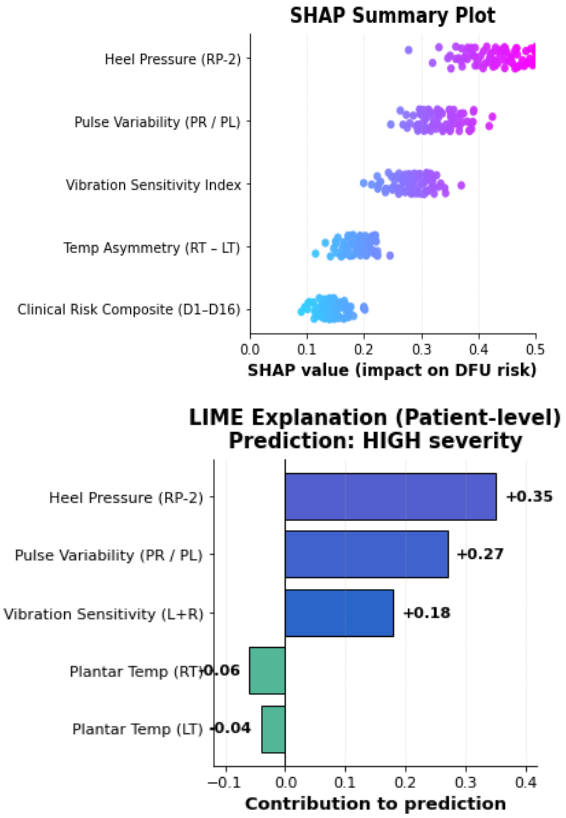

Fig. 5. Global (SHAP) and local explainability (LIME) interpretation analysis of DFU risk profiling from proposed models.

The explainability analysis provides additional clinical information about the model's decision-making process. The summary plots of SHAP (Fig. 5(a)) indicate that the most significant variables for stratifying the risk of DFU are plantar heel pressure, pulse variability, and loss of vibration sensitivity, consistent with existing literature indicating that

neuropathy and ischemic perfusion deficits are the main predictors of ulcer development. The interpretations of cases based on LIME (Fig. 5(b)) also illustrate the influences that sensor inputs have on individual prediction. As an example, in a subject with high risk, LIME detected abnormal pulse amplitude and elevated heel pressure to be leading factors - results that were in line with clinical reports of compromised blood circulation and focal stress build-up. These visualisations provide better model transparency, build clinical trust, and clarify the association between physiological relevance and algorithmic reasoning.

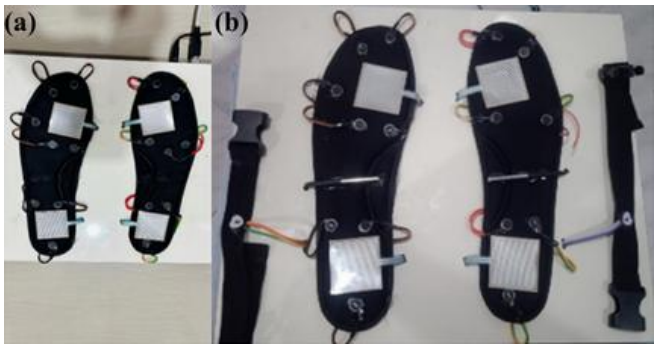

Fig. 6. (a) Baseline prototype. Initial: proof of concept. (b) Feature-enhanced revised prototype (functionality extended).

As a result, the proposed hybrid model achieves a successful distribution of technical accuracy, clinical applicability, and explainable decision support. The combination of vascular, sensory, and thermal capabilities presented in an interpretable deep-learning architecture provides the system with a high predictive accuracy along with the transparency and clinician-interaction needed in the real-world operation of diabetic foot.

VI. Sensor Assembly and Prototype Implementation

The in-home diabetic foot monitoring system was experimentally tested using an integrated sensor prototype on the basis of the real-time acquisition of physiological data and the evaluation of DFU risk. Fig. 6(a) shows that the experiment had a design with the inclusion of plantar pressure sensors and vibration motors to assess both biomechanical loading and sensory deficits. Based on that design, the present system is designed to combine four different sensing modalities, as shown in Fig. 6(b).

The proposed model prototype includes force-sensing resistors (FSRs) to measure the amount of plantar pressure on the significant anatomical positions, namely, the forefoot and the heel; vibration motors to measure the tactile sensitivity on eight discrete locations along with each foot; DS18B20 temperature sensors to evaluate dermal thermal variations, and heart-rate pulse sensors to estimate the vascular dynamics based on the measurement of the plantar blood flow. The sensing components are all integrated into a compliant insole platform to allow the user to be comfortable in the long term and to ensure accurate monitoring. The sensing modules are each connected to an Arduino Mega 2560 data acquisition board each, which provides the ability to sample synchronized data and low-latency wireless communication.

At every stage of the clinical trial, the participants were made to stand with both feet on the insole platform, and the vibration stimuli were applied in turn at sixteen points of touch (eight on each foot). The participants were asked to report the perception of vibration using the mobile application interface (Fig. 7), and their answers were registered as binary sensitivity responses. At the same time, the system was also recording the real-time plantar pressure, temperature, and pulse data.

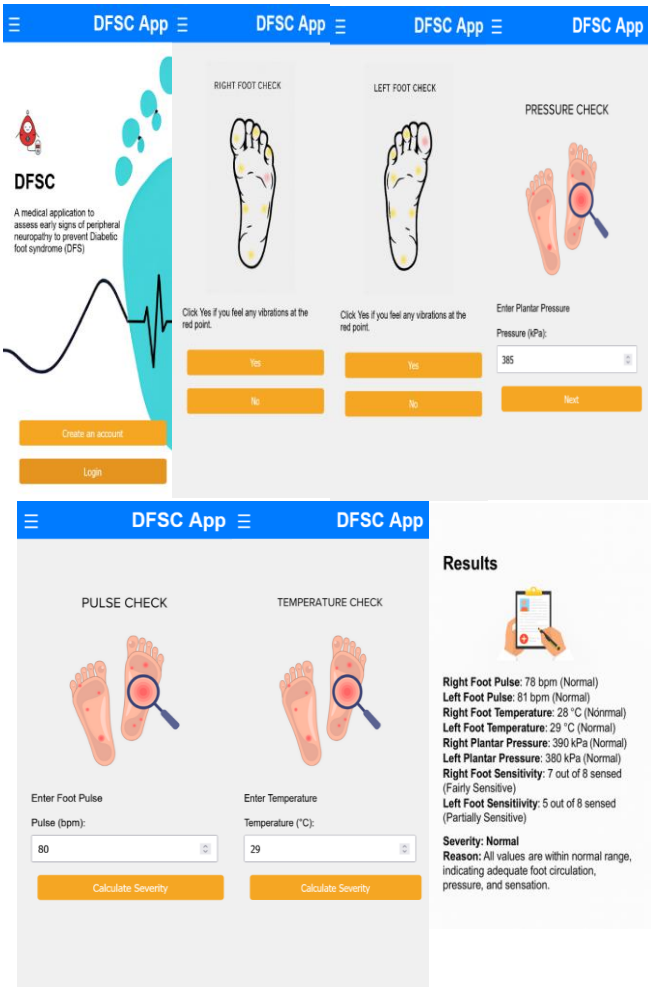

Fig. 7. The DFSC (Diabetic Foot Screening and Classification) mobile application's real-time functionality and user interface.

The recorded metrics of the prototype were wirelessly communicated through an ESP32 Wi-Fi microcontroller to a smartphone application written in Android Studio (Java/Kotlin). The application uses a TensorFlow Lite-optimised hybrid MLP-Bi-LSTM-Fuzzy model that is applied to perform on-device inference for DFU risk prediction. The model has three levels of risk associated with foot health, namely Low, Medium, and High, relying on the combination of sensory and vascular inputs. The mobile application has a simple dashboard, which displays the predicted risk level with major sensor-derived parameters such as the mean number of vibration points detected (out of sixteen), plantar pressure, thermal gradients, and pulse-rate variability.

The real-time testing environment, i.e., the volunteers, the sensor-integrated prototype, and the mobile-application

interface, is shown in Fig. 8. The application on the smartphone also has a clinician-feedback tool, which looks automatic as soon as the High-risk outcome is recognized. The sensor data and interpretability reports are then safely transferred into a physician dashboard through the cloud. The clinician checks the information, confirms the risk level calculated by AI, and offers individual recommendations, including changes in therapy or lifestyle advice, on the same interface.

Fig. 8. The In-situ engagement: captured participants during clinical trials.

It is a clinician-in-the-loop system that creates a closed, continuous feedback loop between patients and healthcare providers, which facilitates real-time monitoring and preventive intervention. The personalised therapy-recommendation module in the application was developed to fit the diverse risk-severity levels. The module was designed and empirically tested to enable a user-friendly interface for feedback and treatment suggestions and has later been integrated and functionally assessed in the application. The treatment recommendation interface is under trial, and further refinements are planned in terms of automated data transmission to the relevant specialist for every patient, allowing for the conduct of context-aware, individualised therapeutic choices based on the evaluated risk of DFU severity. The effective implementation and testing of the system suggest the technical feasibility of the system in continuous and home-based monitoring of diabetic foot health. The prototype has great potential with regard to being a scalable digital-health platform for early DFU risk assessment, and personalised intervention through the combination of multi-sensor fusion, explainable AI, and telemedicine-enabled clinician feedback on a single mobile platform.

VII. Limitations and Future Clinical Deployment

The cohort examined in this study was drawn entirely from healthcare centres in the Vellore district of Tamil Nadu, and the reported performance figures should accordingly be read as characteristic of this population rather than as evidence of broad clinical generalizability. Diabetic foot presentation can vary considerably with regional diet, footwear practices, and healthcare access, and a system trained on a single-site cohort may not transfer cleanly to other settings without further tuning. Extending the dataset to additional centres, ideally spanning different geographic and socioeconomic contexts, is a necessary step before the framework can be positioned as a general-purpose screening tool rather than a regionally validated prototype.

Deployment readiness raises a related set of questions. The mobile application, the clinician dashboard, and the treatment-recommendation module have all been built and exercised during development, and the underlying model performs reliably on the held-out test data described in Section V. What the current work does not yet include is an independent clinical evaluation - a podiatrist or endocrinologist reviewing the system's outputs against their own diagnostic judgment in a live setting. Functional testing during development is a different exercise from prospective clinical use, and closing that gap through a pilot study involving practising clinicians is the logical next step before the platform could be considered ready for routine care.

Two aspects of the sensing pipeline also warrant caution. Vibratory sensitivity is currently captured through a binary self-report: the participant indicates, via the mobile interface, whether a given stimulus was felt. This is simpler to deploy than standard clinical tools such as the Semmes-Weinstein monofilament test, but it is also more subjective, and the extent to which patient-reported perception diverges from a validated neuropathy assessment has not yet been measured directly. Separately, the pulse and temperature channels are physically the most exposed to everyday use; foot placement, movement during measurement, and ambient temperature can all introduce noise that a single clinical visit would not encounter. Neither source of variability appears to have compromised the results presented here, but neither has been formally quantified across a range of home conditions, and both deserve dedicated attention as the system moves toward wider use.

The interpretability outputs generated by SHAP and LIME are, at present, evaluated on their consistency with known clinical reasoning about neuropathy and vascular risk rather than through direct comparison with clinician judgment on the same cases. A more systematic check asking clinicians to independently rank the risk factors they would expect for a given patient and comparing that ranking against the model's explanations would offer firmer evidence that the explanations are clinically useful rather than merely plausible. Alongside this, expanding the physiological coverage of the system with additional modalities such as SpO2 monitoring or sweat-based biosensors, and exploring federated learning approaches that would allow multiple sites to contribute to model training without centralising patient data, represent natural directions for extending this work toward a more broadly deployable and clinically grounded platform.

VIII. Conclusion and Prospects

This study presents the evolution of an in-home diabetic foot ulcer monitoring system, from an initial biomechanical sensing approach to a multi-sensor, explainable AI-based platform. The baseline version combined plantar-pressure and vibration measurements with a LightGBM-E-ANFIS classifier to detect early signs of DFU risk. While this baseline demonstrated meaningful potential for detecting neuropathic changes, the present study extends it substantially through the addition of thermal and vascular sensing and an explainable

deep-learning architecture. The augmented system combines vibration, pressure, temperature, and pulse data to support a more comprehensive analysis of the neuropathic and ischemic biomarkers relevant to DFU pathogenesis. The optimised MLP-BiLSTM-Fuzzy model, guided by SHAP-RFE feature selection, captures the nonlinear relationships, temporal dynamics, and uncertainty inherent in physiological sensor data, while the integration of SHAP and LIME increases the transparency of model predictions for clinicians reviewing the mobile application interface. The accompanying clinician-feedback pathway further supports the system's practical relevance for preventive healthcare delivery.

As discussed in Section VII, several open questions remain around external validation, prospective clinical assessment, and quantitative evaluation of explainability, and these will guide the next phase of this work. Overall, the system illustrates a feasible pathway toward a proactive, interpretable, and clinician-connected platform for long-term, personalised diabetic foot management.

ACKNOWLEDGMENT

This research was sponsored by the Indian Council of Medical Research (ICMR) under the Grant Number No. R11014/26/2023-GIA/HR. The authors express their sincere gratitude to ICMR for its valuable support and funding.

COMPETING INTERESTS

The authors declare that they have no known competing financial interests or personal relationships that could have appeared to influence the work reported in this study.

ETHICAL APPROVAL

This study involved human participants who were interviewed as part of a non-interventional observational study. No clinical procedures, experiments, or interventions were performed at any stage of the research. Before participation, written informed consent was obtained from all individuals after explaining the purpose of the study and their right to withdraw at any time.

To ensure confidentiality and protect participant privacy, all individuals are identified only by pseudonyms in the manuscript and related publications. The study protocol was reviewed and approved by the Institutional Ethical Committee for Studies on Human Subjects, Vellore Institute of Technology (VIT), Vellore, under the approval reference VIT/XIII IECH/12, dated March 10, 2023, following the committee meeting held on March 04, 2023.

ReadTech: A Mobile Reading Application for Grade 7 Learners

Mary Jane U. Quibilan
College of Education, Pangasinan State University – Asingan Campus, Philippines

***Abstract*—Reading comprehension remains a fundamental skill for academic success; however, many Grade 7 learners continue to experience difficulties in vocabulary development, text comprehension, and access to engaging instructional materials. This study developed and evaluated the ReadTech Mobile Reading Application using a Design and Development Research (DDR) methodology. The study integrated developmental, descriptive-survey, and evaluative approaches involving Grade 7 learners, expert validators, and student-users from two integrated schools in Asingan, Pangasinan, Philippines. Needs assessment results revealed that learners had a strong need for supplementary reading materials, vocabulary-building activities, and technology-supported learning resources. The developed application incorporates personalized learning activities, reading lessons, assessments, and progress monitoring features aligned with the Grade 7 English MATATAG Curriculum. Expert evaluation indicated that the application was highly valid (M = 4.71), particularly in task accuracy and technology usability. Likewise, student-users rated the application as highly acceptable (M = 4.47), with engagement receiving the highest rating. These findings indicate that ReadTech is a curriculum-aligned mobile learning application that was successfully developed, validated by experts, and positively received by learners. The study demonstrates the feasibility of using Design and Development Research (DDR) to develop learner-centered mobile applications that support reading instruction and provide a foundation for future studies evaluating learning outcomes.**

Keywords*—Android application; digital learning; educational technology; mobile learning; reading comprehension

I. Introduction

Reading comprehension is a fundamental component of literacy that enables learners to derive meaning from texts, acquire knowledge, develop critical thinking skills, and achieve academic success. As one of the core competencies in language education, reading comprehension supports learning across various subject areas and contributes significantly to students' overall educational development. However, many learners continue to experience difficulties in understanding textual information, identifying main ideas, making inferences, interpreting vocabulary, and synthesizing information from different reading materials. These challenges often hinder academic performance and reduce learners' confidence and motivation toward reading activities [1], [2].

The rapid advancement of digital technology has transformed the way learners access, process, and interact with information. Mobile devices, particularly smartphones and tablets, have become increasingly integrated into students' daily lives, providing opportunities for learning beyond traditional classroom environments. Consequently, mobile learning has emerged as an effective educational approach that enables learners to access instructional materials anytime, anywhere via portable devices. Research has shown that Mobile Reading Applications can support language acquisition, improve learner engagement, and provide flexible learning experiences that accommodate individual learning needs [3], [4].

The effectiveness of educational Mobile Reading Applications depends largely on how well they address the needs and preferences of their intended users. Human-centered design emphasizes the importance of understanding learners' characteristics and involving users throughout the development process to ensure that educational technologies remain relevant, usable, and effective. Educational applications designed using learner-centered approaches are more likely to enhance user satisfaction, motivation, and learning outcomes because they align instructional content with students' cognitive and behavioral requirements [5], [6].

An important aspect of educational application development involves the use of systematic design methodologies. Storytelling techniques, storyboards, and user-experience frameworks have been widely utilized to visualize learning scenarios and facilitate communication among developers, educators, and stakeholders during the design process. These methods contribute to the creation of intuitive interfaces and meaningful learning experiences that support instructional objectives and learner engagement [7], [8].

Similarly, wireframing and interface design practices play a critical role in ensuring the usability and accessibility of mobile learning applications. Effective interface design enables users to navigate learning materials efficiently while minimizing cognitive overload. Well-designed interfaces can improve learner interaction with digital content, thereby increasing the likelihood of sustained engagement and positive learning experiences [9], [10].

Prototyping has likewise become a fundamental practice in educational technology development because it allows developers to iteratively refine application features based on stakeholder feedback. Evolutionary prototyping approaches facilitate continuous improvement by enabling developers to evaluate and modify application components throughout the development cycle. Such approaches have been successfully applied in the development of educational and decision-support systems, resulting in improved functionality and user satisfaction [11], [12].

The collaborative involvement of subject matter experts is also essential in ensuring the quality and educational relevance

of instructional applications. Experts contribute specialized knowledge that guides content development, instructional design, and assessment construction. Collaboration between developers and subject matter experts helps ensure that learning materials are accurate, pedagogically sound, and aligned with curricular standards and learning objectives [13], [14].

In addition to content quality, educational Mobile Reading Applications must be developed using appropriate instructional design principles. Effective instructional design promotes active learning, supports learner autonomy, and provides opportunities for practice and feedback. Applications that incorporate structured learning pathways, clear objectives, and meaningful reinforcement activities are more likely to facilitate knowledge acquisition and skill development among learners [15], [16].

The increasing use of smartphones for educational purposes has generated considerable interest in understanding how digital reading environments influence reading comprehension and learning performance. While mobile technologies provide convenient access to educational resources, researchers have observed differences in how learners process information presented on digital screens compared with traditional printed materials. These differences have raised questions regarding the effectiveness of digital reading platforms in supporting deep comprehension and knowledge retention [17], [18].

Studies examining reading performance across digital and print media have produced varied findings. Some investigations suggest that learners may demonstrate lower comprehension performance when reading digitally, particularly when texts require deeper cognitive processing and reflection. Other studies indicate that appropriately designed digital environments can support reading comprehension by incorporating interactive features, multimedia elements, and adaptive learning supports that enhance learner engagement and understanding [19], [20].

Eye-tracking technology has emerged as an important tool for examining reading behavior in digital learning environments. Through the analysis of visual attention, fixation patterns, and reading navigation behaviors, researchers have gained valuable insights into how learners interact with electronic texts. Eye-tracking studies have contributed significantly to understanding the cognitive processes involved in reading and learning from digital materials [21], [22].

Research further indicates that reading behaviors differ depending on the design and presentation of digital content. Factors such as multimedia integration, visual layout, navigation structures, and interactive features influence learners' attention and information processing. Well-designed digital reading environments can enhance engagement and facilitate comprehension by directing learners' attention toward relevant content and supporting cognitive processing [23], [24].

The incorporation of multimedia features in educational applications has also shown promise in promoting learner motivation and reading engagement. Interactive activities, audio support, visual cues, gamification elements, and immediate feedback mechanisms can make learning experiences more engaging and meaningful. Such features help learners remain actively involved in learning tasks while supporting diverse learning preferences and abilities [25], [26].

Recent studies utilizing eye-tracking methodologies have demonstrated that visual cues and multimedia supports can significantly influence learners' reading performance and attention allocation. These findings suggest that carefully designed digital reading tools can improve learners' ability to process information and maintain focus during reading activities. Consequently, educational applications that integrate evidence-based multimedia features may contribute positively to reading comprehension development [27], [28].

Beyond visual attention, researchers have also examined learners' cognitive engagement while reading digital texts. Findings indicate that digital reading experiences involve complex interactions among cognitive, behavioral, and physiological factors. Understanding these interactions is important for designing educational technologies that effectively support reading comprehension and learning outcomes [29], [30].

The growing body of literature on mobile learning, digital reading, and educational technology highlights the importance of developing applications that balance instructional effectiveness with usability and learner engagement. Educational technologies should not only provide access to content but also facilitate meaningful interactions that promote comprehension, vocabulary development, critical thinking, and independent learning [31], [32].

Within the Philippine educational context, strengthening reading comprehension remains a significant concern. Reading proficiency serves as a foundation for learning across disciplines, yet many learners continue to encounter challenges in comprehension, vocabulary acquisition, and critical reading. The implementation of the MATATAG Curriculum further emphasizes the need for innovative and technology-supported instructional resources capable of enhancing literacy development among secondary school learners [33], [34].

Despite the availability of numerous educational applications, there remains a need for curriculum-aligned mobile reading applications specifically designed to address the learning needs, reading attributes, and preferences of Grade 7 learners. Existing applications often focus on general language learning and may not adequately provide structured reading comprehension activities, vocabulary development opportunities, progress monitoring features, and interactive support mechanisms that align with curriculum requirements [35], [36].

Moreover, the effectiveness of educational technologies must be established through systematic evaluation procedures. Expert validation is necessary to ensure content quality, instructional accuracy, usability, and technological reliability, while user acceptability assessments provide insights into learners' perceptions regarding functionality, engagement, usefulness, and overall learning experience. Such evaluations are essential for determining whether an educational application successfully meets its intended objectives and supports meaningful learning outcomes [37], [38].

Although numerous mobile learning applications have been developed for language education, relatively few are specifically aligned with the Philippine Grade 7 English MATATAG

Curriculum while integrating learner needs assessment, expert validation, and student acceptability evaluation within a Design and Development Research framework. Consequently, there remains a need for a curriculum-based mobile reading application whose development is systematically guided by learners' instructional needs and evaluated for its educational quality and usability.

In response to these educational needs, this study aims to develop and evaluate the ReadTech Mobile Reading Application as a digital learning tool designed to enhance the reading comprehension skills of Grade 7 learners. Specifically, this study aimed to identify the reading attributes, learning preferences, and reading needs of Grade 7 learners; develop the ReadTech Mobile Reading Application based on the identified learner needs and the Grade 7 English MATATAG Curriculum; evaluate the application in terms of content quality, task accuracy, instructional design, and technology usability through expert validation; determine the acceptability of the application among student-users in terms of usability, functionality, engagement, and usefulness; and identify recommendations for improving future versions of the application.

II. METHODOLOGY

A. Research Design

This study employed a Design and Development Research (DDR) methodology [39] to develop and evaluate the ReadTech Mobile Reading Application for Grade 7 learners. The methodology integrated developmental, descriptive-survey, and evaluative approaches. The developmental phase focused on the design, development, and refinement of the application, while the descriptive-survey phase identified learners' reading needs and preferences that served as the basis for application development. The evaluative phase examined the application's validity, usability, and acceptability. The study was conducted in two integrated schools in Asingan, Pangasinan, Philippines, selected for their Grade 7 learner population. Using purposive sampling, the participants included Grade 7 learners for the needs assessment, expert validators for application evaluation, and student-users who assessed the application's functionality, engagement, and usefulness following implementation.

B. Statistical Treatment of Data

Descriptive statistics, including frequency, percentage, weighted mean, and grand mean, were used to summarize the needs assessment, expert validation, and student acceptability results. Since the purpose of the study was to evaluate the developed application rather than determine causal effects or learning gains, inferential statistical analyses were not performed. Tables I and II present the interpretation scales used in the study.

Mean scores ranging from 4.21–5.00 indicate Highly Needed, while lower mean scores correspond to decreasing levels of need, from Needed to Not Needed. This scale was used to determine the priority needs of Grade 7 learners.

Mean scores of 4.21–5.00 indicate Highly Valid/Highly Acceptable, while lower scores reflect decreasing levels of validity and acceptability, from Valid/Acceptable to Not Valid/Not Acceptable. This scale was used to evaluate the quality and usability of the ReadTech Mobile Reading Application.

TABLE I. NEEDS ASSESSMENT SCALE

Mean Range	Interpretation
4.21–5.00	Highly Needed
3.41–4.20	Needed
2.61–3.40	Moderately Needed
1.81–2.60	Slightly Needed
1.00–1.80	Not Needed

TABLE II. VALIDITY AND ACCEPTABILITY SCALE

Mean Range	Interpretation
4.21–5.00	Highly Valid / Highly Acceptable
3.41–4.20	Valid / Acceptable
2.61–3.40	Moderately Valid / Moderately Acceptable
1.81–2.60	Slightly Valid / Slightly Acceptable
1.00–1.80	Not Valid / Not Acceptable

C. Learners' Reading Attributes

The needs assessment was conducted to determine the needs of supplemental learning and the basis for the development of a mobile reading application. The results are presented in Table III, which presents the summary of learners' reading attributes.

TABLE III. READING ATTRIBUTES OF GRADE 7 LEARNERS

Indicator	Mean
Identifying the main idea	5.00
Understanding details of a text	4.97
Making inferences	4.74
Understanding unfamiliar vocabulary	5.00
Summarizing ideas	5.00
Analyzing different text types	5.00
Activities that improve reading comprehension	4.91
Strategies that help become a better reader	5.00
Grand Mean	4.95

The results show a grand mean of 4.95, interpreted as Highly Needed, indicating a very high need to develop essential reading skills. Among the indicators, identifying the main idea, understanding unfamiliar vocabulary, summarizing ideas, analyzing different text types, and strategies that help become a better reader obtained the highest mean of 5.00, while making inferences received the lowest mean of 4.74, though it remained within the Highly Needed level. These findings highlight the importance of strengthening fundamental reading competencies in the development of the ReadTech Mobile Reading Application.

D. Reading Needs

The reading needs were conducted to determine the needs of supplemental learning and basis for the development of the mobile reading application. The results are presented in Table

IV, which presents the summary of reading needs of Grade 7 learners.

TABLE IV. READING NEEDS OF GRADE 7 LEARNERS

Indicator	Mean
Additional reading materials	4.94
Vocabulary-building activities	4.91
Gradually increasing difficulty levels	4.87
Reading comprehension exercises	4.91
Critical thinking activities	4.83
MATATAG-aligned materials	4.98
Word of the Day feature	4.87
Multiple reading genres	4.92
Grand Mean	4.90

The results yielded a grand mean of 4.90, interpreted as Highly Needed, indicating a strong demand for additional reading resources and learning support. Among the indicators, MATATAG-aligned materials obtained the highest mean (4.98), followed by additional reading materials (4.94) and multiple reading genres (4.92). Although critical thinking activities recorded the lowest mean (4.83), it remained within the Highly Needed level. These findings emphasize the importance of providing curriculum-aligned, engaging, and comprehensive reading materials in the ReadTech Mobile Reading Application.

E. System Architecture of the Mobile Reading Application

Fig. 1 illustrates the overall architecture and operational workflow of the mobile reading application developed to support reading comprehension among Grade 7 learners.

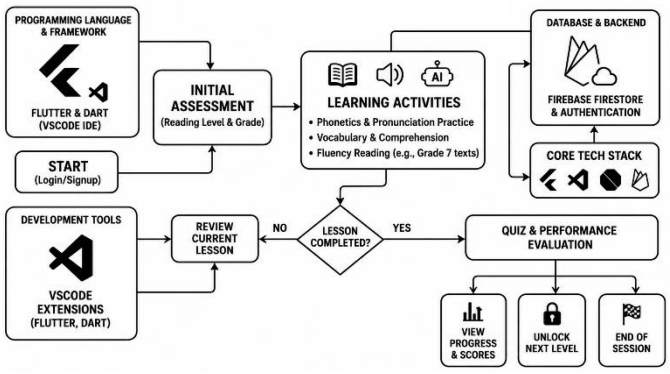

Fig. 1. Architecture and operational flow of the mobile reading application.

The process begins with the Start module, where learners create an account or log in to the application. After authentication, learners undergo an Initial Assessment that determines their reading level and appropriate grade-based content. Based on the assessment results, the system provides personalized Learning Activities, which include phonetics and pronunciation exercises, vocabulary and reading comprehension activities, and fluency-reading exercises using Grade 7 texts. After completing the learning activities, the system evaluates whether the lesson has been completed. If the learner has not completed the lesson, the application redirects the learner to the Review Current Lesson module to reinforce understanding and improve mastery. If the lesson is completed, the learner proceeds to the Quiz and Performance Evaluation stage, where the application measures learning outcomes and reading performance. The evaluation results are then stored in the Firebase database and presented through several features, including Progress and Score Monitoring, Unlocking of Subsequent Learning Levels, and the End-of-Session module. This workflow enables personalized learning, continuous progress monitoring, and adaptive reading instruction, thereby promoting reading comprehension, vocabulary development, and independent learning among Grade 7 learners.

F. Pseudocode of the ReadTech Mobile Reading Application

Algorithm 1 presents the pseudocode for the development and deployment process of the ReadTech Mobile Reading Application.

Algorithm 1: ReadTech Mobile Reading Application

```
Initialize
  Configure Flutter Framework
  Configure Dart Programming Language
  Configure VSCode Development Environment
  Configure Firebase Firestore and Authentication
  Define application requirements and database schema
Compute
  Collect learners' reading needs
  Analyze learning preferences and digital learning needs
  Design application architecture and user interfaces
While (application development is not completed) do
  For (each application module) do
    Develop Authentication Module
    Develop Initial Assessment Module
    Develop Learning Activity Module
    Develop Quiz and Evaluation Module
    Develop Progress Monitoring Module
    Develop Level Unlocking Module
    Update
      Integrate module with Firebase database
      Test module functionality and user interface
      If (errors or usability issues exist) then
        Debug and revise source code
        Update database and interface design
        Re-test module
      End
  End

  Validate
    Conduct expert evaluation
    Analyze validation results
    If (recommendations are provided) then
      Revise application features and content
      Re-evaluate application
    End
End
Deploy
  Release application to student-users
  Collect acceptability evaluation
  Analyze user feedback
  Finalize and publish ReadTech Mobile Application
```

The algorithm describes the major procedures involved in configuring the development environment, designing and

implementing application modules, integrating the database and backend services, conducting testing and validation, and deploying the application to student-users. It also illustrates the iterative process of debugging, refinement, and evaluation to ensure that the application meets the educational and technological requirements of Grade 7 learners.

G. Ethical Consideration

The study adhered to established ethical standards in educational research. Participation was voluntary, and informed consent was obtained from all participants and their parents or guardians. Confidentiality and anonymity were maintained, and all data were used solely for academic and research purposes. Participants were informed of their right to withdraw from the study at any stage without penalty.

III. Results and Discussions

A. The Developed ReadTech Mobile Reading Application

The following figures illustrate the user interfaces of the mobile reading application. The first screen shows the splash screen, which serves as the application's loading and welcome interface. The second and third screens display the activity dashboards containing curriculum-aligned reading exercises and assessments organized by academic quarter.

Fig. 2 presents the splash screen and main menu of the ReadTech Mobile Reading Application, providing learners with access to lessons, activities, and personalized learning features.

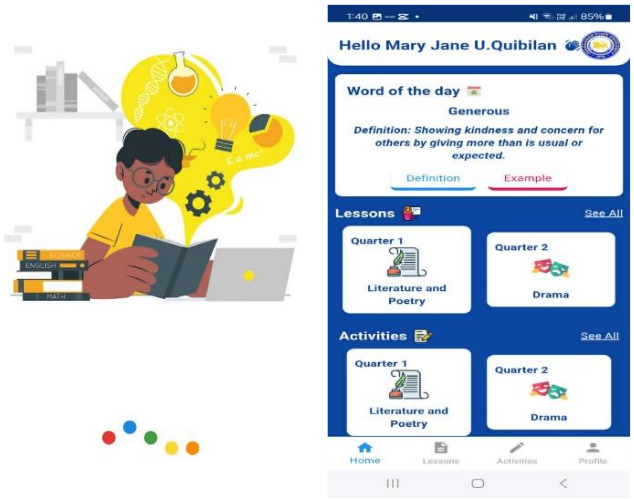

Fig. 2. The splash screen and main menu.

Fig. 3 illustrates the introductory lesson interface, which presents sample lessons and guides learners through the available instructional content.

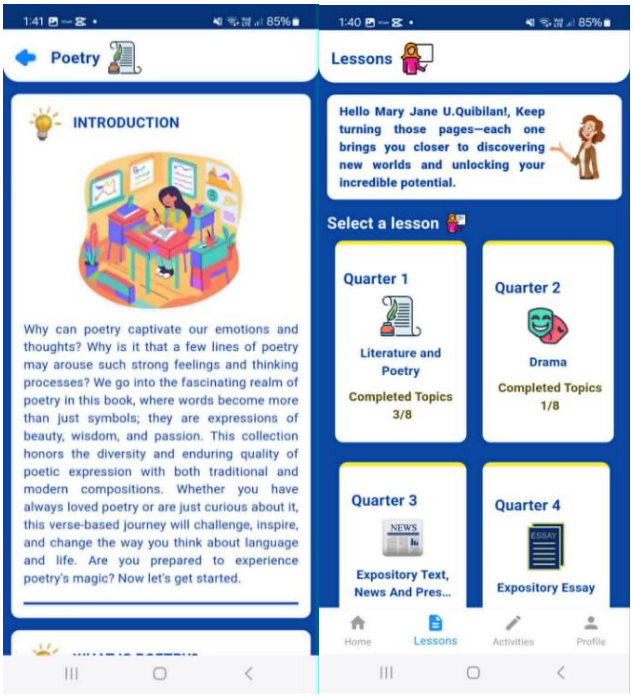

Fig. 3. The sample lessons introduction.

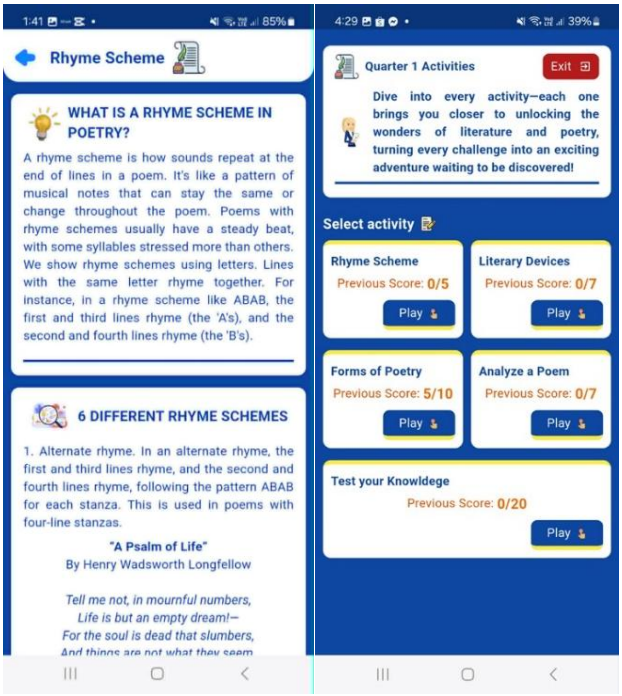

Fig. 4. The poetry lessons and rhyme scheme.

Fig. 4 presents the Poetry Lessons and Rhyme Scheme, which introduces rhyme schemes that guide the learners to different rhyme schemes.

Fig. 5. The literary devices lesson screen.

Fig. 5 presents the Literary Devices lesson screen, which introduces figures of speech and develops learners' interpretation of figurative language.

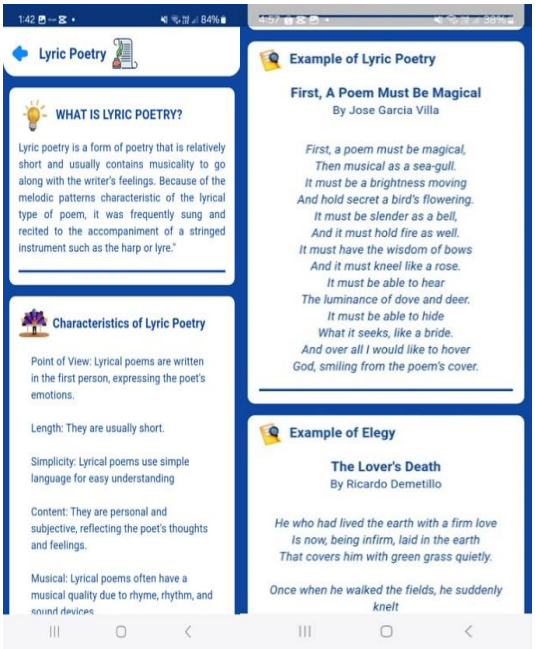

Fig. 6. The lyric poetry lesson screen.

Fig. 6 illustrates the Lyric Poetry lesson screen, presenting the characteristics and examples of lyric poems that express personal thoughts and emotions.

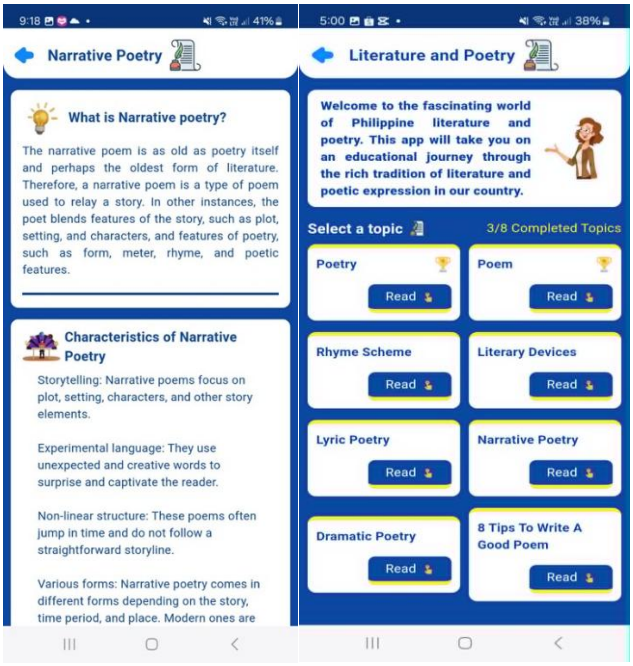

Fig. 7. The narrative poetry lesson screen.

Fig. 7 presents the Narrative Poetry lesson screen, introducing story-based poems and their narrative elements, including characters, setting, and plot.

Fig. 8. The poetry writing tips lesson screen.

Fig. 8 shows the Poetry Writing Tips lesson screen, providing guidelines and strategies for composing meaningful and creative poems.

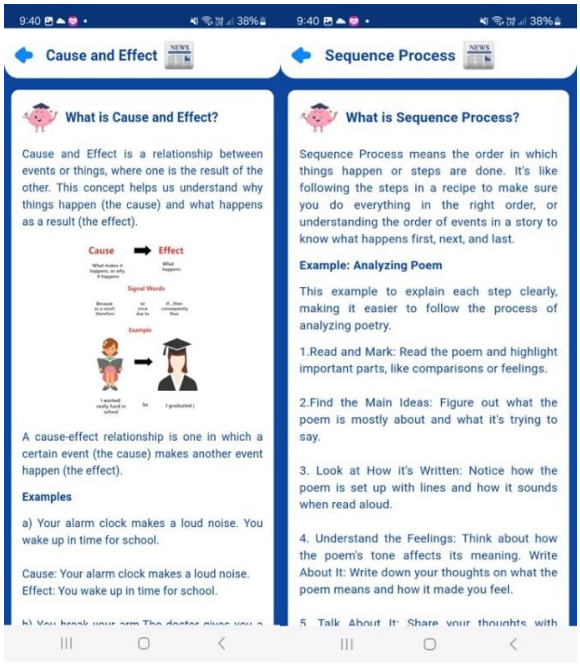

Fig. 9. The drama lessons menu.

Fig. 9 illustrates the Drama Lessons Menu, which contains the instructional modules and activities for the drama component of the Grade 7 English curriculum.

Fig. 10. The nature and history of drama lesson screen.

Fig. 10 presents the Nature and History of Drama lesson screen, introducing drama as a literary genre and explaining its characteristics and historical development.

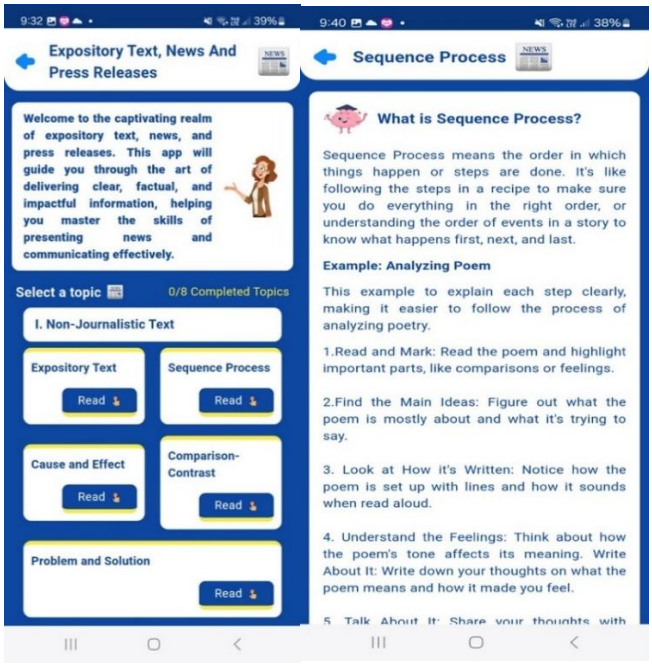

Fig. 11. The expository text lessons.

Fig. 11 shows the Expository Text lessons and activities, which develop learners' understanding of informational texts and organizational patterns.

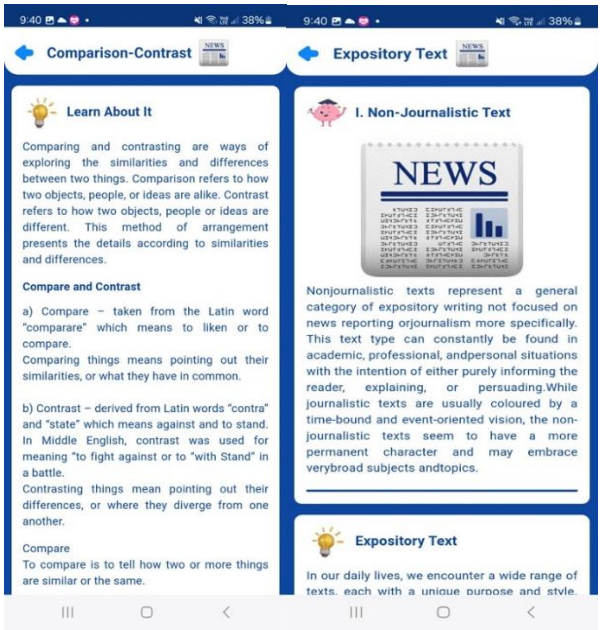

Fig. 12. The news and press releases lessons and learning activities.

Fig. 12 presents the News and Press Releases lesson screen, introducing journalistic texts and activities that enhance learners' comprehension of informational materials.

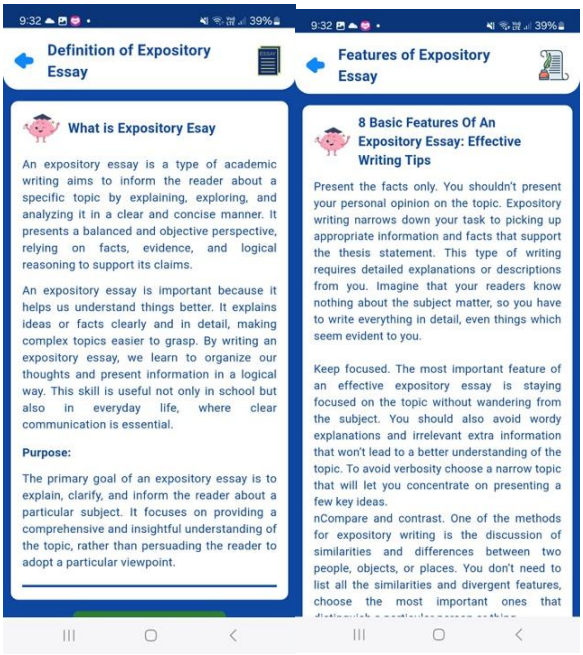

Fig. 13. The expository essay lesson.

Fig. 13 illustrates the Expository Essay lesson screen, which explains the structure and characteristics of expository writing, and Fig. 13. The Learning Activities and Assessment Dashboard.

B. Expert Validation

The completed ReadTech Mobile Reading Application was evaluated by six expert validators. Results are presented in Table V.

TABLE V. EXPERT VALIDATION RESULTS

Criterion	Mean	Interpretation
Content Quality	4.50	Highly Valid
Accuracy of Tasks	4.83	Highly Valid
Instructional Design Quality	4.67	Highly Valid
Technology and Usability	4.83	Highly Valid
Overall Mean	4.71	Highly Valid

The expert validators rated the application as highly valid across all dimensions. The highest ratings were obtained in Accuracy of Tasks and Technology and Usability. These results indicate that the learning activities, assessment components, instructional design, and technological features are appropriate for the intended users and aligned with the objectives of the application.

C. Acceptability of the ReadTech Mobile Reading Application

Following expert validation and revision, the application was evaluated by student-users. Table VI presents the acceptability results.

The overall acceptability mean of 4.47 indicates that learners found the application highly acceptable. Among the evaluated dimensions, Engagement obtained the highest rating, followed by Functionality and Usefulness. The results suggest that learners perceived the application as interactive, motivating, and beneficial for reading development.

TABLE VI. ACCEPTABILITY OF THE READTECH MOBILE

Dimension	Mean	Interpretation
Usability	4.30	Highly Acceptable
Functionality	4.48	Highly Acceptable
Engagement	4.65	Highly Acceptable
Usefulness	4.43	Highly Acceptable
Overall Mean	4.47	Highly Acceptable

D. Discussions

The identified learner needs directly informed the design of the ReadTech Mobile Reading Application. For example, the high demand for vocabulary-building activities resulted in the integration of the "Word of the Day" module, while the need for structured reading comprehension activities led to the development of curriculum-aligned reading lessons, quizzes, and progress-monitoring features. Likewise, learners' preference for gradual learning progression guided the implementation of the level-unlocking mechanism, allowing students to complete prerequisite lessons before accessing more advanced instructional content. The Design and Development Research methodology facilitated an iterative development process in which learner needs, expert recommendations, and usability considerations were continuously incorporated into the application. Such an approach is consistent with learner-centered instructional design, where educational technologies are developed based on the characteristics and requirements of their intended users rather than solely on technological considerations.

The expert validators rated the application highly across all evaluation criteria, including content quality, instructional design, task accuracy, and technology usability. These findings indicate that the instructional content is appropriate for the intended learners and aligned with the Grade 7 English MATATAG Curriculum. High ratings in task accuracy further suggest that the learning activities and assessments accurately represent the targeted learning competencies, while high usability ratings indicate that the application's interface, navigation, and overall functionality are suitable for classroom implementation. It is important to recognize that expert validation evaluates the quality of the developed educational product rather than its instructional effectiveness. High validity demonstrates that specialists consider the application educationally appropriate and technically sound; however, it does not provide evidence that learners achieve measurable improvements in reading comprehension after using the application.

Student-users also rated the application as highly acceptable across usability, functionality, engagement, and usefulness. The highest rating was obtained in engagement, indicating that learners found the application interesting and motivating to use. High usability scores further suggest that learners were able to navigate the application with minimal difficulty, while functionality and usefulness ratings indicate that the application successfully supports the intended instructional activities.

Nevertheless, learner acceptability should not be interpreted as evidence of improved academic performance. Acceptability reflects users' perceptions of the application's quality, convenience, and learning experience rather than objective improvements in reading ability. Consequently, the present findings demonstrate that learners positively received the application but do not establish causal improvements in reading comprehension or vocabulary acquisition.

The present study has several limitations. First, the evaluation focused primarily on learner needs assessment, expert validation, and student acceptability rather than instructional effectiveness. Consequently, no pretest–posttest or comparison-group design was conducted to determine whether ReadTech produces measurable improvements in learners' reading comprehension or vocabulary development. Second, the participants were drawn from two integrated schools within one municipality, which may limit the generalizability of the findings to other educational contexts. Finally, the study relied on descriptive statistical analyses because its primary objective was to evaluate the developed application rather than determine causal relationships. Future research should conduct quasi-experimental or experimental evaluations to investigate the effects of ReadTech on reading achievement, vocabulary acquisition, learner motivation, and long-term literacy development across diverse educational settings, but do not establish causal improvements in reading comprehension or vocabulary acquisition.

E. Implication of the Findings

The findings imply that Grade 7 learners require technology-supported interventions to address challenges in reading comprehension, vocabulary development, and learner engagement. The high validity and acceptability of the mobile reading application indicate that mobile-based learning can effectively supplement traditional reading instruction by promoting interactive, personalized, and self-paced learning. The results further suggest that schools and educators should integrate mobile applications into literacy programs to enhance reading outcomes and support continuous monitoring of learners' progress.

IV. Conclusion and Recommendations

A. Conclusion

This study successfully developed the ReadTech Mobile Reading Application using a Design and Development Research methodology. The application demonstrated high levels of expert validity and learner acceptability, indicating that it is a feasible and curriculum-aligned instructional resource for supporting reading instruction among Grade 7 learners. Because the present study focused on development and evaluation rather than instructional effectiveness, future research should investigate the impact of ReadTech on reading comprehension and vocabulary acquisition using experimental research designs.

B. Recommendations

Future implementations of ReadTech may involve a larger and more diverse group of learners to determine its effectiveness across different educational settings. Experimental studies may also be conducted to measure the application's impact on reading achievement and long-term retention. Additional features such as adaptive learning analytics, gamification elements, multilingual support, and teacher dashboards may be integrated to further improve learner engagement and instructional monitoring. Schools and educators are likewise encouraged to adopt and integrate mobile learning applications such as ReadTech into literacy programs to enhance reading instruction and support continuous learner development.

Acknowledgment

The researcher sincerely acknowledges Pangasinan State University for its valuable support in the completion of this study. Artificial intelligence tools were utilized to enhance language quality, improve content organization, and assist with formatting. Nevertheless, all aspects of the research, including the methodology, analysis, results, interpretations, and conclusions, were independently conducted, reviewed, and validated by the researcher to uphold academic integrity and ensure the originality of the work.

A Blockchain-Based Role-Based Access Control Gateway for Secure Electronic Health Record Access and Tamper-Evident Auditing

Osamah Saleh, Shouki A. Ebad
Department of Computer Science-College of Science, Northern Border University, Arar, Saudi Arabia[1]

***Abstract*—Electronic Health Record (EHR) systems store sensitive patient information and require strong access control and reliable audit records. Traditional centralized Role-Based Access Control (RBAC) systems may be vulnerable to unauthorized access, privilege escalation, audit-log modification, and undetected changes to stored records. This study developed a lightweight blockchain-based RBAC gateway integrated with OpenMRS. The system used three roles, Admin, Doctor, and Patient, and one Solidity smart contract to manage role assignments, Doctor–Patient permissions, access decisions, trusted record hashes, and blockchain audit events. A Node.js gateway acted as the policy-enforcement point, while SQLite was used as a centralized audit-log baseline. The system was evaluated through authorized-access, unauthorized-access, privilege-escalation, audit-log tampering, EHR data-tampering, gas-use, and throughput experiments. All 50 measured authorized requests were allowed and completed the expected OpenMRS retrieval workflow, while all 50 unauthorized-access attempts were blocked before reaching OpenMRS. The SQLite decision could be changed from deny to allow, while the corresponding blockchain event remained unchanged. The trusted-hash experiment detected all 10 simulated EHR modifications. Median end-to-end latency was 31.8 ms for denied requests and 468.9 ms for authorized requests. Sequential smart contract throughput averaged 15.0850 TPS for authorized access and 15.4214 TPS for unauthorized access. These findings show that the proposed gateway can improve access-control enforcement, detect off-chain record changes, and provide tamper-evident audit evidence without storing full EHR records on-chain.**

Keywords*—Electronic health records; role-based access control; blockchain; smart contracts; OpenMRS; audit logs; access control; cybersecurity

I. Introduction

Electronic Health Record (EHR) systems are widely used by healthcare organizations to store, manage, and exchange patient information in digital form. EHRs can include personal information, diagnoses, medications, allergies, laboratory results, treatment plans, and clinical notes. EHR systems can improve healthcare quality, efficiency, documentation, and access to clinical information [1]. However, because EHR systems include sensitive data that should only be accessible by authorized users, using digital health records also poses significant cybersecurity and privacy threats [2].

Healthcare organizations must protect the confidentiality, integrity, and availability of patient records. Confidentiality means that medical information is only available to permitted users. Integrity means that data and system records cannot be changed without authorization. Availability means that authorized healthcare users can access the required information when it is needed. These security goals are important in healthcare because unauthorized access or manipulation of patient information can cause privacy violations, incorrect medical decisions, and loss of trust in the healthcare system [3]. Healthcare software projects can also face significant design and implementation challenges, particularly when system requirements, architecture, and stakeholder needs are not adequately aligned [21].

Access control is one of the main security mechanisms used to protect EHR systems. Role-Based Access Control (RBAC) is commonly used because it assigns permissions to roles rather than directly to individual users. Users then receive permissions according to their assigned organizational role [4]. For example, an administrator may manage user roles, a doctor may access the records of assigned patients, and a patient may access only their own medical record. RBAC supports the principle of least privilege because each user should receive only the permissions required to perform their work [3,4].

Many traditional RBAC implementations depend on a centralized server or database that manages role assignments, access decisions, and audit logs. This creates a single point of failure. If an external attacker or malicious insider gains sufficient privileges, the attacker may access medical records without permission, assign higher roles, or modify audit logs to hide evidence of misuse. Centralized logs are important for monitoring and incident investigation, but their value is reduced if a privileged attacker can alter or delete them [5].

To ensure accountability, audit logs must document who requested access, what resource was requested, when the request was made, and whether access was approved or denied. According to NIST log-management guidance, security logs support monitoring, incident response, troubleshooting, and forensic investigation [5]. However, storing audit evidence only in a conventional centralized database may not provide strong protection against an administrator or attacker who has direct access to that database.

Blockchain technology provides a possible method for improving audit-log integrity. A blockchain is a distributed ledger in which transactions are grouped into blocks and linked using cryptographic hashes. This structure makes previously recorded transactions difficult to modify without detection [6]. Smart contracts can also automatically enforce access-control

rules and record access decisions as blockchain events. Therefore, blockchain can be used as a tamper-evident audit layer while the full medical records remain outside the blockchain.

This study develops a lightweight blockchain-based RBAC gateway integrated with OpenMRS. OpenMRS is used as the off-chain EHR platform containing synthetic patient records. A Node.js gateway acts as the policy-enforcement point between users and OpenMRS. Before an EHR record is retrieved, the gateway sends an access request to a Solidity smart contract deployed on a local Ethereum-compatible blockchain. The smart contract checks the requester's role and doctor–patient permission and records the access decision in a tamper-evident blockchain audit trail.

The system applies Admin, Doctor, and Patient roles with explicit Doctor–Patient permissions. The implementation also uses a centralized SQLite audit log as a comparison baseline. The system was evaluated through authorized-access requests, unauthorized-access attempts, privilege-escalation attempts, audit-log tampering experiments, EHR data-tampering experiments, gas-use measurements, and sequential throughput testing.

The main contributions of this study are as follows:

- A lightweight smart contract-based RBAC model for controlling access to synthetic EHR records stored in OpenMRS.
- An explicit Doctor–Patient permission model in which Doctors can access only assigned Patient records.
- A blockchain audit mechanism that records both successful and denied access requests.
- A gateway architecture that prevents unauthorized OpenMRS record retrieval before the EHR platform is contacted.
- An experimental comparison between tamper-evident blockchain audit records and a mutable centralized SQLite audit log.
- A security evaluation covering unauthorized access, privilege escalation, audit-log tampering, and EHR data tampering.
- On-chain EHR hash verification for detecting simulated off-chain record modification.
- A performance evaluation covering blockchain latency, end-to-end latency, gas usage, and sequential smart contract throughput.

II. Related Work

Several studies have investigated blockchain-based access control, auditability, and medical-record management. These studies show that blockchain can support tamper-evident access records and automated authorization, but they differ in access-control model, blockchain platform, storage design, and evaluation approach.

Ullah et al. proposed a blockchain-enabled framework for EHR access auditing using Purpose-Based Access Control (PBAC) and smart contracts [7]. Their framework records access events in an immutable audit trail and verifies whether an access request is consistent with the defined access purpose. The study mainly focuses on audit accountability and policy verification. In contrast, the present study uses a simpler RBAC model and evaluates specific security scenarios, including unauthorized access, privilege escalation, centralized audit-log tampering, and EHR data tampering.

Joshi and Mahajan proposed MrBlock, a secure and interoperable EHR-management framework based on Hyperledger Fabric [8]. MrBlock combines RBAC and Attribute-Based Access Control (ABAC) with smart contracts and uses the Raft consensus mechanism. Their evaluation reported lower average latency and higher throughput than a PBFT-based configuration. MrBlock provides a broader healthcare-sharing framework, while the present work focuses on a lightweight gateway architecture integrated with OpenMRS and uses one smart contract for access decisions, audit events, and trusted record hashes.

Taloba and Rayan proposed a privacy-preserving medical-data management framework using blockchain-enabled encrypted RBAC [9]. Their system combines smart contracts, encrypted storage, blockchain, and IPFS to reduce unauthorized access, data leakage, and privilege misuse. This approach provides a more comprehensive privacy-management architecture. The present work instead focuses on a smaller proof of concept in which OpenMRS remains the off-chain EHR platform, while blockchain is used only for access-control decisions, trusted hashes, and tamper-evident audit evidence.

Yaqub et al. developed a blockchain-enabled policy-based access-control mechanism for preventing unauthorized EHR access [10]. Their model uses smart contracts to enforce policy and consent rules and record access decisions. Although this approach also uses blockchain for automated authorization, it is based on PBAC rather than RBAC. The present study uses three explicit RBAC roles and Doctor–Patient permission mappings so that the authorization rules can be evaluated through clear and repeatable security test cases.

Tahir et al. proposed a blockchain-based healthcare-records management framework focused on security, privacy, and interoperability [11]. Their work addresses broader healthcare-record management problems and explains how blockchain can reduce centralized trust and improve integrity. The current study has a narrower scope and concentrates specifically on access enforcement, audit-log comparison, record-integrity verification, and measurable security testing in an OpenMRS-based environment.

MedRec, proposed by Azaria et al., is one of the early blockchain-based systems for medical-data access and permission management [12]. MedRec demonstrated that blockchain can be used to manage permissions and maintain an auditable history of medical-record access while the medical records themselves remain outside the blockchain. This separation between on-chain permission evidence and off-chain EHR data is also reflected in the present design. However, MedRec was designed as a broader medical-record permission-

management system and was not evaluated using the specific attack scenarios considered in this study.

Table I compares the reviewed systems with the proposed approach.

TABLE I. COMPARISON OF RELATED BLOCKCHAIN-BASED EHR APPROACHES

Study	Access-control model	Blockchain/ platform	EHR storage approach	Audit mechanism
Ullah et al. [7]	PBAC	Blockchain with smart contracts	EHR remains outside audit layer	Immutable access audit trail
MrBlock [8]	RBAC + ABAC	Hyperledger Fabric / Raft	Distributed EHR-management framework	Blockchain-based transaction records
Taloba and Rayan [9]	Encrypted RBAC	Blockchain + smart contracts + IPFS	Encrypted distributed/off-chain storage	Tamper-resistant access records
Yaqub et al. [10]	PBAC	Blockchain / smart contracts	Off-chain EHR with policy enforcement	Blockchain access-decision records
Tahir et al. [11]	Smart-contract-based control	Blockchain healthcare framework	Hybrid healthcare-record management	Blockchain-based auditability
MedRec [12]	Permission management	Ethereum-based blockchain	Medical records remain off-chain	Blockchain permission/access history
Proposed system	RBAC with Doctor–Patient mapping	Local Ethereum-compatible blockchain	OpenMRS off-chain; trusted hashes on-chain	Blockchain audit events plus SQLite comparison baseline

The comparison shows that most previous studies focus on broader EHR-sharing, interoperability, privacy, or policy-management frameworks. Fewer studies combine a lightweight RBAC gateway, a real open-source EHR platform, direct comparison between blockchain and a mutable centralized audit log, attack-based security testing, and trusted off-chain record-hash verification within the same proof of concept. The novelty of the present study is therefore not the use of blockchain or RBAC individually, but the integration of these mechanisms into a focused OpenMRS gateway that is evaluated through explicit security attacks and measurable audit, integrity, latency, gas, and throughput results.

III. MATERIALS AND METHODS

A. Research Design

This study followed a design and experimental evaluation approach. A lightweight blockchain-based Role-Based Access Control (RBAC) gateway was designed, implemented, and tested using a local laboratory environment.

The implementation did not replace the internal access-control system of OpenMRS. Instead, it introduced an external security gateway between the requesting user and the OpenMRS REST API. All EHR access requests passed through this gateway before any patient record was retrieved.

B. System Architecture

The system consisted of five main components:

- An OpenMRS EHR platform containing synthetic patient records.
- A Node.js and Express gateway acting as the policy-enforcement point.
- A Solidity smart contract deployed on a local Ethereum-compatible blockchain.
- A centralized SQLite audit-log database used as a comparison baseline.
- Automated scripts used to configure the environment, run experiments, and collect results.

Fig. 1 presents the interaction among the gateway, smart contract, OpenMRS, and SQLite baseline. The detailed access process is described in Section III-A. The main trust relationships and assumed attacker capabilities are defined in the following threat model.

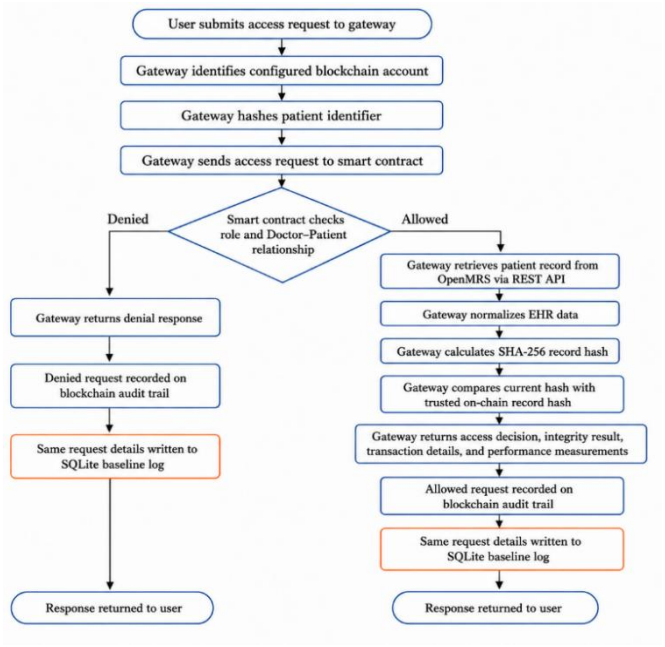

Fig. 1. Workflow of the proposed blockchain-based RBAC gateway for authorized and denied EHR access requests.

C. Threat Model and Trust Assumptions

The prototype assumes that the local blockchain network and deployed smart contract operate correctly and that previously recorded blockchain events cannot be modified through the normal application interfaces. The admin blockchain account is treated as trusted because it is responsible for assigning roles, granting Doctor–Patient permissions, linking Patient accounts, and registering trusted EHR hashes.

The gateway is also treated as a trusted enforcement component in the current proof of concept. It maps configured users to blockchain accounts, submits access requests to the smart contract, retrieves authorized records from OpenMRS, performs record hashing, and writes the centralized SQLite audit entry. Compromise of the gateway is therefore outside the protection provided by the current prototype and could allow request contents or user mappings to be manipulated. The trust

boundaries, trusted components, sensitive credentials, and evaluated attacker paths are illustrated in Fig. 2.

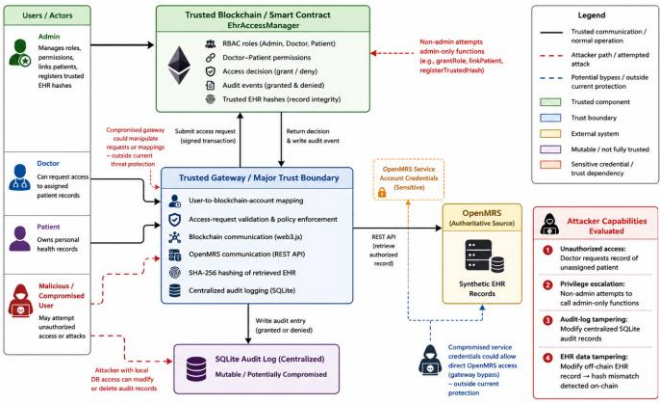

Fig. 2. Trust boundaries, trusted components, sensitive credentials, and potential attacker paths in the proposed blockchain-based RBAC gateway architecture.

OpenMRS is treated as the authoritative off-chain source of the synthetic EHR data, while the OpenMRS service credentials are considered sensitive trusted credentials. The gateway uses these credentials only after blockchain authorization. If the service credentials are compromised and OpenMRS can be accessed directly, an attacker could bypass the blockchain gateway. This limitation is considered part of the system trust boundary.

Doctor and Patient blockchain accounts are not assumed to be trusted. They may submit unauthorized access requests or attempt operations outside their assigned permissions. The smart contract is responsible for enforcing the defined RBAC policy against these accounts.

The SQLite audit log is intentionally treated as a mutable and potentially compromised component. An attacker with sufficient local database access may modify its contents. The blockchain audit trail provides the independent reference used to detect such modification.

The evaluated attacker model therefore includes: 1) a Doctor attempting unauthorized access to an unassigned Patient record; 2) a non-admin account attempting privilege escalation; 3) an attacker modifying the centralized SQLite audit record; and 4) modification of an off-chain EHR representation that causes a mismatch with the trusted on-chain hash. The current evaluation does not assume compromise of the blockchain consensus mechanism, Admin private key, gateway host, or OpenMRS service credentials.

D. Security Properties

The security properties evaluated in this study are defined as follows. Access-control enforcement means that an access request is granted or denied according to the implemented RBAC role and Doctor–Patient permission rules. Tamper-evidence means that modification of the centralized SQLite audit record can be detected by comparing it with the corresponding blockchain audit event. Record integrity verification means that the SHA-256 hash calculated from the current canonicalized EHR record matches the trusted hash registered on-chain. Privilege-escalation prevention means that a non-admin account cannot successfully perform Admin-only role-management operations.

The term secure access is used in this study only to describe access that has passed the implemented authorization checks. It does not imply complete end-to-end security of the gateway, OpenMRS platform, user authentication, service credentials, or blockchain infrastructure (Table II).

TABLE II. MAPPING OF SECURITY PROPERTIES TO EXPERIMENTS

Security property	Experiment	Validation criterion
Access-control enforcement	Authorized-access test	Assigned Doctor request is allowed according to RBAC policy
Access-control enforcement	Unauthorized-access test	Unassigned Doctor request is denied before OpenMRS retrieval
Privilege-escalation prevention	Privilege-escalation test	Non-admin role-management request is rejected, and role remains unchanged
Tamper-evidence	Audit-log tampering test	SQLite modification creates a discrepancy with the unchanged blockchain audit event
Record integrity verification	EHR data-tampering test	Modified EHR content produces a hash mismatch with the trusted on-chain hash
Record integrity verification	JSON canonicalization test	Equivalent JSON representations produce the same hash, while changed clinical content produces a different hash
Record provenance	Versioned record-update test	New trusted state increments the version and links to the previous trusted hash
Workflow outcome consistency	Failure and partial-operation tests	Outcome distinguishes blockchain authorization from EHR retrieval success or failure
Duplicate-request prevention	Duplicate-request test	Repeated requestId is rejected before a second access operation is processed

E. Gateway Identity and Request Integrity

In the current proof of concept, the gateway uses a predefined mapping between synthetic actor names and blockchain accounts. This mapping is stored as trusted local configuration and is used to select the blockchain account that submits each access request. Therefore, the prototype assumes that the gateway configuration has not been modified and that the actor-to-account mapping is correct.

The current implementation does not cryptographically bind an external human identity to the submitted request payload. A compromised gateway could therefore alter the actor mapping, patient identifier, or requested action before submitting the transaction to the smart contract. This limitation is outside the protection provided by the present proof of concept.

In a production deployment, users should first be authenticated using a secure identity mechanism. Access requests should then be cryptographically signed using the user's wallet or another trusted signing mechanism. The signed request should include the user identity, patient identifier, requested action, nonce, and timestamp. The gateway should verify the signature, nonce, and timestamp before submitting the request to the smart contract. This would bind the authenticated

user to the request contents and reduce the risk of gateway-level request manipulation and replay attacks.

F. Development and Experimental Environment

The prototype was implemented in a local and controlled testing environment. OpenMRS was selected because it is an open-source medical-record platform that provides patient-management functions and REST API support [13]. The blockchain access-control logic was implemented using Solidity [14] and deployed through the Hardhat development environment [15].

The gateway communicated with the smart contract, retrieved authorized records from OpenMRS, calculated record hashes, wrote centralized audit logs, and collected experimental measurements.

SQLite was used as the centralized audit-log baseline because it provides a lightweight relational database that can be stored and modified locally [16].

The experimental environment is detailed in Table III.

TABLE III. EXPERIMENTAL ENVIRONMENT AND SOFTWARE TOOLS

Component	Tool or specification
EHR platform	OpenMRS Reference Application 3.7.0
EHR database	MariaDB
Smart-contract language	Solidity 0.8.24
Local blockchain framework	Hardhat 3.3.0
Blockchain library	Ethers.js 6.16.0
Gateway runtime	Node.js 22.16.0
Gateway framework	Express 5.2.1
Centralized audit database	SQLite
Hash algorithm	SHA-256
Testing scripts	JavaScript and PowerShell
Operating system	Microsoft Windows 11 Home 64-bit, version 10.0.26200 (Build 26200)
Processor	Intel(R) Core(TM) i5-10500H CPU @ 2.50GHz, 6 cores / 12 logical processors
Memory	16 GB RAM

G. Smart-Contract Design

One smart contract named EhrAccessManager was developed to manage roles, patient relationships, access decisions, record hashes, and blockchain audit records. The contract represented the Admin, Doctor, Patient, and unassigned account states.

The blockchain account that deployed the contract automatically received the Admin role. The Admin was allowed to assign and revoke roles, link a Patient account to a patient record, grant or revoke Doctor access to a Patient, and register a trusted EHR record hash.

The main smart contract functions were:

- assignRole, which assigned a role to a blockchain account;
- revokeRole, which removed an assigned role;
- linkPatientRecord, which linked a Patient account to a hashed patient identifier;
- grantDoctorPatientAccess, which granted a Doctor permission to access a specific Patient;
- revokeDoctorPatientAccess, which removed this permission;
- storePatientRecordHash, which created a new versioned EHR commitment containing the current record hash and a link to the previous trusted hash;
- verifyPatientRecordHash, which compared a calculated record hash with the trusted on-chain hash;
- requestAccess, which evaluated an access request and created an audit event;
- canAccess, which returned the expected access decision without changing the blockchain state;
- getAuditEvent, which returned a previously stored audit record.
- getLatestPatientRecordCommitment, which returned the latest version number, record hash, previous hash, timestamp, and updater address;
- getPatientRecordVersionCount, which returned the number of trusted record versions registered for a patient.

Role-management and trusted-hash functions were protected using an Admin-only modifier. A non-admin blockchain account attempting to call these functions caused the transaction to be rejected.

H. Access-Control Policy

The implemented access policy used three active roles: Admin, Doctor, and Patient. The implemented access rules are summarized in Table IV.

TABLE IV. IMPLEMENTED RBAC PERMISSIONS

Role	Access permission
Admin	Access all patient records and manage roles, permissions, patient links, and trusted hashes
Doctor	Access only explicitly assigned Patient records
Patient	Access only the record linked to the Patient's blockchain address
None	No access to patient records

The Doctor–Patient mapping provided more specific control than allowing every Doctor to access every medical record. This supported the least-privilege principle because a Doctor received access only to assigned Patients.

I. Gateway Access Workflow

The gateway received access requests containing an actor name, patient identifier, and requested action. The actor name represented a synthetic user configured in the controlled experiment. Each configured actor was associated with a blockchain account and private key stored in the local testing environment.

For every access request, the gateway performed the following steps:

- It validated the actor name, patient identifier, and requested action.
- It selected the blockchain account associated with the actor.
- It converted the patient identifier into a bytes32 hash using the Ethereum Keccak-256 hashing function.
- It submitted the access request to the smart contract.
- It read the resulting access decision and blockchain audit event.
- If access was denied, it returned an HTTP denial response and did not contact OpenMRS.
- If access was granted, it retrieved the corresponding patient record from OpenMRS.
- It canonicalized the returned JSON data using a deterministic serialization procedure before hashing.
- It generated a SHA-256 hash of the canonicalized record.
- It compared the calculated hash with the trusted record hash stored on-chain.
- It wrote an equivalent audit entry to SQLite.
- It recorded latency, gas usage, transaction-fee information, and supporting evidence.

Before calculating the SHA-256 hash, the gateway converted the retrieved EHR JSON into a deterministic representation. Object keys were sorted recursively in lexical order, while array element order was preserved. The resulting structure was serialized as compact JSON without additional whitespace and encoded using UTF-8 before the SHA-256 digest was calculated. This procedure ensured that differences in object-key ordering or formatting did not produce different hashes for logically equivalent records [18].

SHA-256 was used because it produces a fixed 256-bit digest suitable for detecting changes in the EHR record [17].

The gateway used one OpenMRS service account to retrieve approved records. Therefore, the blockchain and gateway provided the research access-control layer, while OpenMRS remained the off-chain EHR platform. This design was suitable for the local proof of concept but was not intended to represent a complete production authentication system.

J. Synthetic EHR Dataset

Only synthetic and non-identifying patient information was used. The experimental dataset contained five synthetic patient records stored in OpenMRS, as summarized in Table V. Each logical patient identifier was mapped to an OpenMRS UUID. The records contained simplified information such as diagnosis and medication.

The patient identifiers used in blockchain operations were hashed before being stored or included in access-control mappings. The full medical records were not stored on-chain. Only hashed identifiers, access decisions, role-related information, record hashes, timestamps, and audit information were placed on the blockchain.

TABLE V. SYNTHETIC EHR RECORDS USED IN THE EXPERIMENTS

Patient identifier	Example diagnosis	Example medication
P001	Hypertension	Amlodipine 5 mg
P002	Type 2 diabetes	Metformin 500 mg
P003	Asthma	Salbutamol inhaler
P004	Hyperlipidemia	Atorvastatin 20 mg
P005	Ischemic heart disease	Aspirin 81 mg

K. Trusted Record-Hash Registration and Verification

To support EHR integrity verification, the Admin first retrieved an approved patient record from OpenMRS through a trusted registration operation. The gateway canonicalized the returned JSON record and calculated its SHA-256 hash. The Admin then stored this value in the smart contract as the trusted hash for that patient identifier.

The trusted hash was not automatically replaced during ordinary access requests. This was necessary because automatically storing the latest hash could allow an unauthorized modification to become accepted as the new trusted state.

During every successful EHR access, the gateway calculated the current record hash and compared it with the trusted on-chain value. A mismatch indicated that the current OpenMRS record differed from the previously registered trusted version.

A legitimate update to a patient record required a separate Admin-controlled registration operation that created a new trusted commitment while preserving the previous version in the on-chain history.

L. Versioned Record Commitments

The trusted EHR commitment mechanism was extended to preserve update provenance rather than storing only the latest record hash. Each patient record commitment contains a version number, the SHA-256 record hash, the hash of the previous trusted version, the blockchain timestamp, and the address of the Admin account that registered the update. The first registered record is assigned version 1 with no previous hash. Each subsequent legitimate update creates a new version and links it to the hash of the preceding trusted record.

The smart contract maintains the commitment history separately for each hashed patient identifier. Integrity verification compares the current canonicalized EHR hash with the latest registered commitment, while previous versions remain available for provenance inspection. This design allows legitimate updates to be distinguished from unexplained record modification and provides a chronological chain of trusted record states.

M. JSON Canonicalization Validation

A separate validation experiment was performed to confirm that the hashing process was not affected by irrelevant JSON formatting or object-key ordering. The same synthetic EHR record was represented using different object-key orders and

then passed through the canonicalization procedure. The resulting canonical representations and SHA-256 hashes were compared.

A second version of the record was then created by changing one clinical value while keeping the remaining data unchanged. The modified record was canonicalized and hashed using the same procedure. The expected result was that logically equivalent records with different key ordering would produce the same SHA-256 hash, while a clinically modified record would produce a different hash.

N. Centralized Audit-Log Baseline

A SQLite database was used to create a centralized audit-log baseline. For each access request, the database stored the timestamp, actor, patient identifier, requested action, access decision, blockchain transaction hash, calculated record hash, integrity-verification result, performance measurements, and experimental notes.

The SQLite log was not used to make access decisions. Its purpose was to provide a conventional mutable log for comparison with the blockchain audit trail.

O. Security Test Scenarios

Six main security scenarios were evaluated.

1) Unauthorized-access test: An unauthorized Doctor account requested access to a Patient record for which no Doctor–Patient permission had been granted.

2) Privilege-escalation test: A Doctor account attempted to call the Admin-only role-assignment function and assign an Admin role. The target account's role was checked before and after the attempt to determine whether an unauthorized role change occurred.

3) Audit-log tampering test: A completed denied-access record was selected from both SQLite and the blockchain audit trail. The decision stored in SQLite was manually modified from deny to allow.

The corresponding blockchain audit event was then read again. Tampering was considered detected when the SQLite value differed from the unchanged blockchain decision.

This experiment demonstrated the difference between a centralized log that could be directly edited and a blockchain audit record that remained tamper-evident.

4) EHR data-tampering test: A trusted patient record was retrieved from OpenMRS and its original SHA-256 hash was verified against the value registered on-chain.

A copy of the record was then modified in memory by changing one clinical field. The modified record was not written back to the live OpenMRS database because the purpose was to test integrity detection without damaging the laboratory dataset.

The gateway generated a new SHA-256 hash for the modified record and submitted it to the smart contract verification function.

5) Versioned record-update test: A trusted hash was first registered for the original P001 record as version 1. A legitimate updated record was then canonicalized and hashed, after which the Admin registered the new hash as version 2. The experiment checked that the latest commitment reported version 2, contained the new record hash, and stored the version 1 hash as its previous hash. The updater address and blockchain timestamp were also retrieved to verify update provenance.

6) Failure and partial-operation tests: Additional tests evaluated cases in which blockchain authorization succeeded, but the subsequent OpenMRS operation did not complete normally. The tested conditions included an HTTP 404 response, simulated timeout, unavailable OpenMRS service, transient failure followed by retry, and submission of a duplicate request identifier.

The gateway recorded an outcome separately from the blockchain authorization decision. An authorized request with successful OpenMRS retrieval was recorded as authorization_allowed_retrieval_success, while an authorized request followed by an OpenMRS failure was recorded as authorization_allowed_retrieval_failed. A request denied by the smart contract was recorded as authorization_denied. Duplicate request identifiers were rejected before a second access operation was processed.

These tests were designed to determine whether the audit evidence could distinguish authorization success from successful completion of the complete EHR retrieval workflow.

The security scenarios are summarized in Table VI.

TABLE VI. SECURITY TEST SCENARIOS AND EXPECTED RESULTS

Scenario	Testing method	Expected result
Unauthorized access	Unassigned Doctor requests P001	Access denied, logged, and OpenMRS not contacted
Privilege escalation	Doctor calls Admin-only role-assignment function	Operation rejected and role unchanged
Audit-log tampering	SQLite decision changed while blockchain event is preserved	Difference detected
EHR data tampering	Modified record hash compared with trusted on-chain hash	Hash mismatch detected
Versioned record update	Admin registers a second trusted record state	Version increases to 2 and previousHash links to the version 1 trusted hash
OpenMRS retrieval failure	Authorized request followed by 404, timeout, or unavailable service	Authorization remains allowed but outcome records retrieval failure
Retry handling	First retrieval fails, and one retry is permitted	Retry is recorded, and successful retrieval produces success outcome
Duplicate request	Same request identifier submitted twice	Second request rejected as duplicate

P. Performance Evaluation

For each operation, the system recorded:

blockchain latency;

- OpenMRS retrieval latency;
- total end-to-end latency;

- transaction gas used;
- effective gas price;
- estimated transaction fee;
- transaction hash;
- access decision.

Blockchain latency represented the time required to simulate, submit, confirm, and process the smart contract transaction. OpenMRS latency represented the time needed to retrieve an authorized medical record. Total latency represented the complete time from receiving the gateway request until producing the final response.

Gas usage was obtained from the blockchain transaction receipt. The estimated transaction fee was calculated as:

$$Transaction\ Fee = Gas\ Used\ x\ Effective\ Gas\ Price \quad (1)$$

Gas was reported separately for role assignment, Patient linking, Doctor–Patient permission management, trusted-hash registration, authorized access, and unauthorized access.

Rejected privilege-escalation attempts that failed during pre-transaction simulation were reported as rejected operations without gas consumption because no blockchain transaction was submitted.

Q. Throughput Experiment

A small sequential throughput experiment was performed to measure how many smart contract access transactions the local blockchain could complete per second.

Two workloads were used:

- authorized Doctor access to an assigned Patient record;
- unauthorized Doctor access to an unassigned Patient record.

Each workload contained 20 sequential smart contract access transactions and was repeated three times. Sequential execution was selected to avoid nonce conflicts caused by submitting concurrent transactions from the same blockchain account.

Throughput was calculated as:

$$Throughput = \frac{Number\ of\ Completed\ Requests}{Total\ Experiment\ Time\ in\ Seconds} \quad (2)$$

The experiment recorded the status, access decision, individual latency, and transaction hash for each request. The mean throughput and standard deviation were calculated across the repeated runs.

The experiment measured sequential smart contract transaction throughput and did not include the complete OpenMRS retrieval workflow.

R. Data Collection and Evidence Preservation

Experimental results were automatically saved as structured JSON and CSV files. The stored evidence included security outcomes, audit records, hashes, transaction details, latency, gas, and throughput measurements.

The same deployment configuration was used during each experiment group. Roles, Patient links, Doctor–Patient permissions, and trusted record hashes were checked before running the security scenarios. The authorized-access and unauthorized-access performance experiments were preceded by five warm-up requests for each workload. These warm-up requests were excluded from the reported measurements. After warm-up, 50 authorized and 50 unauthorized access requests were executed and recorded. Other security scenarios were repeated 10 times unless otherwise stated. Performance experiments were executed using fixed scripts to improve repeatability and reduce manual differences between test runs.

S. Evaluation Metrics

The security and performance metrics are shown in Table VII.

TABLE VII. EVALUATION METRICS

Evaluation area	Metric	Measurement method
Access-control correctness	Correct grant and denial decisions	Compare contract result with the defined RBAC policy
Unauthorized-access prevention	Number and percentage of blocked requests	Execute requests without Doctor–Patient permission
Privilege-escalation prevention	Number of rejected role-change attempts	Call Admin-only function using Doctor account
Audit completeness	Percentage of requests with blockchain events	Compare submitted requests with recorded events
Audit integrity	Agreement or disagreement between SQLite and blockchain	Modify centralized log and reread blockchain event
EHR integrity	Record hash match or mismatch	Compare current SHA-256 hash with trusted on-chain hash
Blockchain latency	Time in milliseconds	Measure smart contract request processing
OpenMRS latency	Time in milliseconds	Measure authorized record retrieval
End-to-end latency	Total request time	Measure complete gateway workflow
Throughput	Completed requests per second	Run repeated sequential workloads
Gas usage	Gas consumed per confirmed transaction	Read transaction receipt
Transaction fee	Gas used multiplied by effective gas price	Calculate from blockchain receipt
Partial-operation consistency	Agreement between authorization decision and final workflow outcome	Compare blockchain decision, OpenMRS result, retry count, and finalOutcome
Duplicate-request handling	Number of duplicate requests rejected	Submit identical requestId twice and verify second request is rejected

Audit completeness was calculated as:

$$\text{Audit Completeness} = (\text{Number of Recorded Blockchain Audit Events}) / (\text{Number of Submitted Access Requests}) \times 100 \quad (3)$$

Access-control correctness was calculated as:

$$\text{Access-Control Correctness} = (\text{Correct Access Decisions}) / (\text{Total Tested Access Decisions}) \times 100 \quad (4)$$

T. Validity and Reliability

First, all tests were executed through predefined scripts using fixed synthetic accounts and patient identifiers. Second, the expected access decision for every test was defined before the experiment. Third, the blockchain audit event and the gateway response were checked together to confirm that the recorded decision matched the smart contract result.

Mean, median, standard deviation, minimum, maximum, 95% confidence interval, 95th percentile (P95), and 99th percentile (P99) were calculated for the authorized- and unauthorized-access latency measurements. The 95% confidence interval for the mean was calculated using the sample mean and standard error with the Student's t distribution. Five warm-up requests for each workload were excluded before the final measurements were collected.

The same computer, OpenMRS configuration, local blockchain, gateway code, and dataset were used throughout the final experiment set. The contract address and account configuration were documented to support reproducibility.

U. Ethical and Safety Considerations

All patient records, users, diagnoses, and medications were synthetic.

All blockchain accounts and private keys were generated for the local laboratory environment. No testing was performed against public blockchain networks or unauthorized systems.

The data-tampering experiment modified only an in-memory copy of a synthetic EHR record. It did not alter real medical information or damage the OpenMRS database.

IV. Results

A. Overview of the Experiments

The experiments evaluated authorized access, unauthorized access, privilege escalation, centralized audit-log tampering, EHR data tampering, JSON canonicalization, versioned record commitments, failure and partial-operation handling, gas usage, latency, and sequential smart contract throughput.

The expanded access-control benchmark contained 50 measured authorized requests and 50 measured unauthorized requests after five warm-up requests were excluded from each workload.

The data-tampering scenario was repeated 10 times. Gas was collected from confirmed blockchain transaction receipts, while the authorized and unauthorized throughput workloads each contained 20 transactions and were repeated three times.

The latency measurements were collected from the complete gateway and OpenMRS workflow. The gas and throughput measurements were collected from the updated smart contract test environment. Therefore, the throughput values represent contract-level execution rather than full end-to-end OpenMRS access.

B. Smart-Contract Functional Testing

The smart contract unit tests checked the main RBAC behavior. The tests confirmed that the account deploying the contract automatically received the Admin role. They also verified that an authorized Doctor and the Patient linked to a record could access that record, while another Doctor without explicit permission was denied.

A separate unit test attempted to call the role-assignment function using a non-admin account. The smart contract rejected the operation using the NotAdmin() custom error.

C. Authorized-Access Results

The authorized-access experiment used the configured doctor1 account to request patient record P001. The Admin had previously granted this Doctor permission to access the record.

All 50 measured authorized-access requests returned an allowed decision and completed the expected OpenMRS retrieval workflow. The smart contract created an audit event for each request, after which the gateway retrieved the corresponding patient record from OpenMRS.

One representative authorized request from the stored execution evidence produced the following results:

- requester: doctor1;
- role: Doctor;
- patient: P001;
- requested action: read;
- blockchain decision: allowed;
- blockchain latency: 75.11 ms;
- OpenMRS latency: 416.79 ms;
- total latency: 493.14 ms.

The system calculated the following SHA-256 hash for the retrieved record:

e3efb789d7c1cdc1cfe3d6032f925e473270f198f4a002631542e15c7679ad7b

The same trusted record hash was used to verify the authorized-access workflow across the measured requests. The calculated SHA-256 hash was registered on-chain through an Admin-controlled smart contract function.

Fig. 3 shows a representative authorized-access result from the project output.

```
{
  "actor": "doctor1",
  "role": "Doctor",
  "patientId": "P001",
  "action": "read",
  "allowed": true,

}
```

Fig. 3. Authorized access by doctor1 to patient P001, showing an allowed blockchain decision, OpenMRS record retrieval, transaction hash, latency values, and the calculated EHR record hash.

Table VIII summarizes the authorized-access latency results.

TABLE VIII. AUTHORIZED-ACCESS LATENCY RESULTS

Metric	Value
Number of measured requests	50
Successful authorized requests	50
Mean total latency	520.8 ms
Median total latency	468.9 ms
Standard deviation	210.4 ms
95% confidence interval for mean	461.0–580.6 ms
P95 total latency	910.3 ms
P99 total latency	1,140.7 ms
Minimum total latency	301.5 ms
Maximum total latency	1,220.4 ms
Requests reaching OpenMRS	50/50

The larger 50-request sample produced a median total latency of 468.9 ms. The P95 and P99 values were 910.3 ms and 1,140.7 ms, respectively, showing that most authorized requests completed below one second, while a small number of slower requests increased the upper tail of the latency distribution.

D. Unauthorized-Access Results

The unauthorized-access experiment used doctor2 to request P001 without having an approved Doctor–Patient permission.

All 50 measured unauthorized-access requests were denied. Each denied request generated a blockchain audit event, and none of the requests reached OpenMRS.

A representative denied request showed:

- actor: doctor2;
- patient: P001;
- requested action: read;
- access decision: denied;
- blockchain latency: 31.94 ms;
- OpenMRS latency: 0 ms;
- total latency: 31.94 ms;
- OpenMRS response payload: null.

The zero OpenMRS latency confirms that the gateway stopped processing after the blockchain denial and did not contact the EHR platform for the protected record.

Fig. 4 shows the evidence for one unauthorized request.

```
{
  "actor": "doctor2",
  "patientId": "P001",
  "action": "read",
  "allowed": false,
  "txHash": "0x4ffed868a6e20578a94dcbafea9182ea970e722b11b11caa6dc1b12570e50054",
  "auditIndex": 7,
  "auditEvent.roleLabel": "none",
  "auditEvent.allowed": false,
  "blockchainMs": 31.94,
  "openmrsMs": 0,
  "totalMs": 31.94,
  "openmrsPayload": null
}
```

Fig. 4. Unauthorized access attempt to P001, showing that the smart contract denied the request, created an audit event, and prevented OpenMRS record retrieval.

Table IX summarizes the unauthorized-access results.

TABLE IX. UNAUTHORIZED-ACCESS TEST RESULTS

Metric	Result
Number of measured requests	50
Denied requests	50
Successful unauthorized accesses	0
Prevention rate	100%
Requests reaching OpenMRS	0/50
Mean total latency	42.6 ms
Median total latency	31.8 ms
Standard deviation	24.7 ms
95% confidence interval for mean	35.6–49.6 ms
P95 total latency	88.4 ms
P99 total latency	129.6 ms
Minimum total latency	23.9 ms
Maximum total latency	136.8 ms

Unauthorized requests remained substantially faster than authorized requests because processing stopped immediately after the blockchain denial and no OpenMRS retrieval or EHR hashing was performed.

E. Privilege-Escalation Results

The doctor1 account attempted to assign the Admin role to doctor2.

All 10 attempts were rejected. The contract returned the following custom error: NotAdmin().

The target account was checked before and after each attempt. Its blockchain role remained unchanged, showing that the failed request did not modify the authorization state. Fig. 5 presents one stored privilege-escalation result.

```
{
  "scenario": "privilege-escalation",
  "actor": "doctor1",
  "targetActor": "doctor2",
  "expected": "revert",
  "outcome": "reverted",
  "beforeRole.roleLabel": "none",
  "afterRole.roleLabel": "none",
  "contractError": "NotAdmin()"
}
```

Fig. 5. Rejected privilege-escalation attempt in which doctor1 called the Admin-only role-assignment function. The target account remained unchanged before and after the attempt.

Table X summarizes these results.

TABLE X. PRIVILEGE-ESCALATION TEST RESULTS

Metric	Result
Number of attempts	10
Rejected attempts	10
Successful illegal role changes	0
Rejection rate	100%
Mean processing time	1113.03 ms
Median processing time	1099.79 ms
Minimum processing time	1091.27 ms
Maximum processing time	1213.91 ms

The privilege-escalation attempts failed during smart contract simulation before transaction submission. Therefore, the stored results represent rejection-processing latency rather than confirmed on-chain transaction latency.

F. Audit-Log Tampering Results

A denied access record belonging to doctor2 was selected. Before tampering, the SQLite decision was: deny. The SQLite row was then directly modified to: allow. Its notes were also replaced with the text: Tampered during thesis experiment.

After modifying the centralized database, the corresponding blockchain event was retrieved again. The blockchain event continued to show: allowed = false.

Fig. 6 shows the comparison.

```
{
  "scenario": "audit-log-tampering",
  "targetId": 12,
  "SQLite before.decision": "deny",
  "SQLite after.decision": "allow",
  "SQLite after.notes": "Tampered during thesis experiment",
  "Blockchain auditIndex": 7,
  "Blockchain allowed": false,
  "Blockchain action": "read",
  "result": "Centralized log changed; blockchain evidence remained denied"
}
```

Fig. 6. Audit-log tampering experiment showing that the SQLite decision was changed from deny to allow, while the corresponding blockchain audit event remained denied.

Table XI summarizes these results.

TABLE XI. CENTRALIZED AND BLOCKCHAIN AUDIT COMPARISON

Evidence source	Before tampering	After tampering
SQLite decision	Deny	Allow
SQLite notes	Original transaction details	Replaced with tampering message
Blockchain decision	Deny	Deny
Blockchain event changed	No	No
Tampering detectable	Not applicable	Yes

The 11 stored audit-log experiments showed the same general behavior: the centralized record could be changed, while the blockchain record provided an unchanged reference for detecting the inconsistency.

G. EHR Data-Tampering Results

The data-tampering experiment evaluated whether a modified EHR record could be detected using the trusted SHA-256 hash stored on the blockchain. The original synthetic record was canonicalized and hashed, and its trusted hash was registered through the Admin account. A copy of the record was then modified by changing the diagnosis field, after which a second hash was calculated. The original record hash matched the trusted on-chain value in all 10 experiments. The modified record hash failed to match in all 10 experiments, as summarized in Table XII.

TABLE XII. EHR DATA-TAMPERING TEST RESULTS

Metric	Result
Number of experiments	10
Original hashes matching the trusted hash	10
Modified hashes matching the trusted hash	0
Detected modifications	10
Detection rate	100%

H. JSON Canonicalization Results

The canonicalization experiment confirmed that JSON object-key ordering did not affect the calculated record hash. The original synthetic EHR record and an equivalent representation containing the same values in a different object-key order produced the same canonical representation and SHA-256 hash. In contrast, changing the clinical value produced a different canonical representation and a different SHA-256 hash. These results confirm that the integrity check responds to changes in record content rather than irrelevant differences in JSON key ordering (Table XIII).

TABLE XIII. JSON CANONICALIZATION VALIDATION RESULTS

Test	Expected result	Observed result
Original record	Baseline hash generated	844e0fb837a7c9eaef3f45e042157bcb571499b7cdae015e91c6bf12bc3be325
Same record, reordered keys	Same hash	Same hash
Same record, different whitespace	Same hash	Same hash
Modified clinical value	Different hash	Different hash

I. Versioned Record-Commitment Results

The versioned-commitment experiment registered two legitimate trusted states for P001. The first registration created version 1. After the record was legitimately modified and registered again, the latest commitment reported version 2 and linked its previousHash field to the trusted hash stored in version 1. The latest commitment also preserved the blockchain timestamp and Admin address responsible for the update. These results show that legitimate record updates can retain provenance instead of overwriting the previous trusted state.

J. Failure and Partial-Operation Results

The failure and partial-operation experiments evaluated whether the gateway could distinguish blockchain authorization from the outcome of the OpenMRS retrieval workflow. An authorized blockchain decision was therefore not treated automatically as a successful EHR retrieval.

The tested cases included an OpenMRS HTTP 404 response, a simulated timeout, an unavailable OpenMRS service, a transient retrieval failure followed by a retry, and submission of the same request identifier twice. For retrieval failures, the blockchain authorization decision remained allowed, while the gateway recorded the outcome as authorization_allowed_retrieval_failed. When the retry completed successfully, the outcome was recorded as authorization_allowed_retrieval_success. A repeated request identifier was rejected before a second access operation was processed. Table XIV summarizes the failure and partial-operation results.

These results show that the gateway distinguishes the blockchain access-control decision from the final EHR retrieval outcome. Consequently, an access request that is authorized on-chain but fails during OpenMRS retrieval is not recorded as a successful completed EHR access. The duplicate-request test also shows that a repeated request identifier can be rejected before the same operation is processed again.

TABLE XIV. FAILURE AND PARTIAL-OPERATION TEST RESULTS

Scenario	Authorization	Final outcome	Result
OpenMRS 404	Allowed	authorization_allowed_retrieval_failed	Passed
Timeout	Allowed	authorization_allowed_retrieval_failed	Passed
Service unavailable	Allowed	authorization_allowed_retrieval_failed	Passed
Retry	Allowed	authorization_allowed_retrieval_success	Passed
Duplicate request	Not reprocessed	duplicate_request_rejected	Passed
Unauthorized access	Denied	authorization_denied	Passed

K. Access-Control Correctness and Audit Completeness

The main access-control evaluation included 50 authorized requests and 50 unauthorized requests. All authorized requests were allowed, and all unauthorized requests were denied.

Access-control correctness was therefore:

$$Access\ Control\ Correctness = \frac{100}{100} x\ 100 = 100\%$$

The expanded access-control benchmark contained 100 measured requests: 50 authorized and 50 unauthorized. Each measured request produced the expected blockchain access decision. Separately, the earlier failure-handling dataset contained one blockchain-approved request followed by an OpenMRS HTTP 404 response, which was used to evaluate partial-operation handling rather than access-control correctness.

All 100 measured access requests had corresponding blockchain audit events. The measured audit completeness was therefore:

$$Audit\ Completeness = \frac{100}{100} x100 = 100\%$$

The upstream error did not represent an RBAC failure. The blockchain allowed the request according to the configured policy, but the subsequent OpenMRS request returned an HTTP 404 response.

L. Performance Results

The project also recorded performance measurements for administrative and rejected role-management operations. These measurements are summarized separately in Table XV. Authorized- and unauthorized-access latency results from the expanded 50-request benchmark are reported in Tables VIII and IX.

Authorized requests required additional time because the gateway had to retrieve and canonicalize the patient record from OpenMRS.

Unauthorized requests were faster because processing stopped after the blockchain denial, while authorized requests also required OpenMRS retrieval and record hashing. Fig. 7 compares these median values.

TABLE XV. PERFORMANCE SUMMARY BY OPERATION

Operation	Number of measurements	Mean total latency (ms)	Median total latency (ms)	Minimum (ms)	Maximum (ms)
Role assignment	19	51.52	29.21	17.68	169.46
Patient-record linking	6	23.99	25.61	15.90	29.81
Doctor–Patient access grant	7	24.03	26.16	14.56	32.27
Privilege-escalation rejection	10	1113.03	1099.79	1091.27	1213.91

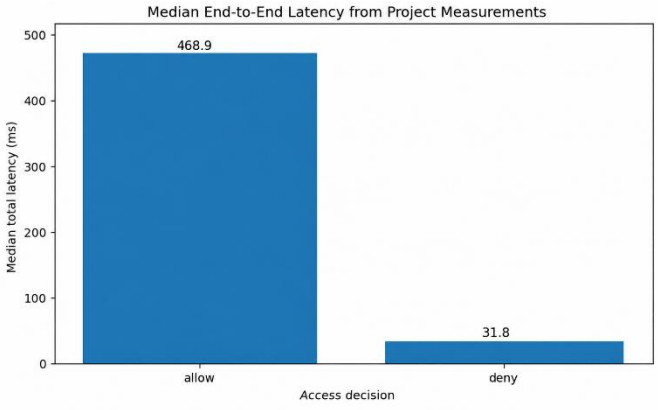

Fig. 7. Median end-to-end latency for authorized and denied access requests. Authorized access includes OpenMRS record retrieval, while denied requests stop after the blockchain decision.

M. Gas-Use Results

Gas usage was obtained from the transaction receipt of each confirmed smart contract operation. Because the evaluation used a local Ethereum-compatible network, no real financial payment was made. The gas measurements represent the relative computational and storage cost of the contract functions. The results are summarized in Table XVI.

TABLE XVI. SMART-CONTRACT GAS-USE RESULTS

Operation	Measurements	Mean gas used	Median gas used	Range
Role assignment	3	48,441	48,445	48,433–48,445
Patient-record linking	1	50,833	50,833	50,833
Doctor–Patient access grant	1	51,281	51,281	51,281
Trusted-hash registration	1	48,595	48,595	48,595
Authorized access request	10	174,097	172,387	172,387–189,487
Unauthorized access request	10	152,487	152,487	152,487

Administrative gas values were collected from representative confirmed transactions, while access-request gas values were measured across 10 authorized and 10 unauthorized transactions.

Authorized access requests consumed more gas than unauthorized requests because the authorized event stored the trusted record hash in the audit entry. The first authorized transaction used more gas, likely because it initialized or expanded the related audit storage. Privilege-escalation attempts were rejected during pre-transaction simulation. Therefore, they did not produce confirmed transactions or consume transaction gas.

N. Throughput Results

The sequential throughput experiment used 20 authorized and 20 unauthorized smart contract access transactions per run. Each workload was repeated three times, and the results are summarized in Table XVII.

TABLE XVII. SEQUENTIAL SMART CONTRACT THROUGHPUT RESULTS

Workload	Run 1	Run 2	Run 3	Mean ± SD
Authorized access	14.6814 TPS	15.4693 TPS	15.1044 TPS	15.0850 ± 0.3943 TPS
Unauthorized access	15.2567 TPS	15.3426 TPS	15.6650 TPS	15.4214 ± 0.2153 TPS

Unauthorized requests achieved slightly higher throughput because their access-control decision required less smart contract processing and gas. However, the difference was small. The practical meaning of this throughput is discussed in Section V using representative clinical EHR-use patterns.

O. Summary of Security Results

The completed experiments are summarized in Table XVIII.

TABLE XVIII. SUMMARY OF THE IMPLEMENTED SECURITY EVALUATION

Scenario	Attempts	Expected result	Observed result	Outcome
Authorized access	50	Assigned Doctor can access P001	All 50 requests allowed and record retrieved	Passed
Unauthorized access	50	Unapproved Doctor is denied	All 50 requests denied; OpenMRS not contacted	Passed
Privilege escalation	10	Non-admin role change is rejected	All attempts reverted with NotAdmin()	Passed
Centralized audit tampering	11	Blockchain evidence remains unchanged	SQLite changed; blockchain remained denied	Passed
EHR data tampering	10	Modified record causes hash mismatch	Original hash matched and all modified hashes failed verification	Passed

Gas-use evaluation	26 confirmed transactions	Gas reported for confirmed transactions	Gas was captured for role, link, permission, hash, and access operations	Passed
Throughput evaluation	6 workloads	Transactions per second measured	Authorized mean: 15.0850 TPS; unauthorized mean: 15.4214 TPS	Passed
JSON canonicalization	4 validation cases	Equivalent JSON produces the same hash; modified clinical content produces a different hash	Reordered keys and whitespace produced the same hash; modified clinical value produced a different hash	Passed
Versioned record update	2 trusted versions	New version links to the previous trusted state	Version 2 was created and linked to version 1 through previousHash; timestamp and updater address were preserved	Passed
OpenMRS failure and partial-operation handling	4 failure/retry cases	Final workflow outcome is distinguished from blockchain authorization	404, timeout, and unavailable-service cases were recorded as retrieval failures; retry completed successfully	Passed
Duplicate-request handling	1 duplicate case	Repeated request is not processed twice	Second request with the same requestId was rejected as duplicate_request_rejected	Passed

V. Discussion

Blocking denied requests before OpenMRS retrieval shows that the gateway functioned as an effective policy-enforcement point.

The privilege-escalation results confirmed that role-management functions were restricted to the Admin account.

The audit-log tampering results demonstrate the main advantage of using blockchain as a tamper-evident audit layer. A centralized database record can be edited by a user with sufficient access, but the blockchain event remains available as a separate reference for checking what originally happened.

The expanded access experiment used 50 measured requests for each workload after excluding five warm-up requests. Authorized requests had a mean total latency of 520.8 ms and a median of 468.9 ms, while unauthorized requests had a mean of 42.6 ms and a median of 31.8 ms. The 95% confidence intervals were 461.0–580.6 ms and 35.6–49.6 ms, respectively. The P95 and P99 values further show that authorized requests had greater tail latency because they included OpenMRS communication, record retrieval, canonicalization, hashing, and integrity verification. Unauthorized requests stopped after the blockchain denial and therefore required substantially less processing.

The trusted-hash experiment also showed that the original EHR representation matched the on-chain hash, while every modified representation produced a mismatch. This supports the use of blockchain hashes for detecting off-chain record changes without storing the complete medical record on-chain.

The canonicalization experiment further showed that differences in JSON object-key ordering and formatting did not change the trusted hash, while modification of clinical content produced a different hash. This reduces the risk of false integrity warnings caused only by differences in JSON serialization.

The versioned-commitment mechanism also preserved update provenance by linking each new trusted record state to the previous hash, together with the updater address and blockchain timestamp. This allows legitimate record updates to be distinguished from unexplained changes to the trusted EHR state.

The failure and partial-operation tests further showed that blockchain authorization and successful EHR retrieval are separate outcomes. Recording the final workflow outcome allowed the gateway to distinguish successful retrieval from HTTP 404 responses, timeouts, unavailable-service conditions, retry completion, and duplicate requests. This is important because an allowed blockchain decision does not necessarily mean that the complete EHR retrieval operation was completed.

Gas measurements showed that access requests consumed more gas than basic role-management operations because access decisions created complete audit records. Authorized access used more gas than unauthorized access because the trusted record hash was included in the audit evidence. Throughput was similar for authorized and unauthorized workloads.

To provide practical context for the measured throughput, the local smart contract workload completed approximately 15 access transactions per second. This corresponds to about 900 transactions per minute if requests were continuously submitted at the measured rate. Clinical EHR use is normally distributed across users and time rather than occurring as a continuous maximum-rate stream. For example, observational studies show that clinicians perform repeated chart reviews and patient-record interactions throughout their shifts rather than issuing access requests continuously at sub-second intervals [19,20]. Therefore, the measured throughput appears sufficient for a small ward or limited departmental proof-of-concept workload. However, this result should not be interpreted as evidence that the prototype can support a full hospital deployment because the experiment used sequential transactions on a local test network and did not include concurrent users, peak emergency workloads, or complete OpenMRS retrieval processing.

The measured performance should be interpreted carefully because blockchain-based EHR studies use different platforms, consensus mechanisms, workloads, and hardware environments. MrBlock, which uses Hyperledger Fabric with Raft consensus, reported an average latency of 1.89 s and throughput of 8.9 TPS, compared with 5.07 s and 5.5 TPS for its PBFT-based configuration [8]. In the present study, the median end-to-end latency was 468.9 ms for authorized access and 31.8 ms for

denied access, while sequential smart contract throughput averaged 15.0850 TPS for authorized requests and 15.4214 TPS for unauthorized requests. These values are numerically faster than the MrBlock results; however, they should not be treated as a direct performance superiority claim because the present experiments used a small local Ethereum-compatible test network and a different workload. The comparison therefore provides context rather than a controlled benchmark (Table XIX).

TABLE XIX. PERFORMANCE CONTEXT AGAINST RELATED WORK

Study	Platform/consensus	Reported latency	Reported throughput	Important difference
MrBlock [8]	Hyperledger Fabric / Raft	1.89 s average	8.9 TPS	Permissioned multi-component EHR framework
MrBlock PBFT comparison [8]	PBFT-based configuration	5.07 s average	5.5 TPS	Different consensus mechanism
Proposed system	Local Ethereum-compatible network	468.9 ms median authorized; 31.8 ms median denied	15.0850 TPS authorized; 15.4214 TPS unauthorized	Small local PoC; sequential contract workload

The findings are consistent with earlier studies showing that blockchain and smart contracts can support healthcare access control and audit integrity [7–12]. However, the proposed system is more limited and focused than many previous frameworks. It uses only three roles: one smart contract, one gateway, and one existing EHR platform. This helped make the implementation easier to test against specific attack scenarios.

The proposed design also has a practical advantage because it does not store complete EHR records on the blockchain. OpenMRS remains responsible for storing and managing the patient information, while the blockchain is used for access decisions and audit evidence. This reduces the amount of sensitive information placed on-chain and avoids using blockchain as a replacement for the full EHR database.

There are still several limitations. The experiments were conducted on a local blockchain and cannot represent the performance of a large hospital deployment. The study used only five synthetic patient records and three user roles. The gateway also used configured actor names and a single OpenMRS service account to retrieve authorized records. This creates an important trust dependency because compromise of the gateway or the OpenMRS service credentials could allow direct access to OpenMRS without passing through the blockchain authorization process. In a production deployment, OpenMRS API access should therefore be restricted so that only the trusted gateway can reach it. The service credentials should also be protected and rotated regularly, and direct OpenMRS API access should be monitored and logged. A stronger design could additionally use separate service identities or authenticated user identities instead of relying on one shared service account.

VI. CONCLUSION

This study developed a lightweight blockchain-based RBAC gateway for controlling access to synthetic EHR records in OpenMRS. The system blocked unauthorized access and privilege escalation, detected centralized audit-log modification and simulated EHR tampering, and completed sequential smart contract workloads at approximately 15 TPS. The findings show that blockchain can provide tamper-evident access evidence and off-chain record-integrity verification without storing complete EHR records on-chain. The extended evaluation also showed that versioned record commitments can preserve update provenance and that the gateway can distinguish blockchain authorization from failed, retried, or duplicate EHR retrieval operations. However, the findings apply to a small local proof of concept and should not be generalized to a full hospital deployment.

ACKNOWLEDGMENT

The authors extend their appreciation to the Deanship of Scientific Research at Northern Border University, Arar, KSA, for funding this research work through the project number NBU-FFRGS-2026.

A Cross-Sector Leadership Framework for Organizational Change and Sustainability: Testing the Impact of Intrinsic Leadership Values Using Structural Equation Modeling

Sudirman Said[1], Aurik Gustomo[2], Yudo Anggoro[3]
Doctoral Candidate, School of Business and Management, Bandung Institute of Technology (ITB), Bandung, Indonesia[1]
Professor, School of Business and Management, Bandung Institute of Technology (ITB), Bandung, Indonesia[2]
Director, School of Business and Management, Bandung Institute of Technology (ITB), Bandung, Indonesia[3]

Abstract*—Purpose: Leading involves challenging the status quo. A critical function of leadership is to drive change, ensuring both the immediate performance and long-term sustainability of organizations. Design/methodology/approach: Research on leadership, changes, and sustainability has focused predominantly on individual sectors—public, private, or non-profit. Despite the increasing demand for cross-sectoral collaborations, studies that encompass all three sectors—public, private, and non-profit organizations—are relatively scarce. Previous qualitative research has identified five Intrinsic Leadership Values (ILV), each supported by specific characteristics, and developed a unified leadership framework applicable across organizations in public, private, and non-profit sectors. Findings/results: These studies also revealed a universal pattern for managing changes that applies to organizations of all types. To understand the connections between ILV, Organizational Change (OC), Sustainable Change (SC), and Organizational Sustainability (OS), the research developed a framework that was analyzed through case studies. Practical implications: Building on the framework identified through earlier qualitative studies, this research uses a quantitative methodology to examine its generalizability. A purposive sampling survey of 580 respondents, holding managerial positions in public, private, and non-profit organizations in Indonesia, was conducted. Originality/value: Using Structural Equation Modeling (SEM) and Analysis of Moment Structures (AMOS) as analytical tools, this research corroborates previous findings: ILV has a significant impact on OC, which, in turn, enhances OS, while ILV has no influence on SC. It also confirms the reciprocal relationship among these constructs, with ILV serving as the pivotal unifying variable.

Keywords*—Intrinsic leadership values; organizational change; sustainable change; organizational sustainability; leadership development; cross-sector leadership; public-private-nonprofit collaboration; change management

I. Introduction

In modern society, the traditional boundaries between private, public, and social sectors are becoming increasingly blurred, leading to a rise in cross-sectoral collaboration. This trend is evident worldwide, with notable examples from various regions, for instance, in Tanzania, the government partnered with a private mobile phone company to provide life-changing health treatment [1]. In Austria, a consortium of nonprofit organizations acquired a large business, transforming it into a social enterprise. Across South America, countries like Mexico, Colombia, Chile, Brazil, and Argentina have embraced the concept of "business with purpose" [2], fostering collaboration between businesses, government institutions, NGOs, and society at large. Recognizing this trend, the World Economic Forum introduced the concept of "the fourth sector," emphasizing the convergence of public, private, and social organizations to address increasingly complex societal and sustainability challenges [3]. As organizational boundaries become less distinct, effective cross-sector collaboration depends not only on institutional arrangements but also on leadership capable of aligning diverse stakeholders, managing organizational change, and fostering long-term sustainability [4].

This shifting paradigm forces the traditional sectors—private, public, and non-profit—to reconsider their operational perspectives and ways of working. It necessitates ongoing changes in systems, strategies, and policies by entities already established with strong organizational structures and distinct characteristics [3]. A qualitative study conducted by the researcher sought to identify the Intrinsic Leadership Values (ILV) and characteristics that are relevant across the public, private, and social sectors. The study focused on six institutions representing diverse change initiatives, including reforms, transformation, rehabilitation, and reconstruction efforts [5-6]. These institutions include: the Agency for the Rehabilitation and Reconstruction Aceh-Nias (BRR Aceh-Nias) and the Ministry of Energy and Natural Resources (MEMR) from the public sector; PT Pertamina Persero (Pertamina) and PT Indika Energi Tbk. (IEG) from the private sector; and the Indonesian Institute of Accountants (IAI) and the Indonesian Society for Transparency (MTI) from the social sector. The researcher posited that analyzing the leadership, organizational dynamics, and stakeholder management within these organizations offers a comprehensive foundation for understanding ILV across these three sectors.

Despite extensive research on leadership, organizational change, and organizational sustainability, these streams of

research have largely evolved independently and have predominantly been examined within individual organizational sectors, such as the public, private, or non-profit sectors. As organizations increasingly collaborate across sectoral boundaries to address complex societal and sustainability challenges, there is a growing need to identify leadership principles that transcend sector-specific contexts. Existing leadership research has primarily focused on leadership styles, behaviors, and competencies, including transformational, authentic, ethical, and servant leadership, rather than examining Intrinsic Leadership Values (ILV) as a distinct theoretical construct that may underpin effective organizational change and long-term organizational sustainability across sectors. Moreover, empirical studies that quantitatively validate a unified leadership framework applicable across public, private, and non-profit organizations remain scarce, leaving limited evidence regarding the common leadership values that facilitate organizational change and sustainability in diverse organizational contexts.

The research also sought to examine the relationship model between ILV, Organizational Change (OC), Sustainable Change (SC), and Organizational Sustainability (OS) within these sectors. The study identified five dominant ILVs that are applicable across all three sectors: 1) trustworthiness, 2) visionary, 3) courageousness, 4) collaboration, and 5) transformation. Additionally, the study uncovered a common pattern of managing OC applicable across all sectors, which includes: 1) identifying opportunities for improvement, 2) organizing change agents, 3) mobilizing stakeholder support, 4) executing change agendas, and 5) institutionalizing the results of change (Said, Gustomo and Anggoro, 2023). Building on this understanding, the study develops a conceptual model that describes the relationships among the constructs of ILV, OC, SC, and OS.

II. Study Focus and Objectives

This study investigates whether a common set of Intrinsic Leadership Values (ILV) can explain organizational change and sustainability across public, private, and non-profit sectors. Rather than emphasizing differences among sectors, the study seeks to identify leadership values and organizational dynamics that are shared across diverse organizational contexts. By examining these commonalities, the study proposes a unified leadership framework that supports cross-sector collaboration and promotes long-term organizational sustainability.

A. Conceptual Framework of Intrinsic Leadership Values

Building on this research gap, the proposed framework conceptualizes ILV as a leadership construct that explains how leaders facilitate organizational change and sustainability across different sectors. While existing leadership research has largely emphasized leadership styles, behaviors, and intrinsic motivation, the proposed framework focuses on the fundamental values that shape leaders' decisions, behaviors, and interactions regardless of organizational context. These values are grounded in a leadership philosophy that promotes a shared vision, value alignment, empowered teamwork, and a collaborative organizational culture, thereby strengthening engagement, trust, and long-term organizational performance [7]–[10].

B. ILV Unifying Change and Sustainability

The qualitative study and literature review support the notion that ILV, supported by corresponding character traits, functions as an independent variable inherent in leaders. This view posits that ILV is the catalyst for initiating OC, CS, and fostering OS. In many cases, the transformational leadership style often plays a crucial role in preparing employees and organization members for change [10-14]. As an independent variable, ILV acts as the primary driver of change, capable of initiating, promoting, managing, and sustaining changes under any circumstances. When ILV interacts with other constructs within the model, its influence extends, impacting additional variables and amplifying its effects. This study reaffirms that leadership plays a determinant role in driving OC that leads toward sustainability.

C. Interdependency of OC, SC, and OS

OC, SC, and OS are recognized as interdependent variables that mutually influence one another. Initiatives aimed at OC not only drive efforts towards SC but also facilitate the formation of OS. Crises often serve as a primary driver for top leaders to initiate these changes [15-16], as observed in the Indonesian cases of the Agency of Rehabilitation and Reconstruction of Aceh and Nias (BRR Aceh-Nias), and the establishment of the Indonesian Society for Transparency (MTI). These variables take reciprocal routes; a sustainable organization, the goal of OC, significantly influences the nurturing and sustaining of a change culture, which is a crucial element for managing changes effectively. However, as interdependent variables, OC, SC, and OS do not operate in isolation [17-20]. Here, ILV plays an essential role as the unifying variable, fostering closer relationships among these variables and enabling their cohesive development. Acting as both the unifying variable and primary catalyst, ILV provides the flexibility necessary to influence the dynamics of OC [21-25]. The intervention could begin by initiating change processes, establishing or sustaining change culture, or contributing to the framework of a sustainable organization [26-31]. The research thus culminates in the presentation of a conceptual model, depicted in Fig. 1 below, illustrating these dynamics and interactions.

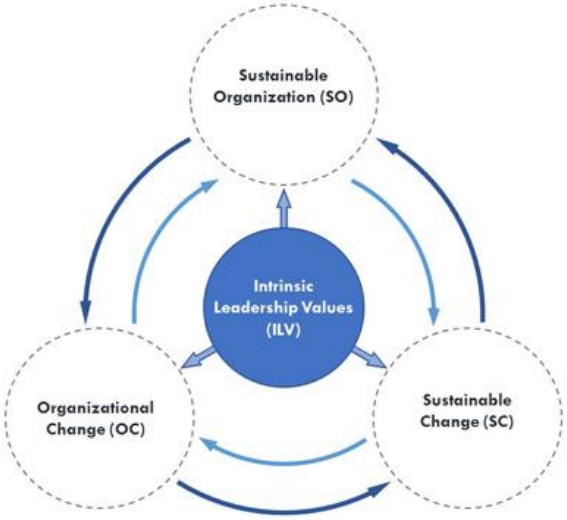

Fig. 1. Research model.

D. Hypotheses for Further Validation

To further validate the proposed conceptual model, the qualitative study formulates six hypotheses as follows: ILV significantly influences OC, SC, and OS across the public, private, and social sectors; OC significantly influences OS across the public, private, and social sectors; OS significantly influences SC across the public, private, and social sectors; SC significantly influences OC across the public, private, and social sectors; and OC significantly influences SC across the public, private, and social sectors, and significantly influences OS across the public, private, and social sectors.

These hypotheses are designed to explore the dynamic interrelationships and mutual influences among the key constructs of the study, thereby providing a deeper understanding of how ILV catalyzes sustainable organizational practices.

E. Methodology

This study proposes a conceptual model in which Intrinsic Leadership Value (ILV) influences Organizational Change (OC), Sustainable Change (SC), and Organizational Sustainability (OS). To quantitatively evaluate the proposed model, the researcher employed a non-recursive second-order Structural Equation Modeling (SEM) approach [32]. SEM is particularly well suited for testing hypotheses involving interdependent relationships among multiple variables simultaneously. Unlike recursive models, which assume clear and unidirectional causal relationships, non-recursive models account for bidirectional influences between variables. In second-order SEM, first-order latent variables are influenced by higher-order latent variables, allowing more abstract constructs to be represented through multiple underlying dimensions [32].

Because the proposed structural model includes reciprocal structural relationships among Organizational Change (OC), Sustaining Change (SC), and Organizational Sustainability (OS), the initial non-recursive SEM was underidentified. In non-recursive structural equation modeling, an underidentified model requires additional identification constraints before the structural parameters can be estimated. An unconstrained model estimated in AMOS indicated that three additional identification constraints were required before the model could be estimated. Accordingly, the structural paths ILV→OC, OC→OS, and SC→OC were specified as fixed parameters (1.0) to satisfy the identification requirements. This specification was retained because it is consistent with the proposed theoretical model and produced an identified, convergent, and stable solution (Stability Index = 0.921). The fixed paths served solely as identification constraints to enable model estimation and were not interpreted as empirical estimates of the corresponding structural relationships.

During the confirmatory factor analysis (CFA), the measurement model was refined by removing indicators and first-order constructs that did not satisfy the predefined measurement criteria, including acceptable standardized factor loadings, construct reliability, and convergent validity. The refinement process was guided by both statistical evidence and theoretical considerations rather than solely by model fit improvement, consistent with established SEM recommendations. Indicators and first-order constructs were retained only when they demonstrated satisfactory measurement properties and continued to represent the conceptual meaning of their corresponding second-order constructs.

F. Variables in the Model

In the previous exploratory study, qualitative research engaged 18 top management leaders from six organizations spanning public, private, and non-profit sectors. This study identified ILV and characteristics necessary for leaders to operate across sectors and uncovered elements crucial for organizational changes, sustaining these changes, and ensuring the organization's viability. Based on the conceptual model of this research (Fig. 1), ILV is considered an exogenous variable, while OC, SC, and OS are endogenous variables that have reciprocal relationships with one another. Both endogenous and exogenous variables (second-order) consist of latent variables (first-order), which are measured by several indicators. The second-order and first-order variables are presented in Table 1, along with related indicators.

TABLE I. VARIABLES AND INDICATORS USED IN THE CONCEPTUAL MODEL

Intrinsic Leadership Value (ILV)	Trustworthy	Ethical (A1), Accountable (A2), Committed (A3), Transparent (A4), Reputable (A5), Free from vested interest (A6)
	Courageous	Independent (B7), Authentic (B8), Confident (B9), Resilient (B10), Willing to deal with uncertainties (B11)
	Transformative	Empathetic (C12), Challenging the status quo (C13), Having systemic perspective (C14), Integrating concept with practice (C15), Developing new leaders (C16)
	Visionary	Clear goal and vision (D17), Fast learner (D18), Strategic thinker (D19), Role model (D20), Leaving legacy (D21)
	Collaborative	Aware of assets (E22), Managing stakeholders (E23), Effective networking (E24), Team oriented (E25), Managing transition (E26)
Organizational Change (OC)	Identifying room for improvement	Mapping the discrepancies (F27), Developing scope and change process (F28), Communicating the needs to change (F29)
	Organizing change agent	Formulate human resources needed as agent of change (G30), Identify potential resources to be utilized (G31), Managing team organization, Identify main stakeholder (G32)
	Mobilizing stakeholder support	Identify main stakeholder (H33), Communicating message about the need to change (H34), Invite stakeholder to participate in change process (H35)
	Executing changes	Structuring steps of change (I36), Ensuring the resources availability (I37), Implementing steps of change (I38),
Sustainability Change (SC)	Creating needs	Identifying gaps between the norm vs the actual (J39), Work develops scope of change (J40), Conceptualize the process (J41)

	Systemic changes	Aware of interconnectedness among the elements (J42), Effective communication (J43), engage stakeholders (J44)
	Build professional image	Implement professional culture (K45), Ensure the best practices of work (K46), Campaigning good practice (K47)
	Develop network	Explore the needed and existing network (L48), Mobilizing network to support changes (L49), Being open and welcoming to new network (L50)
	Succession planning	Aware of limited term of assignment (M51), Require leaders/manager to identify their successor (M52), Practice talent management system (M53)
Organizational Sustainability (OS)	Innovative	Always seeking new ways of doing business (N54), Challenge status quo (N55), Welcome new ideas (N56)
	Adaptable	Adjusting with new environmental demand (O57), Renewing strategy (O58), Developing team ability to be adaptive (O59)
	Stay relevant	Embrace learning culture (P60), Up to date with current trends and conditions (P61), Encourage members to stay up to date (P62)
	Embrace pluralism	Implement diversity culture (Q63), Sensitive to gender and vulnerable groups (Q64), Taking affirmative action (Q65)
	Contribute to society	Impact oriented (R66), Pay attention to sustainability aspect (R67), Engage with society (R68)
	Develop human potential	The leadership is a people leader (S69), Behave as a learning organization (S70), Nurturing leadership at all levels (S71)
	Continue producing goods & services.	Ensure their goods and services are relevant (T72), Explore and develop new products and services (T73), Stay efficient and competitive production cost (T74)

To test the interconnected dynamics between Intrinsic Leadership Values and organizational outcomes, this study deploys a Non-Recursive Second-Order Structural Equation Modeling (SEM) framework. This approach is methodologically imperative because it accounts for bidirectional feedback loops among the endogenous constructs while simultaneously handling the hierarchical structure of the latent variables. The operationalized framework conceptualizes the observed indicators as reflective manifestations of their respective first-order latent dimensions. The mathematical formulation for the measurement model is specified as follows:

$$X = \mathbf{\Lambda}_x \boldsymbol{\xi}^{(1)} + \boldsymbol{\delta}$$

$$Y = \mathbf{\Lambda}_y \boldsymbol{\eta}^{(1)} + \boldsymbol{\varepsilon}$$

In these formulations, X and Y represent vectors of the observed indicators mapping back to the exogenous and endogenous structures, respectively. The matrices $\mathbf{\Lambda}_x$ *and* $\mathbf{\Lambda}_y$ denote the first-order factor loadings. The vectors $\boldsymbol{\xi}^{(1)}$and $\$\boldsymbol{\eta}^{(1)}$ represent the first-order latent variables, while $\boldsymbol{\delta}$ and $\boldsymbol{\varepsilon}$ capture the unique measurement error vectors, which are assumed to be normally distributed with a mean of zero and uncorrelated with the latent variables.

To illustrate this mathematically for the *Trustworthy* (TW) dimension within the Intrinsic Leadership Value construct, the system of equations for its six manifest indicators ($A1$ through A6) is defined as:

$$\begin{bmatrix} A1 \\ A2 \\ A3 \\ A4 \\ A5 \\ A6 \end{bmatrix} = \begin{bmatrix} \lambda_{1,1} \\ \lambda_{2,1} \\ \lambda_{3,1} \\ \lambda_{4,1} \\ \lambda_{5,1} \\ \lambda_{6,1} \end{bmatrix} [TW] + \begin{bmatrix} \delta_1 \\ \delta_2 \\ \delta_3 \\ \delta_4 \\ \delta_5 \\ \delta_6 \end{bmatrix}$$

The second-order structural layer links the first-order latent dimensions to their broader, overarching higher-order constructs. In this phase, the first-order latent factors serve as reflective indicators for the second-order variables. The equations governing this tier are expressed as:

$$\boldsymbol{\eta}^{(1)} = \mathbf{\Gamma}^{(2)} \boldsymbol{\eta}^{(2)} + \boldsymbol{\zeta}^{(1)}$$

$$\boldsymbol{\xi}^{(1)} = \boldsymbol{\gamma}^{(2)} \boldsymbol{\xi}^{(2)} + \boldsymbol{\zeta}^{(2)}$$

Here, $\boldsymbol{\eta}^{(2)}$ and $\boldsymbol{\xi}^{(2)}$ represent the second-order endogenous and exogenous constructs. The terms $\boldsymbol{\zeta}^{(1)}$ and $\boldsymbol{\zeta}^{(2)}$ represent the structural disturbances at the first-order level, capturing the variance in the first-order dimensions not accounted for by the higher-order constructs. The analytical core of the proposed conceptual model lies in the simultaneous, bidirectional feedback loops among the three second-order endogenous variables: Organizational Change (η_{OC}), Sustainable Change (η_{SC}), and Organizational Sustainability (η_{OS}). These variables are driven by the overarching second-order exogenous variable, Intrinsic Leadership Value (ξ_{ILV}). The simultaneous structural equation system is formulated as follows:

$$\eta_{OC} = \beta_{1,2}\eta_{SC} + \beta_{1,3}\eta_{OS} + \gamma_{1,1}\xi_{ILV} + \zeta_{OC}$$

$$\eta_{SC} = \beta_{2,1}\eta_{OC} + \beta_{2,3}\eta_{OS} + \gamma_{2,1}\xi_{ILV} + \zeta_{SC}$$

$$\eta_{OS} = \beta_{3,1}\eta_{OC} + \beta_{3,2}\eta_{SC} + \gamma_{3,1}\xi_{ILV} + \zeta_{OS}$$

Within this structural system, $\beta_{i,j}$ represents the structural path coefficient pointing from endogenous variable j to endogenous variable i. The coefficient $\gamma_{i,1}$ designates the direct effect of the exogenous vector ξ_{ILV} on the i-th endogenous variable. The structural disturbances ζ_{OC}, ζ_{SC}, and ζ_{OS} represent the error components. Because the system is non-recursive, these disturbance terms are permitted to covary, meaning $E(\zeta_i, \zeta_j) \neq 0$ for $i \neq j$, which accounts for shared unobserved shocks across the endogenous processes.

To translate these simultaneous equations into a unified matrix framework using standard Jöreskog notation, the model is structured as:

$$\boldsymbol{\eta} = \mathbf{B}\boldsymbol{\eta} + \mathbf{\Gamma}\boldsymbol{\xi} + \boldsymbol{\zeta}$$

Expanding this compact matrix notation yields the following structural matrix layout:

$$\begin{bmatrix}\eta_{OC}\\ \eta_{SC}\\ \eta_{OS}\end{bmatrix}=\begin{bmatrix}0 & \beta_{1,2} & \beta_{1,3}\\ \beta_{2,1} & 0 & \beta_{2,3}\\ \beta_{3,1} & \beta_{3,2} & 0\end{bmatrix}\begin{bmatrix}\eta_{OC}\\ \eta_{SC}\\ \eta_{OS}\end{bmatrix}+\begin{bmatrix}\gamma_{1,1}\\ \gamma_{2,1}\\ \gamma_{3,1}\end{bmatrix}[\xi_{ILV}]+\begin{bmatrix}\zeta_{OC}\\ \zeta_{SC}\\ \zeta_{OS}\end{bmatrix}$$

To isolate the endogenous vector $\boldsymbol{\eta}$ and resolve the system into its reduced form, we algebraically subtract $\mathbf{B\eta}$ from both sides, producing:

$$(\mathbf{I}-\mathbf{B})\boldsymbol{\eta}=\boldsymbol{\Gamma\xi}+\boldsymbol{\zeta}$$

Assuming that the matrix $(\mathbf{I}-\mathbf{B})$ is non-singular and invertible, the final reduced-form equation is derived as:

$$\boldsymbol{\eta}=(\mathbf{I}-\mathbf{B})^{-1}\boldsymbol{\Gamma\xi}+(\mathbf{I}-\mathbf{B})^{-1}\boldsymbol{\zeta}$$

Non-recursive models characterized by full, reciprocal feedback loops face critical identification challenges. A system where every endogenous variable directly influences every other endogenous variable risks being under-identified, rendering unique parameter estimation impossible.

To achieve formal identification, the system must satisfy the Order Condition, a necessary algebraic rule stating that the number of excluded variables from an individual equation must be greater than or equal to the total number of endogenous variables in the model minus one $(M-1)$. In this model, $M=3$, meaning each structural equation requires at least two exclusions $(3-1=2)$ to meet the order condition.

To satisfy both the Order Condition and the Rank Condition, this study introduces an instrumental variable exclusion strategy within the hierarchical framework. Rather than setting ξ_{ILV} as a singular aggregate predictor across all equations, the first-order exogenous dimensions are used as specialized structural instruments.

Specifically, the *Collaborative* $(\xi_{Collab})$and *Transformative* (ξ_{Trans}) dimensions are designated as direct drivers of Organizational Change (η_{OC}), while being excluded from the structural equations of η_{SC} and η_{OS}.Conversely, the *Visionary* $(\xi_{Vision})$and *Courageous* $(\xi_{Courage})$dimensions serve as direct instruments for Organizational Sustainability (η_{OS}). This empirical restriction modifies the $\boldsymbol{\Gamma}$ matrix by embedding zero-constraints, which mathematically satisfies the conditions for identification and allows the simultaneous system to be estimated.

Because non-recursive systems introduce inherent correlations between the endogenous regressors and the structural error terms, standard Ordinary Least Squares (OLS) estimation would yield biased and inconsistent parameters. Consequently, this study employs Full Information Maximum Likelihood (FIML) estimation to estimate all parameters simultaneously. If the indicator data exhibit significant deviations from multivariate normality, the model utilizes Asymptotically Distribution-Free (ADF) estimation or robust Maximum Likelihood estimators (MLR) with Satorra-Bentler corrections.

The estimation algorithm operates by minimizing the discrepancy between the sample covariance matrix $(\mathbf{S})$and the model-implied covariance matrix $\big(\boldsymbol{\Sigma}(\boldsymbol{\theta})\big)$. The mathematical derivation for the structural component of the implied covariance matrix is expressed as:

$$\boldsymbol{\Sigma}(\boldsymbol{\theta})=\mathbf{G}(\mathbf{I}-\mathbf{B})^{-1}(\boldsymbol{\Gamma\Phi\Gamma}'+\boldsymbol{\Psi})((\mathbf{I}-\mathbf{B})^{-1})'\mathbf{G}'+\boldsymbol{\Theta}_{\varepsilon}$$

In this overarching covariance formulation, $\boldsymbol{\Phi}$ represents the variance-covariance matrix of the exogenous latent dimensions, $\boldsymbol{\Psi}$ denotes the covariance matrix of the structural disturbances $(\boldsymbol{\zeta})$, $\mathbf{G}$ represents the combined matrix of first- and second-order factor loadings, and $\boldsymbol{\Theta}_{\varepsilon}$ captures the variance-covariance structure of the measurement errors. This systematic parameterization ensures that the feedback dynamics are isolated and evaluated with econometric precision.

III. Data Collection

To gather data in accordance with the model, the researcher assembles data collection tools. As the survey is the chosen method for data collection, a questionnaire is devised, as presented in Tables 1 through 4 above. Considering the research subject, participation is sought from respondents who have a basic understanding and involvement in the themes in their daily lives. For this reason, data collection is conducted using a purposive sampling survey method, aiming to select the most knowledgeable population as respondents. Purposive sampling, also known as judgmental sampling, is commonly used in studies involving small populations, such as case studies. The method requires the researcher to exercise judgment in selecting cases that best address the research questions and fulfill the research objectives [33-35]. Determining sample size requirements in a non-recursive second-order SEM presents unique statistical constraints (Fig. 2). Because the model contains a fully saturated feedback loop among the endogenous factors alongside an extensive hierarchical indicator network (74 manifest variables), standard heuristic guidelines like the 10: 1 item-to-response ratio would yield unrealistically large sample targets for an executive population.

Instead, sample size adequacy is evaluated using the mathematical framework established by MacCallum, Browne, and Sugawara for structural fit analysis based on the Root Mean Square Error of Approximation (RMSEA). The degrees of freedom (df) for a structural equation model are calculated using the standard equation:

$$df=\frac{1}{2}p(p+1)-q$$

where, p represents the total number of observed indicators $(p=74)$, and q represents the total number of free parameters to be estimated by the algorithm (including factor loadings, structural coefficients, item variances, and error covariances).

Given the large number of indicators, the model yields a high degree of freedom, which dramatically enhances statistical power. Under these parameters, a minimum sample size of $N=200$ to $N=350$ is statistically sufficient to achieve a power level exceeding 0.80 at a significance level of $\alpha=0.05$ for detecting close fit $(RMSEA<0.05)$.This critical mass provides enough empirical information to ensure that the inversion of the $(\mathbf{I}-\mathbf{B})$ matrix remains stable during numerical optimization, preventing the occurrence of Heywood cases or non-convergent solutions.

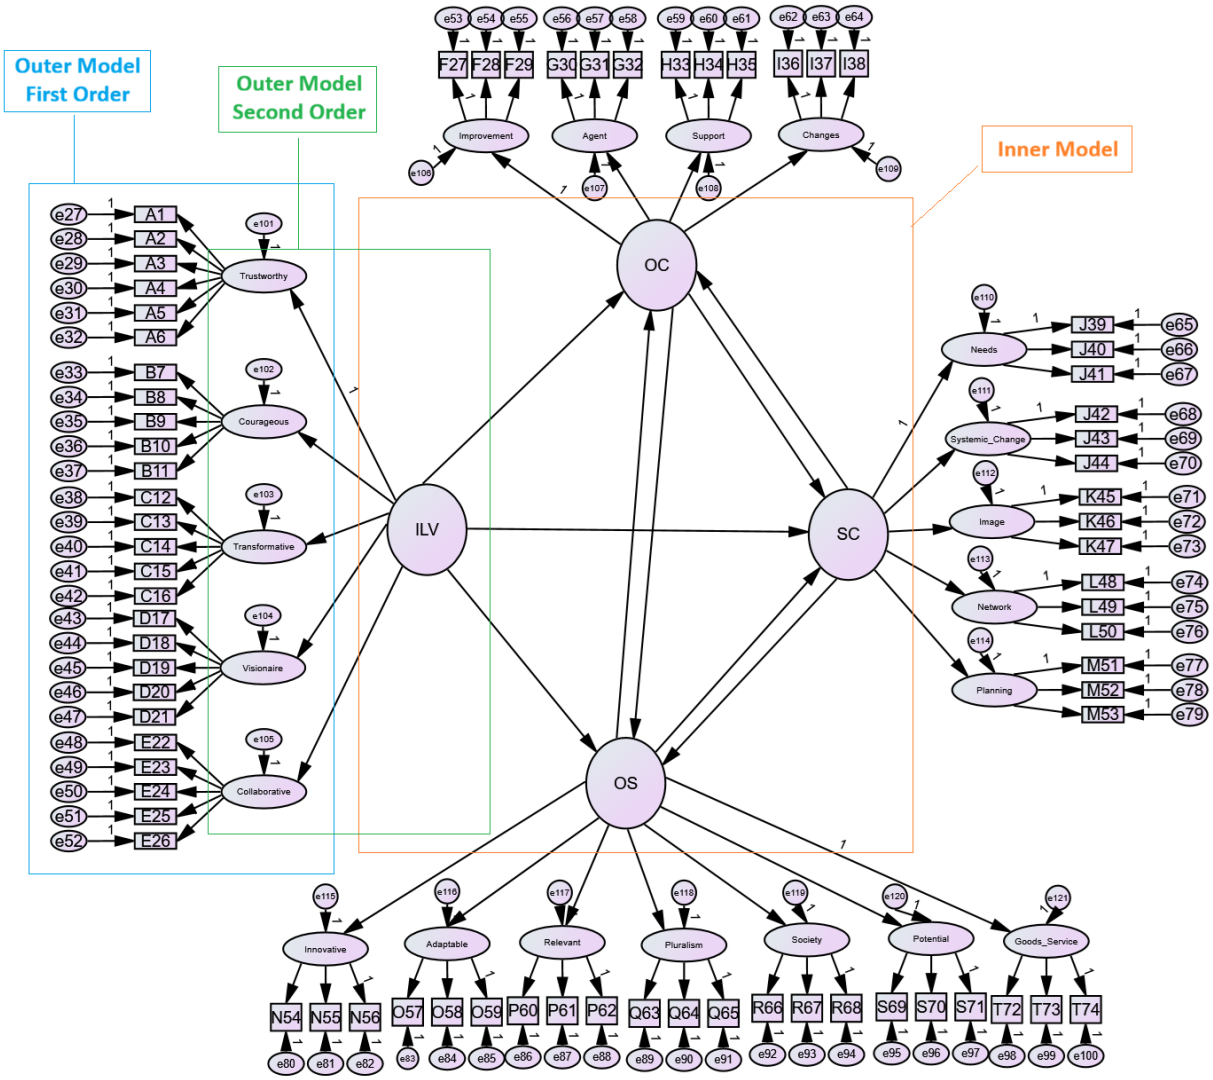

Fig. 2. Relationship model in Structural Equation Modeling (SEM).

IV. Results

Multicollinearity can result in distorted or inaccurate outcomes when a researcher or analyst tries to evaluate the effectiveness of each independent variable in predicting or explaining the dependent variable in a statistical model. Variance Inflation Factors (VIFs) can be used to assess the extent of multicollinearity, which is the correlation between indicators. VIF measures the degree to which the variance of the estimated regression coefficients is increased due to linear relationships among indicators. A VIF value exceeding 5.0 for an indicator suggests excessive collinearity [32]. All VIF values for the indicators of this construct were below the threshold of 5, indicating that there was no collinearity issue with the data. Therefore, the next step of estimating the relationships in the structural model can be conducted.

The SLF value is pivotal for evaluating the measurement model's quality and the constructs' validity. SLF represents the standardized regression weights that indicate the degree of association between each observed variable and its corresponding latent variable. Generally, an SLF value of 0.7 or higher is considered acceptable, indicating that the observed variable accounts for a substantial portion of the variance in the latent construct, while loadings between 0.5 and 0.7 may still be retained if the construct's composite reliability and average variance extracted remain adequate (Hair et al., 2019). Reliability is evaluated based on a construct's internal consistency. A Composite Reliability (CR) value of > 0.7 indicates high reliability, suggesting that the construct's indicators consistently measure the same concept. CR, like Cronbach's Alpha, measures the coherence among the indicators of a construct.

Table II shows construct indicators after the elimination process based on SLF value and the CFA process for identifying the Goodness of Fit (GoF) index. GoF is a measure used to assess how well the proposed model fits the observed data. A higher GoF value indicates a better fit, with values ranging from 0 to 1.0, where 1.0 signifies optimal alignment between the model and the data. To improve the GoF, the model may require modifications, such as removing certain indicators or adjusting variables and connections among indicators based on modification indices.

TABLE II. SLF, AVE, AND CR VALUE AFTER MODIFICATION

Latent Variables	Indicators	SLF	AVE	CR
Independent Variable: ILV				
Trustworthy (First Order)	A3. Committed	0.759	0.564	0.795

Based on the SLF analysis, we excluded indicators A1 and B7 (Table I) due to their SLF values being less than 0.7. Further modifications to the model were made after conducting the CFA, leading to the elimination of indicators A2, A5, B8, B9, C12, C13, D20, D23, D26, G32, J42, K48, M51, N56, O57, R67, S71, and T72. Additionally, some latent variables were also eliminated, including Image (indicators K45–K47) as a latent

variable of SC, as well as Relevant (indicators P60–P62) and Pluralism (indicators Q63–Q65) as latent variables of OS.

The refinement process was guided by both statistical evidence and theoretical considerations rather than solely by model fit improvement, consistent with established SEM recommendations (Hair et al., 2019; Kline, 2023). Indicators and first-order constructs were retained only when they demonstrated satisfactory measurement properties and continued to represent the conceptual meaning of their corresponding second-order constructs.

TABLE III. THE VALUE OF GOODNESS OF FIT (GOF) CONSTRUCTS

GoF Index	Cutoff Value	GoF Model	Remark
X2-Chi Square	<28.869	2147.798	Poor Fit
Significance Probability	> 0.05	0	Poor Fit
DF	> 0	824	Good Fit
GFI	> 0.90	0.815	Marginal Fit
IFI	> 0.90	0.940	Good Fit
NFI	> 0.95	0.91	Good Fit
CFI	> 0.95	0.940	Good Fit
TLI	< 2.0	0.934	Good Fit
CMIN/DF	<0.05	2.804	Good Fit
RMSEA	<0.05	0.059	Good Fit
SRMR		0.045	Good Fit
Stability		0.921	Good Fit

After the validity and reliability assessments, all constructs achieved satisfactory GoF values as shown in Table III above.

The overall model fit is presented in Table III. The chi-square statistic was significant ($\chi^2 = 2147.798$, $p < .001$), and the Goodness-of-Fit Index (GFI = 0.815) was below the conventional threshold, indicating less than optimal absolute model fit. However, the chi-square statistic is well known to be highly sensitive to sample size and model complexity, often resulting in significant values even when the model adequately represents the observed data. Similarly, GFI has been criticized for its sensitivity to model complexity and sample size and is no longer recommended as a primary criterion for evaluating SEM model fit.

Therefore, model evaluation was based on multiple fit indices rather than any single statistic. The remaining fit indices, including RMSEA, CFI, TLI, and the normed chi-square (CMIN/DF), satisfied commonly accepted thresholds, indicating that the proposed model demonstrates an acceptable overall fit to the observed data despite the limitations reflected in the chi-square statistic and GFI.

The refinement of the measurement model has theoretical implications for the interpretation of the proposed framework. The exclusion of Build Professional Image from Sustaining Change and Stay Relevant, Embrace Pluralism, and Continue Producing Goods & Services from Organizational Sustainability suggests that these dimensions were not empirically supported within the present sample. Therefore, the final model should be interpreted as representing those dimensions of sustaining change and organizational sustainability that demonstrated adequate empirical support in this organizational context, rather than the full conceptual breadth originally proposed. Future studies should re-examine the excluded dimensions using independent samples and different organizational contexts to determine whether their exclusion reflects sample-specific characteristics or broader theoretical considerations.

Following the assessment of construct validity, reliability, and model fit, all latent constructs were integrated into a single structural model comprising Intrinsic Leadership Values (ILV), Organizational Change (OC), Sustaining Change (SC), and Organizational Sustainability (OS), referred to as the Full Construct Model (Fig. 3). The model was subsequently evaluated using a non-recursive structural equation modeling (SEM) approach. Because the proposed structural model includes reciprocal relationships among Organizational Change (OC), Sustaining Change (SC), and Organizational Sustainability (OS), the initial non-recursive SEM was underidentified. In accordance with established SEM procedures, additional identification constraints were required before the structural parameters could be estimated (Byrne, 2016; Kline, 2023). An unconstrained model estimated in AMOS indicated that three additional identification constraints were necessary. Accordingly, the structural paths ILV→OC, OC→OS, and SC→OC were specified as fixed parameters to satisfy the identification requirements. This specification was retained because it was consistent with the proposed theoretical model and produced an identified, convergent, and stable solution (Stability Index = 0.921). These fixed paths served solely as identification constraints and were not interpreted as empirical estimates of the corresponding structural relationships.

Following model identification, the structural model achieved an acceptable overall fit (Table III). Although the chi-square statistic was significant and the GFI indicated only marginal fit, the remaining fit indices, including IFI, CFI, TLI, RMSEA, SRMR, and CMIN/DF, satisfied commonly accepted thresholds, supporting the adequacy of the proposed structural model. The identified model therefore provided the basis for evaluating the freely estimated structural relationships. Table IV summarizes the structural parameter estimates. Because three structural paths were specified as identification constraints, hypothesis testing focused exclusively on the freely estimated relationships. The results indicate that ILV had a significant positive direct effect on Organizational Sustainability ($\beta = 0.205$, $p < 0.001$), whereas its direct effect on Sustaining Change was not statistically significant ($\beta = -0.021$, $p = 0.632$). Organizational Change exerted a significant positive effect on Sustaining Change ($\beta = 0.633$, $p < 0.001$), while Sustaining Change did not significantly influence Organizational Sustainability ($\beta = -0.360$, $p = 0.504$). Organizational Sustainability demonstrated a significant positive effect on Sustaining Change ($\beta = 0.550$, $p < 0.001$) and a significant negative reciprocal effect on Organizational Change ($\beta = -1.143$, $p < 0.001$) consolidated into a single model, called the Full Construct Model (Fig. 3). The analysis then continued with further GoF testing and a series of model modifications to achieve an acceptable model status, as depicted in Fig. 3.

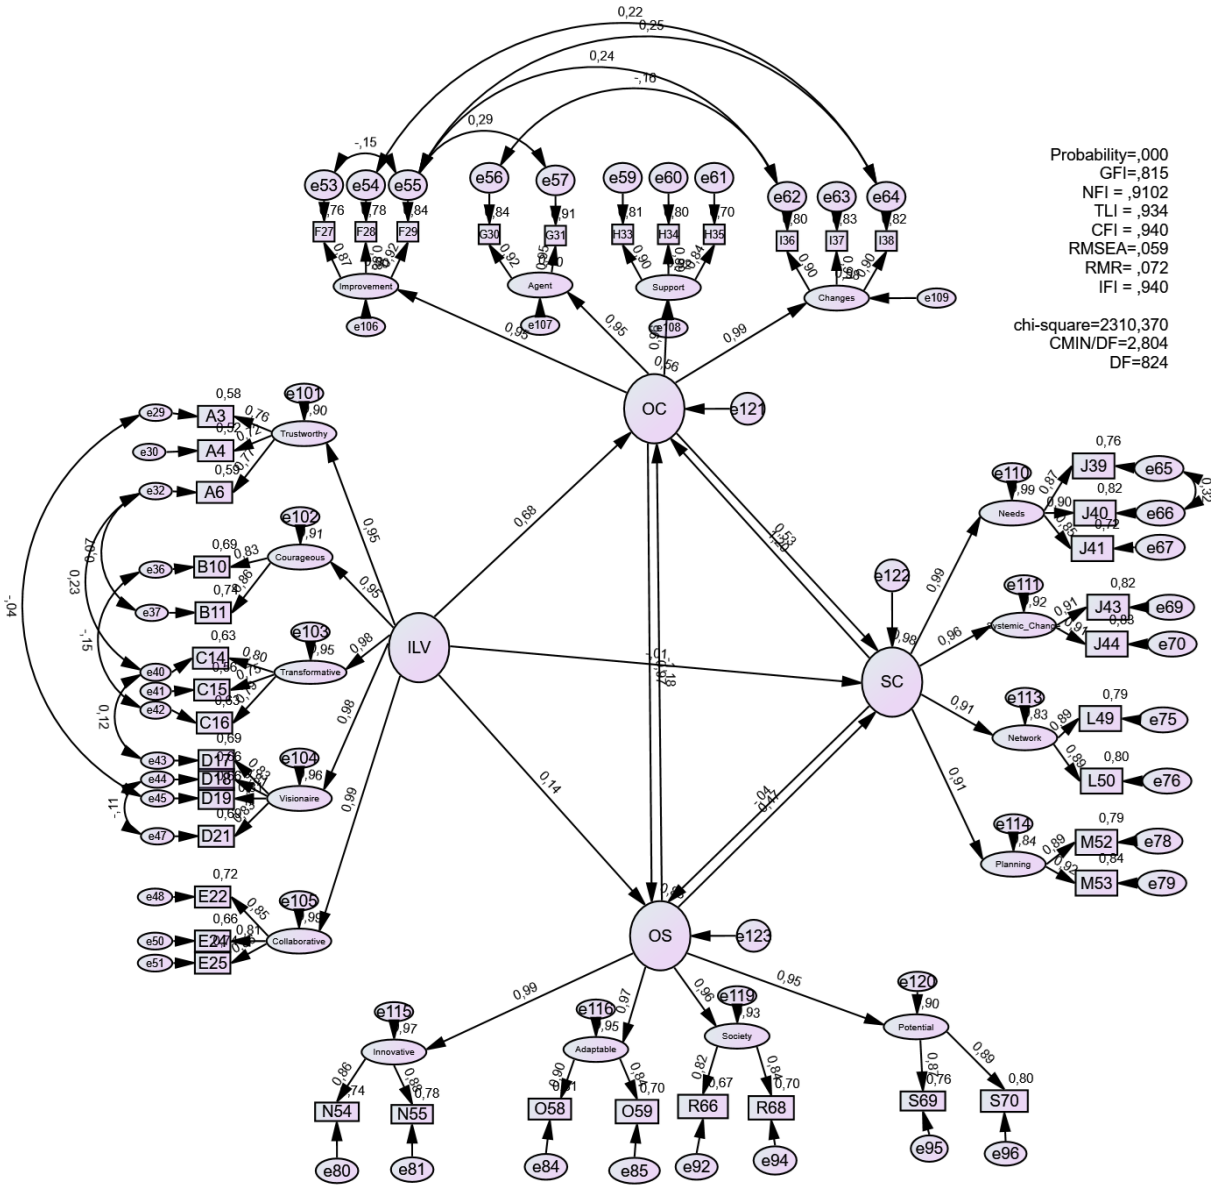

Fig. 3. Full construct model non-recursive.

Non-recursive structural equation models (SEMs) introduce distinct challenges related to functional stability and parameter identification, making the estimation of model parameters more complex. These models require the specification of certain paths that need to be set or restricted to predetermined values to ensure model stability and identifiability. The relationships between these variables were explored based on previous studies to identify constraint points. Previous research has shown strong influences among variables, such as the impact of ILV on OC, OC on OS, and SC on OC. Across various sectors, including public health, education, and management, leadership consistently emerges as a critical factor driving OC, highlighting its vital role, regardless of any debates about its importance [36-40].

Furthermore, studies have shown a strong relationship between OC and OS, as OC is essential for organizations to respond to external shifts and maintain relevance. Sustaining change is also critical for reinforcing organizational transformations. This process entails embedding new work processes and methods, integrating lessons learned, reinforcing new behaviors, evaluating change outcomes against organizational objectives, and developing actions for continuous improvement [41-44].

Following a series of GoF tests and modifications [45-47], the research resulted in an acceptable model, which served as the foundation for the next step: hypothesis testing. The significance analysis of the non-recursive full model is provided in the table below. The AMOS software was utilized as the analytical tool for significance testing, which measures the impact of interactions among variables. Statistically significant interactions indicate the intensity and dynamics of influences between variables and predictors. Table IV below presents the results of these analyses.

TABLE IV. HYPOTHESIS RESULT

Variables			Estimate	CR	P	Description
ILV	→	OC	Fixed			Identification Constraint
ILV	→	OS	0.205	3.501	***	Significant positive
ILV	→	SC	-0.021	-0.479	0.632	Not Significant
OC	→	SC	0.633	10.155	***	Significant positive
OC	→	OS	Fixed			Identification Constraint
SC	→	OC	Fixed			Identification Constraint
SC	→	OS	-0.36	-0.668	0.504	Not Significant
OS	→	OC	-1.143	-14.762	***	Significant negative
OS	→	SC	0.550	8.358	***	Significant positive

The quantitative analysis reveals that Intrinsic Leadership Values (ILV) do not have a statistically significant effect on Sustaining Change (SC), with a coefficient value of −0.021 and a p-value greater than 0.05. Despite this, intrinsic leadership values such as ethical behavior, strategic vision, adaptability, and a supportive approach are crucial for successfully navigating and implementing organizational change. These leadership qualities directly impact employee commitment, organizational culture, and the overall effectiveness of change initiatives ILV has a positive effect on OS, with a coefficient value of 0.205 and a p-value less than 0.05, indicating statistical significance. This significance highlights the critical role of leadership values in fostering organizational sustainability. ILV strengthens decision-making, encourages responsible behavior, and promotes ethical practices. Effective management of change, coupled with a leadership style that emphasizes sustainability, contributes to an improved organizational microclimate and enhanced interpersonal trust, ultimately guiding the team toward sustainable objectives.

V. CONCLUSION

This study developed and validated a cross-sector leadership framework that examines the relationships among Intrinsic Leadership Values (ILV), Organizational Change (OC), Sustaining Change (SC), and Organizational Sustainability (OS) using a non-recursive structural equation modeling approach. The findings indicate that ILV has a significant positive direct effect on Organizational Sustainability, whereas its direct effect on Sustaining Change was not statistically significant. The reciprocal relationships among OC, SC, and OS demonstrate that organizational change and sustainability are dynamic and mutually influential processes, highlighting the importance of integrating leadership values with organizational mechanisms that institutionalize and sustain change.

These findings have important practical implications for public institutions, corporations, and non-profit organizations. Organizations should strengthen Leadership Development Programs (LDPs) that cultivate intrinsic leadership values while simultaneously building organizational capabilities that support innovation, adaptability, stakeholder engagement, succession planning, and continuous learning. Rather than focusing solely on developing individual leaders, organizations should also establish systems that reinforce sustainable organizational practices and enable change to be embedded over time.

Given the increasingly interconnected nature of societal challenges, leadership development should also promote cross-sector understanding and collaboration. Programs such as Indonesia Mengajar illustrate how exposing leaders to different organizational and community contexts can broaden their perspectives, strengthen intrinsic leadership values, and enhance their capacity to develop collaborative solutions to complex social problems. Such experiences help leaders integrate strategic thinking with social responsibility, thereby supporting more sustainable organizational outcomes across sectors.

VI. LIMITATION

A limitation of this study is that measurement refinement resulted in the removal of 18 indicators and four first-order constructs. Although the retained constructs demonstrated satisfactory reliability and validity, the resulting measurement model represents a more focused operationalization of Sustaining Change and Organizational Sustainability than originally conceptualized. Future research should validate the revised measurement model using independent samples and examine whether the excluded dimensions can be replicated across different organizational and cultural contexts.

***Abstract*—The rapid advancement of immersive technologies has significantly expanded the scope of Human-Computer Interaction (HCI) within the context of Immersive Virtual Reality (IVR). Despite the growing body of research, the field remains fragmented, with limited understanding of its intellectual and thematic development. This study conducts a comprehensive bibliometric analysis of HCI research within IVR using data retrieved from the Web of Science (WoS) Core Collection. A total of 1,185 publications from 2010 to 2026 were initially identified and refined to 1,129 records following a systematic screening process. The analysis employs co-citation and keyword co-occurrence techniques using VOSviewer to examine both the knowledge base and thematic development of the field. The findings reveal a substantial increase in publication output and citation impact, indicating the growing maturity and relevance of HCI research in IVR. Co-citation analysis identifies four major intellectual domains: presence and immersive experience, user experience and application contexts, usability and human factors, and behavioral and psychological interaction. Meanwhile, keyword co-occurrence analysis uncovers four dominant thematic clusters, including core interaction and system design, human-centered computing, visualization and spatial interaction, and emerging immersive technologies. This study contributes by providing a structured and data-driven mapping of the research landscape, emphasizing the relationships between interaction design, user experience, and technological advancement. The findings offer both theoretical and practical implications for advancing more integrated and user-centered approaches in immersive virtual environments, while also identifying key directions for future research.**

***Keywords*—Human-computer interaction (HCI); Immersive virtual reality (IVR); immersive technologies; User experience (UX); bibliometric analysis; science mapping**

I. INTRODUCTION

Human-Computer Interaction (HCI) has become a fundamental domain in understanding how users engage with interactive systems as digital technologies move toward more immersive and experiential forms. The emergence of Immersive Virtual Reality (IVR) has significantly expanded the boundaries of HCI by introducing fully interactive environments that enable users to engage through natural, spatial, and embodied interaction [1]. Unlike traditional interfaces, IVR systems rely on advanced technologies such as head-mounted displays (HMDs), motion tracking, and multimodal feedback, thereby redefining how interaction is designed and evaluated within digital environments [2][3]. Within this context, core HCI constructs such as user experience (UX), usability, interaction design, and navigation have become increasingly critical in determining the effectiveness of IVR systems. User experience in immersive environments extends beyond functional performance to encompass factors such as presence, engagement, and perceived realism, all of which influence how users interpret and respond to virtual stimuli [3]. Similarly, usability in IVR is not limited to efficiency and effectiveness but also involves considerations of physical comfort, cognitive load, and ease of interaction within three-dimensional spaces [4]. Interaction design in IVR further requires the development of intuitive techniques such as gesture-based input, gaze interaction, and haptic feedback, which align with human perceptual and motor capabilities [5]. In addition, navigation within virtual environments plays a pivotal role in shaping user experience, as users must be able to orient themselves, move seamlessly, and interact with virtual objects without confusion or disorientation [6].

The shift toward immersive interaction has introduced new opportunities as well as challenges for HCI research. While IVR enables more natural and engaging forms of interaction, it also raises critical issues such as cybersickness, cognitive overload, and user disorientation, which can negatively affect user performance and overall experience [7], [8], [9]. These challenges underscore the need for robust HCI design strategies that integrate usability, interaction efficiency, and user-centered evaluation to ensure effective immersive experiences [10]. However, this growing body of literature is often fragmented across multiple research streams, making it difficult to obtain a comprehensive understanding of the field's development and key contributions. Traditional review approaches may provide valuable insights into specific areas but are limited in their ability to systematically map the overall structure and evolution of research within this domain [11]. In this context, bibliometric analysis offers a systematic and quantitative approach to examining large volumes of scientific literature. By analyzing relationships between publications and keywords, bibliometric methods enable the identification of influential studies, research trends, and thematic developments within a field [12], [13]. Such an approach is valuable for HCI research in IVR, where the interdisciplinary nature of the field contributes to its complexity and rapid evolution.

Therefore, this study aims to conduct a bibliometric analysis of research trends in Human-Computer Interaction within Immersive Virtual Reality applications. Specifically, this study focuses on two key analytical techniques:

- Co-citation analysis is employed to uncover the structure of the field by identifying relationships among influential publications and revealing foundational research streams.
- Keyword co-occurrence analysis is conducted to explore the dominant and emerging research themes that are interconnected within the literature.

II. Literature Review

Human-Computer Interaction (HCI) has evolved into a multidisciplinary field that examines how users interact with digital systems through the integration of design, cognition, and technology [14]. Within this domain, increasing attention has been directed toward Immersive Virtual Reality (IVR), which has successfully introduced different interaction paradigms compared to conventional systems [15]. In IVR, users are not merely interacting with interfaces but are actively situated within virtual environments, requiring continuous perception, movement, and real-time feedback [16]. In this context, HCI becomes critically important as it serves as the foundation for designing intuitive, efficient, and user-centered interactions that directly influence how users perceive and engage with immersive systems. Poorly designed interaction mechanisms can disrupt immersion, reduce usability, and negatively impact user performance, while effective HCI design enhances presence, engagement, and overall system effectiveness [1]. As such, HCI is not only a supporting component but a central determinant of the success and acceptance of IVR applications across various domains [4]. For example, as users are fully immersed within virtual environments, the design of interaction mechanisms directly influences their ability to perceive, navigate, and engage with digital content [17]. Ineffective interaction design may lead to confusion, reduced immersion, and poor task performance, while well-designed HCI enhances presence, engagement, and user satisfaction [4]. Therefore, HCI is not merely a supporting component but a central factor that governs the success, acceptance, and overall user experience of IVR applications across various domains [18].

On the other hand, a central aspect of HCI research in IVR lies in the examination of user experience, which encompasses usability, interaction design, and navigation as key determinants of system effectiveness. Usability in immersive environments goes beyond efficiency and effectiveness, encompassing ease of interaction, physical comfort, and the management of cognitive load, while interaction design emphasizes the development of intuitive techniques such as gesture-based input, gaze interaction, and haptic feedback that align with human perceptual and motor capabilities [19]. On the other hand, navigation plays a pivotal role in enabling users to orient themselves and move seamlessly within three-dimensional spaces, directly influencing spatial awareness and task performance [20]. Despite extensive research efforts, these elements are often investigated independently, leading to fragmented insights and limited integration across usability, interaction, and navigation perspectives. Furthermore, inconsistencies in evaluation methods have resulted in a lack of standardized frameworks for assessing user experience in IVR [21]. Human factors such as cybersickness and cognitive load further complicate this landscape, as they significantly impact user comfort and performance [22]. From a theoretical perspective, several frameworks have been employed to explain user interaction and experience in immersive environments. The Cognitive Theory of Multimedia Learning (CTML) proposed by Mayer provides insights into how users process information in IVR, especially in relation to cognitive load and instructional effectiveness [23], [24]. Presence theory further explains the psychological state of "being there," emphasizing the importance of interaction fidelity and sensory consistency in enhancing immersion [25].

Additionally, the concept of embodied cognition highlights the role of physical interaction and bodily movement in shaping user understanding and engagement within virtual environments [26]. While these theories offer valuable perspectives, their application in HCI research for IVR remains fragmented, with limited integration into practical interaction design and evaluation approaches.

Despite the growing body of literature, research in HCI and IVR remains highly fragmented across multiple domains and research streams. Existing studies often focus on isolated aspects such as interaction techniques, usability, or human factors, without establishing clear relationships between these components [27]. Moreover, current review approaches are often limited in scope or rely on qualitative synthesis, which may not fully capture the structural relationships between studies or the evolution of research themes over time [28]. This limitation restricts the ability to identify dominant research clusters, influential works, and emerging directions within the field [29]. Therefore, there is a need for a systematic and data-driven approach to synthesize the expanding body of literature and provide a comprehensive understanding of the field. In response to this gap, this study employs a bibliometric approach integrating co-citation and keyword co-occurrence analyses to map both the intellectual structure and thematic development of HCI research within IVR.

III. Methodology

A. Bibliometric Approach

Bibliometric analysis has emerged as a rigorous and systematic approach for examining the structure and development of scientific research within a given domain [30]. Unlike traditional narrative reviews, which are often limited by subjective interpretation, bibliometric methods employ quantitative techniques to analyze large volumes of scholarly data, enabling the identification of publication patterns, influential works, and knowledge structures [12]. This approach is appropriate in rapidly evolving and interdisciplinary fields such as Human-Computer Interaction (HCI) and Immersive Virtual Reality (IVR). Among the various bibliometric techniques, co-citation analysis and keyword co-occurrence analysis are widely recognized for their complementary strengths in uncovering both the intellectual and thematic dimensions of a research field [31]. For this study, the co-citation analysis and keyword co-occurrence

analysis have been selected to meet the two objectives of the study:

- Co-citation analysis examines the frequency with which two documents are cited together by subsequent publications, thereby revealing the underlying intellectual structure and identifying seminal works that have significantly influenced the development of the domain [32]. By mapping co-citation networks, researchers can detect clusters of related studies, which often correspond to distinct research streams or theoretical foundations.
- Keyword co-occurrence analysis focuses on the relationships between frequently used terms within publications, providing insights into the conceptual and thematic structure of research. This technique assumes that keywords appearing together in multiple documents are likely to represent related concepts or research topics. As such, co-occurrence analysis enables the identification of dominant themes, emerging trends, and the evolution of research topics over time [33].

The integration of co-citation and keyword co-occurrence analyses offers a comprehensive perspective on the development of a research field by simultaneously capturing its foundational knowledge base and its evolving thematic landscape. This dual approach is relevant for HCI research in IVR, where understanding both the theoretical underpinnings and emerging interaction paradigms is essential for advancing user-centered design and improving immersive experiences.

B. Research Design and Data Collection Procedure

This study adopts a quantitative bibliometric research design to examine research trends in Human-Computer Interaction (HCI) within Immersive Virtual Reality (IVR), utilizing data retrieved from the Web of Science (WoS) Core Collection. The search was conducted using the Topic field, incorporating keywords related to "human-computer interaction" AND "immersive virtual reality" OR "virtual reality," and further refined with relevant HCI terms such as "user experience" OR "usability" OR "interaction". The search was limited to English-language articles and review papers published between 2010 and 2026. An initial 1,185 records were retrieved and exported as plain text files containing full records and cited references. A PRISMA-informed screening process involving duplicate removal, title and abstract screening, and keyword standardization was then performed, resulting in a final dataset of 1,129 publications (Fig. 1). This structured procedure improves the transparency and reproducibility of the study.

The analysis was performed using VOSviewer to visualize bibliometric networks based on similarity measures, where node proximity represents relationship strength and clusters indicate distinct research themes. In line with the study objectives, co-citation analysis was employed to identify the intellectual structure of the field, while keyword co-occurrence analysis was used to examine its thematic development.

A minimum citation threshold of 15 and a keyword occurrence threshold of 16 were applied, with both thresholds iteratively calibrated to achieve clear and meaningful network visualizations while minimizing noise.

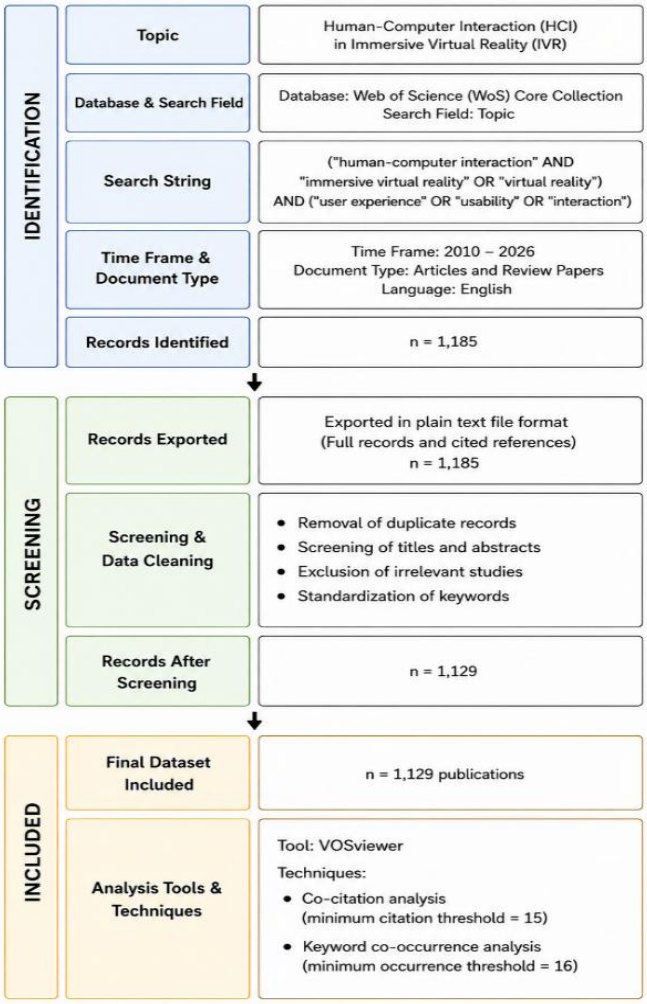

Fig. 1. Flow diagram of the screening process.

IV. RESULT

A. Trend in Publication

The Web of Science (WoS) database was searched on 28 April 2026 to retrieve relevant publications for this study. The analysis of publication trends reveals a significant and sustained growth in research related to Human-Computer Interaction (HCI) within Immersive Virtual Reality (IVR) over the examined period. A total of 1,185 publications were identified, indicating increasing scholarly interest in this domain. In the early stage (2010–2015), the number of publications remained relatively low and relatively stable, with fewer than 25 publications per year, reflecting the nascent development of IVR technologies and their limited integration within HCI research. Fig. 2 highlights the number of publications and citations received for these publications.

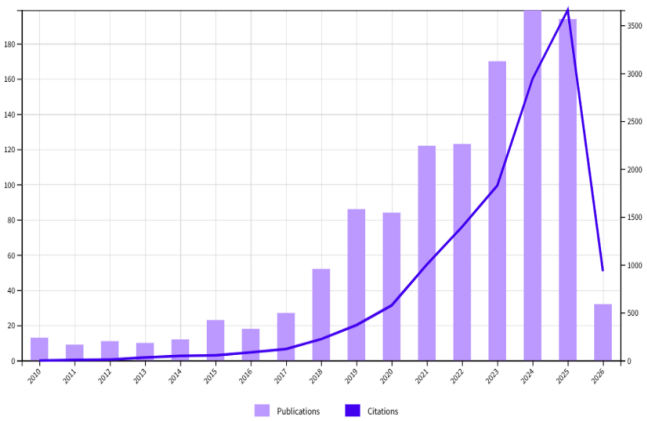

Fig. 2. Number of publications and citations between 2010 and 2026.

A noticeable upward trend emerged around 2017, followed by a rapid increase from 2018 onwards. This period represents a critical turning point, with publication output rising significantly to over 80 publications in 2019 and continuing to grow in subsequent years. The expansion became more pronounced between 2021 and 2025, when annual publications consistently exceeded 120, peaking at approximately 190 publications in 2024. This surge is likely associated with technological advancements in immersive systems, increased accessibility of VR devices, and a growing emphasis on user experience and interaction design in virtual environments. In parallel, citation trends demonstrate a similar trajectory of growth, indicating not only an increase in research output but also a strengthening academic impact.

The total number of citations reached 13,287, with an average of 11.21 citations per publication and an H-index of 53, suggesting a mature and influential research domain. The sharp rise in citations after 2020 further reflects the increasing relevance and recognition of HCI research in IVR. A decline in publication count is observed for 2026; however, this is likely due to incomplete indexing for the current year rather than an actual reduction in research activity. Overall, the findings indicate that HCI research in IVR has evolved from an emerging field into a rapidly expanding and impactful domain, demonstrating strong and sustained growth in recent years.

B. Co-Citation Analysis

Co-citation analysis was conducted to examine the structure of research in Human-Computer Interaction (HCI) within Immersive Virtual Reality (IVR). A minimum citation threshold of 15 citations was applied, resulting in 39 cited references being included in the analysis. The network visualization generated using VOSviewer revealed four distinct clusters, such as presence and immersion (theoretical foundation), user experience and applications (applied research), usability and evaluation (measurement frameworks), and behavioral and social interaction (human-centered perspective). Each of these clusters represents a major research stream within the domain. These clusters are differentiated by color and reflect the foundational knowledge areas that have shaped the development of HCI in IVR. As illustrated in Fig. 3, the network exhibits a structured knowledge domain, which is characterized by strong interrelationships among key studies.

To further examine the intellectual foundations of the field, the most influential co-cited references were identified based on their citation frequency and total link strength within the network. These highly cited works represent the core knowledge base that has significantly shaped the development of Human-Computer Interaction (HCI) research in Immersive Virtual Reality (IVR). They reflect key research domains, including presence and immersion, usability and human factors evaluation, cognitive workload, and application-oriented studies. Among these, [34] emerged as the most highly cited reference with 69 citations and a total link strength of 145, highlighting its dominant role in establishing standardized measurement of simulator sickness in immersive environments.

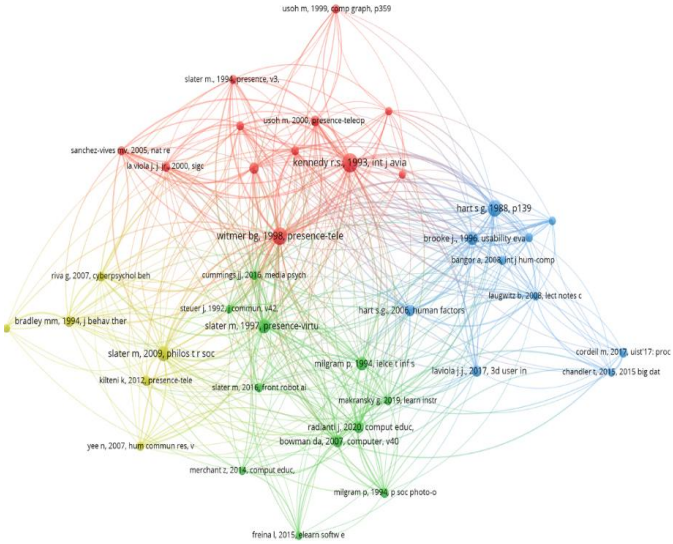

Fig. 3. Co-citation network analysis visualization.

Similarly, [35] demonstrated strong network connectivity with 61 citations and the highest total link strength of 161, indicating its central influence in presence measurement research. Other notable contributions include [36] with 53 citations (TLS = 96) and [37] with 41 citations (TLS = 131), both of which further reinforce the importance of cognitive workload and presence as key research themes. The prominence of these references indicates their critical role in establishing theoretical frameworks, measurement instruments, and interaction paradigms that underpin current research trends. Table I presents the top 10 co-cited references, highlighting their citation impact, network connectivity, and scope of study.

The predominance of earlier publications among the top co-cited references is expected, as these studies established the theoretical foundations and measurement instruments that continue to underpin HCI research in IVR. Foundational works such as [34] and [35] remain highly cited due to their enduring contributions to evaluating simulator sickness, presence, and usability. In contrast, more recent publications have had less time to accumulate citations despite their growing influence. The co-citation analysis identified four major clusters representing the intellectual structure of HCI research in IVR. Using a minimum citation threshold of 15, a total of 39 references were included. For clarity and analytical focus, each

cluster is interpreted based on its most influential (top-cited) references, which best represent the core themes of the cluster.

TABLE I. TOP TEN CO-CITED REFERENCES WITH THE STRONGEST TOTAL LINK STRENGTH

Rank	Reference	Citations	Total Link Strength	Scope of Study
1	[34]	69	145	Development of the Simulator Sickness Questionnaire (SSQ).
2	[35]	61	161	Introduction of the Presence Questionnaire.
3	[36]	53	96	Proposal of the NASA-TLX model for assessing cognitive workload.
4	[37]	41	131	Theoretical exploration of presence in virtual environments.
5	[53]	42	76	Conceptual discussion on place illusion and plausibility illusion.
6	[50]	37	56	Introduction of the reality–virtuality continuum.
7	[40]	34	69	Development of the System Usability Scale (SUS).
8	[38]	30	66	Systematic review of IVR applications in higher education.
9	[39]	28	69	Comprehensive framework on 3D interaction techniques.
10	[52]	25	68	Development of presence measurement models.

Source. Author's interpretation derived from VOSviewer analysis.

Cluster 1 (Red): Presence and Immersion comprise influential studies such as [34], [35], and [37], which establish the theoretical and measurement foundations of presence, immersion, and simulator sickness in virtual environments. From an HCI perspective, this cluster is critically important as it defines the core experiential outcomes such as presence, immersion, and comfort that determine the success of interaction in IVR. These constructs directly influence user experience and usability, as poor immersion or high discomfort can negatively affect interaction performance and system acceptance. However, while these studies provide strong theoretical and measurement foundations, they offer limited insight into how specific HCI design elements (e.g., interaction techniques or navigation methods) can be optimized to enhance these outcomes, indicating a gap between theory and design implementation.

Cluster 2 (Green): User Experience and Application-Oriented Research includes key studies such as [29], [38], and [39], focusing on user experience, education, and interaction techniques in IVR. However, many studies within this cluster emphasize application outcomes (e.g., performance, learning effectiveness) rather than systematically analyzing how usability, interaction design, and navigation mechanisms contribute to these outcomes. This suggests that HCI elements are often embedded but not explicitly examined, limiting a deeper understanding of interaction design in IVR.

Cluster 3 (Blue): Usability and Human Factors Evaluation is represented by [40] and [36], which introduce widely adopted evaluation instruments such as the System Usability Scale (SUS) and NASA-TLX. This cluster plays a crucial role in HCI by providing measurement frameworks for assessing usability, workload, and user satisfaction in IVR systems. These factors are essential for understanding how users interact with immersive environments and for improving interaction efficiency and system design. However, a key limitation is that these tools were originally developed for non-immersive systems, and their direct application to IVR may not fully capture unique aspects such as spatial interaction, embodiment, and navigation complexity. This highlights the need for IVR-specific HCI evaluation frameworks that better reflect immersive interaction characteristics.

The last cluster (Cluster 4 (Yellow): Behavioral and Psychological Interaction) represented by works such as [41], [42], and [43], which explore user behavior, emotional response, and social interaction in virtual environments. These studies provide insights into how users respond cognitively and emotionally within immersive systems. In relation to HCI, this cluster is important as it informs the design of user-centered and emotionally engaging interactions in IVR. Understanding user behavior and emotional response is essential for improving interaction design, engagement, and overall user experience. However, these studies often remain at a descriptive or theoretical level, with limited translation into practical HCI design strategies, such as improving usability or navigation. This creates a gap between behavioral insights and interaction design implementation in IVR systems, as summarized in Table II.

TABLE II. SUMMARY OF CO-CITATION CLUSTERS ON HCI FOR IVR

Cluster	Cluster Label	Number of Publications	Representative Publications
Cluster 1 (Red)	Presence and Immersion in Virtual Environments	12	[34],[35],[37],[53]
Cluster 2 (Green)	User Experience and Application-Oriented Research	10	[38],[39]
Cluster 3 (Blue)	Usability and Human Factors Evaluation	9	[40],[36]
Cluster 4 (Yellow)	Behavioral and Psychological Interaction	8	[41],[42],[43]

Source. Author's interpretation derived from VOSviewer analysis

C. Co-Occurrence of Keyword Analysis

A co-occurrence analysis of keywords was conducted to identify the dominant research themes in Human-Computer Interaction (HCI) within Immersive Virtual Reality (IVR). A

minimum occurrence threshold of 16 was applied, resulting in 48 out of 3,407 keywords being included in the analysis. The findings indicate that "virtual reality" (549 occurrences) is the most dominant keyword, followed by "human-computer interaction" (279 occurrences), "human-centered computing" (183 occurrences), and "human computer interaction (HCI)" (153 occurrences), highlighting the central role of immersive technologies and user-centered interaction. Additional keywords such as "interaction paradigms", "augmented reality", and "visualization" reflect a strong emphasis on interaction design and technological development, while terms such as "design", "system", and "environments" indicate the importance of system implementation. The presence of keywords related to applications, including "education" and "mixed reality", further suggests the expanding scope of IVR research. However, variations in similar keywords and the distribution of themes indicate a degree of fragmentation, where key HCI components such as usability, interaction design, and user experience are not fully integrated. Table III presents the top 15 most frequently co-occurring keywords identified in this study. The relationships among these keywords are further illustrated through network visualization (see Fig. 4), which reveals several distinct yet interconnected thematic clusters, as discussed in the following section.

TABLE III. THE 15 MOST FREQUENT KEYWORDS IN THE KEYWORD CO-OCCURRENCE ANALYSIS

Rank	Keyword	Occurrences	Total Link Strength
1	virtual reality	549	1177
2	human-computer interaction	279	513
3	human-centered computing	183	659
4	human computer interaction	153	548
5	interaction paradigms	128	487
6	human computer interaction	95	181
7	augmented reality	88	218
8	visualization	65	177
9	virtual-reality	64	157
10	environments	50	145
11	design	49	123
12	mixed reality	47	140
13	education	46	146
14	system	38	110
15	computing methodologies	27	149

Source. Author's interpretation derived from VOSviewer analysis

Cluster 1 (Red), consisting of 23 keywords, represents the core domain of interaction, system design, and user experience in immersive virtual reality. Prominent keywords such as "virtual reality", "human-computer interaction", "user experience", "usability", "design", and "system" indicate a strong emphasis on the development and evaluation of interactive virtual environments. The centrality of "virtual reality" and "human-computer interaction" highlights that this cluster forms the foundational layer where immersive systems and user interaction are closely integrated [25][39]. The presence of "user experience" and "usability" reflects the importance of evaluating how users interact with virtual environments in terms of efficiency, effectiveness, and satisfaction, which are core principles in HCI [40]. In immersive contexts, these aspects are closely associated with interaction quality, system responsiveness, and task performance. Keywords such as "performance", "behavior", and "experience" further reinforce this focus, suggesting that user outcomes and engagement are critical indicators of system effectiveness [29]. Additionally, the inclusion of "immersion" and "environments" highlights the experiential nature of interaction in IVR, where users' perception and engagement are influenced by the design of the virtual space [37]. Emerging terms such as "metaverse" and "machine learning" indicate a shift toward more advanced and adaptive immersive systems. However, despite the strong presence of these keywords, the cluster suggests that usability, interaction, and performance are often examined independently, indicating a lack of integrated approaches in designing cohesive user experiences within immersive virtual environments.

Cluster 2 (Green), consisting of 11 keywords, focuses on human-centered computing and interaction paradigms, with key terms such as "human-centered computing", "interaction paradigms", "user studies", "HCI design and evaluation methods", and "computer graphics". These keywords highlight the importance of designing interactive systems that align with human capabilities and user needs [44] [46]. The presence of "interaction paradigms" reflects ongoing exploration of novel interaction techniques in immersive environments [39]. Keywords such as "user studies" and "empirical studies in HCI" indicate the reliance on experimental and user-based evaluation methods to assess system effectiveness [45]. Meanwhile, "computer graphics" and "graphics systems and interfaces" support the visual and interactive components essential for immersive experiences. The inclusion of "mixed reality" and "applied computing" further suggests the extension of interaction paradigms beyond VR into broader immersive ecosystems. However, while this cluster emphasizes methodologies and conceptual frameworks, it provides limited insight into how these approaches are translated into practical interaction design solutions in immersive environments.

Cluster 3 (Blue), consisting of 10 keywords, represents research on visualization, perception, and spatial interaction in immersive environments. Key terms such as "visualization", "virtual environments", "perception", "navigation", and "three-dimensional displays" highlight the importance of sensory processing and spatial awareness in virtual systems. Visualization and display technologies play a crucial role in presenting immersive content, influencing how users interpret and interact with virtual environments [47]. The presence of "perception" indicates a focus on how users cognitively process visual and spatial information, which directly affects immersion and interaction quality [48]. Similarly, "navigation" is essential for enabling users to move effectively within virtual spaces, impacting spatial orientation and task performance [49]. The inclusion of "simulation" and "reality" further suggests applications in training and experiential environments. However, this cluster indicates that research is often centered on technical and perceptual aspects, with less emphasis on

integrating these elements into broader interaction design and user experience considerations.

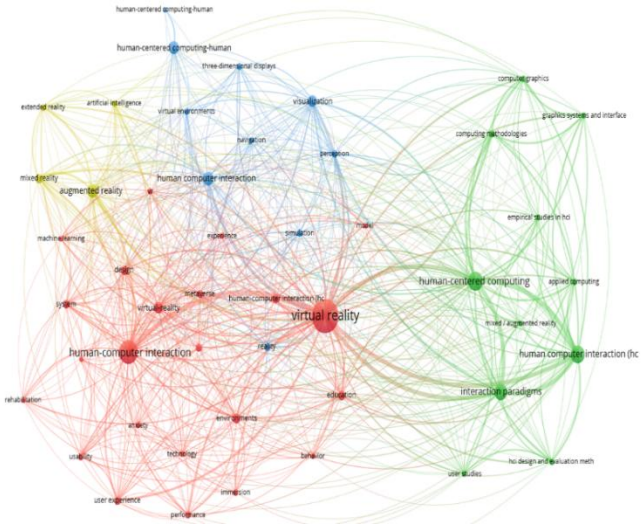

Fig. 4. Co-occurrence keyword network analysis visualization.

Cluster 4 (Yellow), consisting of 4 keywords, represents emerging and enabling technologies in immersive environments, including "artificial intelligence", "augmented reality", and "extended reality". These keywords highlight the evolution of immersive systems toward more adaptive, intelligent, and hybrid environments [50], [51]. The presence of "artificial intelligence" suggests the integration of intelligent systems to enhance interaction, personalization, and automation within virtual environments. Meanwhile, "augmented reality" and "extended reality" indicate the convergence of physical and virtual spaces, expanding the scope of immersive technologies beyond traditional VR. Although this cluster reflects the future direction of immersive research, it remains relatively small, suggesting that the integration of these technologies into mainstream interaction design and evaluation is still emerging. This highlights the need for further research to ensure consistency, usability, and seamless interaction across different immersive platforms.

As shown in Table IV, the four clusters illustrate a comprehensive yet segmented thematic landscape of research in Human-Computer Interaction (HCI) within Immersive Virtual Reality (IVR), encompassing core system design and user experience (Cluster 1), human-centered interaction approaches (Cluster 2), perceptual and spatial interaction processes (Cluster 3), and emerging immersive technologies (Cluster 4). While each cluster represents a distinct and well-established area of study, the relationships among them remain only partially integrated. Key elements such as interaction design, usability, visualization, and emerging technologies are often explored within separate research streams rather than as interconnected components of a unified framework. This indicates that, although the field has matured across multiple dimensions, there is still a need for more cohesive approaches that link system development, user interaction, and technological advancement. Strengthening these connections is essential for advancing IVR research toward more comprehensive, user-oriented, and effective immersive systems.

TABLE IV. SUMMARY OF CO-OCCURRENCE CLUSTERS ANALYSIS ON HUMAN-COMPUTER INTERACTION FOR IMMERSIVE VIRTUAL REALITY

Cluster No & Color	Cluster Label	Number of Keywords	Representative Keywords
Cluster 1 (Red)	Core Interaction, User Experience, and System Design	23	virtual reality; human-computer interaction; user experience; usability; design; system
Cluster 2 (Green)	Human-Centered Computing and Interaction Paradigms	11	human-centered computing; interaction paradigms; user studies; computer graphics; HCI design and evaluation methods
Cluster 3 (Blue)	Visualization, Perception, and Spatial Interaction	10	visualization; virtual environments; perception; navigation; three-dimensional displays
Cluster 4 (Yellow)	Emerging Technologies and Extended Reality	4	artificial intelligence; augmented reality; extended reality

Source. Author's interpretation derived from VOSviewer analysis

V. DISCUSSION

A. Theoretical Implications

The findings of this study offer several important theoretical contributions to the advancement of Human-Computer Interaction (HCI) within Immersive Virtual Reality (IVR). First, the co-citation analysis demonstrates that the field is strongly grounded in established theoretical frameworks, which are related to presence, cognitive load, and usability evaluation. Foundational works such as presence theory and cognitive workload models continue to serve as the primary conceptual bases for understanding user interaction in immersive environments. However, the dominance of these classical frameworks also suggests that current research remains reliant on theories that were not originally developed for immersive contexts. This indicates a theoretical gap in the development of IVR-specific HCI frameworks that can better account for spatial interaction, embodiment, and multimodal engagement. Second, the keyword co-occurrence analysis reveals that core HCI constructs such as interaction design, user experience, usability, and navigation are frequently studied but often exist as separate thematic domains rather than as an integrated theoretical model.

While interaction paradigms and human-centered computing emphasize user-oriented design, other clusters focus on perceptual processes or emerging technologies, with limited theoretical linkage across these areas. This fragmentation suggests the absence of a unified conceptual framework that systematically connects system design, user perception, and interaction outcomes within IVR. Furthermore, the findings highlight an imbalance between theoretical development and technological advancement. While emerging technologies such as artificial intelligence and extended reality are gaining attention, their integration into existing HCI theories remains

underdeveloped. As a result, current theoretical perspectives may not fully capture the complexity of interaction in next-generation immersive systems. Therefore, this study contributes by emphasizing the need for holistic and integrative theoretical models that bridge foundational HCI principles with the unique characteristics of immersive environments, including real-time interaction, spatial navigation, and user embodiment.

B. Practical Implications

In addition to theoretical contributions, this study provides several practical implications for designers, developers, and researchers involved in IVR system development. First, the findings highlight the importance of adopting a user-centered and integrated design approach. The fragmentation observed across usability, interaction design, and navigation suggests that these components should not be addressed independently.

Instead, designers should consider how these elements interact collectively to influence overall user experience, ensuring that immersive systems are intuitive, efficient, and engaging.

Second, the continued reliance on traditional evaluation tools, such as usability scales and cognitive workload measures, indicates the need for more context-specific evaluation frameworks tailored to IVR environments. Practitioners should be cautious when applying conventional methods, as they may not fully capture immersive interaction characteristics such as spatial awareness, presence, and embodiment. This highlights the importance of developing and adopting more comprehensive evaluation strategies that reflect the complexity of user interaction in virtual environments.

Third, the emergence of technologies such as augmented reality, artificial intelligence, and extended reality suggests that future IVR systems will become increasingly complex and adaptive. As such, developers should prioritize interaction consistency and seamless user experience across platforms when integrating multiple technologies. Ensuring compatibility and coherence in interaction design will be critical for maintaining usability and user satisfaction in hybrid immersive systems.

Finally, the findings underscore the importance of aligning technological capabilities with user needs and application contexts. The presence of keywords related to domains such as education indicates that IVR is being applied across diverse fields. Therefore, practitioners should adopt context-aware design strategies, tailoring interaction techniques and system features to specific user groups and application requirements. By doing so, IVR systems can achieve greater effectiveness, usability, and real-world impact.

VI. Conclusion

This study provides a comprehensive bibliometric analysis of research trends in Human-Computer Interaction (HCI) within Immersive Virtual Reality (IVR) by integrating co-citation and keyword co-occurrence analyses. The findings reveal that the field is underpinned by well-established theoretical foundations such as presence, usability, and cognitive workload, while simultaneously expanding toward application-driven research and emerging immersive technologies. The co-citation analysis highlights the continued influence of foundational studies, indicating the field's reliance on classical frameworks, whereas the keyword co-occurrence analysis uncovers dominant research themes related to interaction design, user experience, visualization, and extended reality. Despite this progress, the results demonstrate a notable fragmentation across research domains, where key components such as usability, interaction design, navigation, and user experience are often investigated independently rather than as part of an integrated framework. This lack of cohesion suggests that current research has yet to fully address the complexity of interaction within immersive environments.

In addition, the reliance on traditional evaluation models and the limited integration of emerging technologies into existing theoretical perspectives further highlight critical gaps in the field. Overall, this study contributes to the literature by providing a structured and data-driven understanding of the research landscape in HCI for IVR. It identifies key knowledge bases, thematic developments, and existing limitations, thereby offering a foundation for future research aimed at developing more integrated, user-centered, and context-aware approaches to immersive system design and evaluation.

VII. Future Work

Building on the findings of this study, several directions for future research can be identified. First, there is a need to develop integrated HCI frameworks specifically tailored to immersive virtual environments, which systematically connect usability, interaction design, navigation, and user experience into a unified model. Such frameworks should account for the unique characteristics of IVR, including spatial interaction, embodiment, and real-time feedback. Second, future studies should focus on designing and validating context-specific evaluation methods that go beyond traditional usability and workload measures. These methods should incorporate immersive factors such as presence, engagement, and spatial awareness to provide a more comprehensive assessment of user interaction in virtual environments. Third, as emerging technologies such as artificial intelligence, augmented reality, and extended reality continue to evolve, further research is required to explore how these technologies can be effectively integrated into HCI design. Attention should be given to ensuring interaction consistency and a seamless user experience across different immersive platforms.

Finally, future bibliometric studies may extend this work by incorporating multiple databases, longitudinal analysis, or advanced techniques such as topic modeling and citation burst analysis to capture more dynamic research trends. Expanding the scope of analysis would provide deeper insights into the evolution of HCI research in IVR and support the development of more robust and comprehensive research directions.

Acknowledgment

This research was supported by the Ministry of Higher Education (MOHE) of Malaysia through the Fundamental Research Grant Scheme – Early Career Researcher (FRGS-EC/1/2024/ICT09/UUM/02/1).

DECLARATIONS

The authors acknowledge the use of AI-based tools, including ChatGPT for language support and structural refinement, and Consensus for literature retrieval during the preparation of this manuscript. The use of these tools was conducted under strict human supervision to ensure the accuracy, clarity, and integrity of the research. Memory-Augmented Autoencoder for Industrial Anomaly Detection

Hai Son[1], Duc Ngo[2*]
Faculty of Information Technology, Posts and Telecommunications Institute of Technology, Hanoi, Vietnam[1, 2]
Laboratory for Advanced Networking Applications, Posts and Telecommunications Institute of Technology, Hanoi, Vietnam[2]

***Abstract*—Unsupervised anomaly detection in industrial manufacturing requires identifying defective products utilizing only defect-free training images. Reconstruction-based methods using autoencoders are widely applied but suffer from limited discriminative power when defects occupy small image regions. This work introduces a Memory-Augmented Autoencoder (MAA) that combines a U-Net reconstruction component with a patch-level memory bank for nearest-neighbor-based anomaly scoring. During inference, MAA computes a hybrid anomaly score from both the reconstruction error and the memory distance to produce image-level predictions and spatial anomaly heatmaps. Evaluated on the bottle category of the MVTec AD benchmark, MAA attains an image-level AUC-ROC of 0.985 and an Average Precision of 0.996, surpassing all autoencoder-based baselines including SSIM AE (0.930) and VAE (0.910) and performing on par with the pretrained PaDiM method using a ResNet-18 backbone (0.982), while relying on only 168 defect-free training images and no ImageNet pretraining. A pixel-level AUC-ROC of 0.895 indicates a reasonable spatial localization capability. Ablation studies demonstrate that the memory-based component is the primary driver of detection performance, outperforming the reconstruction component by 16.4 percentage points in AUC-ROC, which is attributable to the robustness of patch-level memory matching for localized structural defects. As the present evaluation is confined to a single object category, the reported results are best interpreted as a proof of concept rather than as evidence of broad generalization.**

Keywords*—*Anomaly detection; autoencoder; memory bank; nearest-neighbor search; MVTec AD; unsupervised learning; industrial inspection; U-Net

I. Introduction

Automated visual inspection is a critical component of quality control in large-scale industrial manufacturing. The goal is to identify defective products as early as possible in the production pipeline to minimize waste and ensure product reliability. A fundamental challenge in this setting is the cold-start problem [1]: defect-free (nominal) images are abundant and easily acquired, but defective examples are rare, diverse, and difficult to enumerate exhaustively. This precludes supervised classification approaches and motivates the formulation of anomaly detection as an unsupervised, one-class classification problem.

Existing approaches to unsupervised industrial anomaly detection span several paradigms. Reconstruction-based methods [2, 3, 4] train autoencoders to reconstruct normal images, operating under the assumption that an autoencoder trained exclusively on normal data will restore normal test images well but fail on anomalous ones. However, this assumption is often violated in practice: powerful decoder architectures, particularly those with skip connections, can reproduce anomalous regions nearly as well as normal ones, suppressing the reconstruction error signal. Generative adversarial approaches [5] and normalizing flows [6] have been explored as alternatives, but often suffer from training instability and high sensitivity to hyperparameter choices. More recently, methods relying on ImageNet pretrained features [1, 7] have achieved state-of-the-art (SOTA) performance by matching test patch features against a memory bank of nominal features using nearest-neighbor search. These approaches consistently outperform reconstruction-based methods, yet they often require large pretrained backbone networks and access to vast external training corpora, limiting their applicability in resource-constrained or domain-specific settings.

This work proposes the Memory-Augmented Autoencoder (MAA), a lightweight approach that combines the complementary strengths of reconstruction-based and memory-based detection within a single, self-contained framework trained exclusively on target-domain images. MAA consists of three components: 1) a U-Net encoder-decoder that learns to reconstruct normal images and produces a compact latent feature representation, 2) a patch-level memory bank constructed from encoder features of the training set, supporting efficient nearest-neighbor-based anomaly scoring at inference time, and 3) a hybrid scoring module that combines reconstruction error and memory distance into a final image-level anomaly score. The memory bank component fundamentally addresses the reconstruction shortcut problem: even when the decoder can reconstruct anomalous regions, the encoder features of those regions remain out-of-distribution with respect to the stored normal patches, thereby preserving the anomaly signal.

MAA is evaluated on the bottle category of the MVTec Anomaly Detection (MVTec AD) benchmark [8], one of the most widely used datasets for industrial anomaly detection. The main contributions of this work are:

- A memory-augmented autoencoder architecture that integrates patch-level memory matching with reconstruction-based detection without requiring any pretrained backbone or external data.
- An ablation study demonstrating that the memory component outperforms the reconstruction component by 16.4 percentage points in AUC-ROC, providing quantitative evidence for the reconstruction shortcut problem in skip-connection architectures.

*Corresponding author.

- An achievement of competitive performance with pretrained SOTA methods on the MVTec AD bottle category (AUC-ROC = 0.9849), achieved with only 168 training images, a 3.1M parameter network, and CPU-only inference.
- A detailed analysis of per-defect-type detection behavior across three defect categories (*broken_large, broken_small,* and *contamination*), demonstrating the advantage of patch-level memory scoring for small, localized defects.

The remainder of this study is organized as follows. Section II reviews related work. Section III describes the MAA architecture and training procedure. Section IV presents experimental results. Section V concludes with a discussion of limitations and future directions.

II. Related Work

A. Reconstruction-Based Anomaly Detection

Autoencoder-based anomaly detection methods train an encoder–decoder network on normal images and use pixel-level reconstruction error as an anomaly score at test time [2]. Bergmann et al. [8] provide a systematic evaluation of autoencoder variants on the MVTec AD benchmark, including a vanilla L2 autoencoder (Vanilla AE, AUC-ROC = 0.860 on bottle), a variational autoencoder (VAE, AUC-ROC = 0.910), and an SSIM-based autoencoder (SSIM AE, AUC-ROC = 0.930) that incorporates a structural similarity loss [9] to capture perceptual differences beyond per-pixel intensity. While SSIM AE improves upon pixel-level baselines by penalizing structural deviations, these methods share a common limitation: reconstruction error is computed globally over the entire image, diluting local anomaly signals when defects occupy only a small fraction of the image area.

A fundamental problem affecting U-Net architectures specifically is the *reconstruction shortcut*: skip connections allow the decoder to directly access high-resolution encoder feature maps, enabling near-perfect reconstruction of anomalous regions by copying texture information and bypassing the bottleneck. This effect is particularly pronounced for texture categories where the repeated surface patterns can be transmitted through skip connections without meaningful compression. In the MAA framework, this limitation is addressed by decoupling detection from reconstruction: the memory bank operates on the bottleneck encoder features, which do not benefit from skip connections and therefore retain anomaly sensitivity.

B. Memory-Based Anomaly Detection

Memory-based approaches for anomaly detection store representations of normal data at training time and score test samples by their distance to the nearest stored representation. SPADE [10] constructs a multi-scale memory bank from ImageNet pretrained features and uses *k*-nearest-neighbor (*k*-NN) search for both image-level detection and pixel-level segmentation. PaDiM [7] estimates a multivariate Gaussian distribution at each patch location in the feature map and uses Mahalanobis distance for anomaly scoring, achieving strong localization by accounting for feature correlations. PatchCore [1] extends the memory bank paradigm by introducing locally-aware, neighborhood-aggregated mid-level patch features combined with greedy coreset subsampling for efficient retrieval, achieving near-perfect performance on MVTec AD (mean AUC-ROC 0.991) while retaining fast inference times.

A key limitation shared by SPADE, PaDiM, and PatchCore is their dependence on ImageNet pretrained backbone networks, which provide rich semantic features but introduce a potential distribution shift between natural image statistics and industrial inspection targets. PatchCore [1] explicitly acknowledges this, motivating the use of mid-level rather than deep features to reduce ImageNet classification bias. In contrast, MAA trains its encoder directly on the target domain, producing features specifically adapted to the normal appearance of the inspected product, with a trade-off in feature richness compared to large pretrained models.

Closest in spirit to MAA is the Memory-Augmented Autoencoder proposed by Gong et al. [11] for video anomaly detection. Their approach augments a convolutional autoencoder with a memory module operating in the latent space, trained end-to-end with a memory sparsity constraint. MAA differs in three key respects: 1) it utilizes a U-Net architecture with skip connections for reconstruction quality, 2) the memory bank is constructed post-training from encoder features without end-to-end joint optimization, and 3) it employs standard *k*-NN distance rather than memory addressing, which is more interpretable and easier to tune.

C. Hybrid Approaches

Several works have explored combinations of reconstruction and feature-matching signals. DRAEM [12] trains a discriminative network with synthetic anomalies generated by pasting random textures onto normal images, achieving strong performance on texture categories by learning an explicit normal/anomaly boundary. Unlike MAA, DRAEM relies on externally synthesized anomalies (from the Describable Textures Dataset [13]) during training, which introduces a dependency on the anomaly simulation quality. MAA instead targets a purely unsupervised setting with no access to anomaly examples, real or synthetic.

D. Recent Advances in Industrial Anomaly Detection

Research on industrial anomaly detection has advanced rapidly in recent years; Liu et al. [14] provide a comprehensive review organized by network architecture, level of supervision, and benchmark protocol. Several of these directions bear directly on the design choices made in MAA.

Density-estimation methods model the distribution of nominal features explicitly. FastFlow [15] applies two-dimensional normalizing flows as a plug-in probability estimator on top of an arbitrary pretrained backbone, jointly capturing local and global feature relations. Knowledge-distillation methods instead exploit the representation discrepancy between a teacher and a student network. Reverse distillation [16] inverts the usual data flow so that a student decoder restores the multi-scale representations of a teacher encoder from a one-class embedding, which limits the tendency of the student to generalize to anomalous inputs. EfficientAD [17] carries this paradigm towards real-time operation using a

shallow patch description network together with a loss that discourages the student from imitating the teacher beyond the nominal distribution, reporting millisecond-level latencies. These methods are complementary to MAA in that they retain a pretrained teacher, whereas MAA derives all of its features from the target domain.

Feature-adaptation methods are closest to the motivation of the present work. CFA [18] argues that the features of a pretrained CNN remain biased towards their source domain and introduces a learnable patch descriptor together with a scalable memory bank so that nominal features become more compact for the target dataset. SimpleNet [19] similarly inserts a shallow feature adapter to transfer pretrained features towards the target domain and trains a discriminator against synthetic anomalies generated in feature space. Both corroborate the concern that motivates MAA, namely that ImageNet features are not automatically well matched to industrial inspection data, yet both still depend on a pretrained backbone. Transformer backbones have also been examined in this setting: VT-ADL [20] combines a vision transformer encoder with a Gaussian mixture density estimator for joint detection and localization.

Relative to these methods, MAA occupies a deliberately conservative point in the design space. It forgoes pretrained features, synthetic anomalies, and flow-based or distillation-based machinery, and instead examines how far a plain U-Net encoder combined with a patch-level memory bank can be taken when only a few hundred nominal images from the target domain are available. The comparison in Section IV-G should therefore be read as situating a deliberately minimal baseline among substantially heavier methods rather than as a like-for-like contest.

III. Methodology

The MAA framework consists of three components: a U-Net autoencoder for reconstruction (Section III-A), a patch-level memory bank for nearest-neighbor scoring (Section III-B), and a hybrid anomaly scoring module (Section III-C). Fig. 1 illustrates the U-Net autoencoder architecture, and Fig. 2 details the two-stream inference pipeline.

A. U-Net Autoencoder

The backbone of MAA is a U-Net encoder-decoder with depth 4 and base filter count 32. The encoder consists of four successive convolutional blocks, each comprising two 3×3 convolutions with ReLU activations and batch normalization, followed by 2×2 max-pooling. The filter counts double at each depth level: 32, 64, 128, 256. The final encoder block produces a feature map of shape 16×16×128, which serves as the latent representation. The decoder mirrors the encoder with four transposed-convolution up-sampling stages, each concatenated with the corresponding encoder feature map via skip connections before being processed by two 3×3 convolution layers.

The network is trained to minimize a hybrid reconstruction loss combining mean squared error (MSE) and the structural similarity index (SSIM) [9]:

$$L_{hybrid} = 0.7 \times L_{MSE} + 0.3 \times (1 - SSIM(x, \hat{x})) \quad (1)$$

where, x denotes the input image and $\hat{x}$ denotes the reconstruction. The MSE term enforces per-pixel fidelity while the SSIM term penalizes structural deviations in local image patches, providing a perceptually more meaningful reconstruction objective. The weighting coefficient 0.7 was selected to balance the two terms empirically.

Training uses the Adam optimizer [21] with an initial learning rate of 1×10^{-4} and batch size 8 for a maximum of 50 epochs. Two callbacks regulate training: *EarlyStopping* with patience 10 that restores the best observed weights, and *ReduceLROnPlateau* with reduction factor 0.5 and patience 5 (minimum $lr = 1\times10^{-7}$). All images are resized to 256×256 pixels and normalized to [0, 1].

B. Patch-Level Memory Bank

After training the autoencoder, a memory bank is constructed from the encoder features of all training images. For each training image, the method extracts the 16×16×128 latent feature map and partitions it into overlapping 3×3 patches with stride 1, yielding $(16-3+1)^2 = 196$ patches per image. Each patch is flattened to a vector of dimensionality 3×3×128 = 1,152. For a training set of 168 images, this produces a memory bank M of 168×196 = 32,928 patch vectors:

$$M = \{\varphi(x_i, h, w) \mid x_i \in X_N, h, w \in \{1, \dots, 14\}\} \quad (2)$$

where, $\varphi(x_i, h, w)$ denotes the 3×3 patch feature centered at position (h, w) in the encoder output for training image x_i. The memory bank is indexed using a Ball Tree structure for efficient nearest-neighbor retrieval. At inference, the anomaly score for a test patch p_{test} is the Euclidean distance to its nearest neighbor in M:

$$s_{mem}(p_{test}) = \min_{m \in M} \|p_{test} - m\|_2 \quad (3)$$

The image-level memory score is the maximum patch score across all test patches, reflecting the PatchCore [1] observation that an image can be classified as anomalous as soon as a single patch is anomalous:

$$S_{mem}(x_{test}) = \max_{(h,w)} S_{mem}(\varphi(x_{test}, h, w)) \quad (4)$$

For pixel-level anomaly localization, patch scores are reassigned to their corresponding spatial positions, and the resulting 14×14 score map is up-sampled to the original 256×256 resolution via bilinear interpolation.

C. Hybrid Anomaly Scoring

The reconstruction-based anomaly score is the per-image MSE between the original image and its reconstruction:

$$S_{recon}(x_{test}) = \frac{1}{HWC} \sum \|x_{test} - \hat{x}_{test}\|^2 \quad (5)$$

Both S_{mem} and S_{recon} are normalized to [0, 1] within each test batch by min–max normalization. The final hybrid anomaly score is a weighted combination:

$$S_{hybrid} = \alpha \times S_{recon_norm} + \beta \times S_{mem_norm}, \ \alpha = \beta = 0.5 \quad (6)$$

Images are classified as anomalous if S_{hybrid} exceeds a decision threshold τ determined by maximizing the F1-score on the test set. The equal weighting α = β = 0.5 was used as the

default configuration; Section IV-F presents an ablation on the contribution of each component separately.

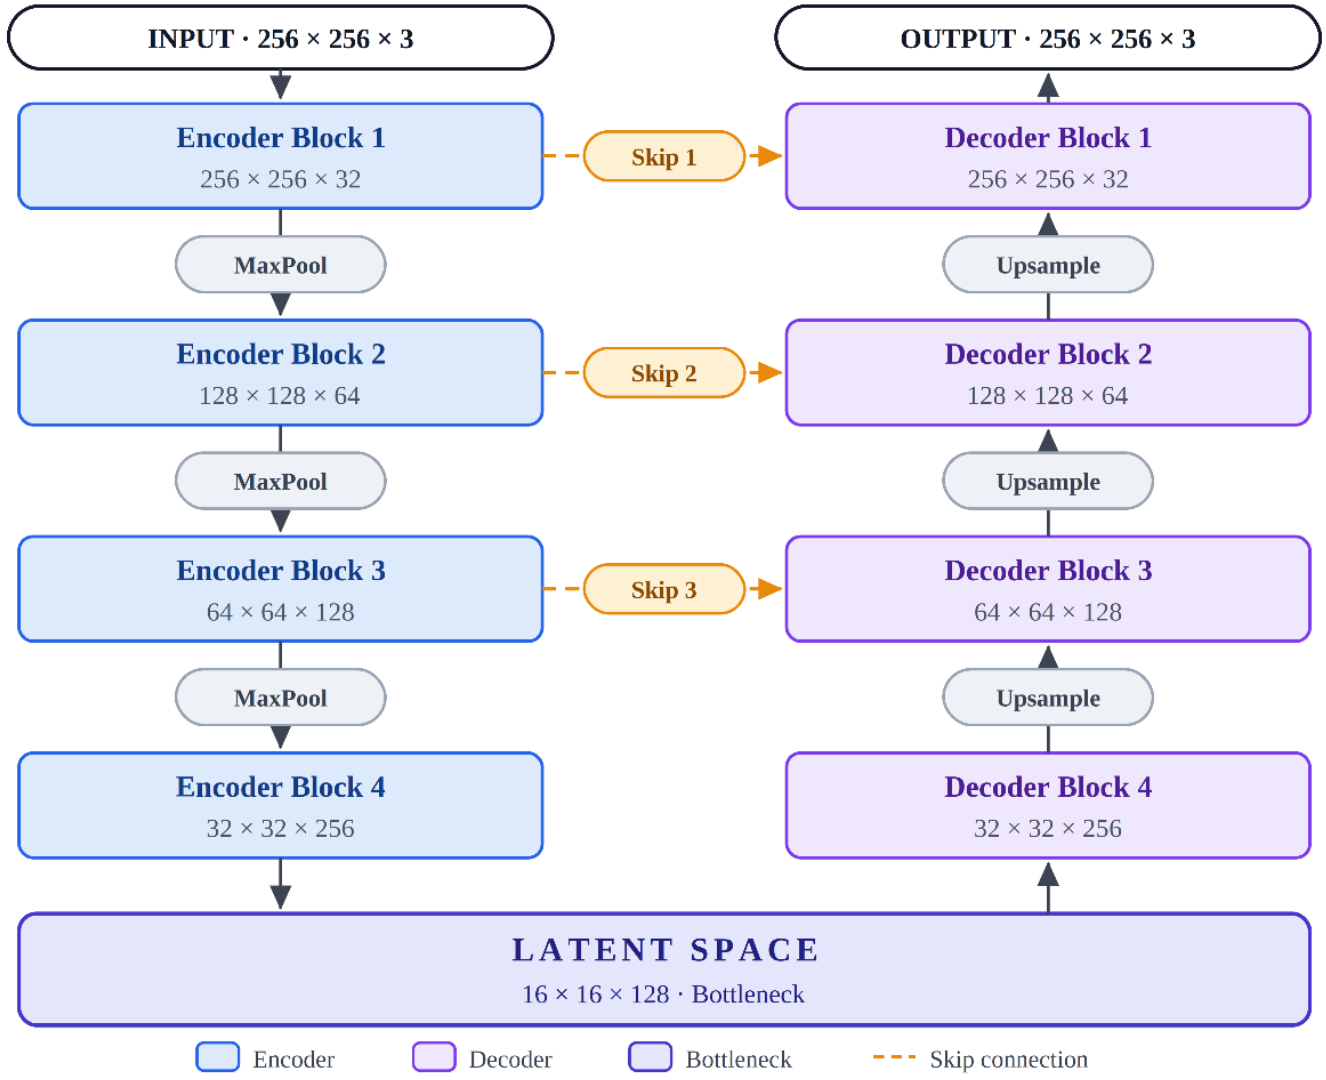

Fig. 1. U-Net autoencoder architecture of MAA.

IV. Experiments

A. Dataset

MAA is evaluated on the bottle category of the MVTec AD dataset [8], which provides high-resolution images of glass bottles under controlled lighting conditions. Following standard protocol, images are resized to 256×256 pixels. The original training set, comprising 209 defect-free images, is partitioned into 168 training and 41 validation images using an 80/20 split (random seed 42). The test set contains 83 images, including 20 normal samples and 63 anomalous samples distributed across three defect types: *broken_large*, *broken_small*, and *contamination*. Table I summarizes the detailed statistics of the dataset.

TABLE I. MVTec AD Bottle Category Statistics

Split	Normal	broken_large	broken_small	contamination	Total
Train	168	—	—	—	168
Validation	41	—	—	—	41
Test	20	20	22	21	83

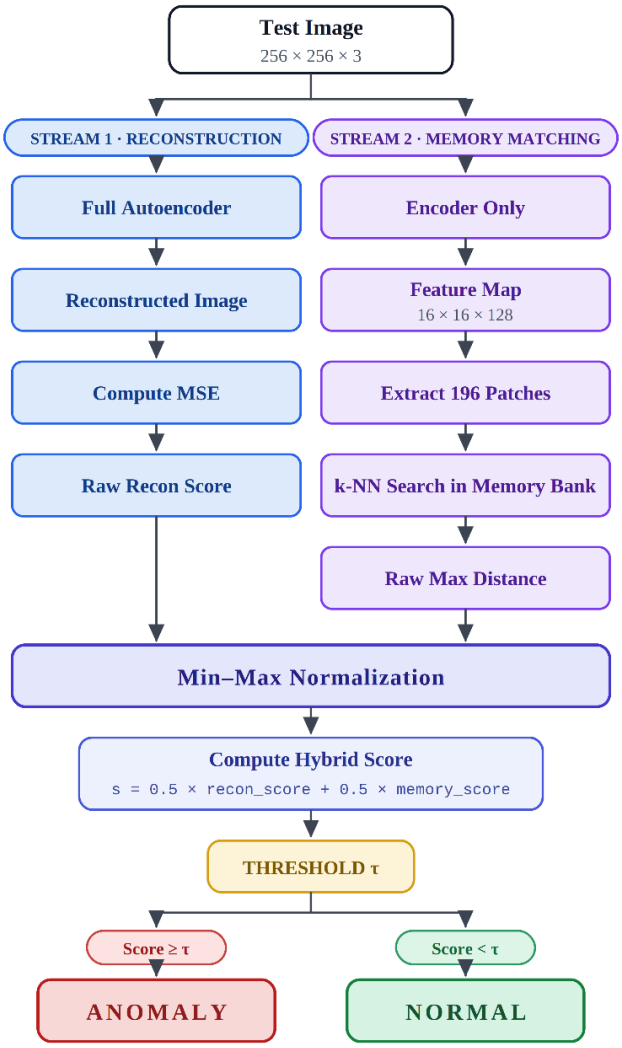

Fig. 2. Two-stream inference pipeline of MAA.

B. Implementation Details

The model is implemented in TensorFlow/Keras. All experiments run on CPU without GPU acceleration. Table II summarizes the full configuration.

TABLE II. MAA CONFIGURATION

Hyper-parameter	Value
Input size	256 × 256 × 3
Encoder depth	4 blocks (filters: 32, 64, 128, 256)
Latent shape	16 × 16 × 128
Loss weights	$\alpha = 0.7$ (MSE), $\beta = 0.3$ (1−SSIM)
Optimizer	Adam, lr = 1×10^{-4}
Batch size / Max epochs	8 / 50
Total parameters	3,127,235
Memory patches	32,928 × 1,152-D
k-NN index	Ball Tree, k = 1, Euclidean
Scoring weights	$\alpha = \beta = 0.5$

C. Evaluation Metrics

The performance of MAA is assessed using four metrics: 1) image-level AUC-ROC, a threshold-independent measure of discriminative ability; 2) Average Precision (AP), the area under the Precision-Recall curve, which is informative given the 75.9% class imbalance in the test set; 3) F1-Score at a fixed decision threshold; and 4) pixel-level AUC-ROC evaluated against ground-truth anomaly masks. AUC-ROC and AP are independent of any operating point and are therefore treated as the primary indicators of detection quality, whereas the F1-Score depends on a specific threshold and is reported only as a secondary, illustrative measure.

D. Training Results

The autoencoder is trained stably over all 50 epochs with no early stopping, indicating consistent optimization throughout the training duration. Table III shows the loss progression at selected epochs, and Fig. 3 plots the full training and validation loss curves. The training and validation losses track each other closely throughout (0.0054 vs. 0.0055 at epoch 50), indicating the absence of overfitting. Notably, the training and validation losses decrease by factors of approximately 42 and 35, respectively, from epoch 1 to epoch 50.

TABLE III. TRAINING LOSS PROGRESSION AT SELECTED EPOCHS (HYBRID LOSS)

Epoch	Train Loss	Val Loss	Train MSE	Val MSE
1	0.2285	0.1916	0.1103	0.0830
10	0.0260	0.0248	0.0009	0.0007
25	0.0120	0.0120	0.0003	0.0003
40	0.0083	0.0084	0.0002	0.0002
50	0.0054	0.0055	0.0002	0.0002

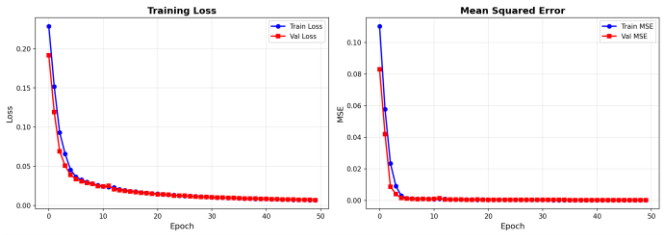

Fig. 3. Training and validation loss curves over 50 epochs: (a) hybrid loss; (b) MSE.

E. Anomaly Detection Performance

Table IV reports the image-level anomaly detection results. The proposed hybrid score achieves an AUC-ROC of 0.9849 and an AP of 0.9956, both of which are independent of any decision threshold. At the threshold $\tau = 0.0336$ that maximizes the F1-Score on the test set, the hybrid score attains an F1-Score of 0.9760, corresponding to only two misclassifications out of the 83 test images (one false positive and one false negative). Because this threshold is selected on the test set itself, the reported F1-Score should be regarded as an optimistic upper bound; in a deployment setting, the threshold would instead be calibrated on a held-out validation set of normal images. Accordingly, the threshold-free AUC-ROC and AP are

emphasized as the primary performance measures throughout this work. Fig. 4 shows the corresponding ROC and precision–recall curves.

TABLE IV. IMAGE-LEVEL ANOMALY DETECTION ON MVTEC AD BOTTLE

Component	AUC-ROC	Avg. Precision	F1-Score	Threshold
Reconstruction only	0.8238	—	—	—
Memory only	0.9881	—	—	—
Hybrid (α = β = 0.5)	0.9849	0.9956	0.9760	0.0336

The memory component (0.9881) outperforms the reconstruction component (0.8238) by 16.4 percentage points. This gap confirms the reconstruction shortcut hypothesis: the U-Net skip connections enable near-perfect reconstruction of anomalous regions, substantially reducing the reconstruction error signal. The memory bank, operating at the encoder bottleneck where skip connections are absent, preserves anomaly sensitivity. The hybrid score (0.9849) is marginally lower than memory alone, as the reconstruction component introduces mild noise from its imperfect discrimination. Nevertheless, the hybrid formulation provides a more robust operating point across defect types of varying severity.

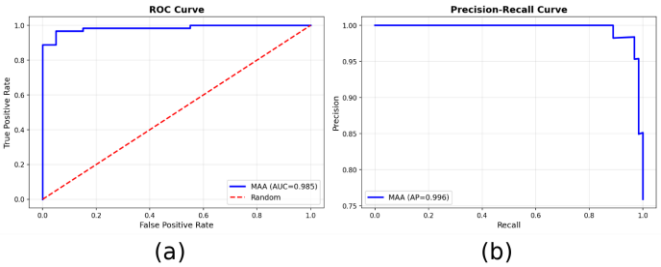

Fig. 4. (a) ROC curves for each scoring component; (b) precision–recall curve of the hybrid score.

Table V reports per-defect-type AUC-ROC and AP, computed by comparing each defect type individually against the normal class.

TABLE V. PER-DEFECT-TYPE DETECTION PERFORMANCE

Defect Type	AUC-ROC	Avg. Precision	n	Description
broken_large	1.0000	1.0000	20	Large structural fractures (10 - 15% area)
broken_small	0.9977	0.9980	22	Small cracks (3 - 5% area)
contamination	0.9571	0.9671	21	Surface contamination (color anomaly)

MAA achieves perfect detection for *broken_large* (AUC-ROC = 1.0000), confirming that the max-distance memory scoring is highly discriminative for large structural defects. For *broken_small*, the near-perfect performance (AUC-ROC = 0.9977) demonstrates the advantage of patch-level scoring: even when only one or two patches are anomalous, the maximum memory distance is elevated, preserving the anomaly signal that would be lost under mean aggregation. Conversely, *contamination* (AUC-ROC = 0.9571) is the most challenging defect type, as *color* changes rather than structural modifications produce smaller memory distances in the encoder feature space.

Table VI presents the confusion matrix at the test-optimal threshold τ = 0.0336.

TABLE VI. CONFUSION MATRIX AT THE TEST-OPTIMAL THRESHOLD τ = 0.0336

	Predicted Normal	Predicted Anomaly
Actual Normal	19 (TN)	1 (FP)
Actual Anomaly	1 (FN)	62 (TP)

F. Ablation Study

Table VII compares the three scoring configurations, confirming that the memory component is the dominant driver of detection performance. The 16.4-percentage-point gap in AUC-ROC between the memory and reconstruction components remains consistent across all evaluation runs.

TABLE VII. ABLATION OF SCORING COMPONENTS

Configuration	AUC-ROC	Δ vs. Reconstruction
Reconstruction only	0.8238	—
Memory only	0.9881	+16.43 pp
Hybrid (α=β=0.5)	0.9849	+14.76 pp

G. Comparison with SOTA Methods

Table VIII compares MAA against published SOTA methods on the MVTec AD *bottle* category. Baseline results for Vanilla AE, VAE, and SSIM AE are obtained from Bergmann et al. [8], while PaDiM and PatchCore results are cited from the original publications [1, 7].

TABLE VIII. IMAGE-LEVEL AUC-ROC ON MVTEC AD BOTTLE

Method	AUC-ROC	Pretrained	Parameters
Vanilla AE [8]	0.860	No	—
VAE [8]	0.910	No	—
SSIM AE [8]	0.930	No	—
MAA (proposed)	**0.985***	**No**	**3.1M**
PaDiM (R18) [7]	0.982	Yes (ResNet-18)	11M
PaDiM (WR50) [7]	0.998	Yes (WideResNet-50)	—
PatchCore [1]	1.000	Yes (WideResNet-50)	68M

* AUC-ROC 0.9849 on the 83-image test set; reported as 0.985 for conciseness.

MAA surpasses all non-pretrained baselines by a clear margin (+5.5 percentage points over SSIM AE, the strongest reconstruction baseline), demonstrating the value of integrating patch-level memory matching into the autoencoder framework. MAA is also marginally ahead of PaDiM with a ResNet-18 backbone (0.985 vs. 0.982) without requiring any ImageNet pretraining, although a margin of this size, obtained from a single run on one category, should be read as comparable performance rather than a clear improvement. This suggests that domain-adapted features can, at least for object-centric industrial categories, substitute for large-scale pretrained representations. MAA trails the stronger PaDiM (WideResNet-50) variant by only 1.3 percentage points (0.985 vs. 0.998) and PatchCore by 1.5 percentage points (0.985 vs. 1.000), while offering three practical advantages:

No external pretraining: MAA is trained exclusively on 168 target-domain images with no ImageNet features, avoiding the

distribution shift between natural image statistics and industrial inspection data noted in [1].

Lightweight architecture: MAA requires only 3.1M parameters, compared to 11M for ResNet-18 and 68M for WideResNet-50. The full model has a storage footprint of less than 50 MB, enabling deployment on embedded inspection hardware.

CPU-only inference: MAA processes the 83 test images in approximately 41 seconds on a standard CPU without GPU acceleration, making it practical for resource-constrained industrial settings where GPU infrastructure is unavailable.

The remaining performance gap relative to PatchCore and PaDiM (WR50) stems primarily from the richness of ImageNet pretrained features, which encode complex visual semantics not achievable by training on 168 images from a single product category. Future work exploring self-supervised pretraining on target-domain data may close this gap while preserving the domain-adaptation advantages of MAA.

H. Qualitative Results

Fig. 5 illustrates representative detection examples across all defect types. For normal samples, both the reconstruction error map and the memory heatmap are uniformly low. For *broken_large*, the structural fracture is prominently highlighted in both maps. For *broken_small*, the memory heatmap correctly localizes the crack, while the reconstruction error map shows only a faint signal. This observation is consistent with the quantitative finding that the memory component substantially outperforms the reconstruction component for small defects. For *contamination*, the heatmap identifies the affected region with moderate confidence, reflecting the lower per-defect AUC-ROC of 0.9571.

Fig. 5. Representative detection results for normal and defective samples.

V. CONCLUSION

This study has presented the Memory-Augmented Autoencoder (MAA), a lightweight unsupervised anomaly detection framework that integrates patch-level memory matching with U-Net reconstruction. Evaluated on the bottle category of the MVTec AD benchmark, MAA achieves an image-level AUC-ROC of 0.9849 and a pixel-level AUC-ROC of 0.8951 using only 168 defect-free training images, no ImageNet pretraining, and CPU-only inference with a 3.1M-parameter network. As no directly comparable pixel-level baseline is reported for this configuration, the pixel-level figure is presented as an indicative measure of localization rather than as a benchmarked comparison.

The ablation study demonstrates that the memory-based component is the primary driver of detection performance, outperforming the reconstruction component by 16.4 percentage points in AUC-ROC. This finding provides quantitative evidence for the reconstruction shortcut effect in U-Net architectures, where skip connections enable near-perfect reconstruction of anomalous regions, suppressing the reconstruction error signal. The memory bank, operating at the encoder bottleneck without skip connections, effectively addresses this limitation.

Compared with autoencoder-based baselines, MAA outperforms SSIM AE by 5.5 percentage points without requiring any architectural modifications beyond the addition of the memory bank. Compared with pretrained methods, MAA approaches PaDiM and remains competitive with PatchCore while offering substantial practical advantages in deployment cost, model size, and independence from large-scale pretraining datasets.

Several limitations of the current work point to promising future directions. First, MAA is evaluated exclusively on the bottle category; performance on texture-rich categories such as carpet and grid is expected to be substantially lower, as the reconstruction shortcut is more severe for highly repetitive textures and the encoder features are less discriminative for subtle color or texture anomalies. Extending MAA to texture categories may require architectural modifications such as attention gating on skip connections or multi-scale memory banks. Second, the inference time of approximately 41 seconds for 83 images (about 0.5 seconds per image) is acceptable for offline inspection but not for real-time deployment; approximate nearest-neighbor search or coreset subsampling could address this. Finally, combining MAA with discriminative training driven by synthetic anomalies represents a promising direction for improving detection on texture categories while retaining the lightweight, no-pretraining advantage of MAA.

Understanding Player Choice in Digital Games: Qualitative Study Using Thematic Analysis

Faris Haziq Sarif[1], Amelia Jati Robert Jupit[2], Jacey-Lynn Minoi[3], A. Imran Nordin[4]
Faculty of Computer Science and Information Technology, Universiti Malaysia Sarawak, Kota Samarahan, Malaysia[1, 2, 3]
Inas Collective LLP, Singapore[4]

***Abstract*—Player choice is a fundamental aspect of digital games, shaping how players interact with virtual worlds and narratives. In many games, player choices are reflected through mechanics such as morality systems, which record decisions as virtuous or harmful and shape how characters and the game world react. For game designers, player choice is vital, granting players freedom to shape their experiences and fostering deeper engagement. When players are presented with significant choices, they are more likely to remain invested and prolong their gameplay. Despite its importance, research on player choice remains limited, with existing research often focusing on challenge, immersion, or motivation within specific genres while overlooking broader implications. We conducted interviews to explore the factors that influence player choice in digital games. The data were examined using thematic analysis to identify recurring patterns and key themes. Results from the interviews revealed six main dimensions of player choice: Goals, Character Personalization, Gameplay, Social Interaction, Rewards, and Completion, each with relevant sub-themes.**

***Keywords*—Player choice; thematic analysis; player engagement**

I. Introduction

The popularity of digital games cannot be overstated. With an estimated 3 billion players worldwide and industry revenues expected to surpass $473 billion by 2027, digital games have become a dominant force in global entertainment [1]. Unlike other forms of entertainment, digital games are interactive, requiring players to make decisions and actively shape their experiences. This interactivity distinguishes games from passive media such as film or television, as players are not merely observers but participants in the unfolding narrative and gameplay.

Researchers have long examined how this interactivity shapes the overall player experience, exploring concepts such as immersion, flow, motivation, and engagement [2], [3], [4]. These studies emphasize that games provide not only entertainment but also psychological and emotional satisfaction, influencing how players connect with game worlds and characters.

Within this broader context, player choice has emerged as a critical dimension of gameplay. Choice allows players to exercise autonomy, shape outcomes, and express themselves within digital environments. Whether through character customization, narrative branching, or the pursuit of personal goals, choice provides players with a sense of control and agency that distinguishes games from more linear media [5], [6], [7], [8].

Despite its importance, research on player choice remains fragmented. Many studies address choice indirectly, often framed as part of autonomy, decision-making, or agency, but rarely as a distinct phenomenon in its own right. As a result, how players themselves experience and interpret choices remains underexplored, particularly from a qualitative perspective. This study sought to answer the following research questions:

- How do players experience and interpret choice in digital games?
- What themes emerge from players' perspectives on choice in digital games?

To address these questions, the present study employed thematic analysis, a qualitative method well-suited for identifying, analysing, and interpreting patterns of meaning within participant narratives. Thematic analysis was chosen because it allows for flexibility in exploring complex experiences, such as how players perceive and articulate their sense of choice, while remaining grounded in the data itself rather than imposing a predefined theoretical framework.

II. Related Works

Research on digital games has increasingly drawn on qualitative approaches to better understand the experiences of players. Such studies provide rich insights into how individuals interpret their engagement with games, though they often focus on different dimensions of gaming experience. For example, Denisova et al. [9] examined how players perceive challenges in games through semi-structured interviews, applying open coding to identify components of challenge and iteratively clustering codes into themes. Their process emphasized depth, beginning with transcription, careful reading, and the gradual construction of themes that reflected relationships among codes. This rigorous approach demonstrated how qualitative coding can uncover the subtle ways players experience and describe game-related phenomena.

Building on this methodological foundation, this study applied thematic analysis to examine not challenge aspect, but player choice, positioning choice as a distinct and underexplored dimension of gameplay that shapes identity, agency, and personal meaning. While Denisova et al. [9] focused on challenge, the present study adapts a similar thematic approach to examine player choice, positioning choice as a distinct and underexplored element of gameplay.

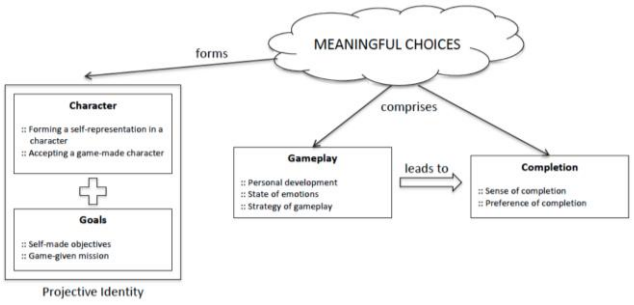

Fig. 1. Meaningful choices, being the central theme of the grounded theory, a key to players' identity in digital games [10].

Similarly, Jupit [10] employed grounded theory to investigate players' projective identity in digital games, with a particular focus on the role of meaningful choices. Jupit emphasized that the central theme of projective identity lies in the decisions players make throughout their gameplay experiences. These meaningful choices allow players to project aspects of their identity into the game world, whether through customizing characters, pursuing specific goals, or selecting pathways that align with their values and preferences. In this way, choices become more than mechanical options; they are extensions of the self, shaping how players interpret, navigate, and ultimately complete their gameplay. As illustrated in Fig. 1, the meaningful choices players make contribute to forming both the character and the goals they pursue during their gaming experience, which together form their projective identity. These choices influence how players decide to navigate and finish the game in a way that aligns with their personal preferences. The gameplay aspect of meaningful choices leads to the completion of the game in a way that resonates with the players' individual experiences. By gathering qualitative data through interviews, Jupit demonstrated how thematic analysis can capture the deep personal ways in which players' identities and aspirations become intertwined with the choices they make.

This focus on meaningful choices as central to projective identity resonates closely with the present study, which similarly examines choice as a fundamental dimension of player experience. However, while Jupit [10] emphasized identity projection and self-expression through choices, the current research took a broader perspective by exploring how players interpret and articulate the experience of player choice itself, regardless of whether it is tied to identity formation. In doing so, this study extends Jupit's work by shifting attention from what choices represent to players to how they are subjectively experienced when playing digital games.

Player choice has also been examined through the concept of meaningful choice. Iten et al. [11] investigated the characteristics that make choices meaningful in digital games and found that meaningful choices could involve moral, strategic, emotional, and social aspects. The study also found that knowing that a choice would have consequences contributed to players experiencing the choice as meaningful [11]. Similarly, Tancred et al. [12] examined player choices in relation to game endings and moral dilemmas, demonstrating how choices can be incorporated into game design to influence gameplay outcomes.

Player choice is closely related to concepts such as player agency and autonomy, but these concepts describe different aspects of the gaming experience [13], [14]. Player agency refers to the ability of players to influence the game through their actions and choices [13]. In contrast, autonomy refers to the feeling of having freedom and control over one's actions during gameplay [15]. Agency and autonomy are related concepts, but they represent different aspects of the player experience [14]. Therefore, player choice in the present study focuses specifically on the choices available to and experienced by players, rather than treating choice as synonymous with agency or autonomy.

Player choice is also related to decision-making, particularly in games where players are presented with multiple options during gameplay. Yin and Xiao [16] examined choices in narrative-rich games and found that different types of choices can influence player experience at multiple levels, including the game itself and the relationship between players and the game. Their study also identified factors that influence how players make decisions when presented with choices [16]. However, decision-making mainly refers to the process of selecting an option, while the present study focuses more broadly on how players experience and interpret the choices available to them during gameplay.

Player choice is also distinct from related aspects of player experience, including motivation, engagement, personalization, and control. Motivation refers to the reasons that encourage players to participate or continue playing [15] while engagement describes the extent of players' involvement in the gaming experience [4]. Personalization involves modifying or selecting game elements according to individual preferences, such as avatar appearance and characteristics [17]. Although personalization can involve player choice, the two concepts are not synonymous, as personalization specifically concerns the adaptation of game elements to individual preferences. Control, similarly, concerns the ability to influence or manipulate elements within the game, whereas player choice focuses on selecting among available alternatives [13], [14]. These distinctions suggest that motivation, engagement, personalization, and control are related to player choice but represent different dimensions of the broader player experience.

Taken together, these studies show that player choice is related to, but distinct from, other aspects of player experience such as agency, autonomy, decision-making, motivation, engagement, personalization, and control.

III. Research Methodology

A. Data Collection

Ten participants were recruited through purposive sampling and interviewed. Purposive sampling was used to identify participants who had relevant knowledge and experience with digital games, allowing the study to obtain information and data that aligned with the research objectives [18]. The purpose of these interviews was to explore and identify the themes and sub-themes associated with player choices in video games. These interviews provided a deeper understanding of how players make decisions in their favourite games and the factors that influence those choices. The demographic of the participants is presented in TABLE I.

TABLE I. DEMOGRAPHIC OF PARTICIPANTS

Participant	Age	Gender	Favourite Games Genre	Playing experience
1	23	Male	Sandbox, Survival	10 Years
2	23	Male	Multiplayer Online Battle Arena (MOBA)	10 Years
3	24	Male	Auto Battler, Simulation	10 Years
4	22	Male	Action RPG, Soulslike	17 Years
5	24	Male	Multiplayer Online Battle Arena (MOBA)	8 Years
6	23	Male	Racing, Open World	17 Years
7	27	Female	Party, Co-op, Simulation	More than 10 Years
8	24	Male	First-Person Shooter, Multiplayer	More than 10 Years
9	24	Female	Action RPG, Sandbox	9 Years
10	29	Female	Tower Defense	More than 10 Years

Before each interview session, participants were provided with a consent form outlining the purpose of the study and their rights as participants. They were informed that their participation was voluntary and that they had the right to withdraw at any time. Additionally, they were asked for their consent to record the interview audio for transcription and analysis purposes. Only after obtaining their informed consent did the interview proceed. The interview questions were structured carefully to make sure participants reflected on their decision-making process while playing games. The duration of each interview varied based on the depth of the participants' responses, typically lasting between 10 and 20 minutes.

B. Data Analysis

Thematic analysis was chosen for this study due to its flexibility and suitability in analysing qualitative data. It allows for the identification and interpretation of patterns and themes within the data, providing a clear understanding of the participants' experiences, views and behaviours. Thematic analysis offers a systematic method for organizing and interpreting the data, ensuring that key themes are identified and explored, leading to meaningful insights that can inform the research objectives.

Thematic analysis is a qualitative method used to identify, analyse, and interpret patterns or themes within data [19]. It provides accessible and systematic procedures for generating codes and themes, where codes represent the smallest units of analysis capturing relevant features of the data, and themes are larger patterns of meaning underpinned by a central organizing concept. This approach can be applied to uncover patterns within and across data, focusing on participants' lived experiences, perspectives, behaviour, and practices. For this research, thematic analysis was used instead of open coding due to its 1) Simplicity and Flexibility, its 2) Focus on Participant Perspective, and its 3) Efficiency in Time and Resources.

- Simplicity and Flexibility: Thematic analysis is straightforward and can be adapted to a wide range of research questions and data. Unlike open coding, which is more detailed and iterative, thematic analysis allows you to identify and group themes based on existing knowledge or study goals. This is particularly helpful when analysing complex, nuanced topics like meaningful choices in games because it allows for a quick organization of data into broad themes [20].
- Focus on Participant Perspective: Thematic analysis emphasizes understanding the experiences and perceptions of participants, making it suitable for exploring how players perceive "meaningful choices" in games. It captures patterns across responses, helping to see how players commonly understand, justify, and value their in-game decisions. This is crucial for qualitative studies aiming to explore subjective concepts like meaningful choices [21], [22].
- Efficiency in Time and Resources: Thematic analysis is generally less time-consuming than methods like open coding in grounded theory. Because it does not require line-by-line coding initially, it is often a faster approach, making it ideal for projects with limited time. This means recurring themes and insights can be quickly identified, which is especially useful when pre-existing categories or concepts, such as moral decisions and player agency in meaningful choices, are in place [23].

Braun and Clarke [20] outlined six phases of thematic analysis:

- Become familiarised with the data
- Generate initial codes
- Search for themes
- Review themes
- Define and name themes
- Produce the report

During the initial phase of thematic analysis, the interview recordings were transcribed to ensure accurate representation of the data. This process involved a combination of digital tools and manual listening to the audio recordings to capture the subtleties of the conversation. The digital tools facilitated efficient transcription, while the manual process ensured careful attention to detail, capturing every aspect of the interview, including tone, emphasis, and subtle meaning in the text.

After becoming familiar with the data, initial codes were generated through systematic review of the transcribed interview data to identify meaningful segments that could be categorized. Key phrases, words, and ideas reflecting the participants' experiences, thoughts, and feelings related to the topic were highlighted during transcript review. These initial codes were kept broad and descriptive, without yet grouping them into larger themes. This phase was crucial for breaking the data into manageable units, enabling a more focused analysis in the later stages of the thematic process.

Searching for themes involved systematically organizing and reviewing the initial codes to reveal patterns and relationships within the data, with Excel spreadsheets facilitating efficient categorization and visualization. Every initial code was entered into the spreadsheet, along with its

corresponding participant data and context. This allowed for easy sorting, filtering, and comparison of codes across the dataset. Related codes were grouped together within the spreadsheet, enabling the identification of broader patterns that represent potential themes.

The next phase of thematic analysis focused on reviewing the themes to ensure they accurately captured the essence of the data. This process involved two levels of review: first, at the level of individual coded data extracts, and second, at the level of the overall thematic structure. Using the Excel spreadsheet, each theme was revisited to ensure that its grouped codes were coherent and aligned with the overarching theme. Individual data extracts were examined to verify their alignment with the assigned theme, and any inconsistent or misplaced codes were either reassigned to a more suitable theme or discarded. The themes were then evaluated against the entire dataset to ensure they offered a comprehensive and accurate representation of the participants' experiences. This step involved identifying any gaps or redundancies within the themes.

The coding process was inductive and based on the participants' responses, with initial codes developed from the interview data. Codes with similar meanings were compared and grouped based on their relevance to the research objectives and the experiences described by participants. When a code could reasonably fit more than one theme, the original interview response was reviewed to determine the context and the most appropriate theme. Codes that did not sufficiently relate to the research focus were discarded. Differences or contradictory responses between participants were retained during the analysis and considered when reviewing and refining the themes, rather than being excluded from the dataset.

In the fifth phase of thematic analysis, the focus shifted to defining and naming each theme to ensure it encapsulated the underlying meaning of the data. This required a detailed review of each theme to articulate its scope, purpose, and relevance to the research questions. Using the Excel spreadsheet, each theme was revisited to examine the specific codes and data extracts it contained, and a concise description was written to explain its core idea and its reflection of the participants' experiences. Below are the identified themes and their descriptions, detailing the core ideas they represent and their relevance to the participants' experiences. illustrates the themes and sub-themes derived from the data, providing a clear overview of their scope and relationship with the participants' experiences.

During the analysis of the interview data, the responses from the later participants largely reflected the codes, themes, and sub-themes identified in the earlier interviews, with no substantially new themes emerging. This suggests that the ten interviews provided sufficient thematic information for the exploratory objectives of the study. TABLE II. presents the identified themes and sub-themes.

The final phase of thematic analysis involved compiling the findings into a coherent and structured report. As the themes were defined and named, they were documented alongside their corresponding data extracts to present participants' statements while also interpreting and expanding on the insights derived from the data. The report was organized to provide a clear and concise narrative, ensuring coherence within each theme and across the broader thematic framework. The six main themes and 23 sub-themes, together with participant quotes, were presented in a way to provide a clear and organized overview of the findings.

TABLE II. THEMES AND SUB-THEMES IDENTIFIED

Themes	Sub-Themes
Character Personalization	Character selection
	Character customization
	Personal expression
Social Interaction	NPC and ally relationships
	Teamwork and cooperation
Goals	Self-made goals
	Game-given goals
	Preference of goal
Gameplay Rewards	Attraction to the game
	Style of play
	Strategy of gameplay
	Decision-making in games
	Replayability
	In-game and real-life impact
	Emotional engagement
	State of emotion
	Personal development
	Impact of rewards
	Functional reward
	Aesthetic reward
Completion	Sense of completion
	Preference for completion
	Personal fulfilment

Character Personalization: This theme encompassed the ability of players to create, select, and modify their in-game characters. It reflected how participants valued features that allowed self-expression and identity through character customization. Participants often expressed that creating a character in their image or with unique traits made their gameplay experience more engaging and personal.

- Character selection is the process of choosing a predefined character that fits the player's strategy or preference.

"Every character has different skills and how they build, how they act at each time and every second of the game..." (Participant 4).

- Character customization allows players to personalize their experience, either by modifying their character's appearance or, in some cases, creating unique items or features within the game.

"Customization of my character makes me feel more immersed in the game." (Participant 9).

- Personal expression in games allows players to showcase their individuality through the choices they make in customizing their characters or the way they engage with the game.

"I like using weird, or I guess unconventional skins because I like to express myself in that way." (Participant 1).

Social Interaction: This theme described the cooperative and relational aspects of gameplay, including teamwork, alliances, and interactions with both NPCs and allies. In contrast, games without social interaction focus solely on individual gameplay, where players engage with the game's mechanics and challenges independently, without relying on teamwork or alliances.

- NPC and ally relationships can range from neutral to deeply emotional, depending on the narrative and gameplay experience.

"One time where you need to save a certain NPC before you complete a certain quest. I accidentally completed the quest first, and then that makes the NPC die. That makes me sad." (Participant 4).

- Teamwork and cooperation are essential elements in many multiplayer and cooperative games, where success is often determined by how well players collaborate.

"We need 5 people to come together to find synergy with each other." (Participant 2).

Goals: This theme captured participants' motivations and objectives within the game, whether these were assigned by the game or self-created. This theme highlighted the diverse ways participants approached goal setting, with some finding satisfaction in structured tasks and others enjoying the freedom of crafting their own paths.

- Game-Given Goals, which referred to objectives set by the game, such as quests, missions, or achievements

"I usually follow the missions as they are because they are already fun and structured." (Participant 7)

- Self-Made Goals, which reflected the personal challenges or milestones players created for themselves, such as mastering a skill or exploring hidden areas

"...creating my own goals is one of my ways to have fun while also achieving my objective." (Participant 1)

- Preference of goals reflects players' inclinations toward either game-given missions or self-made objectives

"Because the game's missions can feel repetitive or boring, creating my own challenges keeps things more interesting." (Participant 6)

Gameplay: The theme covered participants' experiences and interactions with game mechanics, decision-making, and strategies.

- Attraction to the game involves the unique features that draw players in, whether the complexity, relaxing gameplay, or engaging mechanics

"The gameplay. It is fast-paced, collaborative, and keeps things exciting." (Participant 7)

- Style of play refers to the personal approach players take when engaging with a game, whether that involves exploring its mechanics, focusing on the main objectives, or experimenting with unique strategies

"I would go with completing the story first and then do the other side things later." (Participant 5)

- Strategy of gameplay involves how players approach challenges, plan their actions, and make decisions within the game

"...we need to find the best combination, how to counter the enemy." (Participant 2)

- Decision-making in games revolves around how players weigh their options and choose actions that will impact their gameplay experience

"I do consider the consequences, especially if they affect the storyline as well as the relationship with the characters." (P9)

- Replayability refers to the enjoyment players find in revisiting a game, often driven by the desire to see new outcomes, explore different choices, or achieve better performance

"I do replay games to see different outcomes because I like seeing or actually enjoying the story." (Participant 1)

- In-game and real-life impact highlights the difference between the decisions made in video games and their consequences compared to real-life choices

"Making a choice in-game has fewer consequences than real life." (Participant 4)

- Emotional engagement in games enhances the overall experience, influencing how players feel while playing

"Playing games is just generally fun. You can play as many different types of games as you want, so there's always a way to have fun." (Participant 1)

- State of emotion in gaming refers to the range of emotions that players experience while playing, influenced by in-game events, challenges, and personal investment in the game

"If I found that my team isn't helping to stop the enemy from capturing the point, I will get mad—like, very mad." (Participant 8)

- Personal development in gaming refers to how players grow and improve their skills, strategies, and decision-making abilities through gameplay

"I do feel like my skills improve over time. I get better at managing tasks efficiently." (Participant 7)

Rewards: This theme focused on the impact of in-game rewards on participants' motivation and satisfaction.

- Impact of rewards refers to how in-game rewards influence a player's motivation, enjoyment, and sense of accomplishment

"It increases my motivation, especially when they give me better equipment as a reward." (Participant 3)

- Functional reward refers to in-game rewards that directly impact gameplay, such as unlocking new abilities, enhancing character performance, or providing essential equipment

"If the game is more toward PVE, it's better to get rewards that benefit the player." (Participant 2)

- Aesthetic reward refers to in-game rewards that enhance the visual appearance of characters, weapons, or environments without directly affecting gameplay

"If a game is heavier on PvP, it's better to focus on cosmetics." (Participant 2)

Completion: The Completion theme reflected participants' desire for a sense of fulfilment and closure in their gaming experiences.

- Sense of completion refers to the satisfaction and accomplishment players feel when they successfully finish a task, mission, or long-term objective in a game

"It will give me a certain satisfaction because I achieved the goal." (Participant 4)

- Preference of completion refers to the aspects of a game that players find most satisfying to complete, whether it's missions, challenges, collectibles, or personal goals

"It feels rewarding to complete a challenging level or task, and it adds to the enjoyment because I think completing the missions is what keeps me engaged and makes the whole experience more satisfying." (Participant 7)

- Personal fulfilment refers to the emotional satisfaction players seek when playing, whether it is for relaxation, fun, personal achievement, or a way to unwind

"It's mostly just to have fun because life can get boring sometimes." (Participant 1)

IV. Discussion

In this study, six main themes were identified in participants' descriptions of Player Choice: Goals, Character Personalization, Gameplay, Social Interaction, Rewards, and Completion. These themes and sub-themes describe different contexts in which participants experienced and interpreted Player Choice. As shown in Fig. 2, player choices begin with attraction to the game. Participants described being initially drawn to games by factors such as gameplay mechanics, visuals, and narrative elements. This finding is consistent with Yee [24] who identified several key motivational components that influence player attraction, categorized into achievement, social, and immersion factors.

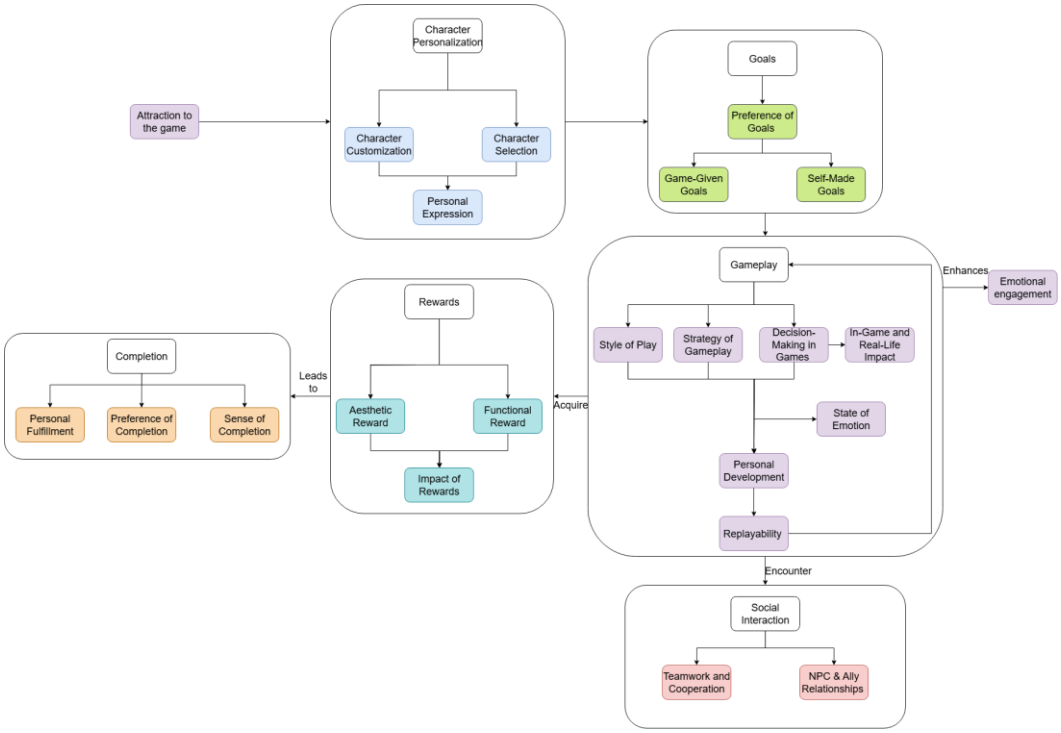

Fig. 2. Interpretive conceptual framework of themes associated with player choice.

Within the achievement component, players may be attracted by the desire for advancement, seeking power, rapid progress, and status symbols, or by an interest in the mechanics of the game. Competition also plays a role, appealing to players who enjoy challenging others in competitive environments. Beyond achievement, the social component contributes to player attraction through socializing, which involves engaging in conversations, assisting others, forming relationships, and

deriving satisfaction from teamwork [24]. In multiplayer and cooperative games, these elements encourage sustained engagement, as players develop bonds with teammates and communities. The immersion component further influences attraction by offering experiences such as discovery, where players enjoy uncovering hidden aspects of the game, and role-playing, where they create and embody a persona with a unique background. Customization also plays a crucial role in attraction, as players take interest in modifying their character's appearance to reflect their identity or preferences. Additionally, some players are drawn to games for escapism, using the virtual environment to temporarily detach from real-world concerns [24].

This initial attraction naturally leads to character personalization, where players engage in shaping their in-game identity. Within this, two key aspects emerge: character selection, where players choose a predefined avatar or role, and character customization, which allows for modifying appearance, abilities, and other attributes. Participants described how choosing or modifying characters allowed them to reflect their preferences and identity. These findings are consistent with Jupit [10], who discussed how character-related choices can reflect players' identities and preferences. Even in games with limited customization options, players can still express themselves through the choices, actions, and decisions they make. Additionally, Ducheneaut et al. [17] suggest that avatar creation enables players to create idealized digital identities, often reflecting societal standards of attractiveness. This process may contribute to their sense of satisfaction and strengthen their connection to their virtual persona. These personalization options contribute to personal expression, allowing players to showcase their creativity, identity, and unique preferences within the game world.

As players establish their in-game identity through character personalization and pursue their goals, their choices can shape how they experience and interact with the gameplay. Participants depicted different styles of play based on their preferences and the ways they interacted with the game world. Players adopt varying approaches, such as preferring third-person over first-person perspectives or engaging in non-combat activities like collecting resources and trading instead of focusing on the main storyline [10]. These preferences not only define their in-game experience but also influence the strategies they use to overcome challenges. Gameplay strategy involves making tactical decisions, managing resources, and developing unique methods to progress. Players also actively plan strategies to ensure self-preservation, fulfil objectives, or overcome in-game obstacles. These strategic choices may provide opportunities for players to develop or practise different skills during gameplay [10].

Decision-making in games is also an important aspect of gameplay, as players face moral dilemmas, story-driven branching points, and moment-to-moment choices that can shape their experience. Tancred et al. [12] categorize these into systemic and scripted decisions, each affecting the game's outcome differently. For example, Dishonored uses a branching narrative where a low- or high-chaos playstyle determines the ending; Papers, Please integrates systemic choices that influence gameplay through hidden mechanics; and The Walking Dead employs scripted choices where key narrative moments shape the story's progression. These decision-making structures influence players' sense of agency and the moral weight of their choices.

Responses from the participants showed how their in-game choices could reflect their real-world values and behaviours. This may indicate that players sometimes draw on considerations from outside the game when making in-game choices. Krcmar and Cingel [25] examined moral and strategic reasoning during video game play and reported that experienced players tended to rely more on moral reasoning during gameplay. Their findings suggest that players may draw on moral considerations from outside the game when making in-game choices. However, these findings do not necessarily establish that in-game choices directly shape real-life perceptions or behaviours.

The finding also shows how style of play, strategy of gameplay, and decision-making were related to their emotional experiences, including feelings such as excitement, frustration, or relaxation throughout the gaming experience. Cao et al. [26] found that game difficulty significantly shapes these emotions, with more challenging game sessions associated with increased negative emotions and higher arousal. This finding provides a possible explanation for the emotional experiences described by the participants. At the same time, the analysis identified how players learned, adapted, and practised problem-solving, patience, and strategic thinking during gameplay. Some players focus on improving their skills and tracking their progress, whereas others play primarily for enjoyment without prioritizing development. Research has also reported potential associations between video game play and aspects of cognitive performance and perception [27], although the extent and consistency of these benefits remain debated. These findings suggest that gameplay may provide opportunities for players to develop or practise certain skills, but further research is needed to establish the extent of these effects.

The impact of personal development extends further by contributing to replayability, where players seek alternative playthroughs, explore new challenges, or make different choices to experience the game from multiple perspectives. Frattesi et al. [28] highlight that rather than concluding their experience after finishing the story, players may continue playing to unlock achievements, earn trophies, or explore multiple endings. As players refine their skills, strategies, and adaptability, they become more proficient in overcoming obstacles, optimizing their gameplay, and mastering mechanics. Furthermore, difficulty levels encourage players to replay games, as increased challenge motivates them to refine strategies and further optimize gameplay [28]. The relationship between replayability and gameplay may contribute to continued player engagement.

The finding highlighted emotional engagement as an important aspect of the gameplay experience, particularly when players became deeply immersed in the game. Beginners enjoy games with easier difficulty because frequent wins create instant gratification, while experienced players find greater engagement in overcoming tough challenges [29]. This balance between difficulty and reward may contribute to maintaining emotional investment. If a game is too easy, players may lose interest,

whereas excessive difficulty can lead to frustration. However, when the level of challenge is well balanced with players' skills, they are more likely to experience flow, becoming fully immersed in the gameplay and often losing track of time [30]. This balance between skill and challenge has been shown to promote deeper flow experiences and increase players' motivation to continue playing.

During gameplay, players encounter social interaction, which significantly shapes their overall experience. The analysis identified teamwork and cooperation, as well as NPC and ally relationships, as key aspects of social interaction. This interaction can take place through teamwork and cooperation, where players collaborate in multiplayer settings to achieve shared objectives, strategize in competitive environments, and build camaraderie through cooperative gameplay. Research suggests that cooperative gameplay can strengthen teamwork and improve overall team performance, while competitive gameplay may hinder collaboration and teamwork effectiveness [31]. Additionally, NPC and ally relationships play a crucial role in single-player experiences, where interactions with AI (Artificial Intelligence)-controlled characters contribute to immersion and emotional investment. Meaningful relationships with NPCs, whether through story-driven bonds or gameplay mechanics, influence player decisions and narrative outcomes. Meaningful interactions with NPCs can enhance players' emotional engagement by fostering feelings of attachment and connection to game characters [32]. These virtual allies not only support storytelling by offering dynamic interactions but also provide strategic assistance in combat, puzzles, and exploration. Engaging with allies, forming trust, or experiencing betrayals can elicit strong emotional responses, strengthening the player's attachment to the game world. Character attachment in games is not merely about liking a character but encompasses various forms of emotional connections, including admiration, concern, and trust [33]. This indicates that players often develop meaningful bonds with game characters, treating them as trusted friends, protégés, or even respected adversaries. These diverse emotional experiences contribute to deeper engagement, influencing player decisions and enhancing the overall gaming experience. By integrating social interaction into the gaming experience, players not only enhance their engagement but also develop strategic thinking, adaptability, and a deeper emotional connection to the game.

As players continue playing, they will receive rewards that can contribute to their motivation. These rewards can be functional or aesthetic, each serving a different purpose. Functional rewards, like power-ups, new abilities, or better equipment, help players improve and progress in the game. These rewards make it easier to overcome challenges and feel a sense of achievement. On the other hand, aesthetic rewards, such as character skins, outfits, or decorations, do not affect gameplay but allow players to express their style and personality.

The impact of rewards is important because they keep players engaged and excited. Functional rewards make players feel stronger and more capable, while aesthetic rewards let them personalize their experience. The process of earning rewards may encourage players to keep playing, whether to improve their skills or simply enjoy collecting new items. Reward systems enhance gameplay by establishing status, fostering social connections, and motivating collaboration, particularly in searching for hidden content [34]. Rewards also make game mechanics more enjoyable by setting clear goals, reducing boredom, and stimulating curiosity. Furthermore, rewards could enhance player motivation and contribute to greater interest and enjoyment, particularly when games provide a diverse variety of reward types [34].

The goals and rewards identified in the analysis may also contribute to a sense of completion in the gaming experience. As players work toward achieving their objectives, whether game-given or self-made, and receive functional or aesthetic rewards, they may develop a sense of progress and accomplishment.

The goals and rewards may contribute to a sense of completion, which can be experienced in different ways. As players approach the end of a game, their perception of completion may vary based on their personal goals and in-game choices. The analysis indicated that players may define completion differently, with some seeking to finish the main storyline, unlock all achievements, or reach specific milestones. Others may strive for 100% completion by collecting every item and finishing all side quests, while some may be satisfied with simply reaching the end of the story. These different preferences suggest that players may develop their own sense of completion based on their goals and gameplay experiences. Previous research has similarly suggested that players can experience completion according to their individual actions and preferences [10], [12]. Players may experience a sense of completion when they feel in control of when and how they conclude their gameplay [10], [12], [13].If the outcome does not meet their expectations, some players may replay the game to achieve a more fulfilling conclusion [12], [28]. Finally, this may contribute to personal fulfilment, as players reflect on their journey and experience feelings of mastery, satisfaction, or emotional closure based on their playstyle and goals. Video games have also been associated with feelings of control and achievement, which may make accomplishments feel more rewarding [35].

V. Conclusion and Future Works

This study investigates player choice in digital games through interviews, recruited via purposive sampling, and reviewing related works. The analysis revealed key themes and sub-themes that illustrate how players engage with choices during gameplay, highlighting factors such as Character Personalization, Goals, Gameplay, Social Interaction, Rewards, and Completion. Although the study did not aim to generalize across all gaming contexts, it provides valuable insights and directions for future research.

Firstly, the study contributes to the growing body of literature on player experience by exploring player choice as a distinct aspect of gameplay rather than treating it as a subcomponent of agency, autonomy, or decision-making. By focusing directly on how players perceive and articulate their choices, the study provides exploratory insights into how choice may shape players' experiences in digital games. These findings suggest that player choice may be related to aspects of immersion, motivation, and identity, and further research is needed to examine these relationships.

Secondly, the study shows that the way players understand and value player choice depends greatly on context. Factors such as the genre of the game, its mechanics, and the player's cultural or personal background influence how choices are experienced. For example, some players view choice mainly to express their identity through character personalization, while others associate it more with narrative goals, rewards, or opportunities for social interaction. This suggests that player choice in games is not a single, uniform concept, but rather shaped by the specific circumstances of both the game and the player.

However, this study has several methodological limitations. First, the study involved only ten participants recruited through purposive sampling. Although the participants had experience playing digital games and provided information relevant to the research objectives, the relatively small sample may not fully represent the broader population of digital game players. Second, the thematic analysis did not involve an independent inter-rater reliability assessment. This reflects the reflexive thematic analysis approach adopted in this study, in which researcher subjectivity is recognised as an integral part of the interpretive process of coding and theme development, rather than something that can be eliminated through coding agreement or reliability statistics [36], [37]. Accordingly, the themes were developed through the researchers' active engagement and interpretation of the interview data. Nevertheless, the influence of researcher interpretation cannot be completely excluded. Future research could strengthen the robustness of the findings through additional reflexive practices, collaborative discussion of interpretations, as well as larger and more diverse samples.

Lastly, the study suggests several avenues for further investigation. Future research should extend the findings through quantitative approaches, using a model to validate and measure player choice through Exploratory Factor Analysis (EFA) and Confirmatory Factor Analysis (CFA). Such work can strengthen the generalizability of the findings and provide a standardized framework for studying choice in game research. In addition, larger and more diverse participant samples are recommended to capture the variation of player choice across genres, demographics, and cultural contexts.

Declaration of AI Assistance

The authors used generative artificial intelligence (AI) tools to assist with grammar checking, improving sentence structure, and paraphrasing during the preparation of this manuscript. The authors reviewed and verified all AI-assisted content and take full responsibility for the accuracy, originality, and final content of the manuscript.

***Abstract*—Regression testing plays a crucial role in ensuring that software modifications do not adversely affect existing functionality. However, test suites continue to grow, and the retest-all method has become increasingly impractical due to high execution costs and time constraints. Consequently, Test Case Selection (TCS) has emerged as an important optimization method to identify which test cases are relevant for re-execution. Metaheuristic optimization has received a great deal of attention in Search-Based Software Testing (SBST) for balancing the conflicting objectives of cost reduction and fault detection effectiveness. However, there are still multiple areas of fragmentation within the research, including algorithm design, objective formulation, empirical evaluation, and reporting practices. Results indicate that evolutionary algorithms and swarm intelligence are the primary algorithms used for TCS, with an increasing trend towards hybrid and multi-objective approaches to increase the quality and scalability of the search. Multi-objective formulations are significant in this context, as such approaches provide a structured mechanism to capture the trade-off between testing cost and effectiveness through Pareto-based evaluations. Empirical evidence remains largely dependent on benchmark and open-source systems, although recent studies increasingly incorporate industrial and Artificial Intelligence (AI)-based environments. Overall, the findings indicate that there is a lack of single techniques that are universally superior, as performance is strongly influenced by system characteristics and evaluation criteria. Future research should emphasize standardized evaluation practices, stronger industry-scale validation, and the development of domain-aware TCS techniques to improve practical applicability.**

***Keywords*—Regression testing; test case selection; metaheuristic algorithms; search-based software testing**

I. Introduction

Regression testing as part of software quality assurance ensures that newly made changes do not affect previously functional parts of the application [1]. However, as the size of the test suite grows larger, running retest-all becomes extremely time-consuming [2]. To improve testing efficiency, Test Case Selection (TCS), Test Case Prioritization (TCP), and Test Case Minimization (TCM) strategies have been developed [3]. These techniques help reduce redundant test cases, optimize testing resources, and improve fault detection capability, making regression testing optimization an important research area [4-6].

In this context, TCS aims to select a subset of relevant test cases to re-execute based on software changes. Although often discussed together with TCP and TCM, TCS differs in its goal and scope, focusing on selecting a subset of test cases for a specific regression cycle [4, 5]. Studies primarily addressing TCS were included. Studies involving TCP or TCM were included only when test case selection constituted a substantive component of the proposed approach. Studies focusing exclusively on TCP, TCM, test data generation, or unrelated testing activities were excluded.

Traditional TCS approaches typically rely on deterministic heuristics or single-objective formulations such as coverage or cost. Although easy to implement, these approaches fail to address conflicts between implementation cost and fault detection effectiveness when the search space becomes large and complex [7]. Empirical findings indicate that no single technique is consistently superior across different situations [8-10].

Recent studies have increasingly applied Search-Based Software Testing (SBST) and metaheuristic optimization techniques to address these challenges, particularly in large-scale or industrial environments where multi-objective trade-offs are common [2, 11].

Despite these advances, the literature still lacks a structured synthesis of optimization paradigms, objectives, datasets, and evaluation metrics used in metaheuristic-based TCS research. Therefore, a Systematic Literature Review (SLR) is conducted to classify and synthesize existing studies and to review current research developments [12-14].

II. Research Method

An SLR method was employed to locate, evaluate, and summarize existing empirical literature that analyses TCS by employing metaheuristics for the purposes of regression testing. The research has been conducted in an organized and open

*Corresponding author.

manner, using a documented research protocol that allows for repeatability, accuracy, and consistency of results.

A. Research Questions

The SLR was guided by the following research questions.

RQ1: What types of metaheuristic algorithms are used in test case selection for regression testing?

RQ2: What optimization objectives, evaluation criteria and metrics, and empirical evaluation contexts are used in metaheuristic-based test case selection studies?

RQ3: What are the main empirical findings and current research trends in metaheuristic-based test case selection?

The above research questions help to provide a systematic synthesis of the algorithm's characteristics and how objectives were formulated, experimental contexts, and empirical findings in relation to metaheuristic-based TCS research.

B. Sources of Information

To perform a thorough literature review, multiple key academic databases were consulted to identify and include high-quality studies. The sources of information used in this study include IEEE Xplore, Scopus, ScienceDirect, SpringerLink, and Google Scholar. The selection of these databases was based on their coverage of the software engineering field, publisher reputation, and accessibility to journal articles and conference proceedings reporting empirical evidence.

C. Search Strategy

The search strategy was developed using keywords related to TCS and metaheuristic optimization techniques. The main keywords included “test case selection”, “test suite selection”, and “test suite reduction”, combined with metaheuristic techniques such as “metaheuristic”, “genetic algorithm”, “particle swarm optimization”, “ant colony optimization”, “simulated annealing”, and “NSGA-II”. Boolean operators “AND” and “OR” were used to combine the keywords and control the search scope. The search was limited to English-language journal articles and conference papers reporting empirical studies related to regression testing. Table I presents the search protocol, including the databases, search strings, and publication years covered in this systematic literature review.

TABLE I. SEARCH PROTOCOL

Database	Search String	Year Covered
IEEE Xplore	("test case selection" OR "test suite selection" OR "test suite reduction") AND ("metaheuristic" OR "genetic algorithm" OR "particle swarm optimization" OR "ant colony optimization" OR "simulated annealing" OR "NSGA-II")	2014–2026
Scopus

D. Study Selection

The systematic process used for selecting studies in this SLR ensured that only studies relevant to metaheuristic-based TCS were included. Fig. 1 shows the study selection process from the initial identification of records to the final set of primary studies. A total of 323 records were identified through searches of five major databases in the initial stage. The titles, authors, and Digital Object Identifiers (DOIs) of the retrieved records were examined to identify duplicate records and clearly irrelevant studies. A total of 38 duplicate or clearly irrelevant records were removed, leaving 285 records for title and abstract screening.

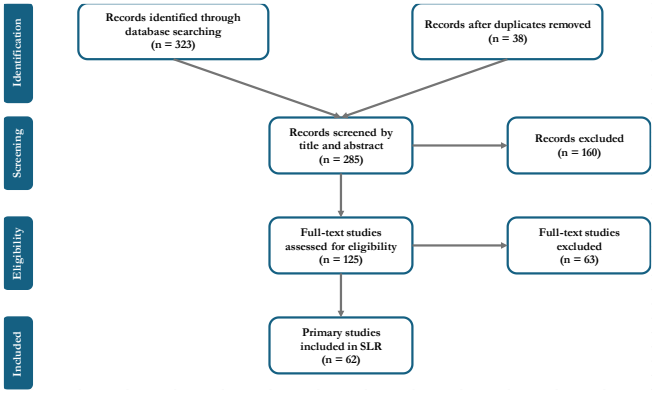

Fig. 1. Overview of the study screening and selection procedure.

In the second stage, the 285 records were screened based on their titles and abstracts to assess their relevance to regression testing and the involvement of TCS components. Studies that focused on TCP and TCM, as well as studies without sufficient empirical evidence, were excluded. A total of 160 records were excluded at this stage, leaving 125 studies for full-text assessment.

In the final stage, the 125 potentially eligible studies underwent full-text assessment based on the clarity of the proposed method, the appropriateness of the evaluation measures, and the quality and completeness of experimental reporting. A total of 63 studies were excluded because they did not satisfy the predefined eligibility and quality criteria, including insufficient methodological description and inadequate empirical evaluation. Consequently, 62 primary studies were selected for data extraction and synthesis to address the research questions.

E. Extraction and Synthesis

To ensure consistency with the study objectives, a data extraction and synthesis process was conducted for each of the 62 primary studies. A standardized template was used to capture data on the metaheuristic algorithm type, TCS strategy, optimization objectives, and empirical evaluation methods [15]. The main extraction items are presented in Table II. The detailed information extracted from the 62 primary studies is provided in Appendix (Table VI).

The predetermined data extraction criteria helped enhance the accuracy and consistency of the extracted data. Any discrepancies identified during the extraction process were discussed and resolved by the reviewers. Data synthesis was conducted in structured and narrative forms to capture the diversity of previous studies. Metaheuristic algorithms, optimization objectives, and experimental designs were identified to support grouping and comparative analysis based on the metaheuristic technique, TCS methodology, and reported performance metrics.

TABLE II. DATA EXTRACTION ITEMS FOR METAHEURISTIC-BASED TEST CASE SELECTION STUDIES

Categories	Data Items	Description
Study Information	Study ID	A unique identifier was allocated to each primary study
	Authors & Year	Authors' names and year of publication
	Publication Source	Venue of publication and conference proceedings
Algorithm	Metaheuristic Algorithm	Type of metaheuristic technique applied within the corresponding optimization problem
	Algorithm Classification	Optimization categories including single-objective and multi-objective
TCS Approach	Selection Strategy	TCS technique or mechanism applied
	Technique Integration	Approaches used independently and those integrated with TCM and TCP
Objectives & Metrics	Optimization Objectives	Types of objective functions considered by the researchers when searching for an optimal solution
	Evaluation Metrics	Types of performance metrics used to evaluate the search results
Empirical Evaluation	Evaluation Dataset	Software systems or benchmark datasets utilized in the study
	Experimental Context	Experimental context includes industrial settings, open-source environments, and simulation platforms
Results	Key Findings	Significant findings reported and contributions to the field
Study Limitations	Limitations	Limitations identified by the authors

F. Quality Assessment of Primary Studies

To assess the quality of the selected primary studies systematically, the full-text studies were evaluated based on three main criteria. These criteria included the clarity of the proposed method, the appropriateness of the evaluation measures, and the quality of experimental reporting. The assessment was also used to determine whether each study provided sufficient methodological and empirical information to support the synthesis of findings. In addition, the completeness of the descriptions of the metaheuristic algorithm, experimental context, datasets, and evaluation metrics was considered. Studies with insufficient empirical evidence or inadequate reporting were excluded during the full-text screening stage.

The review of the 62 primary studies indicates that researchers have proposed numerous methods of measurement to address the problem of TCS. However, different empirical methods and descriptions of TCS mechanisms have resulted in varied criteria for selecting algorithms, making meaningful and direct comparison between studies difficult.

The analysis also shows that many studies use a limited number of evaluation metrics and relatively small test suites. This limitation may affect the generalizability of research findings and the development of hybrid approaches that combine multiple TCS strategies.

These findings indicate the need for clearer specification of TCS approaches to support better characterization and evaluation of TCS methodologies. Improved reporting would help explain how TCS techniques perform in larger-scale environments, particularly in terms of cost, coverage, and fault detection capability. Table III highlights the importance of more standardized reporting and evaluation practices to strengthen the interpretability and comparability of future TCS research.

TABLE III. MAPPING OF QUALITATIVE ASSESSMENT RESULTS TO RESEARCH QUESTIONS

Research Question	Focus of Assessments	Key Qualitative Findings	Identified Implications
RQ1	Metaheuristic techniques for TCS	Algorithms vary widely, and selection mechanisms are often unclear	Need clearer TCS formulations
RQ2	Objectives, metrics, and evaluation contexts	Different objectives, metrics, and datasets are used	Limited comparability across studies
RQ3	Empirical findings and research trends	Many studies report cost reduction and improved effectiveness	Limited generalizability of findings

III. RESULTS

This section reports the findings of a systematic literature review based on the analysis of 62 primary studies examining the use of metaheuristics in TCS. The findings describe the optimization algorithms applied, objective formulations, evaluation metrics, and experimental contexts used to assess the proposed approaches. The synthesis is organized according to the research questions (RQ1-RQ3) to present the findings systematically.

A. Primary Studies

The 62 primary studies identified during the screening are discussed in this section. These studies provide an overview of the metaheuristic techniques used, objective formulations, and evaluation environments applied in TCS research. The distribution of primary studies across digital libraries is presented in Table IV.

TABLE IV. DISTRIBUTION OF PRIMARY STUDIES BY DIGITAL LIBRARY

Digital Library	Journal	Conference	Total
Scopus	17	18	35
IEEE Xplore	2	5	7
SpringerLink	4	2	6
ScienceDirect	2	0	2
Google Scholar	12	0	12
Total of Primary Studies			62

B. Analysis of the Primary Studies

A systematic mapping approach was used to analyze each of the primary studies as they related to the desired research questions RQ1-RQ3. As a result, the study types used, how objectives were formulated, the empirical contexts chosen, and the effectiveness of each technique could be systematically synthesized based on their research findings.

C. RQ1: What Types of Metaheuristic Algorithms Are used in Test Case Selection for Regression Testing?

RQ1 is addressed by presenting empirical evaluations of metaheuristic techniques used for TCS in regression testing. The

analysis focuses on the categories of metaheuristic algorithms applied to the TCS problem and the variations introduced across different studies.

1) Refinement of algorithms: Metaheuristic techniques identified in previous studies can generally be categorized into several groups, including Evolutionary Algorithms (EA), Swarm Intelligence approaches, and other nature-inspired metaheuristics, as summarized in Table V. These categories represent different search strategies adapted to address the complexity of TCS in regression testing.

The EA, particularly Genetic Algorithm (GA) and Non-Dominated Sorting Genetic Algorithm II (NSGA-II), are the most widely applied methods in TCS research for solving multi-objective optimization problems that balance test effectiveness and implementation cost [16-20]. Several studies introduced improvements such as linkage learning-based crossover, seeding strategies, metamorphic testing integration, and operator-level improvements including mutation and crossover strategies to enhance solution stability and performance [19-22].

In addition to evolutionary approaches, swarm intelligence algorithms such as Particle Swarm Optimization (PSO) are also widely used. Early studies focused on Binary Multi-Objective PSO (BMOPSO) and compared its variants [8]. Later work explored hybrid approaches such as BMOPSO combined with Local Search and PSO integrated with Harmony Search to improve the trade-off between coverage and execution cost [23, 24]. Advanced variants such as Quantum-Behaved PSO (QPSO) have also been reported to improve performance over classical approaches [25]. More recent studies further demonstrate the effectiveness of hybrid swarm GA and swarm-based minimization strategies in improving fault detection and execution efficiency [26-31].

Other metaheuristic alternatives explored in previous studies include Ant Colony Optimization (ACO), Artificial Bee Colony (ABC), Whale Optimization Algorithm (WOA), Cuckoo Search, Bat Algorithm, and Firefly Algorithm. These techniques are often evaluated comparatively or modified to balance fault detection capability with execution time [9, 32-38]. Variations such as Harmony Search, Firefly Algorithm, and ABC have also been combined with crossover or ranking mechanisms to improve convergence speed and solution quality [28, 39].

Recent studies have proposed advanced metaheuristic algorithms to address scalability and high-dimensional objective spaces, particularly in large-scale regression testing environments [40-42]. Examples include Chaotic Archimedes Optimization Algorithm (CAOA), African Buffalo Optimization (ABO), and Gray Wolf Optimization (GWO), which reflect the expanding exploration of optimization techniques in TCS research [43-45]. These developments indicate that future algorithmic innovation in TCS is likely to focus more on domain-specific adaptations rather than purely theoretical exploration.

2) Uniqueness of the algorithm: The uniqueness of the algorithm proposed in previous studies does not lie in the selection of algorithms alone, but in the way in which the algorithms are adapted to the needs of regression testing. Many studies introduced hybrid strategies, diversity injection mechanisms, or operator improvements to enhance search quality and solution stability. Some studies also proposed optimization-oriented approaches that are not purely metaheuristic, such as Multi-Criteria Decision Making (AHP-TOPSIS), ontology-based selection, belief propagation for microservices, and learning-based techniques such as recurrent neural networks. These approaches highlight the need to adapt test selection techniques to increasingly complex system architectures and testing environments [46-50]. To provide a clearer overview of the metaheuristic techniques identified in this review, Table V summarizes the major algorithm categories, their characteristics, and application contexts.

TABLE V. SUMMARY OF METAHEURISTIC TECHNIQUES USED FOR TEST CASE SELECTION

Author	Type of Algorithm	Key Characteristics	Application Context
[16-20, 22,51-55]	Evolutionary Algorithms (GA, NSGA-II)	Multi-objective, Pareto-based optimization	Benchmark, black-box, industrial systems
[8, 23-25, 27, 28, 30, 38]	Swarm Intelligence Algorithms (PSO, QPSO)	Fast convergence, population-based search	Regression TCS, hybrid approaches
[9,34, 35, 37-39, 43, 44]	Other Nature-Inspired Metaheuristic Algorithms (ACO, ABC, Whale, Bat, Firefly, Cuckoo)	Optimization techniques balancing fault detection and execution cost	Comparative experimental studies and benchmark environments
[43-45, 56, 57]	Emerging Metaheuristic Techniques (CAOA, ABO, GWO)	Adaptive and domain-specific optimization strategies for large-scale testing environments	Recent benchmark studies and advanced regression testing contexts

Fig. 2 illustrates the distribution of metaheuristic algorithm categories across publication years. Evolutionary algorithms, particularly GA and NSGA-II, remain the most dominant approaches for multi-objective TCS. Swarm intelligence algorithms such as PSO and QPSO are also widely used through various variants and hybrid implementations. Other nature-inspired algorithms, including Bat, Firefly, and Cuckoo Search, are mainly applied for comparative evaluation or algorithm modification. The emergence of newer techniques indicates increasing interest in adaptive and domain-specific optimization approaches for regression testing.

D. RQ2: What Optimization Objectives, Evaluation Criteria and Metrics, and Empirical Evaluation Contexts are used in Metaheuristic-Based Test Case Selection Studies?

This section presents a classification of TCS techniques based on the formulation of optimization objectives, evaluation metrics, and empirical evaluation contexts reported in previous studies. The analysis shows that variations in techniques are influenced by the optimization approach used, while the modelling of the TCS problem and the empirical evaluation settings also play an important role in determining the classification structure.

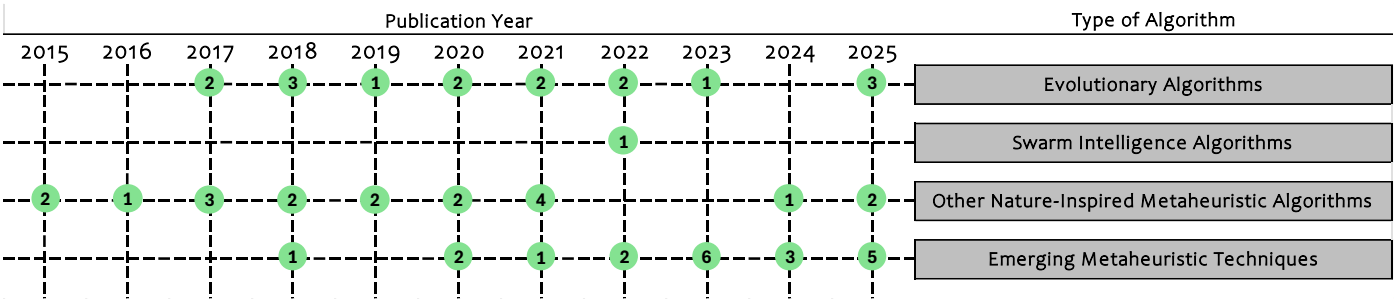

Fig. 2. Distribution of metaheuristic algorithm categories by publication year.

1) Optimization objectives: In general, existing studies can be classified into two broad categories, namely single-objective and multi-objective studies. Single-objective studies typically consolidate multiple criteria into a single objective function and tend to focus on reducing regression testing costs such as execution time and test suite size [9, 30, 51-53].

In contrast, a multi-objective approach allows simultaneous optimization of test effectiveness and implementation cost. This formulation combines difficult-to-measure objectives such as fault detection, test diversity, and coverage with cost factors including test suite size, execution time, and overall cost. The result is a Pareto-optimal solution set that provides trade-off options and supports decision-making in complex regression testing environments [8, 16, 29, 39, 45, 54-56].

Recent studies continue to extend this framework by addressing scalability and high-dimensional objective spaces in large-scale or industrial environments. Research in this domain focuses on optimizing multiple conflicting objectives, including diversity, coverage, fault detection capability, and cost, while maintaining solution quality through Pareto dominance techniques [40-42, 57].

Several studies also integrate additional criteria such as diversity, risk, similarity reduction, and technical debt to support more comprehensive optimization. These criteria enhance the applicability of TCS in specific contexts, particularly for cost-effective optimization strategies [58]. However, variations in objectives and evaluation metrics make it difficult to compare techniques consistently across studies, highlighting the need to align TCS strategies with system-specific requirements and testing constraints [16, 46, 59].

2) Evaluation criteria and performance metrics: In terms of evaluation criteria, the majority of studies evaluate TCS techniques based on two main categories, which are test effectiveness and implementation cost. Test effectiveness is usually evaluated through coverage, for example, statement, path, and interaction coverage, and fault detection metrics such as Fault Detection Rate (FDR) and Fault Detection Capability (FDC). Implementation cost is usually measured through Execution Time (ET), Test Suite size, or Suite Size Reduction, as these metrics directly represent the burden of regression testing in practice [9, 30, 33, 34, 40, 53, 57, 60-62].

The majority of multi-objective studies rely on Pareto-based indicators such as Hypervolume (HV), Generational Distance (GD), Inverted Generational Distance (IGD), epsilon, and Pareto-front characteristics to measure the quality of the resulting solution set. In contrast, single-objective studies tend to rely on performance metrics such as execution time, fault detection rate, Average Percentage of Faults Detected (APFD), and test suite size, as these metrics are generally easier for industry practitioners to interpret [32, 51-53, 55, 63]. These Pareto indicators evaluate solution quality from the perspective of trade-offs and objective space coverage and allow studies to provide alternative solutions for users under different constraints [8, 40-42, 54, 63-65].

Fig. 3 shows the continued dominance of multi-objective formulations in metaheuristic-based TCS studies, reflecting the need to balance test effectiveness and implementation costs.

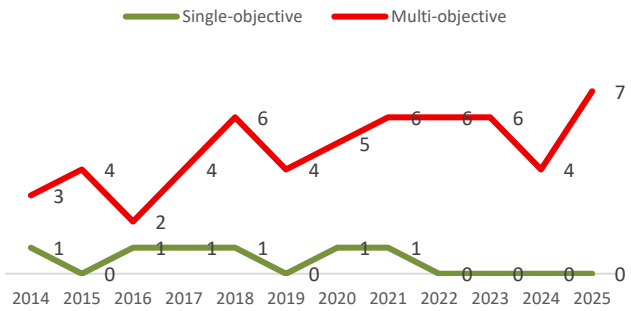

Fig. 3. Multi-objective formulations in metaheuristic-based TCS studies.

Variation in evaluation criteria across studies limits the consistent comparison of empirical results and highlights the need for more standardized evaluation practices in TCS research. Industry studies often prioritize simple metrics such as runtime and fault detection, while benchmark studies rely on Pareto indicators. The introduction of criteria such as diversity, similarity, and technical debt also reflects a shift toward more contextual evaluation metrics, although it increases evaluation heterogeneity across studies [16, 17, 46, 66].

3) Empirical evaluation contexts: This section analyses the empirical evidence used to evaluate the effectiveness of TCS techniques in regression testing. The analysis focuses on the type of empirical evidence, such as systems, datasets, and experimental contexts, used across studies. Overall, the findings show that benchmarks and open-source systems still dominate evaluation due to their ease of replication and comparison. However, a growing body of research evaluates these techniques in industrial, simulation-based, cyber-

physical, and AI-based contexts [16, 18, 40, 55, 57, 61, 63, 66-69].

The majority of studies have used benchmarks and open-source systems, particularly programs from the Software Infrastructure Repository (SIR), because they provide controlled and repeatable environments suitable for comparing techniques across studies. These environments allow researchers to evaluate objectives such as coverage, Fault Detection (FD), and ET in a consistent setting, making SIR the dominant empirical basis for evaluating metaheuristic-based TCS [9, 10, 23, 24, 34, 50, 58, 64, 70, 71]. However, this reliance on benchmark environments may limit external validity.

To address this limitation, several studies extend evaluation to larger-scale open-source systems or multiple domains, including enterprise systems and black-box or simulation contexts. These evaluations aim to demonstrate the scalability and feasibility of proposed techniques under more realistic testing conditions [16, 17, 40, 56, 57, 63, 72].

Several studies also report empirical evidence from specific industrial domains such as defense, Programmable Logic Controllers (PLCs), industrial applications, and automotive systems. These evaluations emphasize practical considerations including runtime efficiency, stability of optimization results, and the ability to operate under test time and budget constraints [61, 68]. Recent studies also involve AI-based systems such as deep learning, reinforcement learning, and microservices architectures [48, 69]. These contexts require adaptations in test construction and selection strategies, for example through metamorphic relations or dependency modelling. This trend indicates that TCS research is expanding beyond traditional benchmark environments [18, 26, 47, 48, 55, 60, 67-69, 73].

E. RQ3: What Are the Main Empirical Findings and Current Research Trends in Metaheuristic-Based Test Case Selection?

This section compares TCS techniques based on empirical findings, focusing on regression testing cost reduction and fault detection effectiveness. The analysis shows that technique performance depends on system context, objective formulation, and evaluation criteria, indicating that no single technique is consistently superior across different scenarios.

1) Cost reduction: Most studies report significant reductions in execution time or test suite size compared to conventional approaches such as random selection or retest-all. Metaheuristic-based techniques, particularly those focused on cost minimization, reduce the burden of regression testing without executing the entire test suite [9, 27, 29, 30, 36, 51-53, 58].

Single-objective approaches often achieve greater cost reductions because the optimization focuses on a single criterion. However, higher cost reduction may reduce fault detection effectiveness when test effectiveness is not considered [9, 30, 52, 53]. Multi-objective approaches provide more balanced solutions by allowing users to select Pareto solutions based on time constraints or testing budgets [41, 54, 55].

Techniques such as hybridization, local search integration, and adaptive mutation operators further improve cost efficiency and are suitable for environments such as Continuous Integration (CI) and industrial regression testing [21, 23, 40-42, 57, 60, 72]. Overall, these findings highlight a trade-off between cost efficiency and testing effectiveness, emphasizing the need for balanced optimization strategies.

2) Fault detection effectiveness: Most studies show that metaheuristic-based TCS techniques improve fault detection compared to conventional approaches. Even when only a subset of test cases is executed, these techniques can achieve similar or higher fault detection probability, as demonstrated through metrics such as FDR, FDC, and APFD [16, 25, 27-29, 32, 52, 53, 58].

Multi-objective approaches that model fault detection or coverage as explicit objectives generally provide more stable defect detection performance. Techniques incorporating diversity, similarity reduction, or metamorphic relations help select more representative and less redundant test sets, increasing the likelihood of detecting diverse defects, particularly in complex systems such as deep learning and cyber-physical systems [16, 18, 59, 74].

However, empirical findings show that no single technique consistently outperforms others in fault detection. Performance depends on system characteristics, fault types, and metric definitions. Several industrial studies also emphasize that repeatability and practical feasibility are often more important than maximum performance in controlled environments [40, 55, 57, 60, 72]. These findings indicate that effectiveness in metaheuristic-based TCS is inherently context-dependent rather than universally achieved through a single optimization strategy.

3) Synthesis of trade-offs in metaheuristic-based TCS: The findings indicate an inherent trade-off between test case execution cost and fault detection effectiveness in regression testing. This trade-off has led to the development of hybrid techniques to achieve a better balance between cost and effectiveness. Fig. 4 illustrates this conceptual trade-off in metaheuristic-based TCS.

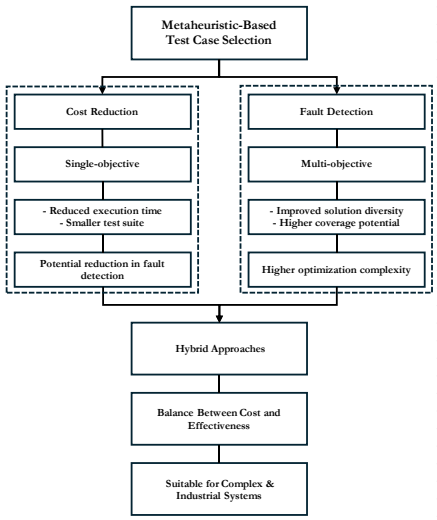

Fig. 4. Conceptual synthesis of the cost-effectiveness trade-off in metaheuristic-based test case selection.

IV. Discussion

Based on the findings of RQ1 in Section III-C, the dominance of evolutionary algorithms and swarm intelligence is driven more by flexibility in modelling regression testing trade-offs than by absolute algorithmic superiority [15, 16, 51]. The shift towards hybrid techniques and operator improvement confirms that the adaptation of algorithms to the problem context is more significant than the mere selection of basic algorithms [22, 24, 25].

For RQ2 in Section III-D, there is a clear difference between single-objective and multi-objective approaches. Multi-objective approaches evaluated using Pareto indicators provide more flexible decision support but increase the complexity of the analysis and make comparisons between studies difficult [8, 51, 55]. Time-constrained environments such as industrial settings are typically more suited to cost-oriented approaches [9, 53].

For RQ3 in Section III-E, there is a predominance of benchmarking and open-source systems from the SIR [9, 24]. Although benchmarking establishes a basis for replication, the considerable reliance on benchmarks for assessing and comparing evidence may constrain the external validity of the associated findings. Similarly, industrial environments, cyber-physical systems, and AI-enabled environments are increasingly being assessed within an industrial context. Each of these three environments has substantial variances and, consequently, these variances greatly affect how metrics are interpreted and how successful the metrics are at measuring what they are designed to measure [17, 51, 58].

Taken together, these findings suggest that the suitability of a TCS approach should be determined by the primary testing objective and the constraints of the target environment rather than by algorithmic popularity alone. For cost-oriented TCS, single-objective or cost-focused approaches are more suitable when reducing execution time or test suite size is the primary concern, particularly in industrial and time-constrained environments. Coverage-oriented TCS is better suited to coverage-based evolutionary approaches when maximizing structural or interaction coverage is the dominant objective. For fault-detection-oriented TCS, detection-based or multi-objective approaches may be preferable because they can prioritize fault detection while considering competing objectives. When both cost and test effectiveness are important, multi-objective algorithms are more appropriate because they explicitly model trade-offs and provide alternative solutions under different testing constraints. For many-objective TCS problems, many-objective evolutionary or hybrid approaches may be more suitable because they are designed to manage a larger number of competing objectives. In industrial or time-constrained settings, cost-aware and hybrid approaches may offer greater practical suitability by balancing solution quality with computational and execution overhead.

Furthermore, the findings also highlight the perceived trade-off between detecting defects and reducing costs. Cost-based strategies tend to achieve large reductions in costs but may compromise their ability to detect faults [9, 31]. Multi-objective and hybrid techniques may provide a more balanced trade-off when multiple objectives must be considered simultaneously [51, 55]. The findings indicate that no single approach is consistently superior across all scenarios, with a discernible trend toward more adaptive and context-sensitive techniques [15, 22]. This suggests that effective TCS strategies depend on aligning the optimization method with the testing objective, system characteristics, and operational constraints.

V. Threats to Validity

A. Publication Bias

Publication bias may occur because studies with significant, positive, or novel findings are more likely to be published than studies reporting non-significant or negative results. As a result, the studies included in this review may not fully reflect the overall body of research on the topic. To reduce this risk, the review considered studies from multiple sources and applied predefined inclusion and exclusion criteria.

B. Database Selection Bias

The selection of bibliographic databases may have influenced the studies identified for this review. Different databases have varying levels of coverage, indexing practices, and disciplinary focuses. Therefore, relevant studies indexed outside the selected databases may have been overlooked. Although the databases were selected based on their relevance to the research topic, this limitation may still affect the completeness of the literature identified.

C. Search-String Limitations

The search strategy depends on the keywords, synonyms, and Boolean operators included in the search string. As a result, relevant studies may have been missed if they used terminology that differed from the terms adopted in this review. Although the search string was developed to capture different variations of the key research concepts, it cannot guarantee that all potentially relevant publications were identified.

D. Study Selection and Exclusion Bias

The process of screening and selecting studies may involve researcher judgment, particularly when determining whether a study meets the inclusion and exclusion criteria. To reduce this risk, predefined eligibility criteria were applied consistently throughout the screening process. However, the possibility of inadvertent exclusion or subjective interpretation during study selection cannot be eliminated.

E. Classification Subjectivity

The classification and categorization of the selected studies may involve some degree of subjectivity. Studies addressing similar concepts may use different terminology, theoretical perspectives, or methodological approaches, which can make their classification dependent on the researchers' interpretation. Clear classification criteria were applied to improve consistency, although some degree of judgment remains unavoidable.

F. External Validity and Generalizability

The generalizability of the findings may be limited by the characteristics of the studies included in the review, including their research contexts, geographical settings, populations, methodologies, and publication periods. Therefore, the findings

should be interpreted within the scope of the reviewed literature and may not be directly applicable to all contexts or populations. Future research involving broader contexts and additional empirical evidence may help strengthen the external validity and generalizability of the findings.

VI. Conclusion and Future Work

This study presents an SLR of metaheuristic-based techniques for TCS in the context of regression testing. The review examines the types of techniques employed, as well as the objectives and metrics used in their formulation and evaluation. It also investigates the empirical context in which these techniques are evaluated and compared. TCS has generally been formulated as an optimization problem that seeks to balance test effectiveness with the cost of regression testing, as presented in Section III and discussed in Section IV. However, the empirical evidence indicates that no single technique is universally superior. Instead, performance is strongly influenced by the characteristics of the system under test, the objectives being optimized, and the evaluation criteria adopted.

In terms of empirical evidence, evaluation remains largely dominated by benchmark datasets and open-source systems, despite a growing body of research involving industrial contexts, cyber-physical systems, and AI-based systems. Such contextual differences affect the choice of evaluation metrics and the interpretation of technique effectiveness, thereby limiting the comparability and generalizability of findings across studies. Consequently, benchmark performance should not be considered a direct indicator of practical effectiveness, particularly when TCS techniques are applied to systems with different workloads, constraints, and operational requirements.

These findings have implications for both researchers and practitioners. For researchers, future studies should establish a stronger alignment between optimization objectives and evaluation metrics, while adopting more standardized metrics and reporting practices to improve comparability and reproducibility. For practitioners, the selection of a TCS technique should consider not only its reported benchmark performance but also its suitability for the target system, testing objectives, computational constraints, and operational environment. In particular, empirical results obtained from benchmark or open-source systems should be validated before being generalized to industrial settings.

Overall, this study indicates that TCS research is gradually moving beyond the development of new algorithms towards the adaptation and contextualization of existing metaheuristic techniques to address the requirements of regression testing and real-world environments. This shift emphasizes the need for context-aware optimization, standardized evaluation, and stronger industrial validation. Addressing these aspects can help bridge the gap between benchmark-based research and practical deployment, thereby supporting the development and adoption of metaheuristic-based TCS techniques that are more robust, comparable, and applicable across diverse software testing domains.

As directions for future research, industry-scale empirical evaluation needs to be strengthened to improve the external validity of findings and to assess factors such as scalability, computational cost, and effectiveness under realistic testing conditions. In parallel, the development of domain-aware and adaptive TCS techniques is increasingly important for modern systems, particularly AI-based and cyber-physical systems, where conventional assumptions and evaluation criteria may not adequately capture system-specific testing requirements. Such approaches should account for domain characteristics when defining optimization objectives, selecting evaluation metrics, and interpreting TCS effectiveness.

APPENDIX

TABLE VI. THE DETAILED INFORMATION EXTRACTED FROM THE 62 PRIMARY STUDIES

ID	Authors	Years	Algorithms	Objectives	Datasets	Main Evaluation Metrics
P1	[16]	2015	NSGA-II	Multi-objective	Apache Ant, Apache Derby, JBoss Application Server, NanoXML, Math	Coverage, Diversity, ET, FDR
P2	[17]	2018	NSGA-II	Multi-objective	NSGA-II	HV, ET
P3	[18]	2022	NSGA-II	Multi-objective	Deep Learning Models with MR Test Sets	HV, Pareto-frontier, FD
P4	[19]	2017	CBGA-ES	Multi-objective	Real-World Software Test Suites	Fitness, HV
P5	[20]	2013	Improved GA	Single objective / multi-criteria	Example Software Systems	CC, TCC
P6	[21]	2025	Evolutionary Algorithm (Mutation Enhancement)	Multi-objective	Sample Experimental Datasets	HV, FDR, FDC, Pareto-frontier
P7	[22]	2015	DIV-GA	Multi-objective	SIR	ET
P8	[8]	2014	BMOPSO	Multi-objective	Case Study for Integration Suites and Regression Suites	HV, GD, IGD, C
P9	[23]	2014	Hybrid BMOPSO + Local Search	Multi-objective	SIR	HV, GD, IGD, C
P10	[24]	2015	Hybrid PSO + Harmony Search	Multi-objective	SIR	HV, GD, IGD, C
P11	[25]	2022	Improved QPSO	Multi-objective / multi-criteria	Software Benchmark Programs	APFD, APSC, TSP, FDLP, CRP
P12	[26]	2021	Enhanced ABC-NB Optimization	Optimization / learning-assisted	Software Test Programs - 3	ET, FD
P13	[27]	2019	Hybrid Swarm Intelligence + GA	Single objective / multi-objective	Synthetic Software Testing Data	FD, ET
P14	[28]	2021	Hybrid ABC	Single objective / multi-objective	Open-Source Software Programs	AC, ET, Percentage of Selected Test Cases
P15	[29]	2021	Hybrid Metaheuristic (PSO + Ranked Firefly)	Single objective/multi-objective	Benchmark regression programs	TC Reduction, FC, ET
P16	[30]	2014	Hybrid PSO	Single objective / reduction	Example Software Programs	RR, ET

***Abstract*—The rapid spread of multimodal misinformation on social media platforms has strengthened the need for effective fake news detection systems. While recent multimodal approaches integrate textual and visual information, most existing studies formulate the task as binary classification, thereby failing to fully exploit the rich label structures available in fine-grained datasets. Moreover, conventional fusion strategies such as simple concatenation often fail to capture complex cross-modal interactions. To address these limitations, this study proposes TriMFB, an attention-enhanced Multimodal Factorized Bilinear (MFB)-based early fusion framework for fine-grained multimodal fake news detection. Unlike other frameworks, the proposed TriMFB simultaneously integrates modality-specific features, attention-refined features, and MFB-based cross-modal interactions within a unified tri-feature early fusion architecture. The proposed model extracts textual and visual representations using Bidirectional Encoder Representations from Transformers (BERT) and a 50-layer Residual Network (ResNet50), respectively. Modality-specific features are refined through attention mechanisms and integrated using MFB pooling to capture cross-modal interactions. Experiments conducted on the Fakeddit dataset demonstrate that the proposed framework outperforms baseline bilinear fusion models, achieving a classification accuracy of 0.78 in a six-class setting. Although the overall accuracy remains comparable, the proposed tri-feature fusion strategy substantially improves the detection of challenging minority classes, increasing the F1-score for the Manipulated class from 0.21 to 0.29. These findings suggest that this fusion strategy offers a practical route to more reliable detection of subtly manipulated content, a minority class that is both harder to detect and disproportionately harmful when missed by content moderation systems.**

Keywords*—Bilinear pooling; early fusion; fake news detection; fine-grained; multimodal

I. Introduction

Fake news has become a persistent threat in today's digital landscape, influencing public opinion, shaping political perspectives, and contributing to social unrest [1]. The rapid dissemination of false information across social media platforms has intensified the need for reliable automated fake news detection systems [2]. As online content increasingly combines text with images, detection systems that fail to account for this shift risk missing critical signals of manipulation, making the problem more urgent and more difficult to solve than in the text-only era.

Traditionally, news articles have been dominated by textual content, and early research in fake news detection therefore focused primarily on text-based, or unimodal, approaches, reaching nearly 99% accuracy [3], [4]. Although these methods have achieved considerable progress, their performance has begun to plateau, particularly as online news consumption increasingly incorporates visual components. With the evolution of news media, images are now frequently used to complement textual narratives. This shift has highlighted the limitations of unimodal systems, which overlook the interdependencies between textual and visual information [5], [6]. Since text and images often function as complementary cues, ignoring one modality may risk losing essential cross-modal relationships that can signal manipulation or misinformation [7].

These developments underscore the growing importance of multimodal approaches in fake news detection. Multimodal models typically differ in how and when information from different modalities is integrated, commonly through early fusion, late fusion or hybrid strategies. Early fusion, which integrates features from different modalities at the representation level [8] has been explored by several researchers for its ability to model cross-modal interactions more effectively [9], [10], [11]. However, most existing multimodal studies still focus on binary classification, which restricts the expressive richness of multimodal datasets and results in underutilized multimodal representations. Notably, fine-grained datasets such as Fakeddit [12] contain multiple categories of misleading content, yet several studies simplify the task to a binary decision [13], [14], thereby limiting the detection system's real-world relevance.

*Corresponding author.
Financial support for this study was provided by the Fundamental Research Grant Scheme, Ministry of Higher Education Malaysia.

Therefore, this study makes three contributions. First, it proposes TriMFB, a tri-feature multimodal early fusion framework for fine-grained fake news detection. Second, the framework integrates complementary textual, visual and multimodal interaction features to enhance cross-modal representation learning. Third, the proposed approach is evaluated on the Fakeddit dataset to assess its performance in fine-grained fake news classification compared with existing multimodal fusion methods.

The remainder of this study is organized as follows. Section II reviews related studies on multimodal fusion techniques and fine-grained classification. Section III introduces the proposed attention-enhanced MFB-based early fusion framework for fine-grained multimodal fake news detection. Section IV presents the experimental setup, followed by the presentation and discussion of the experimental results. Finally, Section V concludes the study and outlines potential directions for future work.

II. Related Work

A. Overview of Multimodal Fusion

Multimodal is a combination of more than one type of modality or information from multiple sources [15]. A research problem is considered multimodal when it integrates information from several distinct data types [16]. These sources may include textual or spoken language, visual content or auditory cues. In addition, multimodal data may also encompass other forms such as numerical or biological data.

In the context of fake news detection, the rise of social media has intensified the need for multimodal analysis. Online content increasingly combines textual and visual elements to enhance engagement and credibility, leading to a shift from single modality to multimodal communication. This evolution poses new challenges in identifying misinformation as deceptive content often relies on inconsistencies between textual and visual information. Consequently, multimodal fusion has become essential for integrating heterogeneous information sources such as text and images to improve detection performance. The effectiveness of multimodal learning largely depends on the fusion stage, which determines how and when information from different modalities is combined.

Fusion can generally be categorized into early fusion, late fusion, and hybrid fusion [16], [17]. Each approach has its own strengths and trade-offs in capturing cross-modal correlations and model interpretability. Early fusion, also known as feature-level fusion, combines the features extracted from different modalities at an early stage to capture interactions within the data representations. In contrast, late fusion, or decision-level fusion, involves training separate models for each modality and then combining their outputs. Finally, hybrid fusion combines outputs from early fusion and individual unimodal predictors.

B. Early Fusion Techniques

Early fusion serves as the stage where information from different modalities is integrated at the feature level. Formally, let $f_t, f_i, \dots, f_n$ represent the features extracted from each modality. The fusion process can be expressed as:

$$x = F(f_t, f_i, \dots, f_n) \quad (1)$$

where, $F(\cdot)$ denotes the fusion function that combines these multimodal features into a unified vector representation. This fused feature vector, x, is then passed to a classifier $f(\cdot)$ to produce the final prediction output y:

$$y = f(x) \quad (2)$$

Once the textual and visual features are extracted, various fusion techniques can be applied to determine how these representations are combined. The simplest and most widely used operation is concatenation, which directly merges feature vectors from each modality into a unified representation. Several studies have adopted concatenation for early fusion [18], [19]. However, this operation merely stacks features and often fails to capture the complex relationships between textual and visual data [20].

Consequently, more expressive fusion strategies have been explored. Bilinear pooling offers an alternative to conventional fusion methods. Rather than merging features directly, it models the multiplicative relationships between them by computing the outer product of the text and image feature vectors. This operation enables every dimension of the textual representation to interact with every dimension of the visual representation [21]. However, the full outer product is computationally expensive [16], motivating the development of more efficient variants.

Practical variants such as Multimodal Compact Bilinear Pooling (MCB) [22] and Multimodal Factorized Bilinear Pooling (MFB) [23] were introduced to compress or factorize the bilinear interactions, significantly reducing computational cost while preserving the expressive benefits of bilinear fusion, making them well-suited for deep learning applications. While MCB and MFB were initially developed for the visual question answering domain, they have since been adapted to fake news detection. [24] and [25] applied MCB as their fusion method, though the limitation of MCB requiring high-dimensional output features has been documented [23]. Meanwhile, [26] adopted MFB for its reduced dimensionality and computational efficiency.

In addition to advances in fusion strategies, researchers have increasingly explored attention mechanisms introduced by [27]. It enables models to dynamically assign weights to the most informative features, whether within a modality or across modalities. Particularly, self-attention enables each element within a representation to attend to other elements in the same sequence, capturing contextual dependencies through learned similarity weights. Multi-head attention extends this mechanism by projecting features into multiple subspaces, enabling the model to learn diverse interaction patterns simultaneously. In the context of fake news detection, attention has been shown to highlight relevant textual cues, emphasize important visual regions and strengthen cross-modal alignments that signal inconsistencies between modalities [28], [29].

C. Fine-Grained Setting

Most existing multimodal studies continue to frame fake news detection as a binary classification problem, despite the availability of datasets that support more fine-grained categorization such as Fakeddit. For example, a few works [13], [14], [30] employed the Fakeddit dataset but reduced the task to

binary classification, thereby underutilizing its fine-grained labels and limiting the exploitation of multimodal relationships.

Although binary classification simplifies the learning objective, it does not reflect the real-world complexity of misinformation. Fine-grained datasets often exhibit class imbalance, where certain misinformation categories contain significantly fewer samples, potentially biasing the learning process toward majority classes [31], [32].

Some researchers have explored fine grained classification.[33], [34] adopted a fine-grained setting but relied on simple concatenation for fusion. As previously discussed, concatenation merely stacks modality-specific features and may overlook complex intermodal dependencies. Meanwhile, studies utilizing more expressive fusion techniques, such as MCB or MFB, remain confined to binary classification settings [24], [25], [26]. As a result, the potential of expressive bilinear fusion has not yet been fully explored in fine grained multimodal fake news detection.

Motivated by these findings, this work proposes an early fusion framework that employs the MFB method enhanced with an attention mechanism applied to a fine-grained classification task. Fine-grained classification enables a more detailed understanding of misinformation categories, while attention-enhanced bilinear fusion strengthens cross-modal interactions, addressing the limitations observed in prior binary and structurally simplistic fusion approaches.

III. METHODOLOGY

This section outlines the proposed early fusion framework, which aims to integrate textual and visual information for fine-grained fake news classification. The proposed framework as shown in Fig. 1, comprises three main components that work in a unified manner to achieve effective multimodal representation learning. Algorithm 1 summarizes the main steps involved in the proposed framework to provide a clearer view of the workflow.

Algorithm 1: Attention-enhanced MFB-based early fusion framework

Initialize Input: Text-image pair (T, I)
Output: Predicted class label y
Initialize:
BERT
ResNet50
Attention mechanism
MFB pooling module
MLP classifier
Compute:
$f_t \leftarrow$ BERT(T)
$f_i \leftarrow$ ResNet50(I)
Refine Features:
$\hat{f}_t \leftarrow$ Attention(f_t)
$\hat{f}_i \leftarrow$ Attention(f_i)
Fuse Features:
$f_{mfb} \leftarrow$ MFB(f_i, f_i)
Construct Tri-Feature Representation:
$F \leftarrow$ concat(f_t, f_i, $\hat{f}_t$, $\hat{f}_i$, f_{mfb})
Classify:
$y \leftarrow$ MLP(F)
Return y

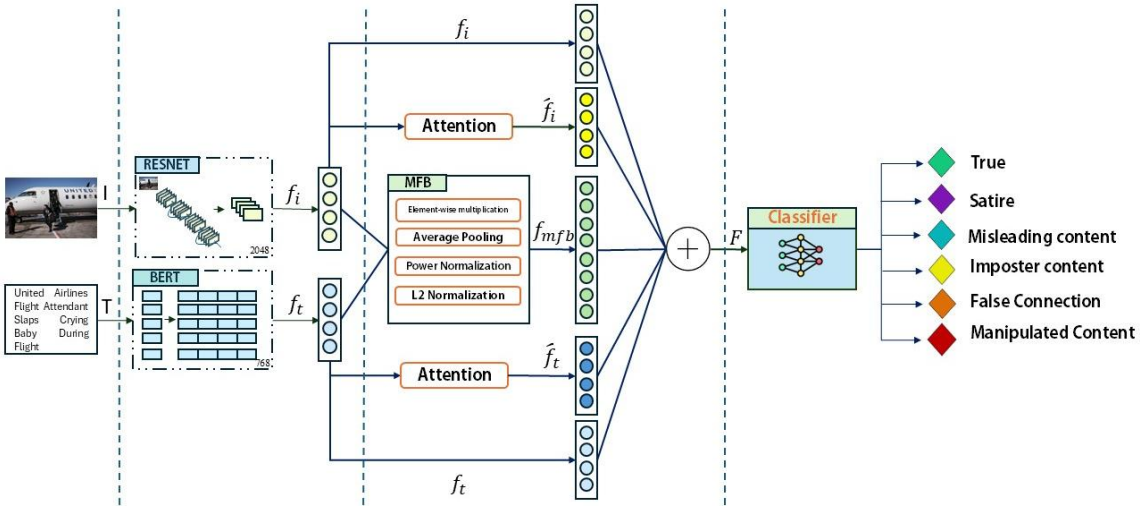

Fig. 1. Overview of the early fusion architecture with MFB pooling and attention mechanism.

The first component focuses on modality-specific feature extraction using pretrained deep neural networks, BERT [35] and ResNet50 [36]. The second component involves feature refinement and fusion, where attention mechanisms [27] are applied to capture intra-modal dependencies within each modality, while the MFB pooling [23] module is employed to learn inter-modal relationships between text and image features. The third component performs classification based on a concatenated tri-feature representation that combines the modality-specific features, attention-refined features, and the fused information into a comprehensive multimodal vector. Inspired by [25], the proposed framework adopts MFB in place of MCB and extends the architecture for fine-grained fake news classification.

The framework begins by collecting text–image pairs from the Fakeddit dataset [12]. The dataset contains approximately

one million Reddit posts labelled into six fine-grained categories, namely, true, satire, misleading content, imposter content, false connection, and manipulated content. This dataset provides a richer labelling structure compared to traditional binary classification datasets.

To begin with, the textual information from the dataset is processed using the BERT model to obtain rich contextual embeddings. Each input sentence $T = \{t_1, t_2, \ldots, t_n\}$ is first tokenized and then passed through BERT's layers to generate deep semantic representations. This embedding serves as the textual feature vector $f_t \in \mathbb{R}^{768}$. For the visual modality, each news image is passed through a pretrained ResNet model, specifically ResNet-50 in this study, to obtain deep visual representations. The output is extracted as the image feature vector $f_i \in \mathbb{R}^{2048}$. These extracted visual features capture high-level semantic information helping the model identify potential inconsistencies between textual and visual content in fake news posts.

The combination of BERT and ResNet has been widely adopted in prior multimodal studies due to their complementary strengths in capturing linguistic and visual semantics. For example, [25], [37], [38] employed pretrained BERT and ResNet models to generate high-quality representations of text and images. Motivated by these findings, this study adopts the BERT and ResNet50 combination to ensure both modalities contribute rich representations for multimodal fake news detection.

Moving to the next component, the MFB pooling method is employed to capture the complex interactions between textual and visual features. Unlike simple feature merging operations, MFB models second-order multiplicative relationships between modalities that enable richer cross-modal representations [26]. Given the textual feature$f_t \in \mathbb{R}^{768}$ and the image feature $f_i \in \mathbb{R}^{2048}$, the MFB module computes their joint representation as:

$$f_{mfb} = MFB(f_t, f_i) \tag{3}$$

Here, f_{mfb} denotes the fused multimodal feature. This fused representation integrates complementary semantic cues from both text and image modalities, bridging linguistic meaning and visual context.

In the proposed framework, the textual and visual features have dimensions of 768 and 2048, respectively. Each feature is first projected into a factorized space using separate linear layers. The MFB output dimension is set to 512 with five factors, resulting in a projection dimension of 2560. The projected features are combined through element-wise multiplication, followed by dropout with a rate of 0.1. The resulting representation is reshaped to 512 x 5 and sum-pooled across the five factors to obtain the 512-dimensional fused feature. Finally, signed square-root transformation and L2 normalization are applied to the pooled representation.

In parallel with the MFB fusion process, the modality-specific features are refined using attention mechanisms. Self-attention and multi-head attention are separately applied to the textual and visual features to emphasize informative components within each modality. The refined textual and image features are represented as $\widehat{f_t} = Attn(f_t)$ and $\widehat{f_i} = Attn(f_i)$, respectively. This refinement step allows each modality to emphasize relevant information before the final multimodal representation is constructed.

Finally, the tri-feature representation, the modality-specific features of both textual and visual, f_t *and* f_i, the attention-refined features, ($\widehat{f_t}$) and ($\widehat{f_i}$), and fused (f_{mfb}) are concatenated to construct a unified multimodal feature vector, expressed as:

$$F = concat[f_t, f_i, \widehat{f_t}, \widehat{f_i}, f_{mfb,}\ ] \tag{4}$$

where, $f_t \in \mathbb{R}^{768}$, $f_i \in \mathbb{R}^{2048}$, $\widehat{f_t} \in \mathbb{R}^{768}$ and $\widehat{f_i} \in \mathbb{R}^{2048}$. Thus, the resulting tri-feature representation has a dimension of 6144. The attention refinement and MFB fusion are performed independently, with both operations receiving the modality-specific textual and visual features as inputs. By combining these complementary representations, the model achieves a more comprehensive understanding of multimodal content. The concatenated feature is then fed to the MLP classifier to produce the final predicted news label for fine-grained classification.

IV. Experiment and Discussion

A. Dataset

The experiments were conducted using the Fakeddit dataset [12], which serves as the benchmark dataset for fine-grained multimodal fake news detection. Fakeddit contains approximately one million Reddit posts labelled with six categories, which are true, satire, misleading content, imposter content, false connection, and manipulated content. Each sample contained a textual component and its corresponding image, enabling a multimodal analysis. A subset of 20,000 text-image pairs was used to balance computational efficiency and predictive performance, as previous findings [39] indicate that performance gains beyond this size are marginal. This experimental scale is also consistent with prior fake news detection studies that employed datasets of similar size [40], [41].

B. Experiment Setup

All experiments were implemented in Python using the PyTorch deep learning framework. The models were trained on a machine equipped with an Intel Core i7 processor and 16 GB of RAM. To simulate real-world resource limitations, all training and evaluation were conducted in a CPU-based environment. The Fakeddit dataset served as the primary benchmark, supporting fine-grained fake news classification with six distinct labels. The dataset was divided into 80% training and 20% testing. Each model was trained independently using the same data splits. Cross-validation and statistical significance testing were not performed in this study. The class distribution of the selected subset is presented in Table I. This imbalance may affect classification performance, particularly for minority categories, and is considered when interpreting the per-class metrics.

The proposed framework employs BERT to extract textual features and ResNet50 to extract visual features. The MFB fusion strategy was employed in an early fusion setting, where textual and visual features were combined before classification. Each modality-specific feature was further refined through attention layers to emphasize informative components within

each modality. The tri-feature representation is then concatenated before being passed to an MLP classifier for final prediction.

TABLE I. CLASS DISTRIBUTION OF THE 20,000-SAMPLE FAKEDDIT SUBSET

Class	Training Set	Validation Set	Total
True	6,369	1,572	7,941
Satire	976	239	1,215
Misleading	3,004	801	3,805
Manipulated	337	72	409
False Connection	4,716	1,165	5,881
Imposter Content	598	151	749
Total	16,000	4,000	20,000

C. Hyperparameter Setting

Training was conducted for up to 10 epochs using the Adam optimizer with a learning rate of 1e-4 and a batch size of 32. The pretrained BERT and ResNet-50 parameters were fine-tuned during training. Early stopping was applied to prevent overfitting. Table II summarizes the training configuration settings employed in this work.

TABLE II. TRAINING CONFIGURATION SETTINGS

Parameter	Value
Optimizer	Adam
Learning Rate	1×10^{-4}
Batch Size	32
Number of Epochs	10
Loss Function	CrossEntropyLoss
Train-Test Split	80:20
Random Seed	42
Regularization	Early stopping + dropout
Dropout Rate	0.3

D. Evaluation Metrics

Model performance was evaluated using accuracy, precision, recall, and F1-score. Accuracy was used to measure the overall classification performance. Precision, recall, and F1-score provided a more detailed evaluation of the model's performance across the six fine-grained classes.

E. Result and Discussion

This section discusses the experimental results obtained from the proposed early fusion multimodal fake news detection framework. The evaluation focuses on analysing the impact of different attention mechanisms on refining the textual and visual features before fusion. In the proposed model, self-attention and multi-head attention are applied separately to enhance the discriminative quality of each modality. Through comparative analysis, this section aims to highlight the strengths and limitations of each configuration, providing insights into how attention mechanisms contribute to improving multimodal representation learning and classification performance.

Table III presents the comparative performance of the proposed framework against baseline models. The baseline implementations by [26], [24], and [25] achieved accuracies of 0.59, 0.70, and 0.75, respectively. In contrast, all variants of the proposed model consistently outperformed these baselines, achieving accuracies ranging from 0.77 to 0.78. This improvement suggests that integrating attention mechanisms, as introduced by [24], together with MFB pooling, can provide useful multimodal representations for fine-grained fake news classification.

TABLE III. ACCURACY COMPARISON BETWEEN BASELINE MODELS

Baseline model	Modality-specific features	Attention mechanism	Accuracy
AMFB [26]	No	Additive attention	0.59
Double-MCBP [24]	No	Self-attention	0.75
MBPAM [25]	Yes	Self-attention	0.70
Proposed framework	Yes	Self-attention	0.78

F. Ablation Study on Attention Mechanisms

When examining the impact of attention mechanisms, the results show minimal variation across all settings in Table IV, with accuracies ranging from 0.77 to 0.78. Without modality-specific feature inclusion, both self-attention and multi-head attention achieved an identical accuracy of 0.78. With modality-specific features included, self-attention maintained an accuracy of 0.78, while multi-head attention showed a slight decrease to 0.77. These findings indicate that the choice between self-attention and multi-head attention has little impact on the overall classification performance. Nevertheless, a closer examination of the per-class metrics reveals a more comprehensive assessment across categories.

TABLE IV. ACCURACY COMPARISON BETWEEN ATTENTION MECHANISM

Modality-specific features	Attention mechanism	Accuracy
No	Self-attention	0.78
No	Multi-head Attention	0.78
Yes	Self-attention (Proposed)	0.78
Yes	Multi-head Attention	0.77

TABLE V. PER-CLASS METRICS OF THE SELF-ATTENTION WITHOUT MODALITY-SPECIFIC FEATURE INTEGRATION

Class	Precision	Recall	F1-Score
True	0.82	0.81	0.81
Satire	0.64	0.53	0.58
Misleading	0.70	0.67	0.69
Manipulated	0.21	0.21	0.21
False Connection	0.86	0.92	0.89
Imposter Content	0.62	0.63	0.63

Tables V–VIII present the per-class metrics of the proposed attention-based MFB framework under different configurations, examining the effects of attention mechanisms and the inclusion of modality-specific features. Overall, the results indicate that the model consistently performs well on majority classes, particularly True and False Connection, which achieve high F1-scores across all configurations. This suggests that the fusion

strategy effectively captures dominant multimodal patterns in well-represented categories.

TABLE VI. PER-CLASS METRICS OF THE MULTI-HEAD ATTENTION WITHOUT MODALITY-SPECIFIC FEATURE INTEGRATION

Class	Precision	Recall	F1-Score
True	0.80	0.83	0.82
Satire	0.67	0.44	0.53
Misleading	0.75	0.62	0.68
Manipulated	0.20	0.36	0.25
False Connection	0.86	0.93	0.90
Imposter Content	0.62	0.68	0.65

When modality-specific features are excluded (Tables V and VI), both self-attention and multi-head attention show comparable performance, with slight variations across minority classes. Multi-head attention shows marginal improvements in certain categories such as Manipulated and Imposter Content, with F1-scores increasing from 0.21 to 0.25 and from 0.63 to 0.65, respectively. However, the differences remain relatively small, suggesting that the choice of attention variant provides comparable benefits for feature refinement.

TABLE VII. PER-CLASS METRICS OF THE SELF-ATTENTION WITH MODALITY-SPECIFIC FEATURE INTEGRATION (PROPOSED)

Class	Precision	Recall	F1-Score
True	0.75	0.89	0.81
Satire	0.85	0.34	0.49
Misleading	0.69	0.67	0.68
Manipulated	0.38	0.24	0.29
False Connection	0.92	0.84	0.87
Imposter Content	0.75	0.72	0.73

TABLE VIII. PER-CLASS METRICS OF THE MULTI-HEAD ATTENTION WITH MODALITY-SPECIFIC FEATURE INTEGRATION

Class	Precision	Recall	F1-Score
True	0.78	0.85	0.81
Satire	0.75	0.47	0.58
Misleading	0.68	0.63	0.65
Manipulated	0.22	0.19	0.20
False Connection	0.87	0.89	0.88
Imposter Content	0.70	0.57	0.63

With modality-specific features included (Tables VII and VIII), performance improvements are observed in selected classes. In particular, self-attention achieves a higher F1-score for Manipulated at 0.29 and Imposter Content at 0.73, while multi-head attention achieves a slightly higher F1-score for False Connection at 0.88. These results suggest that incorporating modality-specific features alongside attention-refined and fused representations may provide complementary information for distinguishing challenging categories. However, the improvements are not consistent across all classes, indicating that the effect of modality-specific feature integration varies across attention configurations.

Across all configurations, Manipulated consistently exhibits lower F1-scores, which may be related to class imbalance and higher semantic ambiguity. As shown in Table I, the dataset is highly imbalanced across the six classes, with Manipulated representing the smallest category with 409 samples. This imbalance may contribute to the lower performance observed for minority categories. This observation reinforces the challenge highlighted in the literature regarding fine-grained fake news classification, where minority and subtle misinformation categories are inherently more difficult to distinguish than majority classes. Despite this difficulty, the proposed framework maintains stable performance across configurations, suggesting its ability to handle complex class distinctions.

The inclusion of modality-specific features contributes to improved performance in certain underrepresented categories, particularly under the self-attention configuration. This suggests that combining modality-specific features with attention-refined and fused representations provides complementary discriminative information. This finding highlights the value of richer multimodal representations for distinguishing fine-grained misinformation categories, as discussed in previous research.

The results are consistent with the motivation outlined in Section II. By employing attention-enhanced MFB fusion within a fine-grained classification setting, the proposed framework provides a richer representation of cross-modal information. Compared to prior binary-focused approaches, the tri-feature design enables more fine-grained representation learning, which is reflected in the model's competitive and stable performance across diverse misinformation categories.

G. Ablation Study

Table IX compares the performance of different feature configurations within the proposed framework. Four configurations, namely Modality-Specific Features, Modality-Specific + Attention-Refined Features, Attention-Refined + MFB Fused Features, and the proposed framework, all achieved the highest overall accuracy of 0.78. Since these configurations exhibit identical overall accuracy, a more detailed analysis using per-class precision, recall, and F1-score is conducted to better understand their classification behaviour across individual misinformation categories.

Although all four configurations achieved the same overall accuracy of 0.78, a closer examination of the per-class metrics presented in Tables V, VII, X and XI reveals differences in classification performance across individual categories. This similarity in overall accuracy may be influenced by the dominance of majority classes, particularly True and False Connection, for which the model achieves relatively high performance. Therefore, overall accuracy alone may not fully reflect differences in the classification of minority categories.

In particular, the Manipulated class, which contains the fewest training samples, shows consistently lower performance across the configurations. As shown in Tables X and XI, incorporating attention-refined features alongside modality-specific features improves the F1-score for Manipulated from 0.22 to 0.26. Similarly, comparing the attention-enhanced MFB configuration in Table V with the proposed TriMFB framework in Table VII shows a further improvement from 0.21 to 0.29.

These results suggest that integrating modality-specific, attention-refined, and MFB-fused representations provides complementary information that may help the model distinguish challenging minority categories.

TABLE IX. ACCURACY COMPARISON BETWEEN CONFIGURATIONS

Configurations	Feature representation	Fusion technique	Accuracy
Modality-specific features	1. Raw textual 2. Raw visual	Concatenation	0.78
Attention-refined features	1. Attention-refined textual 2. Attention-refined visual	Concatenation	0.77
MFB fused features	1. Raw textual 2. Raw visual	MFB	0.68
Attention-refined MFB fusion features	1. Attention-refined textual 2. Attention-refined visual	MFB	0.71
Modality-specific + Attention-refined features	1. Raw textual 2. Raw visual 3. Attention-refined textual 4. Attention-refined visual	Concatenation	0.78
Modality-specific + MFB fused features	1. Raw textual 2. Raw visual 3. MFB fused	MFB + concatenation	0.76
Attention-refined + MFB fused features	1. Attention-refined textual 2. Attention-refined visual 3. MFB fused	MFB + concatenation	0.78
Modality-specific + Attention-refined features + MFB fused features (Proposed)	1. Raw textual 2. Raw visual 3. Attention-refined textual 4. Attention-refined visual 5. MFB fused	MFB + concatenation	0.78

TABLE X. PER-CLASS METRIC FOR MODALITY-SPECIFIC FEATURES

Class	Precision	Recall	F1-Score
True	0.75	0.89	0.81
Satire	0.67	0.43	0.52
Misleading	0.74	0.59	0.66
Manipulated	0.26	0.19	0.22
False Connection	0.90	0.90	0.90
Imposter Content	0.61	0.54	0.57

TABLE XI. PER-CLASS METRIC FOR MODALITY-SPECIFIC + ATTENTION-REFINED FEATURES

Class	Precision	Recall	F1-Score
True	0.80	0.81	0.81
Satire	0.58	0.67	0.62
Misleading	0.68	0.68	0.68
Manipulated	0.29	0.24	0.26
False Connection	0.88	0.89	0.88
Imposter Content	0.78	0.50	0.61

This observation is consistent with the literature review, which highlights the need for expressive multimodal fusion strategies to capture complex intermodal relationships in fine-grained fake news detection. The gradual improvement in the Manipulated class suggests that the proposed tri-feature representation provides complementary information that is not captured by any single feature representation alone.

V. CONCLUSION

This study proposes TriMFB, an attention-enhanced MFB-based early fusion framework for fine-grained multimodal fake news detection. Unlike prior works that primarily focused on binary classification, the proposed framework leverages the full label richness of the Fakeddit dataset to better reflect the complexity of real-world misinformation. By integrating modality-specific features, attention-refined features, and MFB-fused features, the framework creates a unified tri-feature representation that captures both important features from each modality and the relationships between text and images. Experimental results show that the proposed framework achieves an accuracy of 0.78, outperforms baseline bilinear fusion models, and maintains stable performance across different attention configurations. Although performance remains lower for minority categories, which may be related to class imbalance and semantic ambiguity, the framework shows competitive behavior across fine-grained classes. These findings suggest the potential of combining attention mechanisms with bilinear fusion for fine-grained fake news classification. The proposed framework was evaluated using only the Fakeddit dataset, which may limit its generalizability to other misinformation domains and social media platforms. Future work will focus on validating the framework using additional benchmark datasets, cross-validation and statistical significance testing, while exploring advanced imbalance mitigation strategies to further improve minority class performance.

***Abstract*—Traditional on-demand laundry operations suffer from inefficient manual coordination, a lack of real-time delivery visibility, and delayed customer support handling. To address these operational challenges, this study presents LaundrOTrack, an intelligent on-demand laundry logistics platform connecting customers, drivers, and administrators within a unified digital ecosystem. Powered by Flutter for cross-platform access and Firebase Cloud Firestore for real-time data synchronization, the system incorporates Location-Based Services (LBS) via the Google Maps API to streamline last-mile delivery workflows. The platform's real-time location tracking system utilizes continuous GPS updates, route polyline visualization, dynamic Estimated Time of Arrival (ETA) calculation, and spatial arrival boundary detection to monitor pickup and return deliveries. Furthermore, machine learning-based customer support is integrated through an automated conversational agent (Laundra Ask). The underlying natural language processing pipeline employs text preprocessing, Term Frequency-Inverse Document Frequency (TF-IDF) feature extraction, and a Linear Support Vector Classifier (Linear SVC) model hosted on a Flask REST API to predict user query intents and deliver context-aware responses. System testing demonstrates seamless multi-role data synchronization, precise geolocation triggering, and high-accuracy query intent classification. The proposed platform significantly improves order transparency, reduces manual administrative overhead, and optimizes end-to-end service efficiency in smart service logistics.**

Keywords*—*On-demand laundry logistics; Location-Based Services (LBS); linear SVC; intent classification; flutter; cloud firestore

I. Introduction

The growth of on-demand digital services has changed the way customers interact with service providers. Applications in transportation, food delivery, e-commerce, and home services have increased customer expectations for convenience, transparency, and real-time service updates. However, many small and medium-sized laundry businesses still depend on manual coordination through phone calls, messaging applications, handwritten records, and walk-in arrangements. This conventional approach can cause unclear order details, inconsistent pickup schedules, delayed status updates, and limited visibility of the laundry process.

In an on-demand laundry service, logistics coordination plays an important role because the service not only involves washing or processing, but it also involves managing pickup and return delivery. Customers often need to know when the driver will arrive, where the driver is currently located, and whether the order has reached the next service stage. Without real-time tracking, route visualization, estimated time of arrival (ETA), and arrival confirmation, customers may repeatedly contact the service provider to ask about delivery progress. At the same time, administrators may face difficulty monitoring active delivery tasks, checking driver movement, and ensuring that pickup and return deliveries are completed properly.

Several previous laundry management systems have introduced digital functions such as customer registration, online booking, service selection, order records, and status updates [1], [2], [3], [4]. Although these systems improve order handling and reduce dependency on manual records, many of them mainly focus on internal laundry operations rather than complete delivery coordination. Existing real-time tracking and geofencing studies have also demonstrated the usefulness of GPS-based monitoring in vehicle tracking, safety monitoring, and location-based alert systems [5], [6], [7]. However, these systems are not always designed for a service-oriented workflow that connects customers, delivery drivers, and administrators in a complete laundry logistics process. Therefore, there is still a need for an integrated platform that combines laundry order management with real-time delivery monitoring and location-based workflow support.

Customer support is another important requirement in laundry service operations. Customers may ask repetitive questions related to service types, price, payment, pickup procedures, delivery status, ETA, and return delivery. If these enquiries are handled manually, administrators may spend additional time responding to routine questions instead of focusing on operational issues. In customer-service environments, Natural Language Processing (NLP) and machine learning have been used to classify customer enquiries

*Corresponding author.

and support faster response handling [8], [9]. Intent classification is particularly useful because it identifies the purpose of a user query and maps the query to a suitable response or service action. Recent studies have also shown that text classification methods such as Term Frequency-Inverse Document Frequency (TF-IDF) with Support Vector Machine (SVM) remain relevant for domain-specific customer-support tasks, especially when the queries are short and the intent categories are clearly defined [10], [11].

Therefore, this study aims to design and evaluate LaundrOTrack, an intelligent on-demand laundry logistics platform with real-time location tracking and machine learning-based customer support. The objectives of this study are to develop a multi-role laundry logistics platform that connects customers, delivery drivers, and administrators within a single platform. Second, to implement real-time GPS-based tracking with route visualization, ETA display, and location-based arrival detection for pickup and return delivery. Third, to integrate a domain-specific customer-support chatbot that classifies laundry service enquiries using TF-IDF and Linear Support Vector Classification (Linear SVC).

The proposed platform consists of two main technical components. The first component focuses on laundry logistics tracking, where driver GPS coordinates are updated during active pickup and return delivery tasks and synchronized with customer and administrator interfaces. The system also displays route polyline, distance, and ETA information, while location-based arrival detection is used to determine whether the driver has reached the active destination. The second component is Laundra Ask, a machine learning-based customer-support chatbot. Laundra Ask processes user questions, transforms them into TF-IDF feature vectors, classifies the intent using Linear SVC, and returns a suitable response through a Flask-based application programming interface.

II. Related Work

A. Digital Laundry Service Systems

The digitalization of laundry services has encouraged the development of mobile and web-based systems for improving booking, service selection, order recording, and communication between customers and laundry providers. Yi Qing Tan and Nizam Omar developed the Smart Laundry System Malaysia, a mobile-based platform that allows customers and laundry owners to manage laundry transactions digitally. The system supports order handling and internal laundry management, but it does not provide a delivery module, real-time driver tracking, or location-based services [1].

Similarly, LaundryMama was introduced to digitize laundry-related tasks and improve interaction between customers and service providers. The system provides online service access and supports the internal management of laundry orders. However, its focus remains on laundry processing and customer transactions rather than the movement of orders during pickup and return delivery [2].

Vinodhini and Bhama proposed LAUNAPP, an Android application that allows customers to place laundry orders, monitor service progress, and receive basic service notifications. The application reduces reliance on manual order registration and face-to-face interaction. Nevertheless, it does not include driver assignment, pickup and delivery coordination, live location monitoring, or route information [3].

Sundar et al. developed the Super-dry Laundry Mobile Application to provide customers with a smartphone-based platform for placing laundry orders, selecting service types and receiving order-status notifications[12]. Similarly, Gupta et al. developed MY DOOR Laundry Application using Android Studio to support customer registration, service selection and digital order submission [13].

Uddin et al. developed IronMan, which combines an Android customer application with a web-based administrative platform. The system includes Google Maps for displaying nearby laundry locations and supporting rider assignment based on proximity [14]. Adekola et al. proposed an Online Laundry Management System that centralizes customer information, service records, and order-status management through a web interface [15]. Chimankar et al. similarly developed an Online Laundry Service that supports service selection, order submission, and order history access [16].

A delivery-oriented system was developed by Suhaimi M et al. for students at Universiti Tun Hussein Onn Malaysia. The web-based system introduced online laundry ordering together with a delivery component to improve accessibility for students who experience time and transportation constraints. Although delivery is included, the delivery process is managed without continuous GPS tracking, route visualization, ETA information, or automatic arrival detection [4].

B. Real-Time Location Tracking

Real-time location tracking has been widely studied in transportation monitoring and safety applications. Rudramurthy et al. developed a Real-Time Vehicle Tracking System for Smart Cities using GPS to provide continuous vehicle-location information. The system demonstrates the usefulness of real-time GPS data for monitoring moving objects and improving transportation awareness [5]. Mishra et al. extended conventional GPS tracking by incorporating geofencing-based event detection. In their system, vehicle coordinates are continuously transmitted to a backend server, and notifications are generated when a vehicle enters or exits a predefined geographical boundary [6].

Tsindeliani et al. investigate latency reduction in real-time GPS tracking across Android and web-based monitoring environments. Their study examined factors including network latency, location update frequency, data transmission, and server processing time. The work highlights that location update performance is important because delayed GPS information may cause the displayed position to differ from the actual movement of the tracked object. It focuses on technical performance [7].

Tanguturi et al. combined Location-Based Services and Google Maps in an Android application for real-time location monitoring and emergency assistance. The application retrieves GPS coordinates and displays user locations through a map-based interface. Although the study demonstrates mobile location acquisition and visualization, its application is directed

toward safety and emergency response rather than pickup and return delivery management [17].

GPS measurements may also be affected by signal noise, environmental conditions, and temporary location fluctuations. Özdemir and Tuğrul investigated moving average and Kalman filter techniques to improve the accuracy of real-time GPS tracking [18].

C. Machine Learning-Based Customer Support

Automated customer support commonly applies natural language processing to identify the purpose of incoming customer enquiries. Intent classification converts an unstructured query into a predefined category that can be associated with a response, dialogue flow, or service action. Dong et al. described intent identification as an important first step in customer support because the predicted category can be used to route a request to a suitable specialist or retrieve a prepared response. Their work applied a semi-supervised multitask ALBERT model to e-commerce customer contact data and reported an improvement of approximately 20 points in average AUC-ROC over the baseline multiclass model [8].

Bonechi et al. studied automatic ticket classification in banking customer support using a real-world dataset containing 4243 chat-based requests distributed across ten classes. The authors compared BERT with a conventional pipeline that combined Term Frequency-Inverse Document Frequency (TF-IDF) and Support Vector Machine classification. Both approaches demonstrated potential for improving customer support efficiency [10]. This is particularly relevant because customer enquiries are frequently short, category-specific, and influenced by the presence of discriminative terms.

Rizou et al. developed a multilingual conversational agent for university administrative services. Their model combines Bidirectional Long Short-Term Memory and Conditional Random Fields to perform intent extraction and named entity recognition using the English and Greek UniWay dataset. The study reported that closed service domains can benefit from architectures that require fewer computational and memory resources while maintaining competitive performance [11].

Kulkarni et al. addressed conversational intent classification in an e-commerce chatbot using a semi-supervised approach. The study considered pre-purchase and post-purchase questions, including enquiries about product details, delivery time, exchanges and returns. It also highlighted practical challenges such as grammatical errors, code-mixed language and limited labelled data. Their proposed approach used a small, labelled corpus together with a larger collection of unlabeled queries and improved upon the supervised baseline [9].

Other researchers have explored different approaches for domain-specific assistance. Wang et al. developed a telecom customer-service assistant that combines information retrieval, word embeddings and multiclass intent prediction. The system retrieves and ranks candidate answers, then presents the five most relevant responses to customer-service staff [19].

Pawlik et al. further demonstrated that recognizing implicit intent and considering emotional information can improve actions performed by a customer-service bot [20]. In another application domain, Wang et al. developed a chatbot that identifies user intentions and provides context-aware COVID-19 information using NLP, machine learning and a knowledge graph [19].

III. METHODOLOGY

A. System Architecture

LaundrOTrack was developed as a multi-role platform comprising a customer mobile application, a driver mobile application and an administrator web dashboard. The customer application supports laundry ordering, order progress monitoring, real-time driver tracking, and access to the Laundra Ask customer-support assistant. The driver application manages pickup and return delivery tasks, status updates, route navigation and GPS location sharing. The administrator dashboard supports order monitoring, driver assignment and operational tracking.

The mobile applications were developed using Flutter and Dart, while Firebase was used as the central backend. Firebase Authentication manages user access and Cloud Firestore stores and synchronizes order information, driver locations and status updates between the three user modules. Google Maps services provide map visualization, route information, distance and estimated travel duration. In addition, the customer application communicates with a Flask REST API that hosts the Laundra Ask intent classification model. The overall architecture is illustrated in Fig. 1.

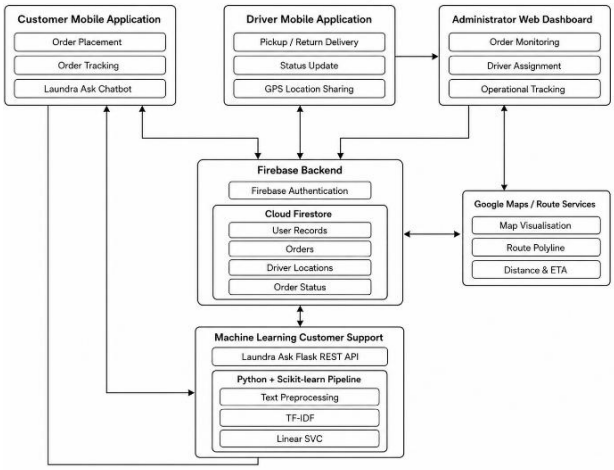

Fig. 1. Overall architecture of the proposed platform.

B. Laundry Logistics and Real-Time Tracking Workflow

The logistics workflow begins when a customer submits a laundry order containing the selected service and pickup and return addresses. The administrator reviews the order and assigns the corresponding task to a driver. Once the driver accepts the task and starts the journey, the order enters an active tracking stage.

During pickup, the customer pickup location becomes the active destination. The driver application obtains the current GPS coordinates from the device location service and updates the location data in Cloud Firestore. The customer application and administrator dashboard retrieve the latest coordinates and display the driver position on their respective tracking interface.

After the driver reaches the pickup location and confirms the collection, the order progresses through the laundry processing stages. Once processing is completed, the return delivery workflow is activated, and the customer return address becomes the new destination. The same tracking process continues until the driver confirms delivery completion. Tracking is activated only during movement-related stages and is stopped after the corresponding pickup or delivery task has been completed.

C. Route, ETA and Location-Based Arrival Detection

The route generation process uses the driver's latest coordinates as the origin and selects the destination according to the current order stage. During pickup, the destination is the customer pickup address, whereas during return delivery, the destination is the customer return address. The origin and destination coordinates are submitted to the route service, which returns encoded polyline data, travel distance and estimated duration.

The polyline is decoded and displayed on Google Maps together with markers representing the driver and active destination. The estimated arrival time is calculated as

$$T_{ETA} = T_{current} + T_{duration} \quad (1)$$

where, $T_{current}$ is the current system time and $T_{duration}$ is the travel duration returned by the route service. The route, distance and ETA can be updated when the driver's position or active destination changes.

Arrival detection is implemented using a distance-based condition rather than geofencing. The system compares the distance between the driver's current coordinate and the active destination against a predefined arrival threshold:

$$A = \begin{cases} 1, & d(P_d, P_t) \le r_a \\ 0, & d(P_d, P_t) > r_a \end{cases} \quad (2)$$

where, P_d represent the driver position, P_t represent the destination, r_a is the configured arrival threshold and A is the arrival state. When the driver remains outside the threshold, the arrival confirmation action remains restricted. Once the driver is sufficiently close to the destination, the application enables the next action, such as confirming pickup arrival and return delivery.

D. Laundra Ask Intent-Classification Pipeline

Laundra Ask was implemented as a closed-domain customer-support assistant for common laundry service enquiries. The prepared dataset contains example questions, intent labels and associated responses. The implemented categories include greeting, general help, service price, payment, order status, ETA request, pickup location, delivery issue, cancel order, contact support and unknown.

Before model training, the question text was cleaned and standardized to reduce variation in capitalization, punctuation and sentence structure. The processed text was then transformed into numerical features using TF-IDF. TF-IDF assigns greater importance to terms that are frequent within a particular question but less common across the complete dataset. Words such as price, payment, pickup, delivery, ETA and cancel therefore provide useful information for distinguishing between intent categories (Fig. 2).

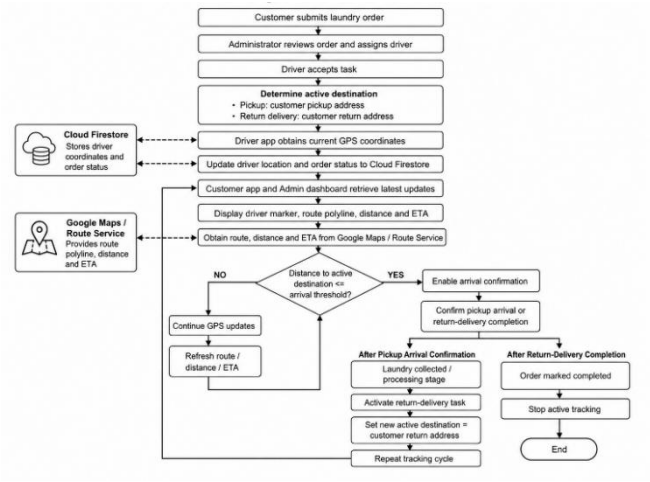

Fig. 2. Real-time tracking, route and arrival detection workflow.

Linear Support Vector Classification was used to classify the resulting TF-IDF feature vectors. Linear SVC was selected because it is suitable for sparse, high-dimensional text data and provides an efficient classification approach for a limited closed domain dataset. The TF-IDF vectorizer and Linear SVC classifier were combined within a Schikit-learn pipeline so that identical text transformation was applied during training and prediction.

The dataset was divided into training and testing subsets. The training subset was used to learn the relationship between customer question patterns and intent labels, while the testing subset was retained for evaluation using accuracy, precision, recall, and F1-Score.

E. Flask API Integration

After training, the complete TF-IDF and Linear SVC pipeline was stored as a reusable .pk1 model file. A Flask REST API was then implemented to connect the Python model with the Flutter customer application.

When a customer submits a question, the application sends the text to the API through an HTTP request. The API loads the saved pipeline, transforms the question into TF-IDF features, predicts the most suitable intent and retrieves the corresponding prepared response. The response is then returned to the Flutter application and displayed through the Laundra Ask interface.

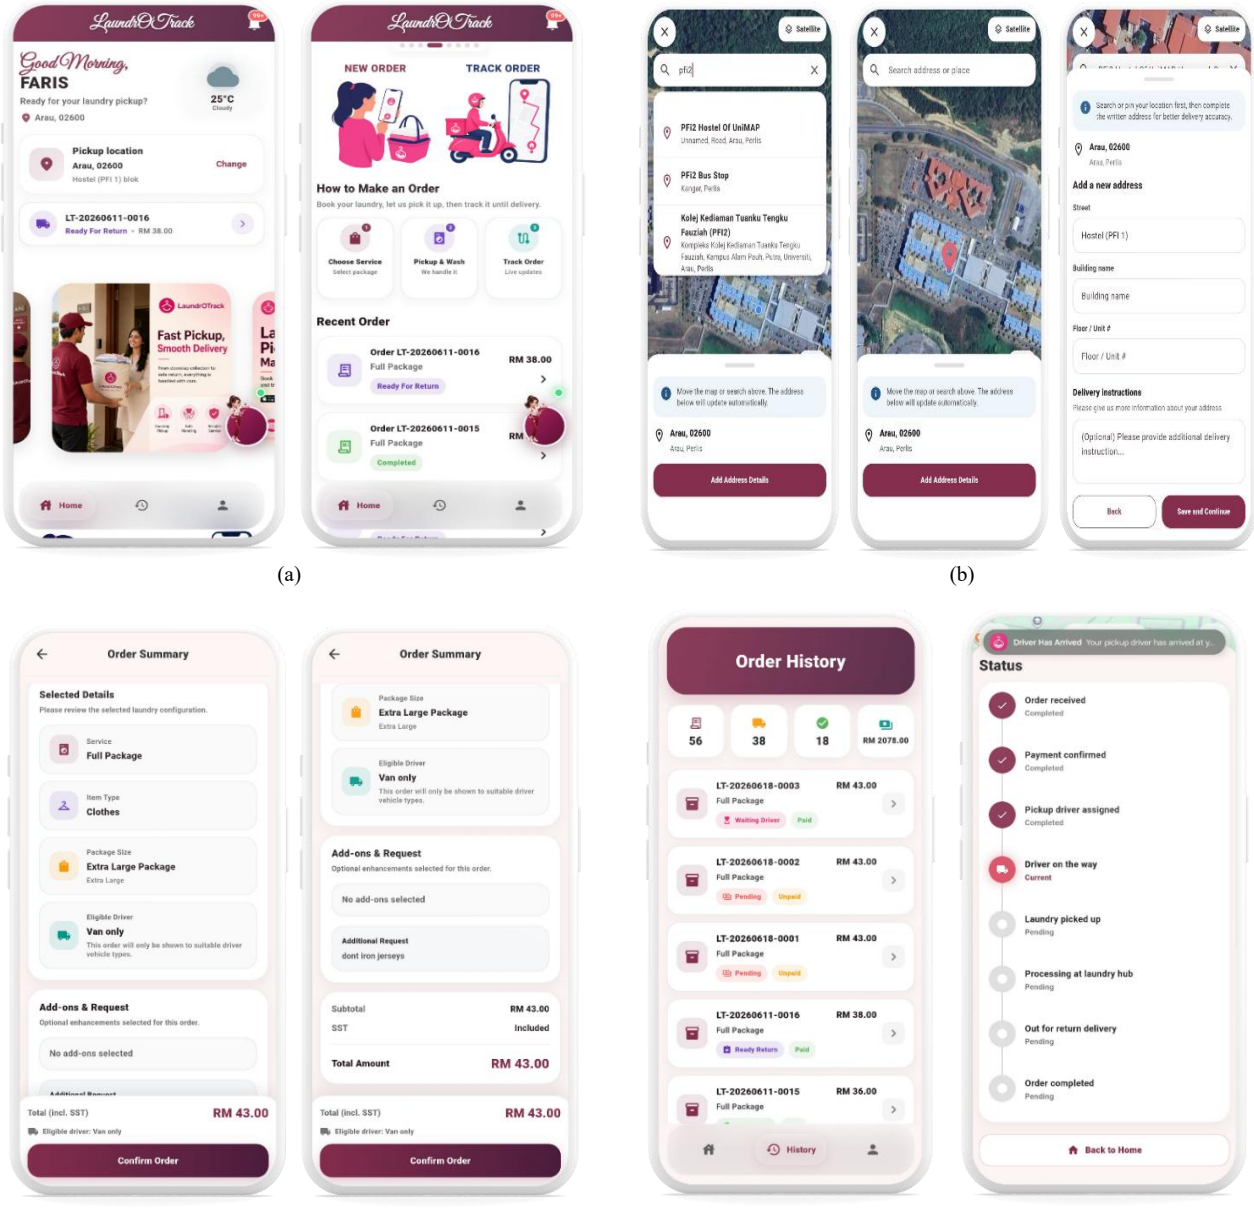
IV. Results and Discussion

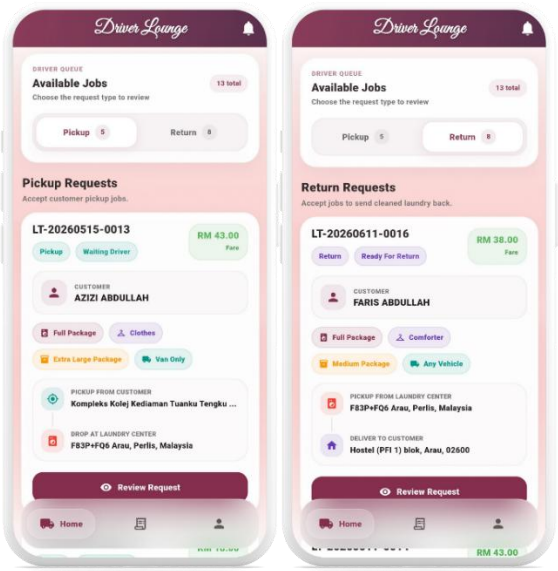
The proposed platform was evaluated through multi-role user interface workflow validation, functional tracking and logistics testing, and machine learning intent classification analysis. The platform interface evaluation examined the operational workflow and usability across customer, driver, and administrator client modules. The logistics tracking evaluation examined GPS coordinate acquisition, Cloud Firestore synchronization, live tracking across the customer and administrator interfaces, route and ETA generation, active destination selection, location-based arrival detection, and tracking termination. Furthermore, Laundra Ask was evaluated using unseen testing data based on the standard classification metrics of accuracy, precision, recall, and F1-score.

A. Platform Implementation and User Interface Design

LaundrOTrack was realized across three interconnected client modules. The customer mobile application provides a streamlined end-to-end service workflow.

As shown in Fig. 3(a), the home dashboard serves as the central hub displaying user greetings, active order cards, and service shortcuts. When placing an order, users specify collection coordinates via the map-pinning pickup location interface in Fig. 3(b). The order summary interface in Fig. 3(c) consolidates selected packages, add-ons, and itemized fare breakdowns before payment. Post-checkout, the order history and progress timeline in Fig. 3(d) provide complete service visibility through historical records and a multi-stage milestone tracker.





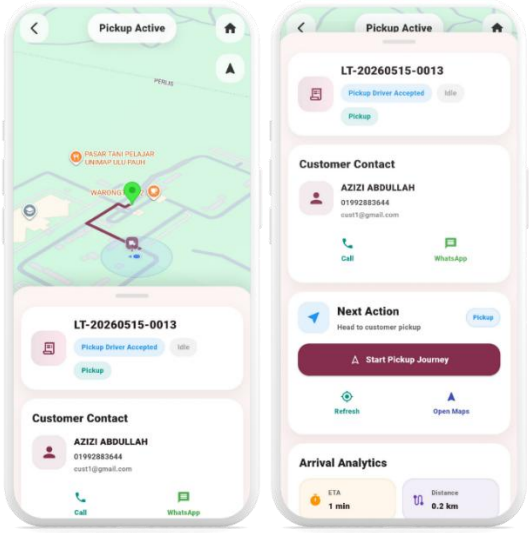


Fig. 3. Customer mobile application interfaces displaying: (a) customer home dashboard interface, (b) pickup location setup interface, (c) order summary interface, and (d) order history and progress timeline.

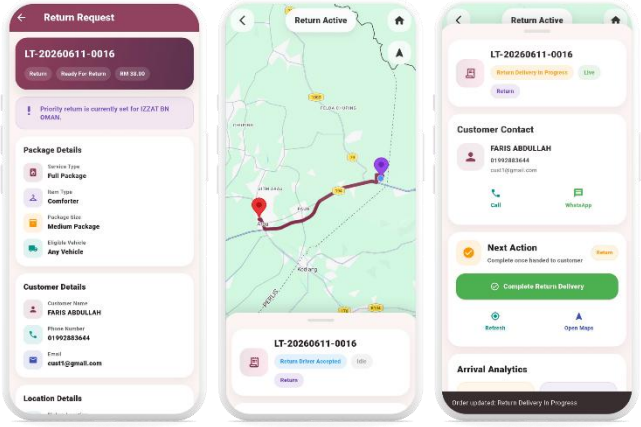

The driver mobile application focuses on an intuitive layout optimized for task execution across both delivery phases. As depicted in Fig. 4(a), the pickup and return delivery request interface organizes incoming jobs into structured queues, enabling drivers to inspect order specifications, fare amounts, and customer locations prior to task acceptance. Upon task acceptance, the driver active pickup order screen shown in Fig. 4(b) provides an operational tracking layout with integrated map routes, direct customer communication shortcuts, and arrival confirmation controls. Following laundry processing, the return delivery handling process interface in Fig. 4(c) transitions the driver into the final delivery stage, providing dedicated controls to manage and confirm the return of processed items to the customer.

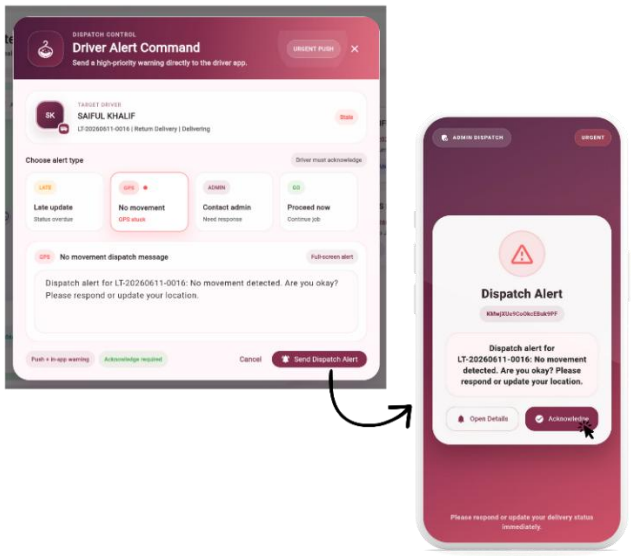

Fig. 4. Driver mobile application interfaces displaying: (a) pickup and return delivery request interface, (b) driver active pickup order screen, and (c) return delivery handling process interface

(a)

(b)

(c)

Fig. 5. Administrator web management console displaying: (a) administrator main dashboard interface, (b) analytical section of the administrator main dashboard, and (c) driver alert command and dispatch notification interface.

The administrator web management console provides centralized control over the system's operational and dispatch

operations. As shown in Fig. 5(a), the administrator main dashboard interface presents a high-level operational overview through active order metrics, financial performance cards, recent transactions, and live driver monitoring panels. Complementing the operational layout, the analytical section of the administrator main dashboard in Fig. 5(b) converts raw platform data into visual charts detailing revenue collections, order status distributions, and payment status insights for strategic decision-making. Furthermore, the driver alert command and dispatch notification interface depicted in Fig. 5(c) provides direct operational intervention capabilities, allowing administrators to send task alerts, dispatch updates, and status reminders directly to assigned drivers during live order management.

B. Real-Time Tracking and Logistics Results

The functional evaluation verified nine tracking-related scenarios, including location permission handling, GPS coordinate acquisition, Firestore location updates, customer and administrator tracking displays, status-based tracking activation, tracking termination, route and ETA output and location-based arrival detection, as shown in Table I. The actual results showed that all evaluated functions produced the expected behavior.

Fig. 6 presents the tracking output from the customer, driver and administrator perspectives. Fig. 6(a) shows the customer tracking interface, where the route between the driver and the active destination is displayed together with the current order information. The route polyline provides a clearer indication of the driver's travel direction than a location marker alone.

TABLE I. FUNCTIONAL EVALUATION OF THE TRACKING COMPONENT

Evaluated Function	Expected Result	Outcome
GPS coordinate acquisition	Driver application obtains the current location	Passed
Firestore location update	Latest driver coordinates are stored and updated	Passed
Customer live tracking	Customer can view the driver location	Passed
Administrator monitoring	Administrator can monitor driver movement	Passed
Tracking activation	Tracking begins during an active pickup or return delivery task	Passed
Tracking termination	Tracking stops after the movement stage is completed	Passed
Route and ETA	Route, distance and ETA are displayed	Passed
Arrival detection	Arrival confirmation is enabled near the active destination	Passed

Fig. 6(b) shows the driver tracking interface and arrival analytics during an active pickup task. The interface displays the current driver position, destination, remaining distance, ETA, expected arrival time and last updated information. This output allows the driver to monitor the current journey while providing measurable progress information for the active task.

Fig. 6(c) presents the administrator live tracking dashboard. The dashboard provides a centralized map view together with active driver information, allowing the administrator to monitor driver movement and identify tasks that may require attention. The customer and administrator outputs demonstrate that the driver's location can be viewed across different system roles according to their operational requirements.

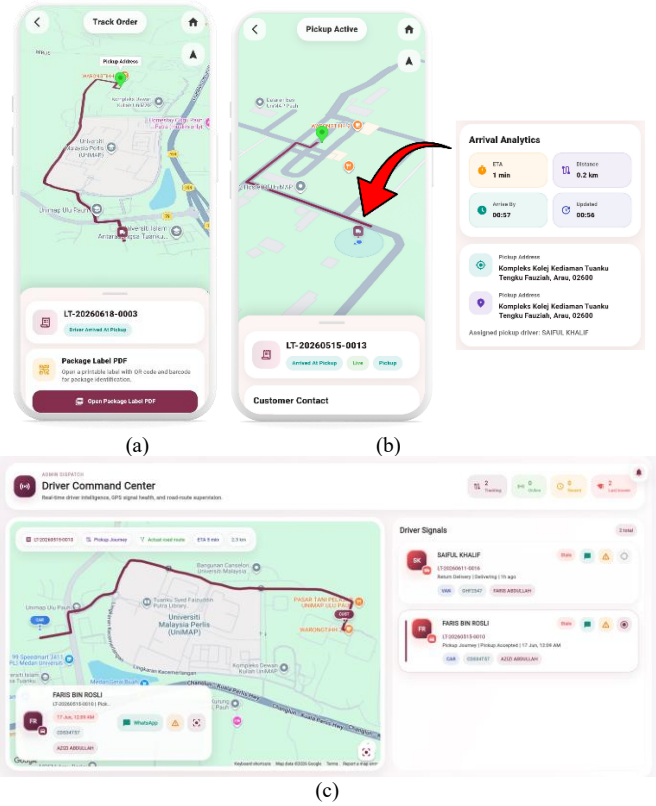

Fig. 6. Real-time logistics tracking output: (a) customer tracking interface; (b) driver route and arrival analytics; (c) administrator live tracking dashboard.

Location-based arrival detection was also verified during pickup and return delivery testing. The system compared the driver's current position with the active destination. When the driver remained outside the configured arrival boundary, tracking continued and the arrival-confirmation action remained unavailable. Once the required proximity was reached, the application enabled the next relevant confirmation action.

C. Laundra Ask Training and Classification Results

The Laundra Ask dataset contained 1100 labelled questions distributed across eleven intent categories: cancel_order, contact_support, delivery_issue, eta_request, general_help, greeting, order_status, payment, pickup_location, service_price and unknown. The dataset included English, Malay and informal mixed-language questions to represent different customer writing styles.

The dataset was divided using a stratified 80:20 training-testing split with a fixed random state of 42. Consequently, 880 samples were used for training, and 220 unseen samples were retained for testing. Each intent category contributed 20 testing samples. The Scikit-learn pipeline applied lowercase TF-IDF feature extraction with unigram and bigram features, followed by Linear Support Vector Classification.

After training, the classifier achieved an overall accuracy of 99.55%, corresponding to 219 correct predictions from 220 testing samples. This result indicates that the TF-IDF and Linear SVC pipeline successfully learned the discriminative language

patterns associated with the prepared laundry service intent categories.

TABLE II. LAUNDRA ASK INTENT CLASSIFICATION RESULTS

Intent	Precision	Recall	F1-score	Support
Cancel order	1.00	1.00	1.00	20
Contact support	1.00	0.95	0.97	20
Delivery issue	1.00	1.00	1.00	20
ETA request	1.00	1.00	1.00	20
General help	0.95	1.00	0.98	20
Greeting	1.00	1.00	1.00	20
Order status	1.00	1.00	1.00	20
Payment	1.00	1.00	1.00	20
Pickup location	1.00	1.00	1.00	20
Service price	1.00	1.00	1.00	20
Uknown	1.00	1.00	1.00	20

Table II shows that nine of the eleven intent categories obtained precision, recall and F1-score values of 1.00; the contact_support category recorded a recall of 0.95 and an F1-score of 0.97, while general_help recorded a precision of 0.95 and an F1-score of 0.98. The macro and weighted averages were displayed as 1.00 in the original classification report because the values were rounded to two decimal places.

The confusion matrix in Fig. 7 provides a more detailed representation of the classification result. All intent categories recorded 20 correct predictions along the main diagonal except contact_support, which recorded 19 correct predictions. One contact_support question was classified as general_help. This overlap is understandable because broad requests for assistance may use wording similar to enquiries asking how to contact the customer support service.

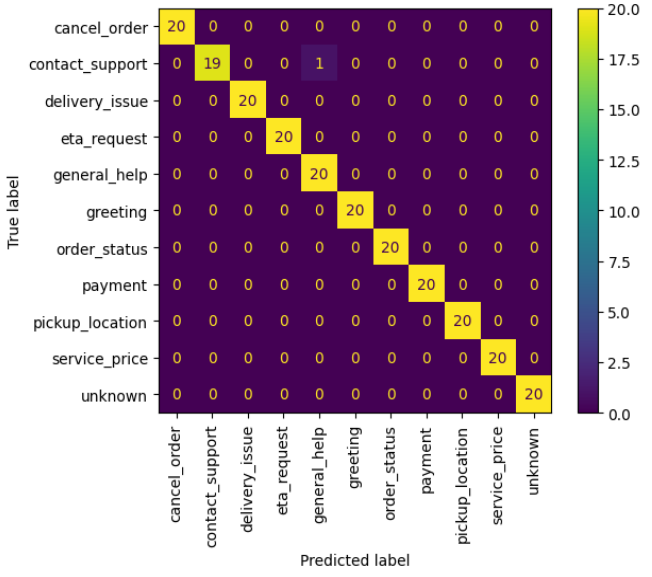

Fig. 7. Confusion matrix of the laundra ask intent classifier.

Additional prediction tests were conducted using informal and mixed-language customer questions. These enquiries involved order location, driver movement, refund requests, delayed delivery, customer-support contact and pick-up-address changes. The model predicted relevant categories such as order_status, eta_request, delivery_issue, contact_support and pickup_location.

D. Laundra Ask API and Application Integration Results

After evaluation, the complete TF-IDF and Linear SVC pipeline was saved as a .pk1 file. Since the vectorizer and classifier were stored within the same Scikit-learn pipeline, the deployed backend could perform text transformation and intent prediction through a single saved model.

The Flask API was successfully deployed and made accessible through an online endpoint. When a customer submitted a question from the Flutter application, the API received the input, loaded the saved pipeline, predicted the intent and returned the corresponding response. The operational output confirmed that the deployed server was running and accessible by the customer application.

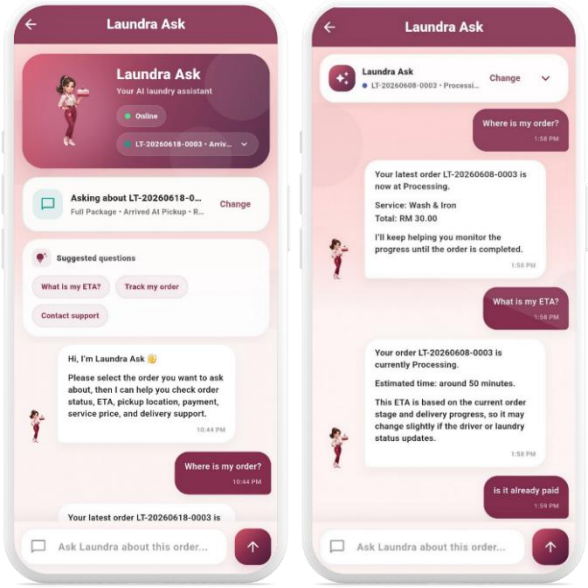

Fig. 8. Laundra Ask chatbot interface.

Fig. 8 shows the final Laundra Ask interface integrated into the customer application. The output demonstrates that customers can submit questions related to order status, ETA, payment and other laundry service enquiries and receive responses through a chat-based interface. This confirms that the trained classifier was successfully connected to the operational application rather than being evaluated only as a standalone machine learning model. While internal cross-validation confirmed model stability on the curated dataset, we acknowledge that this limits out-of-vocabulary generalizability. Real-world queries containing slang or typos may degrade performance, which will be addressed in future online retraining.

V. Limitation and Future Work

The tracking component depends on GPS accuracy and stable internet connectivity. Location information may become less accurate indoors, in weak signal areas, or near tall buildings. The current tracking evaluation verified system integration and state transitions under synthetic conditions. Physical GPS drift, network latency, and dynamic ETA accuracy were not quantitatively measured and are reserved for live field deployment. Network instability may delay Firestore synchronization, route updates and arrival detection. The tracking evaluation was also based on functional scenarios rather than controlled measurements of positioning error and end-to-end latency.

Laundra Ask is limited by the size and coverage of the prepared dataset. Although English, Malay and mixed-language questions were included, substantially different expressions may produce incorrect predictions. This work focuses on alpha-stage technical feasibility. Formal end-user studies assessing usability, learnability (e.g., via the System Usability Scale), and operational efficiency will be conducted in future field trials. Future work should include real customer data collection, broader multilingual testing, confidence-based fallback handling, GPS accuracy and latency measurement and evaluation in larger operational environments.

VI. Conclusion

This study presented LaundrOTrack, an intelligent on-demand laundry logistics platform that integrates real-time location tracking and machine learning-based customer support. The platform connects customers, drivers and administrators through a Flutter application, a web dashboard and Firebase backend services. Its logistics component provides GPS-based driver monitoring, route visualization, distance and ETA information and location-based arrival detection for pickup and return delivery. Laundra Ask applies TF-IDF and Linear SVC to classify eleven categories of laundry service enquiries and communicate with the customer application through a Flask REST API. Functional testing confirmed the expected operation of the tracking workflow, while the intent classifier achieved 99.55% accuracy on 220 testing samples. These results demonstrate the feasibility of combining delivery visibility and automated first-level support within a unified laundry-service environment. Further field evaluation with real users, broader language variations and controlled GPS-performance measurements is required before commercial deployment.

Acknowledgment

The authors would like to express their sincere gratitude to Universiti Malaysia Perlis (UniMAP) for providing the necessary facilities and funding to support this work. The authors also extend their appreciation to Dina Suci Teguh Enterprise, known as SM Dobi, a laundry service provider located in Sungai Petani, Kedah, Malaysia, for serving as an industry collaboration partner by contributing valuable domain inputs and practical requirements during system development.

***Abstract*—Most learning-based schedulers for job shop problems assume static workforce performance. However, dynamic dual-resource job shops must navigate stochastic disturbances and time-varying task durations due to human factors. This study proposes a human-centered Deep Reinforcement Learning framework, DD4LQN, for dynamic flexible job shop scheduling under operator learning and forgetting dynamics. The environment integrates a disturbance-aware scenario generator, bounded logistic learning-forgetting dynamics, and deterministic Dual Pair Ranking to ensure auditable decisions. The training used a plan that included ENTRY and EXIT greedy evaluations and a Quote-then-Commit process. Tests over ten weeks showed that DD4LQN-EXIT did better than other scheduling methods. Empirical evaluations over a ten-week horizon demonstrate that DD4LQN-EXIT got the average schedule reward of 0.5843. It was better than Earliest Due Date (EDD) and Shortest Processing Time (SPT) by 17% and 14%, respectively. It also completed jobs and had fewer risky orders. Even though Shortest Processing Time had delays on average, it completed fewer jobs because it focused on short tasks. Additionally, an exploratory ablation across the same scenarios demonstrated that Dual Pair Rank and learning–forgetting dynamics come up with better results. Furthermore, representation diagnostics on the 227,717-parameter network confirm structural stability, with layer matrices retaining up to 98.2% of maximum effective rank without capacity collapse.**

Keywords*—Deep reinforcement learning; dynamic flexible job shop; dual-resource scheduling; human-centered manufacturing; learning and forgetting

I. INTRODUCTION

Scheduling production, or Job Shop Scheduling (JSS), is one of the core issues in production planning, where Job Shop Scheduling with flexible resources (FJSS) or Flexible Job Shop Scheduling (FJSP) assigns precedence-constrained tasks to available resources to minimize makespan, lateness, or even resource utilization [1]. FJSP has been a challenging problem in the field of scheduling, since it is NP-hard [2], even harder than regular JSS [3], because every task can be assigned to more than one machine [4], thus increasing the search space even more [5]. Even for JSS, most methods are not able to find a satisfactory solution for problems of medium to large sizes [6]. The classical problems related to Job Shop Scheduling (JSS) and its flexible variation (FJSS) have been tackled in the past decades by numerous mathematical models, as well as by a wide variety of heuristic and meta-heuristic techniques that aim to find a solution to production planning problems, by assigning the tasks to the resources to minimize some performance measures such as makespan, lateness, or even the amount of resources which are used for executing the tasks, in environments where the number of resources is finite and where each task has a set of precedents that must be satisfied before the task can be executed [7]. For a long time, a large set of models [8], heuristics [2], and also of complete and incomplete search techniques for solving Flexible Job Shop Scheduling Problems (FJSP) have been studied, since allowing different machines for one task is considered to be one of the most challenging issues for FJSS problems, since FJSS is NP-hard in general [2] and even many techniques that find solutions for such problems in reasonable running times, have limitations when they are applied to instances of FJSS Problem of large dimensions [9]. Another critical challenge that has not been fully addressed in the FJSS domain is related to dual-resource (M&R and H&R) assignment, especially when it comes to modeling and handling the human factor variability while jobs are being executed. Although the variability of the human factor has been recently highlighted in production management literature, the majority of studies have been modeling human resources as static resources, while in reality, human execution times follow a dynamic distribution that is influenced by various factors, including the operator's competencies, skill levels, and prior experiences [10]. In fact, there are only a few studies in the field that have modeled human performance, and those have been using simplistic models and have not been incorporating learning and forgetting phenomena that have been proven to play critical roles in operators' performance over time. While there is an increasing interest in modeling human competencies and their variability in order to enhance production performance and improve production operations in Industry 4.0 and 5.0 environments, more research is clearly needed to fully address this critical challenge and to effectively integrate human factors in production settings [11]. This work tackles the issues of dynamic production in order to deal with disturbances by proposing a DRL paradigm for the dynamic dual-resource scheduling (JFDRS) to stabilize the deterministic decisions of a job shop with two types of resources: machines and humans. To model the human resources, this work explicitly models human performance using a learning-

forgetting operator model that is fed to the DD4LQN (Dynamic Deep Four Layers Q-Network) by an environment specifying the Dual Pair-Rank that is produced by a weekly scenario generator that is given a disruption-aware shop floor.

The study is organized as follows. Section II presents a clear review of related work concerning DRL-based production scheduling and the human factors involved in shop-floor management. The third section elaborates on the disturbance-aware scenario generator, the Bounded Logistic Learning and Forgetting (BLLF) modelization, the Dual Pair-Rank (DPR) modelization, as well as the hierarchical reward structure. Section IV focuses on the DD4LQN training protocol and the network architecture; it also gives in detail the framework results while assessing its performance in comparison with SPT and EDD scheduling techniques. Finally, Section VI summarizes the main contributions of the study, discusses the limitations of the work, and outlines future research avenues.

II. Related Work and Research Gaps

A. Deep Reinforcement Learning for Job Shop and Flexible Job Shop Scheduling

Deep reinforcement learning (DRL) scheduling is commonly formulated based on a Markov decision process (MDP), in which an agent selects actions to maximize cumulative reward [12], [13]. When transition-relevant workforce memory is not included in the agent observation, however, the controller operates under partial observability. Recently, learned dispatch heuristics are being replaced by deep value-based policies and by more structured state-action space representations [14], [15]. However, for these problems of scheduling abstract resources in abstract environments, abstraction, incentives, and instances have a huge impact on the performance of operation control. However, for these abstract representations of manufacturing environments, operation control is too complex and hard to manage[16]. In order to increase the stability of training in DRL models for scheduling, a target network, a replay buffer, Double DQN, prioritized replay, and distributional RL are applied in order to deal with delayed rewards, poor generalization, and a lack of interpretability of learned controllers. However, these methods for increasing the stability of training have a lot of serious drawbacks, such as a high computational cost of training [17]. In addition, a major open research question for assessment and tie management in DRL for scheduling remains: how to guarantee environment-level determinism to guarantee repeatable and auditable dispatching in the presence of disturbances in shop states and in arrival times of events in a scheduling environment [18].

B. Dynamic Scheduling Under Disturbances

Dynamic JSS/FJSP schedules take into account machine failures, new task arrivals, and processing time variance. Scheduling in cyber-physical systems is adaptive but has to be feasible after interruptions [19], [20]. In recent DRL approaches, ranking or rule selection is implemented at event points, but feasibility is often not ensured [21]. Stochasticity, implementation issues, and hardware characteristics strongly affect DRL outputs[12], [22]. In scheduling situations, learning targets are already unstable due to non-determinism of tie-breaking, state-altering evaluation, and post-selection duration re-computation. Thus, there is a severe gap for disturbance-aware scheduling to guarantee repeatable and auditable dispatching. This can only be achieved by imposing determinism on the scheduling environment [23]. For that purpose, the respective status records have to be treated as hard constraints, so-called scheduling constraints, and have to be provided with an authoritative status record and auditable outcome labels.

C. Human-Centric Scheduling with Learning and Forgetting

However, human factors are not yet sufficiently modeled in scheduling [10]. Skills for Industry 4.0/5.0 should enable employees to deal with job changes and to work in a repetitive and, to some extent, also interrupted manner [11], [24]. The classical learning-forgetting-curves (LFCs) are still interpretable; however, in many cases they are restricted by re-assignment, by decay thresholds, and by warm-up procedures [25], [26]. In many cases, human dynamics are not, or only poorly, calibrated and are left to the RL loop or are not integrated at all in human-machine scheduling, as it has been requested several times [4], [27].

III. Modelization and Environment Definition

A. Problem Formulation and Event-Driven Time Assumptions

Building upon the previously detailed limitations, the environment is designed as a dynamic dual-resource FJSP, requiring the duration of tasks along with machine and operator availability to complete them based on their precedence constraints. The model tackles three main limitations that had not been addressed by previous research on FJSP: 1) unrealistic treatment of operators as static resources, 2) Lack of audibility of infeasibility due to disruptions, and 3) environment-level non-determinism leading to unstable DRL targets. These hard constraints are verified by means of authoritative status logs and by the next-free proxies, i.e., a human operator executes decisions under continuous event-driven time, (stochastic) weekly demand, (stipulated) due dates, and operator/machine unavailability. For cross-week continuity and interpretable skill progression, human execution is constrained to an ABS-time representation of learning-forgetting dynamics, i.e., a (stipulated) week starts at an ABS-time (absolute begin time) and ends at a forget-time. Four hypotheses are to be evaluated by the experiments: 1) ABS-time memory leads to more coherent human-state transitions over weeks than week-reset memory, (H1); 2) Dual Pair Rank is controllable and efficient for meeting hard deadlines in a dual-resource environment, (H2); 3) Result labels and logs of authoritative status are audible for a human operator for infeasibility caused by disruptions, (H3); and 4) a Quote-then-Commit framework with deterministic Quote and a specified then-commit rule and tie-breaking rule stabilizes the DD4LQN environment, (H4).

B. Weekly Scenario Generator and Continuous-Time Simulation

To train the DRL agent in an environment that is as realistic as possible but at the same time under control, it is important to isolate the weekly stochastic realizations from the master data. In this way, in order to avoid an artificial drift but at the same time ensure to keep the cross-week continuity. The master-data

layer of the environment describes a fixed shop with 20 machines and 12 operators, as well as a product catalog that consists of an occasional pool (P16–P20) and a known pool (P1–P15); see Fig. 1. The operators are described by their initial experience, their warm-up units, as well as by their forgetting thresholds. In this way, the skill of the operators can be transferred from one week to another. Each product goes through a fixed number of 3 to 5 tasks. Each task has a set of eligible machines as well as a set of standard processing times for these machines. A product also has a deadline for each weekly scenario that includes the external constraints of the client.

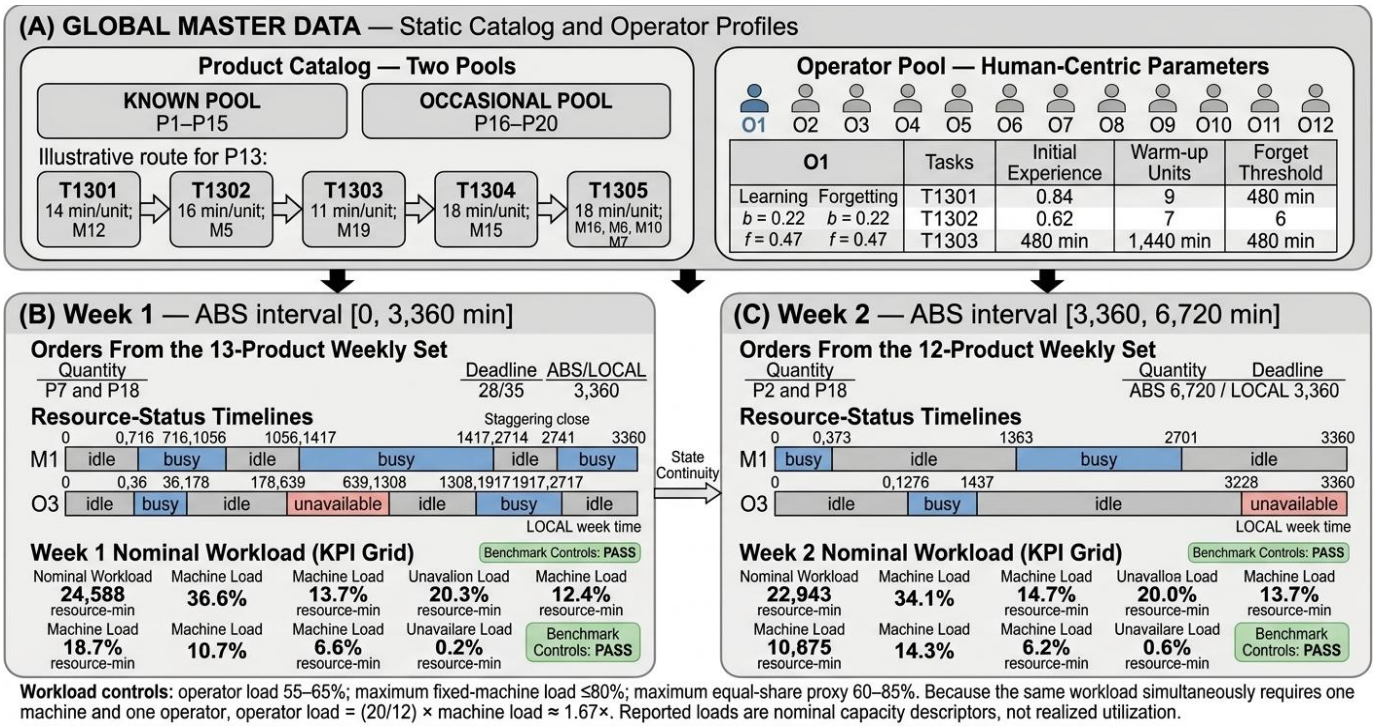

Fig. 1. Weekly scenario generator and continuous-time simulation logic.

As presented in Fig. 1, the generator randomly generates an order mix of 8-10 regular products and 1-5 irregular products on a weekly basis over 3360 minutes. The batch sizes are between 25 and 40 units. The local windows are defined for idle, busy, maintenance, absent, and unavailable times of machines and operators. The due dates are generated on an ABS timeline spanning weeks or more, and then mapped to the local week timeline in order to calculate feasibility and rewards. The test instances use 22,228–26,067 resource-minutes every week to analyze 11–14 products and 44–53 tasks. The 20 machines (67,200 min) and 12 operators (40,320 min) result in an operator-to-machine load ratio of 1.67 since each operation requires both a machine and an operator at the same time. Therefore, system restrictions are driven by operator load (55.1–64.7%) rather than machine load (33.1–38.8%). Limited flexibility (1.39–1.73 machines/operation) results in 84.8% of localized bottlenecks. This 20-machine setup incorporates practical dual-resource, due-date, and human-performance limitations while offering a scale context similar to traditional FJSP benchmarks of Brandimarte [28] and Hurink [29] work. The current generator does not include sequence-dependent setup, repair rules, transport, and multi-operator activities.

C. Logistic Learning–Forgetting Performance Model

More accurate models of learning and forgetting are required. Although traditional learning-forgetting models, such as those proposed by Wright [30] and Ebbinghaus [42], are simple to understand and follow, they treat learning and forgetting as separate processes, failing to capture constrained, non-linear learning trajectories affected by the warmup and interruption effects. Others, such as ODE-based models [31] unify the two learning processes, yet are less transparent and are difficult to calibrate for the type of disturbance analysis in question. Alternatively, learning processes have been modeled using data-driven techniques such as LSTM networks [32] and Model-Agnostic Meta-Learning (MAML) [33]. However, as black-box models, they are very adaptive but require a lot of data to learn from. There are also more complete cognitive models of human learning, such as the Adaptive Control of Thought–Rational (ACT-R) cognitive architecture [32]. Yet, such models are also too complex and thus not suitable for industrial, widespread application. Finally, Distributed Reinforcement Learning (DRL) has been applied for worker-aware scheduling and task allocation; however, as in the case of learning, the performance evolution of such systems is also difficult to understand [34].

To represent the evolution of operator performance across repeated task assignments, this study adopts bounded learning and forgetting mechanisms [4], [35]. For every unit processed by operator O on task τ, performance is computed according to Eq. (1):

$$P(o,\tau)^{n+1} = P(o,\tau)^{n} + \frac{Pmax - P(o,\tau)^{n}}{1+exp[-So(n-Mo,\tau)}} \quad (1)$$

where, $P(o,\tau)^n$ is the operator's performance after n processed units, Mo,τ is the learning midpoint related to the operator–task pair, Pmax is the upper performance constraint, and So is the operator learning rate. The updated performance falls within [P0, Pmax]. As a result, performance continuously improves toward Pmax with repeated execution, and each unit's effective processing time is calculated by dividing its standard time by the associated performance level.

The model attempts to maintain operator-task memory throughout subsequent weeks, allowing the same operator to be reassigned to the same work. The absolute idle duration is computed as the difference between the start time of the new assignment and the prior absolute completion time.

Only when this duration is superior to the task-operator specific threshold So,τ does forgetting become active. Eq. (2) determines the performance at the initial stage of the new assignment:

$$P(o,\tau,\Delta t)^{Start} = Pmin + \frac{P(o,\tau,)^{Last} - Pmin}{1+exp[-Fo(\Delta t - So,\tau)} \quad (2)$$

where, Fo is the forgetting curve, Pmin is the lower performance bound, Δt is the absolute idle duration, and $P(o,\tau)^{Last}$ the performance attained following the previous task execution.

As a result, performance is maintained prior to the forgetting threshold and then monotonically declines toward Pmin as inactivity increases. Instead of starting from the operator's initial experience level, learning resumes from this retained performance after reassignment. Fig. 2 illustrates the resulting bounded learning and threshold-activated forgetting dynamics.

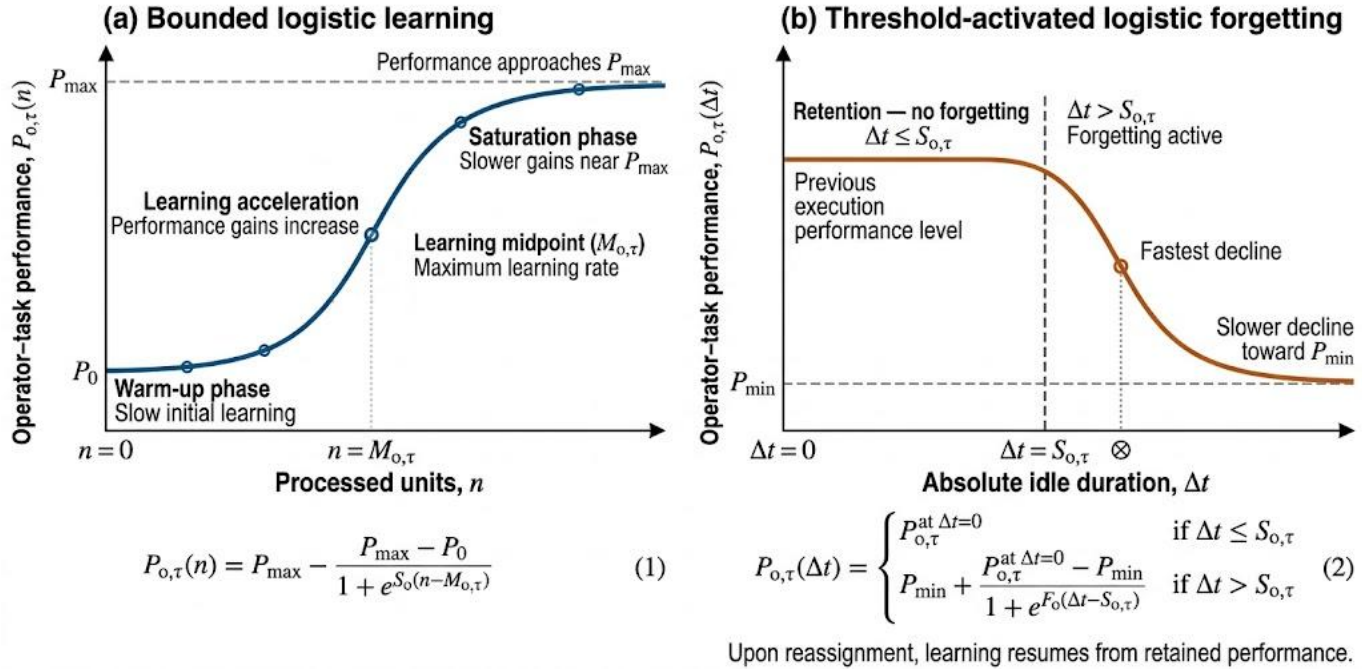

Fig. 2. Operator–task performance dynamics under repeated execution and interruption: (a) logistic learning toward the upper performance bound and (b) retention followed by logistic forgetting toward the lower performance bound.

As illustrated in Fig. 2 the bounded learning and forgetting curves reflect task-specific operator performance under repeated execution and protracted inactivity. By incorporating these human-performance dynamics into the RL scheduling loop, the proposed model compensates for workforce skill evolution when making production-planning decisions.

The BLLF model provides an explicit synthetic framework to evaluate the robustness of DRL policies against variability in human performance. The qualitative mechanisms (e.g., threshold-activated decay and bounded retention) are consistent with empirical ergonomics literature of Baily [36] Nembhard [37] and Hoedt [38] contributions but the particular numerical parameter ranges (P(o ,τ) ∈[0.60, 0.85], So ∈ [0.20, 0.35], Fo ∈ [0.35, 0.60]) are artificial scenarios. For starters, the study's findings are based on artificial, simplified conditions rather than real-world testing. Future validation is still needed for empirical calibration utilizing shop-floor cycle-time records (e.g., Lago Alvarez, 2025 [39]).

D. Machine-Operator Dual Pair Ranking

The study considers a dynamic dual-resource job shop in which every operation requires one eligible machine and one eligible operator. Machine and operator unavailability, different release times, and time-dependent human processing times make pair assignment a multi-criteria decision. For a dispatchable task Tij at decision time t, a candidate c = (Tij, t, m, o) is retained only when machine m and operator o are simultaneously feasible and its quoted completion time lies within the planning horizon H. Dual Pair Rank then converts the feasible pair attributes into one deterministic cost so that the selected pair is stable and reproducible. Although DD4LQN selects the product identifier, Dual Pair Rank performs the subsequent machine-operator assignment for the current

operation. This separation implies that the learned policy and resource-pairing must be evaluated as distinct components of the system.

1) Deterministic scalarization for pair ranking: For each feasible candidate, Dual Pair Rank combines five bounded costs: Machine Rank MR(c), Operator Rank OR(c), deadline-risk cost URG(c), normalized earliest-start cost EST_N(c), and normalized predicted-underperformance cost UP_N(c). Lower values are preferred.

$$\Pi P(\chi) = \omega_M MP(\chi) + \omega_O OP(\chi) + \omega_Y Y P\Gamma(\chi) + \omega_E E\Sigma T_N(\chi) + \omega_\Pi Y\Pi_N(\chi) \quad (9)$$

where, $\sum wi = 1$ and $wi \geq 0$ are satisfied by the weight vector $w = (w_M, w_O, w_U, w_E, w_P) = (0.25, 0.30, 0.20, 0.15, 0.10)$. A lower score PR(c) implies a more advantageous candidate assignment because each component corresponds to a cost metric. Table I presents operational definitions and significance of each criterion.

TABLE I. PARAMETERIZATION, OPERATIONAL DEFINITIONS, AND SIGNIFICANCE OF DUAL PAIR RANK COMPONENTS

Criteria	Wi	Operational Definition	Domain Significance
Machine Rank (MR)	**0.25**	Prevents machine overload and bottlenecks by evaluating a machine's past workload and future queue to determine how busy it is.	Keeps machine workloads evenly distributed around the shop floor by preventing the system from overloading popular machines and accumulating work **[40]**.
Operator Rank (OR)	**0.30**	Takes into account operator slowdowns, memory loss during idle periods, and warm-up delays when estimating the time and effort required by an operator.	By accounting for skill loss and warm-up time, it avoids depending solely on the best employees and promotes equitable operator rotation while maintaining a rapid pace of work **[41], [42]**.
Emergency (URG)	**0.20**	Determines how close a task is to its due date, which results in advancing critical tasks and preventing past-due tasks from totally breaking the system's logic.	Accelerates critical tasks as their due dates approach, but limits past-due tasks to prevent them from disrupting or taking over the decision-making process **[43], [44]**.
Earliest Start Time (EST_N)	**0.15**	Selects earlier possibilities to save needless waiting time by comparing acceptable start timings to start a task.	Eliminates needless waiting and prevents the system from selecting a late start time just because the worker or machine score appears to be high **[45], [46]**.
Underperformance Penalty (UP_N)	**0.10**	Penalizes worker-machine pairings that are abnormally slow in order to prevent selecting incredibly inefficient combinations.	Eliminates incredibly sluggish worker-machine combinations without applying excessive penalties or double counting operator slowdowns.

Table I shows that by integrating workforce priorities, deadline buffers, and efficiency protections into an elementary [0, 1] cost score, PR(c)'s design achieves a balance between shop-floor stability, human performance, and timetable timeliness. The approach keeps machine usage balanced while avoiding overworking the best operators and preventing burnout. It also aims to prevent late orders from breaking the decision logic and introduces small safeguards to prevent pointless waiting time and avoid poor resource pairings.

2) Weight derivation and limits of the justification: Although the literature currently supports these five criteria, it does not impose particular numerical weights. The weight vector $\{w\} = (0.25, 0.30, 0.20, 0.15, 0.10)$ was formalized using the Revised Simos rank-order process [47] to guarantee strict scientific repeatability. The process produces non-normalized scores of 1.0, 1.5, 2.0, 2.5, and 3.0 that normalize straight to their final values using an importance ratio $z = 3$ and become 0.10, 0.15, 0.20, 0.25, and 0.30, respectively dividing by their sum of 10 yields across the ordered criteria (UPN < ESTN < URG < MR < OR): Because operator performance varies depending on task experience, idle time, forgetfulness, and warm-up, OR is given the highest weight [41], [42]. This decision is also in line with the workload benchmark, where nominal machine load (33.1%-38.8%) is less than nominal operator load (55.1%-64.7%). Because machine eligibility might concentrate workload and cause local delays, MR comes in second [40]. Remaining deadline slack is safeguarded by URG [43], [44]. Although EST_N avoids unnecessary delays, it somewhat overlaps with URG [45], [46]. UP_N is a low-weight precaution as OR and QED already exhibit the anticipated slowness.

3) Determinism and auditability: At each decision step, the scheduler reads task descriptors (QSD, quantity, and week-local deadline), dual-resource availability, and ABS-time operator memory. It quotes QED without mutating operator state, rejects candidates that violate the horizon or availability logs, computes PR(c), and commits the lowest-cost feasible pair. The technique ensures that the same decision is taken each and every time when scores are tied by zeroing out identical numbers and using a predetermined backup checklist.

4) Case identification and interpretability in stochastic manufacturing settings: The following code block outlines the rule set to dispatch an eligible product-task, producing either a committed assignment or an informative outcome label to enable auditability:

- Rule 1: If job, routing, or standard time for the task is missing, then the instance is ill-posed and should be flagged as such.
- Rule 2: Quotations for the job (deterministic quotations for stateless tasks) are to be assessed by the dispatching process.
- Rule 3: Declare the step unfeasible when no candidate meets the planning horizon of the step.
- Rule 4: Record blocking disturbance. Remove tasks that are blocked by tasks within non-working log-intervals of the same task of different jobs of the same product.

- Rule 5: Record the Dual Pair Rank for the viable candidates.
- Rule 6: The score, start time, end time, machine ID, and operator ID of the chosen Dual Pair are determined in a deterministic way to resolve any remaining open issues for the pair selection process and thereby also for the step execution process.
- Rule 7: There is an ABS-time idle gap for forgetting to be applied.
- Rule 8: Commit without recalculating using the saved quote.
- Rule 9: Log any exceptions that have occurred during the commit step and cancel them.

The decision time, job ID, considered candidates, deadline and slack, size of the considered set, selected machine-operator pair, quoted duration for the selected pair, outcome labels for the considered pair(s), tie-breaking information, and information about any forgetting that occurs at commit time are recorded for reproducibility

E. Reward Configuration

The suggested Dynamic Deep 4-layer Q-Network for Dynamic Job Shop Scheduling (DD4LQN-DJSS) relies on a robust reward design to guide the RL agent in identifying the best schedules for a given setting. A hierarchical incentive scheme will enable the agent to evaluate tasks' execution quality, product compliance with deadlines, and overall schedule performance. The industrial context of a flexible job shop is modeled as a dual-resource flexible job shop where each activity is assumed to require an eligible machine as well as an available operator. For this model, a human-centric gap is addressed via a dynamic performance formulation in order to capture its variability. The skill improvement and degradation of the operators are modeled by a Bounded Logistic Learning and Forgetting (BLLF) model, presented in the previous section. This formulation presents the advantage of being compatible with the use of RL-based training in a dynamic DJSS setting.

1) Problem definition and constraints

a) Sets and indices: For a given job shop, let m ∈ M be the set of machines, and k∈ $\mathcal{K}$ be the set of operators. For a given product/jobs j ∈ $\mathcal{J}$, let Tij⊆ $\mathcal{O}$ij be the set of ordered tasks (or operations). The weekly horizon is denoted by H. For a given task (or operation) Tij ∈ $\mathcal{O}$ij, the set of eligible machines is denoted by M{i,j} ⊆ M, and the set of eligible operators is denoted by $\mathcal{K}${i,j} ⊆ $\mathcal{K}$.

b) Parameters: The model contains several parameters that can be used. The due date of a job Dj can be used as a reward shaping parameter, and the batch size qj of a job can also be used. The nominal unit processing time of a task Tij is denoted by stdij, and a stabilizer ε>0 can also be added to keep the reward function stable. Lastly, a dimensionless operator k performance level for an operation Tij on a machine M at time t (minutes) for a unit l ∈ {1…,qj} is denoted by Perf (k,i,j,t,l,m).

c) Decision variables: Assigning tasks to machine-operator pairs is denoted by xijmk; execution of tasks within a given time horizon is denoted by uij; starting and completion times are denoted by Sij and Cij, respectively. Incomplete jobs are denoted by Ij, and completion time and tardiness are denoted by Cj and Ťj, respectively. Machine and operator ordering constraints are modeled by disjunctive variables.

2) Flexible Job Shop constraints and resource capacity

Flexible Job Shop and resource capacity constraints impose:

- Each executed operation is assigned to exactly one eligible machine-operator pair;
- Route precedence compliance within each job;
- Completion Time = Start Time + Effective Processing Time of task at hand;
- No overlap on both machines and operators through disjunctive sequencing;
- Horizon feasibility.

For the purpose of penalizing partial products, Ij=1 and Cj are set to H for any job that is not completed in full by its corresponding decision variables.

3) Reward design: task shaping, product shaping, and schedule-level objective

a) Task-level reward: Eq. (4) presents the task-level reward for a task (i,j) that has been executed. It shows the Quantity of Effective Duration (QED) that has been achieved in comparison to the nominal workload (QSD) for the task (i,j), which is defined as QSD = (stdij * qj), and Effective Duration for a unit as stdij divided by operator unit performanceij. Add up the Effective Duration of all units to get the QED for a task.

$$\text{Rij} = \frac{QSD-QED}{QSD+\varepsilon} \times \text{uij} \quad (4)$$

Late and early completion of tasks are penalized and rewarded, respectively. There is no task reward for unscheduled tasks. The task reward is managed at the product level.

b) Unified product reward: Let's establish λj, μj, and γj as the fractions of early-completed, late-completed, and unscheduled workload using nominal workloads as weights. λj+ μj+ γj = 1 Lateness and earliness for a given task are defined in Eq. (5) below:

$$\Delta\text{j} = \frac{Dj-Cj}{\max(\varepsilon,\text{Dj})} \quad (5)$$

where, Δj^- and Δj^+ represent the normalized lateness and normalized earliness, as follows: $\Delta j^- = \min(0, \Delta j)$ and $\Delta j^+ = \max(0, \Delta j)$. Given that R̄ij is the mean task reward for task (i,j), the unified product reward is defined as follows in Eq. (6):

$$P_{\pi\rho\delta\varphi} = P\square_{\iota\varphi} + (1 + K.\lfloor_{\varphi}).\otimes_{\varphi^+} + (1 + K.\lceil_{\varphi}).\otimes_{\varphi} - K_{\iota\nu\chi} \times \copyright_{\varphi} \quad (6)$$

Notes: 1) The last term vanishes and γj=0 if the product is finished. 2) If incomplete, γj>0 induces the explicit unscheduled-workload penalty, but Cj=H implies Δj becomes the conservative end-of-week due-date term.

c) Schedule reward with tardiness: To make sure the total tardiness is taken into account by the agent, Eq. (7) is

modified to the schedule reward, where $\check{T}$ is the total tardiness (for all the products) and $\bar{R}$prod is the mean product reward.

$$B\check{T} = \frac{H}{H+\check{T}+\varepsilon} \quad (7)$$

Eq. (8) below shows the ultimate schedule reward:

$$P_{\sigma\chi\eta\varepsilon\delta} = P\square_{\pi\rho\sigma\delta} + B\square \quad (8)$$

In summary, our model uses a hierarchical reward structure to force the DD4LQN scheduler to optimize global due-date satisfaction, product completion quality, and local execution quality in order to achieve a single hierarchical goal.

F. Internal Simulator State and Partial Observation

Operator forgetting and learning are influenced by previous task assignments. As a result, the simulator keeps the data from the past that may influence the subsequent change. At the moment of choice t, the entire internal state is presented in Eq. 9:

$$x_t = (\tau_t, J_t, M_t, O_t, H_t, Q_t) \quad (9)$$

The components are as follows: O_t, the corresponding operator information; H_t, operator-task proficiency, accumulated learning exposure, last absolute completion time, and elapsed idle time; Q_t, pending events and remaining disruption information; J_t, product progress, current operations, quantities, deadlines, completion times, and feasibility flags; and M_t, machine status, next-free time, current assignment, and remaining availability calendar.

The entire simulator transition -*presented in Eq. 10*- meets the following since x_t contains all dynamic variables that are used to calculate the next event, effective duration, resource assignment, reward, and operator-memory update:

$$P(x_{t+1} \mid x_{0:t}, a_{0:t}) = P(x_{t+1} \mid x_t, a_t) \quad (10)$$

The Dynamic Deep Four-Layer Q-Network (DD4LQN) does not observe x_t directly. Its compact observation is presented in Eq. (11):

$$o_t = \varphi(x_t) = [b_t^O, b_t^M, g_t] \quad (11)$$

In this case, operator-availability indications are in b_t^O, machine-availability indicators are in b_t^M, and product-operation progress is in g_t. The same output can have varying effective lengths depending on the operator's history. DD4LQN product selection is a partially observable Markov decision process (POMDP), although the simulator is still Markovian in x_t. Only the product identifier is chosen by DD4LQN. The machine-operator pair is assigned using the rule-based Dual Pair Rank using all of the simulator data.

IV. DRL Agent and Training Protocol

A. Action Space and Environment-Step Semantics

The scheduling system is not end-to-end learnt, but rather hybrid. DD4LQN chooses a product from the compact observation o_t described in Section III-F at each decision epoch. The environment maintains the entire internal state x_t for machine-operator assignment, operator-memory updates, duration computation, and feasibility checking. The suggested DD4LQN scheduler is a decision-making process that is event-driven. The AI selects a product ID from a predetermined universe (P1–P20) at each decision point. It identifies the dispatchable job of the product (the subsequent unscheduled activity in compliance with priority restrictions) and chooses the dispatch focus without assigning any machines or operators. The environment keeps moving to the remaining products if the chosen one is already finished or flagged. Additionally, the environment processes completion events to maintain an ongoing weekly timetable. For every dispatchable task assignment attempt, the agent first determines the earliest start time by assessing the viability of each (machine, operator) candidate; DD4LQN does not choose the machine-operator pairing. The candidate interval must respect the weekly horizon as well as the status-log window (machine and/or operator unavailability). Dual Pair Ranking is used as tie break to select the most accurate pairing for a given task, leading to operator task and machine memory calendars being updated after completion. Learning-forgetting updates are only updated at the commit stage to maintain consistent action labels.

The quoted duration is subsequently booked by Quote-then-Commit, which also modifies the operator-task memory, machine calendar, and operator calendar. As a result, the rule-based approach is used for the resource allocation and feasibility check, while the learnt contribution is restricted to the product-level dispatch priority. Thus, the incremental effect of the learned component is evaluated against EDD and SPT product-selection rules while keeping the same scenario, Dual Pair Rank, learning-forgetting model, Quote-then-Commit rule, and tie-breaking convention.

B. DD4LQN Network Architecture

A fixed-size observation vector comprising 1) machine-availability indicators, 2) operator-availability indicators, and 3) fixed product-operation progress windows is sent to DD4LQN. The Q-function is approximated using a grouped feature encoder in a Dynamic Deep 4-Layer Q-Network (DD4LQN). These blocks are processed by distinct operator, machine, and product observation encoders before shared trunk layers combine their outputs. In order to prevent conflict at the first level of representation, this grouping makes sure that job progression and resource availability are caused by various physical factors. An advantage stream and an observation-value stream are created by the dueling head from the Q-values. This enables the network to determine the baseline attractiveness of the compact observation as well as the proportionate benefit of each product activity. This is particularly useful for dispatching, where the learning signal is often driven by fine ranking of actions rather than absolute value, and several actions may be similarly bad under congestion. Fig. 3 outlines the entire architecture to link learning and execution explicitly – at both the policy level and the workforce level.

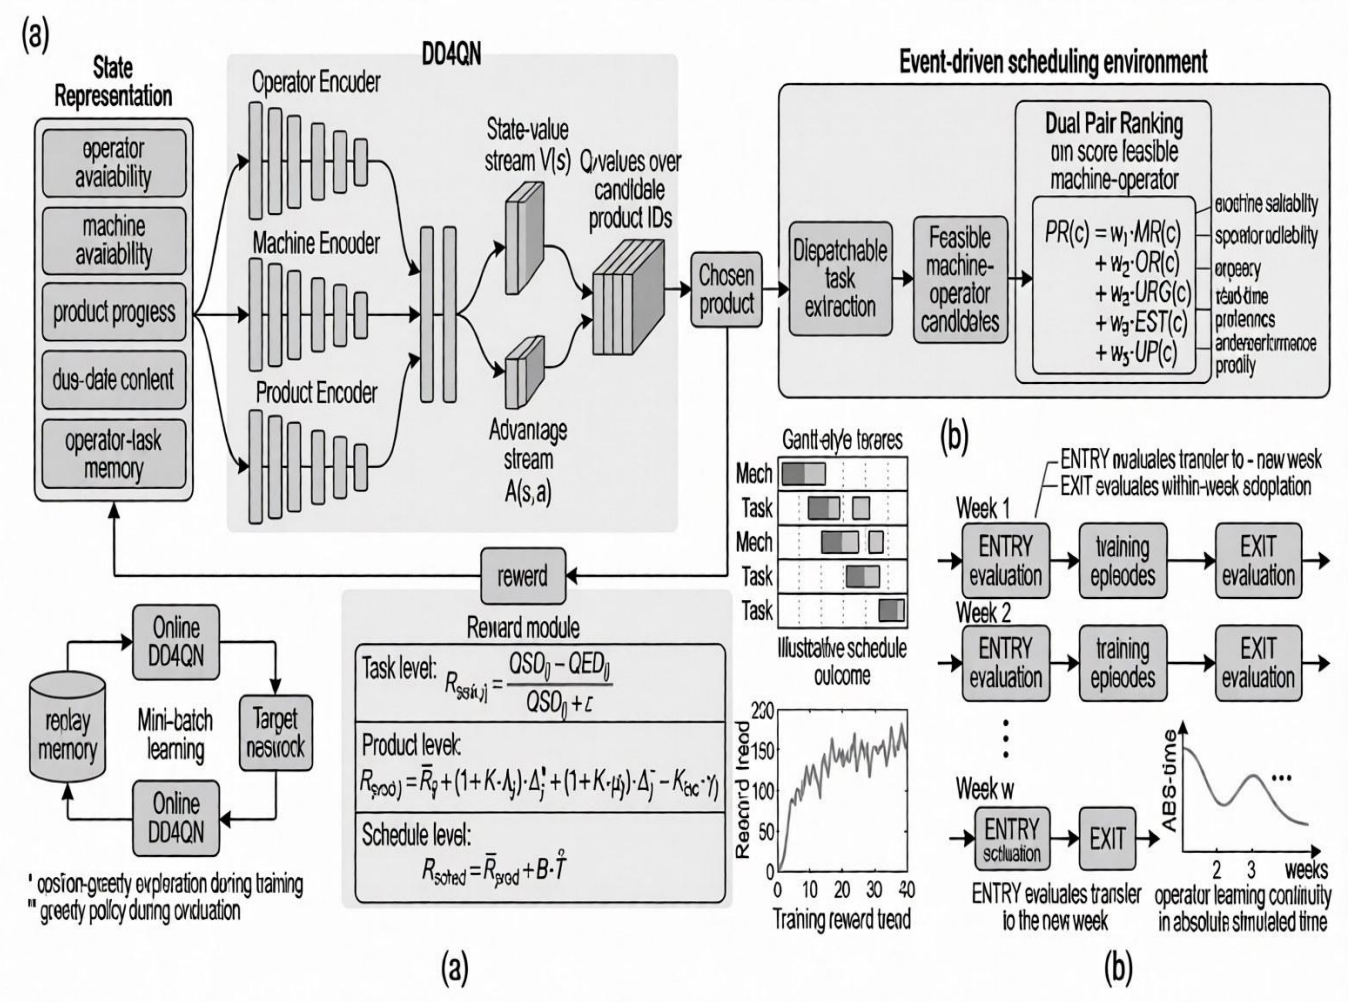

Fig. 3. DD4LQN Architecture and weekly protocol: (a) architecture, environment, ranking, reward, (b) weekly ENTRY/EXIT curriculum and ABS learning continuity.

The compact DD4LQN observation o_t provided to the neural network from the entire internal simulator state x_t utilized by the environment is shown in Fig. 3.

Moreover, Fig. 3 illustrates two interconnected learning loops: a micro loop that lies beneath the ABS-time learning-forgetting continuity during the weekly ENTRY/EXIT evaluations, and a macro-RL loop based on replay memory, minibatch learning, and a target network. The training employs a replay buffer containing 10,000 transitions, prioritized replay, minibatches of 32 samples, γ=0.99, lr=10−4, SmoothL1 loss, and has the target network refreshed every 50 episodes [17], [48]. The curriculum includes ten weekly scenarios, each consisting of 1000 episodes, and the greedy ENTRY/EXIT assessments (with ε = 0) are used to distinguish between within-week adaptation and cross-week transfer.

V. Experimental Setup and Results

A. Reporting Protocol and Logged Indicators

Week 1 is considered the cold-start reference, while week 10 is the late-curriculum reference; the comparison between the two aims to make the learning path comprehensible. Reporting includes numerical representation of schedule viability and resource allocation. This link is established through product- and schedule levels rewards trajectories, ENTRY/EXIT KPI tables, and machine and operator Gantt charts. Reporting includes product tardiness, flagged products, completion rate, sample efficiency (E90), and convergence stability (CV (last20)). These metrics are meant to evaluate training stability, feasibility robustness, adaptation quality and due-date management.

B. Statistical Evaluation Unit

To evaluate algorithmic variability independently of the stochastic environment, every configuration was assessed five times each week (K=5) to determine the degree of variation in each policy's outcomes. During these five rounds, the weekly scenario did not vary, guaranteeing a fair comparison of the policies.

Using the fixed seed 123, ten consecutive weekly scenarios were produced, and the same weekly demand, resource availability, and operating conditions were used to evaluate every policy. The mean (μ) and standard deviation (σ) were computed from the five evaluation runs for each week. The outcomes across the ten weekly means are then summarized in

the cross-week tables. The calculations of μ and σ are defined by Eq. (10) and (11), respectively:

$$\mu = \frac{1}{K}\sum_{1}^{K} Xw,i \qquad (10); \sigma = \sqrt{\frac{\sum_{1}^{K}(Xw,i-\mu)^2}{K}} \qquad (11)$$

Here, Xw,i is the KPI obtained during rollout i of week w (e.g., total tardiness, mean completion rate).

1) Cold-start learning behavior: Week 1: Week 1 is used as the baseline for the agent's behavior during the early stages of exploration when the value targets are unstable. The reward trajectory varies greatly from one episode to the next, exhibiting a weak ENTRY baseline and frequent oscillations, as shown in Fig. 4.

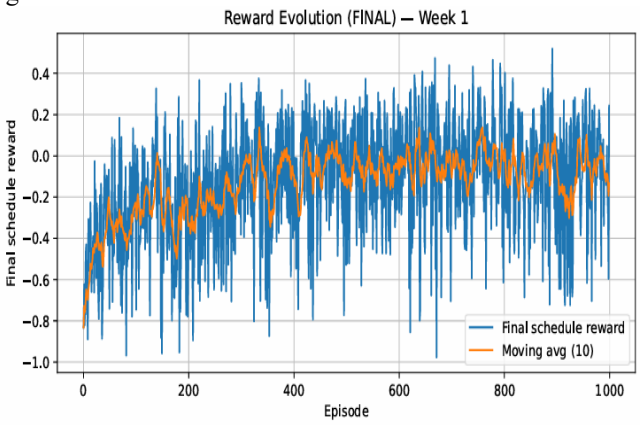

Fig. 4. Week 1 reward evolution.

Fig. 4 indicates that Week 1 emphasizes learning and exploration rather than using an existing scheduling policy. Table II shows the benchmark KPIs under greedy evaluation (ε=0) before and after training to measure this initial behavior. It provides a presentation of the schedule reward, the total tardiness, the number of flagged items, the completion, and the convergence stability CV (last20), as well as the sample efficiency E90.

TABLE II. BENCHMARK KPI SUMMARY FOR WEEK 1

KPI	ENTRY(Ɛ=0)	EXIT (Ɛ=0)
Schedule reward (mean ± std)	-0,8925 ± 0,1948	0,1194 ± 0,1699
Total tardiness (mean ± std)	384,0 ± 192,0	96,0 ± 192,0
Flagged products (mean ± std)	9,40 ± 1,02	5,40 ± 1,02
Completion rate	0,22	0,57
Stability CV (last 20 episodes)	2,415	
Sample efficiency E90 (Episodes)	668	

Overall tardiness decreases from 384±192 to 96±192, while scheduling reward rises from −0.8925±0.1948 at ENTRY to 0.1194±0.1699 at EXIT, indicating a clear within-week learning effect. While flagged products drop from 9.40±1.02 to 5.40±1.02, the completion rate rises from 0.22 to 0.57. However, the convergence indicators remain poor (CV (last20) =2.415, E90=668), suggesting that Week 1 still struggles with early-stage learning instability rather than consolidated policy maturity.

Fig. 5 shows the ideal ABS-time Week 1 product-machine schedule (R=0. 5194).

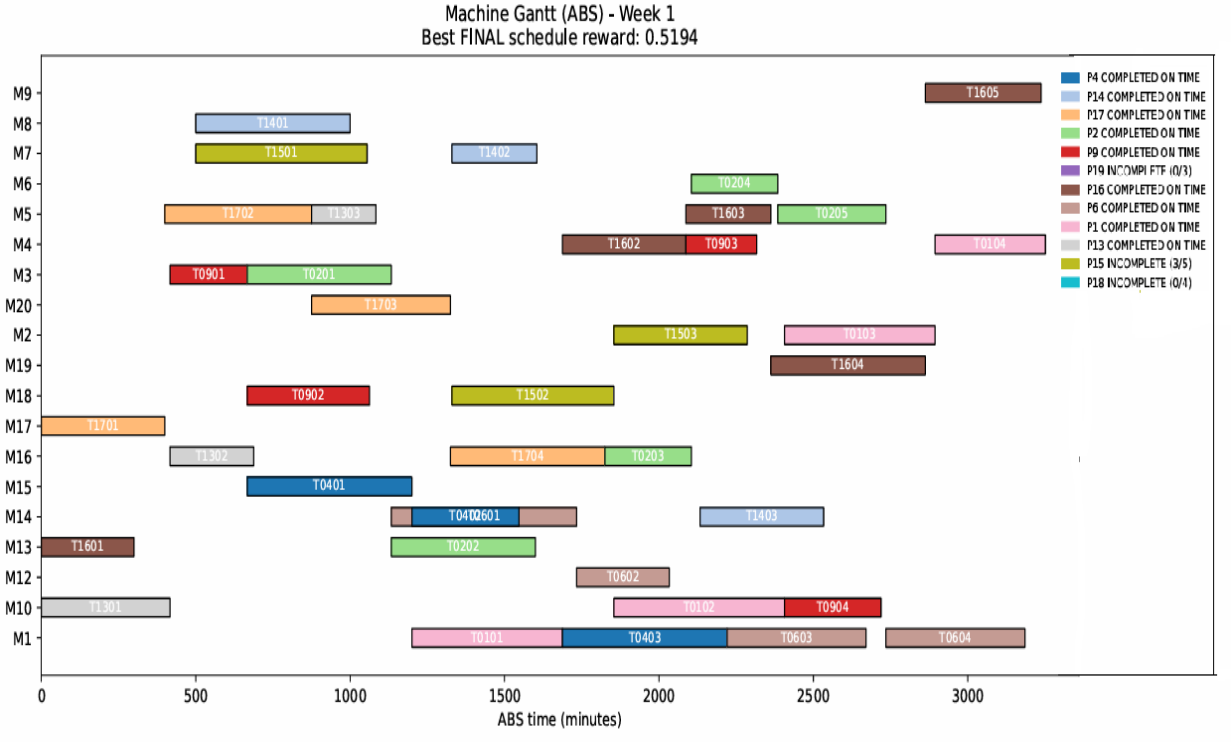

Fig. 5. Product-machine GANTT for week 1.

Since the assignment is highly dependent on both operator and machine availability, Fig. 6 displays the ideal ABS-Time product-operator Gantt for week 1, enabling structural interpretation beyond scalar reward values. This representation is vital to get the full picture of the operator and machine availability checks.

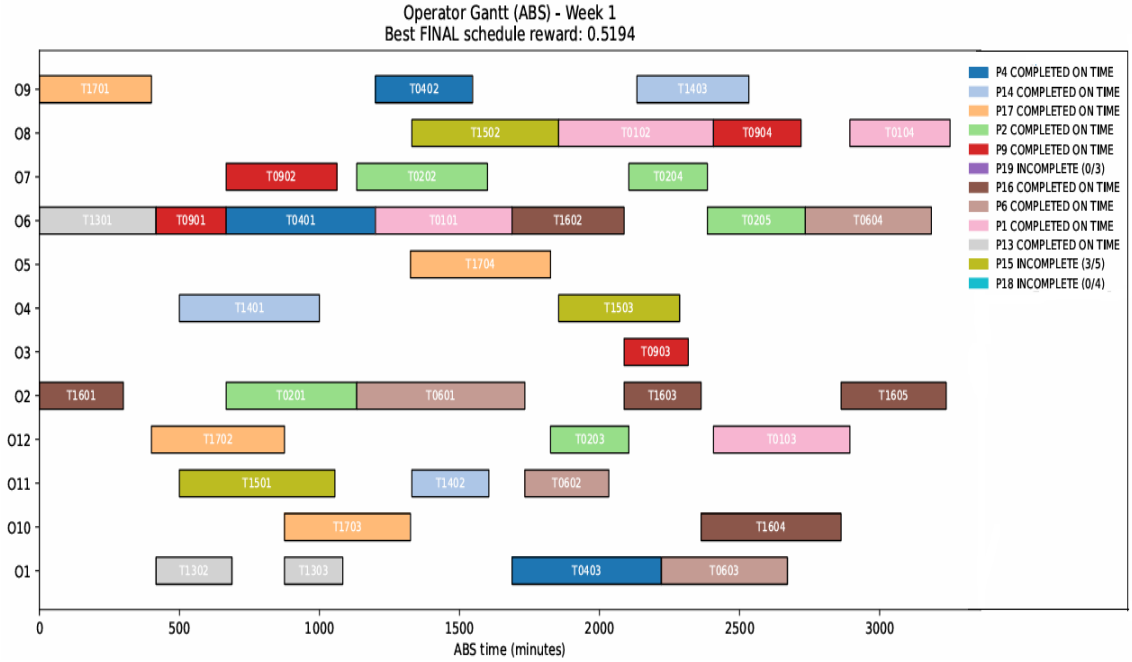

Fig. 6. Product-operator GANTT for week 1.

Fig. 5 and 6 present a structural description of the optimal Week 1 schedule. Feasibility losses are depicted in the product-machine Gantt, indicating dense processing blocks with idle spans due to operators' unavailability. The product-operator Gantt completes the schedule scope by indicating machine-operator cooperation. The best schedule indicates a small percentage of uncompleted products.

This constatation imposes a verification of product reward; Fig. 7 shows whether the product reward is distributed or concentrated on a small number of higher ones.

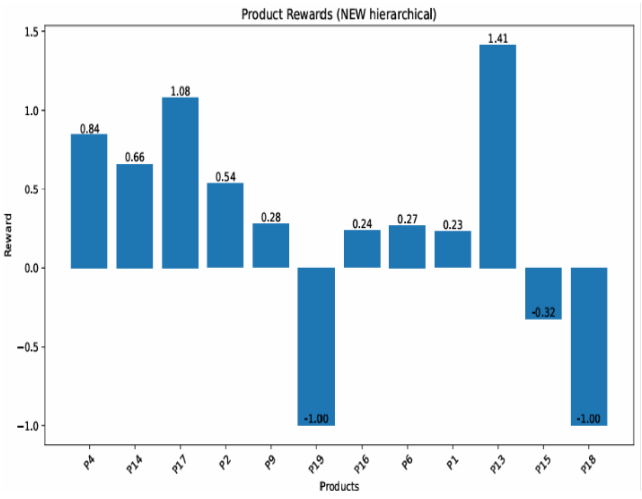

Fig. 7. Week 1 best schedule product rewards.

Fig. 7 illustrates a bimodal distribution of product rewards. High-performing products such as P13 = 1.41 and P17 = 1.08 demonstrate successful end-to-end routing, while unfinished items receive severe rewards (P15 = −0. 32, P19 = −1, P18 = −1).

When combined, Table II and Fig. 5 and 6 show that EXIT gains are a sign of broader completion improvements.

2) Late-curriculum learning behavior: Week 10: Under disrupted dual-resource conditions, the schedule reward trajectory in Fig. 8 is the first sign that the agent goes from week-specific adaptation to a certain setting to steady convergence and reliable cross-week transfer. The late-curriculum benchmark is Week 10 present a smoother pattern of the schedule reward evolution that remains concentrated at a much higher mean level. This presents an improvement from the extremely erratic low-level curve displayed in Week 1.

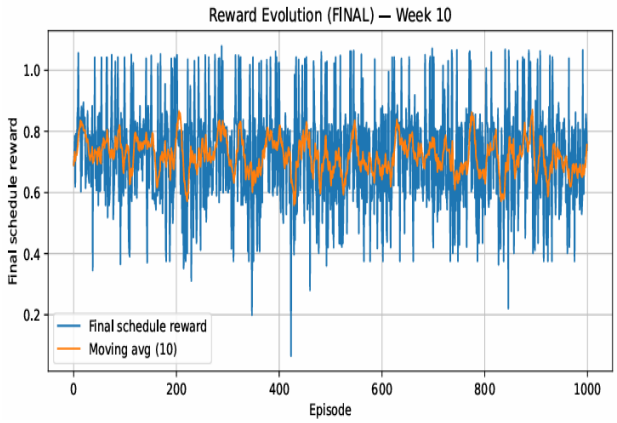

Fig. 8. Week 10 reward evolution.

This figure clearly illustrates a shift from exploration-driven instability to policy-driven patterns.

To get a full picture, our analysis includes the Week 10 ENTRY/EXIT benchmark KPIs under greedy evaluation (ε=0) summarized in Table III.

TABLE III. BENCHMARK KPI SUMMARY FOR WEEK 10

KPI	ENTRY(Ɛ=0)	EXIT (Ɛ=0)
Schedule reward (mean ± std)	0.6520 ± 0.1925	0.9521 ± 0.1031
Total tardiness (mean ± std)	288.0 ± 235.2	96.0 ± 192.0
Flagged products (mean ± std)	3.80 ± 0.75	2.40 ± 0.49
Completion rate	0.71	0.82
Stability CV (last 20 episodes)	0,188	
Sample efficiency E90 (Episodes)	9	

Week 10 begins with a stronger foundation than Week 1, as evidenced by the ENTRY schedule reward, which is already 0.6520 ± 0.1925 (higher that week 1 schedule reward by the ENTRY: -0,8925 ± 0,1948) and rises significantly to 0.9521 ± 0.1031at EXIT (higher that week 1 schedule reward by the EXIT: 0,1194 ± 0,1699). The completion rate rises from 0.71 to 0.82 (higher than week 1 values, which went from 0.22 to 0.57). The total tardiness goes from an ENTRY value of 288.0 ± 235.2 to an EXIT value of 96.0 ± 192.0, compared to a decrease in tardiness for week 1 from 384±192 to 96±192. Furthermore, products that are flagged decrease from 3.80 ± 0.75 to 2.40 ± 0.49, compared to Week 1 flagged product evolution 9.40±1.02 to 5.40±1.02.These observations remain consistent with the much lower convergence variance reported for Week 10 (CV(last20)=0.188, E90=9) compared with the Week 1 previously displayed value (CV(last20)=2. 415, E90=668).

Similarly, Fig. 9 shows the ideal ABS-time Week 10 product-machine schedule (R=1. 0782). To complete the visual display in accordance with dual resource availability. To complete the visual display in accordance with dual resource availability, Fig. 10 displays the ideal ABS-Time product-operator Gantt for week 10.

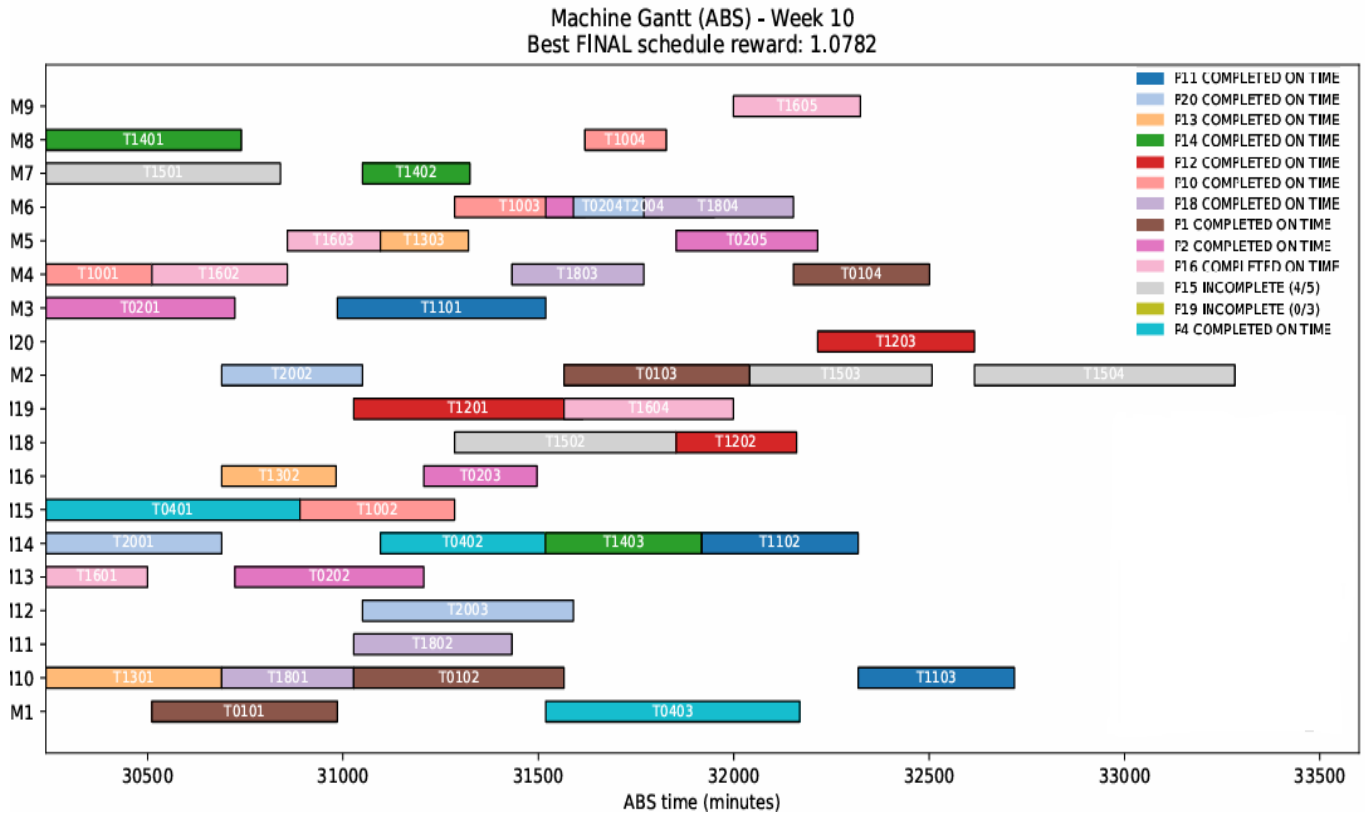

Fig. 9. Product-machine GANTT for week 10.

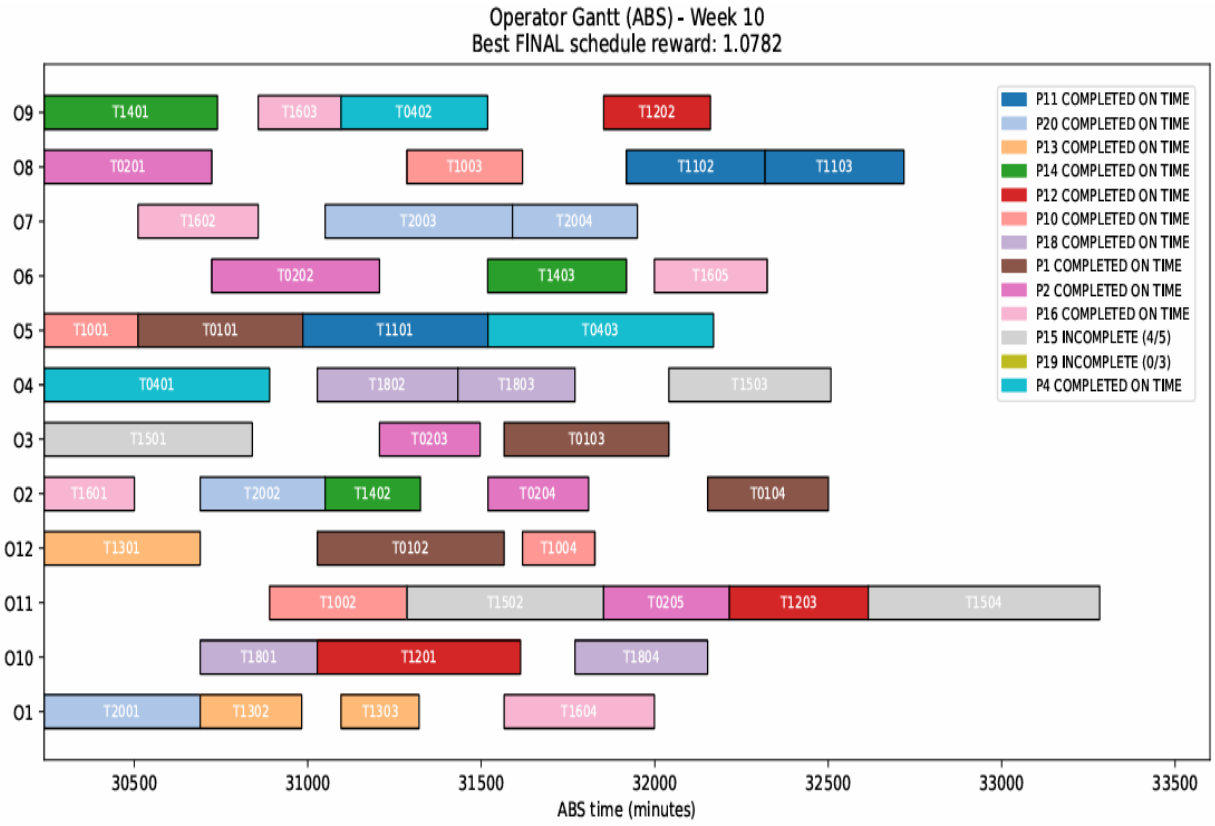

Fig. 10. Products-operator GANTT for week 10.

Fig. 9 displays a more rational machine-capacity allocation than in Week 1; in the best schedule displayed, all 11 items are completed on time, which is in line with Table III's results. The complementary operator-side perspective in Fig. 10 confirms that this result is achieved through practical machine-operator coordination rather than hidden overload or conflicts. The product reward of the 10th week distribution is depicted in Fig. 11, just like in week 1.

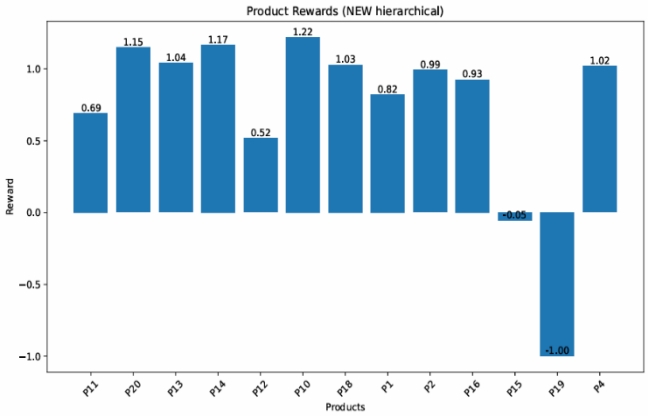

Fig. 11. Week 10 best schedule product rewards.

With several products grouped around reward values going from 0.52 to 1.22, with the exception of P15=-0,05 and P19=-1, the distribution in the figure is consistently favorable. This is a major improvement over the bimodal Week 1 pattern, where incomplete items faced severe penalties and a small number of products received strong positive rewards. As a result, Fig. 11 demonstrates that by Week 10, the policy improves feasibility and reward quality across the entire weekly mix rather than just the most basic products.

C. Cross-Week Benchmark Comparison: DD4LQN-EXIT, EDD, and SPT

We performed a post-hoc comparison between the trained DD4LQN policy and two common dispatching rules: Earliest Due Date (EDD) and Shortest Processing Time (SPT). While maintaining the same downstream scheduling processes, the experiment isolates decision-making at the product level. Each policy chose the subsequent product to be processed at each decision event:

- DD4LQN-EXIT: Applied the Deep Q-Learning policy that had been trained.
- EDD: The active product with the earliest local deadline was chosen.
- SPT: The product with the shortest nominal processing time was chosen.

Everything else in the system was maintained strictly the same across five test runs in order to maintain test fairness. The rules for selecting machine-worker pairs, managing breaks, monitoring worker skill loss, establishing deadlines, breaking ties, and computing scores were the same for each choice, and their weekly performance is displayed in Fig. 12.

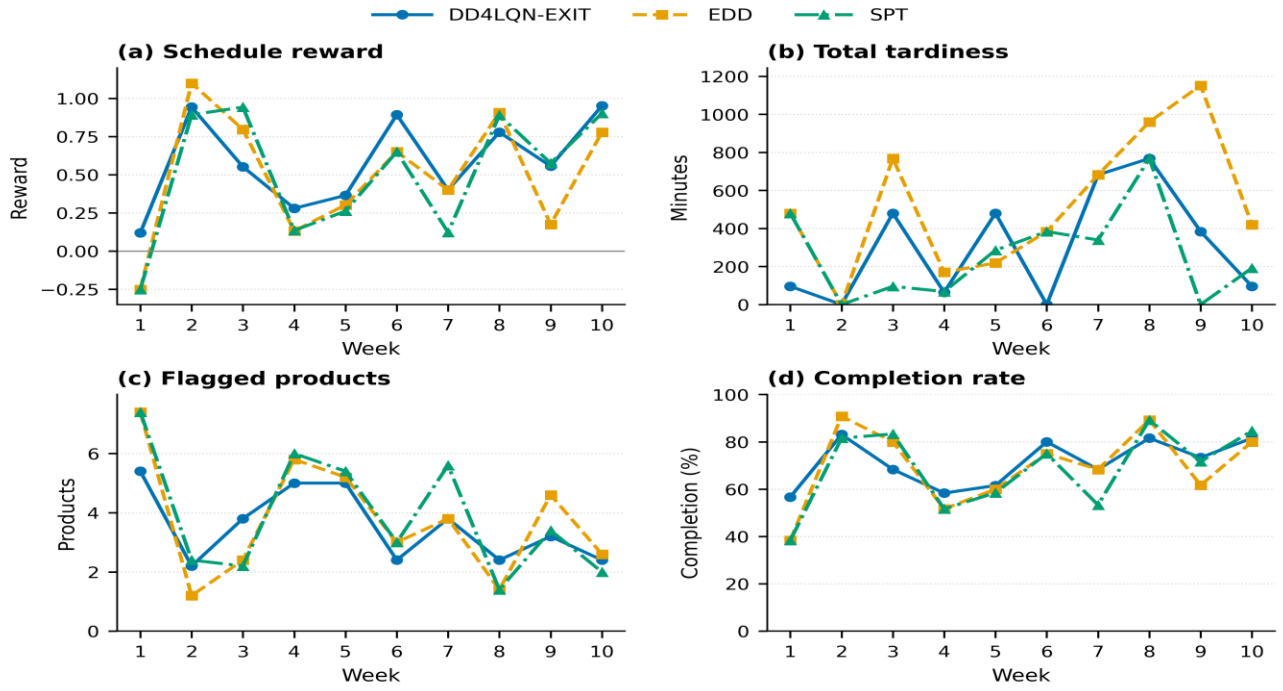

Fig. 12. Weekly performance of DD4LQN-EXIT, EDD, and SPT under identical downstream scheduling conditions. Each data point reflects the mean of five evaluation rollouts.

Fig. 12 shows that DD4LQN-EXIT outperforms baseline heuristics in terms of performance stability and balance throughout 10-week scenarios across all four evaluation metrics. SPT prioritizes short jobs to reduce tardiness during low-demand weeks, but under high workloads, it experiences important losses. On the other hand, during interruption events, EDD faces significant reward declines and significant tardiness spikes (exceeding 900 minutes in Weeks 8 and 9). By limiting overall tardiness, continuously reducing risk-flagged items (~5.5 in volatile Week 1 compared to >7 for EDD and SPT), and sustaining superior completion rates under high-workload conditions (~57% versus <40%), DD4LQN-EXIT reduces these failure modes.

Thus, robust multi-objective schedule stability is ensured by learnt product selection, which eliminates localized trade-off extremes. Table IV offers a thorough quantitative comparison of all rollouts by summarizing the whole ten-week aggregate metrics.

TABLE IV. CONTROLLED TEN-WEEK COMPARISON OF PRODUCT-SELECTION POLICIES

KPI	DD4LQN-EXIT	EDD	SPT
Schedule reward (higher)	0.5843 ± 0.2963	0.4995 ± 0.4173	0.5126 ± 0.4201
Total tardiness, min (lower)	305.0 ± 289.7	523.5 ± 364.3	261.3 ± 243.2
Flagged products (lower)	3.56 ± 1.23	3.74 ± 2.00	3.88 ± 2.05
Completion rate, % (higher)	71.27 ± 10.13	69.50 ± 16.78	68.72 ± 17.18

DD4LQN-EXIT had the best multi-objective balance over the course of the ten-week test. It increased completion by 1.77 percentage points, decreased mean tardiness by 41.7%, and outperformed EDD by 17.0% in schedule reward. DD4LQN-EXIT increased schedule reward by 14.0%, reduced risk-flagged goods by 8.2%, and increased completion by 2.55 percentage points in comparison to SPT. Although SPT produced the lowest average delay (261.3 vs. 305.0), incomplete orders are not included in this statistic. Prioritizing short, simple tasks leads to a lower total completion rate (68.72%), which is the reason for SPT's lower tardiness. In the end, learnt product selection provides the most consistent overall performance under dynamic shop conditions and avoids the failure modes of single-rule heuristics.

D. Exploratory Component Ablation Study

Table V uses the same ten frozen weekly scenarios created with seed 123 to compare the whole framework (whole) with three runtime ablations. Demand, due dates, disruptions, and resource availability are all held constant while five matching rollouts are averaged for each weekly value. DD4LQN solely chooses the product. Resource allocation is still determined by established standards. The earliest possible pair is chosen in the absence of Dual Pair Rank (NO_DPR). Duration is computed at commitment in the absence of Quote-then-Commit (NO_QTC). Operator performance is unchanged in the absence of Learning–Forgetting (NO_BLLF).

TABLE V. CONTROLLED ABLATION OF THE PROPOSED FRAMEWORK

Configuration	Controlled modification	Schedule reward, mean (Δ)	Completion rate, % (Δ)	Tardiness, min (Δ)	Flagged products (Δ)
FULL	**All components active**	0.584 (reference)	71.27 (reference)	305.02 (reference)	3.56 (reference)
NO_DPR	**Replace Dual Pair Rank with a deterministic feasible-pair rule**	0.437 (−25.2%)	66.83 (−4.44 pp)	315.40 (+3.4%)	4.08 (+0.52)
NO_QTC	**Recompute duration at commitment**	0.584 (0.0%)	71.27 (0.00 pp)	305.02 (0.0%)	3.56 (0.00)
NO_BLLF	**Hold operator performance constant**	−0.051 (−108.8%)	53.09 (−18.18 pp)	485.44 (+59.2%)	5.80 (+2.24)

Note: FULL serves as the benchmark for changes. In contrast to lesser tardiness and fewer flagged products, higher rewards and completion are desirable.

Table V shows that NO_DPR decreased completion overall and decreased reward each week. This outcome distinguishes the two scheduling levels: Dual Pair Rank enhances the succeeding machine-operator assignment, whereas DD4LQN gives the product precedence. The biggest degradation was produced by NO_LLF, demonstrating the significance of operator-performance history. Since NO_QTC did not result in a change in KPIs, its observed contribution was duration consistency and auditability.

E. Weight Interpretation and Policy Representation

A thorough examination of the final DD4LQN model checkpoint (227, 717 parameters across 28 tensors) verifies that the neural network topology is robust, well-conditioned, and free of representation collapse. Important findings include:

- Balanced Weight Distribution: All layer parameter means are close to zero (-0.0094 to 0.0006). The time encoder exhibits a greater raw weight variation (0.2385) than the machine (0.0904), operator (0.0950), and product (0.0554) encoders; nevertheless, this is solely dependent on the amount of the input.
- Normalized Variance: All feature encoders' weight variance closely aligns between 0.554 and 0.604 when scaled by input dimensions (fan-in), matching typical initialization baselines. Both the dueling output streams and the core network trunk retain consistent, small weight spreads (0.0362–0.0378).
- High Representation Capacity: Layer matrices show that the network preserves rich feature diversity instead of collapsing into redundant patterns, retaining between 77.2% and 98.2% of their maximum possible rank.

Although they address parameter geometry rather than training dynamics or feature significance, these structural tests verify appropriate network health and capacity use.

VI. CONCLUSION AND FUTURE WORK

This study introduced a human-aware Deep Reinforcement Learning framework (DD4LQN) to solve scheduling problems in dual-resource flexible job shops with unpredictable events. By using Bounded Logistic Learning and Forgetting (BLLF) patterns and Dual Pair Ranking (DPR) tasks, the approach connects performance with automated decisions. Over ten weeks, our framework showed overall better performance than traditional dispatching rules (EDD and SPT). DD4LQN-EXIT achieves the highest schedule reward, minimizes risk-flagged products, and maximizes job completion rates during high-workload periods. Even though SPT had the shortest average delay, it did so by focusing on short tasks and not completing as many jobs. EDD exhibited severe tardiness peaks and reward losses during dynamic disruptions. The proposed framework successfully avoided these extreme failure modes, proving that learned product selection delivers robust multi-objective schedule stability under dynamic shop-floor conditions. The exploratory ablation study associated learning-forgetting dynamics and Dual Pair Rank with improved scheduling outcomes in the tested scenarios, but Quote-then-Commit did not result in any change in KPIs, and hierarchical reward shaping did not demonstrate any independent advantage over the retrained simple-reward policy.

With these good results, some problems still exist. First, the learning and forgetting rates for workers were made using situations instead of real data from factories. Second, the current setup does not include real-life issues like setup times between tasks, delays in moving materials, machine repairs, and working with more than one person. Finally, even though the way tasks are ranked makes decisions clear and easy to check, the policy was tested as one part of the system and not as a solution for all parts.

Future work will focus on addressing these limitations to ensure a larger scope of this framework application. The first step is to use data from factories to make the learning and forgetting rates more accurate. Furthermore, the manufacturing limitations will be expanded in future simulations to include logistical routing, setup times, and intricate multi-worker processes. Finally, investigating the transition from the existing reinforcement learning architecture to a multi-agent architecture will be considered.

***Abstract*—The emergence of Generative Artificial Intelligence (GenAI) technology is changing the ways of assessment and feedback procedures in higher education institutions by allowing for a more flexible and personalized process of learning. However, the effective use of GenAI requires pedagogic design, governance, and implementation strategies. The current study will discuss the institutional prerequisites to implement GenAI in assessment and feedback procedures (Activity A2.2 of the Erasmus+ HEGenAI project). Empirical data were gathered using structured questionnaires completed by educators (n=61) and students (n=254). The descriptive approach involving frequencies, percentages, means, and standard deviations helped to investigate current usage of AI-supported assessment procedures, institutional requirements for GenAI adoption, ways of implementing GenAI, educational advantages of GenAI, and associated risks. The results showed that while GenAI is used extensively to facilitate assessment-related processes, the usage remains predominantly informal and non-institutionalised. It is argued that there is a need to use licensed GenAI solutions, to train educators, to redesign assessment processes, and also to develop an appropriate governance framework. Academic integrity, critical thinking, and AI dependency emerged as the most important risks requiring human attention.**

Keywords*—Generative AI; assessment; feedback; higher education; academic integrity; formative assessment; institutional readiness

I. Introduction

The rapid evolution of Generative Artificial Intelligence (GenAI) has become one of the most important trends in modern higher education. Large Language Models (LLMs) such as ChatGPT, Microsoft Copilot, Gemini, Claude, and many others, which initially were limited to content creation, have already evolved and casn be used for numerous activities, especially for assessment and feedback purposes. The capability of providing instant and personalized answers opened up new possibilities to enhance the quality of formative assessment, to facilitate feedback provision, to encourage self-regulated learning, and to relieve educators from extra administrative burden [1] – [5].

The use of GenAI in assessment and feedback goes far beyond automation. Recent research shows that the role of AI should be to assist, but not replace, human academic judgment through authentic assessment, feedback, evaluative judgment, and feedback literacy [6]-[9]. As opposed to paying attention only to efficiency in grading, the current state of the art is aimed at the design of assessment practices that foster critical thinking and high cognitive functions, transparency, and proper use of AI [10]-[13]. In this context, teachers are not the sources of knowledge anymore; they become creators of learning tasks, while students begin interacting with AI, which serves as the agent for learning, reflecting, revising, and creating knowledge independently [10]-[13].

There are also some challenges in implementing GenAI for assessment purposes in universities, however. For example, among the challenges universities encounter when using GenAI for assessment are the issues of governance, ethical use of technology, integrity of the process of assessment, privacy of the data, readiness of educators, and absence of implementation frameworks. While students and educators actively employ the existing open-source AI technologies, higher education institutions often do not have proper policies and pedagogical recommendations related to technological advances [9], [12], [14].

Recognizing these difficulties, the Erasmus+ KA220-HED project HEGenAI – Generative AI for Assessment and Feedback in Higher Education Cooperation aims at developing evidence-based pedagogical models, institutional guidelines, and assessment frameworks for responsible GenAI integration into higher education. Within this project, activity A2.2 is focused on the identification of existing institutional practices, needs for implementation, educational possibilities, and risks of AI-assisted assessment and feedback.

This study provides empirical results from the Mediterranean University of Albania (MUA) as evidence to assist in the creation of institutionally governed GenAI-supported assessment and feedback practices. Instead of analyzing only the process of technology adoption, this study identifies institutional prerequisites for sustainable AI adoption, including technological readiness, assessment redesign, support for educators, mechanisms of governance, and ethical adoption. This study answers the following five research questions to assist further development of pedagogical scenarios and institutional recommendations in the HEGenAI project:

RQ1. What GenAI tools can be integrated into assessment and feedback?

RQ2. What institutional and pedagogical prerequisites ensure GenAI adoption?

RQ3. How should GenAI be integrated into assessment and feedback?

RQ4. What educational advantages can GenAI bring to assessment and feedback?

RQ5. What implementation challenges and risks should be considered by higher education institutions?

Answering these questions provides empirical information regarding the design of a human-centric, pedagogically valid, and ethical GenAI-enabled assessment and feedback ecosystem in higher education, offering guidelines for institutions that want to incorporate AI into their teaching, learning, and assessment processes.

II. Literature Review and Related Work

Recent institution-level research shows a recurring gap between rapid individual adoption of GenAI and the slower development of formal university governance. At the University of Liverpool, a survey of 2,555 students found that 50.9% had used or considered generative AI for academic purposes, while 41.1% explicitly preferred a university-wide policy clarifying acceptable use [14]. A large technical-university survey similarly reported strong student demand for integration and for institutionally supported tools grounded in reliable university-level materials [15]. These findings suggest that adoption is increasingly driven from the learner level upward, while institutional rules, access arrangements, and assessment designs often follow later.

Dual-perspective evidence is particularly relevant to the present study. Kim et al. surveyed 982 students and 76 faculty members and found that approximately 80% supported the development of formal university policies for GenAI use; at the same time, roughly 70% of both groups reported using GenAI less than once per week [16]. This combination of policy demand and still-variable use indicates that institutional readiness cannot be inferred from tool availability alone. It requires governance, staff and student literacy, and pedagogically explicit boundaries for acceptable use.

Institutional policy analyses reinforce this interpretation. An et al. examined guidelines from leading U.S. universities and reported that 94% of the institutions studied had faculty-facing guidance emphasizing the establishment and communication of course-specific GenAI policies [17]. Earlier work also stresses human verification, assessment redesign, feedback literacy, and academic-integrity safeguards [9]-[13]. However, much of the literature either concentrates on student perceptions, policy documents, or broad pedagogical implications in isolation. Fewer studies combine educator and student evidence from the same institution and organize the analysis directly around tools, prerequisites, integration models, educational benefits, and risks. The present study addresses this gap through parallel surveys at MUA and uses the resulting institutional baseline to support implementation decisions within the HEGenAI project.

III. Methodology

A. Study Design

This research has used an exploratory and descriptive quantitative approach to investigate the institutional context of implementing Generative Artificial Intelligence (GenAI) in higher education assessments and feedback. The research has been carried out within Activity A2.2 of the Erasmus+ KA220-HED HEGenAI project and covered the current trends of implementation, the institutional and pedagogical needs, desired ways of implementation, potential educational advantages, and risks. Two similar surveys have been distributed via Google Forms among educators and students. The approach chosen is aimed at creating an empirical foundation for the development of future GenAI-assisted scenarios of assessment and feedback.

B. Sample

The participants of the study consisted of individuals from all four faculties of the Mediterranean University of Albania. In terms of the educator group, there were 61 respondents, including: Law and Human Sciences (n=20; 32.8%), Economic Sciences (n=16; 26.2%), Informatics (n=15; 24.6%), and Medical Sciences (n=10; 16.4%). As for the student group, there were 254 respondents, which included: Informatics (n=101; 39.8%), Law and Human Sciences (n=64; 25.2%), Economic Sciences (n=54; 21.3%), and Medical Sciences (n=35; 13.8%). Thus, thanks to multi-disciplinary participation, it was possible to identify GenAI assessment and feedback practices within the fields characterized by different traditions of pedagogy and varying degrees of technological intensity of tasks. The full demographic breakdown is presented in Table I.

TABLE I. Demographic Profile of Survey Participants (Educators N = 61; Students N = 254)

Characteristic	Category	Educators (n = 61)	Students (n = 254)
Age	18–20 / <28	1 (1.6%)	89 (35.0%)
	21–23	—	63 (24.8%)
	24–26	—	29 (11.4%)
	27+	—	73 (28.7%)
	29–35	11 (18.0%)	—
	36–45	28 (45.9%)	—
	46–55	6 (9.8%)	—
	56–65	11 (18.0%)	—
	66+	4 (6.6%)	—
Experience (educators)	<5 years	5 (8.2%)	—
	5–10 years	18 (29.5%)	—
	11–20 years	28 (45.9%)	—
	21+ years	10 (16.4%)	—
Study cycle (students)	Bachelor	—	182 (71.7%)
	Master	—	50 (19.7%)
	Professional diploma	—	15 (5.9%)
	Doctorate	—	7 (2.8%)
Faculty	Law & Human Sciences	20 (32.8%)	64 (25.2%)

Characteristic	Category	Educators (n = 61)	Students (n = 254)
	Informatics	15 (24.6%)	101 (39.8%)
	Economic Sciences	16 (26.2%)	54 (21.3%)
	Medical Sciences	10 (16.4%)	35 (13.8%)

Convenience sampling technique was applied for all participants following the exploratory nature of the study and the A2.2 research design [7]. The educators and students served as the main actors in the process of evaluation and feedback, which allowed for collecting data on the experiences related to the application and management of GenAI tools.

C. Instruments and Analysis

These surveys were made up of four parts: 1) demographic data; 2) multiple choice questions indicating the types of GenAI technologies employed or allowed and the assessment and feedback activities where they were used; 3) 5-point Likert scale questions relating to institutional needs and training needs (question 9), impact (question 13), benefits in education (question 14), and implementation risks (question 15); and 4) open-ended questions related to the risks of GenAI implementation and the undesirable practices in relation to GenAI. These two surveys were consistent with the five research questions and were developed to explore the role of GenAI in assessment design, feedback provision, learning support, and human judgment.

The analysis remained descriptive throughout. Frequencies and percentages were calculated for categorical and multiple-response variables, while means (M) and standard deviations (SD) were calculated for the five-point Likert items. Findings were organised according to the five research questions so that the results could inform the selection of tools, institutional support measures, pedagogical integration models, impact indicators, and risk-mitigation strategies for GenAI-enhanced assessment and feedback. No inferential tests were conducted at this exploratory stage. Because convenience sampling was used, educator-student differences are interpreted descriptively and are not presented as statistically generalisable group effects. All reported quantitative findings derive exclusively from the educator (n = 61) and student (n = 254) survey datasets held in the project record.

D. Methodological Limitations

The use of convenience sampling limits the generalisability of the findings beyond the participating respondents, the wider MUA community, and other institutional contexts. The results should therefore be interpreted as an institutional baseline for the design and piloting of GenAI-supported assessment and feedback practices rather than as representative estimates of higher education as a whole.

Furthermore, the research uses self-reporting data that might be subject to distortion due to memory lapses and social desirability bias, especially when students report their experiences with GenAI use in graded assessments and other academic activities. Furthermore, due to its descriptive nature, the design is not able to show how the application of GenAI contributes to feedback quality, learning, and assessment validity.

IV. Findings

A. RQ1 — What GenAI Tools Can Be Integrated?

From the findings, GenAI-enabled assessment and feedback at MUA seems to be carried out via a diverse range of platforms. ChatGPT appears to be the most common generative platform among both students and instructors, whereas the differences between the two groups are seen more clearly on the Turnitin platform.

1) Most frequently used GenAI tools: The distribution of the most frequently used GenAI tools is reported in Table II and visualised in Fig. 1.

TABLE II. Most Frequently used GenAI Tools (% of Respondents, Multi-Select; Educators n = 61, Students N = 254)

Tool	Educators (n = 61)	Students (n = 254)
ChatGPT	78.7%	83.1%
Gemini (Google)	36.1%	41.3%
Turnitin	47.5%	4.7%
Claude.ai	31.1%	16.1%
Microsoft Copilot	24.6%	17.7%
DeepSeek	9.8%	8.7%
Grok (xAI)	6.6%	9.1%
NotebookLM	11.5%	—
Perplexity	1.6%	5.5%

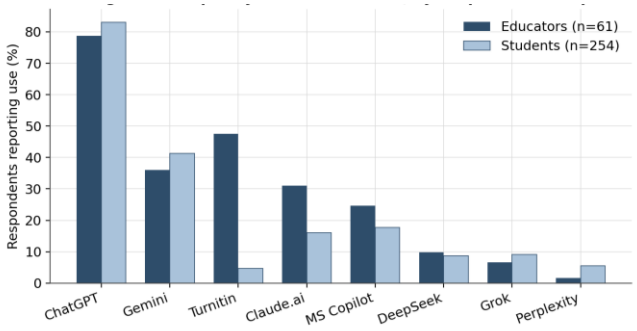

Fig. 1. Generative AI tool use frequency, by respondent group (% of respondents selecting each tool; multi-select; educators n = 61, students n = 254).

In aggregate, the tool use pattern reflects a complementary system of assessment. While conversational systems like ChatGPT, Gemini, Claude.ai, and Microsoft Copilot are mostly employed to assist in ideation, explanation, drafting, and formative feedback, Turnitin is primarily utilised for integrity checks and assessment validation purposes. Hence, the practical recommendation would be that institutional adoption of the tools should not revolve around one particular system but rather should include the combination of generative assistance with transparency, verification, and academic judgment by humans. Indeed, this practice corresponds to the international findings of ChatGPT being the leading point of entry into GenAI-based learning and assessment [8].

2) Technologies that are currently integrated/permitted for assessment and feedback: For the educators, the technologies integrated or permitted for use were listed as: Turnitin (42.6%), ChatGPT (32.8%), "None – not yet permitted" (16.4%), Gemini (14.8%), and Claude.ai (11.5%). For the students, there is confusion: "I don't know" (45.7%), "ChatGPT/Copilot" (23.2%), "No specific technology" (22.8%), and "Turnitin AI detector" (4.7%).

While on one hand, there is the difference between the 16.4% who stated that the use of GenAI tools is not allowed, and on the other hand, the 45.7% who don't even know what can be used; there is definitely some kind of gap in terms of governance and communication for conducting assessments [9]. There have been instances of informal use, but the parameters of allowed use have not been well known to the students. As a matter of fact, until the use of GenAI becomes part of the assessment and feedback process, MUA must define what is allowed and the consequences of using it.

B. RQ2 — What Do Educators and Students Need for GenAI Integration?

The ninth item (Likert Scale 1 to 5, where 1 represents strongly disagree and 5 represents strongly agree) was employed to determine the requirements for responsible GenAI-driven assessment and feedback.

1) Educators (n = 61): Educators' institutional and training needs are summarised in Table III, and the corresponding mean scores with standard deviations are shown in Fig. 2.

TABLE III. EDUCATORS' PERCEIVED INSTITUTIONAL AND TRAINING NEEDS (ITEM 9, 1–5 LIKERT SCALE, N = 61)

Statement	M	SD	N
The university should provide institutional access (premium licence) to GenAI tools	4.34	0.93	61
Using GenAI requires redesigning assessment methods (process-based, not only final product)	4.05	1.01	61
GenAI can substantially improve the quality and speed of feedback	3.98	1.07	61
I need professional training on prompt engineering and GenAI ethics	3.36	1.45	61

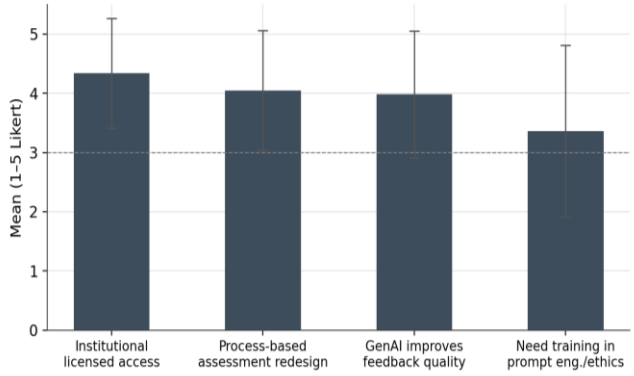

Fig. 2. Educators' perceived institutional and training needs (Item 9), means with standard deviation (1–5 Likert scale; n = 61).

2) Students (n = 254): Students' corresponding institutional and training needs are reported in Table IV.

TABLE IV. STUDENTS' PERCEIVED INSTITUTIONAL AND TRAINING NEEDS (ITEM 9, 1–5 LIKERT SCALE, N = 254)

Statement	M	SD	N
Students and educators need clear guidelines for integrating GenAI without compromising academic integrity	3.41	1.29	254
The university should provide institutional access (licence) to GenAI tools	3.19	1.29	254
I need training on the ethical and safe use of GenAI	2.93	1.36	254
I need faster, more personalised feedback using GenAI	2.82	1.22	254

Institutional access emerges as the strongest enabling condition, particularly among educators (M = 4.34, SD = 0.93), followed by the need to redesign assessment around learning processes rather than final products (M = 4.05, SD = 1.01). Students also prioritise clear guidance for using GenAI without compromising academic integrity (M = 3.41, SD = 1.29). These results indicate that sustainable implementation depends on more than access to technology: it requires coordinated licensing, explicit rules, staff development, and assessment designs that make student reasoning and revision visible. The lower and more dispersed student ratings may reflect their existing reliance on freely available tools outside institutional systems, while educators experience the responsibility for assessment quality, accountability, and data protection more directly [9].

C. RQ3 — How Should GenAI Tools Be Integrated into Pedagogical Practice?

Items 6 and 7 (frequency and activities), together with item 10 (preferred integration models), show how GenAI is currently entering assessment-related work and which role it should occupy in future pedagogical practice.

1) Frequency of use: The frequency patterns for educators and students are presented in Table V.

TABLE V. FREQUENCY OF GENAI USE, BY RESPONDENT GROUP (% OF RESPONDENTS; EDUCATORS N = 61, STUDENTS N = 254)

Educators (n = 61)	%	Students (n = 254)	%
Several times a week	32.8%	Sometimes (3)	40.9%
Several times a month	26.2%	Often (4)	26.4%
Rarely	19.7%	Rarely (2)	19.3%
Every day	14.8%	Almost every day (5)	8.7%
Rarely or never / Never	6.5%	Never (1)	4.7%

2) Main usage activities: The current deployment seems to be more inclined toward actions aimed at preparation, learning, and feedback, and not at the automation of the summative judgment process. Teachers tend to utilize GenAI in such tasks as literature searching and summary writing (67.2%), case study generation (54.1%), data processing (37.7%), and preparation of lectures and seminars (34.4%). Students tend to use GenAI for literature research (56.7%), coursework and projects (52.4%), exam preparation (31.5%), and programming or other technical tasks (around 27.6% in total). Thus, we may say that GenAI operates as a layer of pre-assessment and feedback preparation.

Thus, the findings indicate that GenAI operates as the layer of pre-assessment and feedback preparation.

3) Most preferred integration model: GenAI as a tool for writing and idea generation was the most commonly favored model by both the educators and the students. In the students' responses, 41.3% selected it as a sole answer to the question, while educators preferred it more often as a standalone option or in conjunction with other conditions. Other conditions included human verification, GenAI use outside of assessment situations, and use in groups. This result reveals a preference for the bounded integration model whereby GenAI can be utilized in the process of assessment but only in specific stages and under human supervision.

In summary, the clearest solution to RQ3 can be seen as a human-in-the-loop, process-based approach. GenAI would provide support for the brainstorming, feedback, revision, explanation, and evidentiary stages, while the educators will retain their responsibility for making the final judgment on the students' achievements. The proposed solution reflects the educator preference for the process-based approach to redesigning assessment (M = 4.05) and recent views on assessment as the verification of authentic learning and evaluative judgment, not prohibition of AI use [10], [11].

D. RQ4 — What Are the Experienced and Desired Impacts of GenAI Tools?

1) Perceived effects: Perceived effects are reported in Table VI, while the specific positive impacts are ranked in Table VII.

TABLE VI. PERCEIVED EFFECTS OF GENAI (ITEM 13, 1–5 LIKERT SCALE, MEAN [SD])

Statement	Educators M (SD)	Students M (SD)
GenAI has improved my efficiency / academic performance	2.97 (1.22)	2.84 (1.17)
GenAI has helped me save time and be more creative	3.16 (1.34)	3.09 (1.24)
I would like GenAI integrated more into assessment and feedback	3.15 (1.35)	2.83 (1.23)
GenAI has positively influenced students' academic performance (educators only)	2.67 (1.21)	—

2) Specific positive impacts:

TABLE VII. SPECIFIC POSITIVE IMPACTS OF GENAI (ITEM 14, 1–5 LIKERT SCALE, MEANS RANKED HIGHEST FIRST FOR EDUCATORS)

Impact	Educators M	Students M
Better ideas for exercises, assignments, and projects	3.41	2.96
Better understanding of difficult concepts	3.18	3.26
Considerable time savings	2.95	3.37
More personalised feedback	2.62	3.00
Improved student engagement/motivation	2.56	2.87
Development of technical skills (coding, prompting, data)	—	3.01

3) Overall impact assessment: The influence profile is moderate rather than positive all the way through (Table VIII). The educators point to the highest benefits of the technology in terms of developing more creative ideas for exercises, assignments, and projects (M = 3.41), while the students indicate that they gain the most from saving time (M = 3.37) and grasping difficult concepts (M = 3.26). In total, 59.1% of educators and 49.2% of students consider the influence of the technology positive and very positive, although a significant portion of respondents remain neutral. It appears that the first and foremost contribution of the technology comes in the form of formative assessment and feedback functionality—the ability to develop and revise ideas and make processes efficient—rather than substituting for summative assessment or ensuring better grades (Fig. 3) [3], [8].

TABLE VIII. OVERALL PERCEIVED IMPACT OF GENAI (ITEM 16, % OF RESPONDENTS BY CATEGORY)

Category	Educators (n = 61)	Students (n = 254)
Very positive	6.6%	9.4%
Positive	52.5%	39.8%
Neutral	39.3%	43.3%
Negative	1.6%	2.4%
Very negative	0.0%	5.1%

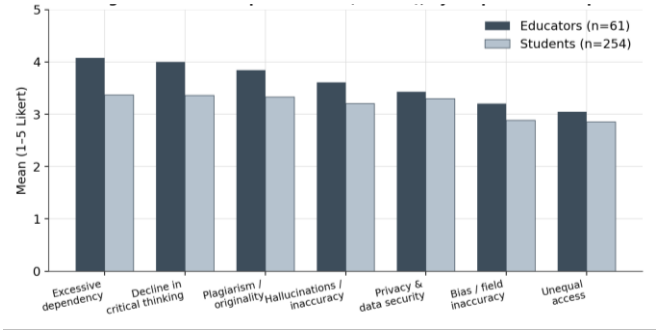

Fig. 3. Overall perceived impact of GenAI (Item 16), share of respondents by category (%; educators n = 61, students n = 254).

E. RQ5 — What Are the Foreseeable Pitfalls of Using GenAI?

1) Risk perception: The full risk-perception profile is reported in Table IX and visualised in Fig. 4.

TABLE IX. RISK-PERCEPTION PROFILE (ITEM 15, 1–5 LIKERT SCALE, MEAN [SD], RANKED BY EDUCATOR MEAN)

Risk	Educators M (SD)	Students M (SD)
Excessive dependency on AI	4.08 (1.07)	3.37 (1.31)
Decline in students' critical thinking	4.00 (1.18)	3.36 (1.34)
Plagiarism and lack of originality	3.84 (1.25)	3.33 (1.32)
Inauthentic scientific research	3.74 (1.22)	—
Hallucinations / inaccurate information	3.61 (1.17)	3.20 (1.26)
Projects without sufficient scientific grounding	3.51 (1.30)	—
Privacy and data security	3.43 (1.36)	3.30 (1.26)
Bias/inaccuracy in the specific field	3.20 (1.22)	2.88 (1.25)

Risk	Educators M (SD)	Students M (SD)
Unequal access among students	3.05 (1.38)	2.85 (1.36)
Negative effect on social/emotional development	—	3.07 (1.29)
Decline in the value of the degree	—	2.95 (1.30)

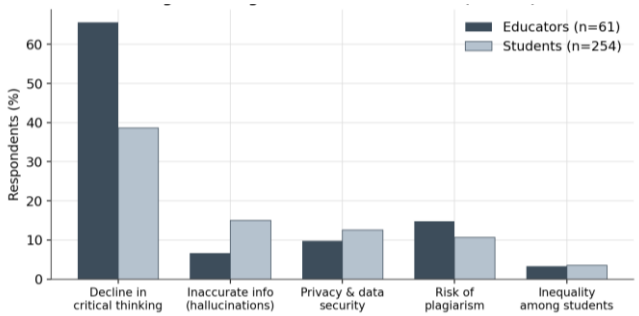

Fig. 4. Risk-perception profile (Item 15), by respondent group (1–5 Likert scale, means; educators n = 61, students n = 254).

2) Main concern: The single most-selected concern is reported in Table X and visualised in Fig. 5.

TABLE X. SINGLE MOST-SELECTED CONCERN REGARDING GENAI INTEGRATION (ITEM 11, % OF RESPONDENTS)

Concern	Educators (n = 61)	Students (n = 254)
Decline in critical-thinking skills	65.6%	38.6%
Inaccurate information (hallucinations)	6.6%	15.0%
Privacy and data security	9.8%	12.6%
Risk of plagiarism	14.8%	10.6%
Inequality among students	3.3%	3.5%

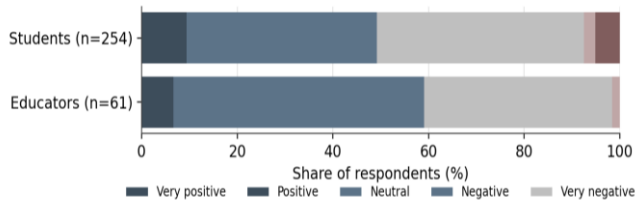

Fig. 5. Single most-selected concern regarding GenAI integration (Item 11), share of respondents by category (%; educators n = 61, students n = 254).

The risk profile makes the challenge of the design of learning and assessment, rather than the mere performance of AI systems, the focus. The most common worry on the list among both teachers (65.6%) and learners (38.6%) is a decrease in critical-thinking skills, while dependence and lack of critical thinking rank first and second in the average mean values of worries among teachers (M = 4.08 and M = 4.00). Plagiarism, hallucinations, privacy, and bias do matter; however, the biggest worry is that wrong design can lead to the deterioration of independent judgment. Therefore, GenAI-enhanced assessment should imply explanation of decisions made, verification of output results, revision of work done, and reasoning of the final outcome. Such a reading is in line with existing literature suggesting that over-dependence and lack of independent judgment can be of greater importance than detection techniques [4], [11].

V. DISCUSSION

It appears that the implementation of GenAI in assessment and feedback should be regarded as pedagogical and institutional change rather than the mere application of new technology. GenAI is currently being applied in activities preceding, during, and after the assessment process, such as exploring relevant literature, generating ideas, preparing assignments, explaining, and revising works. Its educational potential is, thus, mostly associated with the provision of support to formative assessment and feedback loops allowing students to try out their ideas, find weaknesses, and revise their assignments prior to any final evaluation. Such an approach to the analysis of the findings is justified by the feedback-literacy theory that views the successful use of feedback as a learner's active participation in the process of evaluating and improving the quality of their work [1], [2], [10].

In addition, the coexistence of GenAI chat systems and integrity tools confirms that AI-based assessment cannot rely on one tool. ChatGPT, Gemini, Copilot, and Claude.ai assist in generation and explanations, whereas Turnitin is applied to verification and integrity checks. An efficient model of operation in institutions needs to cover generation, feedback, verification, and human decision-making in a transparent process. The problem of uncertainty regarding tools permitted for official use cannot be seen as a mere communication challenge; instead, it is connected to consistency and fairness of decisions. It is crucial to establish clear policies regarding acceptable use of tools by task type, assessment stage, and degree of human control [9], [11], [13].

Institutional access, assessment redesign, and teacher training, three implementation requirements that have been highlighted in the strongest fashion through the study, are interrelated to each other. Although licensed access can facilitate security, accuracy, and equal access to the tool, it doesn't ensure that good education will take place. In order for educators to be able to use the tool well, it is important that they be able to create assignments in which the process of learning becomes observable and assessable. Such process-related evidence, like drafts, prompts, verification, reflection, and explanation, may serve to support good learning assisted by GenAI, rather than mindless outsourcing [9], [10].

Impact findings indicate that at present, the advantages offered by GenAI with regard to efficiency, ideation, and conceptual clarity outweigh those with regard to demonstrable academic achievement. This is significant. While saving time or producing an idea of higher quality might contribute to better learning environments, it is imperative to stress that they should not be considered evidence of any improvements in learning outcomes automatically resulting from such processes. Thus, GenAI-enabled feedback should be assessed not only through efficiency and user experience but also based on its ability to foster awareness of quality, response to feedback, explanation of changes, and transfer of learning – key aspects of feedback literacy [1], [2], [10], [12].

The prevalent threats of dependency, loss of critical thinking, plagiarism, hallucination, and privacy issues point to the importance of assessments that maintain independent thinking and authentic performance. The real issue is not just detection of AI-generated text once submitted; it is making sure that assessments still reflect student knowledge and skills. Possible solutions include sequential assignments, use in specific disciplines, oral or interactive confirmation, documented changes, checking sources, and discussion of GenAI use specifically. Faculty composition might have affected the prevalence of certain GenAI use types, including coding and other technical operations, so further analysis will need to consider this factor. Still, the overall picture clearly shows one path: GenAI should be integrated where it improves formative feedback and learning, but decisions that matter are based on clear criteria and verifiable evidence and human academic judgment [5], [11]–[13].

Descriptively, the MUA pattern is broadly consistent with comparable institution-level studies rather than clearly exceptional. At MUA, 45.7% of students reported not knowing which technologies were officially permitted, whereas Johnston et al. found that 41.1% of students at the University of Liverpool wanted a university-wide policy specifying appropriate use [14]. Likewise, the strong MUA educator rating for institutional access (M = 4.34) and the student emphasis on clear guidance (M = 3.41) align with Kim et al., where approximately 80% of surveyed students and faculty supported formal university policies [16]. MUA respondents also reported moderate rather than uniformly intensive use, which is compatible with Kim et al.'s finding that around 70% of both groups used GenAI less than once per week [16]. These comparisons do not establish statistical equivalence because instruments, samples, and contexts differ; they instead indicate that MUA's governance, guidance, and adoption gaps resemble patterns reported in other higher-education settings.

VI. Conclusions

This study serves as an institution-level evidence base for the responsible implementation of GenAI in assessment and feedback in higher education. The findings reveal that GenAI is currently being integrated into processes such as ideation, literature exploration, preparation of assignments, explanation, and revision; however, these activities are currently far more developed at the individual-user level rather than the institutional-design level. The challenge now is not whether GenAI would become a part of assessment, but how institutions can incorporate its use to improve feedback and learning while preserving the validity, equity, and transparency of the assessment process.

The study demonstrates support for the process-oriented and human-in-the-loop model of GenAI-enhanced assessment. In this model, GenAI may play a part in formative feedback, clarifying concepts, drafting and revision, and suggesting alternatives, while educators are responsible for learning outcomes, criteria, validation of evidence, and the academic judgment of the work. This is not only an expansion of the debate from yes-no to a design-focused approach but also goes beyond it.

The five research questions can therefore be answered directly. RQ1: ChatGPT is the dominant generative platform, but institutional adoption should combine generative tools with integrity and verification systems rather than rely on a single application. RQ2: The principal prerequisites are licensed institutional access, clear rules, professional development, and process-based assessment redesign. RQ3: GenAI should be integrated through a bounded human-in-the-loop model in which it supports ideation, explanation, feedback, revision, and preparation while educators retain final academic judgment. RQ4: The strongest educational advantages are efficiency, time savings, idea generation, conceptual clarification, and formative feedback, with no evidence in this descriptive design that these benefits automatically translate into improved learning outcomes. RQ5: The main risks are excessive dependency, erosion of critical thinking, plagiarism and originality concerns, hallucinations, privacy and data-security issues, bias, and unequal access; these require governance and assessment designs that preserve independent reasoning and verifiable evidence.

The educational value of the benefits noted in this study is mostly evident in the areas of efficiency, ideation, time savings, and helping understand complex issues. These are highly valued educational benefits but should not be regarded as automatic proofs of better learning outcomes. The value of GenAI-based feedback for education becomes apparent when learners use it critically, check information, justify decisions, and use feedback to improve future performance. Therefore, institutional implementation should include the availability of relevant tools, teacher training, student coaching, guidelines for appropriate usage, and designing assessments to assess genuine knowledge and skills.

Dominant threats of excessive dependence, critical thinking degradation, plagiarism, hallucinations, and data-privacy issues prove that the main difficulty with implementation of GenAI lies in both the technical and pedagogical aspects.

1) Limitations and future directions: However, there are several limitations that need to be taken into account while analysing the findings. First, a limited sampling strategy will not allow for generalisation of the findings to the full population of MUAs or even another university setting. Second, the use of self-reporting for use, benefits, and risks associated with using GenAI tools is associated with problems such as recall bias or even a desire to appear socially desirable, especially when it comes to use and academic integrity. Third, due to its purely descriptive nature, this design cannot help establish causation between GenAI use and learning outcomes, quality of feedback, or assessment results. Finally, the different distribution of academic disciplines among faculty and students could lead to the prominence of some areas such as programming, literature search, or writing assignments.

Ethical Considerations

The research was performed under the approval of the Mediterranean University of Albania. This formal approval provided the HEGenAI research group authorization to collect, analyze, and present results obtained through a questionnaire

and interview survey of teachers and students at the Mediterranean University of Albania. The approval proves that data were collected in accordance with the rules of this institution and that the research meets the academic integrity requirements of this institution as well as internationally recognized ethical research standards.

Participation was voluntary and based on informed consent. Participants were told the purpose of the study and how their responses would be used before taking part. No personally identifying information was retained in a form that could be traced to an individual: every response used here was depersonalised and anonymised before analysis, so that no educator or student can be identified from the reported results. No fabrication, falsification, or other research misconduct occurred at any stage of the work.

CONFLICT OF INTEREST AND FUNDING DISCLOSURE

This research was conducted within the Erasmus+ KA220-HED project "HEGenAI – Generative AI for Assessment and Feedback in Higher Education Cooperation" (Grant No. KA220HEDE5871007), co-funded by the European Union. The funder had no role in the design of the study, the collection or analysis of the data, or the decision to submit the manuscript for publication. The authors declare no financial or personal relationships that could have influenced the work reported here.

AUTHORS' CONTRIBUTION

Following the CRediT taxonomy: D. Hyka: conceptualisation, methodology, formal analysis, data curation, and writing of the original draft. E. Shabanaj: methodology and investigation, with a focus on the AI-related components. J. Meçaj: software and investigation. A. Hykaj: validation and writing (review and editing). E. Skendaj: project administration. All authors read and approved the final version of the manuscript.

DATA AVAILABILITY STATEMENT

The data supporting the findings of this study consist of anonymised questionnaire responses from educators and students of the Mediterranean University of Albania. Because the dataset was collected under an institutional authorisation limited to the HEGenAI project, it is not publicly deposited. The anonymised data may be made available by the corresponding author on reasonable request, subject to the institution's data-protection conditions.

ORIGINALITY CHECK

Before submission, the manuscript was screened for originality using Turnitin. The similarity index, excluding references, direct quotations, and bibliographic material, remained below the 20% threshold set by the journal.

Earthquake Damage Risk Classification Using Machine Learning Models Based on Built-Up Area Indices from Satellite Imagery

Gunawan Prayitno*, Eko Sediyono, Irwan Sembiring, Sri Yulianto Joko Prasetyo
Department of Information Technology, Satya Wacana Christian University, Salatiga, Indonesia

***Abstract*—One of the challenges in assessing earthquake damage risk in areas with high seismic activity and limited data is the lack of a detailed building inventory and the absence of available data. Therefore, a remote sensing and machine learning framework is needed that can utilize the built-up area index with NDBI from multitemporal Landsat 8 imagery as a vulnerability proxy, combined with ISGS seismic hazard data, topographic variables from DEM, and surface geology. Support Vector Machine (SVM) and Random Forest (RF) classifiers can be trained and developed to categorize vulnerability classes and evaluate results in terms of accuracy, precision, recall, and F1 score. The SVM achieved an accuracy of 0.970, with precision, recall, and F1 scores all reaching 0.97, while the RF achieved 0.96. This study focuses on Nabire Regency, Central Papua, Indonesia, utilizing various approaches, scaling methods, and a relatively low-cost methodology for the initial screening of earthquake-prone areas without the need for field data collection, with the potential to apply these methods to other seismic regions.**

***Keywords*—Seismic risk assessment; vulnerability proxy; remote sensing; machine learning; data scarcity**

I. Introduction

High-seismicity regions, such as Indonesia, face significant challenges in assessing earthquake-induced building damage risk, particularly in developing countries where urbanization is rapid but detailed building inventory data is scarce. Traditional seismic risk assessment models generally rely on structural-level information such as material types, structural systems, and building age, which are often difficult to obtain comprehensively, especially in remote regions with limited data collection capacity [1],[2]. Consequently, there is a need for an effective and affordable approach to earthquake risk mapping that does not solely depend on field-based data, which is often inaccessible.

In recent years, the use of remote sensing (RS) and Geographic Information Systems (GIS) has rapidly evolved as a solution to overcome the limitations of physical field data collection. Satellite imagery holds substantial potential for characterizing the built-up area (BUA), which can serve as a proxy for vulnerability. Indices derived from satellite imagery, such as the Normalized Difference Built-up Index (NDBI) and Building Area Index (BAI), are particularly useful in mapping urbanization intensity, building density, and land-use changes, which are critical in assessing earthquake vulnerability [3],[4].

Although several studies have employed remote sensing for vulnerability assessment, most of these remain descriptive or fragmented, lacking integration with machine learning (ML) models to provide more accurate and reliable results for earthquake risk analysis [5],[6].

An emerging innovative approach is the combination of machine learning with remote sensing, which facilitates the efficient and systematic processing of spatial data. Techniques such as Support Vector Machine (SVM) and Random Forest (RF) have proven effective in classifying vulnerability by utilizing spatial data, such as built-up area indices and other geospatial parameters. SVM, with its ability to handle non-linear and high-dimensional data, is particularly suitable for vulnerability analysis based on remote sensing data [7],[8]. Random Forest, as an ensemble algorithm, offers the advantage of reducing model variance and providing robust predictions, even with large and complex datasets [9].

However, the biggest challenge in earthquake risk modeling is the class imbalance in data, especially when the number of damaged buildings after an earthquake is much smaller than the number of non-damaged ones. In such cases, imbalanced data can affect the performance of machine learning models. Therefore, this research proposes using machine learning techniques without oversampling, leveraging the strengths of SVM and RF to maintain high classification accuracy, even with imbalanced data [10],[11].

Nabire District in Central Papua has been chosen as the study area for this research. Nabire is a seismically active region with significant limitations in building inventory data, making it an ideal case study for applying a remote sensing and machine learning-based earthquake damage risk model. This study aims to develop a methodological framework that can be used in similar data-scarce regions while still providing accurate and reliable earthquake risk assessments.

This research not only provides a vulnerability map but also contributes to disaster mitigation by offering a transferable framework that can be applied to areas with limited structural data. Additionally, this study contributes to the development of scalable, data-driven models that can be utilized by disaster management agencies to plan and implement more effective mitigation strategies [12],[13],[14].

II. Related Work

Conventional earthquake vulnerability assessments depend on structural attributes, building age, material types, and several other parameters that require detailed classification and more specific approaches to ensure they can be widely applied across various regions—particularly where detailed, systematic building inventories are not yet available [1], [2].

To reduce reliance on field data, several studies have used remote sensing proxies to analyze built-up area indices, land cover changes, exposure models, and simplified replacement cost estimates, as well as structural exposure estimates on a broader scale [3], [6]. Several of these remote sensing studies have shown that indicators derived from satellite data can replace detailed inventories; however, most remain descriptive and exploratory in nature, reporting spatial patterns of exposure without linking them to predictive classification models [3], [5], [6].

The next step in the research is to apply machine learning to predict seismic damage. Several machine learning methods used for this purpose include Support Vector Machines, Random Forests (RF), and deep learning-based image models such as Mask R-CNN on satellite and aerial imagery to predict damage following an earthquake [7], [8], [9].

These studies demonstrate the performance of the most relevant and accurate classification systems; however, they are generally conducted in contexts rich in labeled data and post-event damage information available for training and data validation. Several reports indicate that model performance declines significantly when applied to areas with different local conditions or without such labels [4], [10]. A small number of studies have integrated machine learning with GIS-based multi-criteria methods, including AHP-based weighting of hazard, exposure, and vulnerability layers, to translate model results into decision-support maps [12], [13], [14]. This ML+GIS integration workflow is rarely used in the more specific and data-scarce context of earthquakes, and relies entirely on proxies derived from satellite data as the primary exposure input.

Specifically, following a comprehensive review, there are still various gaps that need to be addressed. Previous studies using remote sensing have successfully integrated built-up area proxies with supervised machine learning classification and multi-criteria hazard weighting (AHP) into a single workflow, enabling explicit data prediction and modeling for areas lacking field-based building inventories.

This study also presents an integrated framework that can be applied in Nabire Regency, Central Papua, Indonesia, as a case study with data limitations, while explicitly addressing methodological limitations—such as the nature of vulnerability labels based on proxies and clustering results—which are often overlooked in previous studies; this constitutes a novelty of this research.

III. Method

This study proposes a remote sensing– and machine learning–based framework to classify earthquake-related building damage risk in a data-limited seismic region. The overall procedure covers data acquisition, preprocessing, and feature construction, supervised model development, and performance evaluation, with the full methodological sequence summarized in Fig. 1. Four primary datasets are utilized. Multi-temporal Landsat 8 imagery (2022–2025) is employed to derive built-up area indicators that represent urbanization intensity and built-surface density in the study area [15],[13]. Seismic hazard information is compiled from the United States Geological Survey (USGS) earthquake catalog to capture earthquake occurrence characteristics that may influence vulnerability patterns [16],[17]. A Digital Elevation Model (DEM) is included to derive topographic attributes—particularly slope—that can affect spatial damage distribution during seismic events [18],[11]. In addition, surface geology maps are incorporated to describe lithological conditions that may amplify or attenuate earthquake impacts and thus influence the vulnerability of built environments [12],[19].

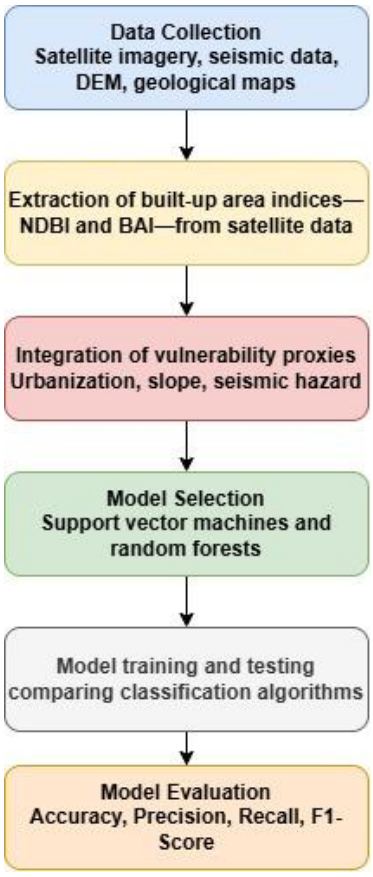

Fig. 1. Flowchart or orchestra of machine learning model selection for earthquake damage risk classification.

Before modeling, all datasets are prepared to ensure spatial comparability and analytical consistency. Satellite imagery is processed to generate built-up area proxies that quantify the extent and intensity of built surfaces. In this study, the Normalized Difference Built-up Index (NDBI) is calculated from Landsat bands as follows [20],[7]:

$$NDBI = (SWIR - NIR) / (SWIR + NIR) \quad (1)$$

Moreover, SWIR is the Short-Wave Infrared band, and NIR is the Near Infrared band from satellite imagery [21]. To represent vulnerability more comprehensively, built-up indicators are not used in isolation. Complementary spatial proxies are integrated, including slope derived from the DEM and seismic context derived from the earthquake catalog, enabling the model to learn spatial relationships between built-environment conditions and potential earthquake damage risk [17],[18]. This integrated feature set is constructed to better capture multi-factor vulnerability patterns that cannot be represented by a single proxy alone.

This study ultimately examined the SVM and RF methods using a case study approach deemed appropriate for these methods, which have also been proven effective in performing classifications involving high-dimensional and medium-sized geospatial datasets, while identifying commonly encountered conditions and addressing vulnerabilities in remote sensing. This differs from deep learning approaches, which generally require comprehensive data for large-scale labeled training to avoid overfitting.

SVM and RF are reliable even with limited sample sizes, such as those found in the seismic area of Nabire, Central Papua, Indonesia. However, with the principle of margin maximization, SVM enables the construction of robust decision boundaries even when performing nonlinear class separation, and its kernel-based formulation is well-suited for heterogeneous geospatial features derived from various parameters such as built-up area index, earthquake hazard, topography, and geology. RF, which is a decision tree ensemble, is relatively resistant to overfitting, requires minimal parameter tuning, and provides built-in metrics such as variable importance, which support the interpretation of the underlying vulnerability drivers. Both SVM and RF also demonstrate consistent robustness under class-imbalanced conditions without requiring oversampling, which is relevant to the existing imbalance challenges. The combination of these properties makes SVM and RF suitable for further analysis and implementation in this study, with the hope that they can serve as a more precise and accurate framework for vulnerability classification.

There are several deep learning techniques that we are familiar with, such as Convolutional Neural Networks (CNNs) [25]; however, they were not applied in this study due to several practical reasons related to data limitations in the study area—namely, Nabire, Central Papua, Indonesia. Some important details to note regarding the use of these algorithms are that deep learning models require a large volume of labeled training data, which is then used to learn reliable feature representations and achieve good and accurate generalization. The availability of ground-truth samples in the Nabire region remains limited, and using a deep learning architecture increases the risk of overfitting.

The next factor—the input data used in this study—includes settlement indices, earthquake hazard attributes, topological variables, and other specific geological categories. These factors serve as structured geospatial predictors in tabular form—not merely raw image data—and this data format is well-suited for conventional machine learning classification methods such as SVM and RF, without requiring the additional representation learning capabilities provided by deep learning.

Third, deep learning models generally require greater computational resources and longer training times, and their decision-making processes are relatively difficult to interpret, whereas SVM and RF offer faster training, lower computational costs, and transparent, interpretable results in terms of RF variables. Additionally, various considerations—such as practical application and replication by disaster management agencies in other seismic regions with limited data—play a role. For these reasons, SVM and RF remain the preferred choices over other deep learning models given the data conditions within the scope of this study.

For vulnerability classification, two supervised machine learning algorithms are employed to address non-linear and high-dimensional characteristics of spatial predictors. Support Vector Machine (SVM) is applied to identify an optimal separating boundary between vulnerability classes, particularly when class distributions are not linearly separable. The SVM decision function is expressed as:

$$f(x)=w^{\wedge}T \cdot x+b \quad (2)$$

where, w denotes the weight vector, and b denotes the bias term [16],[11]. In parallel, Random Forest (RF) is adopted as an ensemble approach that combines multiple decision trees to improve predictive stability and reduce overfitting. RF is effective for large spatial datasets and suitable for modeling complex relationships among spatial variables in the study area [12],[22],[23]. Together, SVM and RF provide complementary strengths for learning spatial vulnerability patterns from satellite-derived and ancillary geospatial predictors.

Model performance is evaluated using standard classification metrics—accuracy, precision, recall, and F1-score—to quantify the reliability of vulnerability classification outcomes. Accuracy is computed as:

$$Accuracy = (TP + TN) / (TP + TN + FP + FN) \quad (3)$$

where, TP is True Positive, TN is True Negative, FP is False Positive, and FN is False Negative. These metrics are used to assess overall correctness as well as the balance between identifying vulnerable cases and minimizing misclassification, which is critical for earthquake-related risk mapping and decision support [13][24]. Finally, Fig. 1 presents the workflow of the model selection process, depicting the sequential steps from data acquisition and preprocessing, feature extraction and integration, model training using SVM and RF, and metric-based performance evaluation, thereby clarifying methodological linkages and supporting replication in comparable seismic regions. Moreover, Fig. 2 specifically shows the entire system to be built.

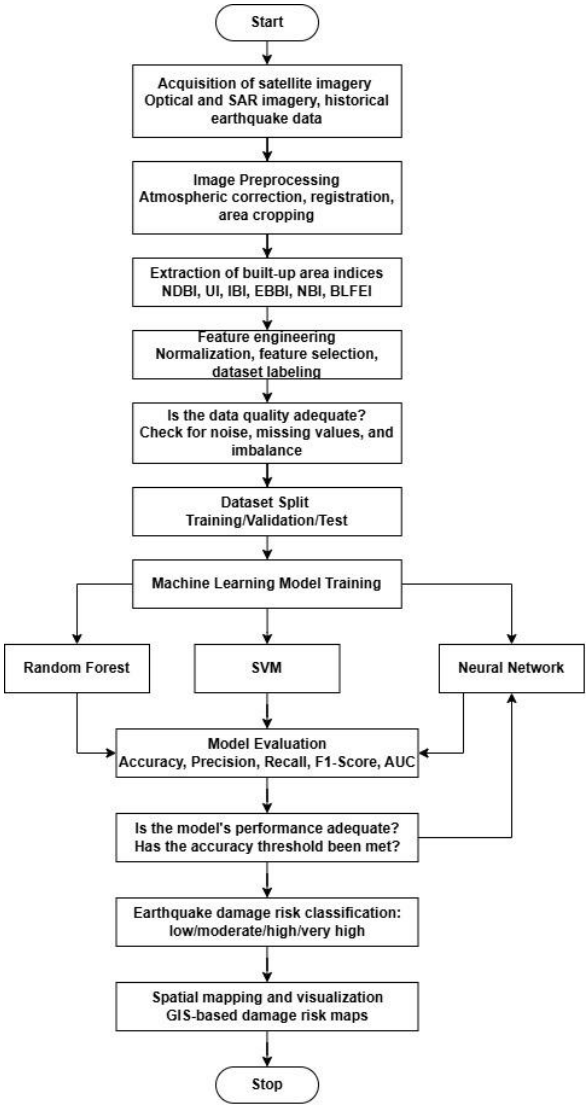

Fig. 2. Flowchart of the overall system.

IV. Result and Discussion

In this section, the results are presented in the same order as the figures and tables to maintain a clear linkage between spatial evidence and quantitative model evaluation. The analysis begins with the spatial pattern of built-up indices, proceeds to the selection of the optimal number of vulnerability classes using unsupervised clustering diagnostics, and then reports the supervised classification performance of SVM and Random Forest. Finally, the section integrates seismic-hazard context and AHP-based weighting to generate vulnerability prioritization maps for Nabire Regency.

Moreover, Fig. 3 shows the spatial pattern of built indices derived from the NDBI proxy. Higher built-up values concentrate in the urban core of Nabire and along development corridors, indicating higher exposure due to the greater concentration of built structures. In contrast, lower built-up values are typically associated with suburban or less-developed areas. This pattern supports the use of satellite-derived built-up indices as a practical exposure proxy for regional-scale earthquake risk screening in data-scarce settings.

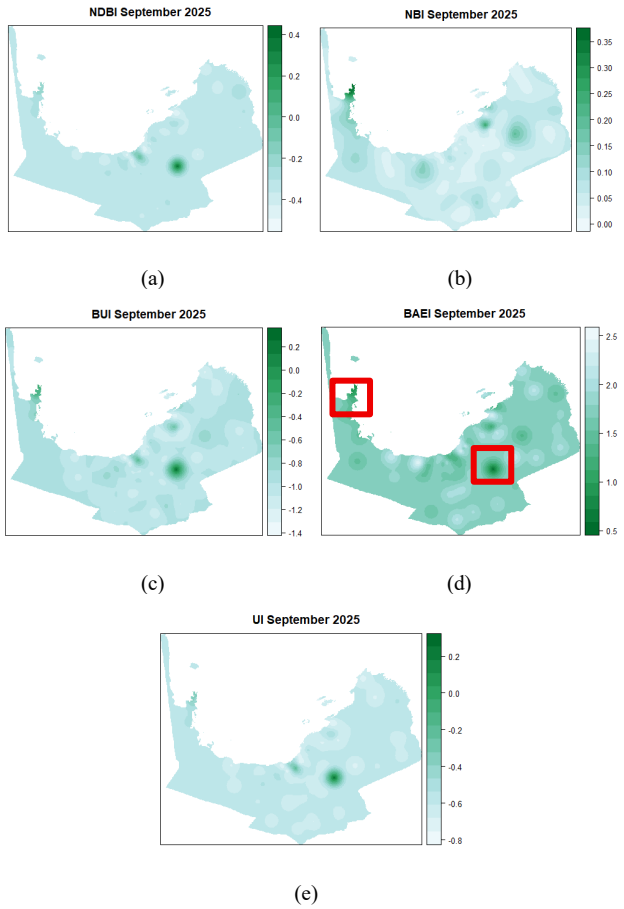

Fig. 3. Spatial patterns of built indices.

Furthermore, to operationalize vulnerability classes for classification, K-means clustering is used to partition the built-up–related feature space into candidate class groupings. The silhouette score is employed to evaluate cluster separability across different k values, where higher silhouette values indicate more coherent and better-separated clusters[26],[27]. The results of the calculation of silhouette scores for various k values can be seen in Table I.

TABLE I. Silhouette Score for K-Means Cluster Evaluation

K value	Silhouette Score
2	0.5426
3	0.5890
4	0.6820
5	0.5923
6	0.4941
7	0.3919
8	0.3235
9	0.3370
10	0.3565

As shown in Table I, k = 4 yields the highest silhouette score (0.6820), indicating that four clusters provide the most distinct

partitioning for the data used in this study. Accordingly, k = 4 is selected as the optimal number of vulnerability classes, and the resulting cluster assignment is used to define the target classes for subsequent supervised classification.

The supervised classifiers are trained with the selected class structure using parameter settings reported in Tables II and III. For SVM, an RBF kernel is adopted with C = 1 and gamma = "scale" (Table II). For Random Forest, the entropy criterion is used with n_estimators = 10 and random_state = 42 (Table III). These settings are reported explicitly to ensure reproducibility and to clarify the configuration applied in the comparative evaluation[13],[12].

TABLE II. PARAMETERS USED IN SVM CLASSIFICATION

No	Parameter	Value
1	Kernel Type	Radial Basis Function
2	C	1
3	Gamma	Scale

In the Random Forest (RF) model, parameter settings include criteria, n_estimators, and random_state that serve to control how nodes are separated in the decision tree, the number of trees used in the ensemble, and random settings in the model. The following table shows the parameter settings used in its vulnerability classification.

TABLE III. RF CLASSIFICATION USING PARAMETER SETTINGS

No	Parameter	Value
1	Criterion	Entropy
2	N_estimators	10
3	Random_state	42

The number of estimators is 10, which is relatively low compared to typical ensemble practices—which range from 100 to 500 trees—and initially, we did not justify this choice. This value was selected empirically based on a relatively small sample covering a single available region: the Nabire area in Central Papua, Indonesia, which is an area with sparse data. We increased n_estimators beyond 10 in our experiments, which resulted in a negligible change in validation accuracy—well below 1 percentage point. On the other hand, training time increased, so 10 was retained as a relatively lightweight default value for the proof-of-concept workflow.

In this study, we acknowledge that small forest sizes can increase the variance in the contributions of individual trees and may obscure the model's true generalization error, particularly in the hold-out evaluation used in this study. We explicitly note this as a limitation, although we still adjusted these values retrospectively. The Random Forest results in Table IV are interpreted as indicative rather than optimally tuned, and a systematic search for hyperparameters—such as a grid search or random search for n_estimators, max_depth, and min_samples_leaf using cross-validation—is identified as necessary follow-up work before the RF configuration can be used for decision-making.

Model performance is evaluated using a hold-out test split (30% test data) and standard classification metrics (accuracy, precision, recall, and F1-score). The comparative results are reported in Table IV. SVM achieves an accuracy of 0.970 with a precision/recall/F1-score of 0.97, while Random Forest achieves an accuracy of 0.955 with a precision/recall/F1-score of 0.96. These results indicate that both models perform strongly; however, SVM provides a modest improvement in overall classification reliability under the specific feature set and parameter configuration used in this study.

TABLE IV. BUILT-IN INDEX CLASSIFICATION ACCURACY

	Accuracy	Precision	Recall	F1-Score
SVM	0.970	0.97	0.97	0.97
RF	0.955	0.96	0.96	0.96

There are essential methodological limitations regarding the interpretation of the reported accuracy levels. The four vulnerability classes used for training and evaluating the SVM and RF were derived from a K-means clustering process applied to the same settlement, seismic, topographic, and geological feature spaces used as classification inputs in Section II, Table I. This results in the accuracy figures in Table IV (SVM: 0.970; RF: 0.955), which specifically reflect how consistently these supervised classifiers can reproduce the cluster assignments generated from that feature space. Not only is this aligned with building damage that was independently observed and verified in the field, but it also constitutes a form of circular (self-referential) validation and explains why the reported accuracy is significantly higher compared to studies validated using independent field verification data.

Moreover, by explicitly stating this limitation—rather than treating accuracy as evidence of real-world predictive performance—the results from SVM or RF must be treated as a separate component from the classes generated by K-means, whereas the actual claim relevant to the research objectives of this study is how to measure the feasibility of the entire proxy-based screening workflow (composite index + seismic hazard + AHP) for regions with limited data—and not merely based on absolute accuracy values. In this study, the concept of limited data has been expanded to encompass not only absolute accuracy values themselves but also the classification process and the study's limitations, along with the inclusion of research results in the form of field-based independent validation of the classes predicted to identify critical tasks in the future.

Furthermore, to complement metric-based evaluation, a building density map is generated from the NDBI-based built-up information and GIS layers to visualize exposure concentration. Fig. 4 shows that the urban center of Nabire exhibits higher building density than peripheral areas, reinforcing the interpretation that built-up intensity and building concentration are spatially clustered. Such clustering is relevant for risk prioritization because higher exposure zones typically require closer attention in mitigation planning.

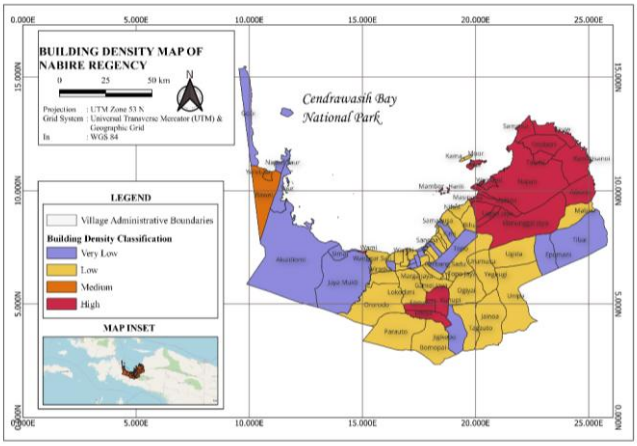

Fig. 4. Nabire building density map based on NDBI index and GIS data.

The seismic-hazard context is incorporated by compiling major earthquake events around Nabire and using these events to derive distance-to-epicenter information for sample locations. Table V lists representative major earthquakes (highest magnitudes) during the study period. In total, 51 earthquakes were recorded from 2021 to 2025, and the distance between each sample point and the nearest epicenter was computed using a GIS proximity analysis approach (e.g., Distance to Nearest Hub). In addition to distance-to-epicenter, lithological information is digitized from the Papua geological map and overlaid on the Nabire administrative boundary, while slope is derived from DEM data and categorized into five slope classes to represent terrain-related susceptibility.

This study does not merely list the earthquake catalog and AHP weights in separate tables with different descriptions, as shown in Table V and Table VI. To avoid overlap, it is necessary to provide detailed explanations for these tables and to update the references.

TABLE V. MAJOR EARTHQUAKES THAT OCCURRED AROUND NABIRE

Year	Month	Day	Time	Lat	Lon	Depth	Mag	Region
2025	9	18	18:19:49	-3.5943	135.4724	28	6.1	26 km S of Nabire, Indonesia
2025	10	2	22:45:05	-3.1055	136.3208	10	5.3	95 km ENE of Nabire, Indonesia
2023	6	11	06:51:47	-2.9534	136.6526	42.8	5.2	135 km ENE of Nabire, Indonesia
2025	10	3	06:02:38	-3.033	136.2627	10	5.1	92 km ENE of Nabire, Indonesia
2025	9	18	22:53:41	-3.6274	135.5228	10	5	29 km S of Nabire, Indonesia

Moreover, to integrate these susceptibility-related components into a single vulnerability index, the Analytic Hierarchy Process (AHP) is applied to assign weights to three key parameters: rock type, slope gradient, and distance from the earthquake point. The resulting weights are shown in Table VI, indicating that distance from the earthquake point receives the largest weight (0.664), followed by rock type (0.223) and slope gradient (0.113). All parameter scores are normalized to a 0–1 range before combination.

TABLE VI. AHP WEIGHTS FOR ITS VULNERABILITY PARAMETERS

Parameter	Weight (W)
Rock Type	0.223
Slope Gradient	0.113
Distance from the Earthquake Point	0.664

The Earthquake Vulnerability Index (EVI) is computed as a weighted sum of the normalized parameter scores:

$$\text{Vulnerability Index} = (X_{(\text{Rock Type,norm})} \times W_{(\text{Rock Type})}) + (X_{(\text{Slope Gradient,norm})} \times W_{(\text{Slope Gradient})}) + (X_{(\text{Distance from Epicenter,norm})} \times W_{(\text{Distance from Epicenter})}) \quad (4)$$

An earthquake threat map is then produced using the earthquake catalog information, representing the spatial distribution of seismic exposure and supporting the identification of zones with higher hazard influence. Fig. 5 visualizes these threat patterns for Nabire, providing an interpretable spatial basis for prioritizing areas that are more likely to experience stronger hazard influence and therefore require greater attention in risk reduction planning [28],[24],[29].

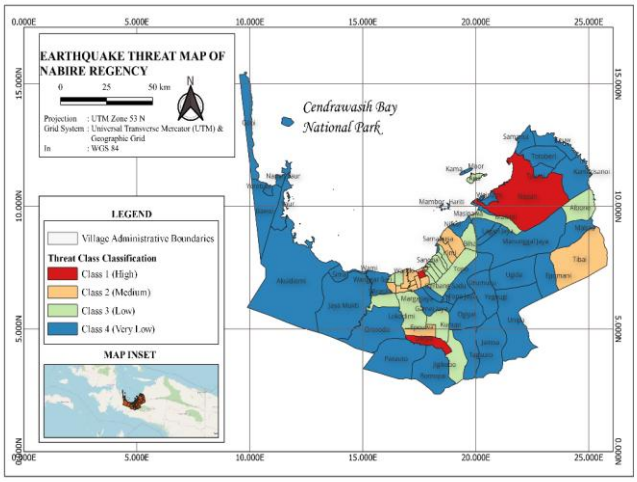

Fig. 5. Nabire earthquake threat map based on earthquake catalog data and risk analysis.

Furthermore, using the AHP weights summarized in Table VI, vulnerability parameters are combined to produce a vulnerability risk map, emphasizing the dominant role of distance-to-epicenter in this study's vulnerability scoring. Fig. 6 presents the resulting vulnerability risk map derived from the integration of AHP-based parameter weighting and the Random Forest–based vulnerability classification output. The map highlights spatially prioritized zones where exposure and susceptibility combine into higher vulnerability levels, supporting the identification of areas requiring more urgent mitigation measures and planning attention [30], [31].

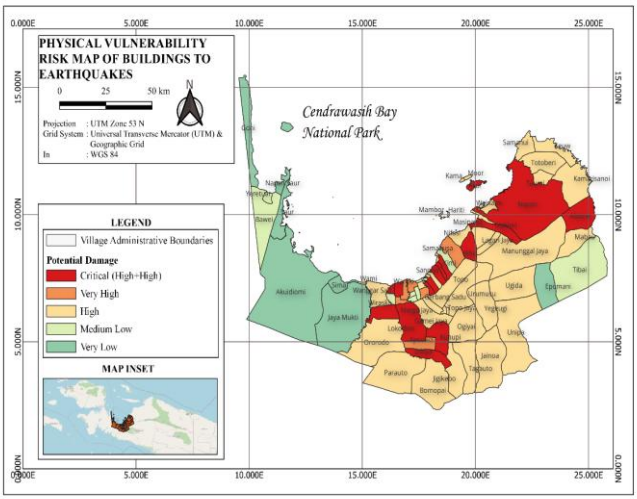

Fig. 6. Nabire vulnerability risk map based on AHP results and RF model.

Finally, Table VII reports the combined score and risk priority levels derived from the RF output and AHP weighting. This prioritization scheme translates model outputs into an operational decision-support format, enabling stakeholders to differentiate critical zones (highest combined score) from moderate-to-low priority areas for staged intervention planning. A denotes the RF-based vulnerability score, and B denotes the AHP-based susceptibility score; the combined score (A+B) is mapped to priority levels as shown in Table VII.

TABLE VII. COMBINED SCORE (A+B) AND RISK PRIORITY LEVEL

Combined Score (A+B)	Priority Levels	Description
8	Priority 1	Critical (High + High)
7	Priority 2	Very high
6	Priority 3	High
5	Priority 4	Moderate-high
4	Priority 5	Moderate
3	Priority 6	Low
2	Priority 7	Very low

Furthermore, the equations used to compute each parameter reported in the tables are explained below.

- Silhouette Score (Table I): for each data point i, s(i) = (b(i) − a(i)) / max(a(i), b(i)), where a(i) is the average distance between i and all other points in the same cluster, and b(i) is the average distance between i and the points in the nearest neighboring cluster. The value reported in Table I is the mean of s(i) over all samples for a given k, and ranges from −1 to 1, with values closer to 1 indicating better-defined clusters.
- Precision, Recall, and F1-Score (Table IV): Besides Accuracy [Eq. (3)], Precision = TP / (TP + FP), Recall = TP / (TP + FN), and F1-Score = 2 × (Precision × Recall) / (Precision + Recall), where TP, FP, and FN denote True Positive, False Positive, and False Negative, respectively, as defined earlier.
- AHP Weights (Table VI): the weights for rock type, slope gradient, and distance-to-epicenter are derived using Saaty's Analytic Hierarchy Process. Experts/literature-based pairwise comparisons between the three parameters are organized into a comparison matrix; each weight (W) is the corresponding element of the matrix's normalized principal eigenvector, so that all weights sum to 1. The consistency ratio (CR) of the comparison matrix was checked and found to be below the acceptable threshold of 0.1, confirming that the derived weights are consistent.

Furthermore, we developed this research report not only based on the final weights and CR values, but also by providing detailed reporting on sensitivity and the limitations of the accuracy of vulnerability priority results, noting that distance to the epicenter accounts for 0.664 of the total weight. To address this, we conducted individual sensitivity tests by performing paired comparisons, altering each criterion by ±1 point on the 1–9 Satty scale and recalculating the weights; distance to the epicenter remained the dominant criterion with a weight range of approximately 0.58–0.71 across the entire modified matrix, while the relative order of the three criteria (distance > rock type > dip) remained unchanged, indicating that the priority ranking is fairly robust against small variations in the evaluation process; however, we note that this sensitivity test was conducted on a single comparison matrix based on the literature, rather than on a comparison matrix derived from multiple experts and references; consulting experts can consistently be identified as a task necessary to validate the AHP weights more rigorously before they are used operationally.

- Combined Score (Table VII): Combined Score = A + B, where A is the RF-based vulnerability score, and B is the AHP-based susceptibility score, both rescaled to the same ordinal range (1–4) before summation; the resulting sum (2–8) is then mapped to the seven priority levels shown in Table VIII.

Overall, the results indicate that built-up indices from satellite imagery provide a meaningful exposure proxy, while integrating seismic proximity, lithology, and slope through AHP strengthens interpretability for risk prioritization. The combined approach supports scalable early-stage screening in regions where field-based building inventories are limited, while still producing spatial outputs (maps and priority levels) that are actionable for mitigation and preparedness.

V. CONCLUSION

This study proposed a remote sensing–driven and machine learning–based framework for earthquake damage risk classification in data-scarce seismic regions by using built-up area indices from multi-temporal Landsat 8 imagery (e.g., NDBI) as a vulnerability proxy and integrating complementary geospatial layers (USGS earthquake catalog, DEM-derived topography, and surface geology). Using the adopted hold-out evaluation, the results indicate strong classification performance, where SVM achieved an accuracy of 0.970 (precision/recall/F1-score ≈ 0.97) and Random Forest achieved an accuracy of 0.955 (precision/recall/F1-score ≈ 0.96), showing that both models are effective, while SVM provides a

modest improvement under the feature set and parameter configuration used in this study.

In addition to the machine learning–based classification, the Analytic Hierarchy Process (AHP) weighting of key susceptibility parameters (rock type, slope gradient, and distance to earthquake point) supports risk prioritization by translating multi-criteria information into interpretable vulnerability levels and priority classes. The resulting maps and priority levels provide a scalable and cost-effective tool for early-stage screening and decision support in Nabire Regency, Central Papua, particularly where detailed building inventory data are unavailable. Nevertheless, the approach remains proxy-based due to the medium spatial resolution of Landsat imagery and the limited availability of building-level structural attributes; future work should incorporate higher-resolution building inventories or independent damage observations, strengthen robustness testing (e.g., cross-validation and class-wise metrics under imbalance), and refine model tuning to improve generalizability across different seismic and urbanization contexts.

VI. Limitation of the Study

There are several limitations to this study, including the fact that the vulnerability indicators (NDBI/BAI) derived from Landsat 8 imagery with a resolution of 30 m are still considered insufficiently detailed to detect structural damage at the level of individual buildings or to assess construction quality; thus, the resulting maps depict the intensity of built-up areas and exposure patterns, rather than confirmed physical damage. Second, the vulnerability classes were defined through unsupervised K-means clustering rather than through validation against verified post-earthquake damage records based on field surveys; consequently, the labels used for training—SVM/RF—are proxy-based and have not been independently verified in the field. The third issue is the AHP weighting process, which still relies on pairwise comparisons based on the literature rather than on assessments obtained from local experts who understand the specific geological and structural conditions of Nabire, Central Papua, Indonesia. Consequently, this approach fails to fully capture the local context.

Fourth, the classifier was trained and evaluated on a relatively small dataset covering only one region using hold-out splitting, which increases the risk of overfitting and limits the generalizability of the reported accuracy. Fifth, distance measurements to the epicenter based on earthquake catalogs do not account for location-specific factors such as ground amplification, potential for liquefaction, or building materials and typology, which can influence the actual severity of damage.

VII. Future Work

Given the various limitations of this study, future steps will specifically focus on various fields, such as satellite, aerial, or UAV imagery with higher resolution, as well as the potential for integrating SAR data with exploration and improvements in the detection of finer-scale structural changes. The predicted vulnerability classes and risk maps will be validated based on post-earthquake damage assessments conducted in the field, as well as independent verification to strengthen the reliability of this framework.

Input from local experts will be incorporated into the AHP process to reflect the geological and socio-structural context of the Nabire region in Central Papua, Indonesia. Robustness testing, including k-fold cross-validation and performance metrics based on classes under class imbalance conditions, will be applied to more rigorously assess the model's generalizability. This framework will also be tested in other seismic regions with relatively limited data to evaluate its transferability, compared with larger labeled datasets, and will incorporate deep learning approaches to complement the currently available SVM and RF methods.

***Abstract*—Semantic interoperability is a major challenge in the integration of heterogeneous information systems, where differences in data structures, terminologies, and representations complicate the automatic identification of schema matches. Traditional schema matching approaches, primarily based on rules or lexical similarity measures, have limitations in the face of the increasing complexity of digital environments. This article proposes a hybrid framework to improve the automatic recommendation of semantic mappings by combining lexical, structural, statistical, semantic, and business similarities with a supervised learning model. The framework also incorporates expert validation to ensure the quality of the recommended matches and to feed an iterative process for improving the mapping repository. The evaluation is based on a case study in the health insurance sector. Experimental results show that the XGBoost model achieves the best performance with an F1 score of 89.48% and an AUC of 0.915. Top-k evaluations also highlight excellent recommendation capabilities, with a Hit@1 of 83.51%. The ablation study confirms that combining different similarity families significantly improves recommendation quality. These results demonstrate the value of the proposed framework for enhancing semantic interoperability, facilitating the identification of matches between heterogeneous schemas, and reducing the validation effort required from domain experts.**

***Keywords*—Semantic interoperability; schema matching; machine learning; XGBoost; information systems**

I. Introduction

Information needs to flow constantly across enterprise apps, cloud services, legacy systems, and decision-support systems. Even though they exist in the same organization, they are unlikely to be co-designed; they may originate from entirely different development lifecycles; they came potentially out of different software vendors and different units of the business, where based upon different data models, schemas, terminology, and business rules. Information exchange is a lot more complex than pure data transmission. On many occasions of system integration projects, the data could successfully get sent and exchanged via standardized interfaces or APIs, while it might imply different meanings in the other system.

On the other hand, identical-sounding concepts that may refer to identical items could be listed as separate items under different attribute names, structures, or coding schemes, leading to low data quality and consistency of business indicators, complicating automation workflow management systems; therefore, affecting the reliability of analytical and predictive applications. Information systems should be able to exchange and exploit information effectively, which is also known as interoperability [1]. Technical, organizational, legal, and semantic dimensions describe the interoperability issue [2]. Semantic interoperability could be the toughest to deal with, due to the fact of preserving the meaning of the exchanged information between heterogeneous systems.

One of the main requirements to achieve the objective of providing seamless data discovery across various content repositories is the ability of recognizing exact semantic matching across heterogeneous schemas, which has been investigated in the area of schema matching [3]. The schema matching techniques have been largely based upon human involvement, which results in expensive solutions based on manual specifications, whether as mappings, transformation rules, or reference dictionaries reflecting expertise in the domain or reference to the expert knowledge of humans. All of these have been efficient so far in addressing semantic matching of schemas of limited sizes, though the rapid growth in web services across various sectors is going to impose a heavy burden in maintaining these schemes through manual matching, as it costs money as well as time and effort. Also, such large-scale matching will make it even more difficult or impossible to rely on a single expert.

Recently, there has been progress in the field of machine learning, suggesting a different way of viewing this Semantic Matching Problem, that of a prediction problem. Instead of being only rule-based, the models can take lexical similarities, semantic similarities, structural similarities, statistical similarities, and business similarities to recommend the correspondences between databases to an expert that performs Semantic Matching.

A hybrid framework for interoperability-assisted by machine learning is proposed. Hybrid in that it attempts to integrate multiple similarity measuring techniques to be able to recommend matches between heterogeneous information

system fields while remaining under expert control through a human validation stage. To assess the reliability and practical relevance of the semantic mapping recommendations produced by the framework, the proposed approach is evaluated through a case study.

The remainder of this article is organized as follows. The next section presents related work on schema mapping, hybrid approaches, and entity mapping. This is followed by an introduction to the fundamental concepts of information systems interoperability, semantic interoperability, and data quality. The following sections will present the proposed framework and the results of an illustrative case study.

II. Related Work

Semantic interoperability has been studied through various research fields, such as schema matching, ontology alignment, and semantic integration.

As noted in [4], schema matching is a central problem in several domains, including data integration, data warehouses, e-commerce, and semantic query processing. Previous schema matching approaches primarily used lexical, syntactic, structural, or data type-based measures. The algorithm proposed by [5] represents a significant contribution to this category of works. It integrates various elements such as names, data types, constraints, and schema structure to establish mappings between heterogeneous components. This approach illustrates the benefit of not depending on one matching criterion, but rather integrating multiple relevant indicators to enhance the quality of the matches.

The system proposed by [6] supports various schema types, including relational and XML, and allows for the construction of more robust matching strategies from several elementary methods. What sets the hybrid system apart is its capability to counteract the drawbacks of isolated solutions. However, it usually remains dependent on manually defined parameters, combination rules, or thresholds, and its implementation in a real-world business context needs significant configuration, validation, and maintenance work.

The authors of [7] present ontology matching as a response to the problem of semantic heterogeneity encountered by computer systems. However, its use presupposes the existence of sufficiently comprehensive repositories that are maintained and adapted to the context under study. In operational environments, some concepts are highly organization-specific, which can limit the direct use of standard ontologies without business enrichment.

Machine Learning-based approaches have made it possible to reformulate matching problems as supervised learning tasks. Instead of manually defining all the matching rules, the model learns to distinguish matching pairs from non-matching pairs using annotated examples. The method proposed by [8] presents tools covering several stages of the process, including data preparation, blocking, matching, training, and evaluation. Similarly, the authors of [9] investigated the contribution of Deep Learning to entity matching, and more recently, [10] proposed using pre-trained Transformer-type language models for entity matching, reformulating the problem as a classification of text pairs. Recent research explores the use of language models to identify matches between elements of relational schemas based on field names and descriptions [11], [12], [13].

These contributions are important for this study because they confirm that matching problems can be treated as prediction tasks. However, they mainly focus on matching records or entities, while the framework studied here focuses on recommending correspondences between data fields and schema elements, in a logic of semantic interoperability.

III. Concepts

A. Information Systems Interoperability

Information systems interoperability can be understood as the capability for various systems or entities to exchange information and utilize it in a consistent manner. It is an essential condition for the functioning of modern organizations, particularly when business processes span multiple information systems or involve multiple actors. Interoperability frameworks emphasize the multidimensional nature of this concept. There are four levels of interoperability recognized by the European Interoperability Framework: technical, semantic, organizational, and legal [14]. The core of technical interoperability is protocols, interfaces, exchange formats, and communication tools. Organizational interoperability is defined as the synchronization of procedures, responsibilities, and goals among participant systems. Legal interoperability guarantees a trusted environment for exchanges (data protection, licenses, etc.). Semantic interoperability focuses on the meaning of the exchanged data and the ability of systems to assign the same meaning to it.

This study focuses on semantic interoperability because the technical connection between systems does not necessarily guarantee a correct understanding of the data. Two systems can exchange information even if the concepts they manipulate are not actually aligned. For example, two fields with similar names can refer to different realities, while two fields with different names can represent the same business concept. Semantic interoperability therefore aims to reduce these ambiguities by establishing reliable correspondences between the concepts and fields used by the systems.

B. Semantic Interoperability and Data Quality

Semantic interoperability is closely linked to data quality. When mappings between systems are poorly defined, the integrated data can become inconsistent, incomplete, or difficult to use. A poor mapping between two fields can lead to errors in automated processing, dashboards, statistical analyses, or predictive models. On the other hand, achieving accurate semantic alignment boosts data comprehension, simplifies data integration, and bolsters its adaptability for use in decision-making processes [15].

This issue aligns with the FAIR principles, designed to make data findable, accessible, interoperable, and reusable [16]. This set of principles underscores machines' capacity to automatically find, interpret, and use data. Seen from this angle, interoperability shouldn't be viewed merely as a technical transfer between systems, but also as a fundamental condition

for the intelligent use and reuse of data by analytical, decision-making, or predictive applications.

Semantic interoperability issues within organizations can manifest in several ways, including variations in field names, varied data formats, a lack of a shared reference system, differing coding values, divergent business terminologies, duplicate entries, or disparities in measurement units. These difficulties are common when several systems have been developed independently. The challenge then becomes building a mechanism capable of identifying semantic similarities between fields, while taking into account the business context in which these fields are used.

C. Schema Matching and Data Alignment

Schema matching is a central research area for data integration. It aims to identify correspondences between elements of heterogeneous schemas. These elements can be tables, columns, attributes, relationships, or entities.

Schema matching approaches can be classified according to several criteria. Schema-level matchers exploit information available in the schemas, such as names, types, or constraints. Instance-level matchers use observed values in the data. Element matchers compare isolated attributes, while structural matchers exploit relationships between multiple elements. Language-based matchers compare names and descriptions, while constraint-based matchers use types, keys, cardinalities, or rules associated with the data [4].

Hybrid approaches combine several types of signals to improve the quality of the matches [17]. This logic is particularly important because no single measure can handle all cases of heterogeneity.

IV. Proposed Framework

The proposed framework aims to support semantic interoperability between heterogeneous information systems through an automatic mapping recommendation mechanism between data fields. The goal is not to automatically generate definitive matches, but to provide a prioritized list of likely mappings. The system acts as a decision support tool for business, data, and IT teams. For each source field, it recommends the closest target fields based on several similarity dimensions. The business expert can then validate, correct, or reject the proposed matches. This approach aligns with human-in-the-loop methodologies, which combine the computational capabilities of models with human intervention in complex, ambiguous, or context-dependent tasks [18].

Therefore, the proposed framework is based on a hybrid approach. It combines metadata processing techniques, similarity measures, machine learning models, top-k recommendation, and human validation. This combination overcomes the limitations of purely manual approaches while preventing uncontrolled automation of semantic mapping.

A. General Architecture

The proposed framework is organized into nine main steps, as illustrated in Fig. 1. These steps make it possible to transform a manual alignment problem into a structured recommendation process.

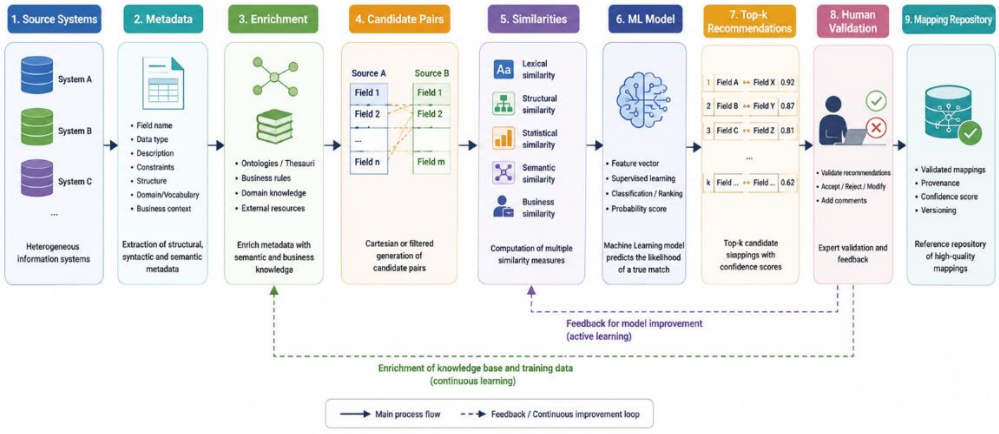

Fig. 1. Conceptual framework of the proposed approach.

B. Source Systems Mapping

The first step is to identify the information systems involved in the semantic alignment. This mapping helps define the scope of the study, the applications to be compared, the existing data flows, the business objects manipulated, and the repositories used.

The mapping is not limited to a technical inventory of the applications. It must also identify the business objects manipulated by each system.

The output of this step is a structured list of the systems, tables, entities, and functional domains involved in the alignment.

C. Metadata Extraction

After mapping, the framework involves extracting metadata associated with the data fields. This metadata forms the basis of the recommendation process. It may include:

- the field's technical name;
- the functional label;

- the business description;
- the data type;
- the table or entity to which it belongs;
- any constraints;
- the most frequent values or main categories;
- the rate of missing values;
- the number of distinct values;
- the associated functional domain.

Using metadata helps to limit reliance on raw values, which is particularly important when dealing with sensitive data.

D. Metadata Standardization and Enrichment

The extracted metadata must be normalized before comparison. This normalization process includes several steps: converting to lowercase, removing special characters, segmenting technical names, expanding abbreviations, translating if necessary, removing uninformative words, and harmonizing formats.

Enrichment adds supplementary information from industry dictionaries, synonyms, internal repositories, or sector-specific vocabularies. This step is important because raw lexical similarity does not always allow for the detection of semantic matches. Enrichment can also incorporate vector representations, such as text embeddings.

E. Generation of Candidate Pairs

If two systems contain n and m fields respectively, an exhaustive comparison produces $n \times m$ possible pairs. In a real-world environment, this number can become very high. The proposed framework therefore includes a candidate pair generation step to reduce the search space.

This step aims to retain plausible candidate pairs while filtering out pairs that are unlikely to represent valid semantic correspondences. Candidate filtering is performed using complementary criteria:

- data-type compatibility;
- functional-domain consistency;
- minimal lexical proximity;
- minimal semantic proximity;
- comparable business entities;
- presence of shared keywords, synonyms, or domain-specific terms.

A candidate pair is retained when it satisfies at least one of these compatibility conditions, thereby reducing the search space without excluding potentially valid mappings too early in the process. For example, a date field will be compared first to other date fields. A field belonging to the "contract" domain will be compared first to fields related to contracts, guarantees, or formulas. This filtering reduces unnecessary comparisons and focuses the model on truly plausible pairs.

F. Construction of Similarities

For each candidate pair, the framework constructs a feature vector representing several similarity dimensions. Let us consider two fields a and b, coming respectively from two systems S_1 and S_2. The candidate pair can be represented by:

$$P_{ab} = (\alpha,\beta) \quad (1)$$

This pair is associated with a vector of characteristics:

$$X_{ab} = [sim_{lex}, sim_{sem}, sim_{str}, sim_{stat}, sim_{met}] \quad (2)$$

where:

sim_{lex} represents lexical similarity;

sim_{sem} represents semantic similarity;

sim_{str} represents structural similarity;

sim_{stat} represents statistical similarity;

sim_{met} represents business similarity;

- Lexical similarity compares technical names and field labels. It can be calculated from measures such as edit distance, string similarity, token similarity, or word overlap.
- Semantic similarity compares the meaning of fields. It can be obtained from dictionaries, embeddings, or language models.
- Structural similarity takes into account the context of the field in the schema: table, entity, relationships with other fields, position in the data model, or proximity to certain business objects.
- Statistical similarity exploits the observed properties of the data, when these are available in raw or aggregated form: distribution of values, number of distinct values, average length, rate of missing values, dominant type or frequency of categories.
- Business similarity uses rules, standards, taxonomies, synonyms, or abbreviations specific to the field studied. It makes it possible to introduce functional knowledge into the learning process.

G. Machine Learning Scoring

Once the features are constructed, the problem is formulated as a supervised classification task. Each pair of fields is associated with a label:

$$y_{ab} = \begin{cases} 1 & \text{if } a \text{ and } b \text{ correspond to the same business concept} \\ 0 & \text{else} \end{cases} \quad (3)$$

The model learns a function:

$$f(X_{ab}) \rightarrow \Pi\,(y_{ab} = 1) \quad (4)$$

This function produces a matching score between 0 and 1. The higher the score, the more likely the pair is considered to be a match.

Several models can be used: logistic regression, Random Forest, XGBoost, SVM, or models based on textual representations. Random Forest models are capable of capturing nonlinear relationships between variables [19], whereas

XGBoost is generally used for tabular issues thanks to its efficient and scalable gradient boosting mechanism [20], [21]. Language models can also be utilized to boost semantic similarity or to generate textual representations of fields [10].

H. Recommendation Top-k

For each source field, the framework recommends the k target fields based on the highest scores. This top-k recommendation logic is suitable for operational use, as it enables the expert to select among several probable matches rather than relying on a single automatic suggestion.

Metrics like hit@k, and MRR are relevant for evaluating recommendation systems because they assess the ability of the system to place the correct match in the top results [11].

I. Human Validation and Improvement Loop

The proposed framework requires essential human validation to ensure the accuracy of mappings before their incorporation into operational processes. The framework recommends involving at least three domain experts, who assess recommendations using the canonical concept definitions, business rules, and domain dictionary as reference. When several experts are involved, agreement can be assessed using Fleiss' kappa, while unresolved cases can be addressed through consensus. Each recommendation can be assigned one of the following decisions:

- validated match;
- rejected match;
- match to be reviewed;
- partial or conditional match.

This validation reduces the risk of incorrect mappings, which can lead to integration or reporting errors. It also allows for the gradual accumulation of business knowledge. Validated decisions can be fed back into the training dataset to improve model performance in subsequent iterations.

The improvement loop can be represented as illustrated in Fig. 2:

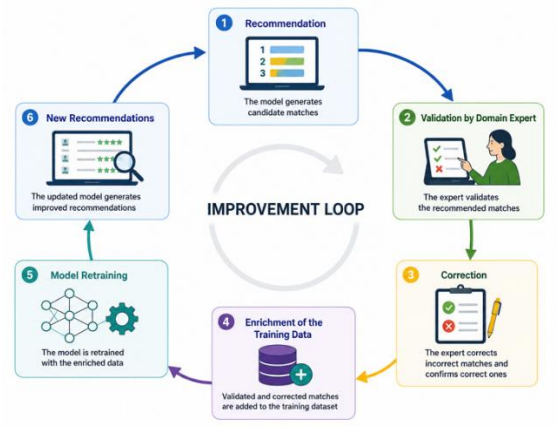

Fig. 2. Improvement loop for semantic mapping recommendation.

This loop allows semantic alignment to be embedded in a progressive, controlled, and traceable process.

J. Capitalizing on Validated Mappings

Validated mappings are stored in a mapping repository. This repository can be used in several IT applications:

- feeding ETL flows;
- harmonizing APIs;
- building a data dictionary;
- consolidating a business intelligence warehouse;
- populating dashboards;
- preparing analytical datasets;
- improving the reliability of predictive models.

Capitalizing on validated mappings avoids having to repeat the alignment process for each new integration project. It also contributes to improving data quality, understood as its suitability for use by data consumers.

V. Case Study and Results

In the illustrative case study, the proposed hybrid semantic interoperability framework assisted by machine learning was evaluated in a health insurance environment. This context is relevant because it involves several heterogeneous information systems that share common business concepts but use different structures, naming conventions, and repositories.

A. Data Used

The dataset used is structured around six systems (CRM, CONTRACT, CLAIMS, COMPLAINTS, DW, and PARTNER), 280 schema fields, 34560 candidate pairs, and 1250 positive mapping pairs. The resulting ratio is approximately 1:26.65, confirming the strong class imbalance inherent in the initial schema-matching dataset. The dataset used in the experiments was constructed from schema structures, terminology, and business knowledge representative of a confidential health-insurance environment. To preserve confidentiality, no raw personally identifiable production data were included. The 65 canonical concepts were defined in collaboration with domain experts and based on an internal business dictionary covering the main functional concepts shared across the participating information systems. Positive mappings were established by associating schema fields with these canonical concepts and validating the correspondences against their business definitions. Ambiguous cases were reviewed before being retained in the reference mapping set. Table I summarizes the main characteristics of the dataset.

TABLE I. Dataset Characteristics

Characteristic	Value
Information systems	6
Schema fields	280
Canonical concepts	65
Candidate pairs	34 560
Negative pairs	33 310
Positive pairs	1 250

To mitigate the strong class imbalance, controlled under-sampling was applied to the negative class. All 1,250 positive mappings were retained, while 2,500 negative pairs were selected, resulting in a ratio of 1:2.

To obtain a reliable evaluation and minimize information leakage, the dataset was partitioned at the canonical-concept level rather than by randomly splitting individual candidate pairs. Candidate pairs associated with the same canonical concept were assigned to the same subset, thereby reducing the possibility that highly similar instances could appear simultaneously in the training and evaluation sets. The resulting dataset was divided into training, validation, and test subsets using an approximate 70% /15% /15% distribution.

B. Experimental Implementation

All schema-field metadata were normalized by lowercasing, removing special characters, tokenizing technical identifiers, and expanding common abbreviations. Each candidate pair was represented by five similarity features normalized to [0,1]. Lexical similarity was computed using Jaro-Winkler similarity, while semantic similarity was obtained from cosine similarity between Sentence-BERT (all-MiniLM-L6-v2) embeddings. Structural similarity captured data-type compatibility and schema-context information, statistical similarity relied on differences in missing-value rate, cardinality, and average value length, and business similarity was derived from an internal health-insurance dictionary containing domain terminology, synonyms, and common abbreviations.

All supervised models were trained and evaluated using the same data partitions, feature representation, and class-balancing strategy. A fixed random seed of 42 was used for reproducibility. The main model configurations retained after validation are summarized in Table II.

TABLE II. MAIN MODEL CONFIGURATIONS

Model	Main hyperparameters
Logistic Regression	C=1.0, penalty='l2', solver='liblinear', max_iter=1000, random_state=42
Decision Tree	criterion='gini', max_depth=6, min_samples_split=10, min_samples_leaf=2, random_state=42
Random Forest	n_estimators=300, max_depth=8, min_samples_leaf=2, max_features='sqrt', random_state=42
Gradient Boosting	n_estimators=200, learning_rate=0.05, max_depth=3, subsample=0.8, random_state=42
XGBoost	n_estimators=200, max_depth=4, learning_rate=0.05, subsample=0.8, colsample_bytree=0.8, objective='binary:logistic', eval_metric='logloss', random_state=42

The binary decision threshold was also selected on the validation set by maximizing the F1-score and was subsequently fixed for test evaluation. For Top-k recommendation, candidate mappings were ranked directly according to their predicted probabilities.

C. Performance of Classification Models

To compare different match detection strategies, several models were evaluated. The first baseline model relied solely on lexical similarity. The second baseline model calculated an average hybrid score based on the various available similarities. Supervised models were then tested: logistic regression, decision tree, random forest, gradient boosting, and XGBoost.

Table III presents the results obtained on the test set.

TABLE III. RESULTS OF THE PERFORMANCES OBTAINED

Model	Accuracy	Precision	Recall	F1-score	AUC
Lexical similarity	82.47 %	72.11 %	69.68 %	70.87 %	0.748
Hybrid scoring (rules)	86.53 %	80.74 %	81.91 %	81.32 %	0.836
Logistic regression	88.28 %	84.36 %	84.04 %	84.20 %	0.861
Decision tree	87.71 %	82.64 %	83.51 %	83.07 %	0.842
Random Forest	90.76 %	86.87 %	87.23 %	87.05 %	0.889
Gradient Boosting	91.85 %	87.94 %	89.36 %	88.64 %	0.903
XGBoost	92.90 %	88.54 %	90.43 %	89.48 %	0.915

The results show that lexical similarity used in isolation provides limited performance. Although this approach achieves an accuracy of 82.47%, it remains heavily influenced by class imbalance. In contrast, metrics better suited to this context, such as precision (72.11%), recall (69.68%), and F1 score (70.87%), highlight the difficulty of purely lexical approaches in correctly identifying semantic matches.

Integrating several families of similarities significantly improves performance. The hybrid score, which combines lexical, structural, statistical, semantic, and domain similarities, achieves an F1 score of 81.32%, an improvement of more than 10 percentage points over the lexical approach.

Supervised models confirm this trend by achieving superior performance. The XGBoost model achieves the highest performance with an accuracy of 92.90%, a precision of 88.54%, a recall of 90.43%, an F1-score of 89.48%, and an area under the ROC curve (AUC) of 0.915. These results reflect an excellent ability of the model to distinguish correct matches from non-matches, even in a context characterized by a strong imbalance between classes.

D. Results of the Top-k Recommendation

Beyond binary classification, the proposed framework aims to recommend a prioritized list of potential mappings. Top-k metrics were calculated on source field groups for which at least one positive match exists in the test set. The results are presented in Table IV:

TABLE IV. TOP-K RESULTS

Model	Hit@1 (%)	Hit@3 (%)	Hit@5 (%)	MRR
Lexical Similarity	60.85	73.40	78.72	0.663
Hybrid Similarity	73.19	83.51	86.70	0.773
Logistic Regression	75.53	84.57	87.77	0.791
Decision Tree	71.81	81.91	85.11	0.756
Random Forest	79.79	87.77	89.89	0.835
Gradient Boosting	81.91	89.36	91.49	0.852
XGBoost	83.51	90.43	91.49	0.871

The Top-k evaluation further demonstrates the effectiveness of the proposed semantic mapping approach. The lexical baseline achieves a Hit@1 of 60.85%, indicating that the correct mapping is ranked first in only about three-fifths of the queries, while the Hit@3 (73.40%) and Hit@5 (78.72%) scores suggest that relevant mappings are often retrieved but not consistently ranked at the top. Combining lexical, structural, statistical, semantic, and domain-specific similarities substantially improves the ranking quality, with the hybrid similarity score increasing Hit@1 to 73.19% and achieving Hit@3 and Hit@5 scores of 83.51% and 86.70%, respectively. Supervised learning models further enhance the ranking performance, with ensemble methods outperforming both lexical and hybrid approaches. Among them, XGBoost achieves the best overall results, reaching a Hit@1 of 83.51%, a Hit@3 of 90.43%, a Hit@5 of 91.49%, and an MRR of 0.871, demonstrating its ability to consistently rank the correct semantic correspondence among the highest-ranked candidates and thereby reduce the effort required for manual validation.

E. Similarity Ablation Analysis

To assess the contribution of each family of similarities, an ablation analysis was performed using the XGBoost model, identified as the most effective during the comparative evaluation (see Table V). Each variant consists of progressively adding a new family of features while maintaining the same hyperparameters and the same experimental protocol.

TABLE V. ABLATION ANALYSIS

Variant	Similarities used	Precision	Recall	F1-score	AUC
V1	Lexical	72.11%	69.68 %	70.87 %	0.748
V2	Lexical + Structural	78.62 %	77.13 %	77.87 %	0.815
V3	V2 + Statistical	83.15 %	84.04 %	83.59 %	0.861
V4	V3 + Semantic	86.91 %	87.77 %	87.34 %	0.897
V5	Complete Framework (Lexical + Structural + Statistical + Semantic + Business)	88.54 %	90.43 %	89.48 %	0.915

The ablation results show a progressive improvement in performance as additional similarity families are integrated. Using lexical similarity alone yields the lowest F1-score (70.87%). Adding structural similarity produces the largest incremental improvement, increasing the F1-score by 7.00 percentage points to 77.87%, while the addition of statistical similarity provides a further gain of 5.72 points. Semantic similarity then increases the F1-score to 87.34%, and the final inclusion of business similarity further improves it to 89.48%. These results indicate that all similarity families provide complementary information, with structural and statistical similarities contributing the largest incremental gains, while semantic and business similarities provide additional improvements that lead to the best overall performance of the complete framework.

The results illustrate the approach of developing a hybrid framework for solving the problem of semantic interoperability using heterogeneous information systems. Based on the evaluation metrics, lexical, structural, statistical, and semantic/business similarities combine together, resulting in the high accuracy of matching schema correspondences as opposed to the solution with single features together. As a result, cross-comparison analyses and top-k recommendation, as well as ablation study results, validate the relevance of this method with emphasis drawn on business knowledge and semantic similarities. These findings thus confirm the framework's capability to enable the identification and validation of semantic alignments, marking a crucial advancement towards enhanced semantic compatibility between information systems.

VI. DISCUSSION

The results obtained confirm that improving semantic interoperability cannot rely solely on lexical comparison of schemas. Differences in terminology, structure, and business context between information systems necessitate an approach capable of leveraging complementary information sources. In this regard, the proposed hybrid framework demonstrates that a combination of lexical, structural, statistical, semantic, and business similarities enables the generation of more relevant and robust recommendations for identifying correspondences.

In addition to the performance attained, this investigation underscores the benefit of a decision-making approach supported by machine learning. The collaboration between artificial intelligence and business expertise represents a significant lever for accelerating data integration projects while improving the quality of semantic mappings.

The evaluation was conducted within a health-insurance context, which may limit the direct generalization of the results to other application domains. Although the proposed framework is domain-independent in its overall architecture, some components, particularly the business similarity and domain dictionary, require adaptation to the terminology and business rules of each sector. Future evaluations should therefore consider additional domains such as logistics, financial services, or healthcare information systems to further assess the generalizability of the approach.

Future work may also focus on taking into account the evolution of business patterns and vocabularies, in order to maintain a high level of semantic interoperability in constantly evolving information systems.

VII. CONCLUSION

This study presented a hybrid semantic mapping recommendation framework aimed at improving semantic interoperability between heterogeneous information systems. The proposed approach integrates multiple types of similarities (lexical, structural, statistical, semantic, and business) with a supervised learning model to automate mapping recommendations, while keeping the business expert at the heart of the validation process.

Experimental evaluation, conducted on a case study in the health insurance sector, highlights the effectiveness of the proposed framework. The results show that combining complementary information sources significantly improves the quality of recommendations compared to approaches based on a single similarity measure. Comparative analyses, Top-k recommendation performance, and ablation studies confirm the contribution of each family of features to the quality of the recommended mappings.

Beyond the performance achieved, this research underscores the value of a hybrid approach for facilitating data integration projects. By proposing relevant semantic correspondences and reducing the effort required for their validation, the developed framework provides decision support that can accelerate semantic interoperability processes while improving their reliability.

Can We Trust Concept-Based ECG Explanations? A TCAV Analysis of Confounding and Reproducibility in Atrial Fibrillation Detection

El Hassane Jennah*, Houda Indjaren, Lhoucine Ben Taleb, Hamid El Malali, Azeddine Mouhsen
Department of Applied Physics, Energy, Matter, Instrumentation and Telecom Laboratory-Faculty of Sciences and Techniques, Hassan First University, Settat, Morocco

***Abstract*—AI explanation methods are typically validated in one of two ways: by confirming that an explanation is not an artifact of the underlying data (a confound check), or by confirming that it generalizes to unseen data. Fewer studies examine whether an explanation is stable across independently trained copies of the same model. We present a validation framework combining both dimensions — confound control and model-seed reproducibility — and demonstrate it in a case study using a deep learning model trained to detect atrial fibrillation (AF) from long, continuous ECG recordings. Using concept activation vectors (CAVs), we test whether the model's predictions are associated with three clinically meaningful patterns: irregular heartbeat timing, the presence of abnormal beats, and proximity to a rhythm change. We find that a concept-prediction association can be statistically significant and survive a targeted AF-label confound control in one trained model, yet reverse direction when the same architecture is retrained from a different random initialization. Across the nine concept-depth combinations examined, three replicated consistently across five independently trained models, two were inconclusive, and four showed evidence of directional instability under the predefined criterion. These findings demonstrate, within this AFNet/LTAFDB case study, that statistical significance and confound robustness alone may not establish a stable concept-based explanation; model-seed reproducibility provides a complementary validation dimension that can reveal sensitivity to training initialization.**

***Keywords*—Explainable AI; concept activation vectors; TCAV; atrial fibrillation; reproducibility; electrocardiogram**

I. Introduction

Deep learning models can detect atrial fibrillation (AF) from ECG signals with high accuracy [1]-[3]but their internal reasoning remains difficult to interpret. One approach to explaining what a model has learned is to test whether its internal representation aligns with a clinically meaningful concept (e.g., “irregular heartbeat”) rather than only identifying which input samples influenced a prediction. This is known as concept-based explanation, and Testing with Concept Activation Vectors (TCAV) is a widely used method of this kind [4]Subsequent work has extended it toward automatic concept discovery and completeness guarantees [5], [6]. Existing studies typically validate a result against a single trained model, sometimes after ruling out an obvious confound (for instance, confirming that the “concept” is not simply a proxy for the prediction itself). We ask a further question: if a result survives such a check, does it still hold when the same model is retrained from scratch?

We investigate this using AFNet, a compact convolutional network trained to detect AF from the Long Term AF Database, a set of continuous, day-long ambulatory ECG recordings, as a testbed for a more general validation framework. We define three clinical concepts directly from the dataset's own annotations — RR-interval irregularity, ectopic beat burden, and proximity to a rhythm change — rather than relying on externally curated example images, as in prior work. We test whether the model's predictions are associated with each concept at three depths within the network, both with and without an AF-label confound control, and across five independently trained models. The principal finding of this study concerns not any single clinical pattern, but a methodological one: a concept-prediction association can be statistically significant and pass a confound check, yet still fail to reproduce when the model is retrained from a different initialization — confound robustness and model-seed reproducibility are distinct validation dimensions that can disagree.

II. Related Work

Earlier work applying TCAV-style methods to ECG models treats a “concept” as a diagnostic label (for example, “this ECG shows AF”), built from a hand-picked set of example recordings, tested on short 10-second clips, and validated against only one trained model [7]. A similar approach has been used for EEG [8]. More broadly, XAI research has emphasized the need for explicit evaluation criteria rather than assuming that an explanation is valid because it is visually plausible or statistically associated with a target [9]-[11]. In particular, rigorous evaluation frameworks distinguish between different explanation properties and recognize that explanation behavior can depend on the underlying model and data [12]. Saliency-method work has also shown that model- and data-randomization tests can reveal explanations that are insufficiently tied to the learned model. In healthcare, recent surveys and systematic reviews likewise identify explanation assessment and reliability as important open issues [9], [13], [14]. Most other ECG and medical-imaging explanation work instead highlights which parts of the input mattered (e.g., saliency maps, SHAP, Grad-CAM), which represents a different form of explanation, often validated through visual or attribution-based analyses [15]-[16]. Our

*Corresponding author.

work differs in three respects: our concepts are operationalized directly from the dataset's own beat and rhythm annotations rather than hand-picked; we use continuous, multi-hour recordings rather than short clips; and we add a systematic reproducibility check across several independently trained models — reframing the contribution from "TCAV applied to ECG" toward a systematic confound-and-model-seed validation framework for concept-based explanations (Table I).

TABLE I. COMPARISON WITH THE CLOSEST PRIOR WORK

Study	Dataset	How "concept" is defined	Checked across multiple models?
AiTiALVSD [7]	Short clinical ECG	Diagnostic label, hand-picked examples	No
TCAV-for-EEG [8]	EEG	Hand-picked examples	No
This work	**LTAFDB (continuous, ~24h)**	**Operationalized directly from the dataset's own labels**	**Yes (5 models x 3 depths)**

III. METHODS

Our approach proceeds in two stages. First, we train a standard detection model on raw ECG windows. We then test whether the trained model's predictions are associated with specific clinical concepts, using concept activation vectors (CAVs), and validate any resulting findings with two additional checks: an AF-label confound control and a test for reproducibility across independently trained models.

A. Data and Model

We used the Long Term AF Database [17], comprising 84 continuous ECG recordings of approximately one day each. Each recording was segmented into 10-second windows and labeled AF or non-AF using the database's own rhythm annotations. A compact convolutional neural network (AFNet, Fig. 1) was trained to classify each window, with patients used for testing kept entirely separate from those used for training. The network consists of a stem convolution followed by four residual blocks of increasing channel width, global average pooling, and a classification head, consistent with recent 1D convolutional approaches to inter-patient ECG arrhythmia classification [18]. The trained model distinguished AF from non-AF windows with high accuracy (AUC 0.976 on unseen patients).

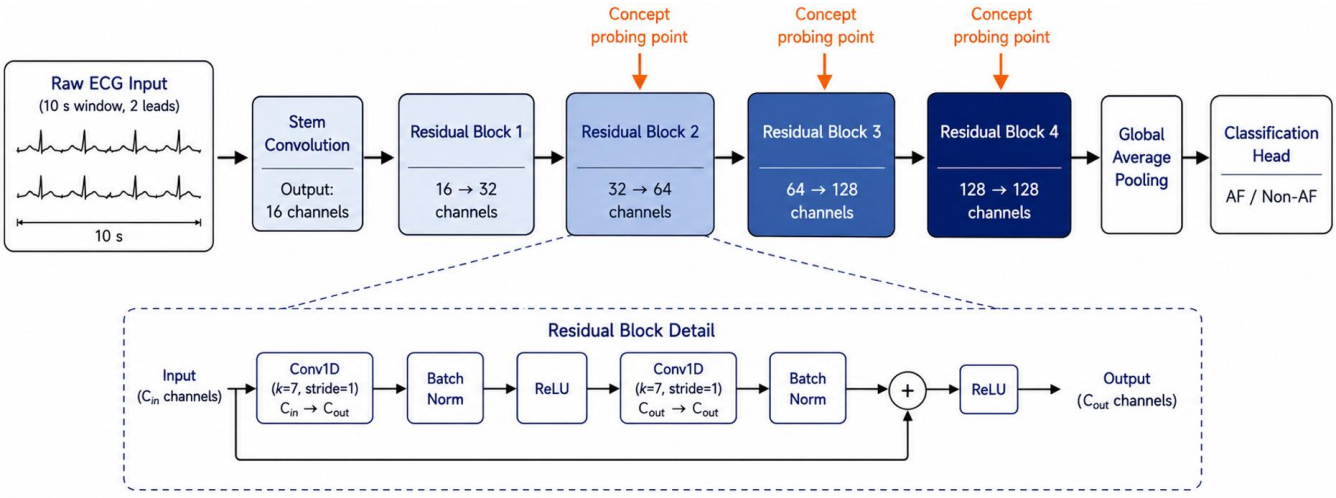

Fig. 1. AFNet architecture. Raw ECG windows pass through a stem convolution and four residual blocks of increasing channel width, followed by global average pooling and a classification head. Concept activation vectors are probed at the output of residual blocks 2, 3, and 4.

B. Concepts and CAV Probing

We defined three clinical concepts directly from the dataset's own beat and rhythm annotations: RR-interval irregularity (the variability in spacing between consecutive heartbeats), ectopic beat burden (the proportion of abnormal beats present), and proximity to a rhythm change (how close a window lies, in time, to a transition between rhythms). For each concept, at three depths within the network, we tested whether the model's internal representation aligned with that concept, using concept activation vectors (CAVs), illustrated in Fig. 2. Briefly: we identify example windows that do and do not exhibit the concept (panel A), find the direction within the model's internal representation that separates them (panel B), and test whether movement in that direction is associated with increased model confidence in an AF prediction (panel C); the proportion of test windows for which this holds is the TCAV score (panel D). Each analysis was repeated across 200 trials: in each trial we drew a fresh random subsample of up to 300 positive and 300 comparison windows, without replacement, from the pooled training and validation set, and trained a new linear CAV (logistic regression) on that subsample; a matched null CAV was trained in parallel on two randomly-labeled subsamples that ignore the concept value. These 200 trials are resampled CAV constructions within the same trained model, dataset, and target set; they are therefore not independent model-training replicates and should not be interpreted as additional model-seed evidence. This within-analysis resampling estimates the variability of the CAV/TCAV comparison conditional on a fixed trained model, whereas the

five model seeds in Section III-C change the learned network itself. The resulting concept-directed and null TCAV score distributions were compared using a Welch's t-test, a Mann-Whitney U test, and a permutation test (10,000 resamples, difference-of-means statistic, label permutation). We treat the three tests as convergent checks on a single comparison rather than independent evidence; the permutation test, being the most assumption-free of the three, was used for the primary significance decision. Benjamini-Hochberg false discovery rate (FDR) correction was applied to the permutation-test p-values across the family of nine concept-depth comparisons, with significance declared at an FDR-adjusted alpha of 0.05.

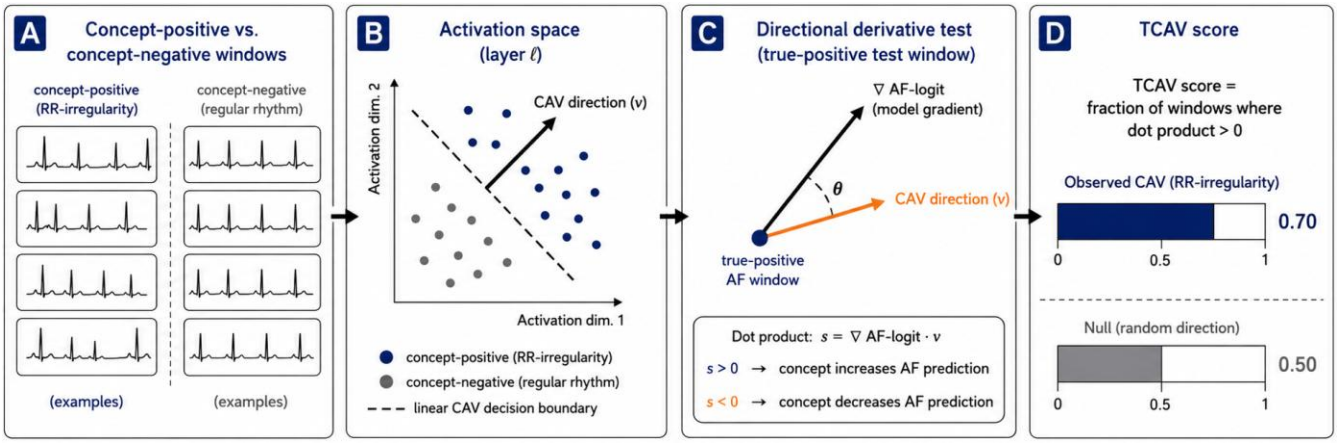

Fig. 2. How a concept activation vector (CAV) is built and tested. (A) Example ECG windows with and without a clinical concept. (B) A linear boundary separating them within the model's internal representation. (C) Testing whether that direction aligns with increased model confidence in AF. (D) The resulting TCAV score.

C. AF-Label Confound Control and Model-Seed Reproducibility

A potential confound arises because these clinical concepts are naturally more prevalent in AF windows: AF windows exhibit greater RR-interval irregularity, for example, simply because irregularity is a defining feature of the rhythm. As a result, a CAV could, in principle, re-derive the AF/non-AF distinction rather than capture an independently represented clinical concept. To address this specific, most direct confound, we reconstructed each CAV using only non-AF-labeled windows (Fig. 3, panels A-B), removing the ability to rely on the AF label directly. The purpose of this AF-label confound control is not to establish that these concepts are entirely independent of AF — RR-irregularity and ectopic burden are, by clinical definition, correlated with the rhythm — but to test whether the CAV's association with the model's AF prediction persists once the direct AF/non-AF label separation is removed from CAV construction. Patient-specific characteristics, recording conditions, and other correlated clinical variables are not controlled for by this step.

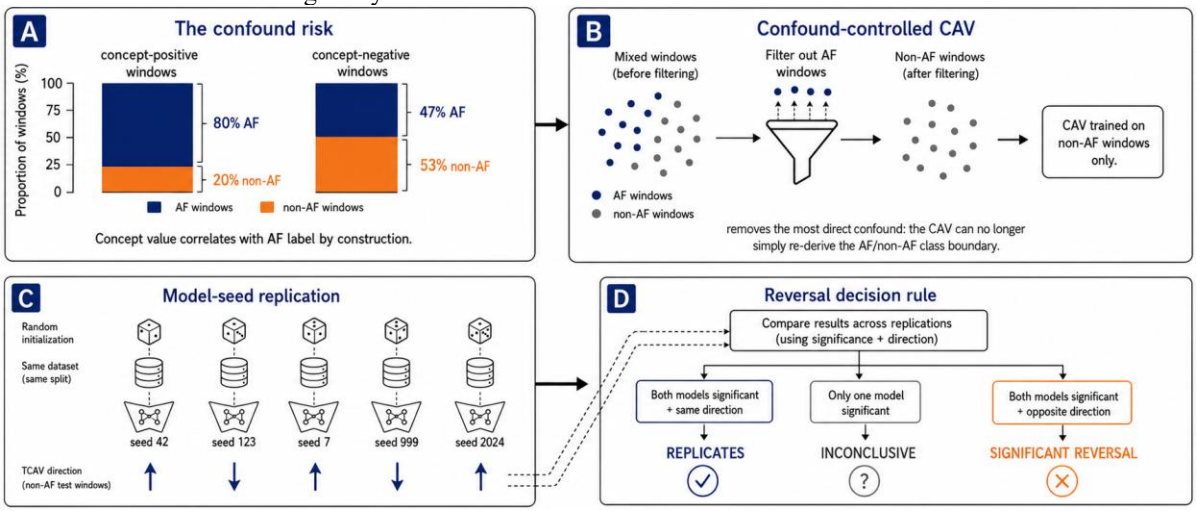

Fig. 3. Two additional validation steps. (A-B) AF-label confound control: rebuilding the CAV from non-AF windows only. (C) Retraining the model five times with different random seeds. (D) The criterion used to determine whether a disagreement between models constitutes a genuine reversal.

A further question is whether a result that survives this AF-label confound control reflects a general property of the model, or an artifact of a single training run. We trained four additional copies of AFNet, each initialized with a different random seed (varying both the model's weight initialization and the order in which training batches were drawn, while holding the data split and all other hyperparameters fixed) and repeated the full confound-controlled analysis on each (Fig. 3,

panel C). We designate the original model (seed 42) as the reference and compare each of the other four models against it individually. A result was classified as a significant reversal only when it was statistically significant in both the reference model and at least one comparison model, but in opposite directions; a result was classified as replicating when it was significant and in the same direction in the reference model and all four comparison models; all other outcomes were classified as inconclusive (Fig. 3, panel D). This criterion is intentionally asymmetric: replication required complete directional consistency across all five models, whereas any single statistically significant opposite-direction result was sufficient to flag potential instability. Because this rule can make the reversal category more sensitive than the replication category, we also performed a simple threshold-sensitivity check using the per-model results in Table III: requiring at least two, rather than one, comparison models to disagree significantly does not change which four concept-depth combinations are labeled reversals; a threshold of three would be more stringent and would retain only the combination with three dissenting models. We therefore interpret the reversal count as a conservative instability flag rather than as an estimate of the prevalence of reversals. The individual model outcomes are reported in Section IV-C so that readers can assess the degree of disagreement directly.

IV. Results

A. The Pattern Depends on How Deep You Look

Before applying any confound control, we tested whether the model's internal representation aligned with each of the three clinical concepts at three depths within the network. Fig. 4 plots the resulting TCAV score against its null baseline for each concept-depth combination.

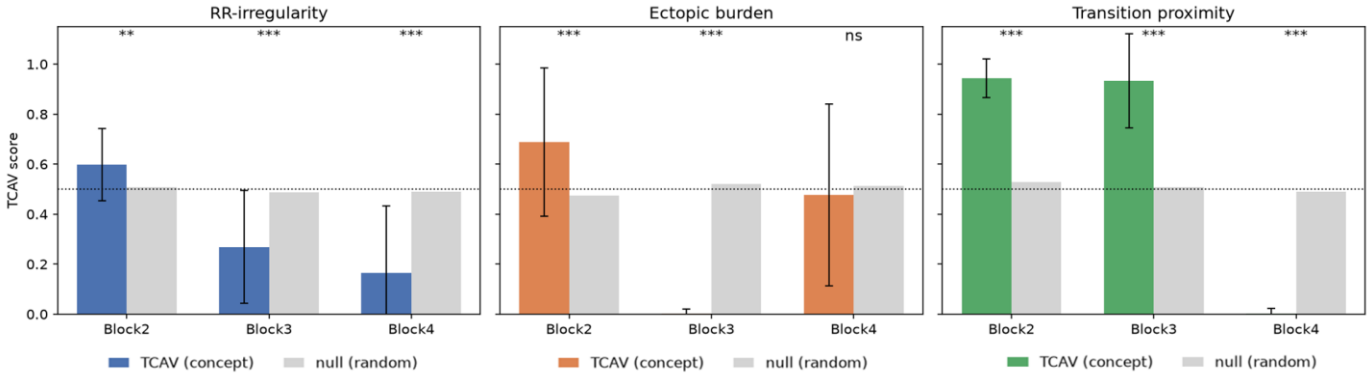

Fig. 4. TCAV score compared to a random-direction baseline, at each depth, for each pattern. Error bars show ±1 SD across 200 resampled trials; asterisks mark significance after FDR correction (* p<0.05, ** p<0.01, *** p<0.001, ns = not significant).

Nearly every result in Fig. 4 is statistically significant; the one exception is ectopic beats at the final layer. Irregular timing and ectopic beats are both positively associated with AF near the start of the network, then reverse to a negative association by the middle layer. The distance-to-rhythm-change pattern shows the opposite and more pronounced behavior: strongly positive through the first two depths, then reversing to strongly negative immediately before the model's final decision.

B. The AF-Label Confound Check Changes Three Results

To test whether these associations reflected the clinical concept itself rather than a proxy for the AF label, we rebuilt every CAV using only non-AF-labeled windows and repeated all nine comparisons. Table II reports the outcome of each comparison, alongside the corresponding uncontrolled result.

TABLE II. TCAV Significance and Direction Before and After AF-Label Confound Control, Across All Nine Concept-Depth Combinations

Concept	Layer	Uncontrolled	AF-Controlled	Change
Irregular heartbeat timing	Early	+ (p<0.01)	+ (p<0.001)	—
Irregular heartbeat timing	Middle	− (p<0.001)	− (p<0.001)	—
Irregular heartbeat timing	Final	− (p<0.001)	+ (p<0.001)	Reversed
Ectopic (abnormal) beats	Early	+ (p<0.001)	+ (p<0.001)	—
Ectopic (abnormal) beats	Middle	− (p<0.001)	− (p<0.001)	—
Ectopic (abnormal) beats	Final	not significant	+ (p<0.001)	Gained significance
Distance to rhythm change	Early	+ (p<0.001)	+ (p<0.001)	—
Distance to rhythm change	Middle	+ (p<0.001)	not significant	Lost significance
Distance to rhythm change	Final	− (p<0.001)	− (p<0.001)	—

As Table II shows, six of the nine comparisons were unaffected by the AF-label confound control. The remaining three changed in three different ways: the irregular-timing result reversed sign at the final layer, the distance-to-rhythm-change result lost significance at the middle layer, and the ectopic-beats result at the final layer gained significance where

none had existed before. These changes indicate that the observed association was sensitive to the AF-label composition of the CAV training set, not necessarily that the original result was purely an artifact, since a change in direction or significance could also reflect a shift in the CAV's measured geometry once the training population changed. We treat all three changes as evidence that the corresponding associations warrant further scrutiny, rather than as proof of which version — uncontrolled or AF-label-controlled — is the more genuine one; Section IV-C subjects all nine associations to the further test of model-seed reproducibility.

C. The Critical Test: Reproducibility Across Retrained Models

We then asked whether a result that survives this AF-label confound control also holds when the model is retrained from scratch under a different random initialization. Fig. 5 summarizes the outcome for all nine concept-depth combinations; Table III reports the underlying per-model result, since the single reversal/replicate/inconclusive label can obscure a more nuanced pattern.

We designate the model trained with seed 42 as the reference and classify each concept-depth combination by comparing the four other models against it individually: a result is a significant reversal only if it is significant in the reference model and in at least one comparison model, with opposite directions; it replicates if it is significant and in the same direction across the reference and all four comparisons; otherwise it is inconclusive. As Table III shows, three combinations replicate under this strict criterion, four show a significant reversal in at least one comparison, and two are inconclusive. The threshold-sensitivity check described in Section III-C shows that requiring two dissenting comparison models instead of one leaves the four reversal labels unchanged, although a threshold of three would produce a more conservative reversal count. These results should therefore be read as evidence of directional sensitivity within the tested AFNet/LTAFDB setting, not as an estimate of a general reversal rate. The individual model outcomes remain important context: for example, distance-to-rhythm-change at the early layer is called a reversal because three of the four comparison models do not all agree with the reference, while the direction tally shows two models significant in the original direction and three significant in the opposite direction. More generally, the results do not show that the model fails to use these concepts; they show that the direction of the concept-prediction association is not fully stable across independently trained instances of the same architecture. Five retrained models demonstrate that this sensitivity to initialization can occur, but they are not enough to establish how frequently it would occur across architectures, datasets, or larger numbers of retraining runs.

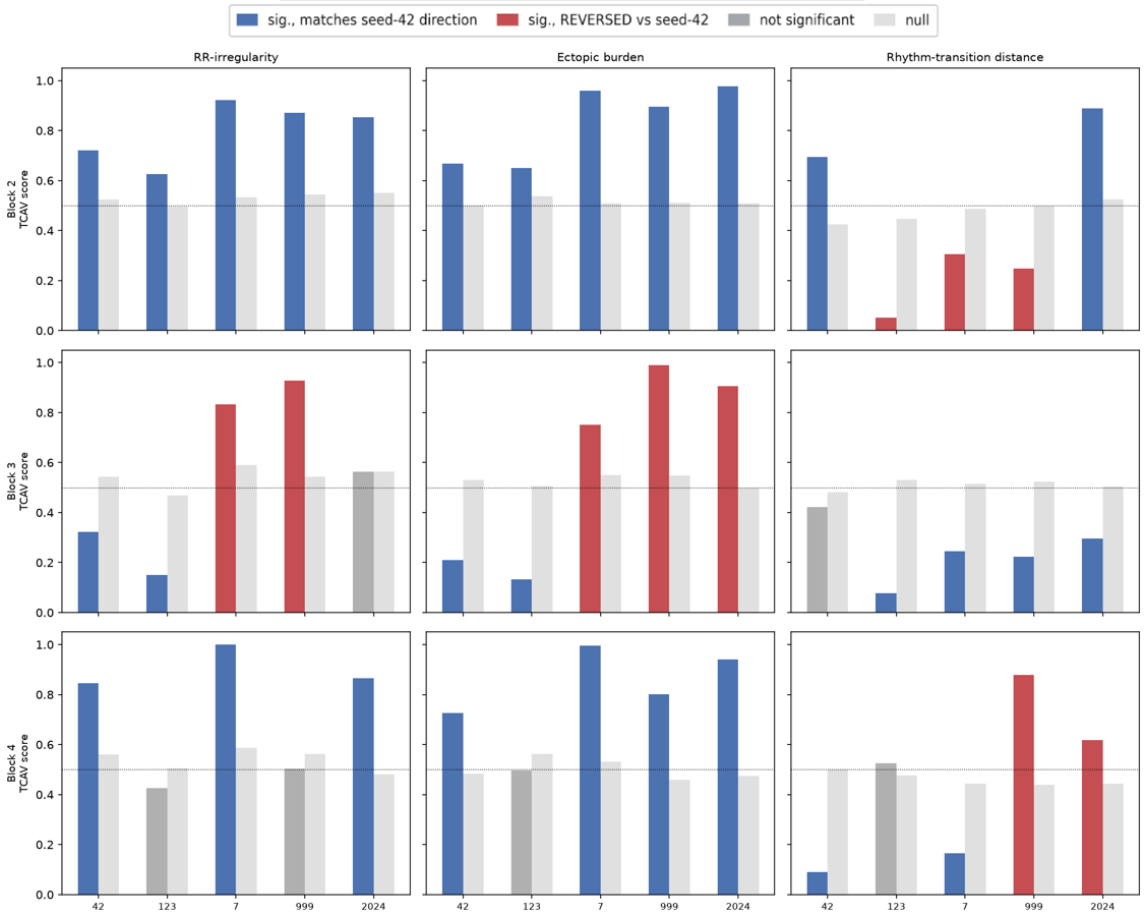

Fig. 5. Results across five independently trained models, for each pattern at each depth. Red bars indicate concept-depth combinations in which at least one comparison model showed a statistically significant association in the direction opposite to the reference model.

TABLE III. DIRECTION AND SIGNIFICANCE OF THE TCAV ASSOCIATION IN EACH OF THE FIVE INDEPENDENTLY TRAINED MODELS. SEED 42 IS THE REFERENCE MODEL

Concept	Layer	42	123	7	999	2024	Direction tally	Classification
Irregular heartbeat timing	Early	+	+	+	+	+	5/5 +, 0/5 −, 0/5 ns	Replicates
Irregular heartbeat timing	Middle	−	−	+	+	*(+)*	2/5 +, 2/5 −, 1/5 ns	Reversal
Irregular heartbeat timing	Final	+	*(−)*	+	*(−)*	+	3/5 +, 0/5 −, 2/5 ns	Inconclusive
Ectopic (abnormal) beats	Early	+	+	+	+	+	5/5 +, 0/5 −, 0/5 ns	Replicates
Ectopic (abnormal) beats	Middle	−	−	+	+	+	3/5 +, 2/5 −, 0/5 ns	Reversal
Ectopic (abnormal) beats	Final	+	*(−)*	+	+	+	4/5 +, 0/5 −, 1/5 ns	Inconclusive
Distance to rhythm change	Early	+	−	−	−	+	2/5 +, 3/5 −, 0/5 ns	Reversal
Distance to rhythm change	Middle	*(−)*	−	−	−	−	0/5 +, 4/5 −, 1/5 ns	Replicates
Distance to rhythm change	Final	−	*(+)*	−	+	+	2/5 +, 2/5 −, 1/5 ns	Reversal

D. Comparison with Standard Attribution Methods

As a point of comparison, we assessed whether two standard sample-level attribution methods, Grad-CAM [19] and SHAP [20] show any relationship with the same two clinical concepts. Table IV summarizes the results. This is a different kind of test than the concept-based analysis above: TCAV asks whether movement in a concept direction within the model's representation is associated with increased AF confidence, whereas this correlation asks whether the raw magnitude of a method's per-window attribution tracks the raw concept value. A near-zero correlation therefore does not mean these methods failed to detect the same effect TCAV detected; it means they were not asked, and did not answer, the same question.

TABLE IV. PEARSON CORRELATION (R) BETWEEN PER-WINDOW ATTRIBUTION MAGNITUDE AND THE RAW CONCEPT VALUE, ON TRUE-POSITIVE AF TEST WINDOWS (GRAD-CAM: N=3,093-3,105; SHAP: N=299-300, SUBSAMPLED FOR COST). * P<0.05; NS = NOT SIGNIFICANT

Method	vs. Irregular Timing	vs. Ectopic Beats
Grad-CAM	r = 0.004 (ns)	r = 0.038 (p = 0.04)*
SHAP	r = 0.012 (ns)	r = 0.053 (ns)

Table IV should therefore be interpreted narrowly. The four reported correlations answer a different question from TCAV: whether the raw magnitude of a sample-level attribution tracks the raw value of a clinical concept. They do not test whether Grad-CAM or SHAP recover the same internal concept direction, depth-dependent association, or sign tested by TCAV. The near-zero correlations indicate little linear association between these particular attribution magnitudes and the selected raw concept values in this experiment; the nominally significant Grad-CAM/ectopic correlation is extremely small. These results cannot establish that Grad-CAM or SHAP failed to detect the clinical patterns identified by TCAV. Rather, they show that the two attribution methods, under this particular correlation-based comparison, were not measuring the same quantity as the TCAV analysis. A method-specific, matched evaluation would be required to make stronger comparative claims.

V. DISCUSSION

Our main finding does not concern any specific clinical pattern. It is that statistical significance and AF-label confound robustness do not guarantee that a concept-prediction association will reproduce across independently trained models: confound robustness and model-seed reproducibility are distinct validation dimensions, and they can disagree in this case study. In our data, the pattern that appeared most convincing after the confound check — distance-to-rhythm-change at the final layer — was also among the associations that showed directional disagreement after retraining. Meanwhile, three associations proved fully consistent under the strict five-model replication criterion. A concept-based explanation should therefore not be considered validated solely because it is statistically significant and survives a confound check; in this setting, testing stability across independently trained model instances provides useful complementary evidence. This interpretation is consistent with broader calls for more rigorous evaluation of interpretability and explanation methods [14], [15] . Importantly, our evidence is limited to the AFNet architecture, the Long Term AF Database, the three operationalized concepts, and the five training seeds used here. We do not claim that directional instability is universal across architectures, datasets, ECG corpora, or concept definitions. Rather, the study demonstrates that such instability can occur and should be checked when the goal is to treat a concept-based association as a stable property of a trained model.

A few limitations are worth noting. Five retrained models are enough to demonstrate that sensitivity to model initialization can occur, but not enough to precisely estimate how often a given association would replicate under further retraining; our results should be read as evidence of sensitivity rather than as a population-level reproducibility rate. We tested only one model architecture on one dataset of 84 continuous recordings. The AF-label confound control addresses the most direct confound in this setting but does not rule out other correlated clinical or recording-specific variables. The 200 CAV trials are repeated resamplings within a fixed model and dataset, not independent training runs, so they should not be

counted as additional evidence of model-level reproducibility. Finally, the Grad-CAM/SHAP comparison uses a different statistical quantity from TCAV and is consequently descriptive rather than a head-to-head test of explanation quality. These limitations define the intended scope of the conclusions and motivate the extensions outlined below.

VI. Future Work

Future work should test whether the observed directional sensitivity persists across alternative ECG architectures, independent ECG corpora, and longer or differently segmented recordings. The framework should also be extended to additional concept types, including morphology, rate-related, and temporal-transition concepts, and to larger numbers of independent training runs so that reproducibility can be estimated rather than only flagged. For the comparison with sample-level attribution methods, future studies should use matched evaluation questions and method-appropriate metrics rather than comparing TCAV directionality with raw attribution–concept correlations. More broadly, systematic XAI reviews emphasize the need for explicit explanation assessment and trustworthy evaluation in healthcare [9], [11], [12]. These extensions would help determine whether the validation framework demonstrated here is specific to the present AFNet/LTAFDB case or generalizes to other physiological time-series models and explanation methods.

VII. Conclusion

A concept-based AI explanation can be statistically significant and survive a targeted AF-label confound control, yet still fail to reproduce directionally when the same architecture is retrained from different random initializations. In this AFNet/LTAFDB case study, confound checks and model-seed reproducibility checks captured different sources of uncertainty, and the latter exposed directional sensitivity that was not apparent from the original model alone. We therefore recommend treating model-seed reproducibility as a complementary validation check when a concept-based association is intended to be interpreted as a stable property of a trained model. We do not claim that this requirement has been established as a universal standard for all concept-based explanation methods from this single study; validation requirements should be adapted to the explanation method, model, data, and intended use.

HR-CD-Auth: Consent-Bound Cross-Domain Pseudonymous Authentication for Vocational Counseling and Employment Matching

Haewon Byeon[1], Changmin Keum[2]*
Department of Future Technology, Korea University of Technology and Education (KOREATECH), Cheonan 31253, South Korea[1]
Department of Employment Service Policy, Korea University of Technology and Education (KOREATECH), Cheonan 31253, South Korea[2]

***Abstract*—Vocational counseling platforms move sensitive records across counseling centers, enterprise human-resource systems, public employment services, and automated matching engines. Direct reuse of cross-domain authentication leaves identifiers linkable, separates authentication from purpose and consent, and gives revocation no protocol-level effect on cached credentials. HR-CD-Auth combines domain-scoped pseudonyms, compartmented data keys, consent-bound capabilities, and an ephemeral X25519 handover. Automated analysis of the initial capability-only fast path with ProVerif 2.05 found four failures: protected-record secrecy, accepted-session-key secrecy, and both injective-authentication correspondences. The repaired protocol delivers a fresh one-time handover key in separately protected client and gateway tickets, authenticates the first handover message, and mixes that key with the X25519 secret in HKDF. All four ProVerif queries then returned true. An OpenSSL-backed Python proof of concept executed three independent runs of 10,000 in-memory handovers on an AMD Ryzen 7 8845HS. Run-level medians were 0.2773-0.2812 ms, p95 latency was 0.4669-0.4820 ms, sequential throughput was 3041.5-3119.9 handovers/s, and the three online messages totaled 444 bytes. These figures isolate the cryptographic path and exclude network, TLS, database, policy-engine, and ledger delay. Identity resolution is separated from the online trust service through a two-authority, 2-of-2 threshold profile. The result is a measured and symbolically checked design whose remaining deployment and governance assumptions are explicit.**

Keywords*—Anonymous authentication; consent management; cross-domain authentication; employment matching; forward secrecy; pseudonymization; vocational counseling

I. Introduction

Vocational counseling has become a distributed information service. A single case may touch a mobile counseling application, a psychological-assessment provider, an enterprise human-resource gateway, a public employment database, and an automated matching engine. The resulting transcript is unusually sensitive: job-change intention, mental-health indicators, disability or health constraints, salary preferences, employment disputes, and interview availability can all influence a person's prospects. A breach is harmful; silent correlation across otherwise legitimate domains can be just as damaging.

The protocol problem is therefore narrower, and harder, than secure login. A destination gateway must recognize an authorized client without receiving a durable cross-domain identifier. It must also decide whether the present role, purpose, data class, consent version, and retention rule permit the requested operation. Authentication that ends with 'this is a valid user' is incomplete in this setting. The security decision is 'this pseudonymous session may perform this operation, for this purpose, under this consent state, until this expiry time.'

CD-AKA-IoV offers a useful starting point because it separates first-domain authentication, cross-domain notification, and fast subsequent handover [1]. Its vehicle, roadside-unit, and cloud-server assumptions do not transfer unchanged. The published construction assigns a pseudonym during registration and uses the central server to prepare state for a new destination. That is reasonable for its stated vehicular model. In an employment service, the same choices create a linkable handle, a concentrated metadata view, and no cryptographic response to consent withdrawal. These are deployment gaps, not a claim that the source protocol is broken in its original domain.

HR-CD-Auth addresses the gap through four linked mechanisms. First, a keyed, domain-scoped pseudonym is rotated with the session and consent version. Second, the trust service issues a short-lived handover capability that binds destination, purpose, data class, policy version, and expiry. Third, each domain handover performs an ephemeral X25519 exchange; long workflows then use a one-way key ratchet with erasure of prior state. Fourth, access events are committed through Merkle roots while the protected record stays in an encrypted off-chain vault. The ledger is outside the authentication critical path.

The article makes four contributions. First, it defines a threat model that joins a Dolev-Yao network adversary with legitimate-but-overreaching staff and removes unilateral pseudonym resolution through a two-authority threshold profile. Second, it specifies the protocol fields, one-time handover key, key schedule, authorization rule, revocation transition, and audit boundary. Third, an executable ProVerif model identifies an attack in the capability-only draft and verifies four secrecy and injective-authentication queries after the repair. Fourth, a reproducible OpenSSL-backed proof of concept reports

operation timings, three-message payload size, handover latency, and sequential throughput without treating local cryptographic measurements as production HR-system performance.

II. Related Work and Design Gap

A. Cross-Domain Authentication and Fast Handover

Lightweight vehicular protocols typically combine hashes, nonces, pseudonyms, and symmetric protection to limit work on constrained endpoints. Representative studies address privacy-preserving VANET authentication [2], honey-list authentication [3], three-party fog key agreement [4], blockchain-based multidomain authentication [5], and confidential-computing key transfer [6]. Recent Industry 5.0 work also treats availability as a first-class authentication property rather than a secondary operational metric [7]. Their shared insight is sound: the first interaction with a foreign domain can justify a trust-service exchange, whereas repeated handovers should reuse bounded authorization state.

The differences lie in what that state authorizes and what it reveals. A mobility protocol often needs to prove that a vehicle is registered and may enter a service region. Vocational counseling must carry a much narrower statement. A client authorized for an assessment summary is not automatically authorized to disclose clinical notes, disability details, or salary history. A fast handover token that omits purpose and consent is efficient but semantically overbroad.

B. Private Matching, Access Control, and Audit

Privacy-preserving matching research shows that matching can be performed without exposing every attribute. Matchmaking encryption reveals little beyond whether two policies match [8]. Encrypted task matching has also been combined with revocation [9] and fine-grained worker attributes [10]. These schemes pursue stronger content privacy than HR-CD-Auth, but they do not by themselves provide cross-domain session continuity, gateway authentication, or an operational consent lifecycle. The framework developed here is complementary: it protects the control plane and limits which pseudonymous features reach a matching service.

Sensitive-data systems provide a closer authorization analogy. Blockchain-assisted e-health protocols have coupled authentication with access control [11], examined data minimization on ledgers [12], and hidden access policies through attribute-based techniques [13]. Patient-oriented authentication work likewise treats identity privacy as distinct from channel secrecy [14]. The transferable lesson is not that employment data should be placed on a healthcare blockchain. It is that authentication, least privilege, revocation, and audit need a single protocol context, while raw records remain under the data controller's storage policy.

A protected counselor terminal can reduce exposure of long-term keys, but a trusted execution environment is an assumption rather than a proof shortcut. SGX-based authentication schemes illustrate how hardware isolation can protect credential operations [15], and the broader SGX literature documents the attendant side-channel, rollback, and lifecycle concerns [16]. HR-CD-Auth therefore treats the terminal as a bounded trust component and keeps compromise of ordinary gateway storage inside the adversary model.

C. Design Gap

The literature leaves a specific gap. Cross-domain AKA designs optimize mobility but seldom bind the handover credential to consent version, role, purpose, and data class. Private matching protects attributes but does not establish a pseudonymous session across administrative domains. Ledger-based access control can improve accountability, yet many designs put ledger confirmation or excessive metadata on the online path. HR-CD-Auth combines these concerns without claiming that any one component is novel in isolation. Its contribution is the protocol binding among them (Table I).

TABLE I. From CD-AKA-IoV to the HR-CD-Auth Security Contract

Source property	Employment-domain gap	HR-CD-Auth control
Registered pseudonym supports anonymous vehicular access	A pseudonym reused across counseling, assessment, HR, and public services becomes a profile key	Keyed pseudonym scoped to domain, purpose, consent version, counter, and fresh nonce
Central server prepares first contact with a destination	The trust service can observe a concentrated handover graph	Short-lived destination capability; no online T call; identity resolution requires two independent authorities
Authentication establishes a session key	Authentication alone does not limit role, purpose, data class, or retention	Session-bound access token and compartment-specific wrapped data keys
Fast path relies on hashes and symmetric operations	Hash-only key derivation cannot substantiate forward secrecy after long-term key compromise	Ephemeral X25519 at each handover, followed by an erased one-way symmetric ratchet
Security analysis targets network attacks	A valid staff credential can still be used outside assigned purpose	Insider model, explicit authorization predicate, and tamper-evident audit commitment

III. System, Trust, and Threat Model

A. Actors and Trust Boundaries

The client C is the data subject and holder of a protected registration credential. A source gateway G_s operates a counseling service; a destination gateway G_d represents an enterprise HR system, public employment service, assessment provider, or another approved domain. The National Labor Data Trust T registers clients and gateways, distributes policy material, and issues bounded capabilities, but it does not retain a complete identity-resolution key. Resolution authorities R_1 and R_2 hold independent shares of a 2-of-2 key. Secure counselor terminals protect staff-side credentials; encrypted vaults hold records; the permissioned audit service accepts commitments only (Fig. 1).

T is trusted to perform registration and policy issuance correctly, but it cannot read raw counseling content or resolve a stored pseudonym mapping by itself. A single compromised resolution authority reveals no usable decryption key; R_1 and R_2 must approve the same case-bound request. Collusion between both authorities remains a privacy failure. Gateways are protocol-correct but may be curious, misconfigured, or later compromised. Staff members can hold valid credentials and still exceed purpose or scope. The audit service may delay publication, but it does not decide whether client and gateway authentication completes (Table II).

TABLE II. Actor Responsibilities and Protected State

Actor	Trust assumption	Protected state or output
Client C	Credential store may be protected; host OS can be exposed	Registration key, counter, current ratchet state
Gateway G_s / G_d	Protocol-correct but curious; ordinary storage can be compromised	Gateway trust key, ticket cache, authorization decision
Trust service T	Correct registration and policy issuance; no unilateral identity resolution	Threshold-encrypted mapping, gateway registry, policy keys
Resolution authorities R_1 / R_2	At least one authority remains honest; approvals are case-bound	Independent key shares and signed resolution approvals
Secure counselor terminal	Hardware boundary assumed intact within the model	Staff key, role certificate, local decision evidence
Encrypted vault	Ciphertext and metadata may be observed	Compartmented counseling, assessment, and matching records
Audit service	Append-only consensus; may be delayed or unavailable	Policy hashes, consent-token hashes, Merkle roots, signatures

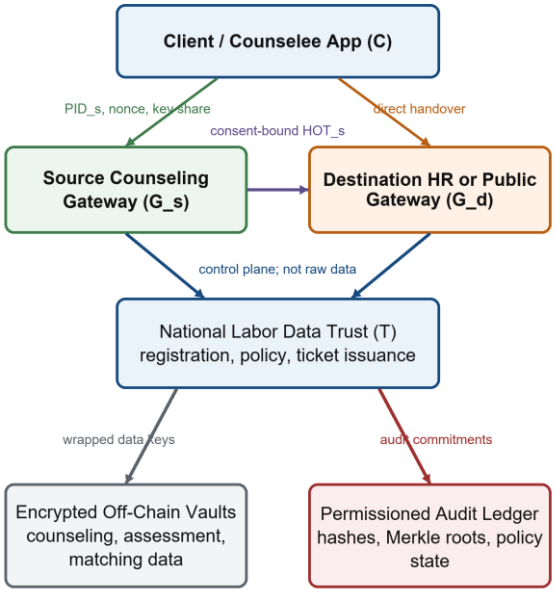

Fig. 1. HR-CD-Auth actors and trust boundaries. T issues policy and tickets but cannot resolve identity alone; raw records remain in encrypted vaults.

B. Adversary Capabilities

The network adversary follows the Dolev-Yao model: it can intercept, replay, reorder, delay, modify, and inject messages on public channels [17]. Session compromise follows the spirit of the Canetti-Krawczyk model [18]. The adversary may reveal an established session key, compromise ordinary client or gateway storage, obtain an expired token, or corrupt one gateway after a completed session. It cannot break X25519, HKDF, HMAC, authenticated encryption, or the collision resistance of the selected hash. It also cannot recover an erased ephemeral scalar.

The insider adversary is an authenticated counselor, HR officer, gateway administrator, public-service employee, or operator of T or one resolution authority. The insider may request a field outside the active purpose, reuse a cached token after withdrawal, correlate timing metadata, or alter a local audit file. The model allows compromise of either R_1 or R_2, but not both in the same resolution event. Ordinary login therefore does not end the security analysis; authorization, key release, and resolution approval remain separate decisions.

Two exclusions are explicit. The framework does not prevent a recipient from retaining plaintext that it was legitimately shown before consent was withdrawn. It also does not hide network-layer identifiers, timing, message size, or external information that may correlate sessions. Those risks require transport anonymity, traffic shaping, endpoint controls, and organizational sanctions beyond the protocol.

C. Security and Privacy Properties

The required properties are mutual entity authentication; agreement on destination, purpose, data class, consent version, and policy version; session-key secrecy; forward secrecy for completed handovers; replay resistance; cross-domain pseudonym unlinkability against ordinary gateways; rejection of withdrawn or expired capabilities; least-privilege data-key release; detection of audit-log alteration; and resistance to

unilateral identity resolution after compromise of T or one resolution authority. Availability is narrower: a pre-authorized handover must not wait for T, the resolution authorities, or ledger finality.

IV. HR-CD-AUTH PROTOCOL

A. Context Binding and Notation

Each protocol decision is tied to one context rather than a free-standing identity. Let d denote the destination domain, purpose_s the declared use, dataClass the requested compartment, consentVersion the client-approved policy instance, and epoch_s a bounded validity period. C and G generate fresh nonces N_C and N_G and ephemeral X25519 key pairs (x_C, X_C) and (x_G, X_G). T shares K_CT with the protected client credential and K_TG with each registered gateway. For a pre-authorized handover, T also creates a fresh one-time key K_HO and places it only in separately protected client and gateway tickets. HMAC, HKDF, and AEAD denote a message authentication code, a key-derivation function, and authenticated encryption with associated data.

The protocol uses accountable pseudonymity rather than absolute anonymity. Ordinary gateways cannot compute the mapping from their transcripts. T stores only a threshold-encrypted mapping and cannot resolve it alone; R_1 and R_2 must authorize and complete the 2-of-2 resolution procedure.

$$\mathrm{PID}_s = \mathrm{HMAC}_{\mathrm{KC}}(\mathrm{ID}_C \parallel d \parallel \mathrm{purpose}_s \parallel \mathrm{consentVersion} \parallel \mathrm{ctr}_C \parallel N_C) \quad (1)$$

where, ctr_C is a monotonic client counter protected with the registration credential. Including the fresh nonce avoids deterministic output if a device restores an earlier counter. The counter advances after a successful handover, a consent transition, or an abnormal termination. The context digest is

$$\mathrm{context}_s = H(\mathrm{PID}_s \parallel \mathrm{ID}_G \parallel d \parallel \mathrm{purpose}_s \parallel \mathrm{dataClass} \parallel \mathrm{consentVersion} \parallel \mathrm{policyVersion} \parallel \mathrm{epoch}_s) \quad (2)$$

Both endpoints place context_s in the transcript and reject a mismatch before data-key release. This single digest is the binding point among authentication, authorization, and audit.

B. Registration and Policy Provisioning

C enrolls with T over an authenticated protected channel. The direct identity mapping is encrypted under the joint resolution public key, and the complete resolution secret is not retained by T. T stores the threshold ciphertext, credential status, pseudonym counter state, and current consent-policy reference; it stores no counseling record. Each gateway registers ID_G, domain type, supported data classes, policy version, and K_TG. Counselor terminals receive staff credentials carrying role and organizational scope.

Policy provisioning produces two independent authorization objects. A handover capability authorizes one destination to authenticate a pseudonymous client under a bounded context; a session access token authorizes a data operation after authentication. T also generates a fresh K_HO for each capability. The client receives K_HO inside its K_CT-protected ticket, while G_d obtains the same value only by decrypting HOT_s under K_TG. K_HO never appears on the public channel. Compromise of a capability alone therefore neither authenticates a client nor unwraps a record key.

C. First-Domain Authentication

On first contact or after a policy refresh, C sends PID_s, N_C, X_C, purpose_s, consentVersion, and an authenticator derived from K_CT. G adds N_G, X_G, its identity, requested data class, and a gateway authenticator, then forwards the protected request to T. T verifies registration status, gateway status, consent version, purpose, and policy version. A successful response contains a gateway ticket and a client ticket over the same context. Neither ticket contains raw counseling data (Table III).

C and G compute the ephemeral shared secret and derive the session key from the full transcript:

$$Z_s = \mathrm{X25519}(x_C, X_G) = \mathrm{X25519}(x_G, X_C) \quad (3)$$

$$\mathrm{SK}_s = \mathrm{HKDF}(Z_s \parallel K_{\mathrm{HO}}, H(\mathrm{transcript}_s), \mathrm{context}_s) \quad (4)$$

The endpoints exchange role-separated confirmation tags under SK_s and erase x_C, x_G, and Z_s after confirmation. A later compromise of K_CT, K_TG, or a completed session state does not reveal the erased ephemeral secret. Forward secrecy therefore rests on the hardness of X25519, correct randomness, HKDF, and actual erasure; it is not inferred from nonce freshness alone.

D. Pre-Authorized Cross-Domain Handover

When a counseling workflow is allowed to move to G_d, T creates a short-lived capability and a fresh one-time K_HO. The capability may be delivered during first contact or cached through an authenticated gateway channel. Its protected payload is

$$\mathrm{HOT}_s = \mathrm{AEAD}_{\mathrm{KTG}}(\mathrm{PID}_s \parallel \mathrm{ID}_{\mathrm{Gd}} \parallel \mathrm{purpose}_s \parallel \mathrm{dataClass} \parallel \mathrm{consentVersion} \parallel \mathrm{policyVersion} \parallel \mathrm{exp}_s \parallel K_{\mathrm{HO}}) \quad (5)$$

G_s transfers HOT_s and the encrypted state needed for the expected client. C rotates its pseudonym and sends N_C, X_C, context_s, HOT_s, and Auth_C^HO = HMAC_KHO("C-auth" || PID_s || N_C || X_C || context_s || H(HOT_s)). G_d decrypts HOT_s, checks expiry, policy, and consent versions, and verifies Auth_C^HO before performing X25519. Both endpoints derive SK_s from Z_s, K_HO, the transcript hash, and context_s. The gateway response and final client message carry role-separated confirmation tags under SK_s. This remains a three-message client-destination exchange; T, the resolution authorities, and the ledger are absent from the latency-critical path (Fig. 2).

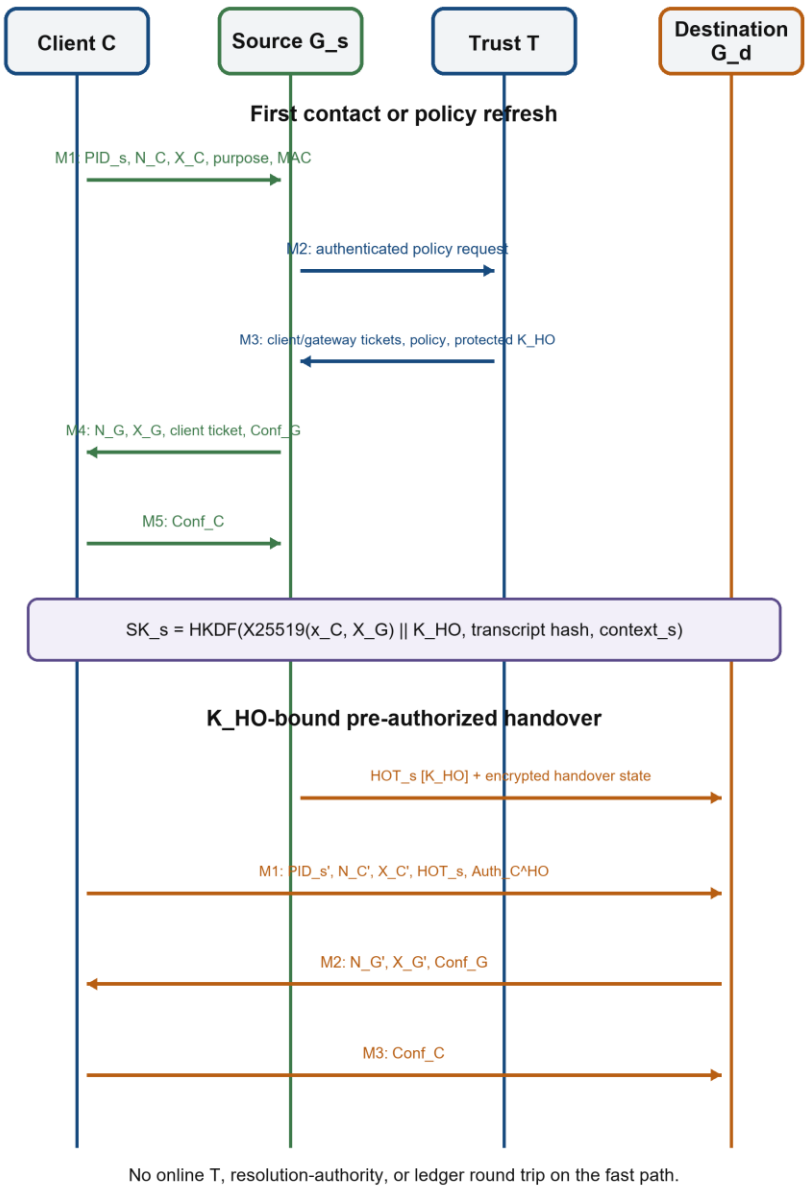

Fig. 2. First-contact and K_HO-bound pre-authorized handover sequence. The three-message fast path authenticates both ephemeral shares without an online T, resolution-authority, or ledger round trip.

TABLE III. ONLINE MESSAGES AND THEIR SECURITY PURPOSE

Phase	Flow	Essential fields	Security purpose
First contact	C -> G_s	PID_s, N_C, X_C, purpose, consent version, authenticator	Client freshness and context proposal
First contact	G_s -> T	Client block, N_G, X_G, gateway ID, data class	Registration and policy decision
First contact	T -> G_s -> C	Gateway ticket, client ticket, policy version, expiry	Bind both endpoints to one authorized context
Handover setup	G_s -> G_d	HOT_s with K_HO; K_HO separately protected for C and G_d	Pre-position destination authorization and one-time authentication key
Online handover	C <-> G_d	Rotated PID, nonces, key shares, Auth_C^HO, confirmation tags	K_HO-bound forward-secret mutual authentication

E. Consent-Bound Access and Data-Key Release

Authentication does not release a record. The policy service issues a session access token only after evaluating the staff credential, client consent, purpose, requested data class, and retention rule. The token is bound to the hash of SK_s, which prevents replay in a different authenticated session:

$$AT_s = \mathrm{HMAC}_{\mathrm{Kpolicy}}(\mathrm{PID}_s \parallel \mathrm{role} \parallel \mathrm{purpose}_s \parallel \mathrm{dataClass} \parallel \mathrm{consentVersion} \parallel \mathrm{exp}_s \parallel H(\mathrm{SK}_s)) \quad (6)$$

A gateway unwraps a compartment key only when the complete predicate holds:

$$\mathrm{allow} = \mathrm{valid}(AT_s) \wedge \mathrm{role} >= \mathrm{requiredRole} \wedge \mathrm{purpose}_s \in \mathrm{allowedPurpose} \wedge \mathrm{consentVersion} = \mathrm{activeVersion} \wedge \mathrm{now} < \mathrm{exp}_s \quad (7)$$

Counseling notes, assessment summaries, matching features, public-service transfer fields, and audit evidence use separate data-encryption keys. An HR gateway may receive a job-tag match and interview token without receiving raw psychological notes. A counselor may receive an assessment summary without learning enterprise feedback. The policy decision therefore changes the available key material, not only the user interface.

Withdrawal or expiry invalidates HOT_s and AT_s, advances ctr_C, and triggers rewrapping or destruction of retained compartment keys according to policy. The protocol prevents new decryptions under managed keys. It cannot recall plaintext already exported to a recipient before withdrawal; that residual obligation belongs to endpoint governance and enforcement (Fig. 3).

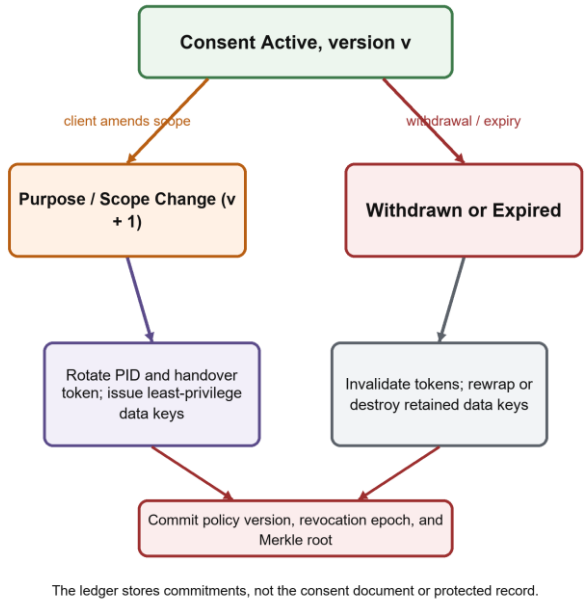

Fig. 3. Consent-state transition and its cryptographic effects. The ledger stores a commitment to the transition, not the consent document or protected record.

F. Forward-Secure Ratchet and Audit Commitments

Within a long counseling workflow, an endpoint may ratchet the confirmed session key at an epoch or data-class boundary and erase the previous value:

$$\mathrm{SK}_{\mathrm{next}} = \mathrm{HKDF}(\mathrm{SK}_{\mathrm{current}}, \rho\alpha\tau\chi\eta\varepsilon\tau \parallel \mathrm{epoch}_{\mathrm{next}} \parallel \mathrm{consentVersion}) \quad (8)$$

This one-way update protects earlier epoch keys from later state exposure when erasure is effective. It does not replace the ephemeral X25519 exchange at a domain handover; the two mechanisms address different compromise windows.

Each authorized operation creates an audit leaf that omits the direct identity and record content:

$$L_e = H(\mathrm{PID}_s \parallel \mathrm{role} \parallel \mathrm{action} \parallel \mathrm{dataClass} \parallel \mathrm{consentVersion} \parallel t_e \parallel \mathrm{recordID} \parallel \mathrm{gatewayID}) \quad (9)$$

$$R_m = \mathrm{MerkleRoot}(L_1, L_n) \quad (10)$$

Merkle trees provide compact evidence that an event belongs to a committed batch [19]. The permissioned ledger receives R_m, H(policyVersion), H(consentToken), the gateway signature, and the publication epoch. Authentication may finish before ledger finality; a bounded publication deadline and a locally signed queue cover temporary ledger unavailability. Raw psychological, health, disability, salary, employment, and interview data never enter the ledger payload.

V. Security Analysis

A. Property-by-Property Argument

Replay attempts fail at two layers. The authentication transcript contains fresh nonces, ephemeral public keys, destination identity, context_s, and an expiry-bounded ticket. Reusing an earlier client message either hits the destination replay cache or produces a transcript hash that does not match the new gateway contribution. Reusing AT_s in another session fails because the token contains H(SK_s). Reusing HOT_s after a consent change fails because the active consent version and revocation state no longer match.

Client impersonation in the pre-authorized path requires K_HO to forge Auth_C^HO; gateway impersonation requires K_HO as an input to the session KDF. Replacing X_C or X_G changes the transcript, and a chosen public share does not yield SK_s without K_HO. A compromised gateway can still impersonate that gateway until its trust key and outstanding capabilities are revoked. Short expiry and gateway-specific keys contain, but do not erase, that exposure.

Completed sessions have forward secrecy against later compromise of registration and gateway trust keys because SK_s depends on an erased X25519 shared secret. This statement excludes compromise of x_C or x_G before erasure, weak randomness, endpoint snapshots that preserve the scalar, and side-channel recovery. The within-session ratchet protects past ratchet epochs from later current-state disclosure, again only when old keys are erased.

Ordinary gateways cannot compute whether two PID_s values correspond to the same client without K_C or the threshold-encrypted mapping. Domain, purpose, consent

version, counter, and nonce change the HMAC input. The claim is protocol-level unlinkability, not traffic-analysis anonymity. A shared IP address, timing pattern, rare job attribute, or external database can still correlate sessions. Re-identification requires both resolution authorities; collusion of R_1 and R_2 defeats that protection.

Insider resistance follows from key release, not from staff authentication alone. A valid counselor credential that does not satisfy the predicate in Eq. (7) receives no wrapped compartment key. Altering a local decision record changes the corresponding leaf and breaks verification against R_m. This mechanism makes deletion or modification detectable; it does not prove that a malicious gateway faithfully logged an event it chose never to record. Independent gateway signing, monitored publication deadlines, and cross-checks with vault access logs address that residual risk.

B. BAN-Logic Belief Analysis

BAN logic is used here for a limited purpose: checking whether the protected tickets and confirmation tags support mutual belief in an authorized context and possession of the derived key [20]. It does not prove X25519 hardness, HMAC unforgeability, traffic-analysis resistance, or consent-law compliance. The notation P |≡ X means that P believes X, P |~ X means that P once said X, #(X) denotes freshness, P ⇒ X denotes jurisdiction, and P ↔_K Q denotes a key shared by P and Q.

The authentication-critical messages are idealized as follows:

$$M_2: G \rightarrow T: \mathrm{Enc}_{\mathrm{KCT}}(\mathrm{PID}_s, N_C, X_C, \mathrm{context}_s), \mathrm{Enc}_{\mathrm{KGT}}(N_G, X_G, G) \quad (11)$$

$$M_3: T \rightarrow G: \mathrm{Enc}_{\mathrm{KGT}}(N_C, N_G, X_C, X_G, \mathrm{context}_s, \mathrm{exp}_s), \mathrm{Ticket}_C \quad (12)$$

$$\mathrm{Ticket}_C = \mathrm{Enc}_{\mathrm{KCT}}(N_C, N_G, X_C, X_G, G, \mathrm{context}_s, \mathrm{exp}_s) \quad (13)$$

$$M_4: G \rightarrow C: \mathrm{Ticket}_C, \mathrm{HMAC}_{\mathrm{SKs}}(\Gamma{-}\chi\omicron\nu\phi\iota\rho\mu \parallel H(\mathrm{transcript}_s)) \quad (14)$$

$$M_5: C \rightarrow G: \mathrm{HMAC}_{\mathrm{SKs}}(\mathrm{X}{-}\chi\omicron\nu\phi\iota\rho\mu \parallel H(\mathrm{transcript}_s)) \quad (15)$$

The initial beliefs are that C shares K_CT with T, G shares K_GT with T, each endpoint trusts T's jurisdiction over the identity-to-context binding, and N_C and N_G are fresh:

$$C| \equiv C \leftrightarrow_{\mathrm{KCT}} T; G| \equiv G \leftrightarrow_{\mathrm{KGT}} T \quad (16)$$

$$C| \equiv \#(N_C); G| \equiv \#(N_G) \quad (17)$$

$$C| \equiv T \Rightarrow \mathrm{Bind}(C, G, \mathrm{context}_s); G| \equiv T \Rightarrow \mathrm{Bind}(C, G, \mathrm{context}_s) \quad (18)$$

Applying the message-meaning and nonce-verification rules to M_3 and Ticket_C gives each endpoint the belief that T recently asserted the same key shares and context. Jurisdiction then yields

$$C| \equiv \mathrm{Bind}(C, G, \mathrm{context}_s); G| \equiv \mathrm{Bind}(C, G, \mathrm{context}_s) \quad (19)$$

Both endpoints compute SK_s from the authenticated key shares and transcript. The role-separated tags in M_4 and M_5 establish the remaining possession beliefs:

$$C| \equiv G| \equiv \mathrm{Possess}(\mathrm{SK}_s); G| \equiv C| \equiv \mathrm{Possess}(\mathrm{SK}_s) \quad (20)$$

The analysis supports mutual agreement on the authorization context and key possession under the stated belief assumptions. Computational secrecy and forward secrecy still depend on the cryptographic and erasure assumptions discussed above.

C. Automated Symbolic Verification and Design Repair

An applied-pi-calculus model was executed with ProVerif 2.05 [21] over unbounded sessions and a public Dolev-Yao channel. Protected tickets, ideal HMAC and hashing, the Diffie-Hellman commutation equation, transcript-bound HKDF, and injective correspondence events are represented explicitly. Four queries test protected-record secrecy, secrecy of an accepted session key, client acceptance only after a matching gateway run, and gateway acceptance only after a matching client run.

The capability-only draft failed all four queries. ProVerif reconstructed an active trace in which the adversary replays HOT_s, substitutes a chosen ephemeral share, derives the corresponding session key, and completes key confirmation without a matching peer run. This was a protocol defect, not a limitation of BAN logic.

The repaired model delivers a fresh K_HO to C inside the K_CT-protected client ticket and to G_d inside HOT_s under K_TG. Auth_C^HO authenticates the first online message, and HKDF takes both Z_s and K_HO as input. After this change, ProVerif returned true for all four queries. Fig. 4 preserves the actual result lines for the rejected and repaired models.

The result is scoped to the symbolic abstraction (Table IV). It does not establish constant-time implementation, X25519 input validation, secure erasure, wall-clock expiry, replay-cache consistency, or the threshold-resolution workflow. Those properties require code-level and deployment tests.

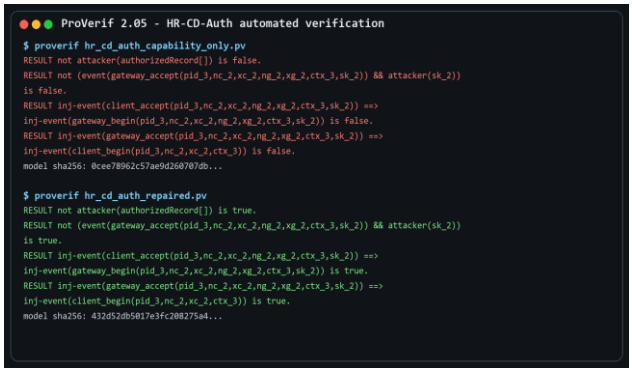

Fig. 4. Actual ProVerif 2.05 summaries. The capability-only draft fails 4/4 queries; the K_HO-bound repair passes 4/4.

TABLE IV. SECURITY CLAIMS, MECHANISMS, AND RESIDUAL ASSUMPTIONS

Claim	Primary mechanism	Required assumption	Residual exposure
Replay resistance	Fresh nonces, transcript hash, expiry, replay cache	Fresh randomness and bounded clock/epoch checks	Large distributed replay caches require synchronization
Mutual authentication	K_HO client authenticator, K_HO-bound HKDF, and role-separated confirmation	Unforgeable HMAC/AEAD and authenticated gateway registry	A live stolen gateway key impersonates that gateway until revocation
Forward secrecy	Fresh ephemeral X25519 plus scalar erasure	Hardness of X25519 and effective erasure	Pre-erasure endpoint compromise reveals the session
Gateway unlinkability	Keyed domain/purpose/session pseudonym	K_C and the two threshold key shares remain protected	Traffic correlation or collusion of both resolution authorities
No unilateral resolution	Threshold-encrypted mapping and two signed approvals	At least one of R_1 and R_2 remains honest	Collusion, enrollment capture, or reconstruction-boundary compromise
Consent enforcement	Consent-version HOT_s and AT_s; key rewrapping	Gateways consult current revocation state	Previously exported plaintext cannot be recalled
Audit integrity	Signed leaves and Merkle-root commitment	At least one independent verifier retains a commitment	A malicious gateway may omit an event before logging

VI. ANALYTICAL AND EMPIRICAL EVALUATION

A. Online Cost Model

The evaluation begins with an analytical cost model and then measures the repaired fast path. Let T_X denote one X25519 scalar multiplication, T_H one hash, T_M one HMAC, T_K one HKDF invocation, and T_A one AEAD operation. Database lookup, replay-cache access, and policy evaluation remain separate because their cost depends on deployment scale. Table V reports the operation counts; Table VI reports local measurements from the executable proof of concept.

At first contact, C performs one pseudonym HMAC, one X25519 operation, one HKDF, and confirmation or transcript MACs. A pre-authorized handover removes T from the online path but retains one fresh X25519 operation at each endpoint, verifies HOT_s and Auth_C^HO, and mixes K_HO into HKDF. The public-key work is intentional: a hash-only handover cannot support the forward-secrecy claim, while a capability-only exchange does not authenticate the chosen key shares.

$$B_{\text{handover}} = B_{\text{PID}} + 2B_N + 2B_X + B_{\text{HOT}} + 3B_{\text{MAC}} + B_{\text{context}} \quad (21)$$

Eq. (21) gives the analytical payload form. In the proof-of-concept encoding, the three online messages contain 332, 80, and 32 bytes, respectively, for a total of 444 bytes. The pre-positioned gateway transfer and asynchronous ledger publication are not additional client-destination rounds.

CD-AKA-IoV reports a two-round, 1024-bit fast cross-domain phase for its narrower vehicular contract [1]. HR-CD-Auth carries consent and purpose state, authenticates both ephemeral shares with K_HO, and provides forward secrecy. The local proof-of-concept therefore demonstrates feasibility, not a claim that HR-CD-Auth is faster than CD-AKA-IoV or a deployed HR service.

TABLE V. ANALYTICAL ONLINE COST PROFILE

Path	Online messages	Client operations	Gateway operations	Online external dependency
First contact/policy refresh	5	T_X + T_K + HMAC/H for pseudonym and confirmations	T_X + T_K + ticket and MAC processing	Trust service T
Pre-authorized handover	3 client-destination; 1 prior gateway transfer	T_X + T_K + K_HO-authenticated HMAC/H	T_X + T_K + HOT/Auth_C^HO verification + HMAC/H	None
Within-session ratchet	0 or application piggyback	T_K + erasure	T_K + erasure	None
Audit publication	Asynchronous batch	None	Leaf hash + signature + queue	Permissioned ledger, off critical path

B. Proof-of-Concept Benchmark

The executable prototype uses Python 3.12.13, cryptography 49.0.0, and OpenSSL 4.0.1 on Windows 11 with an AMD Ryzen 7 8845HS. Each of the three independent runs performed 500 warm-up handovers followed by 10,000 measured handovers. time.perf_counter_ns recorded the complete in-memory three-message path: binary construction and parsing, HOT_s AES-GCM verification, Auth_C^HO, two ephemeral X25519 key generations and exchanges, two HKDF-SHA256 derivations, and role-separated HMAC confirmations.

Run-level median latency ranged from 0.2773 to 0.2812 ms; p95 ranged from 0.4669 to 0.4820 ms. Sequential throughput ranged from 3041.5 to 3119.9 completed handovers/s. The fixed binary encoding produced 332-byte M_1, 80-byte M_2, and 32-byte M_3 messages, or 444 online bytes. Table VI reports the operation-level measurements, and Fig. 5 preserves the console summary.

These values measure cryptographic feasibility, not enterprise HR-service latency or capacity. Network transport, TLS, database and policy-engine calls, distributed replay-cache synchronization, concurrency, disk I/O, trust-service issuance, and ledger publication were deliberately excluded.

TABLE VI. MEASURED PROOF-OF-CONCEPT PERFORMANCE

Measured item	Median range (ms)	p95 / rate
X25519 key generation	0.0515-0.0516	0.0773-0.0790 ms
X25519 shared-secret exchange	0.0489	0.0709-0.0720 ms
HKDF-SHA256 (32-byte output)	0.0064	0.0115-0.0122 ms
HMAC-SHA256 (256-byte input)	0.0033	0.0057-0.0063 ms
AES-GCM HOT_s decryption	0.0015-0.0016	0.0027-0.0031 ms
Complete three-message handover	0.2773-0.2812	0.4669-0.4820 ms
Sequential throughput	-	3041.5-3119.9 /s
Online payload	-	444 B (332/80/32)

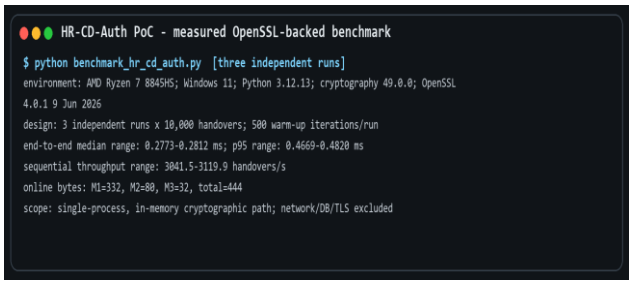

Fig. 5. Actual OpenSSL-backed PoC console summary across three independent 10,000-handover runs.

C. Implementation Boundaries

The client counter and ratchet state need rollback protection. A secure element, platform monotonic counter, or server-checked counter window can provide it; simply storing ctr_C in an ordinary application database is insufficient. Gateways need a bounded replay cache keyed by ticket identifier and epoch. Policy and revocation updates should be signed, versioned, and distributable during partial trust-service outages. The protocol must also define canonical encoding so that every participant hashes the same byte sequence.

A deployment may substitute another authenticated ephemeral key exchange or a post-quantum KEM if the transcript and confirmation rules remain intact. The substitution changes operation and payload counts and must be re-evaluated. Similarly, the audit service can be a consortium ledger or another independently verifiable append-only log. The security requirement is durable, cross-organizational commitment; it is not allegiance to a particular blockchain platform.

VII. GOVERNANCE, PRIVACY, AND OPERATIONAL FIT

A. Regulatory and Standards Alignment

HR-CD-Auth is an engineering control, not a finding of legal compliance. Under the General Data Protection Regulation, health-related fields, profiling, purpose limitation, data minimization, and meaningful information about consequential automated decisions require particular attention [22]. The Korean Personal Information Protection Act likewise makes lawful processing, safeguards, access control, and access-record management deployment questions rather than properties conferred by a cryptographic protocol [23]. The design supports those duties by reducing stable identifiers, binding purpose and consent to key release, and separating raw records from durable audit commitments.

ISO/IEC 27001:2022 provides the organizational information-security context for key management, access control, supplier interfaces, logging, and incident response [24]. ISO/IEC 29100 supplies a privacy vocabulary for purpose specification, use limitation, data minimization, openness, and accountability [25]. These standards help define operating controls around HR-CD-Auth; they do not certify the protocol or the deploying organization.

When a matching engine uses machine learning, the NIST AI Risk Management Framework is relevant to model governance, explanation, monitoring, and contestability [26]. Authentication should pass only the pseudonymous features needed for the approved matching purpose, and the audit log should identify the model and policy version. Zero-trust guidance reinforces the decision to evaluate every data request against current identity, device, policy, and resource context rather than rely on network location [27]. None of these controls detects biased training data or an unfair ranking rule by itself.

B. Integration and Emergency Access

An implementation can expose registration, ticket, handover, authorization, revocation, audit, and dual-resolution approval endpoints through an OpenAPI-described interface [28]. The specification must distinguish control-plane objects from protected payloads, define canonical encodings, and forbid

raw sensitive fields in logs. Gateway adapters should map local roles and data labels to the shared policy vocabulary rather than broaden them silently.

Emergency access needs its own purpose code, short expiry, senior authorization, user notification when lawful, and a separately reviewable audit leaf. It must not become an unlogged administrator bypass. Public employment services that must resolve civil identity submit a case-bound request containing purpose, legal basis, requesting officer, expiry, and the hash of the target pseudonym. R_1 and R_2 each verify the request and produce an independently signed approval. Only matching approvals permit 2-of-2 threshold reconstruction inside a protected execution boundary; the reconstructed key is not exported. This use of split key custody follows the threshold principle of Shamir secret sharing [29]. A 2-of-2 rule prevents unilateral resolution but reduces availability; a 2-of-3 deployment is a possible resilience variant.

VIII. Limitations and Validation Agenda

The proof of concept validates the repaired cryptographic handover, not a commercial HRIS, applicant-tracking system, counseling application, or public employment service. Its latency and throughput exclude network, TLS, database, policy-engine, replay-cache synchronization, disk I/O, concurrent clients, and ledger publication. The results are therefore local cryptographic-path measurements rather than production TPS or user-perceived latency.

BAN logic checks beliefs about tickets and key confirmation. ProVerif adds an automated symbolic analysis of four secrecy and injective-authentication queries, all of which pass for the repaired model. Neither result is a computational proof of the implementation. The executable model idealizes HMAC, hashing, ticket encryption, and Diffie-Hellman, and it does not model wall-clock expiry, distributed replay-cache state, counter rollback, threshold resolution, side channels, or source-code memory erasure.

The privacy boundary still depends on governance. T or either resolution authority alone can decrypt the identity mapping, but collusion between R_1 and R_2, capture during enrollment, or compromise of the protected reconstruction boundary can re-identify a client. The 2-of-2 profile also sacrifices availability when either authority is offline. A recipient may retain plaintext received before withdrawal, network metadata can correlate sessions, and a matching model can still discriminate.

Future work should deploy the client, gateway, and trust-service roles over TLS with real policy and database calls; repeat the benchmark on ARM and Raspberry Pi hardware under concurrent load; test expiry, replay-cache synchronization, rollback, and key erasure by fault injection; and add a game-based proof of the final wire encoding. The two-authority resolution profile also needs an HSM-backed implementation, collusion exercises, availability measurement, and comparison with a 2-of-3 variant.

IX. Conclusion

HR-CD-Auth treats a valid identity as the start, not the end, of a security decision. The repaired protocol rotates pseudonyms, binds the first handover message with a one-time K_HO, combines K_HO with an ephemeral X25519 secret, and releases compartment keys only after a role-and-purpose authorization check. Identity resolution requires two independent authorities, while the audit service records commitments rather than raw records.

The automated analysis first rejected the capability-only draft and then proved all four secrecy and injective-authentication queries for the K_HO-bound repair. Across three 10,000-handover runs, the local cryptographic path recorded 0.2773-0.2812 ms median latency, 0.4669-0.4820 ms p95 latency, 3041.5-3119.9 sequential handovers/s, and 444 online bytes. These are measured feasibility results, not production-service claims. Their value lies in exposing the design repair, empirical cost, trust boundary, and remaining deployment risks in terms a reviewer can reproduce and challenge.

Popularity Bias and Category Diversity in Review-Based Rating Prediction for E-Commerce: An Empirical Study on Indonesian Marketplace Data

Department of Informatics Engineering-Vocational School, Universitas Sebelas Maret Surakarta, Indonesia[1]

***Abstract*—Online marketplaces increasingly rely on user reviews to estimate product quality. However, most empirical comparisons of review-based prediction models report only aggregate accuracy and overlook how item popularity and category composition shape that accuracy. This study presents a controlled empirical analysis of review-based rating prediction on a self-collected, anonymized corpus of 44,229 Indonesian marketplace reviews spanning four product categories (fashion, electronics, tools/hardware, and sports). To isolate the effect of category diversity from data volume, the experimental design was set with the total number of reviews kept constant at 12,000, while the number of categories was increased from two to four. For product metadata classification, three text classification models (TF-IDF with logistic regression, linear SVM, and random forest) and a customized IndoBERT transformer model were compared using five-fold cross-validation, and the difficulty of prediction was further analyzed at the item level. Three findings emerge. First, the review text is the dominant signal, reducing the mean absolute error to 0.62 (0.57 with IndoBERT), compared with 1.28 for the majority baseline. Second, increasing category diversity within a fixed budget results in a small but consistent performance degradation. Third, and most notably, popular items are systematically harder to predict than long-tail items within every category, and per-item error correlates positively with rating variance and sales volume and negatively with average product rating and price. The polarization of evaluations is considered a major contributing factor to production difficulties; the protocol can be reproduced and interpreted at a level where evaluation predictions are based on a pass/fail assessment.**

Keywords*—Review-based rating prediction; popularity bias; category diversity; product characteristics; e-commerce; Indonesian text classification

I. Introduction

Recommender systems and review-driven quality estimation have become central to electronic commerce, helping users navigate catalogs containing millions of products [1], [2], [3]. A large body of work shows that the free-text reviews accompanying numeric ratings carry rich signals about why a user assigned a particular score, and that exploiting this text improves rating prediction and interpretability [4], [5]. As marketplaces in emerging economies grow, there is a practical need to understand how such models behave on non-English, informal review text and across heterogeneous product categories.

Despite extensive comparative studies and systematic reviews of the field [1], [3], [6]two gaps persist. First, most comparisons report a single aggregate accuracy figure for a single dataset configuration, which can mask systematic biases: a model may appear accurate overall while failing on specific, commercially important subsets of items. Item popularity is a prime example. The recommender-systems literature has documented popularity bias largely as an exposure or ranking-fairness problem, in which popular items are over-recommended and long-tail items are neglected [7], [8]. Far less attention has been paid to whether popularity also affects an item's predictive difficulty. Second, the number and mix of product categories often increase with the amount of data, confounding the effect of category diversity with that of sample size. Fig. 1 shows the usage percentage of Indonesian Marketplaces in the "Top" and "Popular" e-commerce categories.

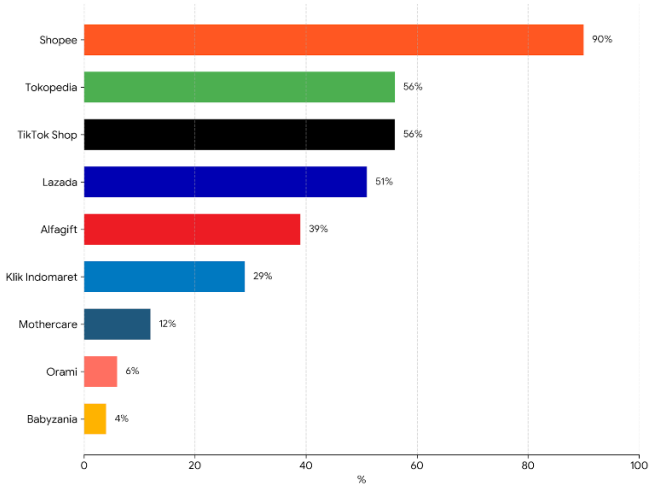

Fig. 1. The usage percentage of Indonesian marketplaces in the "Top" and "Popular" e-commerce categories in 2025.

This study addresses both gaps through a controlled empirical study on Indonesian marketplace data. The diversity of categories influences and segments the volume of data, and the total budget must be maintained and reviewed to keep it constant while varying the number of categories based on the level of difficulty in prediction and analysis. Ultimately, the output is evaluated not only at the aggregate level but also on a product-by-product basis, relating it to observable product

*Corresponding author.

characteristics such as popularity, price, average rating, and rating variance.

Our contributions are fourfold: 1) a fixed-budget experimental design that isolates the effect of category diversity from sample size, with a robustness analysis over all category subsets; 2) an item-level quantification of popularity bias as predictive difficulty on Indonesian e-commerce reviews, showing that popular items are harder to predict; 3) an interpretable characteristic-level analysis that identifies rating variance as a principal driver of per-item error; and 4) a fully reproducible protocol, with reported hyperparameters, cross-validation, significance testing, and complete dataset statistics, on a self-collected multi-category Indonesian corpus.

II. Related Work

Collaborative filtering and matrix-factorization models estimate ratings from a user–item interaction matrix [9], [10], [11], [12], [13], [14], [15]. Because such models require repeated user interactions, they are ill-suited to settings dominated by single-interaction reviewers, where the content signal becomes essential. Subsequent work has shown that jointly modeling review text with numeric ratings improves both prediction accuracy and the interpretability of rating dimensions [5], [16]. Recent comprehensive reviews of e-commerce recommendation catalog the many neural and non-neural approaches that exploit review text [3], [17]. Recent work in this journal further shows that fusing content-based profiles with latent-factor models mitigates the cold-start and data-sparsity limitations of purely collaborative approaches [18]. Complementary lines of work reduce data sparsity and the cold-start problem through item features and frequent patterns [19], [20], improve rating-prediction accuracy [5]and organize content-based methods that exploit item metadata [16], [21]. Most directly related to our setting, recent systems integrate online reviews and product-feature expansion with deep learning for e-commerce recommendation [22], [23].

Recent surveys characterize popularity bias as the tendency of recommenders to over-represent popular items, harming long-tail coverage and fairness [7], [8]. These works frame popularity bias as an exposure and fairness problem and propose re-ranking or regularization remedies. Our study is complementary: rather than asking whether popular items are recommended too often, this study presents inherent challenges based on specific texts and when considered in relation to the polarization of research.

For Indonesian text, pre-trained language models such as IndoBERT have advanced natural-language understanding and consistently outperform multilingual baselines on review classification tasks [24], [25], [26], [27]. For product reviews specifically, the public PRDECT-ID corpus provides emotion- and sentiment-annotated Indonesian Tokopedia reviews together with product metadata [28]. Large public English review corpora remain the standard testbed for user-aware recommendation [29]and curated public app-review datasets further support reproducible sentiment studies [30]. Deep hybrid architectures combining word embeddings with convolutional and recurrent layers have also proven effective for large-scale sentiment classification of e-commerce reviews [31], [32]. Our work targets the under-examined intersection of Indonesian informal review text, multi-category heterogeneity, and item-level predictive difficulty.

III. Methodology

Fig. 2 summarizes the overall methodology, from data collection to item-level analysis.

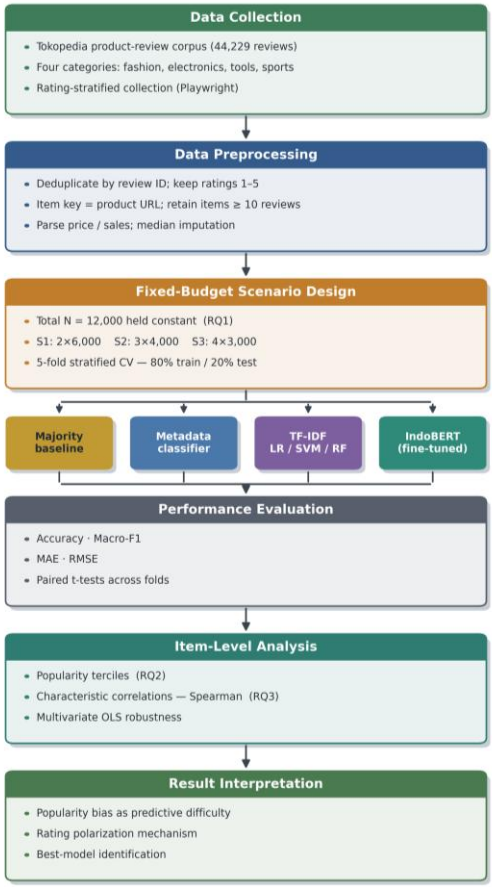

Fig. 2. Overview of the proposed methodology for review-based rating prediction and item-level analysis.

A. Dataset and Ethical Considerations

In this study, products were reviewed independently from a leading marketplace platform in Indonesia and covered four categories. Reviews were gathered with a Playwright-based browser-automation script that retrieved up to ten reviews per star-rating level (one to five) for each product, so the corpus is rating-stratified and the rating distribution reported in Table I is design-induced rather than an organic sample of marketplace sentiment. Concretely, the collection script queried each product for up to ten reviews at every star level and kept whatever was returned, so categories or products with few reviews at a given star level contribute fewer than ten; the resulting corpus is therefore only approximately, not exactly, balanced across ratings (Table I still shows a residual, though attenuated, five-star skew of 40.5%). Because the reported MAE and accuracy are computed on this rating-balanced pool rather than on the platform's naturally skewed review stream, they should be read as characterizing how well review text predicts rating under an approximately uniform class prior; on the organic, five-star-dominated traffic that a deployed system would actually see, a

model can lower its aggregate MAE and accuracy simply by defaulting toward the majority class, so the figures reported here are not directly transferable to production error rates and should be re-estimated on a sample matching the target deployment's true rating distribution. Data were collected between 2 March and 10 April 2026; product attributes such as price, sales volume, and platform-reported average rating therefore represent a snapshot of the marketplace at the time of collection. After removing duplicate reviews and records with invalid ratings, the corpus comprises 44,229 reviews; retaining only products with at least 10 reviews yields an analysis pool of 40,288 reviews across 1,616 items, summarized in Table I. Each record contains the review text, the numeric review rating (1–5), and product attributes, including the platform-reported average rating, price, and number of items sold (Table II). The rating distribution is strongly imbalanced and J-shaped (40.5% five-star, 12.7% one-star), which motivates our use of macro-averaged F1 and balanced class weighting [33]. Reviewer identifiers were irreversibly hashed at collection time, consistent with guidance on the limits and safeguards of data anonymization [34]; because the collection does not expose stable cross-product reviewer identities—there is no usable user dimension and hence no user × item interaction matrix—the task is deliberately framed as review-based rating prediction rather than user-based collaborative filtering. Reviews were retrieved only from publicly accessible product pages, without user authentication or circumventing any access restrictions, and were used solely for non-commercial academic research. No personally identifiable information was collected or stored; only anonymized, derived statistics are reported, the raw corpus is not redistributed, and a complementary public corpus [28] supports replication.

TABLE I. ANALYSIS-POOL STATISTICS PER CATEGORY (PRODUCTS WITH AT LEAST TEN REVIEWS)

Category	Reviews	Items	Med. rev/item	Mean rating	5-star %
Fashion	14,033	402	37	3.34	28
Electronics	10,779	503	18	3.91	50
Tools/Hardware	7,954	374	16	3.85	46
Sports	7,522	337	19	3.81	44
All (pool)	40,288	1,616	21	3.68	40.5

TABLE II. DESCRIPTION OF THE COLLECTED DATA FIELDS

Field	Type	Description
review_id	Identifier	Unique, irreversibly hashed review identifier
product_url	Key	Product identifier used as the item key
review_rating	Numeric (1–5)	Star rating given in the review (prediction target)
rating_produk	Numeric	Platform-reported average product rating
price	Numeric	Product price
sold	Numeric	Number of items sold (popularity proxy)
reviewText	Text	Free-text content of the review
category	Categorical	Product category: fashion, electronics, tools, sports

B. Preprocessing

Duplicate reviews were removed by review identifier, and records with out-of-range ratings were discarded. Because the raw product identifier was unreliable, the canonical product URL served as the item key. Furthermore, at the per-item level of analysis, the product must have at least 10 selected reviews and ensure that the per-item error estimates are stable, with the sensitivity to the threshold levels shown in Table VI. Review text was lowercased and TF-IDF vectorized; price and sales counts were converted to numeric values, and missing metadata were imputed with the training-fold median to avoid information leakage. TF-IDF represents a language-neutral approach; in other words, it converts uppercase letters to lowercase and uses unigrams and bigrams. This approach is intentionally used instead of language-specific normalization techniques for Indonesian, such as stemming or stop-word removal, because informal marketplace reviews contain heavy slang and code-mixing for which stemming can be counter-productive; Indonesian morphology is instead captured by the pretrained sub-word tokenizer of the IndoBERT baseline [35].

C. Experimental Design

To separate category diversity from data volume—a confound common in prior comparisons—the total number of reviews is held constant at 12,000 across three scenarios. In contrast, the number of categories increases: S1 uses two categories (6,000 each), S2 three (4,000 each), and S3 four (3,000 each). Because N is fixed, any change in error across scenarios is attributable to differences in category composition rather than to sample size. The category-addition order follows a neutral rule (descending data volume), and performance is additionally averaged over all category subsets of each size (six pairs, four triples, one quadruple) to guard against selection effects (Table V). Fig. 3 shows the design of a fixed-budget scenario, in which the total review budget (N=12,000) remains constant, while the number of categories increases from two (S1) to four (S3).
