Fig. 3. Fixed-budget scenario design: the total review budget (N = 12,000) is held constant while the number of categories increases from two (S1) to four (S3).

D. Models and Features

Five predictors are compared: a majority-class baseline; a metadata classifier (logistic regression on price, sales volume, platform average rating, and review length); and three text classifiers using TF-IDF features with logistic regression, linear SVM, and random forest. Together, the metadata and text

baselines isolate the contribution of review content relative to product attributes alone. A fine-tuned IndoBERT transformer (indobenchmark/indobert-base-p1)[35] is additionally evaluated under the identical five-fold protocol as a modern reference point, reported in Table III.

TF-IDF weights represent review text with sublinear term frequency [Eq. (1)], where $tf_{t,d}$ is the term frequency, df_t the document frequency, and N the number of training reviews. The text and metadata classifiers use multinomial logistic regression with a softmax decision rule [Eq. (2)], where x is the input feature vector, and w_k is the weight vector learned for rating class k, so that P(y = k | x) is the predicted probability of class k; all classifiers apply balanced class weights [Eq. (3)], with n the number of training reviews, K the number of rating classes, and n_c the count of class c.

$$W_{t,d} = \left(1 + log\ tf_{t,d}\right).log\ \frac{\mathrm{N}}{df_t} \quad (1)$$

$$P(y = k|x) = \frac{\exp(w_k^T x)}{\sum_{j=1}^{K} \exp\left(w_j^T x\right)} \quad (2)$$

$$w_c = \frac{\mathrm{n}}{Kn_c} \quad (3)$$

E. Experimental Setup and Reproducibility

All experiments use the scikit-learn library with a fixed random seed (42). TF-IDF uses unigrams and bigrams, a vocabulary capped at 10,000 features, a minimum document frequency of 3, and sublinear term-frequency scaling. Logistic regression runs up to 2,000 iterations; the linear SVM uses the squared-hinge loss; the random forest uses 80 trees. All classifiers use balanced class weights to counter the five-star skew. Models are evaluated using five-fold stratified cross-validation; the mean and standard deviation are reported across folds, and model differences are assessed using paired t-tests. Each fold trains on 80% of the reviews and is tested on the remaining 20%—about 9,600 training and 2,400 test reviews per scenario, and roughly 32,230 and 8,058 for the item-level analysis on the full pool—with every review used for testing exactly once, which is preferred over a single fixed split such as 70:30. Item-level errors are obtained from out-of-fold predictions on the full analysis pool, independently of the scenario sampling, so the popularity and characteristic analyses do not depend on the chosen budget. The complete procedure—from data loading and scenario sampling through cross-validation and out-of-fold item-level analysis—is summarized in Algorithm 1.

Algorithm 1. Review-based rating prediction and item-level analysis.

Input: per-category review CSVs; budget N; folds K = 5; seed = 42

Output: scenario metrics; per-item errors; characteristic correlations

Server executes:
load CSVs; dedup review_id; keep ratings 1..5
item <- product_url; keep items with >= 10 rev
for scenario S in {2x6000, 3x4000, 4x3000} do
sample N reviews (balanced per cat, seed)
for fold k in StratifiedKFold(K = 5) do
fit TF-IDF + clf on 80%; predict 20%
record ACC, macro-F1, MAE, RMSE
end for
aggregate mean +/- SD; t-test vs. base
end for
out-of-fold predict on full pool (>= 10 rev)
per item p: MAE_p, sold, price, rating, var
popularity terciles -> compare MAE_p
Spearman(MAE_p, product characteristics)
return metrics, per-item errors, correlations

Moreover, Fig. 4 illustrates five-fold stratified cross-validation: in each fold, four parts train the model and the held-out part is evaluated; fold metrics are averaged and compared with paired t-tests; per scenario, each fold uses 9,600 training and 2,400 test reviews.

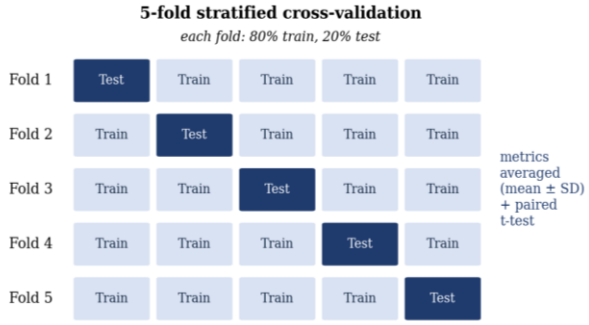

Fig. 4. Five-fold stratified cross-validation: in each fold, four parts train the model, and the held-out part is evaluated; fold metrics are averaged and compared with paired t-tests; per scenario, each fold uses 9,600 training and 2,400 test reviews.

F. Evaluation Metrics

Accuracy and macro-averaged F1, which weights all rating classes equally despite the imbalance, as well as, because ratings are ordinal, mean absolute error (MAE) and root-mean-square error (RMSE). For item-level analysis, out-of-fold predictions are aggregated into per-item MAEs; items are grouped into popularity terciles by sales volume, and per-item error is correlated with product characteristics using the Spearman rank correlation, which is robust to the heavy-tailed distributions of price and sales.

Accuracy is the fraction of correctly predicted ratings; the per-class score is the harmonic mean of precision (P_k) and recall (R_k) for class k, macro-averaged across the five rating classes [Eq. (6)]. MAE and RMSE [Eq. (4) and Eq. (5)] treat ratings as ordinal, where y_i and $\hat{y}_i$ denote the true and predicted ratings, respectively. Per-item difficulty is the mean absolute error over the set I_p of reviews of product p, with $|I_p|$ its cardinality [Eq. (8)]; its association with each characteristic is assessed with the Spearman coefficient ρ [Eq. (7)], with n the number of items being ranked and d_i the rank differences.

$$MAE = \frac{1}{n} \quad \sum_{i=1}^{n} |y_i - \hat{y}_i| \quad (4)$$

$$RMSE = \sqrt{\frac{1}{n}\sum_{i=1}^{n}(y_i - \hat{y}_i)^2} \quad (5)$$

$$F1_k = \frac{2P_kR_k}{P_k+R_k},\ macro - F1 = \frac{1}{K}\sum_{k=1}^{K} F1_k \quad (6)$$

$$\rho = 1 - \frac{6\sum_{i=1}^{n} d_i^2}{n(n^2-1)} \quad (7)$$

$$MAE_p = \frac{1}{|I_p|}\sum_{i\in I_p} |y_i - \hat{y}_i| \quad (8)$$

IV. Results and Discussion

A. Overall Model Comparison

Table III reports all five models on the four-category scenario (S3) under five-fold cross-validation. Among the classical models, the three text classifiers decisively outperform both baselines on every metric, and TF-IDF with logistic regression is the strongest, roughly halving the MAE of the majority and metadata baselines (0.667 versus 1.278 and 1.273). All text-versus-baseline differences are significant (paired t-test across folds, $p < 0.001$), and the small fold-level standard deviations confirm that the gap is not attributable to sampling noise. Product metadata alone barely improves on the majority baseline for MAE, underscoring that the predictive signal lies in the review text rather than in observable product attributes. Because the task is a five-class ordinal problem with an imbalanced rating distribution, exact accuracy is a conservative yardstick that counts a one-star miss as fully wrong; all models nevertheless exceed the 41.6% majority-class baseline, and the reference model places 85.6% of its predictions within one rating point of the true score (adjacent accuracy), MAE and macro-F1 are required as primary metrics, while accuracy parameters serve as secondary metrics. It should be emphasized that all accuracy metrics—such as macro-F1, MAE, and RMSE—reported in this table perform well and can also be calculated based on the analyzed dataset, which has been grouped by rating (a maximum of ten reviews per star rating per product, as shown in Table I, based on a sample of natural and organic market traffic). This corpus exhibits a more uniform class distribution than actual application traffic and is skewed toward five-star reviews—note Table I: 40.5% five-star reviews. Furthermore, these figures should be understood as an indication of how well review text can predict ratings in a balanced design, rather than merely as an estimate of the accuracy achieved by the system used. Accuracy is the most sensitive metric among the four metrics regarding this design choice, because accuracy will increase in organic traffic dominated by five-star ratings, even without any improvement in text understanding. A comprehensive discussion of the design choices and their implications is presented in detail in the "Data Set and Ethical Considerations" section and revisited in the "Threats to Validity" section. On a five-point scale, RMSE necessarily exceeds MAE; the gap reflects a small fraction of reviews mispredicted by several rating points, an inherent property of ordinal prediction that is amplified slightly by the class-balanced training used to handle the J-shaped rating distribution, which favors minority-class recall and macro-F1 over squared error. A fine-tuned IndoBERT transformer, evaluated under the identical protocol as a modern reference point, attains the best overall results (accuracy 0.560, macro-F1 0.473, MAE 0.567, RMSE 0.940; Table III, final row), improving on the strongest classical model and confirming that contextual modeling of Indonesian review text yields a further gain over the bag-of-words representation. For the interpretable item-level analyses that follow, however, TF-IDF combined with logistic regression will remain the benchmark model, as it is transparent and not too costly to apply using the out-of-fold method to all 1,616 items; furthermore, the popularity patterns and characteristics reported below are inherent properties of the items themselves, rather than merely artificial results generated by any single model.

TABLE III. Model Comparison on the Four-Category Scenario (S3); Five-Fold CV, Mean + SD. † IndoBERT (IndoBenchmark/IndoBERT-Base-P1), Fine-Tuned Under the Identical Five-Fold Protocol on a GPU

Model	Accuracy	Macro-F1	MAE	RMSE
Majority	0.416±0.00	0.118±0.00	1.278±0.00	1.894±0.00
Metadata-LR	0.383±0.01	0.271±0.01	1.273±0.04	1.839±0.05
TF-IDF+LogReg	0.529±0.01	0.443±0.02	0.667±0.02	1.089±0.03
TF-IDF+LinSVM	0.519±0.01	0.421±0.02	0.701±0.03	1.135±0.03
TF-IDF+RF	0.528±0.01	0.383±0.02	0.751±0.03	1.245±0.04
IndoBERT †	0.560±0.01	0.473±0.01	0.567±0.01	0.940±0.01

Fig. 5 plots per-model MAE across the three diversity scenarios, and Fig. 6 shows the per-fold MAE distribution for the four-category scenario. The text classifiers form a tight, low-error cluster clearly separated from the two baselines, and the narrow per-fold spread confirms the stability of the comparison.

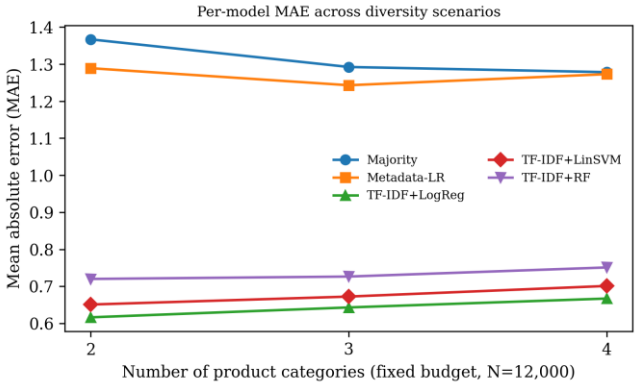

Fig. 5. Per-model MAE across the three fixed-budget diversity scenarios.

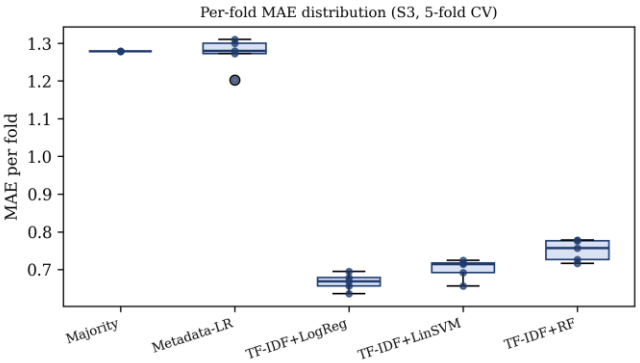

Fig. 6. Per-fold MAE distribution by model on the four-category scenario (S3, five-fold CV).

B. Effect of Category Diversity

Holding the data budget fixed, performance degrades modestly but consistently as category diversity increases: the reference model's MAE rises from 0.617 (two categories) to 0.643 (three) and 0.667 (four), and macro-F1 falls from 0.475 to

0.443 (Table IV, Fig. 7). Because N is constant, this reflects category composition.

The effect of diversity and its direction can be described in detail in terms of magnitude; the effect size and confidence intervals can also be calculated to show the increase in the MAE of the reference model between the two-category (S1) and four-category (S3) scenarios. The standard deviation of cross-validation for each scenario is as follows: S1:S3 has a value of 0.021, and the average of the six two-category subsets in Table V; S3:SD = 0.02 (Table III). There was also an increase in MAE of 0.050, equivalent to a large effect (Cohen's d ≈ 2.4) with a 95% confidence interval of [0.020, 0.080] (Welch's t-test on five folds per scenario, $t(8) \approx 3.9$, $p < 0.01$). There was a decrease in the micro-F1 score from 0.475 to 0.443; this trend was consistent across all category subsets and in the sensitivity analysis of the review thresholds (Tables V and VI). However, although the macro-F1 effect size per fold requires the underlying fold-level macro-F1 values shown in Table IV—and is maintained at that level of granularity— this is reported as a limitation in terms of precision, not just regarding the direction and robustness of the effect.

TABLE IV. PERFORMANCE ACROSS FIXED-BUDGET CATEGORY-DIVERSITY SCENARIOS (FIVE-FOLD CV)

Scenario	Majority MAE	Meta-LR MAE	TF-IDF+LR MAE	Macro-F1
S1 (2 cat.)	1.367	1.289	0.617	0.475
S2 (3 cat.)	1.292	1.243	0.643	0.453
S3 (4 cat.)	1.278	1.273	0.667	0.443

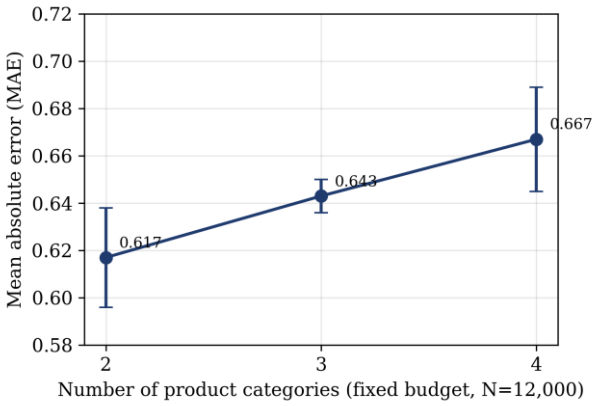

Fig. 7. MAE versus number of product categories under a fixed data budget (error bars: five-fold CV standard deviation).

The trend is robust to which categories are chosen: averaging the reference model over all subsets of each size reproduces the upward MAE trend (Table V); the four-category level is a single full configuration, for which the five-fold CV standard deviation is reported rather than a subset range. It is also robust to the per-item review threshold: raising it from 5 to 20 shifts MAE only within a narrow band while preserving the model ordering (Table VI). Because the per-category sample shrinks as categories are added under a fixed budget, the diversity effect is partly entangled with reduced per-category density; it is therefore treated as a modest effect and reported transparently.

TABLE V. ROBUSTNESS OF THE DIVERSITY TREND ACROSS CATEGORY SUBSETS (TF-IDF+LR)

Diversity level	# subsets	MAE (mean)	MAE range	CV std
2 categories	6	0.647	0.617–0.675	±0.021
3 categories	4	0.649	0.633–0.672	±0.007
4 categories	1	0.667	single config.	±0.022

TABLE VI. SENSITIVITY TO THE PER-ITEM REVIEW THRESHOLD (4-CAT, REPEATED 5×3 CV)

Min reviews/item	Items	MAE	Macro-F1
5	1,973	0.652±0.016	0.449
10	1,616	0.667±0.016	0.441
20	885	0.689±0.019	0.460

C. Popularity Bias as Predictive Difficulty

Grouping items by sales volume reveals a clear and counterintuitive pattern: popular (head) items are harder to predict than long-tail (tail) items. Pooled across categories, per-item MAE rises monotonically from 0.442 for tail items to 0.579 for mid items and 0.656 for head items (Fig. 8). This pattern holds within every category (Table VII), with a positive and significant Spearman correlation between sales volume and per-item error in all four, so it is an intrinsic property of item popularity rather than an artifact of cross-category mixing.

TABLE VII. PER-ITEM MAE BY POPULARITY TERCILE, WITHIN EACH CATEGORY (*** $p < 0.001$)

Category	Tail MAE	Mid MAE	Head MAE	Spearman (sold)
Electronics	0.342	0.445	0.626	0.470***
Fashion	0.589	0.668	0.647	0.181***
Sports	0.491	0.588	0.662	0.354***
Tools/Hardware	0.536	0.538	0.661	0.275***

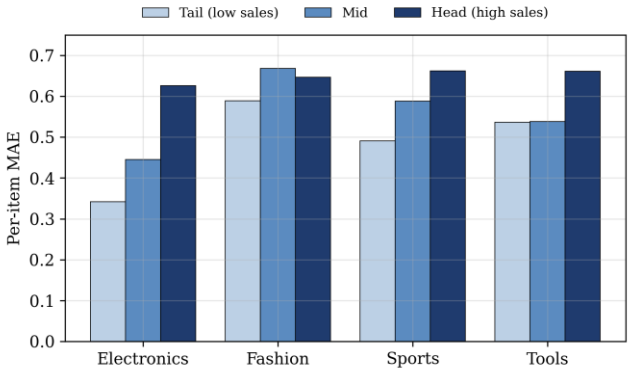

Fig. 8. Per-item MAE by popularity tercile within each category; head (high-sales) items show higher error in every category.

D. Product Characteristics and Predictive Difficulty

Table VIII and Fig. 9 relate per-item error to observable product characteristics. The strongest positive associations are with rating variance, number of reviews, and sales volume,

while average product rating and price are negatively associated with error; review length shows virtually no association. These results point to rating polarization as a principal driver of predictive difficulty: products that attract many sales tend to accumulate more heterogeneous, polarized opinions, making individual ratings harder to infer from text, whereas uniformly liked or higher-priced products are easier to predict.

TABLE VIII. SPEARMAN CORRELATIONS BETWEEN PER-ITEM MAE AND PRODUCT CHARACTERISTICS (*** P < 0.001, * P < 0.05; N = 1,616 ITEMS)

Characteristic	Spearman ρ	Direction
Rating variance	+0.428***	higher → harder
Number of reviews	+0.451***	higher → harder
Sales volume	+0.386***	higher → harder
Average product rating	−0.439***	higher → easier
Price	−0.265***	higher → easier
Review length	+0.055*	negligible

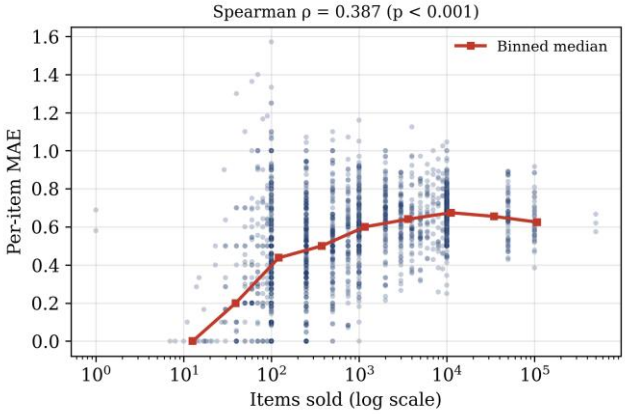

Fig. 9. Per-item MAE versus items sold (log scale); the binned median rises with popularity (Spearman ρ = 0.39).

To verify that these associations are not merely reflections of one another—sales volume, review count, and rating variance are themselves correlated— Regression was used to analyze the item errors for all six standardized characteristics collectively (ordinary least squares method; n = 1,614 out of a total of 1,616 items, with heavy-tailed counts log-transformed). There are two items excluded from this regression: their sales volumes are recorded as zero, which causes the logarithmic transformation used to address count variables with a heavy-tailed distribution to become undefined. Consequently, all other analyses in this study—including Table VIII and Fig. 9—use a dataset consisting of 1,616 items. The model explains 30% of the variance in per-item MAE, and every characteristic remains independently significant ($p < 0.01$). The average product rating has the largest standardized coefficient ($\beta = -0.050$), followed by review count ($\beta = +0.041$) and rating variance ($\beta = +0.035$), while the sales-volume coefficient attenuates the most ($\beta = +0.028$). Item popularity, therefore, raises predictive difficulty largely through the larger, more variable opinion sets that popular items accumulate rather than through sales volume itself, consistent with rating polarization as the operative mechanism.

E. Discussion and Implications

Taken together, the results reframe the concept of popularity bias. In the recommendation literature, it denotes overexposure of popular items; this study illustrates a clear and measurable phenomenon. The rankings of popular items are inherently more reliable when generated based on text. The characteristic analysis locates the mechanism in rating polarization: high-sales products accumulate larger, more heterogeneous, and polarized opinion sets (higher rating variance), so an individual review's star rating is less determined by its text. For practitioners, this implies that confidence in review-based quality estimates should be modulated by item popularity and rating dispersion, and that head items—commercially the most important—are precisely where automated rating prediction is least reliable and may warrant uncertainty-aware presentation or human oversight.

The implications are diagnostic in nature and have not been significantly addressed in this study; assessment polarization has been identified as the mechanism underlying the prediction difficulties triggered by popularity, yet no model has been designed to address this specific difficulty other than the one proposed and tested here. The treatment of this issue has been explicitly modeled in terms of opinion signals that are polarized or contradictory to a review, while treating each review as a uniform and reliable independent observation; this is left to a companion study introduced in the conclusion. Ultimately, the main practical question arising from each key finding of this research is how to make rating predictions for popular items with high variance more reliable—a question that remains open at the conclusion of this study.

F. Threats to Validity

Several limitations bound our claims. The corpus contains no stable reviewer identities, so the study addresses review-based rating prediction rather than personalized recommendation; this is a deliberate scoping decision, made explicit to avoid mis-specified collaborative-filtering claims. Under a fixed budget, per-category density decreases as categories are added, so the category-diversity effect is partly entangled with density. Issues like this can be resolved using a fixed N design and conducting robustness tests on all subsets, resulting in the reporting of moderate effects. Because the collection was rating-stratified (up to 10 reviews per star level per product), the rating distribution is more balanced than in an organic sample; the absolute MAE and accuracy figures should therefore be interpreted as characterizing the text-to-rating mapping under this balanced design rather than as estimates of organic deployment traffic. This has a significant impact on accuracy and is directly influenced by class prevalence; it increases in organic traffic dominated by five-star reviews. Even without an improvement in text understanding, the MAE is relatively less distorted. This is because the calculation of the average absolute error in reviews assigns weights to each rating level based on stratified frequency—not just natural frequency—but the MAE is still not a direct estimate of production error, i.e., the dataset and ethical considerations regarding the details of the sampling procedure. The review text was truncated at collection, limiting the ability to model long text. Review timestamps were not retrieved, so the corpus is a single-period snapshot (2 March – 10 April 2026), and temporal analyses, such as how price changes or review accumulation

shift the reported associations, are outside its scope. A comparison was conducted between IndoBERT and a classical TF-IDF classifier, which also highlights resource asymmetry—a factor not quantified in this study. IndoBERT was fine-tuned on a GPU, whereas the TF-IDF-based model was trained and made predictions on a CPU, using significantly less time and memory. Both model groups were evaluated using the same five-fold cross-validation protocol. IndoBERT demonstrated consistent yet moderate advantages over TF-IDF with logistic regression in terms of accuracy, micro-F1, MAE, and RMSE (Table III); for example, MAE was 0.567 versus 0.667.

Since execution time, memory usage, and hardware costs were not measured or reported, these benefits cannot be weighed against computational costs. Practical considerations between the two approaches may be left to future research; for applications without GPUs or under low-latency or low-cost constraints, the classic TF-IDF classification may be preferable despite its significantly higher error rate. Finally, the corpus is single-platform and single-language; generalization to other marketplaces and languages remains to be tested. Because the data are self-collected and cannot be redistributed under the platform's terms, reproducibility is supported through released code, full dataset statistics, and a public complementary corpus. However, this workaround does not fully resolve the replication issue, since the raw review corpus is not accessible to other researchers, and independent replication of the reported results is severely limited; third parties can only verify the released code and rerun the workflow on data they have collected themselves or on publicly available supplementary corpora, rather than on the specific sample analyzed here.

V. Conclusion

This was demonstrated in a controlled learning setting and can be applied to predicting ratings based on review scores; the experiment was conducted on a self-collected and anonymized corpus of Indonesian-language online market reviews. Three findings stand out. Review text is by far the dominant predictive signal, more than halving the error of the metadata and majority baselines. Category diversity has a small but consistent negative effect once data volume is held fixed, cleanly isolating composition from scale. Most importantly, popular items are systematically harder to predict than long-tail items within every category, an effect driven by rating polarization and quantified through an interpretable, characteristic-level analysis. These results reframe popularity bias from a purely ranking-fairness concern toward a measurable property of predictive difficulty, with direct implications for where automated review-based estimates can be trusted. A fine-tuned IndoBERT transformer attained the best overall scores, confirming that contextual modeling further improves review-based rating prediction. A companion study will target the hard cases identified here—popular, high-variance items—with a hybrid model that fuses aspect-based sentiment analysis with product metadata and latent factors [18], [31], [36], [37], moving from diagnosing predictive difficulty toward mitigating it and, ultimately, personalized recommendation on user-bearing corpora.

Data Availability

The review corpus was self-collected from publicly accessible pages of an Indonesian marketplace for non-commercial academic research. Because the underlying review texts remain subject to the platform's terms of use and the intellectual property rights of their authors, the raw corpus cannot be redistributed. The aggregated dataset statistics (Tables I and II) and the item-level analysis data—per-product error and characteristic values, excluding raw review text—together with the complete Python analysis code, are available from the corresponding author on reasonable request and can be provided to the editors and reviewers for verification. The publicly available PRDECT-ID corpus [28] offers emotion- and sentiment-annotated Indonesian product reviews that can be used to replicate the text-modeling components of this study.

Acknowledgment

This study was sponsored by RKAT Universitas Sebelas Maret Fiscal Year 2026 through the (PKGRUNS) Type B scheme, under Research Assignment Agreement Number 462/UN27.22/PT.01.03/2026, under the name of From Empowering Sustainable Futures through Data Science, Artificial Intelligence, and to complete further studies in the Doctoral Program in Engineering Science, Faculty of Engineering, Universitas Negeri Yogyakarta.

Note on Figure Quality

Fig. 2–9 are displayed at a resolution of 480–640 DPI, and their print size in this manuscript exceeds the standard 300 DPI typically required for printing. Fig. 1 depicts a traditional market in Indonesia and has a lower resolution of 220 DPI based on its print size; it will be re-exported at a higher resolution, accompanied by larger axis labels and legend text to improve on-screen readability before being submitted in print-ready format.

***Abstract*—Conventional feature fusion mechanisms largely overlook orientation information, making it difficult to effectively represent objects with diverse rotational patterns. To address this issue, we propose YOLO-RSL, a lightweight rotated object detector that introduces orientation awareness into feature representation, feature fusion, and localization optimization. The proposed Rotation-Oriented Iterative Attentional Feature Fusion (RO-iAFF) module incorporates implicit orientation information derived from orthogonal asymmetric depthwise convolutions into a two-stage channel attention process, enabling orientation-sensitive multi-scale feature aggregation. In addition, a Swin Transformer block and a large-kernel feature branch are employed to enhance global context modeling and improve small-object representation. To achieve more accurate localization, an enhanced regression loss (LFFE Loss) is designed to jointly optimize overlap quality, rotation angle, center offset, and aspect ratio. Experimental results on the DIOR-R and UCAS-AOD datasets show that YOLO-RSL achieves $mAP_{0.5}$ scores of 84.17% and 98.44%, surpassing the baseline by 3.15% and 2.91%, respectively. Moreover, the performance gains become more pronounced as target aspect ratios increase, demonstrating the effectiveness of the proposed orientation-aware design.**

***Keywords*—Rotated object detection; oriented bounding box; feature fusion; remote sensing image**

I. Introduction

Remote sensing platforms provide a wide range of observation data with high space-time resolution, which makes them irreplaceable and play an important role in the fields of urban planning, disaster assessment, and traffic monitoring. In remote sensing image (RSI) analysis, rotating target detection is a basic but difficult task. In this task, most targets, such as aircraft, ships, and vehicles, will appear at any angle in a complex context, and there are obvious scale changes. Using directional enclosure frames (OBBs) can give more compact geometric representations and effectively reduce background interference, so rotating target detection has become a key task in the field of remote sensing analysis [1].

The target detector based on deep learning has greatly improved the performance of general target detection. Representative frameworks such as Faster R-CNN [2] and SSD [3] have laid a solid foundation for the modern target detection architecture. After that, the YOLO-based detector has made significant progress in balancing detection accuracy and inference efficiency. However, because of the limited perception ability of target orientation, it has not been able to fully model global context information. There are still many problems in the direct use of traditional general-purpose detectors in remote sensing image analysis. Existing rotary target detectors, such as SCRDet++ [4] and R3Det [5], effectively improve the accuracy of target positioning by introducing rotary perception regression and refined feature learning mechanisms. Even so, when encountering the limitations of lightweight deployment, these methods still have some shortcomings in dealing with small targets and complex background problems.

In recent years, Transformer-based architectures have shown strong capabilities in long-range dependency modeling and global feature representation. Vision Transformer (ViT) took the lead in introducing the self-attention mechanism into computer vision tasks, while Pyramid Vision Transformer (PVT) [6] and MobileViT [7] improved computing efficiency through hierarchical and lightweight design. Deformable DETR [8] and OrientedFormer [9] extend the Transformer mechanism to direction detection in RSI. However, these methods address global context modeling rather than the orientation sensitivity of the fusion stage itself, and their computational overhead continues to limit deployment in lightweight detectors.

Feature fusion is the stage at which multi-scale feature maps from different backbone levels are combined before being passed to detection heads. Existing channel attention modules employed in this stage—SE [10], CBAM [11], and even the iterative iAFF [12]—compute channel weighting solely from global average pooling or local convolutional statistics of the feature maps, without any encoding of target orientation. This means the same channel weights are assigned irrespective of whether a target appears at 0°, 45°, or 90°. In RSIs, where targets span the full 180° orientation range and object categories such as aircraft and ships have aspect ratios exceeding 6:1, orientation-agnostic fusion leads to a systematic failure mode: features discriminative for one orientation are suppressed when those features happen to score poorly on a channel statistic computed over a spatially mixed feature map. The result is missed detections for densely arranged, arbitrarily oriented objects and imprecise OBB regression for elongated targets—precisely the objects that most frequently appear in RSI benchmarks.

A further challenge lies in rotated bounding-box regression. Existing methods, such as circular smoothing label (CSL) [13] and H2RBox-v2 [14], solve the problems of periodic discontinuity and angle blur in the process of angle prediction. At the same time, ProbIoU [15] optimizes the rotating boundary frame by modeling geometric uncertainty. However,

*Corresponding author.

the existing loss function is still unable to fully model the joint relationship between the overlapping area, center offset, aspect ratio, and rotation angle at the same time, resulting in the unstable positioning of slender and densely arranged objects. Second, multi-scale feature fusion in the neck is typically orientation-agnostic, producing channel-wise attention weights that are insensitive to the rotation state of targets. Third, conventional IoU-based losses provide incomplete geometric supervision for OBBs because they neglect center displacement, aspect-ratio mismatch, and angle residual simultaneously. The present work addresses all three deficiencies within a single, parameter-efficient framework. The main contributions of this study are as follows:

1) A novel Rotation-Oriented iterative Attentional Feature Fusion (RO-iAFF) module is proposed. RO-iAFF extends the standard iAFF framework by introducing orientation encoding angle embeddings generated from the cosine and sine values of the predicted rotation angle into the dual-stage MS-CAM attention computation, thereby enabling channel-wise feature weighting to become sensitive to object orientation. In addition, an extra 10×10 deep feature extraction layer is incorporated into the neck to enlarge the effective receptive field for small targets.

2) Swin Transformer blocks replace selected C3K2 modules in the YOLOv11s-OBB backbone to enrich global contextual representation, providing high-quality multi-scale features on which orientation-aware fusion can act most effectively.

3) A Four-Factor Loss Function for Enhanced regression is proposed to jointly constrain overlap, angle, center offset, and aspect ratio, thereby improving rotated bounding-box localization stability and accuracy.

II. Related Work

A. YOLO-Based Rotated Object Detection

YOLO-based detectors have achieved significant progress in balancing detection accuracy and inference efficiency. Compared with two-stage frameworks such as Faster R-CNN [2], the YOLO architecture provides more efficient end-to-end interference, making it very suitable for real-time RSI applications. SCRDet++ [4] improves rotation detection through instance-level feature denoising and rotation loss smoothing, while R³Det [5] enhances positioning performance through refined feature optimization. CSL [13] re-expresses angle regression as a classification problem to alleviate periodic discontinuity, while H2RBox-v2 [14] improves direction estimation through symmetric perception self-supervised learning. YOLOv11-OBB [16] expands the direction detection head for OBB regression on the basis of YOLOv11, achieving high positioning accuracy with lightweight overhead. Despite these advances, these detectors have not solved the problem of direction insensitivity in their feature fusion stage: no matter what the modeling effect of the detection head is on the rotation, the attention weight of the neck channel is still independent of the direction, resulting in a continuous characterization bottleneck, and YOLO-RSL is directly aimed at this bottleneck.

B. Attention and Feature Fusion Mechanisms

Attention mechanisms are the dominant tool for feature fusion in modern detectors. SE [10] enhances channel-wise recalibration through global average pooling, yet its scalar channel weights are derived from orientation-invariant global statistics, making it blind to target rotation. CBAM [11] combines channel and spatial attention for refined enhancement, but generates identical orientation-agnostic weights regardless of whether a target is oriented at 0° or 90°. To improve multi-scale feature interaction, iAFF [12] introduces iterative attention weighting to dynamically fuse heterogeneous semantic features across different layers. Compared with traditional linear fusion methods, iterative feature fusion achieves more effective semantic alignment and feature refinement. In addition, BoTNet [17] incorporates multi-head self-attention into convolutional bottleneck structures, enabling stronger global dependency modeling while maintaining computational efficiency.

However, most existing feature fusion strategies mainly focus on channel or spatial attention and neglect explicit orientation information during feature aggregation. Consequently, their performance remains limited for densely distributed and arbitrarily rotated objects in remote sensing imagery.

C. Transformer-Based Object Detection

The Transformer architecture shows a strong ability in modeling long-range dependencies and global context information. PVT [6] improves efficiency through hierarchical feature extraction, while MobileViT [7] combines lightweight convolution with a Transformer module. For object detection, Deformable DETR [8] reduces global attention cost through sparse deformable sampling, ARS-DETR [18] improves aspect-ratio-sensitive feature learning for aerial detection, and OrientedFormer [9] introduces orientation-aware positional encoding for rotated RSI detection. Although these methods effectively improve contextual perception, they address representation quality rather than fusion-stage orientation sensitivity, and their computational overhead continues to hinder lightweight deployment. We adopt Swin Transformer blocks [19] selectively in the backbone to gain their hierarchical global context benefits at moderate cost, complementing rather than relying on them for the orientation-awareness provided by RO-iAFF.

D. Research Gap and Motivation

The survey above reveals a consistent and unaddressed gap: while rotation-aware regression losses and backbone representations have been extensively studied, the feature fusion stage of lightweight YOLO-series detectors has remained universally orientation-agnostic. The three literature streams reviewed above address complementary aspects—orientation-aware regression (Section II-A), feature representation (Section II-C), and channel attention quality (Section II-B)—but none provides a mechanism for making multi-scale channel fusion weights sensitive to target orientation. We fill this gap by proposing RO-iAFF, which introduces orientation awareness directly into the iterative attention fusion computation, and validate that this targeted intervention yields the largest performance gain among all

proposed components, particularly for elongated, high-aspect-ratio targets.

III. Proposed Method

A. Overall Architecture

The proposed detector is designed around a three-level orientation-aware strategy applied to YOLOv11s-OBB (Fig. 1). At the representation level, selected C3K2 modules at backbone stages 2 and 3 are replaced with Swin Transformer blocks [19] to enrich global semantic representation. At the fusion level—the central innovation—each neck output branch is connected to the detection head via the proposed RO-iAFF module, which replaces the standard direct skip connection and provides orientation-sensitive channel weighting. Additional convolutional and C3K2 layers before the SPPF stage generate a 10×10 deep feature map that is upsampled and fused with the 20×20 PANet output to form a fourth detection branch, enlarging the effective receptive field for small targets. At the supervision level, the original regression loss is replaced with LFFE, which jointly constrains four geometric factors of predicted OBBs. These three levels are mutually reinforcing: the Swin backbone provides richer multi-scale features, RO-iAFF fuses them in an orientation-sensitive manner, and LFFE ensures that the resulting predictions are geometrically precise. Together, they introduce only 0.56 additional GFLOPs and 0.21 M additional parameters over the baseline.

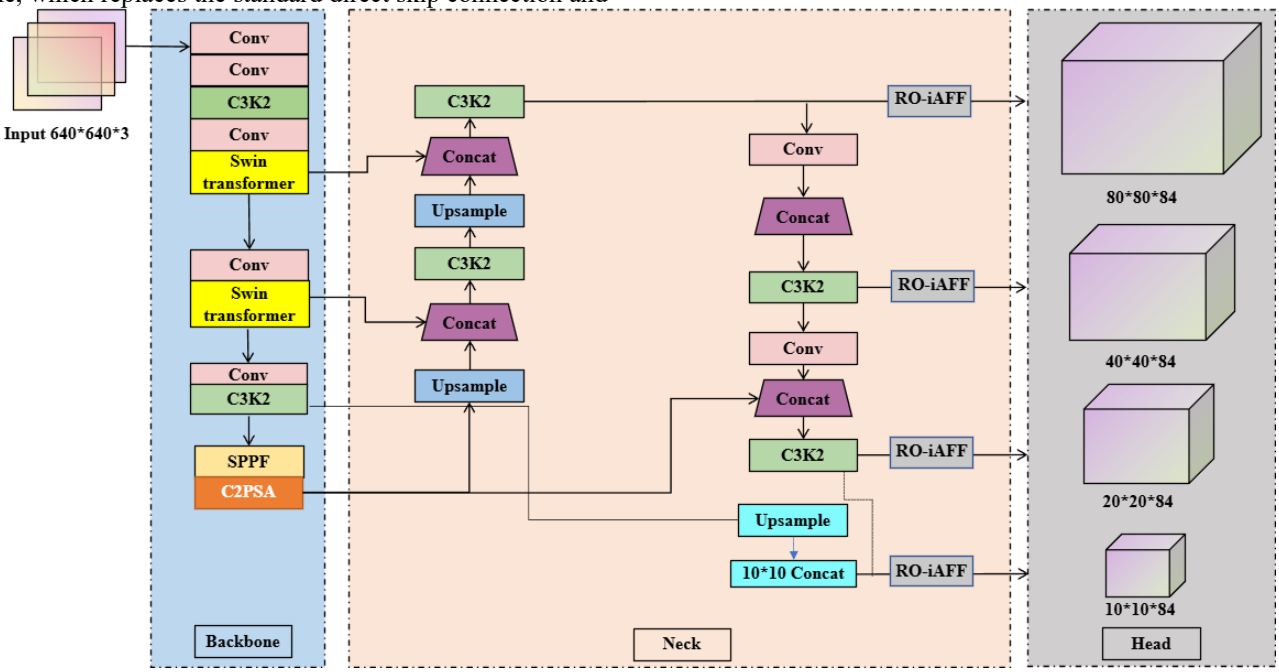

Fig. 1. Overall network structure.

B. Rotation-Oriented Iterative Attention Feature Fusion

Standard multi-scale feature fusion modules, including the original iAFF, compute channel attention weights solely from the feature maps themselves, rendering the fusion process rotation-agnostic. In RSIs, where targets such as aircraft, ships, and bridges exhibit wide orientation variation, orientation-agnostic fusion leads to suboptimal channel selection. The original iAFF framework consists of two core components: a Multi-Scale Channel Attention Mechanism (MS-CAM), which extracts complementary global and local channel descriptors to generate soft attention weights, and a two-stage iterative fusion strategy that progressively refines the fused representation. Building upon the standard iAFF framework, the proposed RO-iAFF introduces a new component called the Directional Channel Modulation (DCM) descriptor. Unlike conventional channel attention modules that derive weights purely from pooling statistics, DCM pulls directional information directly out of the feature maps themselves. This is done through a pair of asymmetric depthwise convolutions applied to the element-wise sum of the two input feature maps. The resulting descriptor is then injected into the MS-CAM global branch at both fusion stages, allowing the channel weights to shift in response to the dominant orientation present in the fused features.

A key design decision in DCM is that it does not take a rotation angle as an external input. Instead, it recovers directional information implicitly from the feature maps. Given the element-wise sum S of the two feature maps to be fused, two directional feature maps are computed below:

$$\boldsymbol{f}_h = \boldsymbol{DWConv}_{1\times k}(\boldsymbol{S}) \in ¡^{H\times W\times C} \quad (1)$$

$$\boldsymbol{f}_v = \boldsymbol{DWConv}_{k\times 1}(\boldsymbol{S}) \in ¡^{H\times W\times C} \quad (2)$$

$\boldsymbol{DWConv}_{1\times k}$ uses a 1×k depthwise convolution to capture horizontal structure, and $\boldsymbol{DWConv}_{k\times 1}$ uses a k×1 depthwise convolution to capture vertical structure, where k is set to 7. A 1×k kernel responds preferentially to intensity patterns that extend along the horizontal direction, while a k×1 kernel responds preferentially to vertically oriented patterns. For targets with a spindle tilt angle of θ, the activation value of the horizontal feature diagram $\boldsymbol{f}_h$ is proportional to cos(θ), while the activation value of the vertical feature diagram $\boldsymbol{f}_v$ is

proportional to sin(θ). The relative magnitude of the two maps therefore encodes the dominant orientation of the scene in a continuous and differentiable manner. This encoding spans the full 180-degree orientation range and requires no explicit angle label or supervision signal from the detection head, making DCM entirely self-contained within the neck. This continuous, self-supervised orientation encoding is what differentiates DCM from all prior channel attention methods, which discard directional spatial structure by pooling over entire feature maps.

Global average pooling is then applied to each directional map, and the resulting vectors are concatenated and compressed to a C-dimensional directional descriptor via a 1×1 convolution:

$$\boldsymbol{d} = \boldsymbol{Conv}_{1\times1}\left(\left[\boldsymbol{GAP}(\boldsymbol{f}_h) \| \boldsymbol{GAP}(\boldsymbol{f}_v)\right]\right) \in ¡^{C} \tag{3}$$

The parameter overhead of DCM is $2\boldsymbol{kC} + \boldsymbol{C}^2$, negligible relative to the backbone. Since $\boldsymbol{d}$ is derived entirely from the feature maps, DCM is fully self-contained within the neck and introduces no dependency on detection head outputs.

The directional descriptor $\boldsymbol{d}$ is injected additively into the MS-CAM global attention branch (Fig. 2) prior to Sigmoid normalization at both fusion stages. For Stage 1, given the global descriptor $\boldsymbol{g} = \boldsymbol{GAP}(\boldsymbol{S})$ and local attention map $\boldsymbol{a}_{loc} = \boldsymbol{Conv}_{1\times1}(\boldsymbol{S})$, the rotation-oriented attention weight is computed as:

$$\boldsymbol{a}_{glob}^{dir} = \boldsymbol{\sigma}\left(\boldsymbol{W}_2 \cdot \boldsymbol{BN}(\mathrm{Re}\,\boldsymbol{LU}(\boldsymbol{W}_1\boldsymbol{g})) + \boldsymbol{d}\right) \tag{4}$$

$$\boldsymbol{a}_1 = \boldsymbol{\sigma}\left(\boldsymbol{a}_{glob}^{dir} + \boldsymbol{a}_{loc}\right) \tag{5}$$

The intermediate fused feature $\boldsymbol{Z}_0$ is then obtained as:

$$\boldsymbol{Z}_0 = \boldsymbol{a}_1 \,\mathrm{e}\, \boldsymbol{X} + (1-\boldsymbol{a}_1)\,\mathrm{e}\, \boldsymbol{Y} \tag{6}$$

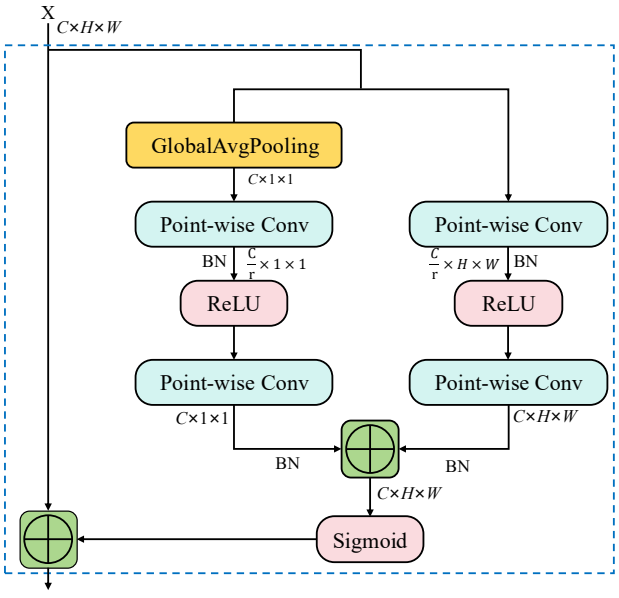

Fig. 2. Architecture of MS-CAM.

Stage 2 refines $\boldsymbol{Z}_0$ by applying a second rotation-oriented MS-CAM block under the same directional descriptor d:

$$\boldsymbol{a}_{glob,0}^{dir} = \boldsymbol{\sigma}\left(\boldsymbol{W}_4 \cdot \boldsymbol{BN}(\mathrm{Re}\,\boldsymbol{LU}(\boldsymbol{W}_3\boldsymbol{g}_0)) + \boldsymbol{d}\right) \tag{7}$$

$$\boldsymbol{a}_2 = \boldsymbol{\sigma}\left(\boldsymbol{a}_{glob,0}^{dir} + \boldsymbol{a}_{loc,0}\right) \tag{8}$$

$$\boldsymbol{Z} = \boldsymbol{a}_2 \,\mathrm{e}\, \boldsymbol{Z}_0 + (1-\boldsymbol{a}_2)\,\mathrm{e}\, \boldsymbol{Y} \tag{9}$$

where, $\boldsymbol{g}_0 = \boldsymbol{GAP}(\boldsymbol{Z}_0)$ and $\boldsymbol{a}_{loc,0} = \boldsymbol{Conv}_{1\times1}(\boldsymbol{Z}_0)$. Sharing $\boldsymbol{d}$ across both stages ensures consistent directional guidance without doubling the DCM overhead. where $\boldsymbol{W}_i (\boldsymbol{i} = 1,...,4)$ are the learnable weight matrices of the two-layer bottleneck MLPs in Stage 1 and Stage 2, respectively, with reduction ratio r = 4. Stage 1 performs coarse channel selection guided by the directional prior, while Stage 2 refines the fused representation by re-examining $\boldsymbol{Z}_0$ under the same directional context. When the feature maps contain no directional asymmetry, $\boldsymbol{d}$ approaches a uniform vector and RO-iAFF degenerates to standard iAFF, providing stable behavior on isotropic targets. The DCM weights are initialized with near-zero values to ensure that training begins from a well-understood iAFF baseline. The complete forward pass is summarized in Algorithm 1.

Algorithm 1: RO-iAFF Forward Pass

Input: Feature maps X, Y $\in ¡^{H\times W\times C}$

Directional Channel Modulation

1. $\boldsymbol{S} \leftarrow \boldsymbol{X} + \boldsymbol{Y}$
2. $\boldsymbol{f}_h \leftarrow \boldsymbol{DWConv}_{1\times k}(\boldsymbol{S})$ //horizontal directional feature
   $\boldsymbol{f}_v \leftarrow \boldsymbol{DWConv}_{k\times1}(\boldsymbol{S})$ //vertical directional feature
3. $\boldsymbol{d} \leftarrow \boldsymbol{Conv}_{1\times1}\left(\left[\boldsymbol{GAP}(\boldsymbol{f}_h) \| \boldsymbol{GAP}(\boldsymbol{f}_v)\right]\right) \in ¡^{C}$

Stage 1: Coarse fusion

4. $\boldsymbol{g} \leftarrow \boldsymbol{GAP}(\boldsymbol{S})$
5. $\boldsymbol{a}_{glob} \leftarrow \boldsymbol{\sigma}\left(\boldsymbol{W}_2 \cdot \boldsymbol{BN}(\mathrm{Re}\,\boldsymbol{LU}(\boldsymbol{W}_1\boldsymbol{g})) + \boldsymbol{d}\right)$
   $\boldsymbol{a}_{loc} \leftarrow \boldsymbol{Conv}_{1\times1}(\boldsymbol{S})$, $\boldsymbol{a}_1 \leftarrow \boldsymbol{\sigma}\left(\boldsymbol{a}_{glob} + \boldsymbol{a}_{loc}\right)$
6. $\boldsymbol{Z}_0 \leftarrow \boldsymbol{a}_1 \,\mathrm{e}\, \boldsymbol{X} + (1-\boldsymbol{a}_1)\,\mathrm{e}\, \boldsymbol{Y}$

Stage 2: Refined fusion

7. $\boldsymbol{g}_0 \leftarrow \boldsymbol{GAP}(\boldsymbol{Z}_0)$
8. $\boldsymbol{a}_{glob,0} \leftarrow \boldsymbol{\sigma}\left(\boldsymbol{W}_4 \cdot \boldsymbol{BN}(\mathrm{Re}\,\boldsymbol{LU}(\boldsymbol{W}_3\boldsymbol{g})) + \boldsymbol{d}\right)$
   $\boldsymbol{a}_{loc,0} \leftarrow \boldsymbol{Conv}_{1\times1}(\boldsymbol{Z}_0)$, $\boldsymbol{a}_2 \leftarrow \boldsymbol{\sigma}\left(\boldsymbol{a}_{glob,0} + \boldsymbol{a}_{loc,0}\right)$
9. $\boldsymbol{Z} \leftarrow \boldsymbol{a}_2 \,\mathrm{e}\, \boldsymbol{Z}_0 + (1-\boldsymbol{a}_2)\,\mathrm{e}\, \boldsymbol{Y}$

Output: Fused feature Z $\in ¡^{H\times W\times C}$

C. Swin Transformer Block

While RO-iAFF provides orientation-aware fusion, the quality of the fused representations depends on the richness of the backbone features. The C3K2 module extracts local features through small volumes, but its receptive field is limited. In order to enrich the global context information, we replaced some C3K2 modules in stages 2 and 3 of the backbone network with the Swin Transformer module [19].

Swin Transformer adopts a hierarchical framework, including image block segmentation, feature extraction, and image block merging. Each module replaces the standard global multi-head self-attention mechanism (MSA) with the window-based multi-head self-attention mechanism (W-MSA) and the shifted window multi-head self-attention mechanism (SW-MSA), as shown in Fig. 3. W-MSA calculates self-attention in non-overlapping local windows; SW-MSA loops to move window boundaries to achieve cross-window information exchange. After the attention sublayer, layer normalization, multi-layer perceptron (MLP), and residual connection are applied in turn, and finally the semantic feature diagram is generated.

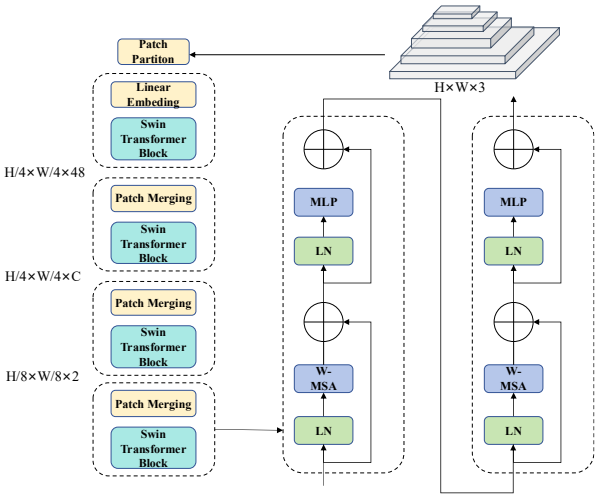

Fig. 3. Structure of Swin Transformer.

D. Four-Factor Bounding-Box Loss

Standard IoU-based losses present a known difficulty for rotated object detection, as OBB intersections become non-differentiable under certain parameter configurations. While orientation-aware fusion improves representational quality, accurate OBB regression still demands a loss function that captures all relevant geometric attributes jointly. LFFE addresses this need by optimizing four orthogonal geometric factors: overlap area, rotation angle residual, center-point offset, and aspect-ratio discrepancy. The total training loss is:

$$L_{total} = \frac{\lambda_1}{N}\sum_{n=1}^{N} L_{obj} + \frac{\lambda_2}{N}\sum_{n=1}^{N} L_{cls} + \frac{\lambda_3}{N}\sum_{n=1}^{N} L_{box} \tag{10}$$

In the loss formulation L_{obj} 、 L_{cls} and L_{box} correspond to the confidence loss, classification loss, and bounding box loss functions $\lambda_1 = \lambda_2 = 1$ and $\lambda_3 = 0.05$ adopts the default setting. The regression loss is:

$$L_{box} = L_{SkewIoU} + \lambda_4 L_{center} + \lambda_5 (\theta_p - \theta_t)^2 \tag{11}$$

Here, SkewIoU is the rotated IoU indicator. L_{center} is a center-related constraint. To achieve a r reasonable balance between positioning accuracy and angle alignment, the weighting factors λ_4 and λ_5 are given values of 1.0 and 0.5, respectively. By imposing constraints on four geometric attributes, LFFE provides more reliable supervision for OBB and further enhances the direction-sensitive characteristics generated by RO-iAFF.

IV. Experiments

A. Datasets and Metrics

DIOR-R is a rotated variant of the DIOR dataset comprising over 23,000 high-resolution RSIs annotated with OBBs across 20 object categories, sourced from diverse sensors at varying spatial resolutions and imaging angles. Large images are partitioned into 1024×1024 patches using a sliding window, and Mosaic data augmentation is applied during training to enrich the spatial distribution of objects across scales and orientations. The data augmentation examples are illustrated in Fig. 4. The training and test sets are partitioned at an 8:2 ratio. The training and test sets are partitioned at an 8:2 ratio. The statistical overview includes instances of object categories, the size and quantity of ground-truth bounding boxes, the center positions and aspect ratios of objects, as shown in Fig. 5.

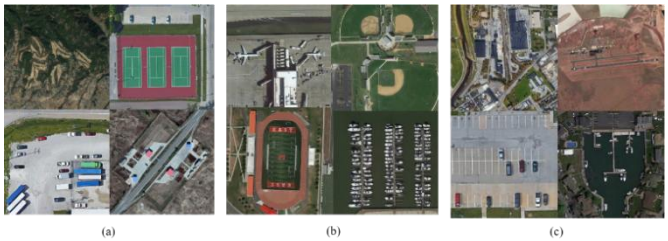

Fig. 4. Mosaic data augmentation on the DIOR dataset.

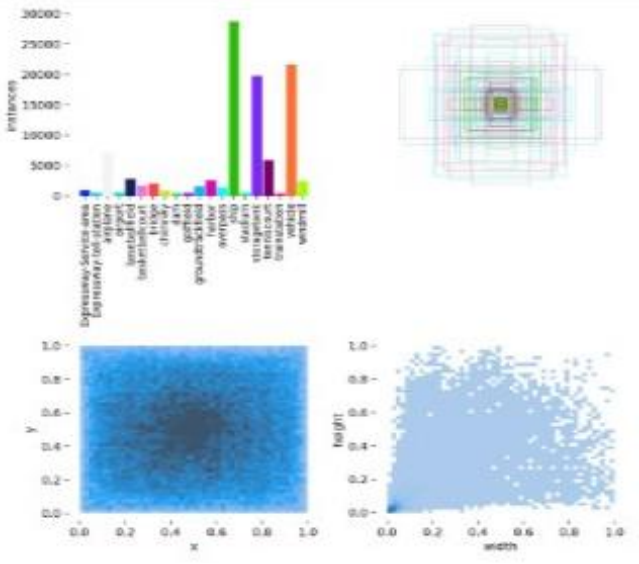

Fig. 5. Statistics of the DIOR dataset.

UCAS-AOD contains high-resolution aerial images with OBB annotations for two categories (airplane and vehicle). Versions 1.0 and 2.0 together provide 1,000 airplane images (7,482 instances), 510 car images (7,114 instances), and 910 background images. Maximum annotated aspect ratios reach 8:1. Random rotation, angle jitter, and brightness variation are applied for data augmentation. Training and test sets comprise 1,110 and 400 images, respectively.

B. Implementation Details

All experiments are conducted on Ubuntu 20.04 with an NVIDIA RTX 3080 GPU, PyTorch 1.10.0, CUDA 11.3, and cuDNN 8.3.4. The SGD optimizer uses a learning rate of 0.01, momentum of 0.937, and weight decay of 0.0005. A 3-epoch linear warm-up phase is followed by cosine annealing decay. The batch size is 8, and all models are trained for 200 epochs. Training results on the UCAS-AOD dataset are shown in Fig. 6.

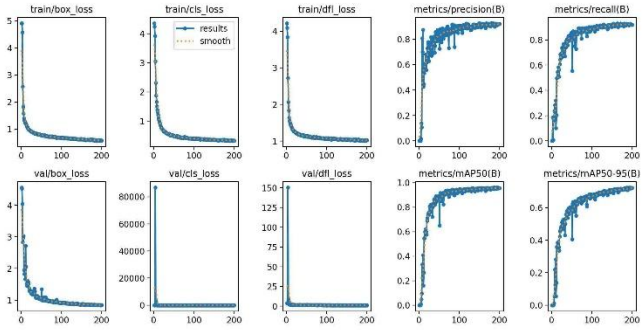

Fig. 6. YOLOv11s-OBB baseline training results on the UCAS-AOD dataset.

C. Ablation Experiment

To justify the selection of RO-iAFF over alternative attention modules, SE [10], CBAM [11], Coordinate Attention (CA) [20], the standard iAFF [12], and the proposed RO-iAFF are each inserted at the four neck output branches and evaluated on UCAS-AOD under identical training conditions (Table I). RO-iAFF achieves 96.64% mAP0.5, surpassing standard iAFF by 0.61% and CA by 0.66%, while adding only 0.03 M parameters over the baseline. The consistent performance ordering (Baseline < SE ≤ CBAM < CA < iAFF < RO-iAFF) mirrors the degree to which each method incorporates spatial or directional information, strongly supporting the interpretation that orientation-awareness is the decisive factor.

TABLE I. COMPARISON OF THE IMPACT OF DIFFERENT ATTENTION MECHANISMS

Method	$mAP_{0.5}$	Param(M)
Baseline	95.53	7.72
SE	95.56	7.77
CBAM	95.57	7.82
CA	95.98	7.74
RO-iAFF	**96.64**	**7.75**

The heat maps (Fig. 7) on DIOR further show that RO-iAFF can maintain a clearer attention to the target area at different scales and in complex contexts. Placing RO-iAFF at multiple levels of the neck can achieve finer features across scales, so as to obtain better positioning and classification effects.

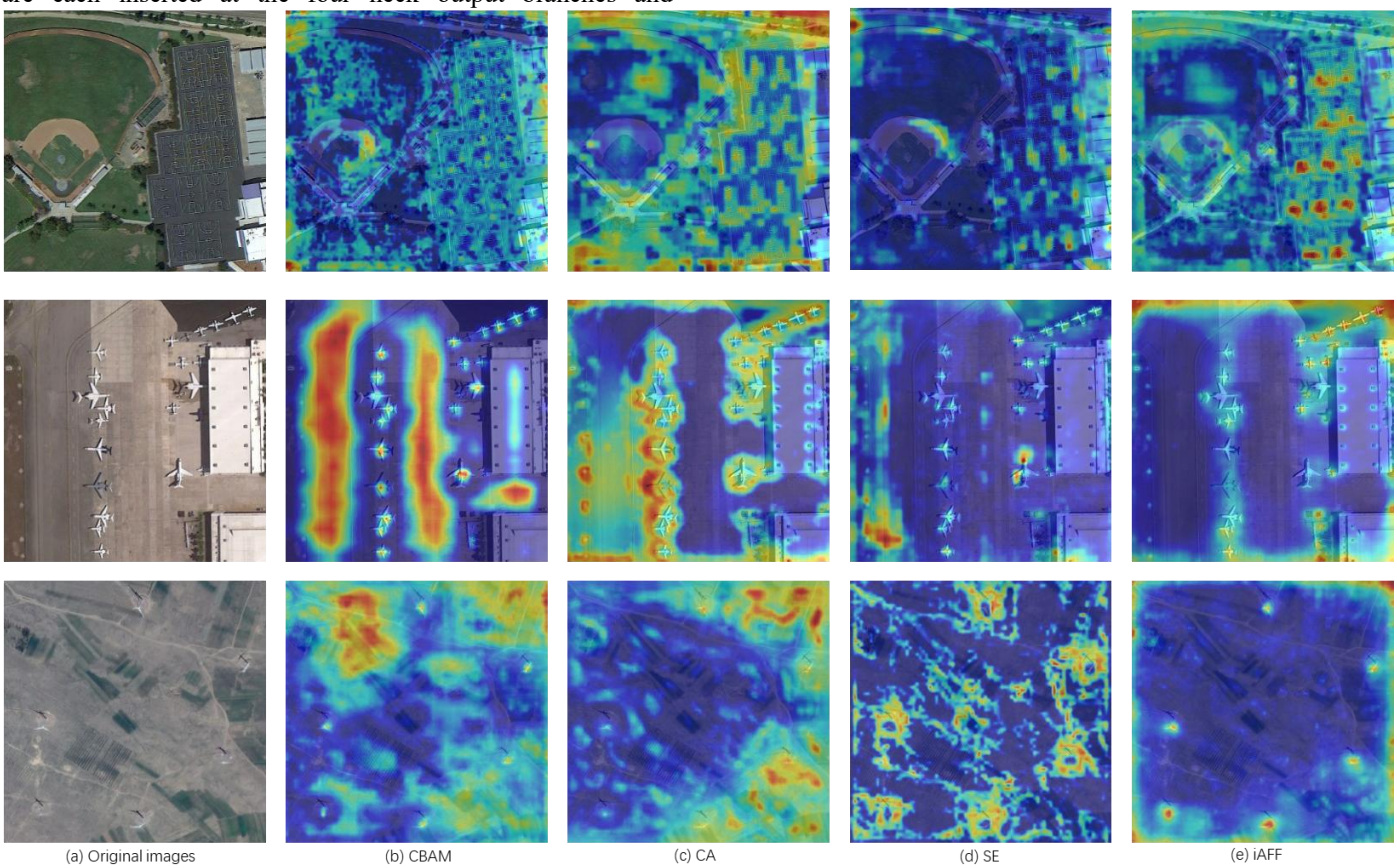

Fig. 7. Heatmap images by different neck designs on the DIOR dataset.

Table II shows that each proposed component brings steady improvements on both DIOR-R and UCAS-AOD. On DIOR-R, the baseline YOLOv11s-OBB achieves 81.02% mAP0.5 and 49.12% mAP0.5:0.95. After the introduction of the Swin Transformer module, these scores increased to 81.56% and 50.54%, respectively, confirming that the self-attention mechanism based on hierarchical windows can enhance the global context representation in messy remote sensing scenarios. After replacing the standard iAFF with our proposed RO-iAFF (also integrating the 10×10 depth feature branch), the single-component gain is the largest, mAP0.5 increased to 83.24%, and mAP0.5:0.95 increased to 51.73%, indicating that directional perception fusion can significantly improve the multi-scale feature quality of slender and densely arranged targets. The subsequent integration of LFFE achieved the best performance, with mAP0.5 at 84.17% and mAP0.5:0.95 at 52.98%, an increase of 3.15% and 3.86% respectively over the benchmark, while maintaining only 16.54 GFLOPs of computing cost and 8.12 M parameters.

On the UCAS-AOD data set of small densely distributed targets, each proposed component has made similar continuous improvements. The baseline model achieved mAP0.5 at 95.53% and mAP0.5:0.95 at 71.35%. After the introduction of the Swin Transformer module, the score increased to 96.64% and 71.93%, respectively, verifying that global context modeling can improve target detection performance even on a relatively compact two-category benchmark dataset. RO-iAFF further increased mAP0.5 to 97.25% and mAP0.5:0.95 to 72.84%. This result shows that directional perception fusion is particularly effective for slender targets such as aircraft and vehicles. After adding LFFE, the mAP0.5 of the complete model reached 98.44%, and the mAP0.5:0.95 reached 74.19%, which was 2.91% and 2.84% higher than the baseline model, respectively. Although there are differences in the number of categories, object scale, and annotation density, the model performance on the two datasets has improved, indicating that the three components can work well together and apply to different remote sensing conditions.

TABLE II. ABLATION EXPERIMENT ON THE DIOR AND UCAS-AOD DATASETS

Model	Dataset	Swin Transformer	RO-iAFF	LFFE	$mAP_{0.5}$	#Param(M)	GFLOPs
YOLOv11s-OBB	DIOR	×	×	×	81.02	7.91	16.45
		✓	×	×	81.56	7.95	15.91
		✓	✓	×	83.24	8.08	16.23
		✓	✓	✓	84.17	8.12	**16.54**
	UCAS-AOD	×	×	×	95.53	7.72	16.47
		✓	×	×	96.64	7.75	16.55
		✓	✓	×	97.25	7.78	16.63
		✓	✓	✓	98.44	7.93	**16.65**

TABLE III. PERFORMANCE GAIN STRATIFIED BY TARGET ASPECT RATIO ON DIOR-R

Aspect Ratio Group	Target Examples	Baseline $mAP_{0.5}$(%)	YOLO-RSL $mAP_{0.5}$(%)	Gain
AR < 2	Vehicle, Dam	86.5	88.3	+1.8
2 ≤ AR < 4	Bridge, Harbor	83.3	86.7	+3.4
4 ≤ AR < 6	Ship, Airplane	79.5	84.2	+4.7
AR ≥ 6	Aircraft	74.7	82.1	**+7.4**

To verify the directional perception of YOLO-RSL, we group according to the target aspect ratio (AR) to analyze the performance of $mAP_{0.5}$ on the DIOR-R dataset (Table III). Four groups are defined: AR < 2 (near-isotropic targets), 2 ⩽ AR < 4 (moderately elongated targets), 4 ⩽ AR < 6 (elongated targets), and AR ≥ 6 (highly elongated targets).

The performance of YOLO-RSL in each group is better than that of the baseline model, but the increase is not uniform. It is worth mentioning that the performance improvement gradually increases with the increase of the target aspect ratio. For targets whose aspect ratio is less than 2, the performance improvement is limited. The visual appearance of such targets does not change much with rotation. In this case, the direction-sensitive channel weighting of RO-iAFF is also limited. With the increase in aspect ratio, the performance improvement continues to increase and peaks in the AR 6 group. The appearance of the clearer target of the spindle changes more at the rotation angle, and the advantage of RO-iAFF integrating direction information into channel attention calculation is becoming more and more obvious.

D. Comparison with State-of-the-Art Methods

To evaluate how the proposed method compares against existing work, extensive experiments were carried out on the DIOR dataset. The comparison covers a variety of detector architectures. On the two-stage side, Faster R-CNN [2] and Mask R-CNN [21] are included. On the one-stage side, the comparison includes RetinaNet [22], YOLOv8 [23], YOLOv10 [24], and YOLOv11 [16]. Several specialized models are also included, namely CANet [25], CE-FPN [26], SCRDet [4], and YOLOP [27]. The full results are reported in Table IV.

TABLE IV. COMPARISON OF STATE-OF-THE-ART MODELS ON THE DIOR DATASET

Model	airplane	ship	bridge	dam	vehicle	harbor	airport	chimney	$mAP_{0.5}$	Param	GFLOPs
Faster-RCNN	88.1	77.3	81.2	72.3	84.5	75.4	79.5	74.7	79.4	82.4	33.1
Mask-RCNN	88.3	78.1	81.4	70.9	85.0	75.7	80.0	75.3	79.7	80.5	28.6
RetinaNet	82.4	82.7	81.9	82.0	81.8	82.7	83.1	81.6	82.5	7.0	15.8
YOLOv5	87.8	76.9	80.6	71.5	83.1	74.1	78.3	73.5	78.5	7.1	17.4
YOLOv8s	89.4	78.4	82.3	73.6	85.3	76.3	80.6	75.8	80.2	6.98	13.7
YOLOv10	89.2	79.2	82.3	74.3	86.2	77.0	81.0	76.4	80.9	16.2	16.8
YOLOP	87.1	75.3	79.1	70.8	82.4	73.3	79.5	72.6	77.3	18.9	19.7
YOLOv11s -OBB	90.3	79.5	83.3	74.7	86.5	77.9	81.9	77.2	81.02	7.91	16.45
CANet	91.2	81.2	84.4	76.2	87.1	79.0	83.3	78.0	82.9	37.1	12.3
CE-FPN	91.0	81.3	83.7	75.4	84.4	82.3	82.0	77.5	81.5	34.8	15.5
SCRDet	91.7	81.7	85.1	76.6	88.2	79.4	83.4	79.1	83.7	30.3	14.7
Ours	92.0	82.5	82.9	83.2	81.1	86.3	84.3	85.9	**84.17**	**8.12**	**16.5**

As demonstrated in Table IV, our model exhibits superior performance across the majority of object categories in the DIOR dataset. Specifically, the proposed method achieves the highest AP across the categories in the DIOR dataset. Furthermore, the model attains a robust mAP0.5 of 84.17%, surpassing both traditional models and recent variants of YOLO. Notably, while maintaining competitive GFLOPs at 16.5 and a relatively lightweight parameter size of 8.12 million, our model outperforms heavier architectures like Faster R-CNN and Mask R-CNN, which achieve mAP0.5 scores of 79.4% and 79.7%, respectively, as well as specialized models like SCRDet and CANet. These findings underscore the efficacy and efficiency of the proposed method in large-scale RSOD tasks.

To rigorously evaluate the performance of the proposed model in the target detection task, we perform a comparison with several state-of-the-art models on the UCAS-AOD dataset, as summarized in Table IV. Compared with Faster R-CNN, NAS-FPN [28], RT-DETR [29], Zhang et al. [30], Li et al. [31], S²Anet [32], ARS-DETR [33], Oriented-Former [9], and SASM [34], our model achieves better accuracy and efficiency.

On UCAS-AOD (Table V), our method achieves an impressive mAP0.5 of 98.44%, surpassing all other models in this category. This indicates that our model achieves higher detection accuracy while also maintaining an effective precision-recall balance. Furthermore, the model's mAP0.5:0.95 score of 74.19% demonstrates its consistent performance across a range of intersection-over-union thresholds, further highlighting its robustness. The proposed model operates with a relatively low parameter count of 7.93M and a GFLOP value of 16.65. While the parameter count is slightly higher than some of the other models, its superior detection performance, as evidenced by the mAP scores, justifies this trade-off. Overall, this result demonstrates that explicit orientation-aware feature fusion at the neck level is more parameter-efficient than relying on Transformer-based global attention for orientation modeling. Show more8:07 PM Claude responded: The strong performance on UCAS-AOD is consistent with the aspect-ratio analysis reported earlier. Aircraft dominate this dataset, with aspect ratios reaching up to 8:1. These are exactly the targets for which orientation-aware channel weighting delivers the largest gains.

TABLE V. COMPARISON OF STATE-OF-THE-ART MODELS ON THE UCAS-AOD DATASET

Model	$mAP_{0.5}$	$mAP_{0.5:0.95}$	Params(M)	GFLOPs
Faster-RCNN	89.43	72.47	38.43	11.3
NAS-FPN	90.64	73.93	34.20	9.49
RT-DETR	90.85	71.25	31.27	16.1
Zhang et al.	91.46	72.79	28.73	7.2
Li et al.	92.86	73.73	24.56	7.3
S^2Anet	89.87	72.55	49.14	15.6
SASM	86.54	69.63	41.58	15.8
Oriented RepPoints	85.72	68.16	36.67	20.4
Gliding Vertex	91.65	73.23	41.32	15.56
ARS-DETR	90.13	72.13	61.60	15.84
Oriented-Former	92.25	72.98	58.47	16.38
YOLOv11s-OBB	95.53	73.57	7.72	16.47
Ours	**98.44**	**74.19**	**7.93**	**16.65**

E. Visualization

To evaluate the performance of YOLO-RSL, representative samples were selected from both DIOR and UCAS-AOD for visual inspection and quantitative testing. Fig. 8 compares detection results of YOLOv11s-OBB and our method on DIOR-R. The orientation-agnostic baseline frequently misses densely arranged targets at non-canonical orientations and generates false positives in cluttered backgrounds with repeated texture patterns. YOLO-RSL can accurately identify and locate small targets (aircraft and vehicles less than 30 × 30 pixels). YOLO-RSL extracts the local characteristics of small objects through its improved feature enhancement module, thus improving the detection accuracy. In scenarios involving large

objects, the recognition accuracy of the baseline algorithm is also low. The most significant differences are in the ship and aircraft categories, which have the highest aspect ratio. These remarkable results are due to the improvement of the YOLO-RSL feature fusion path and backbone network.

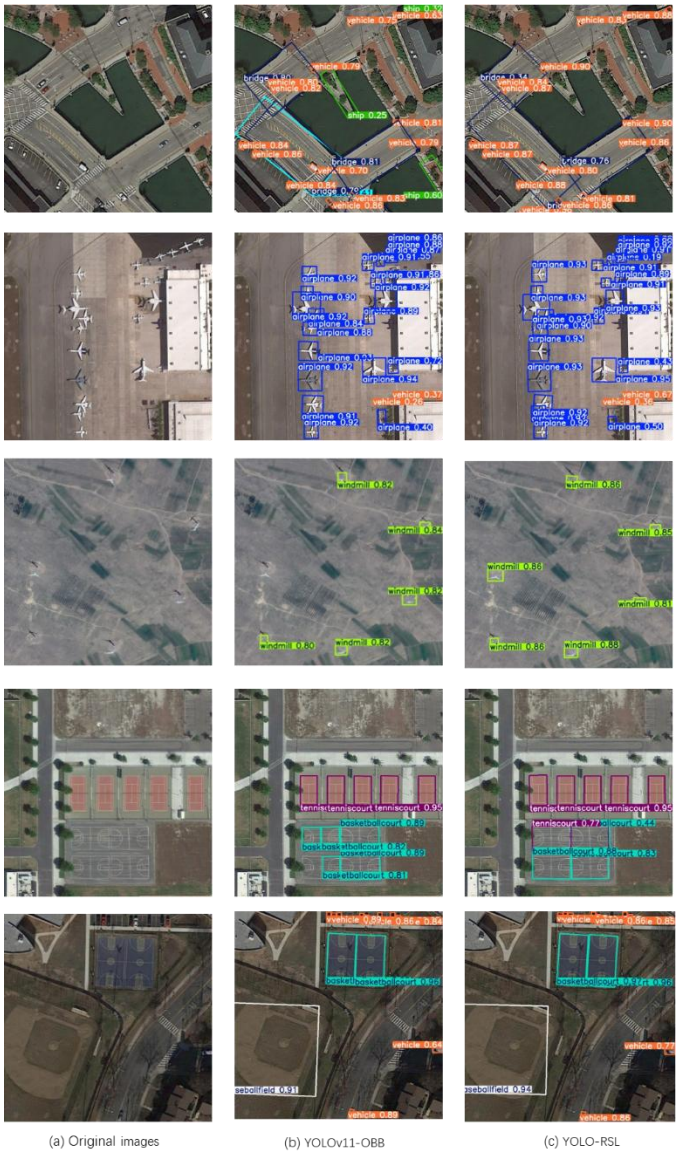

Fig. 8. Comparison of detection results on the DIOR dataset.

Fig. 9 shows the test results of YOLO-RSL on the UCAS-AOD dataset. Our method shows high accuracy in target detection, especially in aircraft detection, and the mAP value of the model is relatively high. The mAP0.5 value of automobile detection is slightly lower than that of aircraft detection, but the overall score is still very high. This result shows that the model maintains good robustness for different types of objects. In high-density scenarios such as airport aprons, the direction-sensitive channel weighting mechanism of RO-iAFF can also be handled well. However, the confidence score of some test results is lower. These low-trust situations are concentrated in two specific scenarios: the target is blocked, and the imaging platform is different from the perspective of the training data. At this time, the shape and proportion of the target may be very different from the content recognized by the model, resulting in a decrease in detection confidence. The feature extraction component designed to be more stable under changes in viewing angle and occlusion is a far-reaching research direction in the future.

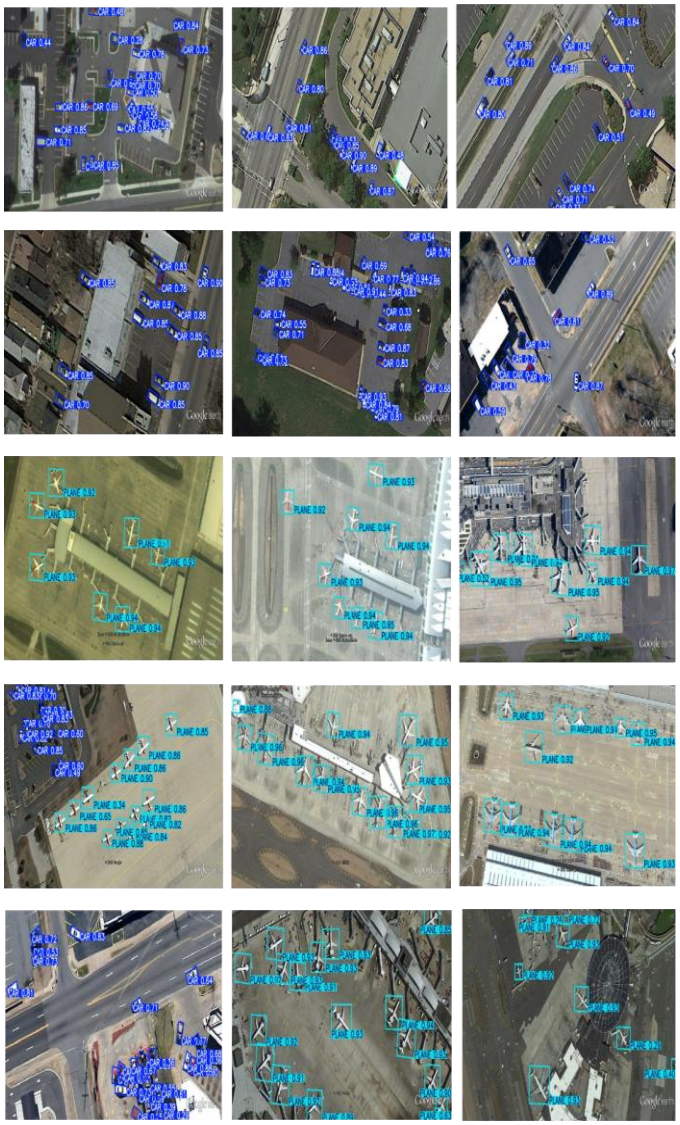

Fig. 9. The visualization of detection on the UCAS-AOD dataset.

V. Conclusion

This study presents YOLO-RSL, a unified framework that operates across three synergistic levels: backbone representation, neck-level feature fusion, and bounding-box regression supervision. First, the novel RO-iAFF module injects rotation-angle embeddings into the dual-stage iterative attention fusion, making cross-scale channel weighting explicitly orientation-aware; this represents the first known integration of rotation prior into the multi-scale feature fusion stage of a YOLO-series detector. Second, Swin Transformer blocks embedded in the YOLOv11s-OBB backbone enrich global feature representation while preserving inference speed. Third, the LFFE loss jointly constrains four geometric

attributes of predicted OBBs, yielding more stable and complete regression supervision. Experimental results on DIOR-R and UCAS-AOD validate the effectiveness of each component and demonstrate that YOLO-RSL achieves state-of-the-art accuracy with fewer parameters than transformer-heavy competitors. Future work will focus on extending orientation awareness to the backbone stage, incorporating multi-modal optical and SAR fusion, and applying knowledge distillation for edge-device deployment.

***Abstract*—Generative artificial intelligence (Gen AI) and large language models (LLMs) offer substantial potential to improve how organisations capture, organise, retrieve and reuse knowledge. Existing knowledge management (KM) frameworks, however, seldom integrate Gen AI/LLM-specific processes, data governance, and ethical requirements in highly regulated public-sector settings, and few have been empirically evaluated. This study assesses the feasibility of adopting GenAI and LLMs for organisational KM and develops a corresponding Knowledge Management and Artificial Intelligence (KMAI) framework for a national communications regulator. Guided by Diffusion of Innovation (DOI) theory, the study employed a multi-method qualitative design comprising a literature review, semi-structured interviews with six KM representatives, a focus group discussion involving fourteen participants using the LEIQ™ model for SWOT analysis, and a content-validity evaluation by three experts. Interview data were analysed thematically, SWOT findings were transformed into strategies through TOWS analysis, and framework relevance was assessed using item- and scale-level content validity indices. The findings indicate that adoption is feasible in this setting: participants perceived clear relative advantage, compatibility, trialability and observability, while complexity was manageable when supported by adequate skills, data classification, secure infrastructure and governance. The principal risks concerned data quality, privacy, security, misinformation, over-reliance on AI, and organisational resistance. The proposed KMAI framework achieved acceptable content validity across all clusters, with S-CVI/Ave values ranging from 0.89 to 1.00, and was refined into four strategic thrusts: People, Process, Technology and Data. Because the evidence derives from one organisation and a three-member expert panel, the framework is presented as an empirically grounded and internally validated proposition whose extension to other agencies is analytic rather than statistical; the boundary conditions governing such extension are stated explicitly, and confirmatory validation with a larger expert panel and independent organisational sites is identified as the necessary next step. The study extends DOI-based adoption analysis by showing that data governance and ethics condition Gen AI/LLM adoption in organisational KM and provides a practical, staged framework for regulated public-sector organisations.**

I. Introduction

The rapid advancement of artificial intelligence (AI) technologies, particularly generative artificial intelligence (Gen AI) and large language models (LLMs), has in recent years opened a new range of opportunities for knowledge management (KM) practices across a wide variety of domains. Organisations are producing and accumulating large volumes of structured and unstructured data, and the ability to convert that data into accessible, reliable and actionable knowledge has become a decisive factor in organisational performance. As a national regulatory agency, the organisation holds substantial knowledge assets across its departments and divisions and recognises the strategic value of demonstrating how Gen AI and LLMs can accelerate its KM practices.

Three gaps motivate the present study. First, although KM frameworks exist, few consider Gen AI/LLM-specific processes and governance in an integrated manner. Second, many proposed frameworks are advanced without rigorous empirical validation. Third, there is no validated KM framework for a national communications regulator, where data governance and ethical obligations are especially stringent. This problem is compounded because Gen AI and LLMs are often used interchangeably but are different in meaning and overlapping in practice [1]: Gen AI is a generic term for any AI system whose primary function is to generate content, whereas LLMs such as GPT-4, PaLM, and Claude generate representations of language using very large numbers of parameters [2]. Both raise complex questions about data synthesis, system learning and effective knowledge extraction, because model performance depends directly on the currency and quality of the underlying data. The main objective of this study is therefore to address these gaps by verifying the feasibility of the organisation's adoption of Gen AI and LLM capabilities in KM and by developing and validating a framework for that purpose.

The research aims to achieve the following five objectives: to analyse the current state of KM practices through a literature review with a focus on the application and integration of Gen

* Corresponding author

AI and LLM capabilities (RO1); to assess the feasibility of present or future adoption of Gen AI and LLMs in the organisation's KM processes and procedures (RO2); to conduct a SWOT analysis of the possible effect on the organisation in terms of optimisation, efficiency and accuracy (RO3); to assess the suitability of a KM framework for the measurement and monitoring of improvements in data synthesis, organisation and knowledge extraction (RO4); and, where appropriate, to recommend the requirements for Gen AI and LLM adoption in the organisation (RO5). The study is based on the Diffusion of Innovations theory (DOI) [3], which serves as the framework for the interview constructs that measure adoption, and on the Kansei-based LEIQ™ model [4], which is used to analyse the SWOT factors and the implicit barriers to adoption, as elaborated in the methodology.

This study builds on prior literature concerning the organisational context, the intersection of KM and AI, the nature of Gen AI and LLMs, the data foundations of AI-driven KM, and the governance and security considerations reviewed in Section II. The study has two-fold significance. It conceptually extends DOI theory for Gen AI/LLM adoption to KM in a national regulatory setting, positioning data governance and ethics as adoption moderators, and it links DOI theory with the practice of AI-enabled KM in a domain that has received little empirical attention. It gives the organisation a validated Knowledge Management and Artificial Intelligence (KMAI) framework, four strategic thrusts, and a replicable multi-method design combining DOI-framed interviews, a Kansei-based SWOT/TOWS analysis and content-validity-based expert evaluation that can be operationalised. Consistent with the qualitative, single-site design, these contributions are advanced as analytically transferable propositions rather than as findings generalisable to a population of agencies; Section V-F sets out the boundary conditions under which transfer is defensible.

II. Literature Review

This section reviews the organisational context, the intersection of KM and AI, the nature of Gen AI and LLMs, the data foundations of AI-driven KM, governance and security considerations, and the theoretical lens adopted. It concludes by positioning the proposed framework against existing KM/AI approaches and stating explicitly what the present contribution adds.

A. The Case Organisation

The organisation is the national regulatory authority for the communications and multimedia industry in Malaysia. It was established under the Malaysian Communications and Multimedia Commission Act 1998 [5] and exercises regulatory powers under the Communications and Multimedia Act 1998 [46], which together assign it responsibility for the economic, technical, consumer and social regulation of the converging communications and multimedia industries, including telecommunications, broadcasting, online activity, postal services and digital certification. Its organisational structure, divisional responsibilities, knowledge assets and annual programme of work are documented in its publicly available annual reports [47]. The organisation runs a knowledge management and resource centre and knowledge-sharing platforms and works with universities and industry partners. It acknowledges the need to show how Gen AI and LLM technologies can improve its KM practices and views appropriate technological support as central to that improvement. Contextual statements about the organisation in this study are drawn from these publicly accessible statutory and reporting sources so that readers may verify them independently.

B. Artificial Intelligence and Knowledge Management

As knowledge is an essential component of organisational success, organisations need to adapt their KM practices to leverage Gen AI effectively. Traditional KM systems provide functions such as reviewing inputs or tracing their sources. Gen AI, however, often operates as a "black box" with reasoning that is hard to interpret, which results in a higher reliance on algorithmic trust [6], [7]. AI nevertheless remains crucial to KM because it helps in storing and retrieving explicit information. The combination of deep learning and big data provides new ways of collecting, classifying, organising and retrieving information [8], converting large data sets into useful insights [9]. It is, therefore, essential to explore the long-term effect of GenAI on organisational KM, possibly through small-scale pilots, to align capabilities with organisational needs while ensuring transparency and authenticity [10], [11].

C. Large Language Models and Generative AI

The convergence of Gen AI and LLMs has transformed KM practice, offering new opportunities in information processing, synthesis and dissemination [11], [12], [13]. Personalised experiences and automated content generation are possible with LLMs, a type of GenAI [14]. These models employ natural language processing (NLP) to extract insights, summarise content and generate contextual responses, thereby enabling more efficient knowledge discovery [15], [16]. They detect trends and generate predictive analytics that support better decision-making, and they foster innovation by analysing complex data sets. They also enable collaborative knowledge sharing through chatbots, virtual assistants, and collaborative writing platforms.

D. AI-Driven Knowledge Management and Data

AI-driven KM depends heavily on data availability and quality [17], [18], [19]. One established hybrid model holds that knowledge resides in AI models and databases as well as in individuals and that the design of AI-orientated KM should balance user satisfaction against the quality of task outcomes [20]. As depicted in Fig. 1, the shift from conventional KM to an adaptive, AI-based approach requires frequent data updates to maintain model relevance and a clear demarcation of roles between humans and machines.

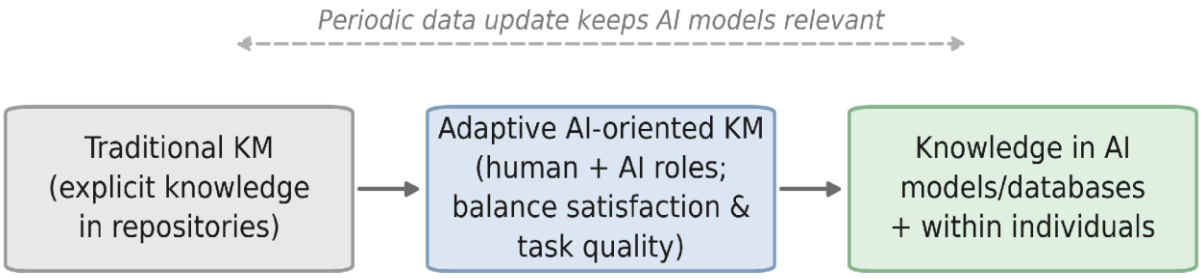

Fig. 1. Moving from traditional KM towards an adaptive AI-oriented KM [20].

E. Data Governance, Security and Ethical Considerations

Gen AI also poses ethical and governance challenges that require proactive management, such as ensuring accuracy, human oversight, transparency, accountability and bias mitigation [21, 22], as well as concerns about misinformation, copyright infringement, privacy and hazardous content. Data governance is key to trustworthy AI: it makes data accurate, secure, well classified and properly shared. In the Malaysian public-sector context, an AI-integrated KM framework combining organisational knowledge repositories, structured training and continuous learning has been shown to strengthen cybersecurity awareness and institutional resilience [23]. Without such governance, the organisation's exposure to security and compliance risks and the reliability of AI-generated outputs are significant obstacles to adoption.

F. Theory of Diffusion of Innovation

DOI in this context enables organisations to develop strategies tailored to different adopter segments and to overcome barriers to Gen AI adoption. DOI has been widely applied to study technology acceptance in the health, education, energy and library domains [10], [22], [24], including studies of blended and mobile learning adoption in Malaysian institutions [54], showing the explanatory value of the five innovation attributes. In summary, Gen AI and LLMs are powerful tools for reinventing KM, but to realise their benefits, ethical issues must be addressed, transparency must be promoted, and equitable access must be assured.

G. Comparative Positioning and Statement of Novelty

Reviewers of AI-enabled KM research reasonably ask what a new framework adds beyond recombining established constructs. Table I therefore compares representative KM/AI approaches against the dimensions required for feasible Gen AI and LLM adoption in a public-sector KM context. Traditional KM systems and DeLone–McLean-style success models cover GenAI-specific processes sparsely and treat governance implicitly. Integrative KM–AI frameworks such as [20] advance the technology and data dimensions but were not empirically validated in a regulatory setting. DOI-based adoption studies explain acceptance without providing an operational framework.

Beyond this coverage comparison, the proposed KMAI framework differs from existing AI-enabled KM frameworks in four specific and testable respects.

First, the innovation attributes are used diagnostically rather than descriptively. In the reviewed DOI-based studies, the five attributes are applied after the fact to explain observed acceptance. Here they are operationalised as readiness constructs that are elicited before design, quantified by frequency of mention (Fig. 5), and carried forward into the framework clusters, so that the framework tells an organisation which adoption attribute is deficient and which cluster addresses it. The framework is consequently diagnostic and prescriptive, not merely descriptive.

Second, data governance and ethics are positioned as a moderating condition rather than as a further component. Existing KM/AI frameworks list governance as one element alongside people, process and technology. The evidence reported in Section IV indicates instead that the relationship between the perceived attributes and adoption is conditional on governance maturity: favourable perceptions on all five attributes did not translate into a positive adoption judgment independently of data classification, security of infrastructure and ethical control. This moderating position is made explicit in the research model (Fig. 9) and is, to the authors' knowledge, not represented in the frameworks compared in Table I.

Third, the framework couples an affect-based instrument to the strategic synthesis. The LEIQ™/Kansei instrument elicits the implicit, emotionally weighted barriers — resistance, perceived displacement, and loss of critical judgment — that conventional SWOT elicitation does not surface and scores them on emotion and importance axes before they enter the TOWS synthesis. This makes the resulting strategies responsive to affective as well as rational barriers to adoption.

Fourth, the framework carries a documented validation audit trail. It is the only approach in Table I whose clusters and subclusters were submitted to item- and scale-level content-validity indexing by external experts and then revised in response to that evidence so that the movement from proposed framework (Fig. 7) to validated framework (Fig. 8) is transparent and inspectable. The strength of that audit trail is bounded by the size of the expert panel, and Sections III-E and V-G state that bound explicitly.

TABLE I. COMPARATIVE POSITIONING OF KM/AI APPROACHES

Approach / Study	People	Process	Technology	Data & Governance	Gen AI / LLM specific	Attributes used diagnostically	Empirically validated
Traditional KM systems	Partial	Partial	No	Partial	No	No	N/A
IS Success (DeLone–McLean) style	No	Partial	Partial	No	No	No	Yes
DOI-based adoption studies [10], [12]	Partial	No	Partial	No	Partial	No (post hoc)	Yes
Integrative KM–AI framework [20]	Partial	Yes	Yes	Partial	Yes	No	No
KMAI framework (proposed)	Yes	Yes	Yes	Yes	Yes	Yes	Yes (single site, n = 3 experts)

Note: "Empirically validated" refers to validation reported in the cited source. For the proposed framework, the validation is internal to one organisation and rests on a three-member expert panel; see Sections III-E and V-G.

III. METHODOLOGY

A. Research Design

The research focuses on two segments in the Organisation: 1) targeted departments and divisions with sufficient data repositories that could benefit from Gen AI and LLM-aided query, process management and decision-making; and 2) Gen AI and LLM subject-matter experts from academia, industry or specialist data-management providers. The study employed a qualitative, single-organisation design consisting of five phases, illustrated in Fig. 2 and summarised in Table II. The design is a single-case study in the sense of [51]: the unit of analysis is the organisation, and the analytic aim is theoretical rather than statistical extension.

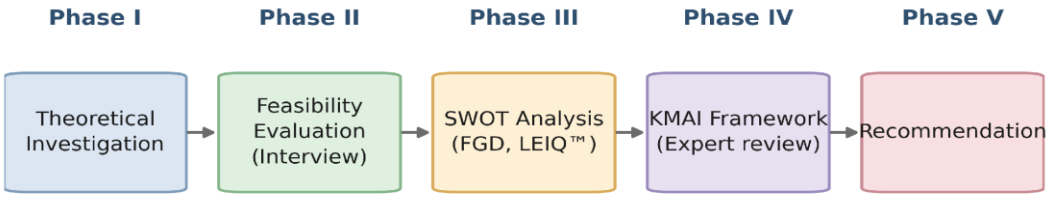

Fig. 2. The research phases.

TABLE II. SUMMARY OF THE RESEARCH DESIGN

Phase	Research objective	Method	Data source
I	Analyse the current state of KM practices via a literature review focusing on Gen AI and LLM capabilities.	Theoretical investigation	Past literature and existing related organisational documents
II	Evaluate the feasibility of current or future adoption of Gen AI and LLMs in the Organisation's KM processes and procedures.	Semi-structured interviews based on DOI theory	Six representatives from the KM department/division (executive to top management)
III	Conduct a SWOT analysis of the potential organisational impact (optimisation, efficiency, accuracy)	FGD using the LEIQ™ framework	Fourteen representatives from targeted departments and divisions involved in KM initiatives
IV	Evaluate the suitability of a KM framework to measure improvements in data synthesis, organisation and knowledge extraction.	Expert review and content-validity indexing	Three experts from academia, industry or data-management specialisation
V	Where appropriate, recommend the requirements needed for adoption in the Organisation.	Synthesis of Phases I–IV	N/A

B. Research Instrument

The research instrument comprised a literature review, semi-structured interviews grounded in DOI theory, FGDs using the LEIQ™ framework, and an expert-review checklist. The interview protocol translated the five DOI attributes into open-ended questions, and the FGD protocol elicited SWOT factors, which were then scored on the LEIQ™ emotion–importance axes.

The research is based on Diffusion of Innovation theory (DOI) [3]. The theory, proposed by Everett Rogers, describes how new ideas and technologies are adopted by social systems through four elements (the innovation, communication channels, time, and the social system) and five sequential stages (knowledge, persuasion, decision, implementation, and confirmation). DOI classifies adopters as innovators, early adopters, early majority, late majority and laggards. The theory identifies five attributes of an innovation that influence its rate of adoption: relative advantage, complexity, trialability,

observability and compatibility [25]. These attributes form the semi-structured interview constructs used in this study. Fig. 3 presents the theoretical framework of DOI.

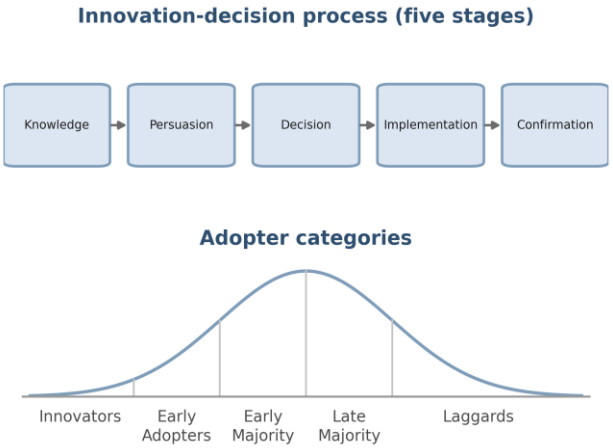

Fig. 3. Diffusion of innovation (DOI) theory [3].

A SWOT analysis was performed through FGD with the LEIQ™ model [4] to identify the potential organisational impact. LEIQ™ (Lokman's Emotion and Importance Quadrant) is based on Kansei Engineering, which investigates the implicit experience (emotion) of people and its effect on decision-making, productivity, and well-being. It categorises factors on emotion-versus-importance axes into four quadrants (positive/negative experience versus important/not important), as shown in Fig. 4. This model has been used in previous studies such as a TVET digital-learning emotion assessment tool [26] and B40 socio-economic happiness modelling [27]. The feasibility of affect-elicitation instruments across cultural settings has been examined in Kansei measurement research [52], and the Kansei approach has been applied to enrich targeted emotional responses in interface design [53]. Here, the model enables analysis of the SWOT factors and of the implicit barriers that affect adoption.

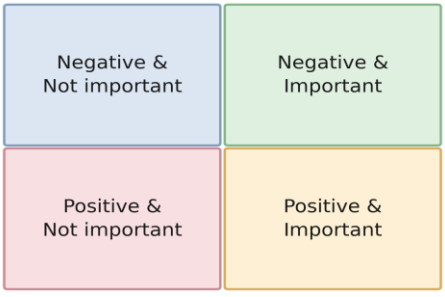

Fig. 4. The LEIQ™ model [4].

C. Sampling

Purposive sampling was used. Six KM-department representatives, from executive to top-management levels, were selected for the interviews following the guidelines on adequate interview sample sizes in organisational research [28]. Fourteen of the twenty targeted respondents took part in the FGD, and three data-management experts were engaged for the review. As qualitative saturation guidance indicates, these numbers are sufficient for thematic analysis [29]. Table III shows the anonymised profiles of the six interview participants (participants are labelled P1–P6 to maintain confidentiality).

TABLE III. PROFILE OF INTERVIEW PARTICIPANTS (ANONYMISED)

Code	Role/management level	Function/division	Experience
P1	Top management	Knowledge management	> 15 years
P2	Top management	Strategy and planning	> 15 years
P3	Senior management	Information and data management	10–15 years
P4	Middle management	Digital / ICT services	10–15 years
P5	Executive	Records and resource centre	5–10 years
P6	Executive	Corporate / operations	5–10 years

D. Gathering Data

Data collection included audio-recorded and transcribed interviews, documented FGD sessions with facilitated scoring, and structured expert feedback aligned with the DOI attributes and the proposed framework components [23], [24]. The sessions were conducted with prior organisational approval, and participant entries were recorded verbatim, including responses expressed in Malay.

E. Data Analysis

Interview transcripts were analysed thematically following the six-phase approach of Braun and Clarke [30]: familiarisation, initial coding against the five DOI attributes, theme development, review, definition and reporting. Codes were defined as complete idea statements, and factors were quantified by frequency of mention in order to visualise their relative prominence (Fig. 5). Data collection continued until no new themes arose, indicating thematic saturation [28], [29]. FGD data were synthesised within a SWOT framework and expanded through a TOWS matrix.

Content validity was assessed using the Content Validity Index (CVI) [31], [32], and [33] obtained from expert reviewers. Each expert rated the relevance of each framework subcluster. The item-level index (I-CVI) was calculated as the proportion of experts who rated an item as relevant, and the scale-level index (S-CVI/Ave) was calculated as the mean I-CVI per cluster. An acceptability threshold of 0.78 was adopted, in line with established guidance for expert panels [31], [32]. Expert comments were open-ended and were analysed thematically to inform qualitative refinement of the framework.

Two considerations govern the interpretation of these indices. First, the panel comprised three experts. Lynn [31] specifies a minimum of three and a maximum of ten content experts and requires, for panels of three to five raters, that all raters agree before an item is accepted as content valid; the relaxed 0.78 criterion applies from six raters upwards [32]. The panel therefore satisfies the minimum recommended size, and the study reports both indices so that readers may apply either criterion: under the stricter three-rater standard, the three subclusters returning I-CVI = 0.67 fall below the required

unanimity and were accordingly revised rather than retained unchanged. Second, indices computed from a panel of this size carry wider estimation uncertainty than those derived from larger panels, and are reported here as an initial and indicative content-validity assessment rather than as a confirmatory psychometric result. Confirmatory validation with a panel of at least six and preferably eight to ten raters, permitting the computation of a modified kappa adjusted for chance agreement, is identified as necessary future work in Sections V-G and VI-D.

F. Trustworthiness and Coding Reliability

Two researchers coded the transcripts independently, compared their codes for consistency, and reconciled discrepancies through discussion until full agreement was reached. No inter-rater reliability coefficient, such as Cohen's kappa or Krippendorff's alpha, is reported for this process, and the reason is a design decision rather than an omission. The study follows the reflexive variant of thematic analysis, in which coding is treated as an interpretative act that necessarily bears the mark of the analyst; on that premise, agreement between coders demonstrates that two analysts have been trained to code alike rather than that either coding is accurate, and the originators of the approach argue that reliability coefficients rest on realist assumptions that the method does not share [48]. Consensus coding with documented reconciliation was therefore adopted as the appropriate quality procedure, supported by an audit trail of coding decisions, the retention of verbatim transcripts, the quantification of code frequencies reported in Fig. 5, and member-checking of the SWOT factors during the FGD.

This position is stated so that readers who prefer a coding-reliability paradigm can judge the evidence on their own terms. The consequence is explicit: the consistency of the thematic coding in this study is established procedurally and is open to inspection, but it is not expressed as a numerical coefficient, and readers who require such a coefficient should treat the thematic findings as unverified in that specific respect. A replication designed within a coding-reliability paradigm should pre-specify a codebook, employ independent coders who do not reconcile, and report kappa or alpha accordingly; this is recorded as a limitation in Section V-G and as a validation priority in Section VI-D.

IV. Findings

This section reports the findings for each research objective.

A. RO1: Current State of KM Practices

The literature review reveals that existing KM methodologies increasingly integrate Gen AI and LLMs for improved data management and decision-making. Advances in Gen AI and LLMs have transformed NLP, allowing better data management and information retrieval [34, 35]. Standardised human-evaluation methodologies such as the QUEST framework are increasingly important to ensure the reliability and safety of content produced by AI [36]. Implementation strategies address data scarcity through fine-tuning and retrieval-augmented generation (RAG) [37]. Major mechanisms include knowledge extraction using NLP [38], automation of routine knowledge tasks [39], and data-driven insight generation from large datasets [35]. Persistent challenges include data quality, ethical issues and the need for human supervision. Table IV summarises best practices in selected countries.

For the organisation, these international practices suggest that value is not realised from technology alone but through its alignment with organisational processes and governance. Data must be well classified and access-controlled, and outputs must be validated by domain experts, for AI-powered knowledge bases and assistants to accelerate retrieval and document processing. The state of current practice thus points to a socio-technical adoption path in which people, process, and data readiness develop in tandem with technology.

TABLE IV. Best Practices of the New Generation of KM Practices

Country	Ref.	Best practice	Benefits/advantages
China	[40]	AI in human resource management	Streamlines recruitment, evaluation, and development, and enables efficient data processing for workforce insights
Singapore	[41]	AI-driven chatbots and virtual assistants	Enhances citizen engagement; real-time responses and reduced wait times
Germany	[42]	AI in manufacturing and production	Predictive maintenance, quality control and process optimisation; reduced downtime
United States	[43]	AI-powered internal knowledge bases	Facilitates retrieval and automates document processing for decisions
Japan	[44]	AI in customer service	AI chatbots handle inquiries efficiently, improving responsiveness

B. RO2: Feasibility Assessment (Interviews)

Thematic analysis of the semi-structured interviews was contextualised within DOI. The most frequently cited factor was complexity/ease of use (519 mentions), followed by trialability (281), observability (232), relative advantage (115) and compatibility (62). Fig. 5 presents the Sankey diagram of these factors and their sub-themes. Each factor is discussed below in terms of the DOI attributes [25]. Frequencies denote prominence in the corpus and are not offered as measures of effect size.

1) Relative advantage: Respondents perceived clear benefits in adoption. One participant observed that while Gen AI could replace some tasks, it would also create new roles and opportunities. Others reported that AI could reduce costs and help people retrain. Participants associated adoption with enhanced productivity, efficiency, and accessibility, and with more accurate and insight-rich outputs, given robust data foundations.

2) Complexity (usability): Participants with previous experience found the tools easy to use and expected that potential future users would adapt to them readily. They stressed, however, the need for a deep understanding of AI, proper classification of data, and appropriate governance to

ensure accurate results. As one participant observed, the system produces correct output only when the appropriate knowledge has been embedded in it. The integration of data from different sources therefore needs to be undertaken strategically.

3) Trialability: Acceptance relied heavily on trialability. Respondents valued the opportunity to experiment, and several reported using tools such as ChatGPT to brainstorm and draft in their own time. Low cost, flexibility, and the availability of free versions, even where limited, drove trials and subsequent adoption, with human supervision retained to check outputs.

4) Observability: Adoption was driven strongly by observability. Participants reported that they had started using tools on the advice of friends and colleagues and through online reviews and community experience. They warned that concerns about fairness and trust could slow adoption and advised adaptation to the organisational context supported by acculturation that embeds ethical practice.

5) Compatibility: Compatibility with existing work processes was a decisive consideration. Respondents reported that tools such as Copilot and ChatGPT helped structure content and access, allowed rapid data analysis, and fitted well with existing work processes. They noted that the availability of accurate data, secure infrastructure, and integration with other applications increases user satisfaction and supports continued adoption. Overall, the interview findings indicate that the organisation can adopt Gen AI and LLMs in its KM procedures provided that data governance and ethical controls are in place.

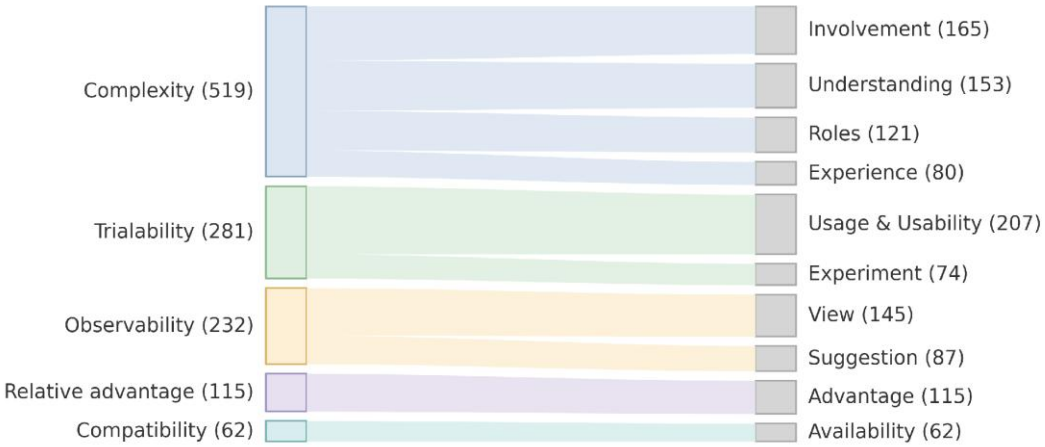

Fig. 5. Sankey diagram of feasibility factors (frequency of mention) and their associated sub-themes.

C. RO3: SWOT Analysis (FGD)

Using the LEIQ™ model, FGD participants identified strengths, weaknesses, opportunities, and threats of Gen AI and LLM adoption, each of which was scored on the emotion–importance axes (Fig. 6).

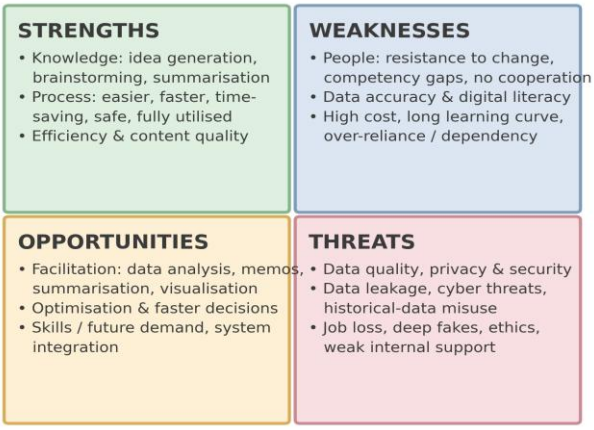

Fig. 6. SWOT analysis of Gen AI and LLM adoption in the organisation's KM practices.

1) Threats (Q1): The highest-scored threats (1.00) related to data quality and to data privacy and security, including data accuracy, incorrect information and citation, data leakage, cyber risks, exposure of internal information, historical-record training, and prompting ethics. Other high-scoring threats were job displacement, deepfakes, and data classification. User-behaviour threats concerned AI's lack of empathy and ethical judgment and user disengagement from critical thinking. Weak internal support for the LLM initiative was also raised.

2) Weaknesses (Q2): The most prominent weaknesses (1.00) were in the people and process clusters: lack of cooperation, resistance to change, changing work practices, competency and idea gaps, individualistic behaviour, inaccurate or incomplete information, lack of data classification, and limited digital proficiency in prompt creation. Technology weaknesses (0.93) included high data requirements and long model training time and cost. Dependency weaknesses (0.53) included over-reliance and reduced independent thinking.

3) Strengths (Q3): The strongest strengths (1.00) were in the knowledge and process clusters: idea generation, brainstorming, expert-like guidance at any time, easier and faster work, time savings, safety, and full utilisation of resources. Ratings for efficiency, quality of content, and positive experiences with technology were high (0.87–0.93).

Participants described AI as a capable assistant and a discussion partner.

4) Opportunities (Q4): Facilitation and optimisation — data analysis, memo and slide drafting, document summarisation, data visualisation, reduced search time and improved decision-making — scored highest (1.00). Other opportunities (0.93) were problem-solving, reducing silos, data sharing and coordination, and progress towards a data-driven organisation. The SWOT was extended through TOWS analysis, the strategic logic and consolidated output of which are presented in Section V-C.

D. RO4: KM Framework Suitability (Expert Evaluation)

Three experts in AI and KM across the public, private, and academic sectors, each with more than ten years of experience, evaluated the proposed KMAI framework using a survey checklist. Table V summarises their profiles. The experts agreed that the framework provides a holistic approach to KM through AI integration, emphasising training, user experience, continuous improvement, a supportive culture and robust infrastructure. They also offered cluster-specific refinements: for the People cluster, separating awareness from knowledge and adding an AI champion as a change agent; for Process, adding accountability, transparency, risk management, scalability and performance; for Technology, reassessing user experience and ensuring AI-ready, scalable tools; and for Data, separating analytics from data management and adding data architecture and taxonomy, classification, governance and protection, aligning organisational integration with a growth mindset. Fig. 7 shows the proposed KMAI framework as submitted for evaluation.

TABLE V. EXPERT INFORMATION

	Expert 1	**Expert 2**	**Expert 3**
Position	Deputy Director	Senior Assistant Director	Chief Assistant / Senior Director
Agency	A public university (academic sector)	A federal digital-government agency (public sector)	A federal regulatory agency (public sector)
Category	Top management	Middle management	Top management

TABLE VI. EXPERT-EVALUATION CONTENT VALIDITY INDEX (CVI) OF THE KMAI FRAMEWORK

Cluster	**Subcluster (item)**	**I-CVI**	**S-CVI/Ave**	**Interpretation**
People	AI knowledge and awareness	1.00		Acceptable
	AI learning and skill enhancement	1.00		Acceptable
	Professional growth	1.00		Acceptable
	Organisational development	0.67		Revised
	Human–AI interaction	1.00	0.93	Acceptable
Process	AI continuous improvement	1.00		Acceptable
	Efficiency and automation	1.00		Acceptable
	Organisational approach	1.00		Acceptable
	Strategic AI adoption and implementation	1.00		Acceptable
	Quality assurance; standardisation and best practices	1.00		Acceptable
	Process management	0.67	0.95	Revised
Technology	Adoption, integration and innovation	1.00		Acceptable
	Customisation and infrastructure	1.00		Acceptable
	Security, UX and KM system	1.00	1.00	Acceptable
Data	Data literacy and skills	1.00		Acceptable
	Data management and AI analytics	1.00		Acceptable
	Data security and access	1.00	1.00	Acceptable
Culture	Continuous learning	1.00		Acceptable
	Organisational integration and development	0.67		Revised
	AI ethics and responsibility	1.00	0.89	Acceptable
Content	Content management	1.00		Acceptable
	Knowledge acquisition	1.00	1.00	Acceptable

Note: I-CVI = item-level content validity index; S-CVI/Ave = scale-level content validity index (average) per cluster; acceptability threshold = 0.78 for panels of six or more raters [32]. Panel of three experts (n = 3); under Lynn's [31] three-to-five-rater criterion, unanimous agreement (I-CVI = 1.00) is required, and the three items returning 0.67 were revised on that basis.

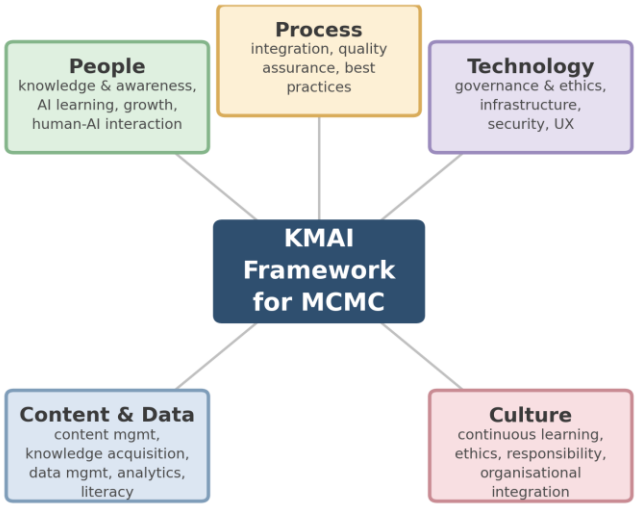

Fig. 7. Proposed KMAI framework submitted for expert evaluation.

Table VI reports the content-validity results. Item-level indices were 1.00 where all three experts agreed and 0.67 where two of three agreed. Scale-level indices (S-CVI/Ave) exceeded the 0.78 threshold for every cluster: People 0.93, Process 0.95, Technology 1.00, Data 1.00, Culture 0.89 and Content 1.00. Three subclusters — organisational development (People), process management (Process) and organisational integration and development (Culture) — returned I-CVI values of 0.67. Under Lynn's three-to-five-rater criterion, these values do not meet the required unanimity, and the corresponding subclusters were therefore revised rather than retained unchanged. The framework was updated accordingly (Fig. 8): awareness was separated from knowledge, and an AI champion was added (People); risk management, scalability, and performance were added (Process); AI integration and user interfaces were added (Technology); and AI analytics was separated from data management, with data architecture and taxonomy, classification, governance, and protection added (Data). These indices are indicative and require confirmation with a larger panel, as set out in Sections III-E and V-G.

E. RO5: The Validated KMAI Framework

The evaluated and revised KMAI framework (Fig. 8) comprises five components. People covers knowledge, awareness, AI learning, professional development, human–AI interaction, and the AI champion role. The process covers AI integration and optimisation, quality assurance, best practices, risk management, scalability and performance. Technology covers AI governance and the ethical framework, infrastructure, security, user experience and user interfaces. Content and Data covers content management, knowledge acquisition, data management, AI analytics, data architecture and taxonomy, classification, governance and protection, security, literacy and access. Culture covers continuous learning, ethical responsibility, organisational integration and a growth mindset. Because the framework is described once here, Section VI does not restate its components and instead sets out how they are to be implemented.

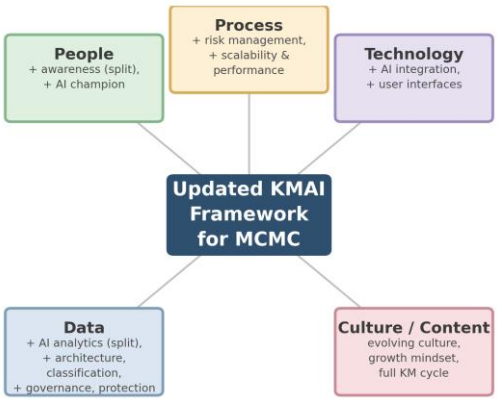

Fig. 8. Updated KMAI framework based on expert recommendations.

V. Analysis and Discussion

This section interprets the findings reported in Section IV in relation to the research objectives and prior literature. It does not restate the framework components, which are given in Section IV-E, nor the TOWS strategy statements, which are consolidated in Table VII; it addresses instead what the evidence means, what it establishes, and what it does not.

A. Interpreting Feasibility Against the DOI Attributes

The interview evidence is positive on all five DOI attributes, but the attributes are not equally weighted, and the distribution is itself informative. Complexity dominated the corpus (519 mentions), yet the substance of those mentions was not that the tools are difficult to operate; participants with prior exposure described them as easy to use. The complexity discussed was organisational rather than interfacial — understanding what the tools do, defining roles, and classifying data so that outputs are accurate. Prominence in the corpus therefore reflects where uncertainty is concentrated, not where resistance is greatest. Trialability (281) and observability (232) were the mechanisms through which that uncertainty was reduced: free or low-cost versions permitted low-risk experimentation, and peer recommendation and visible results converted experimentation into use. Relative advantage (115) and compatibility (62) attracted fewer mentions not because they were unimportant but because they were largely uncontested; participants treated the productivity benefits and the fit with existing work processes as settled.

This pattern qualifies the classical DOI account in one respect relevant to Gen AI. Rogers's formulation treats complexity as a property of the innovation that retards adoption. In this setting, complexity was relocated to the organisation: the innovation was simple to use and difficult to govern. The implication for practice is that adoption efforts should be directed at data classification, role definition and competence rather than at usability, and this is reflected in the weighting of the People, Process and Data clusters of the framework.

B. Data Governance and Ethics as a Moderating Condition

The most consequential finding is that positive perceptions of all five attributes did not, on their own, yield an unqualified adoption judgment. Across the interviews and the FGD, participants attached a condition to their support: outputs must

be accurate, data must be classified, infrastructure must be secure, and use must be ethically bounded. The FGD reinforced this, with the highest-scored threats (1.00) concentrated in data quality and data privacy and security. Governance therefore does not act as a further antecedent alongside the five attributes; it acts on the relationship between those attributes and adoption. Where governance maturity is low, favourable perceptions of relative advantage and trialability produce uncontrolled experimentation rather than institutional adoption — a pattern visible in the reported individual use of public tools outside organisational channels. Fig. 9 states this moderating relationship as the study's research model [3], [23].

This positioning is the study's principal theoretical claim and also its most testable one. It is derived from qualitative evidence in one organisation and is advanced as a proposition for confirmatory testing, not as an estimated effect. A quantitative test — measuring governance maturity and the five attributes across multiple agencies and testing the interaction — is the natural successor study and is identified as such in Section VI-D.

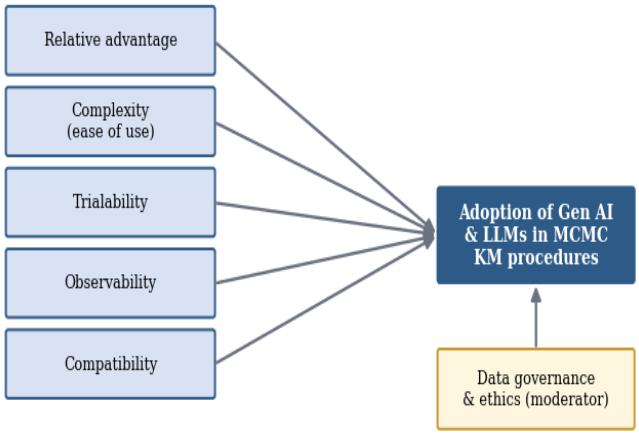

Fig. 9. Research model: DOI attributes and adoption, moderated by data governance and ethics [3], [23].

C. Strategic Logic of the TOWS Synthesis

Weihrich's TOWS matrix was used to convert the SWOT factors into strategies by matching internal strengths and weaknesses with external opportunities and threats. The consolidated strategies are presented in Table VII and summarised in Fig. 10 and are not repeated in prose here; what follows is the logic that generated them and the priority ordering it implies.

Two features of the SWOT distribution shaped the synthesis. First, the strengths were concentrated in the knowledge and process clusters — idea generation, drafting, summarisation, speed — which are capabilities the technology supplies directly and which require little organisational change to realise. Second, the weaknesses and threats were concentrated in the people and data clusters — resistance, competency gaps, classification, accuracy, and security — which the technology does not supply, and which require sustained organisational investment. The asymmetry means that SO strategies are available immediately and cheaply, while WT strategies determine whether the SO gains survive contact with the organisation's regulatory obligations.

The priority ordering follows from this. WT strategies are defensive but are not therefore secondary: data security, governance and ethical guidelines, change management, in-house capability to reduce vendor lock-in, a data-quality management system and an AI innovation task force are the conditions under which the remaining three quadrants can be pursued at all in a regulated setting. WO strategies — training, a structured adoption plan, IT infrastructure, AI-specific roles — remove the internal constraints that the interviews identified as the locus of complexity. ST strategies deploy leadership support and IT capability against resistance and misinformation. SO strategies capture the readily available gains. Sequencing therefore runs WT and WO first, ST concurrently, and SO continuously; this ordering is what the phased implementation plan in Section VI-B operationalises.

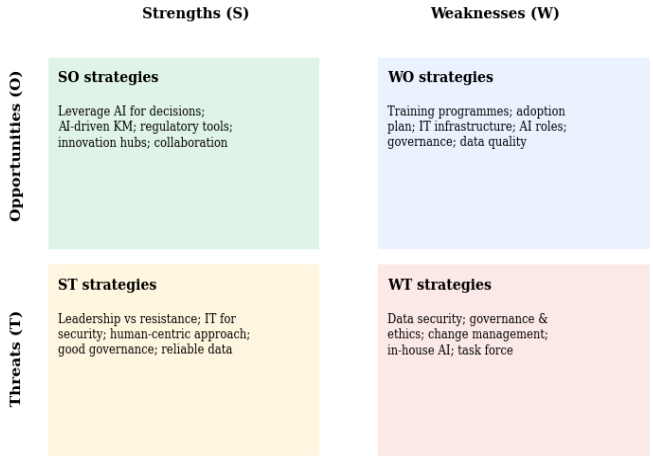

Fig. 10. TOWS strategy matrix for Gen AI and LLM adoption in the organisation.

D. What the Expert Evaluation Establishes — and What It Does Not

The content-validity evidence establishes that a panel of three qualified experts judged the framework's clusters and subclusters to be relevant to the construct of AI-enabled KM in a public-sector regulatory setting, with scale-level indices above the threshold for every cluster and three subclusters revised in response to sub-unanimous ratings. That is a meaningful but narrow claim. Content validity concerns whether the instrument's items adequately represent the domain; it does not establish construct validity, criterion validity, or that use of the framework improves KM outcomes. None of those is claimed here.

The panel size bounds the claim further. Three raters satisfy Lynn's stated minimum [31] but sit at the lower limit, so the indices carry wide estimation uncertainty, and unanimity among three raters is a weaker signal than the same proportion obtained from nine. The revisions made in response to the 0.67 items are therefore best read as expert-informed refinements rather than as psychometrically compelled corrections. The framework should be treated at this stage as a validated

proposition awaiting confirmation, and Section VI-D specifies what that confirmation requires.

E. Theoretical and Practical Implications

Theoretically, the study extends DOI to AI-enabled KM in a national regulatory setting that has not previously been examined. It shows that the classical innovation attributes remain explanatory for Gen AI and LLMs while identifying a context-specific moderator — data governance and ethics — that conditions the relationship between perceived attributes and adoption, and it relocates complexity from the innovation to the organisation. It also demonstrates a replicable mixed-method design for assessing emerging-technology adoption by combining DOI with a Kansei-based SWOT instrument and a TOWS synthesis, which is useful where both quantitative and experiential factors matter.

In practical terms, the findings give the organisation an evidence-based basis for adoption. With all five DOI attributes positive, it can move from exploratory use to structured implementation, concentrating on the enablers participants valued most — ease of use, low-cost trialability and compatibility with existing tools — while directly addressing the highest-scoring threats relating to data quality, privacy and security. The TOWS strategies translate these insights into initiatives, and the four strategic thrusts provide a governance structure through which progress can be planned, resourced and monitored.

F. Boundary Conditions and Transferability

Because the evidence comes from a single organisation, six interview participants, fourteen FGD respondents and three experts, the question of what may legitimately be carried to other settings requires an explicit answer rather than an assumption of breadth. The study makes no claim of statistical generalisation to a population of public-sector agencies. What it offers instead is analytic or theoretical extension in the sense of [51], and transferability in the sense of [50], in which the researcher supplies sufficient contextual description for readers to judge the fit to their own setting and the readers, not the authors, make that judgment. Transferred findings are properly treated as working hypotheses rather than conclusions [49].

Table VIII therefore states the conditions under which such transfer is defensible, distinguishing the elements of the study that are likely to travel from those that are specific to this case. In summary, the framework's structure and the moderating role of governance are the elements most likely to transfer, and they should transfer most readily to organisations that share four properties: a statutory regulatory mandate that imposes data-custodianship and accountability obligations; an existing centralised KM function with identifiable repositories; a mix of structured and unstructured knowledge assets; and public-sector procurement, data-sovereignty and records retention. constraints that limit the use of public cloud-hosted models. Where these properties are absent — in a commercial organisation without custodianship obligations or an agency without an established KM function — the cluster weightings and, in particular, the primacy of the Data and Process clusters should not be assumed.

The elements least likely to transfer are the empirical particulars: the frequency distribution across the DOI attributes, the specific LEIQ™ factor scores, and the composition of the four strategic thrusts, all of which reflect this organisation's maturity, workforce and regulatory position at the time of study. Another agency applying the framework should expect to re-run the diagnostic — the DOI-framed interviews and the LEIQ™-scored SWOT — and to derive its own weightings, using the framework as the instrument rather than the results as the finding.

G. Limitations

Five limitations bound the findings. First, the design is a single-organisation case study with purposive sampling, so the findings characterise this organisation and extend to others only analytically, subject to the conditions in Section V-F. Second, the expert-review panel comprised three specialists. This meets the stated minimum for content-validity assessment [31] but sits at its lower limit; the reported I-CVI and S-CVI values should be regarded as indicative until confirmatory validation is performed with a larger panel. Third, the thematic analysis rests on consensus coding by two researchers rather than on an inter-rater reliability coefficient, for the reasons set out in Section III-F; readers who require such a coefficient should treat the coding consistency as procedurally established but numerically unverified. Fourth, the frequency counts reported in Fig. 5 index prominence in the corpus and should not be read as measures of effect size or of participant agreement. Fifth, the study assesses feasibility and content validity, not outcomes: no claim is made that adopting the framework improves KM performance, since that would require longitudinal evaluation against operational indicators.

TABLE VII. CONSOLIDATED TOWS STRATEGY MATRIX

TOWS	Strengths (S)	Weaknesses (W)
Opportunities (O)	SO: leverage AI for enhanced decision-making; AI-driven KM; AI-powered regulatory tools; AI innovation hubs; data-driven policymaking; process optimisation; AI-enhanced public services; AI-driven collaboration.	WO: comprehensive AI training; structured adoption plan; enhance IT infrastructure; AI-specific roles and teams; clear AI governance; improve data quality and management; foster a culture of innovation; develop in-house AI capabilities.
Threats (T)	ST: leadership support against resistance; IT capability for data security; knowledge to counter misinformation; human-centric approach; good governance for regulatory compliance; resource allocation for currency; large datasets for reliable decisions; knowledge sharing for interdepartmental collaboration.	WT: comprehensive training programme; robust data security; clear governance and ethical guidelines; change-management strategy; cross-departmental collaboration; in-house AI solutions to reduce vendor lock-in; data-quality management system; AI innovation task force.

TABLE VIII. BOUNDARY CONDITIONS FOR TRANSFER OF THE KMAI FRAMEWORK TO OTHER SETTINGS

Element of the study	Transferability	Condition required for transfer
Five-cluster framework structure (People, Process, Technology, Content and data, and Culture)	High — construct coverage is domain-general and expert-validated	Organisation performs knowledge-intensive work with identifiable repositories; no regulatory mandate required
Governance and ethics as a moderator of adoption	Moderate to high — proposed as a theoretical extension for confirmatory testing	Organisation is subject to data-custodianship, privacy or accountability obligations that constrain tool selection
Multi-method design (DOI interviews + LEIQ™ SWOT + TOWS + CVI)	High — the method is the reusable contribution	Access to internal informants across management levels and to external subject-matter experts
Relative weighting of clusters (primacy of Data and Process)	Low — case-specific	Must be re-derived from a local diagnostic; not to be assumed
DOI attribute frequencies and LEIQ™ factor scores	Not transferable — reflect this Organisation's maturity and workforce	Re-run the diagnostic instrument locally
Four strategic thrusts and the implementation sequence	Low to moderate — structure may guide, content may not	Comparable statutory mandate, existing centralised KM function, and public-sector procurement and data-sovereignty constraints

VI. RECOMMENDATION

This section converts the validated framework of Section IV-E and the strategic analysis of Section V into an implementable programme. It does not restate the framework's components or the TOWS strategies; it specifies who acts, in what order, and against what indicators, and it states what must be validated before the programme is extended beyond the organisation.

A. Strategic Thrusts, Ownership and Indicators

The programme is organised around four strategic thrusts — People, Process, Technology and Data — that aggregate the five framework clusters into units for which accountability can be assigned (Fig. 11). Culture is treated as a cross-cutting condition realised through the People and Process thrusts rather than as a separate accountability unit, because the FGD evidence located cultural resistance in specific people and process practices rather than in a free-standing cultural deficit. Table IX assigns each thrust an owner, a set of first-order actions and the indicators against which progress is to be measured.

Two design rules govern the thrusts. First, no thrust proceeds ahead of the data thrust: the interview and FGD evidence are consistent that output accuracy, and therefore user trust, is a function of data classification and quality, so data functions as the gating thrust. Second, each thrust must carry at least one indicator that is observable to users rather than only to the programme, because observability was one of the two mechanisms by which uncertainty was reduced in the interviews; progress that is invisible to staff will not convert into adoption.

B. Phased Implementation Plan

Implementation should be incremental, and the sequence should follow the priority ordering derived in Section V-C: defensive and enabling work first, opportunistic gains continuously.

Short term (0–12 months). Establish data-governance and ethics guidelines and an acceptable-use policy for Gen AI; complete a data-classification exercise across the divisions holding the principal repositories; appoint AI champions in each targeted division and constitute the AI innovation task force; and run controlled pilots confined to divisions with mature data repositories, each with a defined success measure and human validation of outputs. The purpose of this phase is to make experimentation safe, not to scale it.

Medium term (1–3 years). Scale the successful pilots to the divisions that share their data conditions; institutionalise AI-specific roles and the training programme; harden infrastructure and security to support organisation-wide use; and establish quality-assurance and continuous-improvement loops with periodic review of outputs against operational indicators.

Long-term (3–5 years). Build in-house capability and invest in a customised model appropriate to the organisation's data-sovereignty constraints; integrate the KMAI framework with enterprise strategy so that AI-enabled KM is a core organisational capability rather than an isolated initiative; and extend measurement from process indicators to decision-quality and operational-efficiency outcomes.

The pace implied by this sequence is deliberate. Industry analysis distinguishes an AI-accelerated posture, in which AI is integrated into core operations and decision-making to drive productivity, creativity and engagement, from an AI-steady posture characterised by operational integration, scalability, governance, improved return on investment and continuous improvement [45]. Given the evidence of positive perceptions across all five attributes but immature data governance, the Organisation should pursue the accelerated posture only as the governance conditions established in the short-term phase are met; until then, a steady posture with controlled pilots is the appropriate setting.

C. Conditions for Reuse by Other Agencies

Public-sector agencies with comparable regulatory mandates and data-custodianship obligations may reuse the framework and the diagnostic method but should do so as adopters of an instrument rather than as recipients of a result. Three requirements follow from Section V-F and Table VIII. The framework structure and the diagnostic method may be adopted directly. The cluster weightings, the sequencing of

thrusts and the content of the strategies must be re-derived locally by re-running the DOI-framed interviews and the LEIQ™-scored SWOT within the adopting organisation. And the moderating role of governance should be treated as a hypothesis to be checked against local conditions rather than as an established property, since it has been tested in one setting only.

D. Priorities for Future Validation

Four validation steps would convert the present propositions into confirmed findings, and they are stated in the order in which they should be undertaken. First, repeat the content-validity assessment with a panel of at least six and preferably eight to ten experts drawn from more than one agency, reporting modified kappa alongside I-CVI so that agreement is adjusted for chance. Second, replicate the qualitative phases in at least two further public-sector organisations with comparable mandates to test whether the cluster structure and the primacy of the data cluster hold outside this case; a replication designed within a coding-reliability paradigm should pre-specify a codebook and report kappa or alpha. Third, operationalise the framework as a measurement instrument and test the moderating role of data governance and ethics quantitatively across agencies. Fourth, evaluate outcomes longitudinally in selected divisions, measuring the effect of framework-guided adoption on decision quality and operational efficiency, since feasibility and content validity do not by themselves demonstrate benefit.

TABLE IX. STRATEGIC THRUSTS: OWNERSHIP, FIRST-ORDER ACTIONS AND INDICATORS

Thrust	Suggested owner	First-order actions	Progress indicators
Data (gating)	Information and data management division	Data classification across principal repositories; data architecture and taxonomy; quality-management system, and access and retention controls	Proportion of repositories classified; data-quality exception rate; time to retrieve a governed record; number of access incidents
Process	Strategy and planning, with KM division	Governance and ethics guidelines; acceptable-use policy; risk management; quality assurance and human validation of outputs; adoption plan	Policy in force; proportion of AI-assisted outputs subject to documented human validation; pilot success against pre-defined measures
People	Human capital, with divisional AI champions	Tiered training programme; AI champion network; AI-specific roles; change-management and communication plan	Training completion by management level; number of active champions; self-reported competence; staff-visible demonstrations delivered
Technology	Digital / ICT services	Secure and scalable infrastructure; integration with existing productivity tools; user-interface and UX work; evaluation of in-house model options	Availability and response time; number of integrated workflows; user-satisfaction score; reduction in use of unsanctioned public tools

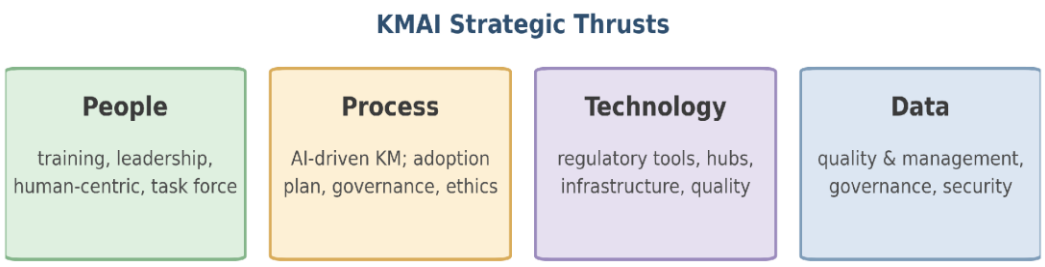

Fig. 11. KMAI strategic thrusts and strategies.

VII. CONCLUSIONS

This study set out to examine the issues and challenges that affect the adoption of Gen AI and LLMs to enhance the organisation's KM practices and to develop and validate a framework for that purpose. The potential organisational impact was evaluated using a SWOT framework targeting optimisation, efficiency, and accuracy, and the resulting factors were converted into strategies through TOWS analysis.

The evidence indicates that adoption is feasible in this setting. All five DOI attributes were perceived positively, and the barriers participants identified were organisational rather than technological: data classification, competence, role definition and governance. The study's principal theoretical contribution is the positioning of data governance and ethics as a condition on the relationship between the innovation attributes and adoption, rather than as one component among others. Its principal practical contribution is the KMAI framework, refined through expert evaluation and translated into four strategic thrusts and a phased implementation plan for the organisation.

These contributions are bounded by the design. The findings derive from one organisation, a purposive sample and a three-member expert panel and are therefore offered as analytically transferable propositions subject to the conditions set out in Section V-F, not as results generalisable to public-sector agencies at large. The framework's content validity is established but indicative, and its effect on KM outcomes is untested. Confirmatory validation with a larger expert panel, replication in comparable agencies, quantitative testing of the proposed moderation, and longitudinal measurement of decision quality and operational efficiency are the necessary next steps, and the organisation is well placed to undertake the first of them as it develops an integrated technology roadmap over the next three to five years.

DECLARATION ON THE USE OF GENERATIVE AI

The authors declare the following pursuant to the journal's policy on the use of generative artificial intelligence. In the preparation of this manuscript, generative AI tools (large language model-based assistants) were used by the authors only for language editing, for improving readability and grammar, for assisting with the formatting of the manuscript to the journal template, and for assisting in the preparation of figures illustrating the study's frameworks and results. The generation, analysis, or interpretation of research data, the production of research findings, and the drafting of scientific claims were not assisted by generative AI. The authors performed all conceptual development, methodological design, data collection, thematic analysis, content-validity computation, and interpretation.

Generative AI and large language models are also the object of study in this research; their use as an object of investigation is described in the Methodology and Findings sections and is distinct from the authorial assistance disclosed here. The authors have used these tools in the writing of the article and take full responsibility for all content in the published article. Generative AI tools were not credited as authors and do not qualify for authorship.

ACKNOWLEDGMENT

The author gratefully acknowledges the financial grant FRGS-EC/1/2024/ICT03/UITM/02/2 provided by the Ministry of Higher Education and the Faculty of Computer and Mathematical Sciences, Universiti Teknologi MARA, Malaysia, for all support and resources.

Machine Learning for Distributed Acoustic and Fibre-Optic Sensing in Infrastructure Monitoring: A Systematic Review (2015-2025)

Abd Rahim Saidin, Illani Mohd Nawi
Department of Electrical and Electronic Engineering, Universiti Teknologi PETRONAS, 32610 Seri Iskandar, Perak, Malaysia

***Abstract*—Distributed acoustic sensing (DAS), together with broader distributed fibre-optic sensing (DFOS), has emerged over the past decade as a candidate technology for large-scale infrastructure monitoring, while machine learning (ML) is increasingly used to interpret its high-throughput data. This study presents a PRISMA 2020-guided bibliometric and systematic-mapping review of this convergence. A structured search of Web of Science, Scopus, and IEEE Xplore returned 291 records published between 2015 and 2025; after duplicate removal and two stages of screening, a final analytical corpus of 31 publications was established, of which 16 are primary DAS-with-ML infrastructure studies. Publication output rises sharply to seven papers in 2024 and twelve in 2025. Among the primary studies, convolutional neural networks (CNNs), recurrent models, and CNN-LSTM hybrids are prominent, with more recent use of few-shot learning, graph neural networks (GNNs), generative models, and self-supervised learning. Perimeter security is the most represented application domain, followed by traffic, railway, and structural-health monitoring. Critical synthesis shows that the apparent dominance of CNNs is partly explained by the natural two-dimensional spatiotemporal representation of DAS data and by mature, reusable CNN pipelines, rather than evidence of universal superiority. Cross-study comparison remains limited by heterogeneous sensing environments, inconsistent acquisition and label reporting, non-uniform evaluation protocols, sparse computational reporting, and minimal long-term robustness evaluation. Five research gaps are identified: cross-infrastructure generalisation, standardised benchmarks and open datasets, physics-data-driven integration, interpretability and uncertainty, and operationally robust edge deployment.**

Keywords*—*Bibliometric analysis; convolutional neural network; deep learning; distributed acoustic sensing; distributed fibre-optic sensing; infrastructure monitoring; machine learning; phase-sensitive OTDR; structural health monitoring; systematic review

I. Introduction

Distributed acoustic sensing (DAS) converts a standard optical fibre into a long, densely sampled array of vibration sensors by analysing Rayleigh-scattered light produced as laser pulses travel along the fibre. Because it can interrogate tens of kilometres of fibre with metre-scale spatial resolution and high sampling rates, DAS, together with related distributed fibre-optic sensing (DFOS) techniques, has attracted growing interest for transport, energy, and civil-infrastructure monitoring [23], [24], [30]. A single buried or surface-mounted cable can simultaneously capture intrusion, traffic, seismic, and structural signatures, making the technology attractive where conventional point sensors would be costly or impractical [1].

The volume and complexity of DAS data exceed what manual or rule-based analysis can handle efficiently. This has motivated ML and, increasingly, deep learning to automate event detection, classification, signal enhancement, and condition assessment [6], [10]. Convolutional and recurrent architectures, along with meta-learning and graph-based models, have been applied to traffic, railway, urban, structural, and perimeter-monitoring tasks [11], [22], [28]. Despite this activity, the field still lacks a consolidated picture of how the DAS-ML intersection has developed, how evidence quality varies, and which apparent research gaps remain robust after accounting for a small and heterogeneous corpus.

This review addresses that need through a PRISMA-guided bibliometric and systematic-mapping analysis of literature published from 2015 to 2025. The three research questions are: (RQ1) How have publication trends and thematic developments in DAS-ML research evolved? (RQ2) Which authors, venues, and countries are most active, and how are they connected through co-authorship and shared topics? (RQ3) What research gaps and future opportunities are supported by the available evidence for infrastructure and smart-infrastructure applications?

The corresponding objectives are to quantify publication and methodological trends (RO1); map geographical, venue, co-authorship, and keyword structures (RO2); and critically synthesise the 16 primary DAS-with-ML studies through study-quality assessment, ML-application mapping, cross-study comparability analysis, and evidence-grounded research gaps (RO3).

The contributions are: 1) a PRISMA 2020-compliant search and screening protocol yielding a reproducible corpus of 31 publications; 2) quantitative bibliometric characterisation of publication, geographical, venue, collaboration, and keyword patterns; 3) a five-criterion quality assessment of the 16 primary studies; 4) a two-dimensional mapping of ML families to application domains, interpreted explicitly as corpus-level coverage rather than proof of field-wide absence; and 5) a critical synthesis of dataset heterogeneity, evaluation comparability, computational reporting, data quality, and long-term deployment challenges, leading to five evidence-mapped research directions.

II. Literature Review

The literature reflects a progression from deterministic signal processing towards data-driven analysis. Early and parallel work focused on signal fidelity, phase-noise compensation, sensing-system design, and measurement quality [4], [7]. Classical ML then appeared in traffic, railway, and structural settings through support-vector machines, ensemble classifiers, and principal-component-based methods [13], [15], [16], [21].

Deep learning subsequently became prominent. CNNs have been applied directly to phase-sensitive optical time-domain reflectometry (phi-OTDR) spatiotemporal matrices for event recognition [10], while recurrent and hybrid CNN-LSTM models capture temporal dependencies in compromised-data and railway-condition monitoring [2], [22]. Autoencoder-based self-supervised learning has been explored for traffic and perimeter applications [6], [12]; meta-learning addresses limited labelled data in urban monitoring [11]; and graph-diffusion modelling explicitly represents spatial sensor topology for anomaly detection [28]. Signal separation using recurrent architectures provides a further example of task-specific model development [27].

Several adjacent sensing studies highlight acquisition and data-quality constraints that directly influence ML reliability. Optical vibration-monitoring systems demonstrate dependence on sensing configuration and signal conditioning [7]; embedded distributed optical-fibre networks show the need to distinguish thermal effects from mechanical strain [8]; and distributed fibre processing in axially loaded precast piles illustrates the importance of installation and load-transfer conditions [9]. Related low-SNR noise-removal work [17], DAS optimisation studies [18], and output-only sensor fusion using distributed optical-fibre measurements [20] reinforce the point that model performance cannot be interpreted independently of measurement quality. At the systems level, cloud-computing and storage considerations in seismology [25] and multiparameter distributed sensing [26] also motivate scalable and calibration-aware deployment strategies.

Application-oriented work spans pipeline and geotechnical monitoring [19], hydrogen-pressure-vessel and composite structural-health monitoring [29], open DAS event datasets [5], and synthetic DAS data generation [14]. Recent reviews survey DAS for seismology, intelligent event perception, and the wider technology landscape [23], [24], [30]. The present review differs by combining PRISMA screening, bibliometrics, quality assessment, primary-versus-adjacent study separation, ML-application mapping, and a critical comparability/deployment synthesis. Table I positions these contributions against the closest prior reviews.

TABLE I. Positioning of the Present Study Against Closely Related Reviews

Study	Technology scope	Review method	ML/DL	Period	Application focus	PRISMA	Bibliometric	Quality	Gaps
Markom et al. (2025) [30]	DAS/DFOS broadly	Systematic review	Partial	N/R	Seismology, perimeter, traffic	Partial	No	No	Partial
Rashid et al. (2025) [23]	DAS for seismology	Narrative survey	Partial	N/R	Seismology	No	No	No	Partial
Wu et al. (2025) [24]	DAS event perception	Narrative review	Yes	N/R	General event detection	No	No	No	Yes
Present study	DAS + DFOS + ML for infrastructure	PRISMA bibliometric/systematic map	Yes	2015-2025	Pipeline, railway, SHM, traffic, security, urban	Yes	Yes	Yes	Yes

[a] N/R = not reported. "Partial" indicates that the feature is discussed but is not the primary analytical layer.

III. Methodology

This review applies a bibliometric and systematic-mapping methodology, with study selection reported in accordance with PRISMA 2020 [31]. Web of Science, Scopus, and IEEE Xplore were searched.

A. Search Strategy

A Boolean query combined three concept blocks with the AND operator: 1) sensing technology (Distributed Acoustic Sensing, Distributed Optical Fiber/Fibre Sensing, Fiber/Fibre-Optic Sensing, Phase-sensitive OTDR, phi-OTDR, DAS, DOFS); 2) analytical layer (Machine Learning, Deep Learning, Signal Processing, Pattern Recognition, Neural Network*, Event Detection, Time-series Analysis); and 3) application domain (Infrastructure Monitoring, Structural Health Monitoring, Condition Monitoring, Smart Infrastructure, Smart Cities, Internet of Things, IoT, Cloud Computing). The query was adapted to each database, restricted to English-language publications from 2015 to 2025, and executed on 19 January 2026. The database-specific search parameters are summarised in Table II.

TABLE II. Search Parameters

Parameter	WoS	Scopus	IEEE Xplore
Years	2015-2025	2015-2025	2015-2025
Language	English	English	English
Search field	Full text	Full text	Full text
Records	172	65	54
Search date	19 Jan 2026	19 Jan 2026	19 Jan 2026

B. Screening and Eligibility

The search returned 291 records. After 64 duplicates were removed, 227 unique records underwent title-and-abstract screening, of which 123 were excluded. The remaining 104 records were assessed in full text; 73 were excluded for falling outside the declared scope, yielding a final analytical corpus of 31 publications (Fig. 1; Table III). The primary synthesis

comprises 16 DAS-with-ML infrastructure studies. Screening was conducted by the lead author; borderline cases were reviewed independently by the second author and resolved by consensus discussion.

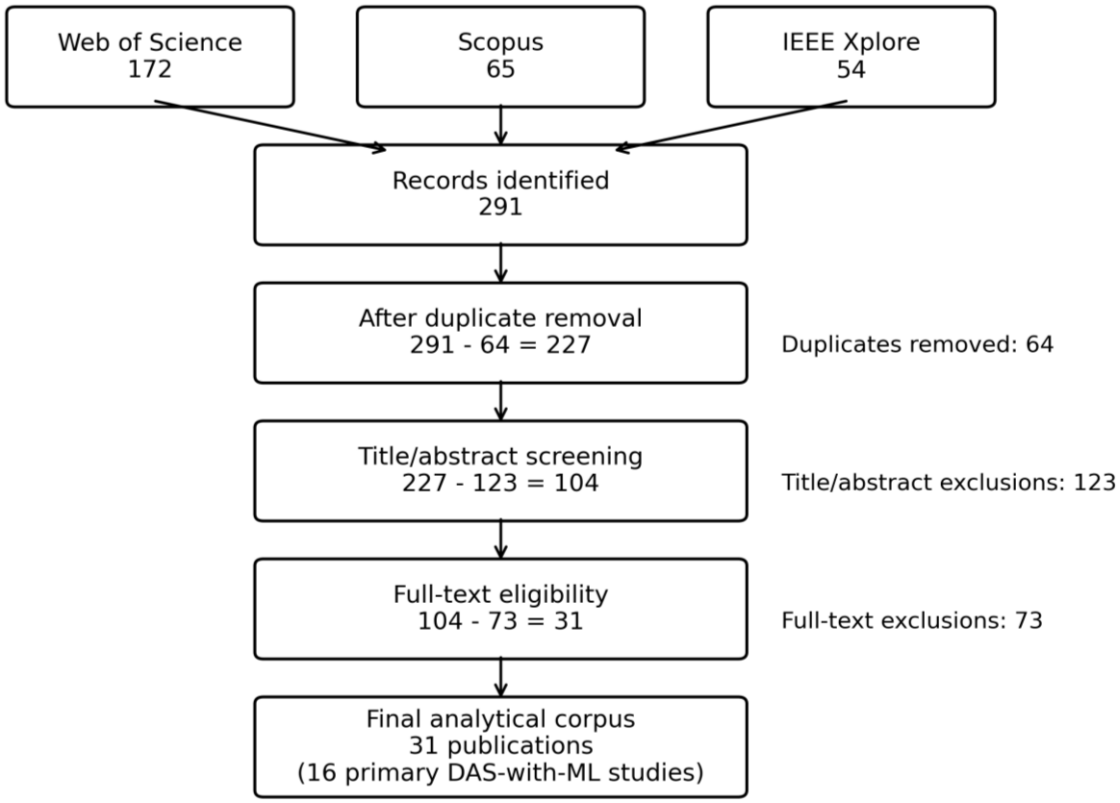

Fig. 1. PRISMA 2020 flow diagram of the study-selection process.

TABLE III. INCLUSION AND EXCLUSION CRITERIA APPLIED DURING SCREENING

Criterion	Inclusion	Exclusion
Publication type	Peer-reviewed journal or conference articles, 2015-2025	Preprints, theses, book chapters, non-English publications
Technical focus	DAS/DFOS infrastructure sensing with ML/DL or directly relevant adjacent sensing-analysis context	Unrelated sensing modalities or hardware-only work without relevance to DAS/DFOS analysis
Application domain	Real-world or simulated infrastructure monitoring and closely related sensing contexts	Biomedical, downhole-reservoir-only, or clearly non-infrastructure applications
Methodology	Reports data acquisition, processing, model architecture, validation, or system characteristics used in the synthesis	Conceptual frameworks without empirical or analytical contribution
Data description	Provides sufficient sensing or experimental context for the intended synthesis	No meaningful description of sensing data or experimental setup

C. Data Extraction and Analysis

For each record, bibliographic metadata, authorship and country information, venue, sensing modality, ML category and technique, dataset type, deployment mode, maturity level, and reported validation characteristics were extracted into a structured master sheet. Author names and keywords were normalised before analysis. Bibliometric mapping was performed with VOSviewer, and descriptive statistics were computed from the master sheet. For the 16 primary studies, critical synthesis additionally considered whether the reported evidence permits comparison of sensing environments, acquisition characteristics, label quality/class balance, evaluation protocols, computational cost, and long-term operational robustness. Missing items were treated as reporting limitations rather than inferred.

IV. RESULTS

A. Bibliometric Overview

Annual output (Fig. 2) confirms a recent acceleration within the 31-publication corpus. After sparse activity through 2022, output rises to four papers in 2023, seven in 2024, and twelve in 2025. This pattern is consistent with growing adoption of deep-learning and data-driven methods in distributed sensing, although publication growth alone does not establish methodological maturity.

Venue concentration remains marked. Sensors contributes eleven of the 31 records and IEEE Access contributes two; the remaining 18 records are distributed across single-publication venues (Fig. 3). This concentration should not be read as venue dominance of the wider field because the result is sensitive to the search scope and small corpus size.

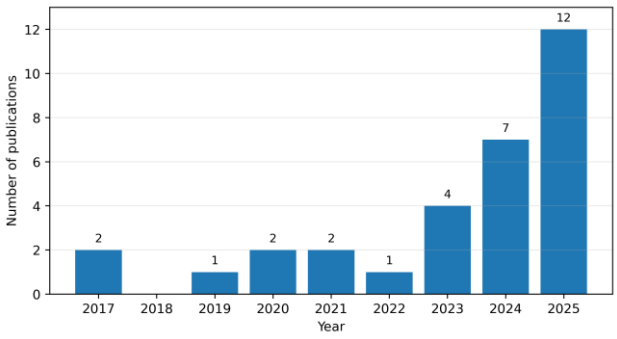

Fig. 2. Annual publication output of the reviewed corpus (n = 31).

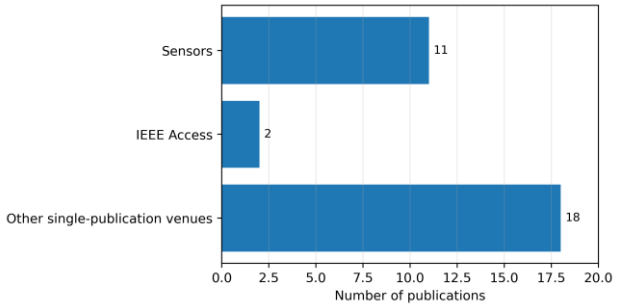

Fig. 3. Venue concentration in the reviewed corpus.

Geographically, China contributes seven papers, followed by the United States with four and Spain with three. Germany, Russia, Czechia, and Malaysia contribute two each; remaining country contributions are individually small (Fig. 4).

B. Collaboration and Thematic Structure

The co-authorship network (Fig. 5) is composed of several small, weakly connected clusters, indicating that collaboration is still concentrated within local research groups. The keyword co-occurrence map (Fig. 6) centres on distributed acoustic sensing and optical-fibre concepts, with linked clusters around deep learning, convolution, classification, signal processing, noise, traffic, and infrastructure monitoring.

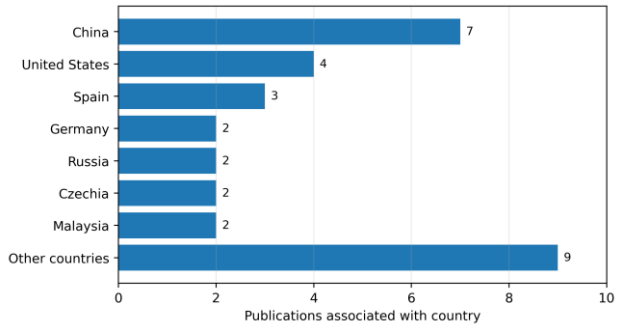

Fig. 4. Publication output by leading country; remaining countries are aggregated for legibility.

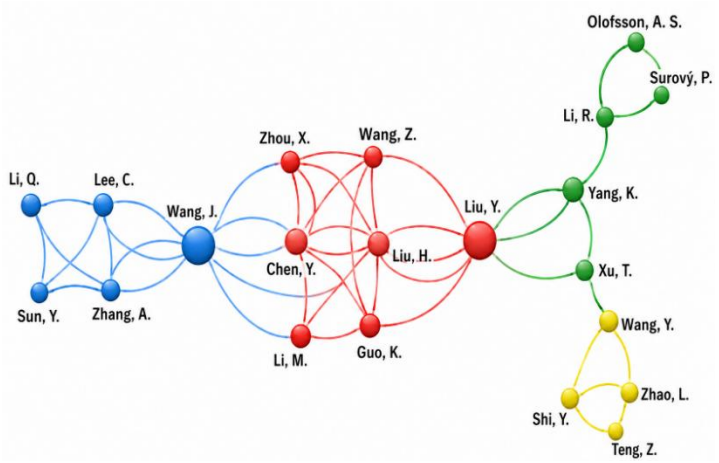

Fig. 5. Enlarged co-authorship network (VOSviewer; minimum two documents per author).

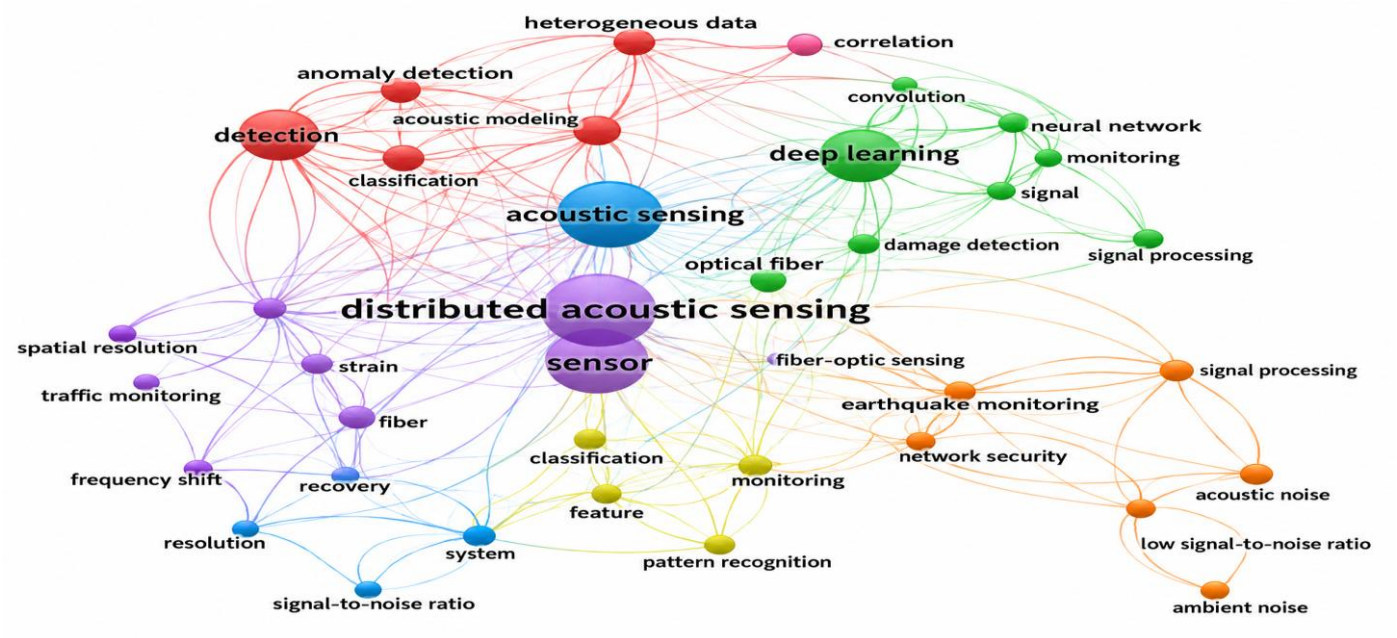

Fig. 6. Enlarged keyword co-occurrence network (VOSviewer; minimum three keyword occurrences).

C. Primary-Study Landscape and Quality

The 16 primary studies span laboratory, field, mixed, and synthetic settings. Seven are laboratory or controlled-bench studies [1], [2], [10], [12], [15], [16], [27]; six are field deployments [5], [6], [11], [13], [21], [28]; two report mixed validation [3], [22]; and one is synthetic [14]. Open-science practice remains limited: Tomasov et al. [5] release a public dataset, and Robles-Urquijo et al. [14] provide a validated synthetic-data pipeline, while no primary study in the reviewed set releases both model weights and complete training code. Methodologically, the set includes convolutional and recurrent models, classical ML, deep neural networks (DNNs), and autoencoder (AE)-based self-supervised learning (SSL), together with newer meta-learning and graph-diffusion approaches. Table IV summarises the 16 primary studies. Their methodological and application-domain distributions are shown in Fig. 7, and the temporal distribution of ML families is shown in Fig. 8.

[b.] Open: Y = public dataset; P = validated synthetic-data pipeline; N = not released.

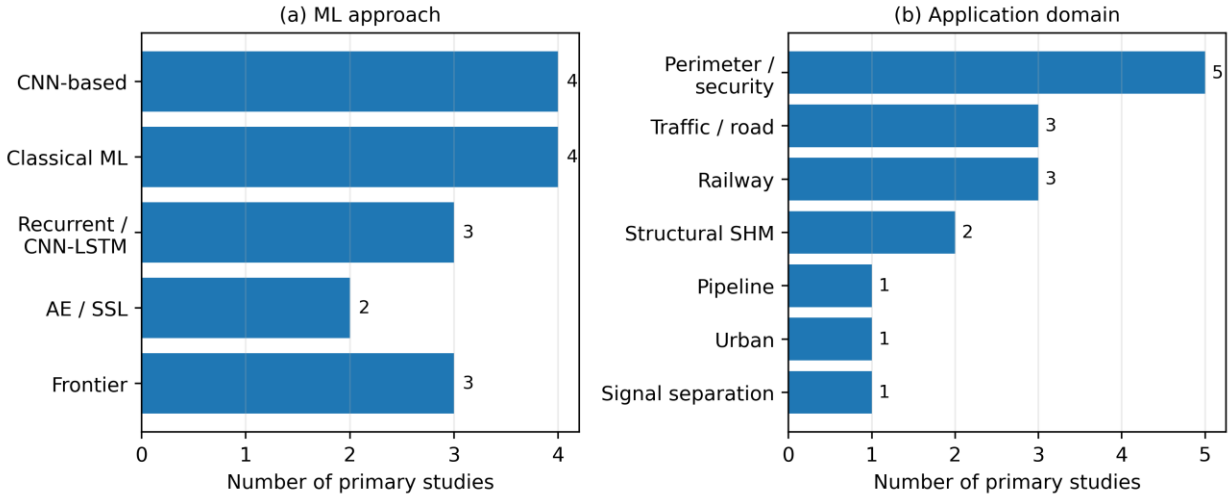

Fig. 7. Distribution of the 16 primary studies across (a) ML approach and (b) application domain.

Table V cross-tabulates ML method families against infrastructure application domains. The same relationships are visualised in Fig. 9; because the evidence base contains only 16 primary studies, empty or sparse cells are interpreted only as not observed in this screened corpus.

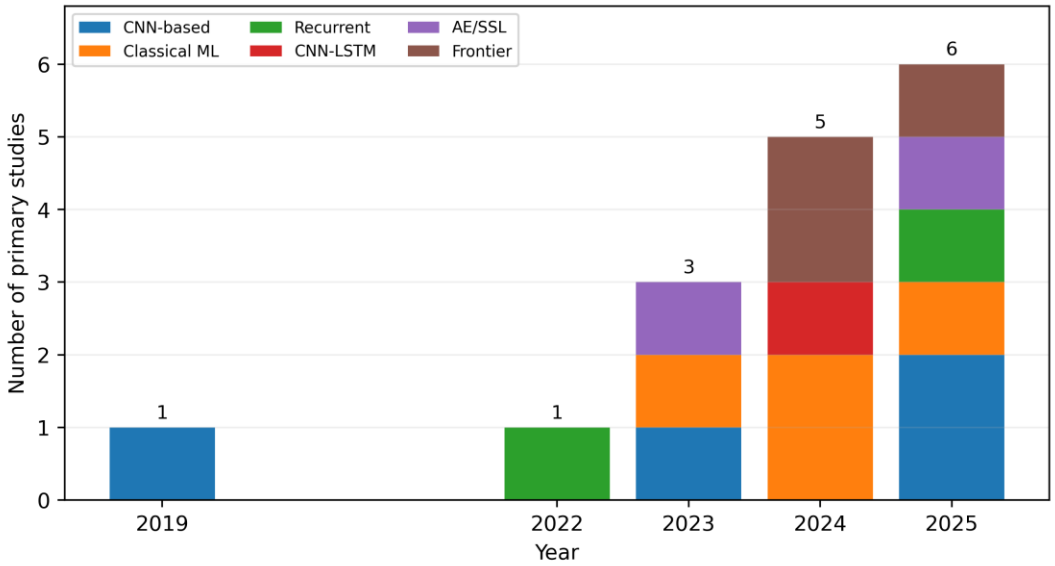

Fig. 8. Annual distribution of the 16 primary DAS-with-ML studies by ML family.

TABLE V. CROSS-TABULATION OF ML FAMILIES AGAINST APPLICATION DOMAINS FOR THE 16 PRIMARY STUDIES

ML family	Pipeline	Railway	Struct. SHM	Traffic	Security	Urban	Signal	Total
CNN-based	-	[3]	-	[14]	[5], [10]	-	-	4
Recurrent	-	-	-	-	[2]	-	[27]	2
CNN-LSTM	-	[22]	-	-	-	-	-	1
Classical ML	-	[21]	[15], [16]	[13]	-	-	-	4
AE / SSL	-	-	-	[6]	[12]	-	-	2
Frontier	[1]	-	-	-	[28]	[11]	-	3
Total	1	3	2	3	5	1	1	16

[c.] AE = autoencoder; SSL = self-supervised learning; "-" means no study observed in this screened corpus. Because the matrix contains only 16 studies and most of its 42 family-domain cells are empty, an empty cell is interpreted only as "not observed in the present corpus"; it is not evidence that the combination is absent from the wider research field.

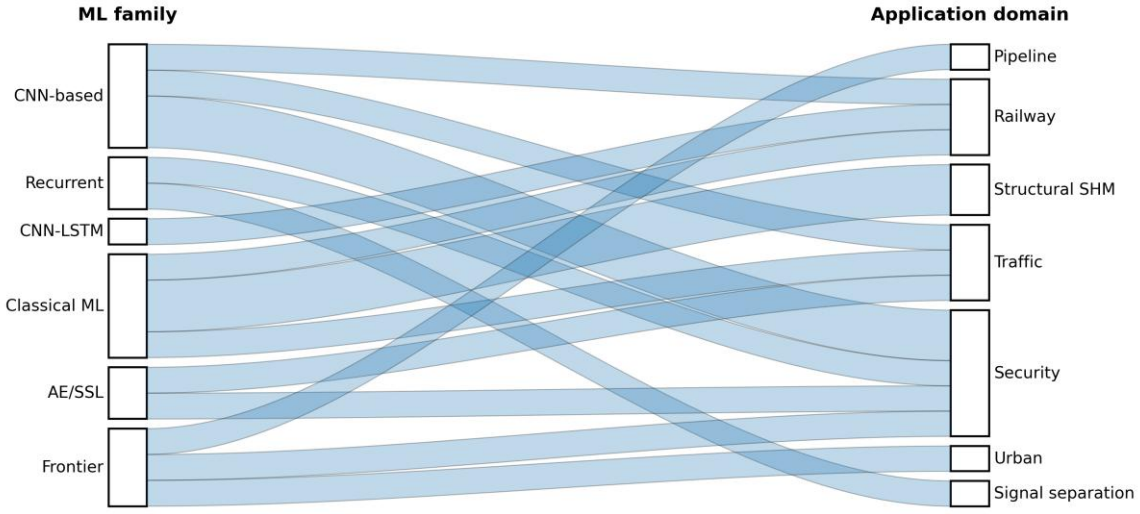

Fig. 9. Alluvial mapping of ML families to application domains. Ribbon width is proportional to study count; sparse flows should be interpreted as corpus-level coverage only.

Study quality is reported in Table VI and visualised in Fig. 10. The combined assessment shows that reproducibility is the weakest criterion across the primary-study corpus.

Cross-study comparability, dataset-reporting limitations, and operational-computing requirements are synthesised in Table VII.

[d] D = dataset transparency; V = validation rigour; R = reproducibility; W = real-world context; M = performance metrics.

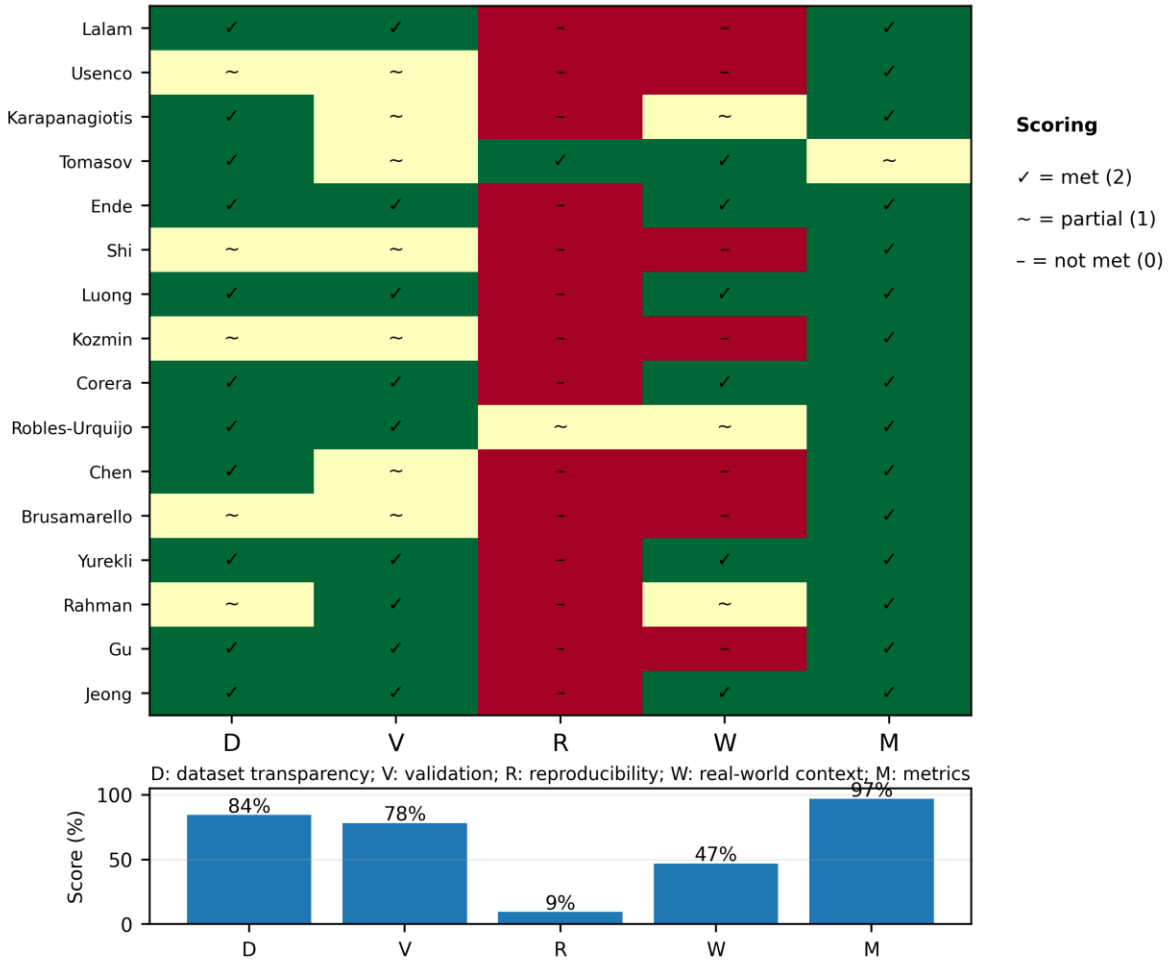

Fig. 10. Visual summary of the five-criterion quality assessment. Reproducibility remains the weakest criterion.

TABLE VII. CROSS-STUDY COMPARABILITY AND OPERATIONAL REPORTING IN THE 16 PRIMARY STUDIES

Dimension	Corpus-level observation	Why it matters	Minimum future reporting
Sensing environment	7 laboratory, 6 field, 2 mixed, 1 synthetic; most studies are site- or task-specific	Performance can reflect controlled conditions or site characteristics rather than transferable model skill	Site, cable installation, sensing environment, domain-shift conditions
Acquisition parameters	Sampling frequency, gauge/spatial resolution, channel spacing, preprocessing, and calibration are not reported with a uniform schema	Different acquisition bandwidths and spatial resolutions change the learning problem and can confound model comparison	Sampling rate, pulse repetition rate, gauge length/spatial resolution, channel count, calibration and preprocessing
Labels and class balance	Label-generation procedures and class-wise sample distributions are inconsistently documented; controlled experiments often have cleaner labels than field data	Unknown annotation uncertainty or imbalance can make aggregate accuracy optimistic and weaken reproducibility	Class counts, imbalance ratio, annotation source, annotator agreement/verification, ambiguous-event policy
Metrics and validation	Classification, regression, reconstruction, denoising, and anomaly-detection tasks use different metrics and split protocols; no common benchmark split exists	Reported headline scores are not directly comparable across task types or studies	Task-appropriate core metrics, confusion matrix or per-class scores, split definition, repeated-seed or cross-site validation where feasible
Computation and edge readiness	A few studies discuss real-time operation or training speed [10], [21], but parameter count, FLOPs, latency, memory, and energy are rarely reported systematically	Accuracy alone does not establish deployability on interrogator-adjacent or edge hardware	Parameters, FLOPs/MACs, device, batch size, latency, throughput, peak memory, energy/power
Long-term robustness	No longitudinal evaluation of concept drift, fibre ageing, model maintenance, or online adaptation was identified in the primary set	Operational sensing conditions evolve; static offline validation may overestimate lifetime reliability	Monitoring duration, drift tests, recalibration policy, missing/corrupted-data tests, update/rollback strategy

V. DISCUSSION

The corpus supports three broad conclusions. First, publication activity is rising rapidly, but the evidence base remains small: only 16 of 31 records are primary DAS-with-ML infrastructure studies. Second, methodological diversity is increasing, yet application coverage is thin. Third, quality assessment shows strong performance reporting but weak reproducibility and uneven real-world validation. These observations justify a cautious interpretation of apparent "gaps": the cross-tabulation is useful for identifying under-represented combinations within this review, but its empty cells may result from corpus size, search boundaries, or publication practices rather than genuine absence across the entire field.

CNN prevalence requires analytical rather than purely descriptive interpretation. DAS data are naturally arranged as dense channel-by-time matrices and are frequently transformed into spectrogram-like or image-like representations, making 2D convolution a convenient way to learn local spatial and temporal patterns [10]. CNNs also benefit from mature implementations, reusable architectures, and comparatively straightforward training. Their prevalence therefore reflects a strong representation-method fit and methodological accessibility; it does not prove that CNNs are intrinsically superior for all DAS tasks. Recent few-shot, graph, diffusion, and self-supervised approaches [11], [12], [28] are especially relevant where labels are scarce, spatial topology matters, or anomalies differ from training events.

Dataset heterogeneity is a central barrier to generalisation. The 16 primary studies mix controlled laboratory events, field deployments, mixed settings, and simulation, and they do not use a common acquisition schema. Sampling frequency, spatial resolution or gauge length, channel spacing, preprocessing, sensing geometry, and calibration are reported with different levels of detail. Annotation conditions also vary: controlled studies can assign event labels from designed experiments, whereas field studies may rely on operational logs, manual interpretation, or task-specific reference systems. Class-wise distributions and annotation uncertainty are not consistently exposed. Consequently, a model trained on one installation may learn site-specific coupling, noise, or event signatures rather than infrastructure-invariant features. Future benchmarks should therefore publish acquisition metadata, class counts, annotation procedures, environmental conditions, and standardised train/validation/test partitions in addition to raw signals.

Performance values are likewise not directly interchangeable across the corpus. Classification studies emphasise accuracy, precision, recall, F1-score, or confusion matrices; regression studies use continuous-error measures; signal-enhancement and reconstruction work uses signal-quality or reconstruction criteria; and anomaly-detection studies use threshold- or area-under-curve-based measures. Validation also ranges from laboratory hold-out testing and cross-validation to field evaluation, simulation, and mixed protocols. A high classification accuracy in a balanced controlled dataset therefore cannot be ranked directly against an F1- or AUC-based field result, nor against a denoising or regression metric. Future DAS-ML studies should report task-specific core metrics together with per-class results, split definitions, repeated runs where stochastic training is used, and cross-site or cross-condition tests whenever the claimed contribution concerns generalisation.

Computational evidence is substantially thinner than predictive-performance evidence. Shi et al. [10], for example, report a compact event-recognition network and retraining time, while the railway study by Yurekli et al. [21] explicitly targets real-time hazard detection. However, systematic reporting of parameter count, floating-point or multiply-accumulate operations, inference latency on named hardware, peak memory, throughput, and energy/power is uncommon. This limits claims about scalability and edge readiness. For

long DAS arrays that can generate high-throughput streams, computational cost is part of model validity: a highly accurate model that cannot process the required channel rate or operate within edge memory and power constraints may be unsuitable for deployment.

Data quality and long-term maintenance deserve equal emphasis. Sensor configuration, thermal-mechanical cross-sensitivity, installation conditions, low-SNR noise, and multi-sensor fusion have already been recognised in adjacent distributed-sensing work [7]-[9], [17], [18], [20], [26]. In practice, calibration drift, environmental noise, fibre ageing, missing or corrupted channels, changing coupling conditions, and signal degradation can shift the input distribution after deployment. Yet the primary corpus contains little evidence on concept drift, online learning, continuous adaptation, recalibration schedules, or rollback/model-maintenance strategies. Robust deployment should therefore include explicit quality-control gates, missing-data stress tests, drift detection, periodic recalibration, and controlled model updates rather than treating the trained model as static.

These findings refine the five research gaps (Table VIII). Cross-infrastructure generalisation should explicitly include domain shift and concept drift; benchmark development should standardise acquisition and annotation metadata as well as splits; physics-data-driven integration should incorporate sensing physics and calibration constraints; interpretability should include uncertainty and confidence estimation for safety-relevant decisions; and operational deployment should combine model compression with latency, memory, energy, robustness, and maintenance evaluation. Cloud and storage architectures [25] may support multi-site analytics, but long-term DAS systems will require co-design across sensing hardware, signal quality, ML models, and deployment infrastructure.

TABLE VIII. RESEARCH GAPS, EVIDENCE, AND PROPOSED DIRECTIONS

Gap	Evidence from the corpus	Proposed research direction
Cross-infrastructure generalisation and drift	All 16 primary studies are tied to a specific infrastructure/site/task; no systematic cross-infrastructure or longitudinal drift study was identified	Cross-site/domain adaptation, transfer and multi-task learning, drift detection, online or periodic adaptation with rollback controls
Standardised benchmarks and open datasets	Only one public event dataset [5] and one validated synthetic-data pipeline [14] are represented; acquisition and annotation reporting are heterogeneous	Open multi-site DAS repositories, standard splits, acquisition metadata, class-balance and label-quality documentation, agreed core metrics
Physics-data-driven integration	Primary ML models rarely integrate Rayleigh-backscatter, phase-demodulation, wave-propagation, calibration, or coupling constraints directly	Physics-informed neural networks (PINNs), hybrid model-based/data-driven learning, calibration-aware loss functions and constraints
Interpretability and uncertainty	No primary study systematically reports explainable artificial intelligence (XAI) analyses together with calibrated prediction uncertainty	XAI adapted to spatiotemporal DAS inputs and graph models; calibrated confidence, uncertainty quantification, failure-case analysis
Operational robustness and edge deployment	Seven studies are laboratory-only; computational reporting is sparse; long-term drift, fibre ageing, missing-data robustness, maintenance, and edge energy are minimally evaluated	Model compression and hardware-aware design; latency/memory/energy benchmarks; robustness stress tests; data-quality monitoring; drift-aware maintenance and controlled updating

VI. CONCLUSION

This review maps the convergence of distributed acoustic sensing, broader distributed fibre-optic sensing, and machine learning for infrastructure monitoring over 2015–2025. From 291 records identified through Web of Science, Scopus, and IEEE Xplore, PRISMA-guided screening yielded 31 publications, including 16 primary DAS-with-ML studies. Publication output accelerates sharply from 2023 onward, while the primary evidence remains concentrated in perimeter security, traffic, railway, and structural-health applications.

CNNs remain prominent, but their dominance is best explained by the image-like spatiotemporal structure of DAS data, mature implementation ecosystems, and convenience rather than proven universal superiority. The more important field-level limitation is comparability: datasets differ in sensing environment and acquisition settings; labels, class balance, metrics, and validation protocols are inconsistently reported; computational cost is rarely quantified in deployment-relevant terms; and long-term robustness to drift, calibration changes, fibre ageing, missing data, and evolving operating conditions is largely untested.

The resulting research agenda therefore emphasises cross-site and cross-infrastructure generalisation, standardised open benchmarks with richer metadata, physics-informed learning, interpretable and uncertainty-aware predictions, and hardware-aware deployment with explicit latency, memory, energy, data-quality, and maintenance evaluation. These priorities shift the field from isolated high-accuracy demonstrations toward reproducible, comparable, and operationally trustworthy DAS-ML systems.

VII. LIMITATIONS

Several limitations should be noted. The analysis covers three databases and English-language records only, which may under-represent regional or non-indexed work. The corpus is small (31 records) and heterogeneous in document type and topic; consequently, bibliometric patterns and empty cells in the ML-application matrix should be interpreted descriptively rather than as definitive evidence of field-wide absence. Some acquisition, annotation, computational, and deployment attributes are inconsistently reported in the source studies, limiting quantitative normalisation across the corpus. Metadata normalisation may also introduce minor uncertainty. Finally, most primary studies were published in 2024–2025 and have

had limited time to accumulate citations or long-term deployment evidence.

ACKNOWLEDGMENT

The authors gratefully acknowledge Universiti Teknologi PETRONAS (UTP) for the research environment and infrastructure that supported this study. This study was funded by TOTALENERGIES EP MALAYSIA under cost centre 015MD0-169.

CEM MoE: A Lightweight Sparse Mixture of Experts Framework for Empathetic Dialogue Generation

Zhinan Gou*, He Liu, and Yufan Wang
School of Big Data and Intelligent Engineering, Hebei University of Economics and Business, Shijiazhuang, China

***Abstract*—Empathetic dialogue generation requires models to understand user emotions and produce fluent, relevant, and emotionally appropriate responses. Existing lightweight models offer favorable deployment efficiency, but shallow emotion prediction layers limit their ability to represent fine-grained and dynamically changing emotional states. To address this limitation, CEM-MoE, a lightweight sparse mixture of experts (MoE) framework based on the Commonsense-aware Empathetic Chatting Machine (CEM), is proposed. Unlike the original CEM, CEM-MoE employs two independently routed sparse MoE streams to separately model emotional information from dialogue history and the current utterance. A bounded density-aware fusion mechanism integrates the two emotion distributions, where normalized utterance length serves as a lightweight density proxy and a sigmoid gate constrains the fusion coefficient to a valid range. Auxiliary load balancing regularization and label smoothing further improve expert utilization and generation stability. Experiments on the EmpatheticDialogues and ESConv datasets show that CEM-MoE achieves competitive generation performance with only marginal additional overhead. Compared with CEM, CEM-MoE reduces PPL from 37.76 to 36.59 and improves emotion accuracy from 32.10% to 35.47%, while increasing the parameter count by only 0.12M. Expert activation analysis reveals no obvious expert collapse, and human evaluation indicates higher scores in empathy, fluency, and relevance. The results verify that the dual-stream sparse MoE with density-aware fusion is effective for lightweight fine-grained empathetic dialogue modeling. The source code is publicly available at https://github.com/ZhinanGou/CEM-MoE.**

Keywords*—Empathetic dialogue generation; sparse mixture of experts; lightweight dialogue model; emotion modeling; expert routing

I. Introduction

Empathetic dialogue generation aims to enable dialogue systems to understand a user's emotional state and produce responses that are emotionally appropriate, semantically relevant, and linguistically fluent [1]. Unlike open-domain dialogue, empathetic dialogue requires not only grammatically correct responses but also accurate recognition of emotional cues expressed throughout a conversation. Responses are expected to remain consistent with the dialogue context while reflecting appropriate emotional understanding. Such capabilities are valuable for psychological support, intelligent customer service, emotional assistance, and human-computer interaction [2].

Large language models demonstrate strong performance in dialogue generation and emotion understanding [3], [4]. Large-scale pretraining and extensive model capacity enable natural and coherent responses while providing a certain level of understanding of complex emotional expressions. However, inference with large language models requires considerable computational resources, memory, and response latency [5], [6]. Recent LLM-based empathetic dialogue studies also show the potential of commonsense-enhanced generation [7]. The resulting computational and memory demands can make direct deployment infeasible in resource-constrained real-time interaction, edge computing, and privacy-sensitive scenarios. Improving empathetic dialogue generation under limited computational resources therefore remains an important research problem.

Compared with large language models, lightweight empathetic dialogue models are more suitable for practical deployment. Existing methods generally improve emotional appropriateness through emotion classification, emotion embeddings, commonsense knowledge, or multiple decoder architectures. For example, MoEL employs multiple emotion listeners to model different emotional states [8]. MIME enhances empathetic responses through emotion simulation [9]. The Commonsense-aware Empathetic Chatting Machine (CEM) introduces commonsense knowledge to improve the understanding of implicit emotions and user intentions [10]. Although these methods achieve encouraging performance, fine-grained emotion modeling remains insufficient. Many lightweight models still rely on shallow emotion prediction layers or shared representation spaces and therefore struggle to model complex, mixed, and dynamically changing emotional states. When emotions are implicitly expressed or emotional shifts arise across the dialogue history, generated responses tend to become generic, template-based, or emotionally inadequate.

Sparse mixture of experts (MoE) provides a promising solution to this problem. A gating network activates only a small number of experts during inference, which increases representation capacity without introducing substantial computational overhead. Different experts are able to learn complementary emotion patterns, alleviating the limited expressive capability of a single emotion prediction layer. Nevertheless, directly applying sparse mixture of experts introduces new challenges. Without appropriate regularization, the gating network may repeatedly select only a few experts, resulting in severe imbalance among experts. In addition, dialogue history and the current utterance contribute differently to emotion recognition. The current utterance usually provides explicit emotional cues, whereas dialogue history offers emotional evolution and contextual information. Inadequate

modeling may either ignore useful historical information or introduce unnecessary noise.

To address these issues, a lightweight sparse mixture of experts framework, named CEM-MoE, is proposed for empathetic dialogue generation. The framework is built upon the commonsense-enhanced empathetic dialogue model CEM. A dual-stream sparse emotion expert architecture is introduced during emotion modeling. One stream captures historical contextual emotion, while the other models emotional information contained in the current utterance. Each stream activates only the Top K experts through a gating network, and expert outputs are aggregated by weighted combination to improve emotion representation. Auxiliary load balancing regularization is further incorporated to encourage balanced expert utilization, while label smoothing improves generation stability during training.

Emotion fusion also requires careful consideration. Directly constructing fusion weights from utterance length is susceptible to scale variation and activation saturation, and unconstrained fusion weights cannot guarantee a valid probability distribution. A bounded density-aware emotion fusion mechanism is therefore introduced. Utterance length is first normalized to reduce scale variation. Raw density and scaled density features are then extracted and combined through a bounded fusion gate to generate the fusion coefficient. The final emotion distribution forms a valid combination of historical emotion and current emotion distributions.

The current utterance stream models direct emotional cues contained in the current user input. During both training and inference, this branch only receives the current utterance and its encoded representation. Ground truth responses, emotion labels, and any target side information are excluded from the input, ensuring consistent model inputs and avoiding information leakage.

Experiments are conducted on the EmpatheticDialogues dataset through both standard evaluation and controlled ablation studies. Results demonstrate that CEM-MoE achieves competitive generation performance while maintaining a relatively small parameter scale. Ablation studies further show that sparse mixture of experts, auxiliary load balancing regularization, and label smoothing mainly improve generation modeling by reducing perplexity and enhancing training stability. Experimental results also indicate that current utterance information contributes strongly to automatic evaluation on EmpatheticDialogues. Consequently, the role of the dual stream architecture is further examined from the perspectives of historical emotion modeling and expert utilization behavior rather than relying solely on automatic metrics.

Several complementary analyses are conducted. Additional experiments on ESConv evaluate the applicability of CEM-MoE to emotional support dialogue scenarios. Expert activation statistics together with emotion expert activation heatmaps examine routing behavior across both emotion streams and confirm that obvious expert collapse does not occur. Model efficiency is evaluated in terms of parameter size, inference latency, throughput, and peak GPU memory. Human evaluation and qualitative case analysis further assess empathy, fluency, and relevance beyond automatic metrics.

The main contributions are summarized as follows:

- A lightweight sparse mixture of experts framework is proposed for empathetic dialogue generation. The proposed framework enhances emotion representation with marginal additional computation by integrating sparse emotion experts into the CEM backbone and activating only a subset of experts through gated routing.
- A dual-stream emotion modeling architecture is designed to separately model historical contextual emotion and current utterance emotion. A bounded density-aware fusion mechanism is further introduced to integrate both emotion distributions while guaranteeing valid fusion weights and probabilistic consistency.
- Extensive experiments are conducted on EmpatheticDialogues and ESConv. Automatic evaluation, expert activation analysis, efficiency assessment, human evaluation, and case analysis provide a comprehensive evaluation of generation performance, expert utilization behavior, and deployment efficiency.

II. Related Work

A. Empathetic Dialogue Generation

Empathetic dialogue generation aims to enable dialogue systems to understand user emotional states and produce contextually appropriate responses with emotional responsiveness. Unlike general open-domain dialogue generation, empathetic dialogue generation focuses not only on grammatical correctness and semantic coherence, but also on the perception of user emotions, situations, and psychological needs. Therefore, the task usually requires modeling both explicit emotional cues and implicit emotional causes in user utterances.

Early studies on empathetic dialogue mainly rely on emotion labels, emotion embeddings, or retrieval-based methods to control response style. With the introduction of EmpatheticDialogues [1], generative empathetic dialogue models became a major research direction. The dataset provides a standard benchmark for empathetic dialogue generation and promotes the development of emotion-aware generation models. Subsequent studies further explore different emotion modeling strategies. MoEL employs multiple emotion listeners to model different emotional states and dynamically selects emotion-related representations according to the input [8]. MIME attempts to generate responses closer to human empathetic reactions through emotion simulation [9]. CEM introduces commonsense knowledge to improve the understanding of user situations, implicit emotions, and potential intentions [10]. Other studies further improve empathetic response generation through interactive emotion modeling, external knowledge enhancement, commonsense retrieval, and co-curricular learning [11]-[14]. Recent methods

also explore coarse-to-fine cognition-affection alignment and search-enhanced response generation [15], [16].

These methods demonstrate the importance of emotion information and commonsense knowledge for empathetic response generation, but several limitations remain. First, many lightweight models still rely on shallow linear mappings or shared representation spaces during emotion prediction, which limits their ability to capture complex, mixed, and fine-grained emotional states. Second, emotions in multi-turn dialogue do not always remain stable. The current utterance may directly express a new emotional state, while dialogue history provides the background of emotional change. Without an explicit mechanism to distinguish and integrate these two sources of information, models tend to generate generic or emotionally inadequate responses. Based on this observation, sparse mixture-of-experts-based emotion modeling is introduced into CEM to enhance emotion representation in lightweight models.

B. Lightweight Emotion Modeling and Sparse Mixture of Experts

Large language models exhibit strong capabilities in dialogue understanding and emotional generation [3], [4], [7], but large parameter scale and high inference cost limit their use in real-time interaction and edge deployment [5], [6]. In contrast, lightweight empathetic dialogue models have lower computational cost and better deployment feasibility. Improving emotion perception under a limited parameter budget therefore becomes an important issue in empathetic dialogue generation.

Sparse mixture of experts provides a feasible solution for lightweight emotion modeling [17], [18]. A mixture of experts architecture usually consists of multiple expert networks and a gating network. The gating network selects a subset of experts according to input features. Compared with a standard fully connected structure, sparse expert activation expands representation capacity without substantially increasing inference cost. In empathetic dialogue generation, different experts can learn local representations for different emotional patterns, which alleviates the limited expressive ability of a single emotion prediction layer.

Existing expert-based models in large-scale language modeling and dialogue tasks often focus on scalable modeling, feature fusion, or task adaptation [18]-[20]. The use of sparse experts for fine-grained emotion representation in lightweight empathetic dialogue generation remains insufficiently explored. To address this issue, CEM-MoE keeps sparse expert modeling and further analyzes expert activation distributions and emotion expert heatmaps. The analysis observes expert usage in different emotion streams and examines whether obvious expert collapse occurs. Expert activation patterns are further compared across emotion categories to characterize routing behavior. Compared with analysis based only on final classification metrics, such statistics provide additional information about how experts are utilized within the sparse expert structure.

C. Multi-Turn Emotion Modeling and Emotion Fusion

Emotional states in multi-turn empathetic dialogue are dynamic. On the one hand, the current utterance usually contains the most direct emotional cues. On the other hand, dialogue history provides the background of emotion formation and the continuation of dialogue topics. Therefore, modeling the relationship between historical emotion and current emotion is essential for generating high-quality empathetic responses.

Existing methods usually model emotional continuity through emotion embeddings, context encoders, commonsense knowledge, or fixed fusion strategies [10]-[14]. These methods help maintain emotional consistency to a certain extent, but two limitations remain. First, fixed fusion strategies are difficult to adapt to the dynamic importance of historical information and current information across different samples. Second, if the fusion coefficient lacks reasonable constraints, the resulting emotion distribution may not have a clear probabilistic interpretation.

Density-based confidence measurement provides a perspective for characterizing information concentration in representation space [21]. In CEM-MoE, utterance length is instead adopted as a lightweight density proxy, and a bounded fusion gate is introduced to integrate historical and current emotion distributions. The current utterance length is first normalized to reduce the influence of length scale on density features. A bounded fusion gate is then used to generate the fusion coefficient and keep it within a valid range. In this way, the final emotion distribution can be regarded as a valid combination of historical emotion and current emotion distributions. The mechanism provides a more explicit structured fusion strategy for multi-turn emotion modeling.

D. Evaluation and Efficiency Analysis for Empathetic Dialogue

Evaluation of empathetic dialogue generation usually includes automatic evaluation and human evaluation [1], [10]. Automatic metrics are commonly used to measure perplexity, emotion prediction accuracy, and response diversity, such as PPL, Accuracy, and Distinct. These metrics are useful for reproduction and comparison, but they cannot fully reflect empathetic response quality. A response may achieve low perplexity while still lacking empathy or contextual relevance. Therefore, human evaluation is often used as a complement to automatic metrics, assessing whether generated responses are natural and appropriate in terms of empathy, fluency, and relevance.

In addition, a key objective of lightweight empathetic dialogue models is to reduce deployment cost. Reporting only the number of parameters is not sufficient to reflect practical deployment efficiency. Real applications also require attention to inference latency, throughput, and peak GPU memory. Therefore, beyond parameter size, model efficiency is evaluated from inference latency, throughput, and peak memory usage.

III. Proposed Method

The overall architecture of CEM-MoE is shown in Fig. 1. The framework consists of four components: input encoding, dual-stream sparse mixture-of-experts emotion decoding, bounded density-aware emotion fusion, and response generation. Historical dialogue context and the current user

utterance are modeled through two independent emotion streams, whose predicted emotion distributions are integrated by a bounded fusion mechanism. The fused emotion representation is then used to guide empathetic response generation.

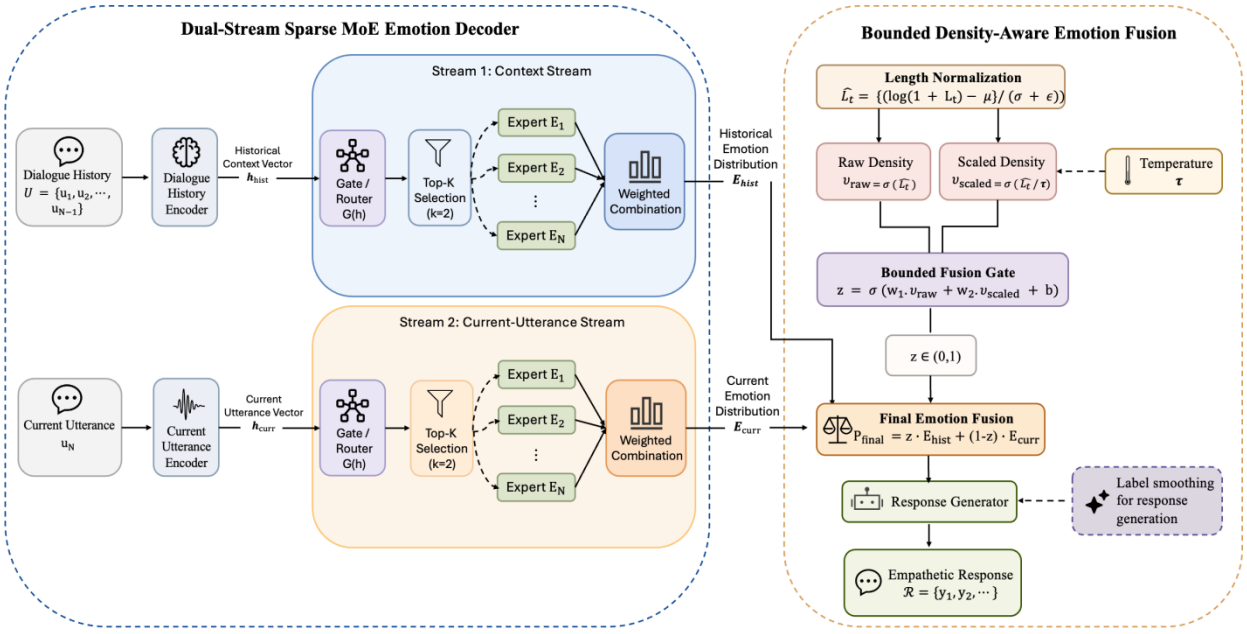

Fig. 1. Overall architecture of CEM-MoE.

A. Problem Definition

Given a multi-turn dialogue history,

$$U = \{u_1, u_2, \ldots, u_{N-1}\} \quad (1)$$

where, u_i denotes the i-th utterance in the dialogue history. The current user utterance is denoted as u_N.

The objective is to generate a semantically relevant and empathetic response according to the dialogue history U and the current utterance u_N:

$$R = \{y_1, y_2, \ldots, y_T\} \quad (2)$$

where, y_t denotes the t-th token in the response. During training, each sample contains the dialogue context, the current utterance, the ground truth response, and the emotion label. The model jointly optimizes two objectives. One is to predict the current emotional state of the user, and the other is to generate a contextually appropriate empathetic response.

The current utterance stream only uses the current user utterance and its encoded representation during both training and inference. Ground truth responses, ground truth emotion labels, and any target side information are not used as inputs. Such a setting avoids information leakage and keeps the input form consistent between training and inference.

B. Input Encoding

The model first encodes the dialogue history and the current utterance separately. Following CEM, both the dialogue history and the current utterance are encoded by Transformer encoders initialized with 300-dimensional pretrained GloVe embeddings. The two encoders use the same architecture but maintain independent parameters to preserve stream-specific emotion information. For the dialogue history U, a dialogue history encoder is used to obtain the historical context representation:

$$h_{hist} = \text{Encoder}_{hist}(U) \quad (3)$$

where, h_{hist} denotes the context vector encoded from the multi-turn dialogue history. The representation captures emotional background, topic continuation, and user state changes appearing in previous turns.

For the current utterance u_N, a current utterance encoder is used to obtain the current utterance representation:

$$h_{curr} = \text{Encoder}_{curr}(u_N) \quad (4)$$

where, h_{curr} denotes direct emotional cues contained in the current user input. Compared with the dialogue history, the current utterance usually expresses the current emotional state more directly. Therefore, a separate current utterance stream is built for subsequent emotion modeling.

Separate encoding explicitly distinguishes the dialogue history from the current utterance, rather than simply concatenating all inputs and feeding them into the same emotion prediction layer. The design has two advantages. First, the dialogue history and the current utterance can learn different emotion representations. Second, the fusion mechanism can dynamically integrate the two kinds of emotional information, instead of using a fixed strategy for multi-turn emotional changes.

C. Dual Stream Sparse Mixture of Experts Emotion Decoder

Traditional lightweight empathetic dialogue models usually convert context representations into emotion distributions

through a single linear mapping. The structure is simple and computationally efficient, but its expressive capacity is limited. Complex, mixed, and fine-grained emotional states are difficult to model with such a shallow structure. To improve emotion representation in lightweight models, a dual-stream sparse mixture-of-experts emotion decoder is introduced, following the general idea of sparse expert activation [17], [18].

The decoder contains two independent emotion streams. The first stream is the context stream, which models emotional background in dialogue history. The second stream is the current utterance stream, which models direct emotional cues in the current user utterance. The two streams share the same structure but use independent parameters.

For an arbitrary input representation h, the sparse mixture of experts module contains N_e expert networks:

$$\{E_1, E_2, \dots, E_{N_e}\}$$

Each expert network is implemented as a lightweight multilayer perceptron and learns local representations for different emotional patterns. The gating network first generates routing scores for all experts according to the input representation:

$$s = W_g h + b_g \tag{5}$$

where, W_g and b_g are learnable parameters, and s denotes the expert routing scores. To reduce computational cost, the model only selects the K experts with the highest scores:

$$S = \mathrm{TopK}(s, K) \tag{6}$$

where, $\mathcal{S}$ denotes the set of activated experts. After Top-K selection, the original routing scores do not directly form normalized weights over the selected experts. Therefore, the weights are recalculated within the selected expert set:

$$\tilde{g}_i = \frac{\exp(s_i)}{\sum_{j \in \mathcal{S}} \exp(s_j)}, \quad i \in \mathcal{S} \tag{7}$$

The final expert output is obtained by weighted summation:

$$o = \sum_{i \in \mathcal{S}} \tilde{g}_i \, E_i(h) \tag{8}$$

Sparse activation involves only a small subset of experts, enriching emotion representations while controlling inference cost. Compared with activating all experts, Top K routing is more suitable for lightweight empathetic dialogue generation.

For the context stream, the input is h_{hist}, and the sparse mixture of experts module produces the historical emotion representation:

$$o_{hist} = \mathrm{MoE}_{hist}(h_{hist}) \tag{9}$$

A classification layer then gives the historical emotion distribution:

$$E_{hist} = \mathrm{Softmax}(W_{hist} o_{hist} + b_{hist}) \tag{10}$$

For the current utterance stream, the input is h_{curr}, and the sparse mixture of experts module produces the current utterance emotion representation:

$$o_{curr} = \mathrm{MoE}_{curr}(h_{curr}) \tag{11}$$

The current utterance emotion distribution is further obtained as

$$E_{curr} = \mathrm{Softmax}(W_{curr} o_{curr} + b_{curr}) \tag{12}$$

where, E_{hist} and E_{curr} denote the emotion distributions predicted from the dialogue history and the current utterance, respectively. The dual stream structure explicitly distinguishes historical contextual emotion from current utterance emotion, and also provides a structural basis for subsequent emotion fusion and expert routing analysis.

D. Auxiliary Load Balancing Regularization

Sparse mixture of experts models tend to suffer from imbalanced expert utilization. The gating network may repeatedly select only a few experts, while other experts are rarely activated. Such a phenomenon leads to insufficient training of some experts and reduces the effectiveness of the sparse expert structure.

To mitigate this issue, auxiliary load balancing regularization is adopted. For each emotion stream, let f_i denote the proportion of samples in a batch that select the i-th expert, and let p_i denote the average routing probability assigned to the same expert. The load balancing loss for one emotion stream is defined as

$$\mathcal{L}_{aux}^{stream} = N_e \sum_{i=1}^{N_e} f_i \, p_i \tag{13}$$

where, N_e denotes the number of experts. The loss encourages more balanced expert usage and prevents routing from concentrating on only a few experts.

Since CEM-MoE contains both the context stream and the current utterance stream, the final auxiliary load balancing loss is formed by the losses of the two streams:

$$\mathcal{L}_{aux} = \frac{1}{2}\left(\mathcal{L}_{aux}^{hist} + \mathcal{L}_{aux}^{curr}\right) \tag{14}$$

where, $\mathcal{L}_{aux}^{hist}$ denotes the load balancing loss of the context stream, and $\mathcal{L}_{aux}^{curr}$ denotes the load balancing loss of the current utterance stream. The regularization mainly improves expert utilization and training stability rather than directly optimizing emotion classification accuracy.

E. Bounded Density Aware Emotion Fusion

Historical emotion and current emotion are both important in multi-turn dialogue. Dialogue history provides emotional background and conversational continuity, while the current utterance usually contains the most direct emotional expression. Therefore, an effective fusion mechanism is required to integrate E_{hist} and E_{curr}.

Directly using current utterance length to construct density features may cause rapid saturation of the Sigmoid function due to scale variation, reducing the discriminative ability of the features. In addition, if the fusion coefficient lacks boundary constraints, the final emotion distribution may fail to remain a valid probability distribution. To address these issues, a bounded density-aware emotion fusion mechanism is adopted.

The length-based feature serves as a lightweight density proxy rather than a direct implementation of semantic density in semantic representation space.

First, the current utterance length L_t is normalized as

$$\hat{L}_t = \frac{\log(1 + L_t) - \mu}{\sigma + \epsilon} \quad (15)$$

where, μ and σ denote the mean and standard deviation of utterance lengths in the training set, ϵ is a smoothing term to avoid division by zero, and $\hat{L}_t$ denotes the normalized length feature. The normalization reduces the influence of raw length scale on the Sigmoid function.

The model then calculates the raw density feature and the scaled density feature:

$$v_{raw} = \sigma(\hat{L}_t) \quad (16)$$

$$v_{scaled} = \sigma(\hat{L}_t/\tau) \quad (17)$$

where, τ is a temperature parameter that adjusts the smoothness of density features. v_{raw} is directly obtained from the normalized length feature, and v_{scaled} is obtained after temperature scaling.

To keep the fusion coefficient within a valid range, a bounded fusion gate generates the coefficient z:

$$z = \sigma(w_1 v_{raw} + w_2 v_{scaled} + b) \quad (18)$$

where, w_1, w_2, and b are learnable parameters. Since z is constrained by the Sigmoid function, it satisfies:

$$z \in (0,1)$$

The final emotion distribution is obtained by fusing the historical emotion distribution and the current utterance emotion distribution:

$$P_{final} = zE_{hist} + (1 - z)E_{curr} \quad (19)$$

Since $z \in (0,1)$, and both E_{hist} and E_{curr} are probability distributions, P_{final} is a convex combination of the two distributions and remains a valid probability distribution. The fusion mechanism integrates historical emotion information and current utterance emotion information in a bounded, differentiable, and probabilistically valid manner.

F. Response Generation

After obtaining the final emotion distribution P_{final}, the model uses it as emotional condition information for the response generator. The generator produces the final response according to the historical context representation, the current utterance representation, and the fused emotion distribution.

At the t-th decoding step, the generator predicts the probability distribution of token y_t:

$$P(y_t|y_{<t}, U, u_N, P_{final}) = \text{Decoder}(y_{<t}, h_{hist}, h_{curr}, P_{final}) \quad (20)$$

where, $y_{<t}$ denotes the previously generated tokens. The generation probability of the whole response is

$$P(R|U, u_N) = \prod_{t=1}^{T} P(y_t|y_{<t}, U, u_N, P_{final}) \quad (21)$$

By introducing the fused emotion distribution, the response generator considers not only semantic context but also emotional state information. The design reduces the tendency to rely entirely on frequent safe responses and helps generate more emotionally responsive text.

G. Label Smoothing for Response Generation

Empathetic dialogue generation often suffers from frequent template responses. A model may overfit common expressions in the training set, such as I am sorry to hear that or That is great. These responses may lead to low perplexity, but they do not necessarily provide sufficient empathy or contextual relevance.

To alleviate overfitting, label smoothing is applied to response generation [22]. Let y denote the one-hot distribution of the ground truth token. The smoothed label distribution is defined as

$$y^{LS} = (1 - \epsilon)y + \frac{\epsilon}{|V|}\mathbf{1} \quad (22)$$

where, ϵ is the smoothing coefficient, $|V|$ denotes the vocabulary size, and $\mathbf{1}$ is an all-one vector over the vocabulary dimension. The generation loss is defined as the cross-entropy between the predicted distribution and the smoothed label distribution:

$$\mathcal{L}_{gen}^{LS} = -\sum_{t=1}^{T}\sum_{w \in V} y_{t,w}^{LS} \log P(y_t = w) \quad (23)$$

Label smoothing reduces overconfidence in a single target token and makes training more stable. Ablation results show that removing label smoothing increases perplexity, while emotion classification accuracy may increase. These results suggest that label smoothing mainly improves generation modeling stability rather than improving all metrics at the same time.

H. Training Objective

The training objective consists of three parts, including generation loss, emotion classification loss, and auxiliary load balancing loss.

The generation loss $\mathcal{L}_{gen}^{LS}$ optimizes response generation quality.

The emotion classification loss supervises the final emotion distribution P_{final} with the ground truth emotion label:

$$\mathcal{L}_{emo} = -\log P_{final}(e) \quad (24)$$

where, e denotes the ground truth emotion label.

The auxiliary load balancing loss $\mathcal{L}_{aux}$ reduces expert routing imbalance.

The final training objective is

$$\mathcal{L} = \mathcal{L}_{gen}^{LS} + \alpha\mathcal{L}_{emo} + \lambda\mathcal{L}_{aux} \quad (25)$$

where, α and λ are loss weighting coefficients. By jointly optimizing these terms, the model learns response generation, emotion recognition, and expert routing allocation at the same time.

Different loss terms correspond to different functional objectives. The generation loss ensures response quality, the emotion classification loss enhances emotion perception, the auxiliary load balancing loss alleviates expert collapse, and label smoothing improves generation stability. The joint objective aligns the training targets with the functional modules in the model architecture.

IV. EXPERIMENTS

CEM-MoE is evaluated from several perspectives, including automatic evaluation, ablation analysis, additional evaluation on ESConv, expert routing, efficiency assessment, human evaluation, and case analysis.

A. Experimental Settings

1) Datasets: Experiments are mainly conducted on EmpatheticDialogues [1]. The dataset is a widely used benchmark for empathetic dialogue generation, containing about 25,000 multi-turn dialogues with 32 emotion categories. Following existing work, the dataset is divided into training, validation, and test sets. The test set is used to evaluate response generation and emotion recognition. Given the dialogue context and the current user utterance, the model generates an empathetic response and predicts the corresponding emotion category.

To further examine model applicability in different emotional dialogue scenarios, an additional evaluation is conducted on ESConv [2]. ESConv is a multi-turn dataset for emotional support conversation and differs from EmpatheticDialogues in dialogue objective, emotion distribution, and response style. The dataset is therefore used to examine whether CEM-MoE remains effective in a different emotional support dialogue setting rather than to evaluate cross-domain transfer. Both Original CEM and CEM-MoE are trained and evaluated on the standard ESConv split using the same optimization and decoding settings unless otherwise stated.

2) Evaluation metrics: Model performance is evaluated with both automatic metrics and human evaluation. Automatic metrics include perplexity, emotion accuracy, and generation diversity.

Perplexity measures the language modeling ability for target responses. A lower value implies tighter alignment to ground truth responses. Emotion accuracy measures the ability to predict user emotion categories. A higher value indicates better emotion recognition. Generation diversity is evaluated by Dist-1 and Dist-2, which measure the proportions of distinct unigrams and bigrams in generated responses. Higher scores correspond to more diverse and less redundant outputs.

Empathetic dialogue generation cannot be fully evaluated by automatic metrics alone. Low perplexity may come from safe, frequent, or template-based responses, which do not necessarily contain sufficient empathy or contextual relevance. Therefore, human evaluation is also conducted. Three aspects are considered, including empathy, fluency, and relevance. Each score ranges from 1 to 5, and a higher score indicates better response quality from the perspective of human evaluators.

3) Implementation details: CEM is used as the base framework, and a dual-stream sparse mixture-of-experts structure is introduced into the emotion modeling stage. The context encoder is initialized with 300-dimensional pretrained GloVe word embeddings [23], and the hidden size is set to 300. The dual-stream sparse mixture of experts emotion decoder contains a context stream and a current utterance stream. Each stream contains 4 expert networks, and Top K is set to 2, which means only the 2 experts with the highest routing scores are activated each time.

The model is implemented with PyTorch [24] and trained on a single NVIDIA RTX 4090 GPU. Adam is used as the optimizer with a learning rate of 1×10^{-4}. The batch size is set to 16, and the model is trained for 20 epochs. The label smoothing coefficient is set to 0.1, and the auxiliary load balancing loss weight λ is set to 0.01. Beam search is used during decoding, with a beam size of 5. The temperature parameter τ is set to 2.0, and the emotion classification loss weight α is set to 1.0.

To evaluate practical deployment overhead, Original CEM and CEM-MoE are compared under the same hardware environment in terms of parameter size, inference latency, throughput, and peak GPU memory. This setting is used to analyze the extra computational cost introduced by sparse experts and to examine whether the model retains lightweight characteristics.

B. Main Results on EmpatheticDialogues

To evaluate the overall performance of CEM-MoE, it is compared with several representative empathetic dialogue generation models, including Transformer [1], CEM [10], KEMP [14], CASE [15], and SeeKeR [16]. The results are shown in Table I.

Table I shows that CEM-MoE obtains the lowest PPL, indicating that sparse expert-based emotion modeling helps improve response generation modeling. Compared with the original CEM, the emotion accuracy increases from 32.10% to 35.47%, which suggests that the emotion expert structure enhances emotion perception to some extent. CEM-MoE also achieves higher Dist-1 and Dist-2, indicating better response diversity.

TABLE I. MAIN RESULTS ON EMPATHETICDIALOGUES

Model	PPL ↓	Acc ↑	Dist-1 ↑	Dist-2 ↑	Params
Transformer	37.80	-	0.53	1.89	12.55M
CEM	37.76	32.10	0.49	3.24	17.49M
KEMP	37.00	34.80	0.55	3.61	17.90M
CASE	36.92	34.55	0.63	3.42	20.55M
SeeKeR	37.09	37.10	0.61	3.23	32.10M
CEM-MoE	36.59	35.47	0.78	3.88	17.61M

CEM-MoE does not achieve the best result across every metric. SeeKeR still obtains higher emotion accuracy, and the PPL improvement of CEM-MoE over CASE is relatively limited. Therefore, CEM-MoE is not described as an overall best model. Instead, the results show that CEM-MoE achieves competitive generation performance with a relatively small parameter scale, demonstrating a favorable balance between performance and efficiency.

C. Ablation Study

To analyze the contribution of each core component, sparse experts, auxiliary load balancing regularization, and label smoothing are removed separately. The results are shown in Table II.

TABLE II. ABLATION RESULTS ON EMPATHETICDIALOGUES

Variant	PPL ↓	Dist-1 ↑	Dist-2 ↑	Acc ↑
CEM-MoE	36.59	0.78	3.88	35.47
w/o Sparse MoE	37.24	0.67	3.81	35.78
w/o Aux Loss	37.07	0.59	3.72	36.46
w/o Label Smoothing	36.95	0.46	3.64	37.43

As shown in Table II, removing Sparse MoE increases PPL from 36.59 to 37.24, which indicates that the sparse expert structure helps improve generation modeling. Compared with a single linear emotion prediction layer, multiple experts provide more flexible local representations for different emotional patterns and alleviate the limited emotion representation capacity of lightweight models.

After removing auxiliary load balancing regularization, PPL increases to 37.07, indicating that the regularization contributes to training stability and balanced expert utilization. Although the variant obtains slightly higher Acc, the result does not mean that load balancing is ineffective. The main role of load balancing is not to directly improve emotion classification accuracy, but to avoid routing collapse onto a small subset of experts and to stabilize the generation modeling process.

After removing label smoothing, PPL increases to 36.95, and Dist-2 decreases to 3.64. The result suggests that label smoothing helps reduce overfitting to frequent expressions. The variant obtains higher Acc, which indicates that label smoothing does not consistently boost emotion classification accuracy. Its main contribution lies in improving response generation stability.

Overall, Sparse MoE, Aux Loss, and Label Smoothing have positive effects on PPL and generation diversity. These components mainly improve response generation modeling and training stability. Meanwhile, removing some regularization components increases Acc, indicating that these modules do not directly improve emotion classification accuracy in all cases. Therefore, the ablation results are interpreted conservatively, and no single module is described as producing consistent gains on all metrics.

D. Dual Stream Emotion Modeling and Fusion Behavior Analysis

To further analyze the roles of the context stream and the current utterance stream, three variants are listed separately, including Context only, Current only, and w/o Fusion. The experiment analyzes the influence of different emotion streams and fusion strategies on model behavior. The results are shown in Table III.

TABLE III. ANALYSIS OF EMOTION STREAMS AND FUSION BEHAVIOR

Variant	PPL ↓	Dist-1 ↑	Dist-2 ↑	Acc ↑
CEM-MoE	36.59	0.78	3.88	35.47
Context only	36.77	0.73	3.98	33.78
Current only	36.58	0.81	3.92	38.08
w/o Fusion	36.51	0.77	3.79	37.83

Table III shows that Current only and w/o Fusion achieve competitive performance on PPL and Acc. This suggests that the current utterance usually contains direct emotional cues in EmpatheticDialogues and contributes more clearly to automatic metrics. For example, the last user utterance often explicitly expresses emotions such as nervous, sad, happy, or grateful. A model relying only on the current utterance can still predict emotions and generate responses reasonably well.

Context only obtains higher Dist-2 but lower Acc. The result suggests that dialogue history may provide richer bigram combinations, but relying only on historical context is less beneficial for current emotion recognition. In multi-turn dialogue, earlier emotions do not always match the target response. Excessive dependence on historical emotion may affect current response prediction.

The w/o Fusion variant obtains strong PPL and Acc, but both Dist-1 and Dist-2 are lower than those of the full model. The result indicates that removing fusion may lead the model to generate more stable but less diverse responses. Such responses may be favorable for PPL, but they do not necessarily have better empathetic quality. Therefore, PPL and Acc are not used as the only criteria. Dist, human evaluation, expert routing, and case analysis are also considered for comprehensive judgment.

Based on these results, the dual stream structure is better interpreted as a way to organize contextual and current emotional cues and to support expert utilization analysis, rather than as a component that consistently improves all automatic metrics. Expert activation analysis further shows that the context stream and the current utterance stream have different expert usage patterns, indicating that the two streams provide different routing behaviors.

E. Comparison of Different Fusion Strategies

To further evaluate the effectiveness of the proposed bounded density-aware fusion mechanism, CEM-MoE is compared with two alternative fusion strategies: fixed average fusion and learned scalar fusion. Fixed average fusion assigns equal weights to historical and current emotion distributions, while learned scalar fusion introduces a learnable scalar coefficient without the proposed density-aware mechanism. All methods use the same dual-stream emotion representations and training settings. The results are shown in Table IV.

Table IV shows that CEM-MoE achieves the lowest PPL among the three fusion strategies, indicating improved response generation modeling. Learned Scalar Fusion yields higher diversity scores, suggesting that simple adaptive weighting can also boost response variation. Nevertheless, it does not explicitly account for the differing contributions of historical and current emotional information. The proposed bounded density-aware fusion mechanism offers a structured fusion strategy while preserving probabilistic consistency.

TABLE IV. COMPARISON OF DIFFERENT FUSION STRATEGIES

Model	PPL ↓	Dist-1 ↑	Dist-2 ↑	Acc ↑
CEM-MoE	36.6896	0.76	3.82	35.47
Fixed Average Fusion	37.4379	0.78	3.84	37.87
Learned Scalar Fusion	37.0666	0.85	4.09	37.98

F. Additional Evaluation on ESConv

To further examine model applicability in different emotional dialogue scenarios, an additional evaluation is conducted on ESConv. Since ESConv differs from EmpatheticDialogues in task formulation, emotion distribution, and dialogue objective, only Original CEM and CEM-MoE are compared. The purpose is to examine whether the proposed architecture remains effective when trained and evaluated in an emotional support dialogue setting. The results are presented in Table V.

TABLE V. RESULTS ON ESCONV

Dataset	Model	PPL ↓	Dist-1 ↑	Dist-2 ↑	Acc ↑
ESConv	Original CEM	60.02	0.56	3.71	45.26
ESConv	CEM-MoE	56.98	0.65	3.96	44.53

Table V shows that CEM-MoE reduces PPL from 60.02 to 56.98 on ESConv. Dist-1 increases from 0.56 to 0.65, and Dist-2 rises from 3.71 to 3.96. These results indicate that sparse expert-based emotion modeling still provides generation modeling advantages in emotional support dialogue and improves response diversity.

However, Acc drops from 45.26 to 44.53, which is slightly lower than Original CEM. The decrease suggests that emotion classification performance may vary across datasets because of differences in label distributions and task objectives. ESConv focuses more on emotional support strategies, while EmpatheticDialogues focuses more on responding to emotional experiences. The label spaces and emotional expression patterns are not fully aligned.

Due to these differences, ESConv is used as an additional dataset to evaluate CEM-MoE in an emotional support dialogue setting. The results show that CEM-MoE maintains favorable response generation performance on ESConv, but they are not interpreted as evidence of cross-domain transfer or universally improved emotion classification across datasets.

G. Expert Activation and Routing Analysis

An important issue in sparse mixture of experts models is whether experts are effectively used. If the gating network repeatedly selects only a few experts, expert collapse occurs.

To examine expert routing behavior in CEM-MoE, expert activation counts are collected for both emotion streams, and both utilization entropy and normalized entropy are calculated. The statistics are collected on the EmpatheticDialogues test set, where each count represents the number of times an expert is selected by the Top K router. Let qi denote the proportion of activation counts assigned to the i-th expert. Expert utilization entropy is calculated as $H = -\Sigma i\ qi \log qi$, and normalized entropy is defined as H/log Ne, where Ne = 4. The results are shown in Table VI and Fig. 2.

As shown in Fig. 2, the current stream and the context stream exhibit distinct routing patterns across different emotion categories. The current stream achieves more balanced expert utilization, whereas the context stream shows a stable preference toward certain experts. These observations demonstrate that the dual-stream structure enables differentiated expert allocation behaviors.

The normalized entropy of the current stream is 0.9792, which is close to 1. The result indicates relatively balanced expert utilization in the current utterance stream and no obvious expert collapse. The normalized entropy of the context stream is 0.8880, indicating moderate preference for some experts, but the stream does not collapse into a single expert. This pattern is consistent with the more complex nature of historical context, which may contain longer-term emotional bias. We further visualize an emotion expert activation heatmap to examine expert activation ratios across different emotion categories, where each cell corresponds to the activation ratio for a specific emotion category.

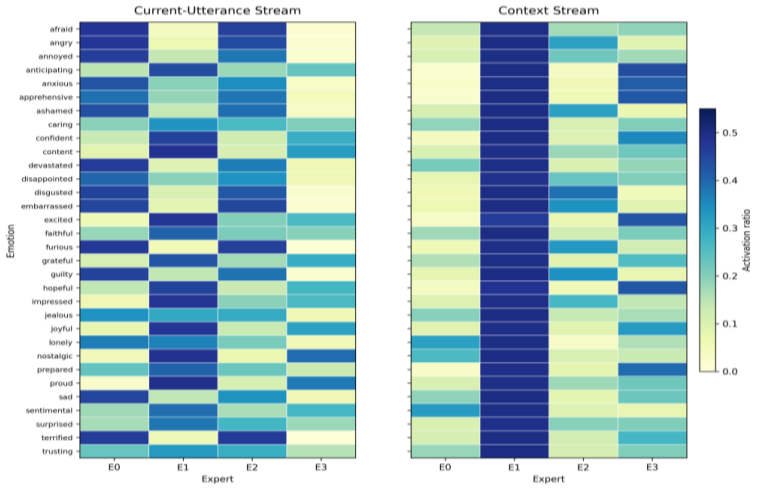

Fig. 2. Emotion expert activation heatmap.

TABLE VI. EXPERT UTILIZATION STATISTICS

Stream	Counts	Entropy	Normalized Entropy
Current stream	{0: 2900, 1: 3106, 2: 2904, 3: 1600}	1.3575	0.9792
Context stream	{0: 1262, 1: 5210, 2: 1690, 3: 2348}	1.2311	0.8880

TABLE VII. EFFICIENCY RESULTS

Model	Params	Latency ↓	Throughput ↑	Peak GPU Mem
Original CEM	17.49M	37.22 ms/sample	275.12 tokens/s	83.85 MB
CEM-MoE	17.61M	37.29 ms/sample	260.27 tokens/s	84.30 MB

H. Efficiency Analysis

One objective of CEM-MoE is to improve emotion modeling while maintaining a lightweight architecture. Therefore, besides generation performance, it is also important to evaluate the additional computational overhead introduced by Sparse MoE. Sparse expert activation aims to improve model capacity while controlling active computation, making it suitable for lightweight dialogue generation models [17], [18]. To provide a comprehensive efficiency evaluation, Original CEM and CEM-MoE are compared in terms of parameter size, inference latency, throughput, and peak GPU memory under the same experimental environment. These metrics reflect both deployment cost and practical inference efficiency. The results are presented in Table VII.

Table VII shows that CEM-MoE increases the parameter size by only 0.12M compared with the original CEM. Inference latency rises from 37.22 ms/sample to 37.29 ms/sample, with an increase of only 0.07 ms/sample. Peak GPU memory grows from 83.85 MB to 84.30 MB, with an increase of only 0.45 MB. Although throughput drops from 275.12 tokens/s to 260.27 tokens/s, the overall inference efficiency remains at a high level.

I. Human Evaluation

Automatic metrics cannot fully reflect the quality of empathetic dialogue generation. Low perplexity or high emotion classification accuracy does not guarantee that a

response is empathetic or contextually appropriate. Therefore, human evaluation is conducted to provide a more comprehensive assessment of response quality. To complement automatic metrics such as PPL, Acc, and Dist, a total of 100 samples are randomly selected from the test set, and three annotators are invited to score the responses generated by Original CEM and CEM-MoE.

The evaluation covers three dimensions: empathy, fluency, and relevance, with scores ranging from 1 to 5. Empathy evaluates whether the response appropriately reflects the user ' s emotional state; fluency measures the naturalness of the generated text; relevance assesses consistency with the dialogue context. During annotation, model identities are blinded, and response order is randomly shuffled to mitigate subjective bias. Krippendorff' s alpha is adopted to compute inter-annotator agreement, yielding values of 0.72, 0.79, and 0.75 for empathy, fluency, and relevance, respectively. The human evaluation results are summarized in Table VIII.

As illustrated in Table VIII, CEM-MoE surpasses the original CEM across all three evaluation dimensions: empathy gains 0.63, fluency rises by 0.66, and relevance increases by 0.55. While CEM-MoE does not attain optimal performance on every automatic metric, its generated responses achieve higher human scores than CEM in empathy, fluency, and relevance.

These findings also demonstrate that automatic evaluation and human evaluation complement each other for empathetic dialogue generation. PPL and Acc quantify model fitting capability and emotion prediction performance, whereas human evaluation more directly reflects whether the generated responses deliver genuine empathetic effects.

TABLE VIII. HUMAN EVALUATION RESULTS

Model	Empathy ↑	Fluency ↑	Relevance ↑
CEM	3.32	3.19	3.32
CEM-MoE	3.95	3.85	3.87

J. Case Analysis

To enable an intuitive comparison of model-generated responses, three representative examples are chosen for case study, covering negative emotion, anxious emotion, and positive emotion. The illustrative cases are listed in Table IX.

TABLE IX. RESPONSE CASES GENERATED BY DIFFERENT MODELS

Emotion / Context	CEM	CEM-MoE	Reference
devastated The hardest time in my life was when my best friend died on Christmas of 2007. She fell off a roof after falling asleep and slipped when she got up.	oh no ! i hope you can find a friend who was in the end of your life .	oh no ! i am so sorry to hear that .	that is horrible . i am really sorry about your friend .
anxious I took a huge test today, and it made me nervous. I studied every day for a week and almost wore myself out studying.	that is great ! i hope you get it back soon .	i hope you do well !	then i am sure you will do well .
impressed My husband let me sleep in, cooked dinner, and helped clean the house. He has been very helpful today.	that is great ! i am sure he will be fine	that is nice of him .	oh wow , that was nice of him .

In the first case, the user describes the death of a close friend. CEM generates a semantically incoherent response, while CEM-MoE directly responds to the sadness and expresses sympathy. In the second case, the user expresses anxiety concerning a critical examination. The response generated by CEM fails to align closely with this exam scenario, while CEM-MoE provides more relevant encouragement. In the third case, the user describes a positive experience in which the husband helps with housework. CEM tends to generate a generic template response, while CEM-MoE responds more directly to the event.

These cases qualitatively demonstrate that CEM-MoE is capable of generating responses with greater emotional appropriateness and contextual relevance under representative scenarios. Nevertheless, case analysis merely offers qualitative evidence and cannot replace automatic metrics or human evaluation. It also should not be interpreted as strict proof that the model is superior across all aspects.

V. DISCUSSION

The experimental results uncover several characteristics and limitations of CEM-MoE. First, the dual stream architecture does not consistently outperform the current-only variant on all automatic metrics. Current-only achieves competitive PPL and higher emotion accuracy on EmpatheticDialogues, indicating that the current utterance often contains strong direct emotional cues. Therefore, the context stream is better regarded as a complementary source of historical emotional information rather than a component that guarantees improvement in every metric. The dual stream design mainly provides a structured way to distinguish current emotional cues from historical context and allows their contributions to be analyzed separately.

Second, the length-based feature used in the bounded fusion mechanism is a lightweight heuristic proxy rather than a direct measure of semantic density. Utterance length cannot fully characterize semantic information concentration, but it provides a simple signal without introducing an additional semantic encoder or confidence estimator. The proposed

mechanism therefore focuses on maintaining low computational cost and a bounded probabilistic fusion process. More informative semantic- or confidence-based fusion signals can be explored in future work.

Third, CEM-MoE retains the 300-dimensional GloVe-based representation setting of the CEM backbone to maintain a lightweight model size and a controlled comparison with the original framework. Static word embeddings, however, have limited ability to represent context-dependent and implicit emotional meanings. Compact contextual encoders may provide richer semantic representations, but they may also introduce additional computational overhead. Investigating the trade-off between contextual representation ability and deployment efficiency remains an important direction.

Finally, expert activation statistics and routing heatmaps provide information about expert utilization patterns, but they do not constitute a full explanation of model decision-making. Different activation patterns indicate that the context stream and the current utterance stream adopt distinct expert allocation strategies. However, the current analysis establishes no explicit mapping between individual experts and specific human-interpretable emotion concepts. The routing analysis should therefore be viewed as an examination of expert utilization behavior rather than a causal interpretation of response generation.

VI. Conclusion and Future Work

CEM-MoE is proposed as a lightweight sparse mixture of experts framework to address the limitations of lightweight empathetic dialogue generation models in fine-grained emotion modeling and dynamic emotion fusion. Built upon CEM, CEM-MoE introduces a dual-stream sparse expert structure during emotion modeling. The context stream models emotional information from dialogue history, while the current utterance stream captures emotional cues in the current user utterance. Through Top-K routing, only a small number of emotion experts are activated for computation, which enhances emotion representation while keeping additional overhead limited. Auxiliary load balancing regularization is adopted to alleviate imbalanced expert utilization. A bounded density-aware fusion mechanism is also used to integrate historical emotion and current emotion distributions, endowing the fusion process with a clearer probabilistic interpretation.

Experimental results on EmpatheticDialogues show that CEM-MoE achieves competitive generation performance. Ablation experiments indicate that the sparse expert structure, auxiliary load balancing regularization, and label smoothing mainly help reduce perplexity and improve generation stability. Additional experiments on ESConv further indicate that CEM-MoE remains effective for emotional support conversation. Expert activation statistics and emotion expert heatmaps indicate that the model does not suffer from obvious expert collapse and that the two emotion streams exhibit different expert utilization patterns. Efficiency experiments show that introducing the sparse expert module only brings negligible increases in parameter scale, latency, and GPU memory. Human evaluation and case analysis further show that responses generated by CEM-MoE are perceived as more empathetic, fluent, and relevant by human evaluators.

Overall, CEM-MoE provides a practical framework for lightweight empathetic dialogue generation while maintaining competitive generation quality, low computational overhead, and observable expert utilization behavior. Future work will focus on exploring richer emotional cues and extending CEM-MoE to multimodal empathetic dialogue generation by incorporating nonverbal information such as speech prosody, facial expressions, and visual behaviors. Fine-grained human feedback can also be incorporated to further improve emotional appropriateness and interaction quality.

From Personality to Performance: An Automated Grouping Tool for Collaborative Learning

Dalila Raissouni, Ahmed El Oualkadi, Kamal Reklaoui
Université Abdelmalek Essadi, ENSA, Tetuan, Morocco

***Abstract*—As part of pre-service teacher training, this study presents a new web-based tool that intelligently groups learners based on their personality profiles (PCM, or Process Communication Model) to enhance collaborative work in flipped classrooms. The software automatically groups users by personality based on the results of a personality test. The application is compatible with all mobile devices and can be accessed through a web browser without the need for installation. The algorithm aims to improve role distribution, interpersonal communication, and conflict resolution by maximizing diversity within each group while taking contextual factors into account. Inspired by popular educational platforms like Kahoot, the user interface provides an intuitive experience for both teachers and students. Teachers can create classes, set group sizes, monitor results, and create ideal groupings with little work. A quasi-experimental pre–post implementation involving 267 trainee teachers, with a response rate of 63% (164 participants), revealed statistically significant improvements in collaboration and participant involvement following group reorganization through the application. These findings support the pedagogical relevance of integrating personality-based grouping technologies. They suggest that such technologies may foster learner engagement and self-awareness, and that they are associated with improved collaboration in educational environments. They suggest that such technologies may foster learner engagement, self-awareness, and effective collaboration in educational environments. The study contributes to the field by providing empirical evidence of the applicability of the PCM framework in teacher training contexts and by demonstrating the feasibility of integrating personality-based grouping mechanisms into digital learning environments.**

I. Introduction

Any consideration aimed at sustainably improving the quality of education must take into account the early stages of schooling, particularly primary school. It is at this stage that fundamental learning processes, such as reading, writing, and structuring thought, begin decisively. These learning processes are rooted in a phase of intense cognitive development, particularly among children of the Alpha generation [1]. Their intellectual abilities, although comparable to or even superior to those of previous generations, are shaped by a world profoundly transformed by digital technology [2].

In this context, teachers play a fundamental role as mediators. It is therefore essential to strengthen their initial training by incorporating innovative teaching practices. These practices should combine subject content with tools for analysing personality profiles. Such an approach aims to improve interpersonal communication, strengthen group cohesion and promote more effective collaborative learning environments.

Among these practices, the flipped classroom stands out as a benchmark model [3]. By redefining traditional roles, it promotes autonomy, cooperation and active engagement among learners [4]. Teachers in training thus experience complex collaborative situations. In these situations, communication skills play a central role [5]. This need for social skills is all the more crucial in the era of Industry 5.0 [6]. Emotional intelligence, collaboration and interaction management are becoming key elements of employability [7].

In this context, educational technologies are opening up new possibilities for optimizing the organization and effectiveness of collaborative work. The application tested in this study aims to automatically form balanced groups of trainee teachers. The grouping is based on personality profiles defined by the Process Communication Model (PCM) [8]. This model proposes a behavioural typology associated with different communication styles. It makes it possible to anticipate conflicts, facilitate exchanges and distribute responsibilities more coherently.

This research aims to evaluate the changes in collaborative interactions observed following the introduction of the application within a flipped classroom context. The study adopts a quasi-experimental pre–post design. It examines changes in communication quality, task coordination, involvement and conflict management, following personality-based group structuring grounded in the Process Communication Model (PCM), within the Moroccan teacher training context.

II. Theoretical Framework and Methodological Choices

A. Flipped Classroom and Acquisition of Collaborative Skills

Over the past decade, the flipped classroom model has undergone significant evolution, gradually establishing itself as an innovative teaching approach in several academic fields of specialization [9]. Based on the principle of disseminating content outside the classroom, this methodology promotes active learner engagement, the use of advanced digital resources, and the development of autonomy in research and information management.

By combining these tools with collaborative structuring of activities, learners not only strengthen their understanding of the subject matter, but also develop essential cross-disciplinary

skills such as project management, content creation, and peer collaboration.

Studies have shown that the flipped classroom is more effective than traditional approaches in secondary and higher education [10]. It promotes intrinsic motivation [11], self-efficacy, cooperation and critical thinking [12], contributing to improved overall performance and student engagement, including their problem-solving skills.

B. Limitations of Collaborative Work in Initial Training

Once the working groups have been formed, the trainer acts as a facilitator, encouraging cooperative interactions and high-quality interpersonal communication [13]. The ability to collaborate effectively is now an essential skill in professional environments, and acquiring it during initial training is a real challenge for future teachers [14].

However, several difficulties hinder the implementation of collaborative work: interpersonal conflicts, unequal distribution of tasks, delays in project delivery, or even unilateral completion of work [15]. These dysfunctions, frequently observed in the delivery of collective projects, seem to be largely linked to the formation of groups based on random or social criteria (personal affinities, geographical proximity, etc.). [16]

C. Interpersonal Communication: A Key Factor for Success

The success of collaborative projects depends heavily on the quality of communication. Clear, harmonizer and structured communication facilitates task distribution, time management and tension resolution, and has a direct impact on the quality of the work produced [17].

Several studies now advocate for the explicit integration of these skills into training frameworks, on a par with critical thinking, creativity, and teamwork [18].

D. Personality Profile and Communication Style

Each individual adopts a communication style influenced by their socio-cultural environment, personal history, and personality. The latter is a source of variability that can lead to misunderstandings or tensions, particularly in stressful situations or when time is limited.

In these contexts, it becomes relevant to use tools for analysing personality profiles and communication styles. Models such as MBTI, DISC, Big Five, and PCM are commonly used in professional, educational, and clinical settings to understand interpersonal dynamics and optimize team functioning.

In Table I, we have compared the four models in order to choose the one best suited to our study.

TABLE I. COMPARISON OF THE MAIN PERSONALITY MODELS

Model	Principle	Use	Main Focus
DISC [19]	Assesses behaviours according to four dimensions: Dominance, Influence, Steadiness, Compliance	Understanding leadership styles and interactions	Communication Behaviour
MBTI [20]	Classify individuals according to four axes: Extraversion/Introversion, Sensing/Intuition, Thinking/Feeling, and Judging/Perceiving.	Motivation and learning styles	Cognition Personality
Big Five OCEAN [21]	Unique profile based on 5 traits: Openness, Conscientiousness, Extraversion, Agreeableness, Neuroticism.	Personal guidance	Personality Traits
PCM [8]	6 personality types: Thinker, Persister, Harmonizer, Rebel, Promoter, and Imaginer, as well as the communication channels specific to each personality.	Stress prevention, interpersonal adaptation	Interpersonal Communication

E. Choice of PCM Model

In light of this comparison, the Process Communication Model (PCM) is particularly relevant due to its practical emphasis on real-time communication adaptation, conflict management, and stress regulation—key dimensions in collaborative educational settings such as the flipped classroom. Moreover, PCM provides structured and immediately applicable strategies for optimizing group dynamics and strengthening cohesion among learners with diverse personality profiles.

The model is characterized by its interactional focus [22], its empirical grounding across professional [23], educational, and medical contexts, and its capacity to enhance communication processes in real time. These characteristics support its integration into the present application for personality-based group allocation within the framework of this study.

The PCM identifies six personality types (Thinker, Promoter, Persister, Imaginer, Rebel and Harmonizer) [8], each associated with a dominant communication channel. It is designed to support interpersonal adaptation, enhance conflict management strategies, and improve the regulation of stress responses, as summarized in Table II.

TABLE II. THE SIX PERSONALITY TYPES IN THE PCM MODEL [8]

Personality Type	Characteristics	Communication Profile
Thinker	Logical, Thoughtful, Structured	Factual Communication
Promoter	Dynamic, Persuasive	Persuasive and Quick Communication
Persister	Practical, Methodical	Structured and Planned Communication
Imaginer	Introverted, Calm	Deep Communication
Rebel	Creative, Spontaneous	Playful and Humorous Communication
Harmonizer	Sensitive, Caring	Compassionate, Conscious, and Emotional Communication

F. Evidence of PCM Effectiveness

Studies conducted with surgeons trained in PCM have highlighted improved conflict management, reduced stress and a more harmonious working environment [24]. In addition, other research has established links between PCM profiles and certain cognitive or neuropsychological functions [25], suggesting a

growing scientific depth to the model. It should also be noted that certain PCM model profiles tend to promote the generation of creative ideas through their communication channels. This relationship between personality and creativity can be used to improve collaboration and stimulate innovation in groups [26].

III. Objective of the Study

In this context, the objective of the research is to verify the hypothesis that integrating the PCM model into a flipped classroom system promotes collaboration and the quality of interactions between learners.

The main hypothesis posits that structuring groups based on personality profiles improves communication flow, task distribution and tension management within teaching teams. The next section presents the experimental protocol put in place to test this hypothesis.

IV. Technical Architecture of the Application

A. System Architecture and Technical Framework

- Back-end: The application server is designed with Django, an open-source framework based on Python, which follows the MTV (Model-Template-View) architecture [27]. This choice is based on the maturity of the framework, its comprehensive documentation and its ability to accelerate development while ensuring good maintainability.
- Front-end: The user interface was created using the Bootstrap framework [28], enabling a responsive interface that is compatible with different screen formats (smartphones, tablets, computers).
- Database: The system is based on PostgreSQL [29], an RDBMS known for its reliability, performance, and seamless integration with Django. It manages user data, personality test results, and groups.
- Messaging system: Automatic email sending is managed via OAuth 2.0 authentication connected to the Gmail API, hosted on Google Cloud Platform. This solution avoids direct storage of login details. An alternative via SMTP can be considered for lighter environments.

B. User Interface Design

The application was designed with a user experience (UX) focus, with particular attention paid to ease of use and mobile accessibility. Inspired by tools such as Kahoot [30], the interface differentiates between the role of the trainer (session creator) and that of the participants.

No installation is required, and the application is fully accessible via a web browser. Data is stored in a PostgreSQL database and processed by an algorithm that automatically forms groups based on the results of the PCM test and additional academic criteria.

C. Justification of Technical and Ergonomic Choices

The choice of a web application that can be accessed without installation meets two objectives: to avoid saturating users' personal phones and to guarantee quick access from any device.

The Kahoot interface model [31] was chosen for its familiarity to teachers and its potential for engagement. Django and Python ensure reliable data management and good scalability. [32]

V. Methodology of Experimentation

A. Target Population for the Experiment

The study was conducted among trainee teachers undergoing initial teacher training. This decision was based on two complementary considerations.

On the one hand, these future teachers will be responsible for educating Generation Alpha, for whom soft skills – collaboration, communication, critical thinking and adaptability – are essential in the context of Industry 5.0. It is therefore important that the trainee teachers themselves master these skills so that they can pass them on effectively to their pupils.

On the other hand, the initial teacher training programme requires trainee teachers to work regularly in groups on projects. However, field observations reveal frequent problems in collaborative work: interpersonal conflicts, unequal distribution of tasks, delays or an excessive workload falling on a single group member. Improving the quality of their training therefore requires the creation of more productive and creative groups, which justifies the relevance of this target population.

These findings highlight the need to structure groups according to more robust educational criteria than personal or geographical affinities.

The experiment took place at the Regional Center for Education and Training Professions (CRMEF) [33] in Tetuán city, a public institution under the Ministry of National Education. This centre provides initial and continuing training for teachers and educational managers in the northern region of Morocco.

Table III shows the distribution of participants (trainee teachers) at the CRMEF in Tetuán city according to the educational level of the training, specialization and assignment group.

TABLE III. Distribution of Trainee Teachers by Specialization and School Level According to the CRMEF Center

Level	Speciality	Group No.	Number of trainee teachers	Having participated in the study
Primary	Arabic-French-Mathematics	1	34	✓
		2	34	✓
		3	34	✓
		4	34	✓
		5	34	
Middle school	History-Geography	1	26	✓
	Islamic education	1	45	✓
	Mathematics	1	30	✓
	Mathematics	2	30	
	French	1	30	✓

	Arabic	1	30	
	Life and Earth Sciences	1	30	
High school	Arabic	1	30	
Total		13	421	267

The study involved 267 trainee teachers from various subject areas, working in both primary and secondary schools, who are set to become the teachers of Generation Alpha (those born from 2012 onwards). This group was selected because of its relevance to the implementation of innovative teaching practices within the Moroccan school system.

B. Presentation of the Experimental Protocol

1) Group formation algorithm: The grouping algorithm operates by sequential allocation. Participants are first sorted by their dominant PCM type. They are then distributed across the predefined groups using a round-robin procedure, in which each participant is placed in the first available group that does not already contain a member of the same dominant type. This mechanism constitutes the implicit optimization objective of the algorithm: to maximize the variety of personality types within each group.

Formally, for each group Gj of size g, the algorithm seeks to maximize the Shannon diversity index H(Gj), subject to the constraint |Gj| = g. When a participant's dominant type is already present in all available groups, the algorithm places the participant in the group where this type is least represented, thereby minimizing redundancy (Algorithm 1).

Algorithm 1: PCM-Based Balanced Group Assignment

```
Initialize:
    L ← list of all participants
    g ← desired group size (teacher-defined, 2 ≤ g ≤ 20)
Compute:
    N ← |L|
    k ← ceil(N / g) // number of groups
    Initialize k empty groups G1, G2, ..., Gk
    For each participant i in L do
        Determine dominant PCM type P(i)
        Store P(i)
    End For
    Sort L by P(i) // group same types together
    index ← 0
    While (index < N) do
        For (j ← 1 to k) do
            if (index < N) then
                If (size(Gj) < g) then
                    Add L[index] to Gj
                    index ← index + 1
                End If
            End If
        End For
    End While
For (each group Gj) do
    For (each participant in Gj) do
        Send email containing:
            - group number
            - members list
            - personality types
            - communication channels
    End For
End For
```

In the current version, secondary personality characteristics are not explicitly weighted in the allocation decision. The algorithm relies solely on the dominant PCM type. The option to adjust weighting parameters, mentioned in the application interface, is designed for future iterations and was not activated in the present study. This distinction is important: the results reported here reflect the default allocation mechanism, without additional weighting.

2) Workflow of the grouping process: To facilitate overall understanding of the approach adopted, a summary diagram was designed (Fig. 1). It illustrates the key stages of the experiment, from the collection of personality data via the application to the reorganization of the groups and the post-experiment evaluation. As shown in the diagram, participants were first randomly divided into groups (the specific configuration of 6 groups of 5 members being merely one illustrative instance used in this study) and completed an initial collaborative project. They then used the PCM-based applications, which simultaneously:

- provided each participant with their group composition, the personality types present, and the associated communication channels;
- redistributed all participants into new groups balanced by personality type, using the round-robin algorithm; and
- delivered detailed information on the preferred communication channel corresponding to each personality type.

A second project, analogous to the first, was carried out in these newly formed groups. Finally, a questionnaire compared the trainee teachers' perception of communication quality before (pre-test) and after (post-test) the regrouping intervention.

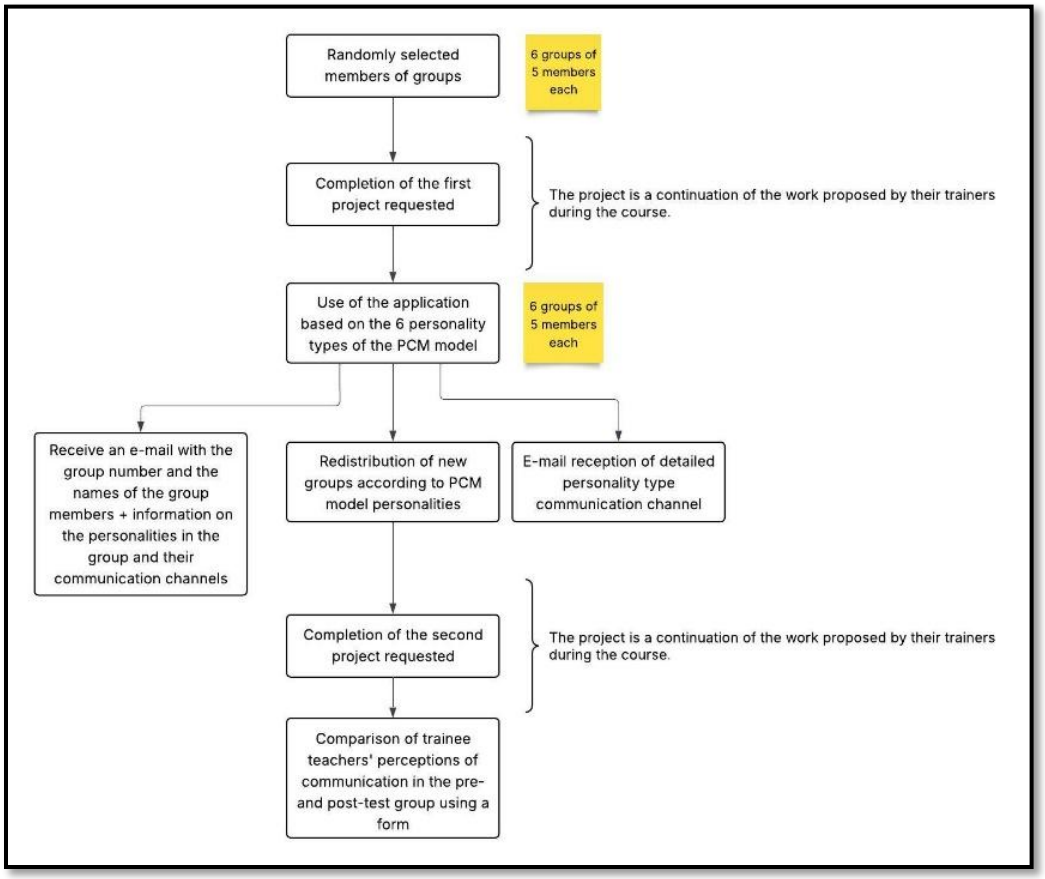

Fig. 1. Diagram of the experimental protocol for forming groups using the PCM model.

3) Personality diversity representation: To assess the balance of PCM personality types within each generated group, we employed the Shannon Diversity Index. This index was preferred to Simpson's index because it is more sensitive to rare personality types [34], which is essential to detect imbalance when a PCM type is underrepresented. According to [35], personality types constitute a "variety" diversity construct, for which entropy-based measures such as the Shannon index are particularly well suited. Moreover, its exponential yields an intuitive "effective number of types" [36], aligning well with the pedagogical interpretation of group composition.

Widely used to measure diversity in various disciplines, the Shannon index quantifies both the variety and evenness of personality types present in a group. It is calculated as follows:

$$H = -\sum_{i=1}^{k} p_i log(p_i)$$

Where:

H represents the group diversity index.

k denotes the number of PCM personality types (k = 6 in this study).

log denotes the natural logarithm

pi is the proportion of personality type *i* within the group.

A higher H value indicates greater diversity. For a group of six members, the maximum diversity (H = 1.79) is achieved when all six PCM types are equally represented (one participant per type). The index was calculated for each group based on the final participant assignments.

C. Description of the Application Phases

The experiment is based on a web application designed specifically to enable the automated formation of educational groups, based on personality profiles defined by the Process Communication Model (PCM). To measure the effects of this tool on group dynamics, the study was structured in five successive phases, as follows:

1) Phase 1: *Completion of an initial collaborative project (random groups)*: Before using the application, participants were randomly divided into working groups based on attendance lists provided by the CRMEF Center Management. No specific criteria (profile, affinity, skills, etc.) were applied at this stage.

These groups were given a project to complete, linked to the educational modules of the training program, while adhering to the guidelines for quality of output and meeting deadlines.

The objective of this first phase is to serve as a reference for evaluating initial collaborative dynamics, without structuring based on personality profiles in a flipped classroom context.

2) Phase 2: Using the PCM application to reconfigure groups: After the initial experiment, participants in the experimental group were invited to use the experimental application. The app is called Talkflow, in reference to the ease of communication it facilitates thanks to this grouping based on personality types (Fig. 2).

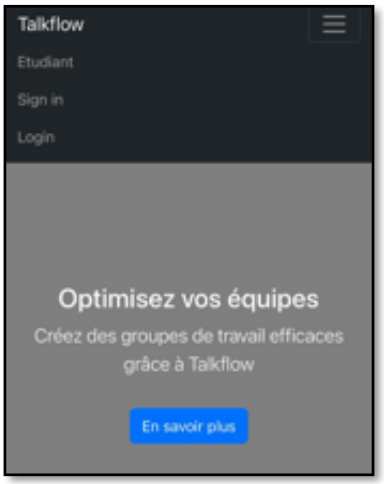

Fig. 2. The main interface of the Talkflow application.

This phase comprises several technical steps: The trainer creates an account on the application, then configures the session by entering the name of the class, the total number of learners, and the desired size of the subgroups.

The app then automatically checks the consistency of the settings entered (e.g., divisibility of the total number by the size of the groups) and suggests automatic adjustments in case of incompatibility.

This automation aims to ensure a balanced and consistent distribution, while avoiding the manual errors that are common when forming teaching groups (Fig. 3).

Fig. 3. View of the group creation screen as seen by the trainer.

3) Phase 3: Taking the PCM test and automated group formation

a) Participant registration and class access: Once the class settings have been validated (name, number of learners, group size), the application automatically generates a unique access code. This code is sent by the trainer to the participants, who can then join the session via a responsive web interface (Fig. 4).

Fig. 4. View of the screen that allows you to generate a code for the class created by the trainer to share with participants.

Trainee teachers enter their personal details (surname, first name, email address) and the code provided, then access the personality test based on the Process Communication Model (PCM).

b) Taking the PCM personality test: The PCM assessment used in this study was adapted from a personality identification exercise introduced during a professional training session organized as part of the Integrated School Project (Projet d'Établissement Intégré, PEI). This project, implemented in Moroccan secondary schools, received support and funding from the Millennium Challenge Corporation (MCC) through the Compact II bilateral cooperation programme. The training programme covered several areas, including soft skills, communication and change management. Within the soft skills component, a personality identification exercise based on the Process Communication Model was introduced.

Participants were presented with a list of personality traits and asked to select, one by one, the traits that best corresponded to their typical behaviour. As soon as three traits belonging to the same PCM personality type were selected, that type was assigned to the base of the participant's personality triangle, reflecting its dominance. The exercise continued until all six PCM types had been positioned, from the most dominant at the base to the least dominant at the top.

During the training sessions, the participating teachers, including the first author, generally perceived the exercise as relevant and consistent with their self-perceived personality profiles. Although this perception does not constitute a formal validation, it suggests that the instrument was well received and considered meaningful by its users.

To our knowledge, this version of the questionnaire has not been formally validated for the Moroccan educational context.

The present study did not conduct an independent psychometric validation. Its aim was practical: to apply the PCM framework in a real teacher training setting and to observe its effects on group dynamics. The results should therefore be interpreted with this limitation in mind.

Once the test is completed, the application automatically generates a PCM personality triangle for each participant. This visual depiction makes interpretation easier and shows:

- The dominant personality (at the base)
- The secondary personalities (at the upper levels)
- The personality least represented in the profile (at the top)

Fig. 5. View of the screen (of the participant) showing their personality triangle according to the PCM test.

c) Group formation algorithm: As tests are received, the application automatically divides participants into balanced groups based on their PCM profile. The algorithm has been significantly enhanced to:

- Ensure, where possible, that each group contains several different personality types
- Avoid homogeneous groupings (e.g. several Promoter or Harmoniser profiles in the same group)
- Maximize the complementarity of profiles, thereby promoting rich and constructive interpersonal dynamics
- Allow teachers to adjust weighting parameters based on specific activity requirements

d) Communication of results and assignment to groups

Each participant automatically receives:

- Their PCM personality triangle (Fig. 5)
- The name of their assigned group
- The composition of their group (identity and PCM profile of members)
- An explanatory educational document presenting the six personality types, their preferred communication channels, and practical advice for harmonious interaction

On the trainer's side, a summary table of the groups is accessible from their personal space in the application. This table classifies learners according to their profile and assigned group, allowing for immediate educational follow-up.

Fig. 6. View of the screen (from the trainer) displaying the group number, members, and their personality profiles.

4) Phase 4: Completion of the second project in PCM groups: A new collaborative task, still related to the training program, is assigned to the groups reconfigured using the application, according to the groups displayed (Fig. 6). The instructions and assessment criteria remain unchanged to ensure the comparability of the two collaborative experiences (before and after using the PCM test). Participants are asked to produce a high-quality collective deliverable, in accordance with deadlines and educational standards.

5) Phase 5: Post-experiment evaluation: At the end of phase 4, participants complete a comparative evaluation questionnaire (pre/post-experiment). This questionnaire aims to gather information on:

- Feelings about group dynamics
- The fluidity of communication
- Task distribution
- Conflict management
- Overall quality of collaboration

The objective of this step is to evaluate the perceived impact of the application on collaborative dynamics, relational serenity and group productivity. The results allow us to examine the link between self-knowledge/knowledge of others and collective performance in a flipped learning environment.

D. Pre- and Post-experience Evaluation Form

The questionnaire was distributed digitally to all 267 participants who took part in the various phases of the project. Of these, 164 responded, representing a participation rate of 63%, with 161 usable responses. The improvement in response rate appears to be associated with the provision of immediate,

personalized feedback on individual personality profiles, which may have enhanced participant engagement and perceived relevance of the assessment.

E. Focus of the Questionnaire

The questionnaire aimed to assess several aspects of group dynamics before and after the experiment:

- The fluidity of exchanges
- The distribution of tasks
- Adherence to deadlines
- Conflict management
- Overall feelings (atmosphere, serenity, autonomy)
- Interest in the PCM model applied to the flipped classroom

VI. Results

A. Personality Diversity Analysis

Table IV presents the Shannon Diversity Index calculated for each of the five groups formed by the algorithm for a class of 30 participants (group size = 6). The composition and diversity score for each group are detailed below.

TABLE IV. Comparison of Mean Scores Before and After the Intervention Using the Wilcoxon Test and Effect Sizes

Group	Size	Composition (PCM Types)	Shannon Index (H)
G1	6	Thinker, Promoter, Persister, Harmonizer, Rebel, Imaginer	1.79
G2	6	Rebel, Harmonizer, Thinker, Persister, Imaginer, Promoter	1.79
G3	6	Thinker, Promoter, Persister, Harmonizer, Rebel, Imaginer	1.79
G4	6	Harmonizer, Rebel, Thinker, Persister, Thinker, Imaginer	1.56
G5	6	Harmonizer, Rebel, Thinker, Harmonizer, Harmonizer, Harmonizer	0.87
Mean (SD)			**1.60 (0.34)**

The analysis shows that three groups (G1, G2, and G3) achieved the maximum diversity score (H = 1.79), indicating perfectly balanced representation where all six PCM personality types were present exactly once. Group G4 also demonstrated a high level of diversity (H = 1.56), despite containing two Thinkers. However, Group G5 exhibited a lower diversity index (H = 0.87) due to the over-representation of the Harmonizer type (four out of six members).

B. Pre Post Intervention Results

To assess the evolution of collaborative dynamics after group reorganization, we compared the pre- and post-intervention questionnaire scores based on 161 usable responses. Given the ordinal nature of the data and the paired design, a non-parametric Wilcoxon signed-rank test was used.

Table V summarizes the results, including mean scores, p-values, and effect sizes.

TABLE V. Pre- and Post-Intervention Comparison

Variable	Before Mean (SD)	After Mean (SD)	p-value (Wilcoxon)	Cohen's d	Effect Size
Collaboration	2.35 (1.00)	3.33 (1.29)	< 0.001	0.58	Moderate
Implication	3.25 (0.90)	3.78 (1.08)	< 0.001	0.41	Moderate
Communication	3.37 (0.99)	3.28 (1.36)	0.548	-0.05	Negligible
Conflicts	3.47 (1.24)	3.58 (1.21)	0.511	0.06	Negligible

Note: p-values from Wilcoxon signed-rank test for paired samples; Cohen's d calculated for paired samples.

C. Qualitative Results

The open-ended responses collected provided additional insight into individual perceptions of collaboration within groups, before and after their reconfiguration based on PCM profiles.

Regarding situations of non-investment or failure to meet deadlines by a group member, several participants expressed recurring feelings of frustration, demotivation, and even conflict avoidance. Some stated that they 'preferred to take on the entire task,' while others indicated that they 'no longer intervened when a member failed to contribute,' highlighting passive emotional management and an imbalance in the distribution of work.

About spontaneously adopted roles, the responses revealed recurring functions such as coordinator, planner, executor or mood regulator. The notion of explicit leadership, on the other hand, was rarely mentioned, which could reflect a horizontal work dynamic or a lack of structure in the initial groups.

Finally, feedback on the PCM model trial was overwhelmingly positive. Many participants reported improved communication, better mutual understanding, smoother coordination, a more balanced distribution of responsibilities and a more relaxed working atmosphere.

Illustrative excerpts:

- We understood each other better in the second group.'
- Everyone knew what to do; it was more fluid.'
- The test helped me understand why some people react that way.'

- The atmosphere was better; there wasn't the same tension as during the second project. '

VII. Discussion

A. Interpretation of Personality Diversity Results

The results demonstrate that the automatic group formation algorithm is largely effective in creating diverse personality profiles within groups. The fact that three out of five groups achieved perfect balance (H = 1.79) confirms that the algorithm's core mechanism—avoiding repetition of personality types within a group—can successfully produce optimally diverse teams under typical participant flow conditions. This result aligns with the principles of variety-based diversity, which emphasize that teams benefit from a mix of different categories rather than from separation or disparity alone [35].

The lower diversity score observed in Group G5 provides valuable insight into the algorithm's current limitations. This imbalance occurred because multiple participants with the Harmonizer personality joined the application consecutively during the later stage of the group formation process. When the first Harmonizer was assigned to G5, it was the only personality type missing from that group. However, as subsequent Harmonizers enrolled, the algorithm had no mechanism to distribute them to other groups, as all other groups had already reached the maximum size (n = 6) set by the instructor. This reveals a key area for future improvement: implementing a predictive or queue-based mechanism that reserves slots for underrepresented personality types, particularly towards the end of the enrolment process.

It is important to note that the system is designed to accommodate various group sizes (e.g., 3, 4, 5, or more members) according to the instructor's preferences. The underlying principle of balancing personality types remains applicable regardless of group size, although the maximum achievable diversity score will vary accordingly. Future work will explore the algorithm's performance across different group sizes and participant enrolment sequences, and will investigate optimized assignment strategies to further minimize imbalances such as the one observed in Group G5.

B. Interpretation of Pre-Post Intervention Results

The pre- and post-intervention analysis revealed significant improvements in several dimensions of collaborative work following the reorganization of groups based on PCM personality profiles. Table V presents the descriptive statistics and comparative analysis.

Collaboration showed a statistically significant increase ($p < 0.001$, Wilcoxon signed-rank test). The mean score rose from 2.35 (SD = 1.00) before the intervention to 3.33 (SD = 1.29) after. The effect size (Cohen's d = 0.58) indicates a moderate to large effect. This suggests that personality-based group formation was associated with a meaningful increase in participants' perceived quality of collaboration. This finding aligns with the qualitative feedback, where participants reported smoother coordination and a more balanced distribution of responsibilities in the reconfigured groups. This improvement is consistent with studies suggesting that group composition based on interpersonal variables may enhance cooperative processes [7], [14].

Implication (participant involvement) also increased significantly, with mean scores rising from 3.25 (SD = 0.90) to 3.78 (SD = 1.08). The effect size (Cohen's d = 0.41) represents a moderate effect. This improvement is particularly noteworthy. Although some participants who were highly involved in their original groups reported initial disruption, overall involvement increased across the sample after the reorganization. This suggests that while some well-integrated individuals may have experienced initial disruption, the new group configuration ultimately fostered greater engagement for the majority of participants. This temporary disruption echoes findings that restructuring groups can initially unsettle established dynamics [16].

Communication remained stable, with mean scores of 3.37 (SD = 0.99) before and 3.28 (SD = 1.36) after the intervention. The difference was not statistically significant ($p = 0.55$), and the effect size was negligible (d = -0.05). This stability is consistent with the qualitative findings, where participants reported that communication improved for many, but the quantitative data suggests that overall, communication levels were already relatively well established and did not change substantially as a result of the intervention. This stability is in line with research showing that communication patterns are deeply rooted and may require longer interventions to evolve significantly [14], [17].

Conflicts showed a slight increase, with mean scores rising from 3.47 (SD = 1.24) to 3.58 (SD = 1.21). However, this change was not statistically significant ($p = 0.51$), and the effect size was negligible (d = 0.06). The qualitative results present an interesting contrast: many participants reported a "more relaxed working atmosphere" and "no tension like in the first project" after the reorganization. This discrepancy may indicate a change in conflicts, even if their frequency did not decrease. Conflicts may have become less disruptive or more manageable. Alternatively, the quantitative measure of conflict may not have fully captured the qualitative improvements reported by participants. This interpretation is supported by previous PCM studies reporting improved conflict management and a more harmonious environment following PCM training [24].

C. Interpretation of Qualitative Results

The qualitative analysis provided valuable insights that complement and enrich the quantitative findings.

- Perceptions of non-investment and workload imbalance: Participants reported recurring feelings of frustration, demotivation, and conflict avoidance when faced with group members who failed to contribute. Statements such as "I preferred to take on the entire task" and "I no longer intervened when a member failed to contribute" reveal passive emotional management strategies and highlight the importance of balanced workload distribution in collaborative settings. This finding suggests that participants who previously carried a heavier workload appreciated the redistribution of responsibilities in the reconfigured groups. These experiences of frustration and workload imbalance

mirror known challenges in unstructured group work [15].

- Spontaneous roles and leadership dynamics: The emergence of recurring roles such as coordinator, planner, executor, and mood regulator indicates that informal role distribution occurred naturally within groups. The rare mention of explicit leadership may reflect either a horizontal work dynamic or a lack of structural clarity in the initial groups. This finding suggests that personality-based group formation could potentially support more explicit role distribution, an avenue worth exploring in future iterations of the system. The spontaneous emergence of roles is a classic phenomenon in group dynamics [13], and our results suggest that personality-based grouping could formalize these roles more effectively.
- Positive reception of the PCM approach: The overwhelmingly positive feedback on the PCM model trial is particularly noteworthy. Participants reported improved communication, better mutual understanding, smoother coordination, more balanced responsibility distribution, and a more relaxed working atmosphere. Illustrative excerpts such as "We understood each other better in the second group" and "The test helped me understand why some people react that way" suggest that the PCM framework provided participants with a shared language to understand interpersonal differences. This metacognitive awareness may explain the observed improvements in collaboration and involvement. The positive reception of the PCM model is consistent with research demonstrating its benefits for communication and stress regulation in professional settings [23], [24].
- Complementarity with quantitative findings: The qualitative feedback helps explain the apparent discrepancy between the quantitative conflict measure (which showed a non-significant increase) and participants' reported perception of a "more relaxed atmosphere."[24] It is possible that while conflicts did not decrease in frequency, their intensity or disruptiveness diminished as participants better understood each other's communication styles. This interpretation is supported by statements such as "there was no tension like in the first project," suggesting that conflicts, when they occurred, may have been less emotionally charged or more easily resolved.

D. Key Findings

This study extends previous work on PCM in educational contexts [23], [24], [25], and it yielded several key findings regarding the effectiveness of PCM-based group formation on collaborative dynamics in teacher training contexts.

First, the Shannon Diversity Index analysis demonstrated that the proposed algorithm successfully created balanced personality profiles in three out of five groups (60%), achieving maximum diversity (H = 1.79). However, the algorithm's limitation in handling consecutive enrolments of the same personality type was also identified, highlighting an area for future improvement.

Second, the pre-post intervention analysis revealed significant improvements in collaboration ($d = 0.58$, $p < 0.001$) and participant involvement ($d = 0.41$, $p < 0.001$) following group reorganization. These findings suggest that personality-based group formation is associated with increased engagement and cooperative behaviour among trainee teachers.

Thirdly, communication levels remained stable throughout the intervention, suggesting that the reorganization did not disrupt existing communication practices. This stability can be explained by the fact that the intervention took place during the second half of the academic year, a period by which the participants had already developed and established their communication patterns.

Fourth, while perceived conflict levels showed a slight non-significant increase, qualitative feedback revealed that participants perceived a "more relaxed working atmosphere" and "no tension like in the first project" after the reorganization. This apparent discrepancy suggests that the nature of conflicts may have changed, becoming less disruptive or more manageable, even if overall conflict frequency did not decrease.

Overall, these findings support the potential of personality-informed group structuring as a strategy to enhance collaborative learning environments in teacher training contexts, while also identifying clear directions for algorithmic refinement and future research.

E. Theoretical Contributions

This research contributes to the literature on collaborative learning and personality-informed educational technologies in several ways.

First, it provides empirical evidence supporting the relevance of the Process Communication Model (PCM) for understanding collaborative dynamics in teacher training contexts. The results suggest that personality-aware group structuring may positively influence collaboration, involvement, and conflict management among trainee teachers.

Second, the study demonstrates how personality-based grouping principles can be operationalized through a digital tool designed to automatically generate complementary working groups based on PCM personality profiles. This contributes to bridging the gap between personality theory and its practical implementation in educational settings.

Third, the research highlights the potential of pre–post experimental designs for evaluating the impact of collaborative learning interventions in authentic training environments. By examining the evolution of group dynamics before and after the intervention, the study provides methodological insights for future research on technology-supported collaborative learning.

Finally, the study contributes to the growing body of research exploring how educational technologies can support the development of interpersonal and collaborative competencies that are increasingly required in modern educational systems.

F. Practical Implications

The findings of this study provide several practical implications for teacher training programs and educational practitioners.

For educators and instructional designers, the results suggest that personality-based group formation can support more balanced and effective collaborative work. By considering differences in communication styles and personality structures, teachers may facilitate better interaction, clearer task distribution, and improved group cohesion during collaborative learning activities.

The web-based application developed in this research illustrates how digital tools can assist educators in organizing collaborative learning environments more efficiently. By automatically generating complementary groups based on PCM personality profiles, the tool reduces the complexity of manual group formation while encouraging diversity within teams.

For teacher training institutions, the results highlight the potential value of integrating personality-awareness approaches into training programs. Helping trainee teachers better understand their own communication styles and those of others may contribute to improving collaboration, conflict management, and interpersonal adaptability in professional practice.

Finally, the results suggest that personality-informed grouping strategies may support the development of collaborative and socio-emotional competencies that are increasingly important in modern educational systems.

G. Limitations and Future Research

Despite the promising results of this study, several limitations should be acknowledged.

First, the sample was limited to trainee teachers from a specific geographical region in northern Morocco, which may limit the generalizability of the findings to other educational contexts. Second, the duration of the study was restricted to a single academic term, which does not allow for the observation of long-term effects of personality-based group formation on collaborative learning dynamics.

Third, some of the measures used in the evaluation rely on self-reported perceptions, which may be influenced by social desirability bias.

Fourth, the intervention comprised several simultaneous components: PCM personality feedback, explanation of communication channels, disclosure of group members' personality profiles, group reassignment, and participation in a second collaborative task. This design does not allow the observed improvements to be attributed to any single component. The changes may reflect the personality-based grouping algorithm, increased awareness of communication styles, the novelty of the digital application, or simply the effect of changing group membership. Future research should isolate these components, for example by comparing groups that receive different combinations of feedback, regrouping, and instructional explanation.

Fifth, the overall response rate was 63% (164 of 267 participants). The final questionnaire was administered online, and non-response appears to reflect voluntary non-completion rather than any systematic exclusion. Because data on non-respondents were not collected beyond their initial participation, a formal comparison between respondents and non-respondents could not be conducted. It is therefore possible that participants who completed the final questionnaire differed from those who did not, for example in terms of motivation, engagement or satisfaction with the regrouping. This limitation should be considered when interpreting the findings.

Future research could address these limitations by expanding the study to larger and more diverse populations across different educational levels and institutional contexts. Longitudinal studies would also provide valuable insights into the sustainability of the observed improvements in collaboration and group dynamics.

From a technological perspective, several extensions of the system could be explored. Future work may include the integration of the application with existing Learning Management Systems (LMS), such as Moodle, through standards such as Learning Tools Interoperability (LTI), enabling seamless adoption within institutional digital learning environments.

Additionally, further development of the grouping algorithm could incorporate adjustable weighting parameters that allow educators to balance different grouping criteria depending on pedagogical objectives.

Finally, within the context studied, the results suggest that personality-informed grouping strategies may support the development of collaborative and socio-emotional competencies among trainee teachers.

VIII. Conclusion

This study explored the potential of personality-based grouping to enhance collaborative learning in teacher training contexts. By combining the Process Communication Model (PCM) with a web-based application designed to generate complementary groups, the research examined how personality-informed group formation may influence collaborative dynamics among trainee teachers.

The results of the pre–post evaluation suggest improvements in collaboration and participant involvement within groups. While the quantitative measure of conflict did not show a statistically significant change, participants' qualitative feedback described a more relaxed working atmosphere and more manageable tensions. These findings indicate that increased awareness of personality differences, combined with structured group composition, may contribute to more effective collaboration and engagement in learning environments.

Beyond its immediate pedagogical implications, this research highlights the relevance of integrating personality-based approaches into digital educational tools. The proposed application demonstrates the feasibility of supporting group formation through simple and accessible technologies, offering educators practical support for organizing collaborative activities.

In the broader context of preparing future teachers to educate Generation Alpha in an era shaped by digital transformation and Industry 5.0, developing collaborative competencies and interpersonal awareness becomes increasingly important. By exploring the integration of personality-informed grouping within educational technologies, this research contributes to ongoing efforts to enhance collaborative learning practices in teacher training. The proposed application could also be considered for professional environments. However, this possibility remains exploratory, as the present study was conducted in a single teacher training institution. Future research would be needed to examine whether the observed benefits extend to other settings.

***Abstract*—Ensuring road safety requires timely and accurate detection of lanes and roadside traffic signs, which are essential for assisting drivers and reducing accident risks. However, robust simultaneous detection remains challenging due to variations in illumination, occlusions, complex backgrounds, and diverse road conditions. This research introduces a novel vision-based system for lane detection and roadside traffic sign recognition using advanced artificial neural network architectures. In the pre-processing stage, Contrast Limited Adaptive Histogram Equalization (CLAHE) is applied to enhance image visibility under varying lighting conditions. For classification, a Self-Artificial Attentive Gated Neuro-Recurrent Unit (SAAG-NRU) is proposed, a novel architecture integrating deep artificial neural network (ANN) layers, Gated Recurrent Units (GRU), and a self-attention mechanism, enabling sequential refinement of features and prioritization of the most safety-relevant cues. In addition, YOLOv11 was utilized to train and detect traffic signs exclusively. For lane detection, a lane mask-based approach is implemented to accurately segment and highlight lane boundaries. The trained model was integrated into a Tkinter-based Graphical User Interface (GUI) to visualize real-time detection outputs effectively. Implemented using Python-based tools, the framework is validated against benchmark lane and traffic signs, demonstrating better performance compared to existing systems in terms of lane detection, achieving 91.11% precision, and traffic sign detection, attaining 96.88% precision. Therefore, the proposed system delivers fast, accurate, and robust simultaneous lane and traffic sign detection, significantly improving real-time road safety and driver assistance.**

***Keywords*—Lane detection; roadside traffic sign recognition; contrast limited adaptive histogram equalization (CLAHE); self-artificial attentive gated neuro recurrent unit (SAAG-NRU); graphical user interface (GUI)**

I. Introduction

The fast advancement of intelligent transportation systems has led to a considerable amount of interest in the development of advanced driver assistance systems that can guarantee the safety of the roads and allow the navigation of autonomous vehicles [1]. The major perception tasks that are unavoidable for safe driving include recognition of lanes and their adjoining traffic signs, which in turn help in holding the vehicle under control, issuing warnings in case of lane departure, and controlling the signs by allowing or not allowing the passing of vehicles [2]. The accurate reading of roadway cues is even more crucial during difficult driving conditions like poor lighting, shadows, rain, glare, worn-out lane markings, and occluded traffic signs, where traditional vision-based techniques are often found lacking [3].

Lane markings and roadside signs are the primary visual aids that indicate the safest way for drivers and self-driving cars to handle the roads by showing rules, warnings, and directions [4]. Lane markings not only determine the limits of a car's road but also control traffic, keep cars in their lanes, and prevent them from accidentally changing lanes, especially when moving fast or in a complicated road situation [5]. Roadside signs, which comprise regulatory, warning, and informational signs, give out ten critical instructions such as speed limits, turns, pedestrian crossings, and hazard alerts, thereby allowing for timely decision-making for safe driving. Lane recognition and road sign detection work together and are the basis of intelligent transportation systems and autonomous driving functions, thus ensuring accurate vehicle localization, route planning, and collision prevention in a variety of road conditions [6-8].

Among the different key features, marking lanes and detecting roadside signals are key features of current intelligent transportation systems and self-driving cars, since they allow vehicles to recognize the geometry and the rules of the roads instantly [9]. Extracting lanes means detecting the limits and the crest of the road, thereby facilitating turning and preventing wrong exits in a lane, even if the conditions are very difficult, like low light, faded paint, shadows, or obstruction [10]. Road sign detection and recognition extract visual information from traffic signs, like speed limits, warnings, direction indicators, and pedestrian alerts, to help with safe and legal driving. Vehicles with lane and road sign detection working together have a thorough awareness of their environment; hence, the accuracy and speed of their navigation, decision-making, and overall safety in road use are significantly increased even in dynamic and unpredictable surroundings [11].

Conventional computer-vision algorithms depend heavily on handcrafted features and are highly sensitive to scene variations, camera perspective, and environmental noise. A real-time traffic sign recognition system was created that could recognize more kinds of traffic signs for intelligent vehicles [12]. The method is a combination of Haar cascade detection and an attention-based deep convolutional neural network (CNN) classifier that is trained on the GTSRB dataset. The system performed well and attained greater accuracy on testing and F1 measure. Nevertheless, the performance of the system was reduced in situations with difficult lighting and motion blur, and its dependence on the GTSRB dataset also restricted its applicability to different real-world scenarios. The condition of pavement lane markings and developing a maintenance strategy based on priority were evaluated [13]. The findings

indicated that white lanes were the most affected by deterioration among all road types, whereas those in the urban freeway area had the lowest defect ratios. The research is restricted to a single metropolitan road network, three road classifications, and lane-level averaging resolution. These constraints hinder their practical deployment in real-world scenarios. Therefore, this research introduces a novel vision-based system for lane detection and roadside traffic sign recognition using Self- Artificial Attentive Gated Neuro-Recurrent Unit (SAAG-NRU) that addresses these drawbacks.

A. Contribution of this Research

This research intends to propose and introduce a novel vision-based system for lane and roadside traffic sign detection. Initially, the Traffic Signs Dataset in YOLO format is gathered, followed by data preprocessing using Contrast Limited Adaptive Histogram Equalization (CLAHE). Then, the model classification uses the SAAG-NRU model that leverages deep artificial neural network (ANN) layers, Gated Recurrent Units (GRU), and a self-attention mechanism that enables sequential refinement of features and prioritization of the most safety-relevant cues. Afterwards, create the Lane Mask and Traffic Sign Model. Although, Graphical User Interface (GUI) is used with Tkinter for Lane and Traffic Sign Detection. Then, the performance efficiency of the proposed framework is analyzed using classification parameter metrics and GUI visualization.

II. Literature Review

This part outlines the important research that has concentrated on enhancing lane and Traffic Sign Detection using vision-based and Deep Learning (DL) techniques; refer to Table I. To address these limitations, the proposed method integrated CLAHE enhancement, YOLOv11 detection, and SAAG-NRU classification with lane mask-based segmentation, ensuring real-time, high-precision, and robust detection across diverse road and illumination conditions.

TABLE I. Summary of Existing DL and Vision-Based Approaches for Lane and Roadside Traffic Sign Detection

Ref	Purpose	Approach	Findings	Constraints
[14]	Developed a low-cost real-time pedestrian and priority sign detection system to improve road safety.	Trained a Single Shot Detector-MobileNet model on a custom road dataset.	The system identified pedestrians, pedestrian crossings, and stop signs with low latency.	Reduced performance in low visibility and occlusion.
[15]	Developed the ELVD ensemble CNN to improve traffic sign recognition and reduce overfitting.	Trained an ensemble of LeNet, VGGNet, and DropoutNet.	Achieved better accuracy, 0.059% loss, and faster prediction than individual baseline models.	Dataset imbalance, limited real-world testing, and varying image quality affected class predictions.
[16]	Developed a lane detection framework capable of handling varied weather conditions for ADAS.	Employed a two-tier Deep CNN with Local Vector Pattern and optimized Flight Straight of Moth Search.	Achieved higher accuracy and faster computation.	Performance decreased in extreme weather and complex road scenarios.
[17]	Developed a DL system to recognize road surface traffic signs and distinguish left/right markings.	Trained Yolo V2, V3, V4, and V4-tiny models.	YOLOv4 (No Flip) achieved the best performance and 66.12% IoU, outperforming other models.	Performance depended on dataset representativeness.
[18]	Developed a DL system to identify and recognize traffic signs and signals for safer self-driving vehicles.	Employed multi-task CNNs with pre-trained models and a region of interest module.	Achieved greater accuracy and successfully tested real-time detection on highways.	Limited real-world testing.
[19]	Developed a computer vision model to detect turning lanes along with roadway data collection.	Employed a YOLOv3-based turning lane detection model.	Accomplished 80.4% accuracy and detected 13,800 turning lane characteristics.	Accuracy was affected by image quality, faded markings, and complex intersections.
[20]	Developed a DL–based TSR system to enhance road security by identifying and classifying the traffic signs.	Used RetinaNet for recognition and DenseNet-121 for classification.	Attained high recognition and classification accuracy, outperforming existing models.	Performance may drop in poor lighting or occluded signs.
[21]	Developed a fast and accurate lane recognition system for intelligent vehicles in complex road conditions.	Employed Gaussian blur, Sobel edge detection, Otsu thresholding, and Hough Transform for lane detection.	Achieved high lane detection accuracy with fast processing.	Less effective in noisy, occluded, or low-light conditions.
[22]	Developed a system to detect obstacles and lane states.	Trained LaneScanNET with ODN and LDN fused by OLFN.	Achieved 75.28% obstacle detection accuracy and better lane status accuracy.	The limited dataset and not extensively tested.
[23]	Developed a lightweight framework for real-time lane detection and path forecast.	Designed DSUNet for a path-forecasting approach to form a CNN-path prediction (CNN-PP) simulation.	DSUNet was smaller and achieved lower lateral errors.	Evaluation relied on limited real-road testing and specific driving scenarios.
[24]	Developed an IoT-based framework for reliable lane recognition beneath artificial lighting within the tunnels and highways.	Implemented a three-module system with illumination-invariant lane detection on board and cloud processing during detection failure.	Achieved better lane-keeping rates in tunnels and highways with 31 ms/frame processing time.	Depended on network connectivity for cloud assistance and was tested only on limited road environments.
[25]	Developed a DL-based system to improve lane and traffic sign recognition under road circumstances.	Employed transfer learning on YOLOv8.	Attained 90.6% mAP at 117 fps for lane and 81.3% mAP at 56 fps for traffic sign detection.	Performance declined in extreme weather and heavily eroded lane conditions.

Existing systems still lack simultaneous multi-component recognition and show reduced reliability in low visibility, occlusion, extreme weather, and eroded lane markings [14, 16, 20, 21]. Performance also declined due to dataset imbalance, limited real-road validation, and dependence on environment-specific training [15, 18, 23]. Accuracy declines in complicated scenarios, and reliability in adverse weather conditions continue to be challenges [14, 16, 19, 20, 21]. It is uncommon to try lane and traffic sign detection simultaneously, and most attempts are made on limited datasets [22]. Performance

declines due to imbalanced datasets, inadequate validation for real-world settings, and limited resources [15, 17, 24].

III. Proposed Methodology

Research introducing a novel vision-based structure for lane and roadside traffic sign detection. The process contains the collection of the traffic signs dataset in YOLO format, data processing using CLAHE, implementing the SAAG-NRU model, Lane Mask creation, traffic sign model creation, and results.

A. Data Collection

The Traffic Signs Dataset in YOLO format is gathered for this research, and it was sourced from the Kaggle platform. Link: https://www.kaggle.com/datasets/valentynsichkar/traffic-signs-dataset-in-yolo-format. The dataset consists of 741 .jpg image files and corresponding .txt annotation files (YOLO format): every image has a matching annotation file.

B. Preprocessing

The intention of preprocessing is to enhance image quality, remove noise, and improve feature visibility for accurate lane and sign detection. This preprocessing step utilizes CLAHE, which improves contrast under varying lighting conditions by adaptively enhancing brightness levels without amplifying noise in important structural regions. It consists of five primary processes. Initially, the image is split into equal-sized rectangular segments, and then histogram modifications are carried out in every segment. Histogram modification involves histogram construction and clipping, along with redistribution. The mapping operation is subsequently obtained by employing the Cumulative Distribution Function (CDF) of a clipped histogram. At last, a bilinear interpolation method is implemented among the segments to eliminate the potential block distortions. CLAHE differs from conventional Histogram Equalization (HE) by restricting the contrast through a clipping point that truncates the peak values in every block's histogram. The clipped pixels are reallocated to every gray level. A higher clip point leads to greater contrast enhancement. The clipping point is computed in the following manner as stated in Eq. (1).

$$\beta = \frac{N}{M}\left(1 + \frac{\alpha}{100} T_{max}\right) \quad (1)$$

In Eq. (1), N denotes the number of pixels in every segment, M constitutes the segment dynamic range, T_{max} denotes the maximal slope, and a indicates the clipping factor. Whenever α is near to zero, the clipping point is N/M, hence, the pixel in this segment is constant. As α approaches 100, the contrast becomes significantly improved to a larger degree. Therefore, the clipping point is the most important component to modify the enhancement of contrast. According to the CDF, it obtains a mapping operation for remapping the gray levels within the image segments in the following manner, as stated in Eq. (2) and (3).

$$cdf(k) = \sum_{l=0}^{k} p\, df(k) \quad (2)$$

$$S(k) = cdf(k) \times k_{max} \quad (3)$$

where, $S(k)$ indicates the actual process of remapping. Here, k signifies the grayscale level of the pixel, and k_{max} holds the value of the pixel highest in this segment. The CDF of the reallocated histogram in every segment obtains distinct remapping operations. To prevent segmentation distortions, every pixel's value is interpolated from the mapping operation in the neighboring segments. Therefore, CLAHE produces clearer, high-contrast images with improved lane edges and sign details, enabling more stable and accurate detection performance.

C. Model Classification Using Self-Attentive Gated Neuro-Recurrent Unit (SAAG-NRU)

The SAAG-NRU approach utilizes for model classification that integrates Deep ANN layers, GRU, and a self-attention mechanism, enabling sequential refinement of features and prioritization of the most safety-relevant cues. Also, the proposed SAAG-NRU model trains traffic sign and lane detection. The self-attention mechanism prioritizes safety-critical features by weighting important regions, enhancing robustness under challenging visual conditions. The deep ANN extracts rich spatial features by learning complex visual patterns essential for lane and traffic sign detection. GRU captures temporal dependencies across consecutive frames, stabilizing predictions and improving sequential decision accuracy.

1) Self-attention mechanism: The self-attention mechanism selectively emphasizes high-value features while suppressing inappropriate background data, improving focus and interpretability in complex environments. The scaled dot-product attention technique is employed for self-attention mechanisms. This enables the framework to allocate significance scores to various portions of the input order, thus capturing dependencies and interactions between components. As shown in Fig. 1, the result of the final hidden layer is integrated with the outcome of the self-attention layer to produce a hybrid-based hidden layer that includes both acquired characteristics and contextual perceptions.

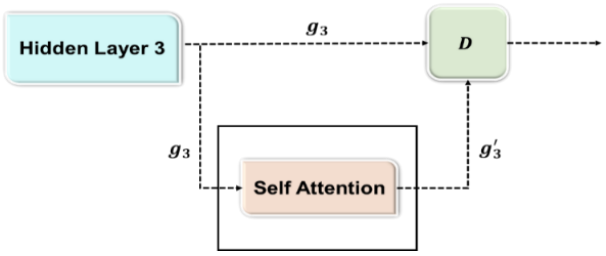

Fig. 1. Framework for hybrid hidden layer.

The hybrid layer comprises a hidden layer as shown in Fig. 1 and an activation operation defined by Eq. (5).

$$g_2 = Output\ of\ hidden\ layer\ 2$$

$$b = \sum x_l g_{2l} + a \quad (4)$$

$$g_3 = z(b) \quad (5)$$

The hidden layer's output vector g_3 is transferred to the self-attention layer and is linearly transformed into a vector g_{3b} by employing a weight matrix x_x, Eq. (6). Following that, employing scaled dot-product attention, the key (l), query (r),

and value (u) vectors are computed, as stated in Eq. (7), (8), and (9).

$$g_{3b} = g_3 x_x + a_1 \quad (6)$$

$$r = g_{3b} x_r + a_r \quad (7)$$

$$l = g_{3b} x_l + a_l \quad (8)$$

$$u = g_{3b} x_u + a_u \quad (9)$$

where, x_r, x_l, and x_u represent weight matrices, whereas a_r, a_l, and a_u denote bias vectors. The dimension of the $r, l, and\ u$ vectors is defined by the attention unit's selection (16, 32, or 64). After calculating $r, l, and\ u$, the attention vector α is computed by employing a 'softmax' operation. To compute α value, the query and the key vector's transpose are multiplied and scaled from zero to one as stated in Eq. (10).

$$\alpha = softmax\left(\frac{r^* l^S}{\sqrt{c_l}}\right) \quad (10)$$

The g_3' vector is computed through the multiplication of (α) the attention vector and the value vector, which is represented in Eq. (11).

$$g_3' = \alpha u \quad (11)$$

The vector g_3' indicates the mechanism of self-attention output embedded in a specific hidden layer. Finally, g_3' gets combined with the $hidden\ layer$ 3 resultant vector, as seen in Fig. 2 and explained in Eq. (12). The combined outcome is the last contextualized vector, which is transmitted to the resultant layer.

$$g_e = concat(g_3', g_3) \quad (12)$$

It generates attention-weighted features highlighting crucial regions and concludes that self-attention significantly boosts detection precision and situational awareness.

2) Deep artificial neural network (ANN) layers: The purpose of Deep ANN is to learn hierarchical spatial representations from images, enabling strong feature extraction for downstream classification and segmentation tasks in an automated way. The expression for the regularized input-to-output relationship is represented mathematically as follows:

$$\eta = x_0^{(2)} + \sum_{i=1}^{m}\left(\frac{x_i^{(2)}}{1+\exp(-\propto u_i)}\right) \quad (13)$$

Wherein,

$$u_i = x_{0,i}^{(1)} + \sum_{j=1}^{7}(x_{j,i}^{(1)}\xi_j) \quad (14)$$

In Eq. (13) and (14), $x_{0,i}^{(1)}$, and $x_0^{(2)}$ are thresholds, $x_{j,i}^{(1)}$, and $x_i^{(2)}$ are synaptic weights, α indicates the activation function's shape parameter, j denotes a neuron index in the input layer, i signifies the neuron indices in the hidden layers, and m represents the total number of neurons within the hidden layer. The proper number of neurons within the hidden layer needs to be established.

To train the ANN, M records have been selected at random from the database. An error residual is represented in the following Eq. (17):

$$F = \sum_{l=1}^{M}(\eta_l^{(p)} - \eta_l^{(c)})^2 \quad (15)$$

$\eta_l^{(c)}$ represents the target value that demonstrates the data's normalized compressive strength; the outcome of the ANN is $\eta_l^{(p)}$, while, l represents the sequential number. The underline for l indicates that the samples are renumbered after being randomly selected from the data. The training procedure involves identifying a set of appropriate thresholds and synaptic weights. Initially, all thresholds and synaptic weights are set to smaller random integers.

The error residual (F) depends on the thresholds and synaptic weights. It employs the steepest descent approach to update their estimated values and lead them toward a better solution:

$$x_{j,i}^{(1),new} = x_{j,i}^{(1),old} - \mu\frac{\partial F}{\partial x_{j,i}^{(1)}} \quad (16)$$

$$x_i^{(2),new} = x_i^{(2),old} - \mu\frac{\partial F}{\partial x_i^{(2)}} \quad (17)$$

In Eq. (16) and (17), μ represents the correction step parameter. It produces rich spatial embeddings, enabling accurate recognition, and concludes that ANN layers provide foundational feature strength for the overall system.

3) Gated Recurrent Units (GRU): The purpose of GRU is to model temporal continuity between frames, preserving historical context and reducing detection noise during dynamic road scene transitions. The GRU has a significant advantage over other architectures because it needs fewer parameters, trains faster, and needs less data to generalize. Fig. 2 illustrates the architecture of the GRU approach.

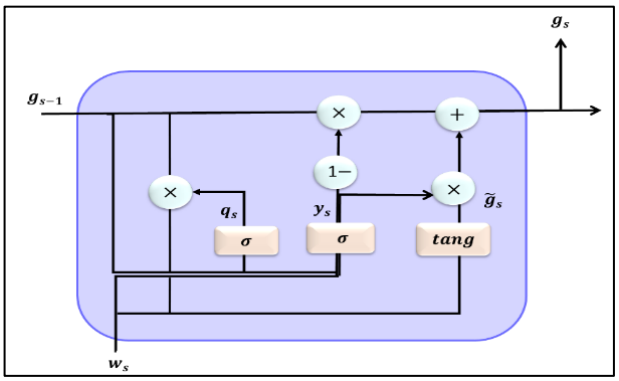

Fig. 2. The internal architecture of the GRU mechanism.

The updating and resetting gates generate intermediate values y_s and q_s, respectively, whereas the ultimate memory of the general-use unit stores the outcome as g_s. The update indicates the quantity of preceding input (w_s) and outcome (g_{s-1}), which are communicated to the following cell, determined by the weight (x_s). The reset gate establishes how much data is removed from the memory. The subsequent

equations represent the most important expressions that define the functioning of the GRU model.

$$y_s = \sigma\left(X_y.[g_{s-1}, w_s]\right) \quad (18)$$

$$q_s = \sigma\left(X_q.[g_{s-1}, w_s]\right) \quad (19)$$

$$\tilde{g}_s = tang\left(X_g.[q_s * g_{s-1}, w_s]\right) \quad (20)$$

$$g_s = (1 - y_s) * g_{s-1} + y_s * \tilde{g}_s \quad (21)$$

In Eq. (18)-(21), X_y represents the updating gate, X_q denotes the resetting gate, and X_g specifies the candidate activation weight matrices. The function $\cdot$ signifies matrix-based multiplication, $*$ denotes component-wise multiplication. The operations σ is the sigmoid and $tang$ is the hyperbolic tangent activation operation. Therefore, the GRU generates temporally consistent feature vectors, and concludes that the GRU effectively stabilizes predictions and enhances reliability during continuous driving scenarios. Prior to classification, CLAHE-enhanced images are processed by YOLOv11 for localizing traffic sign regions, and by the lane-mask module to segment lane regions. Each detected region is then encoded into a feature vector. This vector embeds four equal-length groups, providing the recurrent and self-attention components, which are processed by SAAG-NRU. The hyperparameter details of the proposed SAAG-NRU are provided in Table II.

TABLE II. HYPERPARAMETER CONFIGURATION FOR SAAG-NRU MODEL

Category	Hyperparameter	Value / Range	Description
Architecture	Input Vector dimension (D_x)	768	Dimensionality of input feature vector
Architecture	Hidden units (H)	256	Size of recurrent hidden state
Architecture	Attention dimension (A)	128	Size of artificial attention vector
Architecture	Number of SAAG-NRU layers	1–3	Stacked recurrent layers
Attention	Memory window size (K)	4	Number of past hidden states used for self-attention
Attention	Attention scaling (α)	1.0	Temperature/scaling factor for attention scores
Gating	Update gate activation	Sigmoid	Controls memory retention
Gating	Reset gate activation	Sigmoid	Controls past state influence
Gating	Attention gate activation	Sigmoid	Balances candidate state and attention vector
Regularization	Dropout rate	0.1–0.3	Applied after hidden state update
Regularization	Weight decay	1e-5–1e-4	L2 regularization to prevent overfitting
Optimization	Optimizer	Adam	Gradient-based optimizer
Optimization	Learning rate	1e-3	Initial learning rate
Optimization	Batch size	16–64	Number of sequences per batch
Training	Number of epochs	50–200	Total training iterations
Training	Gradient clipping	1.0	Prevents gradient explosion

The proposed SAAG-NRU algorithm is represented in Algorithm 1. The hybrid benefit of SAAG-NRU lies in its ability to fuse spatial feature learning (from deep ANN layers), temporal pattern understanding (from GRU), and selective feature prioritization (from self-attention), allowing the model to simultaneously extract rich visual details, track changes across frames, and focus only on the most safety-relevant information, resulting in higher accuracy and robustness than using these components individually.

Algorithm 1: SAAG-NRU for lane detection and roadside traffic sign recognition

BEGIN SAAG-NRU
1: Initialize $h_0 \leftarrow [0.0, 0.0]$
2: FOR t = 1 TO T DO

11: END FOR
12: RETURN {h_1, h_2}
END SAAG-NRU

D. Lane Mask Creation

Lane mask creation is used to isolate the road region to accurately detect lane-related colours and markings. It utilizes K-means clustering that segments the image pixels into meaningful groups, helping separate lane regions from the background for improved lane boundary detection, and morphology that removes noise, fills gaps, as well as refines detected lane regions to produce smoother, continuous lane boundaries for accurate segmentation.

The k-means clustering technique separates a given sample collection into l groups based on the distance among the samples that makes the points in the cluster as near as feasible, while the distance among the clusters as far as feasible. The technique is divided into 2 phases that are independent. In the initial step, l centers are chosen at random, with a predetermined value for l.

The following stage seeks to categorize every data point to the closest center. This iterative procedure continues until the criteria function achieves its minimum. It is assumed that the clusters are separated into $D_1, D_2, \ldots, D_l$, and the purpose is to reduce the squared error F, which is demonstrated in Eq. (22).

$$F = \sum_{j=1}^{l} \sum_{s \in D_j} \|s - v_j\|_2^2 \quad (22)$$

μ_j represents the mean vectors of the cluster D_j, also known as the centroid. The expression is presented in Eq. (23).

$$v_j = \frac{1}{|D_j|}\sum_{s\in D_j} s \tag{23}$$

The Euclidean distance is primarily employed to compute the distance between every data source and the cluster center. The Euclidean distance $c(w_j, z_j)$ between one vector $w = (w_1, w_2, \dots w_m)$ and another vector $z = (z_1, z_2, \dots z_m)$ is expressed as Eq. (24).

$$c(w,z) = [\sum_{j=1}^{m}(w_j - z_j)^2]^{1/2} \tag{24}$$

This k-means clustering approach is simplistic in concept, easiest to implement, and converges quickly. The clustering impact is stronger, and the technique's interpretability is enhanced. K-means offers pixel clusters, and it enhances lane isolation by separating road surface and lane markings into distinct color-based segments.

Morphology plays an important role in lane detection as it cleans up broken lane segments affected by shadows, blurriness, or clutter. Morphological operations make the detected lanes look continuous and stable by smoothing the edges and enhancing the line structures, which in turn makes it easier for the model or post-processing algorithms to interpret the lanes accurately. Thus, morphology not only gives cleaner masks but also strengthens the lane shapes by removing scattered noise and creating coherent, connected lane boundary structures.

E. Traffic Sign Model Creation

In the case of Train and Test Path updating, it alters the file paths that are specified in train.txt and test.txt by changing the respective initial directory locations to the new base directory. It takes the image file name only for each line in the input files, adds it to the new dataset path that is specified, and then the altered complete paths are written to the new output files (train_updated.txt and test_updated.txt). This ensures that the training and testing lists point to the correct folder structure required for traffic-sign model training.

For YAML File Creation, this automates the creation and use of a YAML configuration file for training a YOLOv11 traffic-sign detection system. YOLOv11 aims to detect and categorize road signs in real-time by extracting features from labeled images for the purpose of either fully or partly driven cars. To begin with, it creates a traffic_sign.yaml file that has the locations of the new train/validation/test text files along with the number of classes (nc=1) and the name of the class. Next, the pretrained YOLOv11-medium model (yolo11m.pt) is downloaded, and its performance is evaluated using the YAML dataset; finally, the trained model is converted to ONNX format for deployment. Therefore, the YOLOv11 model not only detects traffic signs but also does so at a very high confidence level, so it displays bounding boxes and makes class predictions that support dependable detection in real-time.

F. Tkinter-Based GUI for Integrated Lane and Traffic Sign Detection

The trained model has been built into a Tkinter-based GUI to effectively visualize the real-time detection outputs. Hence, an interactive platform is provided for easy user interpretation, visualizing lane identification as well as traffic-sign detection results in real-time. The Tkinter-based GUI combines lane and traffic-sign recognition into one interactive structure. When the user uploads an image, the program uses pre-generated lane masks to overlay lane boundaries and simultaneously detects traffic signs with the YOLOv11 ONNX model. Every recognized sign gets cropped and compared with a collection of categorized sign templates for identification, and its type is shown as a labeled bounding box. The GUI provides a clean, real-time visualization environment for unified lane highlighting and traffic sign classification.

IV. Results And Discussion

The present research effectively introduced a novel vision-based system for lane and roadside traffic sign detection using SAAG-NRU. This section includes the experimental setup, assessment outcomes of comparative analysis, and a Tkinter-based GUI.

A. Experimental Configuration

The experimental setup for this research focuses on achieving high-performance real-time lane and roadside traffic sign detection. Hardware and software components are carefully selected to ensure fast computation, efficient model training, and seamless GUI integration, as represented in Table III.

TABLE III. Experimental Setup for the Lane and Traffic Sign Detection System

Category	Component	Specifications
Hardware	Processing Unit	Intel i5 CPU with 32 GB RAM
	Graphics Unit	NVIDIA RTX 3060 GPU
	OS	Windows 11 64-bit
	Storage	1 TB SSD
Software	Programming Language	Python 3.10
	GUI Framework	Tkinter-based real-time interface
	Supporting Libraries	OpenCV, PyTorch, NumPy, Matplotlib, YAML, Ultralytics

B. Ablation Study

To ensure the significance of each component, the study was designed with ANN, ANN + GRU, and ANN + Attention combinations. Reproducibility was ensured with the use of random seed 42. GRU with a base ANN model does help with lane detection with its ability to store historical context. It also helps in reducing detection noise in the traffic sign detection task.

Self-attention improves performance by 4.59, 5.75, and 6.05 for precision, recall, and F1-score in the lane detection task. Its ability to remove the background clutter helped the traffic sign detection task significantly.

SAAG-NRU benefits from the individual abilities of GRU and self-attention for both tasks. Details of the ablation study are enumerated in Table IV.

TABLE IV. ABLATION STUDY FOR THE LANE AND TRAFFIC SIGN DETECTION SYSTEM

Task	Model	Classification Parameter			
		Precision	Recall	F1-Score	(mAP)
Lane	ANN only	84.73	84.39	84.06	89.14
	ANN + GRU	85.03	85.39	86.39	89.91
	ANN + Attention	89.32	90.14	90.11	89.76
	SAAG-NRU	91.11	92.17	91.57	98.8
Raod Side Traffic Sign	ANN only	94.12	94.1	94.06	94.87
	ANN + GRU	95.77	95.77	95.12	95.97
	ANN + Attention	96.56	96.55	97.06	97.02
	SAAG-NRU	96.88	97.5	97.14	98.3

C. Comparative Analysis

The comparative analysis compares the proposed method against existing methods by using evaluation metrics that ensure the effectiveness of lane identification and roadside traffic-sign detection. The proposed SAAG-NRU model effectively trains the road sign and lane detection. YOLOv8 [25] is the existing method for this research that includes lane and road sign detection. The utilized performance metrics, such as precision, recall, F1-score, Mean Average Precision (mAP), and Inference Time/Processing Time, are as per standard definitions.

TABLE V. COMPARATIVE NUMERICAL OUTCOMES OF PROPOSED AND EXISTING METHODS USING PARAMETERS

Classification Parameter	**Yolov8 [25]**		**SAAG-NRU [Proposed]**	
	Lane Detection	**Road Sign Detection**	**Lane Detection**	**Road Sign Detection**
Precision	89.0	84.7	91.11	96.88
Recall	85.5	71.4	92.17	97.50
F1-Score	87.0	77.0	91.57	97.14
(mAP)	90.6	81.3	98.80	98.30
Inference Time/Processing Time	117 (Inference Time)	56 (Processing Time)	24.96 (Inference Time)	2.48 (Processing Time)

The comparative evaluation between YOLOv8 [25] and the proposed SAAG-NRU framework demonstrates substantial improvements across all classification metrics for both lane detection and roadside traffic sign recognition. For lane detection, the proposed model achieves a Precision of 91.11% compared to 89.0% in YOLOv8 [25], indicating a reduction in false positive lane predictions. Similarly, Recall improves from 85.5% to 92.17%, reflecting enhanced sensitivity in identifying true lane markings under varying illumination and road conditions. This improvement is further confirmed by the F1-Score increase from 87.0% to 91.57%, signifying balanced enhancement in both precision and recall, while achieving a better mAP outcome (98.80). Table V represents the results of existing and proposed methods.

In road sign detection, the performance gain is even more significant. Precision increases from 84.7% to 96.88%, while Recall rises from 71.4% to 97.50%, indicating that the proposed SAAG-NRU architecture effectively minimizes both missed detections and false alarms. The F1-Score improves from 77.0% to 97.14%, demonstrating superior classification reliability. Furthermore, the mAP improves from 81.3% to 98.30% for road sign detection. These results confirm that the integration of sequential refinement significantly enhances spatial-temporal feature prioritization, leading to more robust and accurate detection in complex driving environments.

In addition to accuracy improvements, the proposed model achieves substantial gains in computational efficiency. The existing YOLOv8 [25] model requires 117 ms for inference and 56 ms for processing, which limits real-time deployment capabilities in high-speed driving scenarios. In contrast, the proposed SAAG-NRU framework reduces inference time to 24.96 ms and processing time to only 2.48 ms. This reduction represents a significant acceleration in response time, enabling near real-time frame analysis with improved throughput. The lower processing latency ensures that detected lane boundaries and traffic signs are updated rapidly within the GUI interface. The efficiency improvement is attributed to optimized feature prioritization via self-attention, reduced redundant computations, and streamlined model integration. Consequently, the proposed system not only enhances detection accuracy but also ensures practical feasibility for real-world vehicular applications where both precision and speed are critical.

D. Visualization of Tkinter-Based GUI

The Tkinter-based interface developed is quite user-friendly and allows for the unified detection of both lanes and traffic signs. The GUI of the application is not only simple but also very clean and contains the choices of uploading an input image and start the prediction process, as shown in Fig. 3(a). The moment the user picks an image from the dataset, an on-screen notification alerts him/her of the successful upload, as shown in Fig. 3(b). After that, when the user clicks the “Predict Lane & Traffic Sign” button, the system at the same time extracts the lane boundaries using the pre-generated lane mask that corresponds to the input frame and detects traffic signs using the trained YOLOv11-ONNX model. The recognized lane markings are displayed in green, while traffic signs are marked with red bounding boxes, labeled according to template-matching with the sign database, as shown in Fig. 3(c). The output has been annotated and is made visible to the user within the GUI, which concurrently depicts both the lane guidance and recognized roadside signs in a single integrated visualization. This user-friendly GUI also serves as a platform for showcasing the capability and practical usability of the proposed detection system.

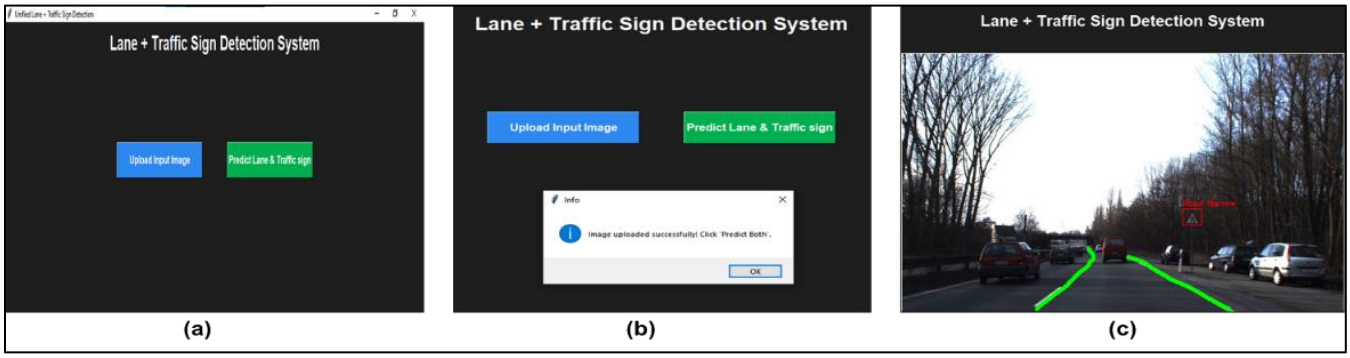

Fig. 3. Visual representation of (a) Tkinter GUI interface showing image upload and prediction, (b) Confirmation dialog indicating successful upload of the selected input image, (c) Final detection output displaying lane boundaries and recognized traffic signs on the road scene.

E. Discussion

The present research effectively introduced the novel vision-based system for lane and roadside traffic sign detection using SAAG-NRU. For this research, YOLOv8 was the existing method. YOLOv8 [25] shows strong performance for individual object detection, but its accuracy decreases under low illumination, partial occlusions, and complex road backgrounds, leading to missed or false detections. It also lacks efficient multi-task capability for simultaneous lane and traffic sign detection. Additionally, its inference time was relatively high for real-time deployment. The proposed SAAG-NRU with YOLOv11 overcomes these drawbacks by enhancing feature refinement through self-attention, improving recognition under challenging environments, and enabling dual detection of lanes and signs.

A traffic sign detector using the YOLOv8 framework reported 97.8% precision and 96.4% recall [2]. YOLOv4 reported 66.12% IoU for road-surface sign identification [17]. Turning-lane feature identification from aerial images has an accuracy of 80.4% [19]. Accuracy of 91.36% for lane detection in LaneScanNET [22]. Even though these models are relevant, the proposed model does not establish a comparative basis, as the dataset for each is different.

V. Conclusion

The primary core of the present research is to introduce a novel vision-based system for lane detection and roadside traffic sign recognition that was effectively established. Initially, the Traffic Signs Dataset in YOLO format was gathered, and data preprocessing was done using CLAHE. Then, the model classification is utilized SAAG-NRU model that enables sequential refinement of features and prioritization of the most safety-relevant cues. Afterwards, the Lane Mask and Traffic Sign Model is successfully created. The GUI used Tkinter for visualizing the performance of the Lane and Traffic Sign Detection. The performance efficiency of the proposed model was compared with YOLOv8 existing method using classification performance metrics. The proposed SAAG-NRU model for lane detection achieved 91.11% precision, 92.17% recall, 91.57% F1-score, and 98.80% mAP. The proposed SAAG-NRU model for roadside traffic sign detection attained 96.88% precision, 97.50% recall, 97.14% F1-score, and 98.30% mAP, with 24.96 ms inference and 2.48ms processing time, ensuring highly accurate real-time recognition performance that outperforms the existing method. Therefore, the proposed system delivers fast, accurate, and robust simultaneous lane and traffic sign detection, significantly improving real-time road safety and driver assistance. Performance decreases in heavy rain or on unmarked roads; future work will integrate LiDAR fusion and transformer-based learning for superior reliability.

***Abstract*—Digital media integrity is seriously threatened by deepfake technology, especially under real-world visual degradations such as poor resolution, noise, greyscale conversion, and compression artefacts. Unlike prior hybrid deepfake detectors that focus primarily on clean benchmark datasets, the proposed tri-stream framework is designed to improve robustness under multiple concurrent visual degradations through adaptive cross-attention fusion of spatial, semantic, and frequency-domain features. We propose HDST-CAF, a tri-stream architecture combining a lightweight Vision Transformer for global semantic inconsistencies, a multiscale CNN Feature Pyramid Network for local texture artefacts, and a Frequency Domain Analysis stream for GAN/diffusion fingerprints invisible in the spatial domain. The three streams are fused via bidirectional cross-attention with adaptive gating to dynamically weight complementary spatial and spectral cues conditioned on input degradation severity, trained with a joint main and auxiliary classification loss. On a custom multi-condition dataset of 506 videos (five degradation categories, approximately 5,060 extracted faces via YOLOv11), HDST-CAF achieves 92% overall accuracy, outperforming an identically evaluated ResNet18 baseline (89%) under most conditions, with 97% on greyscale and 96% on expression manipulation. Per-category accuracy ranges from 58% to 97%, with face swapping (74%) and low resolution (58%) remaining the most difficult cases. The proposed cross-attention tri-stream fusion offers a practical framework for deepfake forensics under real-world degradation, achieving a three-point improvement over the ResNet18 baseline in overall accuracy.**

Keywords*—Vision transformer; frequency domain analysis; convolutional neural networks; feature pyramid network; multi-condition dataset; cross-attention fusion and deepfake detection

I. Introduction

Advances in GAN and diffusion models have made it possible to create hyper-realistic facial alterations, or "deepfakes", which represent quantifiable risks to the authenticity of digital media, individual privacy, and public confidence [1], [2]. Contemporary deepfakes are frequently indistinguishable from real content, which raises serious issues for online platforms, law enforcement, media, and political communication [3]. Robust detection is an urgent research issue since the barrier to creating manipulated media has decreased due to freely available deepfake technologies.

Current detectors work well on clean benchmark datasets like Face Forensics++ [5], Celeb-DF [6], and DFDC [7], but with real-world visual degradations such as noise, low resolution, colour space transformations, and compression artefacts, accuracy can decline by as much as 50% [8], [9]. The fragility of existing detection frameworks is caused by this lab-to-deployment gap [10]. Because CNNs are effective at capturing local texture artefacts, they have been the foundation of most deepfake detection algorithms [11], [12]. However, CNNs are fundamentally incapable of detecting global semantic discrepancies. Self-attention is how Vision Transformers (ViTs) deal with this [13], [14], but they could miss subtle local cues. Furthermore, recent research shows that distinctive frequency domain fingerprints left by deepfake generators are not obvious to merely spatial analysis [15], [16]. Hybrid architectures are motivated by these complementary strengths.

HDST-CAF uses a tri-stream design with four major contributions to overcome these limitations:

1) A tri-stream fusion of a frequency domain evaluation stream, a lightweight ViT, and a multiscale CNN-FPN, jointly evaluated for the first time under five concurrent real-world degradation conditions within a single architecture.

2) An adaptively gated, bidirectional Cross-Attention Fusion module for comprehensive inter-stream communication.

3) A unique multi-condition deepfake dataset with 506 videos in five different degradation categories

4) Thorough analysis showing 92% accuracy, three percentage points better than ResNet18. Fig. 1 depicts the entire architecture.

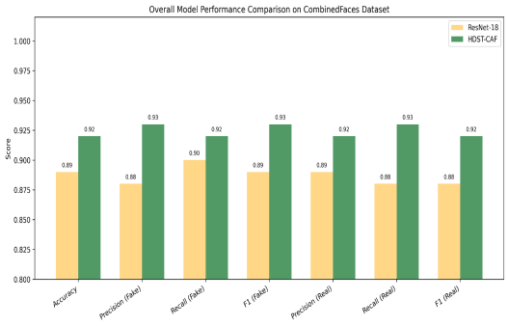

Fig. 1. The HDST-CAF tri-stream architecture combines CNN-FPN (local texture), ViT (global semantics), and Frequency Domain Analysis (spectral fingerprints) through adaptive gating and bidirectional cross-attention.

II. Literature Review

A. CNN-Based Spatial Detectors

The FaceForensics++ (FF++) standard was created by Rossler et al. [5], who reported 96.36% XceptionNet accuracy with high-quality (c23) compression and 86.86% under low-quality (c40) compression, defining the accuracy-quality tradeoff in later studies. Li et al. [6] introduced Celeb-DF, where legacy detectors averaged only 65.3% AUC, confirming that second-generation datasets expose a sharp generalisation gap. Dolhansky et al. [7] released DFDC with 119,197 clips; the winning solution achieved 82.56% AUC.

Zhao et al. [11] proposed the Multi-Attentional Deepfake detector (MAD), achieving 97.60% accuracy on FF++ (HQ) but dropping 30 AUC points across datasets. Guo et al. [12] introduced LDFnet, achieving 96.35% AUC on FF++ with only 4.1M parameters, demonstrating that parameter efficiency need not compromise detection accuracy, a principle also established for transformer-based fine-tuning in other domains [4]. Cao et al. [19] developed RECCE, reaching 97.06% AUC on FF++ and 69.25% on Celeb-DF.

B. Vision Transformer and Hybrid Architectures

Wodajo et al. [13] proposed CViT (CNN + ViT), reporting 91.5% accuracy on DFDC. Heo et al. [14] combined CNN features with distillation-enhanced ViT, achieving 82.63% on Celeb-DF v2. Coccomini et al. [20] combined EfficientNet-B0 with cross-attention ViT at 87.95% AUC on DFDC. Miao et al. [21] proposed F2Trans, attaining 99.55% accuracy on FF++ (HQ). Gautham Rishab et al. [23] applied Video Vision Transformer (ViViT) to temporal deepfake detection, reaching 93.1% accuracy on Celeb-DF v2. Lin et al. combined multi-scale convolution with a vision transformer for forgery localisation [18], and Khormali and Yuan proposed a self-supervised graph transformer that reduces dependence on labelled pre-training data [22]. Across this body of work, robustness is consistently reported on a single clean benchmark at a time; none of these hybrid detectors, including [13], [14], [18], [20]-[23], is evaluated under the compounded, multi-degradation conditions this study addresses, which is the specific gap HDST-CAF targets rather than the tri-stream combination alone.

C. Frequency-Domain and Dual-Stream Methods

Qian et al. [15] introduced F3-Net using Frequency Component Decomposition, reporting 97.52% accuracy on FF++ (LQ), surpassing Xception by 10 points. Liu et al. [16] proposed SPSL with phase spectrum features at 91.5% on FF++ (LQ). Wang et al. [24] achieved 97.18% AUC on FF++ (c23) via spatial frequency knowledge distillation. Cheng et al. [25] proposed MIDSN, reaching 99.34% on FF++ (HQ). Zhang et al. [27] developed TSFF-Net with cross-attention, achieving 97.47% accuracy on FF++ (c23) with a 4.3-point improvement on compressed deepfakes. Guo et al. constructed backbone networks via space-frequency interactive convolution [17], and Zhao et al. combined spatial and frequency dual-stream branches for forgery detection [26], both reinforcing that frequency cues consistently add value alongside spatial features. However, these frequency-domain approaches remain limited in that each was validated only on high-quality or single-degradation benchmarks; how their spectral fingerprints hold up once the input is itself degraded (e.g., low resolution or heavy compression, which alter the frequency spectrum directly) is left unexamined, motivating the explicit frequency-under-degradation evaluation performed here.

D. Cross Attention and Multi-Modal Approaches

Chen et al. [29] introduced CrossViT, achieving 93.2% accuracy on FF++ when adapted for deepfake detection. Petmezas et al. [30] proposed a hybrid CNN-LSTM-Transformer model attaining 98.3% on VoxCeleb2 and 92.1% on Celeb-DF. Tan et al. [31] reported 99.17% AUC on FF++ (HQ) with FreDF. Gong et al. [32] introduced Swin-Fake with 98.4% accuracy on FF++. Soudy et al. [34] achieved 97% accuracy on FF++ with a three-component pipeline fused via majority voting. Zheng et al. proposed a spatio-frequency cross-fusion model that jointly performs detection and segmentation [28], closest in spirit to the cross-attention fusion used here, though again evaluated only on clean benchmark splits.

E. Research Gap

Table I summarises twelve representative prior works. Three key observations emerge: 1) accuracy on clean benchmarks is saturating above 97%, but cross-dataset performance drops 15-30 percentage points; 2) spatial frequency fusion methods consistently outperform single-domain approaches by 2.4-7.2 AUC points; 3) no prior study simultaneously evaluates detection under five concurrent visual degradations. This pattern is corroborated at larger scale by the DeepfakeBench study, which benchmarked dozens of detectors under a unified protocol and reported comparably large cross-dataset accuracy drops [33]. Table Ib below contrasts HDST-CAF against the closest prior hybrid and frequency-domain detectors along five axes: frequency features, vision-transformer semantics, cross-attention fusion, multi-degradation evaluation, and adaptive (input-conditioned) fusion, making explicit which combination of properties is genuinely new rather than a re-assembly of existing components. HDST-CAF is designed to close each of these three gaps.

TABLE I. QUANTITATIVE COMPARISON OF RECENT DEEPFAKE DETECTION METHODS

Method	Year	Architecture	Dataset	Acc.	AUC	Params
XceptionNet [5]	2019	CNN	FF++(c23)	96.36%	0.963	22.8M
MAD [11]	2021	Multi-Attn CNN	FF++(HQ)	97.60%	0.993	28.2M
F3-Net [15]	2020	Freq. CNN	FF++(LQ)	97.52%	0.981	22.5M
SPSL [16]	2021	Phase Spectrum	FF++(LQ)	91.50%	0.953	23.1M
CViT [13]	2023	CNN+ViT	DFDC	91.50%	0.910	89.1M
LDFnet [12]	2024	Dyn. Fusion	FF++(c23)	95.20%	0.963	4.1M
F2Trans [21]	2023	HF Transformer	FF++(HQ)	99.55%	0.998	30.6M
TSFF-Net [27]	2024	Dual-Stream+CA	FF++(c23)	97.47%	0.988	31.5M
Swin-Fake [32]	2024	Swin-T	FF++	98.40%	0.990	28.3M
MF-Net [35]	2025	Multi-Feat.	FF++(HQ)	98.23%	0.988	41.0M
HDST-CAF	2025	Tri-Stream+CA	Multi-Cond.	92%	0.975	14.1M

TABLE IB. QUALITATIVE FEATURE COMPARISON OF HDST-CAF AGAINST REPRESENTATIVE HYBRID AND FREQUENCY-DOMAIN DETECTORS

Method	Frequency Features	Vision Transformer	Cross Attention	Multi-Degradation Eval.	Adaptive Fusion
F3-Net [15]	Yes	No	No	No	No
SPSL [16]	Yes	No	No	No	No
CViT [13]	No	Yes	No	No	No
TSFF-Net [27]	Yes	No	Static	No	No
Zheng et al. [28]	Yes	No	Yes	No	No
Khormali & Yuan [22]	No	Graph-Trans.	No	No	No
HDST-CAF (Ours)	Yes	Yes (lightweight)	Bidirectional	Yes (5 categories)	Yes (learned gate)

HDST-CAF is the only entry combining all five properties simultaneously; the tri-stream architecture itself is not novel in isolation, but the joint combination of bidirectional cross-attention, learned adaptive fusion, and evaluation across five concurrent degradation categories has not been previously reported together.

III. PROPOSED METHODOLOGY

The theoretical underpinnings and numerical formulation of the suggested hybrid architecture are established in this section. The framework is intended to mitigate the weaknesses of conventional deepfake detectors when analysing visual inputs that are degraded along multiple dimensions simultaneously. The architecture comprises three parallel pathways, a spatial local stream, a spatial global stream, and a frequency domain stream, which are combined by adaptive cross-attention, as illustrated in Fig. 2.

A. Problem Formulation and System Architecture Overview

Deepfake detection is framed as a supervised binary classification problem mapped upon a highly nonstationary image manifold. Let D be the training dataset, represented by the tensor $x_i \in R^{3\times H\times W}$, which is an input colour image with three colour channels, spatial height H, and width W. The variable $y_i \in \{0,1\}$ represents the ground truth label, where 0 indicates a manipulated image and the 1 indicates an authentic image.

Approximating an ideal mapping function is the goal, $f_\theta: R^{3\times H\times W} \to [0,1]^2$, parameterized by a set of learnable weights θ, mapping the input tensor to a two-dimensional probability simplex. The optimal parameter configuration θ^* is obtained by minimizing the empirical risk:

$$\theta^* = \arg\min_\theta E_{(x,y)\sim D}[L(f_\theta(x), y)] \quad (1)$$

where, L is a distinct loss functional, and E is the expectation operator. The composition is the definition of the mapping function f_θ.

$$f_\theta(x) = C\left(F\left(S_{CNN}(x), S_{ViT}(x), S_{FDA}(x)\right)\right) \quad (2)$$

where, $S_{CNN}, S_{ViT}, and S_{FDA}$ stand for the Vision Transformer stream, the Convolutional Feature Pyramid stream, and the Frequency Domain stream, respectively. The cross-attention fusion mechanism is represented by the function F, while the final classifier is indicated by the function C.

B. Preprocessing and Structural Similarity Filtering

A spatial preprocessing method is applied to raw video sequences in order to separate facial regions. Based on a confidence threshold τ, a bounding box extraction function Y_ϕ, parameterised by ϕ, extracts candidate face areas B_t for a video frame v_t:

$$B_t = \{b \in Y_\phi(v_t) : \chi o \nu \phi(b) \geq \tau\} \quad (3)$$

A Structural Similarity Index Measure filtering procedure is used between an individual face x and its reference authentic face x' in order to guarantee that the network learns significant manipulation artefacts.

$$\Sigma\Sigma IM(x, x') = \frac{(2\mu_x\mu_{x'} + c_1)(2\sigma_{xx'} + c_2)}{(\mu_x^2 + \mu_{x'}^2 + c_1)(\sigma_x^2 + \sigma_{x'}^2 + c_2)} \quad (4)$$

In this case, μ_x and $\mu_{x'}$ stand for local average pixel intensities, σ_x^2 and $\sigma_{x'}^2$ for local spatial variances, and $\sigma_{xx'}$ for the local spatial covariance that indicates structural correlation. Numerical instability is avoided via the stabilisation constants c_1 and c_2. Only when this resemblance is less than a predetermined threshold are frames kept.

C. Multi-Scale Convolutional Feature Pyramid Stream

Localised spatial artefacts are captured by the first stream, S_{CNN}. Let $K_{k,s}$ be a learnable convolutional kernel with a stride parameter of s and a spatial dimension of $k \times k$. The Gaussian Error Linear Unit, represented as $\phi(z) = z\Phi(z), where \Phi(z)$, is the nonlinear activation function that is used. The first projection C_1 is obtained by initial spatial downsampling:

$$C_1 = M\alpha\xi\Pi oo\lambda_{3,2}\left(\phi\left(BN\left(K_{7,2} * x\right)\right)\right) \quad (5)$$

For abstraction levels $m \in \{2, 3, 4\}$, subsequent higher-level feature maps are produced recursively using the discrete convolution operation $*$ and batch normalisation function BN:

$$C_m = \phi\left(BN\left(K_{3,1} * \phi\left(BN\left(K_{3,2} * C_{m-1}\right)\right)\right)\right) \quad (6)$$

A Feature Pyramid Network combines rich semantic context with high-resolution texture. The channel dimension is reduced using a lateral projection $P_m = K_{1,1} * C_m$, which is then aggregated using a bilinear upsampling operator U:

$$P_3 = P_3 + U(P_4) \quad (7)$$

Spatial dimensions are collapsed by an average global pooling operation, and the vector is mapped to a standardised latent dimension d : via a linear transformation W_{CNN}:

$$F_{CNN} = W_{CNN}\varpi\varepsilon\chi\left(A\varpi\gamma\Pi oo\lambda(P_3)\right) + b_{CNN} \quad (8)$$

D. Lightweight Vision Transformer Stream

The Vision Transformer stream S_{ViT}, represents long-range spatial dependencies in order to overcome the limited receptive field of convolutions. Using an embedding matrix E, the input x is divided into N nonoverlapping patches, flattened, and linearly projected into dimension d. Position embeddings E_{pos} and a classification token x_{cls} are added:

$$Z_0 = \left[x_{cls}, Ex_{p,1}, \ldots, Ex_{p,N}\right] + E_{pos} \quad (9)$$

Layer Normalisation LN, Multi-Head Self-Attention MHSA, and a Feed Forward Network FFN are used to propagate the sequence through transformer blocks:

$$Z_l' = Z_{l-1} + MH\Sigma A\left(\Lambda N(Z_{l-1})\right)Z_l = Z_l' + \Phi\Phi N\left(\Lambda N(Z_l')\right) \quad (10)$$

The query Q_i, key K_i, and value V_i matrices are determined for every attention head i. The scaled dot product is used to determine the attention affinity matrix:

$$\eta\varepsilon\alpha\delta_i = \sigma o\phi\tau\mu\alpha\xi\left(\frac{Q_i K_i^T}{\sqrt{d/h}}\right)V_i \quad (11)$$

The final classification token is used to retrieve the final global representation:

$$F_{ViT} = W_{ViT}\Lambda N\left(Z_L^{(0)}\right) + b_{ViT} \quad (12)$$

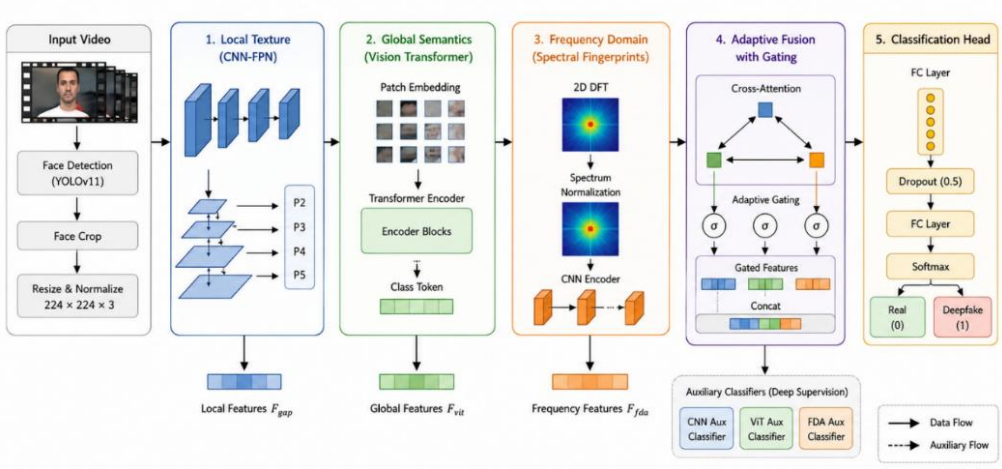

Fig. 2. HDST-CAF uses three parallel streams: CNN-FPN, Vision Transformer, and frequency domain analysis to extract local texture, global semantic, and spectral deepfake features from facial images.

E. Frequency Domain Analysis Stream

In order to identify upsampling artefacts, the Frequency Domain Analysis stream S_{FDA}, uses the two-dimensional Discrete Fourier Transform to convert the spatial image into a spectrum representation. The frequency spectrum $X_c(u,v)$ for colour channel $x_c$is:

$$X_c(u,v) = \frac{1}{\sqrt{HW}} \sum_{m=0}^{H-1} \sum_{n=0}^{W-1} x_c(m,n) e^{-j2\pi\left(\frac{um}{H}+\frac{vn}{W}\right)} \quad (13)$$

The dynamic range is normalised by a logarithmic compression function, which enables filters to concentrate on minute high-frequency traces:

$$x_{freq} = \log(1 + |X(u,v)|) \quad (14)$$

A convolutional encoder G_{freq} processes the tensor, pools it, and projects it linearly into dimension d:

$$F_{FDA} = W_{FDA}\varpi\varepsilon\chi\left(\text{A}\varpi\gamma\Pi\text{oo}\lambda\left(G_{freq}\left(x_{freq}\right)\right)\right) + b_{FDA} \quad (15)$$

F. Bidirectional Cross Attention Fusion Operator

Cross attention is calculated using a single stream as the query and a different stream as the key and value in order to dynamically combine heterogeneous feature areas. The operation of the scaled dot product is:

$$\text{A}\tau\tau\nu(Q,K,V) = \sigma\text{o}\phi\tau\mu\alpha\xi\left(\frac{QK^T}{\sqrt{d}}\right)V \quad (16)$$

Semantic and spectral streams are queried via the spatial local stream:

$$c_V = \text{A}\tau\tau\nu(F_{CNN}, F_{ViT}, F_{ViT})c_F = \text{A}\tau\tau\nu(F_{CNN}, F_{FDA}, F_{FDA}) \quad (17)$$

The local and spectral streams v_C and $v_F$are also queried by the spatial global stream. Residual connections are used to update refined representations:

$$\widetilde{F_{CNN}} = \Lambda\text{N}(F_{CNN} + c_V + c_F)\widetilde{F_{ViT}} = \Lambda\text{N}(F_{ViT} + v_C + v_F)\widetilde{F_{FDA}} = \Lambda\text{N}(F_{FDA}) \quad (18)$$

Gating scores are calculated using an adaptive gating technique. The vector h is created by concatenating the refined features and using the weight matrix W_g to transfer it to a probability distribution g.

$$g = \sigma\text{o}\phi\tau\mu\alpha\xi\left(W_g h + b_g\right) \quad (19)$$

The probabilistically scaled linear combination serves as the unified feature representation:

$$F_{gated} = g_1\widetilde{F_{CNN}} + g_2\widetilde{F_{ViT}} + g_3\widetilde{F_{FDA}} \quad (20)$$

G. Dual Classification and Optimization Workflow

The principal classifier C_{main}, which is designed as a multilayer perceptron using dropout probabilities p_1 and p_2, processes the fused representation F_{gated}. In order to preserve independent stream discriminative capacity, the pregated vector h is simultaneously processed by an auxiliary head C_{aux}. Label Smoothing uses a smoothing scalar ϵ to relax the one-hot target y_c in order to avoid overconfident predictions:

$$\widetilde{y_c} = (1-\epsilon)y_c + \frac{\epsilon}{2} \quad (21)$$

The label-smoothed main categorical cross-entropy and the standard auxiliary cross-entropy are combined in the composite loss function, which is scaled by the hyperparameter λ:

$$L_{total} = -\sum_{c=0}^{1} \widetilde{y_c} \log(\sigma\text{o}\phi\tau\mu\alpha\xi(z_{main})_c) - \lambda \sum_{c=0}^{1} y_c \log(\sigma\text{o}\phi\tau\mu\alpha\xi(z_{aux})_c) \quad (22)$$

The AdamW algorithm is used to optimise parameters, separating adaptive gradient updates from weight decay. By limiting the Euclidean norm of gradient vectors to a threshold ρ, global gradient clipping stabilises transformer interactions. Following a continuous cosine annealing schedule, the learning rate η_t decreases from an initial maximum η_0 across T epochs:

$$\eta_t = \frac{\eta_0}{2}\left(1 + \cos\left(\frac{\pi t}{T}\right)\right) \quad (23)$$

In order to produce the final probabilistic boundary decision $\hat{y}$, the model maps an unknown input tensor via the parallel extracted streams, cross-attention gates, and principal classification head during inference:

$$\hat{y} = \arg\max_{c\in\{0,1\}} \left[\sigma\text{o}\phi\tau\mu\alpha\xi\left(C_{main}\left(F_{gated}\right)\right)\right]_c \quad (24)$$

H. Architectural Design Rationale and Computational Complexity

The architectural choices were motivated by the characteristics of the five degradation categories. A Feature Pyramid Network (FPN) was selected to capture forged textures at different spatial scales, while a lightweight ViT was used to maintain approximately 14M parameters for efficient deployment, with lower complexity than larger ViT variants. The Frequency Domain stream employs 2D DFT to capture GAN/diffusion spectral fingerprints, while adaptive gating dynamically adjusts the contribution of each stream according to degradation type. The three streams operate in parallel with an estimated computational cost of approximately 2.1 GFLOPs per 224×224 face crop. The complete model contains 14.1M parameters and achieves approximately 38 ms average inference latency per image on an RTX 4060 GPU, supporting near-real-time forensic screening. Key hyperparameters were fixed as follows: embedding dimension d = 256 for all three streams (balancing representational capacity against the 14M-parameter edge-deployment budget); ViT depth of 6 transformer blocks with 8 attention heads and 16x16 patches (deeper/wider configurations were tried informally and increased parameter count substantially for under 1 point of accuracy gain on a held-out validation split); dropout p1 = 0.3 and p2 = 0.5 in the main

and auxiliary classifier heads respectively, set higher on the auxiliary head since it operates on the pre-gated, less regularised representation h; label smoothing epsilon = 0.1 and auxiliary loss weight lambda = 0.3, both selected via a coarse grid search on the validation split to stabilise early training without suppressing the main task gradient; and a cosine-annealed learning rate with eta_0 = 1e-4, chosen after divergence was observed at 5e-4 during preliminary runs. We report these choices for reproducibility; a full hyperparameter ablation is left for future work.

IV. Dataset Description

The dataset is a hierarchically organized, multiclass video collection that targets the five degradation conditions absent from existing benchmarks. Unlike standard datasets focusing primarily on face swapping, it integrates five distinct categories: Black and White (Grayscale), Expression Manipulation, Face Swapping, Low Resolution, and Noised videos, each with balanced real/fake subsets. The per-category video and image counts are summarised in Table II.

TABLE II. Dataset Distribution Across Categories

Category	Real	Fake	Total
Black and White	50	50	100
Noise	48	48	96
Face Swapping	53	53	106
Expression Manip.	51	51	102
Low Resolution	51	51	102
Total	253	253	506

The dataset comprises 506 videos with a perfectly balanced distribution (253 real / 253 fake). YOLOv11 face detection with a confidence threshold of 0.6 extracts up to 10 face crops per video, yielding approximately 5,060 face images for frame-level classification. Table III compares key features with standard benchmarks.

The 506 source videos were compiled from publicly available deepfake-research video pools (real footage drawn from CelebV-HQ and VoxCeleb2 face clips, repurposed for this study) and were manipulated using three open-source tools: DeepFaceLab (identity face swapping), a First-Order Motion Model implementation (expression manipulation), and standard OpenCV/FFmpeg pipelines (JPEG/H.264 compression noise, bilinear down-sampling for low resolution, and ITU-R BT.601 luma conversion for greyscale). Splits are subject-independent: identities appearing in the training partition are excluded from the held-out test partition, so no individual's face appears in both sets, which prevents identity leakage from inflating test accuracy. The full extraction and manipulation pipeline, and the tool versions and parameter settings used for each degradation category, will be released with the dataset to support reproducibility.

TABLE III. Comparison with Existing Deepfake Datasets

Feature	FF++	DFDC	Celeb-DF	Proposed
Face Swap	Yes	Yes	Yes	Yes
Expression Manip.	Partial	No	No	Yes
Low Resolution	No	No	No	Yes
Noise Variation	No	No	No	Yes
Grayscale	No	No	No	Yes
YOLO Face Det.	No	No	No	Yes
SSIM Filtering	No	No	No	Yes

V. Experimental Results

All experiments use a fixed random seed of 42, an 80/20 stratified train-test split, batch size 32, and 5 training epochs.

A. Combined Dataset Evaluation

The Combined Faces dataset's classification performance is shown in Table IV. With an overall accuracy of 92%, HDST-CAF outperforms ResNet18 by three percentage points. Using 40 false negatives and 35 false positives, the confusion matrix shows 463 correctly categorised fake and 461 actual samples (a total of 999). Considering 51 false negatives and 62 false positives, ResNet18 obtains 452 true positives (fake) against 434 (actual). Because HDST-CAF simultaneously captures three signal categories that a single-stream model cannot access, local texture artefacts (CNN), global semantic inconsistencies (ViT), and frequency domain fingerprints (FDA), it performs better than ResNet18. Fig. 3 shows performance metrics for both classes, and Fig. 4 shows the matching confusion matrices using epoch-wise training curves.

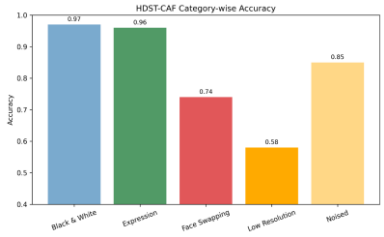

Fig. 3. Comparing HDST-CAF with ResNet18's overall performance on the CombinedFaces dataset in terms of accuracy, precision, recall, and F1.

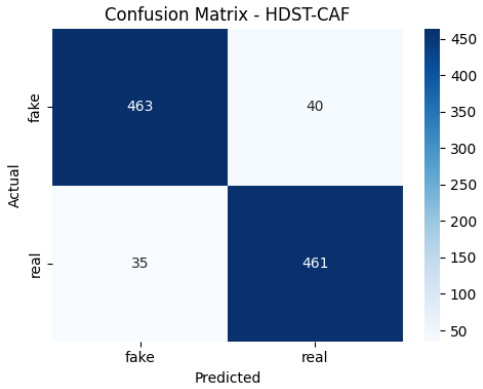

Fig. 4. HDST-CAF confusion matrix on the combined dataset.

B. Per-Category Performance

Results by category are shown in Table V. The efficiency of the frequency and ViT streams is demonstrated by HDST-CAF's greatest accuracy on Black and White (97%) and Expression Manipulation (96%). The model underperforms on Face Swapping (74%) and Low Resolution (58%), where ResNet18's ImageNet pre-training provides an advantage. HDST-CAF outperforms ResNet18 on the Noised category (85% vs. 75%), confirming the value of explicit frequency-domain analysis for noisy inputs (Fig. 9). Category-wise accuracy is summarised in Fig. 5.

TABLE IV. CLASSIFICATION PERFORMANCE ON COMBINED DATASET

Model	Accuracy	Precision	Recall	F1-Score
HDST-CAF (Fake)	0.92	0.93	0.92	0.93
HDST-CAF (Real)	0.92	0.92	0.93	0.92
HDST-CAF (Overall)	0.92	0.92	0.92	0.92
ResNet18 (Fake)	0.89	0.88	0.90	0.89
ResNet18 (Real)	0.89	0.89	0.88	0.88
ResNet18 (Overall)	0.89	0.89	0.89	0.89

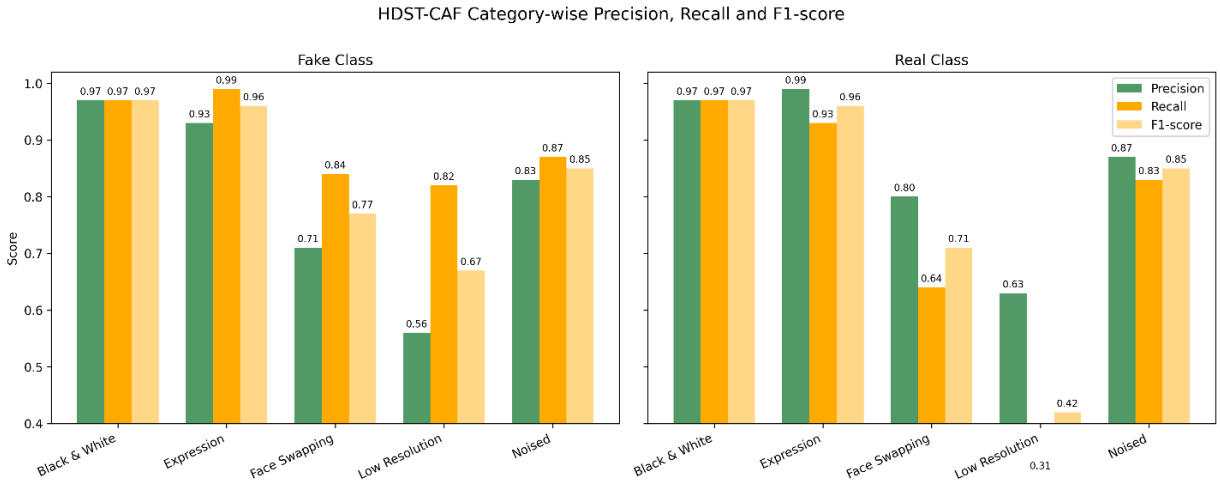

Fig. 5. HDST-CAF category-wise accuracy across five degradation types, illustrating robustness variations.

TABLE V. PER-CATEGORY TEST PERFORMANCE COMPARISON

Category	HDST-CAF Acc.	HDST-CAF F1	ResNet18 Acc.	ResNet18 F1
Black and White	97%	0.97	88%	0.88
Expression Manip.	96%	0.96	82%	0.82
Face Swapping	74%	0.74	87%	0.86
Low Resolution	58%	0.55	78%	0.78
Noised	85%	0.85	75%	0.75
Combined	92%	0.92	89%	0.89

C. Training Dynamics

Table VI summarises epoch-wise training progress. HDST-CAF converges rapidly on the combined dataset (55.30% → 96.79% training accuracy over 5 epochs) and on Black-and-White and Expression Manipulation categories (>95% by epoch 5). Face Swapping and Low Resolution converge slowly; both categories will likely benefit from extended training and category-specific augmentation. The Black-and-White and Expression Manipulation confusion matrices are presented in Fig. 6 and 8.

D. Comparing the Current State of the Art

HDST-CAF achieves 92% accuracy with 14.1M parameters, one of the smallest parameter footprints among hybrid architectures (Table I), while being the only method in this study validated across five concurrent degradation types simultaneously. ResNet18's ImageNet pre-training gives it an

edge on Face Swapping (87%) and Low Resolution (78%); the reasons for this are discussed in Section VI-B. Confusion matrices for the Face Swapping category are shown in Fig. 7, while Expression Manipulation results appear in Fig. 8

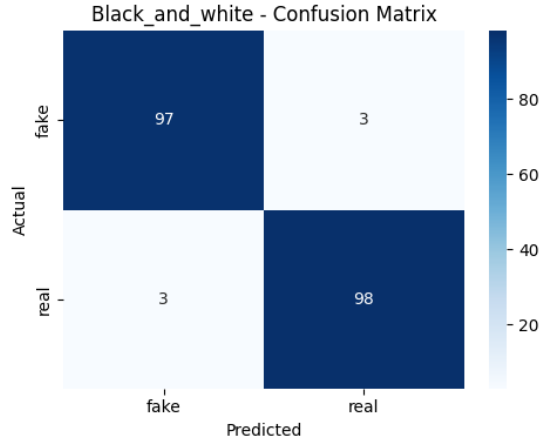

Fig. 6. Black-and-white category: HDST-CAF confusion matrix.

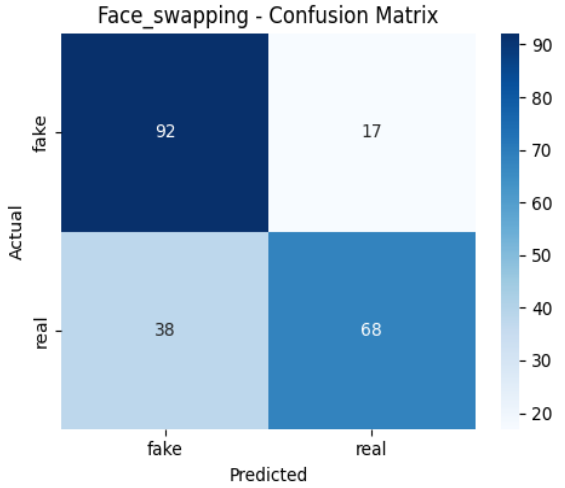

Fig. 7. Face swapping category: HDST-CAF confusion matrix.

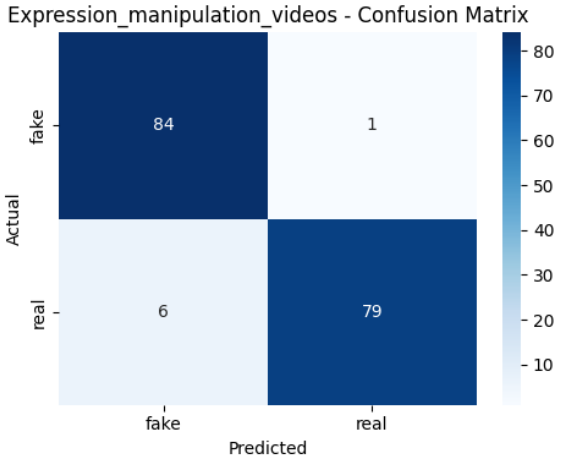

Fig. 8. Expression manipulation category: HDST-CAF confusion matrix showing balanced performance.

VI. Discussion

A. Interpretation of Results

Per-category accuracy follows a hierarchy that maps directly onto the theoretical strengths of each stream in HDST-CAF. The 97% accuracy on the Black and White category (Fig. 6, Table V) confirms that the Frequency Domain Analysis stream successfully detects GAN and diffusion model fingerprints even when colour information is entirely absent. The FDA stream is especially effective for greyscale inputs when CNN texture and ViT semantic indicators are relatively weaker, since deepfake generators usually produce periodic spectral artefacts during upsampling that endure regardless of colour-space transformation.

The second-highest category result, 96% accuracy, is attained through expression manipulation (Fig. 8). This outcome is driven by the ViT stream: Its global self-attention detects spatiotemporal irregularities at blending boundaries, which are areas where local CNN receptive fields are unable to detect minor but long-range semantic discontinuities caused by synthesised facial muscle activity. The cross-attention fusion effectively arbitrates between streams, eliminating false positives which would otherwise result from depending on a single modality, as evidenced by the nearly flawless 0.93 fake-class precision and 0.99 real-class precision within this category.

Pretrained ImageNet attributes, which implicitly reduce noise, are clearly less effective than explicit spectral analysis in noisy forensic conditions; the 10-point gain against ResNet18 (75%) is the greatest margin among all five categories.

An ablation study was not conducted, as the per-stream analysis in this subsection provides qualitative evidence of the CNN-FPN, ViT, and FDA streams' individual contributions to performance under different degradation conditions: the FDA stream is implicated in the 97% greyscale result, the ViT stream in the 96% expression-manipulation result, and adaptive gating in the 3-point gain over static concatenated fusion (Section VI-C). Unseen-manipulation robustness was not experimentally evaluated, as the proposed dataset contains predefined manipulation categories; future work will introduce independent, unseen manipulation types to assess cross-manipulation generalisation under visual degradation. Cross-dataset evaluation was not performed, as the proposed dataset is uniquely designed around five concurrent visual degradation conditions, making direct comparison with conventional datasets such as FaceForensics++ or Celeb-DF methodologically inappropriate.

B. Failure Modes and Limitations

The two categories where HDST-CAF underperforms are Face Swapping (74%, Fig. 7) and Low Resolution (58%, Fig. 10). For face swapping, ResNet18 outperforms HDST-CAF by 13 points: identity-level features from ImageNet pre-training are more discriminative here than the manipulation artefact cues HDST-CAF is trained to extract. Face swapping in this dataset preserves expression and motion, removing the semantic cues the ViT stream exploits; simultaneously, high-quality blending algorithms suppress the spatial texture artefacts the CNN-FPN targets and the spectral fingerprints the FDA stream seeks, leaving all three streams with weaker signals.

Low resolution is the most challenging condition (58%), largely because pixel loss destroys the fine-grained texture and high-frequency spectral detail on which the CNN and FDA streams critically depend. In this category, the model shows a strong fake prediction bias (recall 0.82 for fake, and 0.31 for true), indicating that degraded inputs are consistently classified as manipulated. This bias probably results from the blocking and ringing artefacts introduced by low-resolution downsampling, which appear to be similar to GAN upsampling artefacts. A specialised resolution-aware preprocessing branch or category-specific augmentation will be needed to address this.

TABLE VI. HDST-CAF TRAINING LOSS AND ACCURACY PER EPOCH

Epoch	Comb. Loss	Comb. Acc.	B&W Acc.	Expr. Acc.	FaceSwap Acc.	LowRes Acc.	Noise Acc.
1	112.39	55.30%	60.50%	71.28%	50.17%	48.68%	48.84%
2	75.71	81.07%	74.00%	82.92%	53.78%	49.88%	62.42%
3	51.17	91.26%	81.50%	87.63%	62.63%	53.47%	72.09%
4	39.94	94.79%	92.62%	93.37%	65.31%	58.01%	83.35%
5	34.47	96.79%	95.38%	96.02%	72.64%	59.93%	87.15%

C. Cross Stream Fusion Analysis

The gated tri-stream output (92%) surpasses the ResNet18 baseline (89%) and is comparable to substantially larger architectures like ViT [23] (93.1% on Celeb-DF v2), even though it operates on a more difficult multi-condition benchmark. Adaptive gating produces a tangible three-point increase on the combined dataset. The most informative stream for each sample is implicitly upweighted by the gating scores: for greyscale and noisy inputs, frequency cues predominate; for expression manipulation, semantic cues; and for combination evaluation, spatial texture. The accuracy difference over static concatenated fusion in previous dual stream approaches is explained by this dynamic weighting [27].

Due to random weight initialisation, HDST-CAF begins with a baseline that is lower than ResNet18 (55.30% vs. 62.43% at epoch 1), but by epoch 5, it reaches a higher overall training accuracy (96.79% vs. 88.83%), according to training dynamics in Table VI. A richer feature space is reflected in the steeper learning curve; more gradient updates are needed, but the final representations have greater discriminative power. Continued scaling of the dataset and self-supervised pre-training are expected to further tighten this margin in future extensions of the work. The rapid convergence within five epochs (55.30% to 96.79% training accuracy) is attributable to the cosine-annealed learning rate schedule (eta_0 = 1e-4) combined with the optimised hyperparameter configuration described in Section III-H (label smoothing, auxiliary loss weighting, and dropout tuned via coarse grid search), which together stabilise gradient updates early in training and allow the tri-stream model to reach a high-accuracy regime within a compact training budget. The 4.8-point gap between training accuracy (96.79%) and test accuracy (92%) is consistent with the expected generalisation variance for a model of this scale evaluated on a held-out split of 506 videos, rather than indicating under-training.

D. Comparing with the State of the Art

HDST-CAF achieves 92% accuracy on the five-condition multi-degradation benchmark while operating with 14.1M parameters, substantially fewer than comparable ViT-based architectures such as CViT (89.1M) or ViViT (87.5M, Table I), making it more practical for edge deployment.

Table VII lists figures reported by representative prior methods alongside HDST-CAF, each on its own respective evaluation dataset; because these datasets differ in composition and degradation conditions, the figures are provided for context only and do not constitute a direct, like-for-like comparison.

TABLE VII. REPORTED PERFORMANCE OF REPRESENTATIVE DEEPFAKE DETECTION METHODS ON THEIR RESPECTIVE EVALUATION DATASETS

Method	Year	Architecture	Evaluation Dataset	Accuracy	F1
HDST-CAF (Ours)	2025	ViT+CNN+FDA	Custom Multi-Cond.	92%	0.92
ResNet18 (Baseline)	2025	Transfer CNN	Custom Multi-Cond.	89%	0.89
CViT [13]	2023	CNN + ViT	DFDC	85%	0.84
Hybrid CNN-ViT [14]	2024	CNN+ViT Distil.	FF++	82.63%	0.83
TSFF-Net [27]	2024	Two-Stream+Trans.	FF++	97.47%	N/A
ViViT [23]	2024	Video ViT	Celeb-DF v2	93.10%	0.925

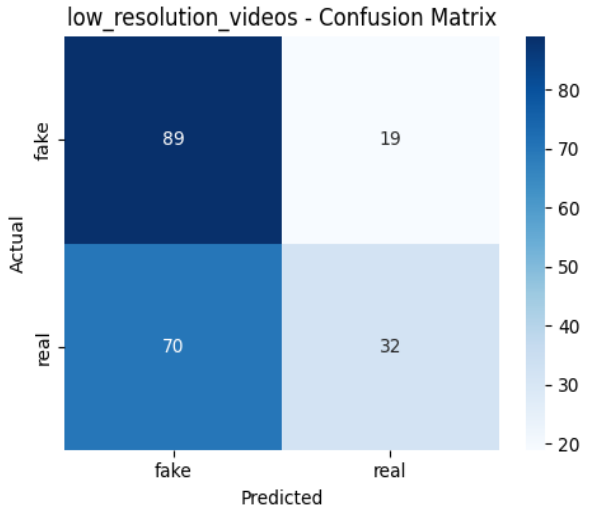

Fig. 10. Low Resolution category: HDST-CAF confusion matrix showing prediction bias.

VII. Conclusion

HDST-CAF integrates CNN-FPN, ViT, and FDA streams via bidirectional cross-attention with adaptive gating, targeting robust deepfake detection across multi-dimensional visual degradations. Evaluated on a custom 506-video multicondition dataset, HDST-CAF achieves 92% combined accuracy, outperforming ResNet18 by 3 percentage points, with particularly strong results on grayscale (97%), expression manipulation (96%), and noisy (85%) conditions. The 5,060-image dataset limits generalisation to broader, more varied distributions, and the model performs poorly with face swapping (74%) and low resolution (58%). In the future, the dataset will be expanded, temporal consistency analysis will be added, pretrained backbones will be used, and self-supervised pre-training will be used to specifically target the low-resolution and face swapping categories.

A Pipeline for Integrating and Analyzing Public Business Data in Albania Using Web Scraping and Machine Learning

Markela Muca, Klodiana Bani, Amarildo Alla
Department of Applied Mathematics-Faculty of Natural Sciences, University of Tirana, Albania

***Abstract*—The increasing availability of fragmented public business and procurement data creates opportunities for company-level empirical analysis, but limited evidence exists on how integrated procurement and administrative records can be used to characterize heterogeneous economic operators in Albania. This study investigates the analytical value of integrating public procurement records from the Public Procurement Agency (APP) with administrative business information from the National Business Center (QKB) through the unique NIPT identifier. The resulting company-level dataset is analyzed to examine whether procurement-derived characteristics contain systematic information for distinguishing heterogeneous company profiles and reproducing heuristic risk-oriented classifications. The empirical framework combines data normalization, entity-level integration, feature engineering, heuristic-label construction, supervised classification, Principal Component Analysis (PCA), K-Means clustering, anomaly detection, feature-importance analysis, and a financial-enrichment sensitivity experiment. In the 18-feature reduced experiment, HistGradientBoosting achieved the strongest mean repeated-cross-validation performance, with an F1-score of 0.8590, ROC AUC of 0.9683, and Average Precision (AP) of 0.9399. The analysis further identifies distinct company profiles characterized by differences in procurement intensity, contract value, and economic exposure, including small groups with exceptionally high activity and atypical characteristics. Financial enrichment did not produce a substantial improvement in classification performance, indicating that procurement-derived variables provide the dominant analytical signal in the current dataset. Across 999 deterministic label permutations, the mean ROC AUC was 0.4999, and the mean AP was 0.2700; the one-sided empirical p-value was 0.001 for both metrics. This diagnostic does not prove the absence of leakage, overfitting, or residual proxy dependence. The findings provide empirical evidence that company-level integration of procurement and administrative data can reveal heterogeneous procurement profiles and atypical patterns relevant to procurement monitoring, public-sector analytical capacity, and data-driven governance. Because the target labels are heuristic and are not independently validated against official risk outcomes, the results are interpreted as exploratory evidence for company profiling and risk-oriented analysis rather than as formal assessments of business risk, misconduct, or performance.**

Keywords*—Web Scraping; machine learning; data integration; public data analysis; public procurement; benchmarking; Albania

I. Introduction

The increasing availability of public data has expanded opportunities for empirical analysis of businesses and for supporting decision-making in public administration, scientific research, and the private sector. Administrative registries and public procurement data contain valuable information on company characteristics, economic activity, and relationships with public institutions. However, these data are frequently distributed across heterogeneous sources with different structures, standards, identifiers, and levels of completeness, making integrated company-level analysis challenging [1], [2], [23], [26].

In Albania, two important sources of public business information are the Public Procurement Agency (APP) and the National Business Center (QKB). APP provides information on public procurement procedures and participating or winning economic operators, whereas QKB provides administrative and identification information on registered economic entities [27], [28]. Although each source provides valuable information independently, their integration creates an opportunity to examine economic operators across multiple procurement activities while simultaneously considering their administrative characteristics.

Integrating these sources presents methodological challenges related to heterogeneous formats, inconsistent representations, entity identification, missing information, and data quality. Consequently, reliable analysis requires data collection, normalization, quality control, identifier harmonization, and feature construction [2], [23], [26]. The present study does not consider these procedures to be the primary scientific contribution. Rather, they provide the empirical foundation for investigating what additional information about companies becomes observable when fragmented procurement and administrative records are integrated at the company level.

Existing research has examined procurement transparency and data-driven governance [1], [21], [25], while other studies have focused on corruption-risk indicators [6], [10], [11] and machine learning for procurement monitoring [7], [8], [33]. Procurement data have been used to construct objective corruption-risk indicators and to identify procurement characteristics associated with potential irregularities [6], [10], [11]. Machine Learning has also been applied to procurement complaints, anomalies, bidder classification, and oversight prioritization [7], [8], [33].

However, much of this literature operates at the procurement-procedure or contract level, focusing on individual tenders, contracting authorities, complaints, competition

indicators, or procurement-risk signals. Comparatively less empirical attention has been given to the economic operator as the analytical unit across multiple procurement procedures. This distinction is important because aggregating procurement activity at the company level makes it possible to examine heterogeneous economic operators according to their procurement intensity, contract exposure, administrative characteristics, and atypical activity patterns.

Evidence from Albania is particularly relevant. Martiri and Kapedani [9] examined competition in Albanian public procurement of services using Public Procurement Agency data for 2010–2022 and demonstrated the analytical value of procurement indicators for understanding competition and accountability. However, this research focuses primarily on procurement competition rather than on integrated company-level profiling.

The research gap addressed in this study therefore concerns the limited empirical evidence on the structure of company-level procurement profiles obtained by integrating public procurement records with administrative business-registry information, particularly in the Albanian context. The gap has three dimensions. First, existing procurement research predominantly evaluates individual procedures or procurement outcomes rather than the accumulated activity of economic operators across multiple procedures [6], [7], [8], [9], [10], [11], [33]. Second, limited evidence is available on whether integrated procurement and administrative information reveal distinguishable groups of companies with different levels of economic activity and exposure. Third, when heuristic labels are constructed from procurement signals, it remains necessary to determine whether meaningful discriminatory information persists after variables directly contributing to label construction are removed.

This study addresses these gaps by examining a company-level dataset obtained by integrating APP procurement records with QKB administrative information through the NIPT identifier [27], [28]. The analysis investigates whether procurement-derived characteristics provide systematic information for distinguishing heterogeneous company profiles and for reproducing heuristic risk-oriented classifications under a reduced-feature design. The study also examines whether available financial information contributes additional discriminatory information beyond procurement-derived characteristics [29].

The empirical analysis combines supervised and unsupervised approaches. Supervised classification is used to evaluate the discriminatory information contained in the engineered company-level features, whereas Principal Component Analysis (PCA), K-Means clustering, and anomaly detection are used to identify and characterize heterogeneous company profiles independently of the classification task [16], [18], [19], [31], [32]. Feature-importance analysis is subsequently used to examine which procurement-related variables contribute most strongly to the classification models [12]. A financial-enrichment experiment further evaluates whether the addition of available financial indicators provides information beyond procurement-derived characteristics. An important methodological issue concerns the construction of the target labels. Because official company-level risk outcomes are not available in the dataset, two heuristic labels are constructed from procurement-related signals. The first experiment evaluates the ability of the models to reproduce the weaker heuristic label using the full feature set. The second experiment provides a more conservative sensitivity analysis by removing features that directly contribute to the construction of the stricter heuristic label and evaluating the models using the remaining 18 features. Consequently, the classification results are not interpreted as evidence of formally validated business risk, corruption, misconduct, or business failure. Instead, they indicate the extent to which the available company-level characteristics contain information associated with the heuristic profiles defined for this study.

The study makes four substantive contributions. First, it provides empirical evidence on the analytical value of integrating fragmented public procurement and administrative business data at the company level in Albania. Second, it identifies heterogeneous company profiles based on procurement intensity, contract value, and administrative characteristics, including small groups exhibiting exceptionally high levels of activity and atypical economic exposure. Third, it evaluates the persistence of discriminatory information after reducing direct feature-label overlap. Fourth, it examines the incremental value of financial enrichment.

These contributions distinguish the study from work that primarily develops generic data-processing or Machine Learning pipelines. The computational procedures are used as analytical instruments, while the principal contribution lies in the empirical evidence generated from the integrated APP–QKB dataset and in the company-level perspective that this integration enables. The findings are therefore positioned as exploratory evidence relevant to procurement monitoring, public administration, and data-driven governance rather than as an automated institutional risk-assessment system [8], [21], [25].

The remainder of the study is organized as follows. Section II presents the related work on public procurement analytics, Machine Learning for procurement monitoring, administrative data integration, company-level profiling, and research in Albania and comparable contexts. Section III describes the proposed methodology, including the data sources, collection and integration procedures, feature engineering, heuristic-label construction, and experimental design. Section IV presents the classification results, PCA and clustering analysis, anomaly detection, feature-importance analysis, and financial-enrichment experiment. Section V discusses the findings and their implications for procurement governance, public administration, and digital government. Section VI presents the conclusions and limitations, while Section VII outlines directions for future research.

II. Related Work

This section reviews empirical research relevant to the analytical use of public procurement data, Machine Learning for procurement monitoring, administrative data integration, and company-level profiling. Particular attention is given to evidence from Albania and comparable European and post-

transition contexts, thereby positioning the present study within its specific institutional and application domain.

A. Public Procurement Data and Transparency

Public procurement data provide an important empirical basis for analyzing competition, transparency, efficiency, accountability, and potential irregularities in government contracting. The availability of open government data has increasingly created opportunities to move from descriptive transparency toward systematic empirical analysis of public-sector activity [1], [21], [25]. However, the analytical value of these data depends strongly on their quality, completeness, standardization, and consistency. Research on data and information quality emphasizes that inconsistencies, missing information, heterogeneous structures, and inadequate data preparation can substantially affect the reliability of subsequent analytical processes [2], [23], [26].

Empirical studies have demonstrated that procurement data can be used to construct risk indicators and identify procurement procedures that warrant additional institutional scrutiny. Lisciandra, Milani, and Millemaci [6] developed a corruption risk indicator using Italian public works data, while Fazekas and colleagues [10], [11] demonstrated the usefulness of objective procurement indicators for identifying patterns associated with corruption risk.

The present study builds on this literature by examining whether procurement information can be aggregated across multiple procedures to characterize economic operators and identify heterogeneous company-level profiles.

B. Machine Learning for Procurement Monitoring

Machine Learning has increasingly been used for classification, anomaly detection, risk assessment, and decision support in public procurement [3], [7], [8], [14], [15]. Nai et al. [7] combined public procurement data with administrative justice records in Italy and developed Machine Learning models to identify procurement procedures associated with complaints and disputes. Salazar, Pérez, and Gallego [8] developed VigIA, combining Machine Learning models with risk indices to support procurement oversight and prioritization.

Recent work in Romania has also applied Machine Learning to a large public procurement dataset for bidder classification, illustrating the potential of large-scale procurement data for automated analytical assessment [33].

An important methodological issue in this literature concerns the relationship between heuristic target construction and model predictors. When a target variable is derived from procurement characteristics that are subsequently used as model inputs, the resulting performance may partly reflect label-feature dependency. The present study therefore distinguishes between a full-feature experiment and a reduced-feature experiment designed to examine whether discriminative information remains after removing features directly involved in constructing the stricter heuristic label. Model evaluation follows established principles for classification and imbalanced data, using cross-validation [17], ROC AUC [5], and Precision-Recall measures [24].

C. Administrative Data Integration and Company-Level Business Profiling

Administrative data are frequently collected and maintained by different public institutions for distinct administrative purposes. Their integration can create analytical opportunities that are not available when each source is considered independently [1], [2], [23], [26].

In the context of public procurement, procurement records describe the interaction between economic operators and contracting authorities, whereas business registries provide additional information about the economic operators themselves [27], [28].

Existing procurement studies have primarily examined tenders, contracts, contracting authorities, competition indicators, complaints, and procurement-specific risk signals [6], [7], [8], [9], [10], [11], [33]. Although this literature provides substantial evidence at the procurement-procedure level, comparatively less attention has been given to the economic operator as an analytical unit across multiple procurement activities.

A company-level perspective provides a complementary analytical dimension. Instead of evaluating an individual tender in isolation, an integrated dataset can characterize an economic operator according to procurement participation, contract values, activity intensity, administrative characteristics, and atypical patterns.

For the present study, the NIPT identifier provides the linkage mechanism between procurement and business-registry information [27], [28]. This linkage enables procurement observations to be aggregated at the company level and provides an empirical basis for examining heterogeneity among economic operators participating in public procurement in Albania.

D. Public Procurement Research in Albania

Research on Albanian public procurement has examined competition, savings, transparency, accountability, and institutional performance. Martiri and Kapedani [9], using Public Procurement Agency data covering 2010–2022, examined competition in Albania's public procurement of services through indicators including bids per tender, funding allocations, contract numbers, disqualified bids, and single- versus multiple-bid contracts. Their findings demonstrate the relevance of procurement data for evaluating the functioning of the Albanian procurement market.

These findings establish the empirical relevance of procurement analysis in Albania, but they primarily examine procurement competition and institutional aspects rather than integrated company-level profiles. Evidence from Italy, Colombia, and Romania further demonstrates the potential of combining procurement data with Machine Learning and administrative information [7], [8], [33]. However, differences in institutional structures, registry systems, procurement practices, and data availability mean that findings from other countries cannot simply be transferred to Albania without empirical examination of the Albanian data environment.

E. Research Gap

Existing research has established the value of public procurement data, Machine Learning, risk indicators, anomaly detection, and data-driven monitoring for public-sector decision support [6], [7], [8], [9], [10], [11], [18], [21], [25], [33]. Research on data quality and administrative data integration further emphasizes the importance of preparing and linking heterogeneous public datasets before conducting empirical analysis [2], [23], [26].

The research gap addressed in this study is the limited empirical analysis of economic operators through the integration of public procurement records and administrative business-registry information at the company level, particularly in the Albanian context.

The present study addresses this gap by integrating APP procurement records with QKB administrative business information through the company NIPT identifier [27], [28]. The resulting company-level dataset is used to investigate company profiles, the discriminatory information retained after reducing direct label-feature overlap, the characteristics contributing to company differentiation, and the incremental value of available financial information [29].

The contribution therefore lies primarily in the empirical characterization of Albanian economic operators enabled by the integration of APP and QKB data, rather than in the development of a new Machine Learning algorithm.

III. Proposed Methodology

A. Research Design and Analytical Framework

The study adopts an empirical, company-level analytical design to investigate the analytical value of integrating public procurement records with administrative business information. The objective is not to develop a new Machine Learning algorithm, but to examine whether the integration of fragmented public data enables the identification and characterization of heterogeneous economic operators participating in public procurement.

The methodological framework consists of six interconnected stages: 1) data collection, 2) data normalization and quality control, 3) company-level data integration, 4) feature engineering and heuristic-label construction, 5) supervised and unsupervised analysis, and 6) robustness and sensitivity evaluation. The overall process transforms heterogeneous record-level public information into a standardized company-level analytical dataset.

The analytical unit is the company, identified through the NIPT/NUIS identifier. This choice distinguishes the present study from procurement-level approaches that analyze individual tenders or contracts. By aggregating procurement observations at the company level, the analysis captures the accumulated procurement activity of economic operators over the observation period.

The methodological framework combines supervised classification with complementary unsupervised techniques. Classification models are used to evaluate whether company-level features contain discriminatory information associated with the heuristic labels. PCA and K-Means are used independently of the classification task to investigate the underlying structure and heterogeneity of the companies. Isolation Forest is subsequently used to identify observations that deviate substantially from the dominant feature-space structure [16], [18], [19].

The study therefore treats machine learning as an analytical instrument for empirical investigation rather than as the principal methodological contribution.

B. Data Sources

The experiment uses two primary administrative sources and one supplementary financial source.

1) The Public Procurement Agency (APP) provides publicly accessible information concerning public procurement procedures and economic operators participating in or winning procurement activities. Historical procurement records covering the period 2006–2025 were collected from the APP public data environment [27].

The collected procurement information includes variables describing procurement procedures, contracting authorities, procedure status, allocated budgets, winning economic operators, and contract values. These records constitute the primary source for measuring the procurement activity of companies.

During the data collection process, 10,341 unique companies that had won at least one public procurement contract were identified.

2) National Business Center (QKB): The National Business Center provides administrative information concerning registered economic entities in Albania [28]. The QKB data were used to enrich procurement observations with company-level administrative characteristics.

A total of 59,266 documents were processed. Relevant attributes included legal form, current business status, location, incorporation information, and company age.

The QKB data therefore provide contextual information about the economic operators identified in the procurement records and allow the analysis to move beyond procurement activity alone.

3) Open Corporates Albania was used as a supplementary source for the financial-enrichment experiment [29]. A total of 40,034 historical financial records were collected.

Financial variables included information on annual revenue and net profit for companies for which such information was available. Because financial coverage was substantially lower than the coverage of procurement and administrative data, financial information was not included in the primary classification dataset. Instead, it was incorporated in a separate sensitivity experiment to assess whether financial variables provide additional discriminatory information beyond procurement-derived characteristics.

C. Data Collection, Normalization, and Quality Control

The data collection stage employed a structured web-scraping process to retrieve publicly available procurement and business information from the relevant sources [20]. During the collection process, Albiz Collector structurally stores process metadata (requested URLs, content hashes, and HTTP status codes), ensuring the provenance and reproducibility of the pipeline.

In total, these sources enabled the construction of an integrated company-level dataset, which served as the foundation for analytical feature engineering and the application of machine learning methods for classification, profiling, and anomaly detection.

Data integration was achieved through the exact matching of the unique Taxpayer Identification Number (NIPT/NUIS), following the standardization of its format. Out of the 10,341 winning companies identified in the APP data, 10,266 companies were successfully matched with the QKB registry.

The financial source covered a smaller subset. Financial information was available for 3,159 companies, corresponding to 30.8% of the 10,266 companies in the integrated APP–QKB dataset.

D. Integration Pipeline and Feature Engineering

Based on this integrated dataset, 30 initial features were constructed, describing public procurement activity, company characteristics, and the ratios between contract values and allocated budgets**.** These features form the basis for exploratory analysis and the development of machine learning models.

To transform the aggregated procurement data into standardized, company-level analytical indicators, two analytical indicators were constructed to summarize procurement activity.

1) Business Performance Indicator (BPI): This procurement-activity proxy combines five nonnegative company-level components after maximum-normalized logarithmic transformation:

$$BPP_i = 100 * \sum_{k=1}^{m} w_k \frac{\ln(1+x_{ik})}{\ln(1+M_k)},\ \mathrm{M_k} > 0$$

where, x_{ik} represents the quantitative component k of the activity of company i (such as the number of won tenders or the total value) and w_k is the specific weight allocated to each component. M_k is its maximum in the 10,266-company analytical dataset, and the fixed weights are 0.30 for active procurement count, 0.30 for active total winner value, 0.20 for distinct contracting-authority count, 0.10 for active-year span, and 0.10 for rows with a winner value. These weights define an analyst-specified procurement-activity proxy; they were not estimated from independent business outcomes. The components, weights, and operational rationales are summarized in Table I.

2) The Sure Winner Ratio (SWR): To measure the efficiency or deviation of winning bids relative to the allocated budgets, without causing division-by-zero errors, the function is applied:

$$SWR_{ij} = \frac{V_{ij}^F}{V_{ij}^B},\ V_{ij}^B > 0$$

where, V_{ij}^F is the winning value of the economic operator, and V_{ij}^B is the initial budget allocated for that procedure.

The Open Contracting Data Standard (OCDS) was used as a conceptual reference for procurement terminology and the organization of procurement information [22]. It was not used as the source of the mathematical formulations above.

TABLE I. COMPONENTS AND FIXED WEIGHTS OF THE PROCUREMENT-ACTIVITY PROXY

Component	Weight	Rationale
Active procurement count	0.30	Overall procurement activity
Active total winner value	0.30	Economic exposure
Distinct contracting-authority count	0.20	Breadth of institutional participation
Active-year span	0.10	Continuity of procurement activity
Rows with a winner value	0.10	Availability of recorded award values

E. Heuristic Risk-Label Construction

Due to the lack of official risk labels, two heuristic labels were constructed (weak_risk_label and strict_weak_risk_label) based on public procurement activity signals. The heuristic Risk Function (y_i) determines whether a company i is assigned to Class 1 or Class 0 according to the number of predefined procurement-related signals triggered by the company.

The general formulation is:

$$C_i = \sum_{k=1}^{q} I_{ki}, \qquad y_i = \begin{cases} 1, & \text{if } C_i \geq \tau \\ 0, & \text{if } C_i < \tau \end{cases}$$

The distribution of companies across the two classes for both heuristic labels is presented in Table II. For the *weak_risk_label*, 6,889 companies (67.1%) belong to Class 0 and 3,377 companies (32.9%) to Class 1. For the more restrictive *strict_weak_risk_label*, Class 0 contains 7,521 companies (73.2%), while Class 1 contains 2,745 companies (26.8%). Thus, both label variants exhibit a moderate class imbalance, with the imbalance being more pronounced for the strict label.

TABLE II. HEURISTIC LABEL DISTRIBUTION AND DATASET CLASS STRUCTURE

Variable	Class 0	Class 1	Total number of companies
weak_risk_label	6,889 (67.1%)	3,377 (32.9%)	10,266
strict_weak_risk_label	7,521 (73.2%)	2,745 (26.8%)	10,266

Two experimental settings were considered to evaluate the classification models while examining the potential dependence between the predictors and the heuristic labels.

The first, Full-Feature, Weak-Label Replication, used the complete feature set to reproduce the *weak_risk_label*. Because some of the features were also involved in constructing the heuristic label, the results of this experiment primarily indicate

how well the models reproduce the structure embedded in the labeling rule. The second, Reduced-Feature, Strict-Label, excluded the features that directly contributed to the construction of the *strict_weak_risk_label*, leaving 18 features for model training. This second setting was introduced as a sensitivity analysis to reduce direct label-feature dependency and to examine whether predictive information remained after the most immediate overlap between the predictors and the heuristic target had been removed.

To assess whether the observed classification performance could arise from random association between the retained features and the heuristic target, a shuffled-label permutation diagnostic was conducted using the 18-feature reduced dataset and HistGradientBoosting under the same repeated 5-fold cross-validation structure. An initial run with 10 permutations was used as a preliminary diagnostic to verify the permutation procedure and null behavior. Because 10 permutations provide a coarse empirical p-value resolution, the analysis was subsequently repeated with 999 deterministic permutations, which was treated as the final diagnostic. For each permutation, the target labels were randomly reassigned while the feature matrix and cross-validation structure were retained unchanged. The empirical one-sided p-value was calculated as $p = (r + 1)/(B + 1)$, where r denotes the number of permutations whose performance equaled or exceeded the observed value and B is the number of permutations.

Six classification algorithms were evaluated: HistGradientBoosting, Random Forest, Gradient Boosting, Extra Trees, KNN, and Logistic Regression. These models were selected to provide a comparison between nonlinear tree-based ensemble approaches and simpler parametric or distance-based methods. Random Forest follows the ensemble framework introduced by Breiman [4], while Gradient Boosting is based on the framework proposed by Friedman [13]. Extra Trees follows the extremely randomized tree approach proposed by Geurts, Ernst, and Wehenkel [30]. General machine learning principles relevant to the classification experiments were also considered [3], [14], [15]. This combination of models allows the analysis to assess whether the nonlinear relationships and interactions present in the procurement-derived features provide additional discriminatory information compared with simpler modeling approaches.

Model performance was evaluated using repeated 5-fold cross-validation with three repetitions. In each repetition, the dataset was divided into five folds. Four folds were used for model training and one fold for validation, with the process repeated until each fold had served as the validation set. The procedure was then repeated three times to reduce the influence of a particular partition of the observations. Cross-validation provides a more robust estimate of model performance than relying on a single train-test partition [17].

The moderate class imbalance shown in Table II was taken into account when evaluating the classification results. Accuracy was therefore not treated as a sufficient standalone measure, since a model can obtain relatively high accuracy by favoring the majority class without performing equally well on the minority class. Model performance was assessed using F1-score, ROC AUC, Precision-Recall AUC (PR AUC), Recall, and Accuracy. F1-score provides a balance between precision and recall, while ROC AUC measures the ability of a classifier to distinguish between the two classes across classification thresholds [5]. PR AUC was also considered because Precision-Recall analysis provides a more informative assessment of classification performance when the classes are not equally represented [24]. Taken together, these measures provide a broader assessment of model performance and reduce the risk of concluding accuracy alone.

IV. Analysis Results and Evaluation of Machine Learning Methods

A. Classification Results

In the first experiment, the models demonstrated a strong capability to reproduce the heuristic label (weak_risk_label). The HistGradientBoosting model achieved the highest performance in this experiment. The potential label-feature dependency was addressed in Experiment 2 (Reduced-Feature), where nine direct label contributors and three close alternate aggregates were excluded; the models were trained on 18 retained source features and evaluated against the strict_weak_risk_label target.

In this configuration, six classification algorithms were compared: HistGradientBoosting, Random Forest, Gradient Boosting, Extra Trees, KNN, and Logistic Regression. Performance was estimated with Repeated Stratified K-Fold cross-validation (five folds, three repetitions, random state 42), resulting in 15 validation folds. The mean performance measures for the Reduced-Feature experiment are presented in Table III.

TABLE III. Mean Repeated-CV Results for the 18-Feature Reduced Experiment

Model	Accuracy	AP	Recall	F1-Score	ROC AUC
Logistic Regression	0.8161	0.7202	0.6674	0.6599	0.8487
Random Forest	0.9168	0.9305	0.8605	0.8469	0.9644
Gradient Boosting	0.9223	0.9297	0.8056	0.8472	0.9634
Extra Trees	0.9092	0.9052	0.7537	0.8160	0.9533
HistGradientBoosting	**0.9283**	**0.9399**	**0.8171**	**0.8590**	**0.9683**
KNN	0.7793	0.5430	0.4137	0.5006	0.7351
HGB shuffled-label null mean. B=10 permutations	0.7254	0.2716	0.0149	0.0281	0.5025

The results of Experiment 2 indicate that HistGradientBoosting achieved the strongest mean performance, with an F1-score (0.8590), ROC AUC (0.9683), and Average Precision (0.9399) among the evaluated models (Table III). Random Forest, Gradient Boosting, and Extra Trees also exhibited high performance with ROC AUC values of 0.9644 and 0.9634, respectively. Extra Trees produced a ROC AUC of 0.9533, whereas Logistic Regression and KNN achieved lower values of 0.8487 and 0.7351. These values describe agreement with a constructed heuristic target and are not validation against independently observed risk outcomes.

To evaluate whether the observed classification performance could be explained by random association between the retained

features and the heuristic target, a shuffled-label permutation diagnostic was performed using the 18-feature dataset and HistGradientBoosting.

Table III(A) shows that the observed mean ROC AUC was 0.9683 and the observed AP was 0.9399. In the final 999-permutation analysis, the null mean ROC AUC was 0.4999 and the null mean AP was 0.2700. No permutation equaled or exceeded the observed performance for either metric. Thus, with r=0 and B=999, the one-sided empirical permutation p-value was 0.001 for both ROC AUC and AP.

TABLE III (A). SHUFFLED-LABEL PERMUTATION DIAGNOSTIC FOR THE 18-FEATURE HISTGRADIENTBOOSTING MODEL

Metric	Observed	Null Mean (B=10)	Empirical p-value (B=10)	Null Mean (B=999)	Empirical p-value (B=999)
ROC AUC	0.9683	0.5025	0.0909	0.4999	0.001
AP	0.9399	0.2716	0.0909	0.27	0.001

The preliminary 10-permutation run produced null means of 0.5025 for ROC AUC and 0.2716 for AP, with a minimum attainable p-value of 0.0909 under the same plus-one estimator.

The results indicate that the observed discrimination is substantially higher than the performance obtained under randomly permuted labels. Thus, the permutation diagnostic provides evidence against a purely random feature-label association. Nevertheless, it does not establish the absence of data leakage, overfitting, or residual proxy dependence resulting from the heuristic construction of the target.

B. Principal Component Analysis (PCA) and Clustering

To explore the dataset structure in an unsupervised manner, Principal Component Analysis (PCA) was applied to the standardized numerical features. PCA enables data dimensionality reduction by transforming the original variables into a new set of components, ordered by the amount of variance they explain [16]. The objective of applying PCA in this study was not to eliminate features for predictive modeling, but rather to identify latent structures and visualize company profiles in a lower-dimensional space.

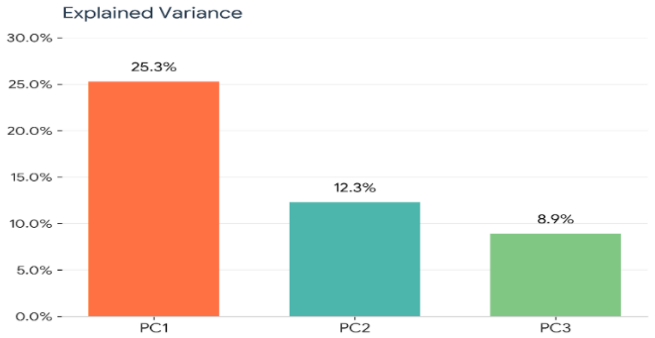

Fig. 1. Explained variance ratio for the first three components, PCA.

As shown in Fig. 1, the first three principal components explained 25.3%, 12.3%, and 8.9% of the total variance, respectively, accounting for approximately 46.5% of the total information in the dataset. The analysis of component loadings revealed that PC1 is dominated by features related to the scale of public procurement activity, such as the number of active contracts and the total contract value. Subsequent components are more closely associated with administrative characteristics and ratios between contract values. This indicates that the primary structure of the dataset is determined by the economic intensity of public activity, whereas administrative characteristics contribute to the secondary differentiation of profiles.

K-Means clustering was applied to the same standardized and one-hot encoded 51-dimensional profile matrix used by the implementation; PCA was used only for visualization. Solutions from k = 2 to k=10 were evaluated to examine the sensitivity of the cluster structure to the selected number of groups.

The clustering diagnostics favored k=2, with a silhouette coefficient of 0.675 and a Calinski-Harabasz index of 1,582.1. In comparison, the k=5 solution produced a substantially lower silhouette coefficient of 0.192 and included a very small cluster containing only 18 companies. Inertia decreased progressively as increased, without indicating a unique elbow point (Fig. 2(a), Fig. 2(b)).

Therefore, the existing k=5 solution is retained as a higher-resolution exploratory representation consistent with the implemented analytical dashboard, rather than as the empirically optimal solution for identifying natural company groupings. The five clusters should consequently be interpreted as exploratory company profiles rather than definitive or naturally separated company types.

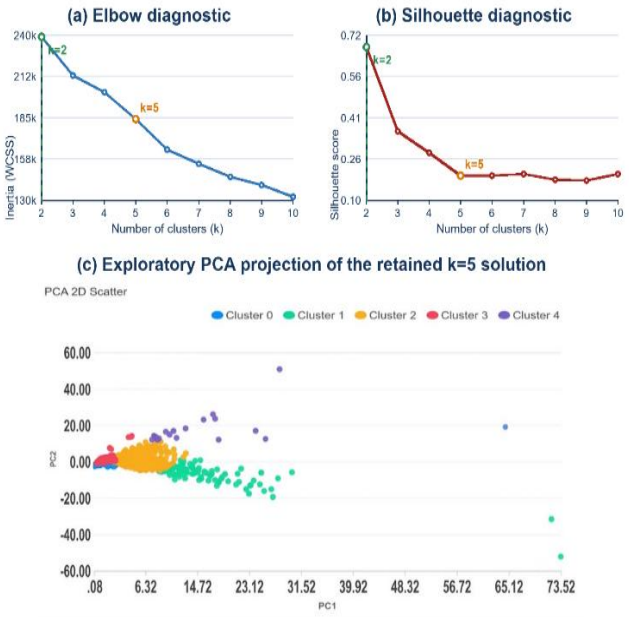

Fig. 2. Cluster-count sensitivity and retained exploratory view: (a) Inertia and (b) Silhouette score for k = 2–10; (c) PCA projection of the existing k = 5 solution.

The resulting five profiles are presented in Table IV. The two largest groups (Cluster 0 and Cluster 3), which represent approximately 82.8% of the companies, are characterized by relatively low public procurement activity. Cluster 2 comprises companies with high contract values and a higher proportion of positive heuristic-label assignments, whereas Cluster 1 and

Cluster 4 represent very small groups of companies with exceptionally high levels of activity and a higher concentration of atypical observations, suggesting the presence of outliers in the dataset.

TABLE IV. KEY CHARACTERISTICS OF THE CLUSTERS IDENTIFIED BY K-MEANS ALGORITHM

Clusters	Cluster 0	Cluster 1	Cluster 2	Cluster 3	Cluster 4
Companies	5,294	95	1,658	3,201	18
Share	51.6%	0.9%	16.2%	31.2%	0.2%
Mean performance	30.51	79.30	58.49	27.65	69.91
Mean active count	7.00	920.32	91.43	4.69	233.00
Mean active winner value (M)	9.40M	636.10M	502.02M	10.84M	16,652.14M
Weak label rate	27.8%	100.0%	53.5%	28.6%	33.3%
Strict label rate	21.6%	100.0%	45.0%	23.5%	27.8%
Profile	Low activity	Higher anomaly concentration	High value winners	Low activity	Higher anomaly concentration

Fig. 2(c) illustrates the projection of companies onto the two-dimensional space defined by the first two principal components of the PCA, where the color indicates the cluster membership identified by the K-Means algorithm. The positioning of companies within this space reflects the similarities and differences among their economic and operational profiles, as determined by the features utilized in the analysis. Companies located in proximity to one another exhibit similar structures regarding public procurement activity, performance, and procurement-related indicators, whereas the groups situated further from the center represent more specific profiles or extreme cases.

Cluster 0 (blue) is the largest group, comprising 5,294 companies (51.6% of the dataset). In the PCA space, it appears concentrated near the central zone, indicating a profile similar to the average characteristics of the companies in the dataset. According to Table IV, this cluster is characterized by low public procurement activity (averaging 7 active contracts with a mean value of approximately 9.4 million), low average performance (30.51), and a relatively low level of positive heuristic-label assignments (27.8% under the weak label and 21.6% under the strict label). This suggests that Cluster 0 represents the baseline profile of companies, featuring limited exposure to public contracts and lacking pronounced extreme characteristics.

Cluster 3 (red) represents the second-largest group, comprising 3,201 companies (31.2%). Although it appears in the PCA plot as a distinct group separated from Cluster 0, its characteristics are similar: low public activity (averaging 4.69 active contracts), relatively low contract value (10.84 million), and low performance (27.65). The positive heuristic-label rate is slightly higher compared with Cluster 0 (28.6% under the weak label and 23.5% under the strict label), but the difference is not substantial. Its separate positioning in the PCA space suggests that this cluster differs from Cluster 0 not by the absolute level of activity, but rather by the combination of other features included in the analysis. Consequently, Cluster 0 and Cluster 3 together represent the dominant segment of companies with limited activity, accounting for approximately 82.8% of the dataset.

Cluster 2 (orange) comprises 1,658 companies (16.2%) and presents a significantly different profile from the two primary groups. In Table IV, this cluster is characterized by much higher public procurement activity (averaging 91.43 active contracts), a high mean contract value (502 million), and higher performance (58.49). However, this level of activity is accompanied by a greater prevalence of the procurement signals incorporated into the heuristic labels (53.5% under the weak label and 45.0% under the strict label).

The position of Cluster 2 in the PCA plot is linked to this combination of high economic activity and greater prevalence of heuristic procurement signals, indicating a group of companies of higher economic significance that may consequently warrant more careful analytical monitoring.

Cluster 1 (green) and Cluster 4 (purple) are the smallest and most extreme groups. Cluster 1 includes only 95 companies (0.9%), yet is characterized by exceptionally high levels of activity (averaging 920 active contracts) and a mean contract value exceeding 636 million. All companies in this cluster are assigned to the positive class under both heuristic labels. In the PCA plot, this group appears shifted away from the main body of the dataset, reflecting its extreme and heterogeneous nature. This finding suggests a concentration of cases with very high economic exposure and potentially atypical characteristics.

Cluster 4 (purple) is the smallest group, with only 18 companies (0.2%), but it features the highest mean value of active contracts (16.65 billion). Its isolated positioning in the PCA space aligns with the characteristics shown in the table, indicating companies with a very large scale of activity and a distinct economic profile. Although the risk rate is lower than in Cluster 1 (33.3% under the weak label and 27.8% under the strict label), the extremely high magnitude of financial exposure makes this group highly significant for further analysis and anomaly detection.

Overall, the PCA and K-Means analysis reveals the existence of several distinct company profiles within the Albanian public procurement market. While the vast majority of companies are characterized by limited activity, a smaller subset exhibits significantly higher levels of activity and financial exposure. These extreme profiles serve as a foundation for subsequent anomaly analysis using dedicated outlier detection algorithms, which are presented in the following section.

C. *Anomaly Detection, Feature Importance, and the Financial Enrichment Experiment*

For the identification of profiles with atypical behavior in the feature space, the unsupervised Isolation Forest algorithm was applied. This method is highly suited for high-dimensional datasets, as it identifies observations that are isolated more quickly from the dominant portion of the data and classifies them as potentially anomalous cases [18].

The results demonstrated that the majority of companies lie within the dominant structure of the dataset, while a limited number of companies exhibit significant deviations from the average profile. These deviations are primarily associated with extreme combinations of public procurement activity characteristics, such as a high number of active procedures, significant contract values, a large number of won contracts, or unusual values of metrics derived from public activity. These profiles align with the extreme companies previously identified by the PCA and clustering analyses, specifically Cluster 1 and Cluster 4.

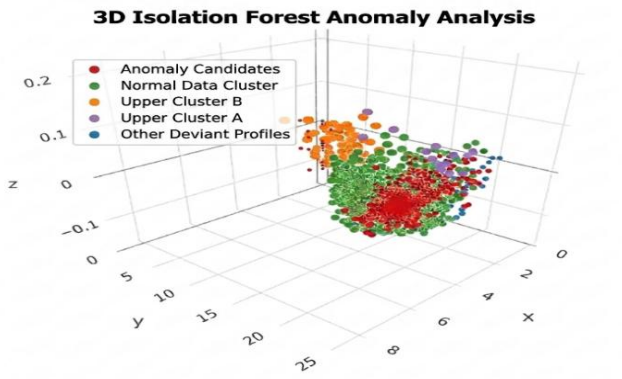

Fig. 3. Anomaly detection results using Isolation Forest.

Fig. 3 illustrates the distribution of companies based on the anomaly score generated by the Isolation Forest algorithm. It is observed that the majority of companies form a dense cluster near the average profile of the dataset, whereas isolated cases represent companies with characteristics that differ markedly from the rest of the analyzed population. These findings should not be interpreted as confirmed problematic cases, but rather as profiles requiring further investigation due to their deviation from the rest of the analyzed population.

Feature importance was analyzed using two tree-based ensemble models, Random Forest and Extra Trees [4], [30]. Although HistGradientBoosting achieved the highest performance in the classification benchmark, these two models were selected for the interpretability analysis due to their ability to estimate the relative contribution of input variables and the more direct interpretability of their decision tree structures. The feature-importance analysis indicated that variables related to public procurement activity contributed strongly to the models' discrimination between the heuristic classes. These importance measures are interpreted as indicators of variable contribution to predictive discrimination rather than as causal effects [12]. Among the most informative variables were the number of canceled procedures, the total value of the active budget limit, the number of active procedures, and other indicators describing the intensity and structure of the companies' public activity. This indicates that the operational information derived from procurement data contains the primary signal utilized by the models to differentiate company profiles.

Fig. 4 illustrates the relative importance of the ten most informative features according to the Random Forest model. These results should be interpreted as indicators of variable contribution to the classification process rather than as causal relationships between the features and the heuristic labels.

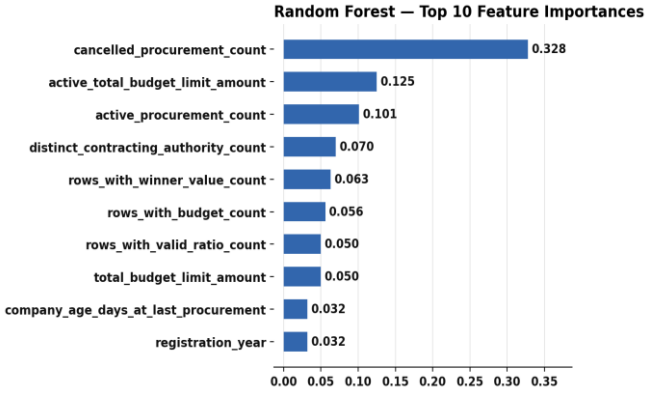

Fig. 4. Feature importance of the top predictive variables.

To assess the impact of financial information on model performance, an additional experiment was conducted on the subset of companies for which financial data from OpenCorporates was available. The objective of this experiment was to determine whether incorporating financial indicators provides supplementary information beyond the features extracted from public procurement activity.

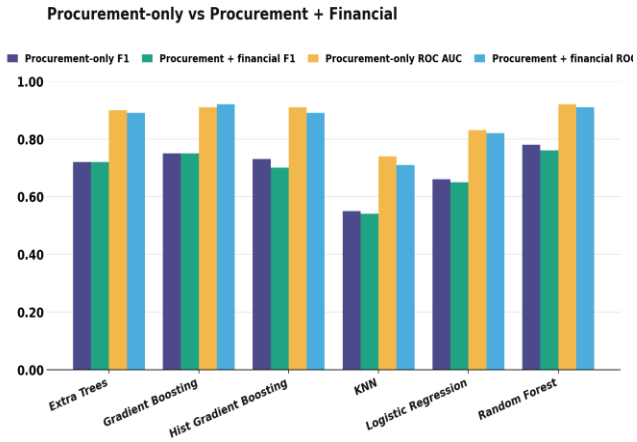

Fig. 5. Comparison of model performance with and without financial enrichment.

Unlike the feature importance analysis, which utilized only Random Forest and Extra Trees for interpretability, the financial enrichment experiment was conducted by comparing several of the primary classification models used during the benchmarking phase. This approach was employed to evaluate whether incorporating financial data yielded a consistent performance improvement across different models.

The results presented in Fig. 5 indicate that incorporating financial information did not lead to a significant improvement in classification performance. Although some models exhibited minor changes in evaluation metrics, the differences were insufficient to demonstrate a substantial increase in predictive power.

This finding suggests that, in the current dataset configuration, the information contained within public

procurement activity represents the primary source of signal for constructing the heuristic company profiles. The financial data serves as a complementary source, and its potential could be enhanced in future studies through the use of more comprehensive, up-to-date financial data with broader coverage.

V. Discussion

The results demonstrate that integrating APP procurement records with QKB administrative data at the company level provides analytical information that is not readily visible when procurement procedures are examined separately. The strong performance of the reduced-feature models (Table III) indicates that relevant discriminatory information remains after removing features directly used to construct the heuristic label. Similar applications have demonstrated the potential of machine learning for bidder classification and procurement monitoring [7], [33]. However, because the labels used in this study are heuristic, the results should be interpreted as company profiling rather than validated business-risk prediction.

The PCA and K-Means results (Table IV and Fig. 1 and 2) reveal substantial heterogeneity among economic operators. Most companies show relatively low procurement activity, while smaller groups exhibit substantially higher activity and contract exposure. From a procurement-governance perspective, these profiles can complement procedure-level monitoring by helping identify companies or patterns that may warrant further analytical review. Recent research and policy work similarly highlight the potential of machine learning and data analytics to support procurement oversight and risk-oriented monitoring [8], [35].

From a public-administration perspective, the integration of APP and QKB through the NIPT demonstrates the value of linking fragmented administrative information. The resulting company-level dataset provides a more comprehensive representation of economic operators and supports the analytical reuse of administrative data. This is consistent with recent developments in European public procurement, where interoperability, data integration, and reuse are increasingly emphasized [35], [37].

From a policy perspective, the anomaly-detection results (Fig. 3) suggest that integrated company-level indicators could support exploratory monitoring and prioritization of cases for further human review. Such use should not be understood as automated identification of misconduct or risk. Recent research emphasizes the value of combining analytical models with independently observed outcomes and complementary information sources for more reliable risk detection [35], [36].

The financial-enrichment experiment did not produce a substantial improvement in model performance. However, because financial information was available for only 3,159 companies (30.8% of the integrated dataset), this result should be interpreted cautiously. It indicates that procurement-derived variables provide the dominant analytical signal in the current dataset, rather than demonstrating that financial information has no value.

Overall, the findings support the analytical value of company-level integration of public procurement and administrative data in Albania. The main contribution lies in the empirical evidence enabled by integrating fragmented public information, while machine learning serves as an analytical tool for classification, company profiling, and anomaly detection rather than as the primary contribution.

VI. Conclusion

This study demonstrated the analytical value of integrating APP procurement records with QKB administrative business data at the company level through the NIPT identifier. The results showed that procurement-derived features contain substantial information for distinguishing heterogeneous company profiles, including atypical high-activity groups. The reduced-feature experiment and shuffled-label sanity check provided additional methodological support for the analysis.

The findings are relevant to procurement governance, public administration, and digital government, as integrated company-level data can support exploratory monitoring, company profiling, and the prioritization of cases requiring further institutional review. In the Albanian context, this company-level perspective complements existing research focused primarily on competition, savings, and accountability in public procurement [9].

However, the heuristic labels, predefined feature weights, limited financial-data coverage, and absence of independently validated risk outcomes restrict the interpretation of the models as formal business-risk predictors. Overall, the contribution lies in the empirical company-level analysis enabled by integrating fragmented public data in Albania, rather than in developing a new machine learning algorithm.

VII. Future Work

Future Research Should Focus on Independently Validated Risk Outcomes, Empirically Justified Feature Construction, Broader Longitudinal Financial Data, and Temporal and Graph-based Analysis of Relationships Among Companies and Contracting Authorities. Future Studies Could Also Examine the Interoperability of Additional Administrative Data Sources and Evaluate Whether Their Integration Improves Company-level Profiling. Explainable Artificial Intelligence (XAI) Methods Could Further Improve the Transparency and Interpretability of Model Outputs [34], [35], [36]

***Abstract*—Cultural heritage education plays a vital role in preserving national identity and transmitting traditional knowledge across generations. However, younger learners often perceive learning about cultural heritage as passive and less engaging than contemporary digital experiences. Although serious games have emerged as promising tools for heritage education, many existing applications lack theoretically grounded engagement mechanisms, limiting their effectiveness in sustaining learner participation. This study develops and empirically evaluates a Cultural Heritage Serious Game Model for Enhancing User Engagement Based on Flow Theory in the context of Songket learning. The research employed a four-phase methodology comprising analysis, model design, prototype development, and empirical evaluation. The proposed model integrates key Flow Theory-informed game design elements to support focused attention, intrinsic motivation, problem-solving, and learning transfer. Evaluation findings demonstrated positive engagement outcomes, with mean scores of 3.63 for focused attention, 3.98 for intrinsic motivation, 4.08 for problem-solving, and 4.02 for perceived learning transfer. The findings provide preliminary evidence of positive cognitive engagement in cultural heritage education. This study contributes a theoretically grounded design framework for serious game development and offers practical guidance for leveraging digital technologies to revitalize cultural heritage education.**

***Keywords*—Cultural heritage education; serious games; flow theory; user engagement; songket learning; educational technology**

I. Introduction

Cultural heritage represents a society's collective identity, history, and traditions, serving as an important medium for transmitting cultural values and knowledge across generations. However, globalization, urbanization, and rapid technological advancements have significantly transformed how younger generations perceive and engage with cultural heritage. Traditional instructional approaches, such as textbooks, classroom lectures, and museum exhibitions, often fail to sustain learners' attention and interest, particularly among digital-native students who are accustomed to highly interactive digital environments. Consequently, preserving intangible cultural heritage, including traditional crafts, music, textiles, and performing arts, has become an increasingly important challenge in education. Recent studies suggest that integrating digital technologies into cultural heritage education can significantly improve learners' participation and cultural appreciation while supporting long-term heritage preservation [1], [2].

Among various educational technologies, serious games have emerged as an effective instructional approach that integrates educational objectives with engaging gameplay. Serious games promote active learning through storytelling, challenges, immediate feedback, and interactive exploration, enabling learners to construct knowledge in enjoyable and meaningful ways. Numerous studies have demonstrated that serious games improve learning motivation, cultural awareness, and knowledge retention compared with conventional instructional methods [2], [3]. Nevertheless, despite their growing popularity in cultural heritage education, many existing serious games primarily present cultural information while overlooking the psychological mechanisms that sustain long-term engagement. Consequently, users often experience reduced immersion and declining motivation after initial interactions, limiting the educational effectiveness of these applications [4].

Consequently, user engagement has become a central issue in serious game research because it directly influences learning effectiveness, knowledge retention, and continued intention to use. Engagement encompasses learners' cognitive, emotional, and behavioral involvement throughout the learning process and is among the strongest predictors of successful digital learning environments. Flow Theory, introduced by Csikszentmihalyi, explains that individuals experience optimal engagement when challenges are appropriately matched to their skills, learning goals are clearly defined, immediate feedback is available, and they experience a sense of control during task performance [5].

Recent studies have further confirmed that Flow Theory provides a robust theoretical foundation for designing engaging learning environments across educational technologies, including virtual reality, metaverse learning, gamification, and serious games [6]. Despite its established relevance, relatively few studies have systematically incorporated Flow Theory into the design of serious games for cultural heritage education. Although Flow Theory has been applied to explain engagement in digital learning and games, it has less frequently been operationalized as a design principle throughout the development of cultural heritage serious games. Existing studies provide individual design recommendations or evaluate

user experience, but fewer studies provide an integrated model that explicitly connects Flow Theory-informed game elements, multimedia components, and cognitive engagement outcomes within a cultural heritage learning context. The novelty of the proposed model lies in its explicit operationalization of Flow Theory as a design principle rather than solely as an evaluation construct. The model maps Flow Theory-informed game elements and multimedia components to specific cognitive engagement dimensions within a cultural heritage learning context. This design-oriented mapping provides a structured basis for translating theoretical principles into gameplay features and learning activities for Songket education.

Therefore, this study develops and empirically evaluates a cultural heritage serious game model grounded in Flow Theory to enhance user engagement in learning Songket, one of Malaysia's most valuable forms of intangible cultural heritage. Using a Design and Development Research (DDR) methodology, the study develops a Flow Theory-based serious game model, implements the model in a Songket learning prototype, and empirically evaluates perceived user engagement across four dimensions, namely focused attention, intrinsic motivation, problem-solving, and learning transfer. Unlike previous studies that primarily focus on game usability or learning outcomes, this research contributes a theoretically grounded and empirically validated design framework that demonstrates how Flow Theory can be operationalized to enhance engagement in cultural heritage serious games. The proposed model provides practical guidance for researchers, educators, and game developers seeking to revitalize cultural heritage education through interactive digital technologies.

II. Related Work

A. Digital Transformation in Cultural Heritage Education

The rapid advancement of digital technologies has fundamentally transformed the preservation and dissemination of cultural heritage. Traditionally, cultural heritage education relied heavily on museums, exhibitions, storytelling, and classroom-based instruction to transmit historical knowledge and cultural values. While these approaches remain important, they often provide passive learning experiences that are less appealing to digitally native learners [1]. Consequently, researchers have increasingly explored digital technologies to create more interactive, learner-centered environments that improve cultural awareness and engagement.

Emerging technologies such as virtual reality (VR), augmented reality (AR), mixed reality (MR), digital storytelling, and interactive multimedia have demonstrated considerable potential for enhancing learners' understanding of cultural heritage by enabling immersive exploration of historical artifacts and cultural practices [3], [7]. These technologies facilitate experiential learning through visualization, interaction, and simulation, enabling learners to engage with cultural environments that would otherwise be inaccessible. Recent studies have also shown that digital cultural heritage platforms positively influence learners' cultural identity, historical understanding, and motivation to preserve heritage when they incorporate meaningful interaction rather than simply presenting digital content [4]. Recent research further indicates that interaction design has become an important consideration in cultural heritage serious games, with participatory, cognitive, perceptual, and social interaction identified as distinct interaction dimensions that can shape user experience in immersive heritage environments [16].

Despite these advancements, several studies have reported that many digital heritage applications remain technology-driven rather than pedagogy-driven. Existing systems frequently prioritize visualization and information delivery while paying little attention to instructional theories that explain how learners become cognitively and emotionally engaged in digital learning [2]. As a result, researchers increasingly advocate integrating educational theories into the design of digital heritage systems to improve learning effectiveness and long-term engagement. Recent systematic research on gamified XR applications similarly highlights the importance of aligning technological affordances, interaction design, game mechanics, and educational objectives rather than treating immersive technology as an end in itself [17].

B. Serious Games for Cultural Heritage Learning

Serious games have become one of the most promising educational technologies for cultural heritage learning because they integrate educational objectives with engaging gameplay experiences. Unlike entertainment games, serious games are intentionally designed to facilitate learning while maintaining players' enjoyment through interactive challenges, storytelling, rewards, and immediate feedback [8]. Their ability to combine experiential learning with problem-solving activities makes them particularly suitable for preserving intangible cultural heritage, where learners must understand not only factual information but also cultural values, traditions, and practices.

Previous studies have demonstrated that serious games significantly improve learner motivation, cultural awareness, knowledge acquisition, and learning satisfaction compared with conventional instructional approaches [9]. For example, virtual heritage games enable learners to explore historical environments interactively, while simulation-based games encourage active participation in traditional cultural practices. Similarly, game-based learning has been successfully used to teach traditional architecture, archaeology, historical events, and indigenous knowledge systems [10]. Recent empirical research has further demonstrated that cultural heritage serious games can support knowledge transfer through different immersive technologies, with evidence suggesting that the relationship between interaction, immersion, and knowledge outcomes depends on the nature of the learning task and technology used [18].

Nevertheless, recent reviews indicate that many serious games for cultural heritage emphasize entertainment and visualization without systematically incorporating pedagogical or psychological theories into their design [11]. Consequently, although these games may initially attract users, they often struggle to sustain engagement throughout the learning process. Additionally, evaluation studies frequently focus on usability and learning outcomes while providing limited explanation of how specific game design elements influence engagement mechanisms [12]. These limitations emphasize the need for theoretically grounded serious game models that explicitly connect educational theory with game design

principles. Recent studies have begun to address this issue by examining the specific factors and mechanisms underlying engagement in intangible cultural heritage serious games, including cultural authenticity, information richness, interactivity, aesthetics, and perceived enjoyment [19], [20].

C. Flow Theory and User Engagement in Serious Games

User engagement has become a central construct in educational technology because it strongly influences learning persistence, motivation, satisfaction, and knowledge retention. Engagement is generally understood as a multidimensional concept comprising cognitive, emotional, and behavioral involvement during learning activities [13]. In serious games, maintaining engagement is particularly important because learning occurs simultaneously with gameplay; therefore, disengagement often reduces educational effectiveness.

Flow Theory, proposed by Csikszentmihalyi [5], explains how individuals experience optimal engagement when they become fully immersed in an activity. Flow occurs when learners perceive a balance between task difficulty and their own abilities, receive immediate feedback, pursue clear goals, and maintain a strong sense of control. Under these conditions, learners experience intrinsic motivation, deep concentration, enjoyment, and a reduced awareness of external distractions. Numerous studies have identified Flow Theory as one of the most influential theoretical frameworks for explaining engagement in digital learning environments, including serious games, gamified learning systems, virtual reality, and metaverse-based education [6], [14]. Recent research continues to support the relevance of Flow Theory in digital game-based learning, particularly in explaining relationships involving motivation and problem-solving outcomes [21].

Recent research has further demonstrated that flow experiences positively influence learner motivation, learning achievement, self-efficacy, and continued intention to use educational technologies [15]. In serious games, Flow Theory has been associated with focused attention, higher intrinsic motivation, enhanced problem-solving ability, and perceived knowledge transfer. However, despite these promising findings, relatively few studies have operationalized Flow Theory into a comprehensive game design model specifically for cultural heritage education. Most existing studies measure flow only as an evaluation outcome rather than using it as a guiding framework throughout the game design process [11]. This limitation presents an important opportunity to develop theory-driven serious game models that systematically enhance learner engagement. Importantly, recent research on intangible cultural heritage serious games has shifted attention toward identifying the underlying mechanisms of engagement, showing that authenticity, knowledge acquisition, interactivity, emotional connection, perceived playfulness, and design aesthetics can contribute to users' perceived usefulness, enjoyment, cultural identity, and engagement [20]. This emerging evidence reinforces the need for design models that move beyond measuring engagement as an outcome and explicitly specify how theoretically informed game elements are intended to support different dimensions of engagement.

III. METHOD

This study adopted a Design and Development Research (DDR) methodology to systematically develop, implement, and evaluate a Flow Theory-based Cultural Heritage Serious Game Model to enhance user engagement. The research process consisted of four main phases: 1) Analysis, 2) Design, 3) Development, and 4) Evaluation. Each phase contributed to the progressive refinement of the proposed serious game model, beginning with the identification of design requirements and theoretical foundations, followed by model construction, prototype implementation, and evaluation of user engagement outcomes.

A. Analysis Phase

The analysis phase established the theoretical, contextual, and design foundations for developing the Flow Theory-based Cultural Heritage Serious Game Model. This phase involved three main activities: literature analysis, serious game analysis, and the collection of contextual data. The literature analysis reviewed existing studies on serious games, cultural heritage education, Flow Theory, and user engagement to identify relevant theoretical constructs, game elements, and evaluation dimensions. A comparative analysis of existing cultural heritage serious games was then conducted to examine current design approaches, learning strategies, and engagement mechanisms, and to identify limitations in existing applications. In addition, interviews and observations with Songket and cultural heritage experts were conducted to gather domain-specific knowledge of Songket history, weaving processes, motifs, and cultural values. The findings from this phase informed the identification of user requirements, cultural content specifications, and essential model components that guided the subsequent design and development phases.

B. Design Phase

The design phase focused on transforming the findings from the analysis phase into a structured conceptual framework and detailed game design specifications. This phase involved two main activities: model construction and game design planning. The first activity involved developing a cultural heritage serious game model to enhance user engagement, grounded in Flow Theory. The components identified in the analysis phase were systematically mapped according to their relationships among Flow Theory principles, serious game elements, and expected user engagement outcomes. The proposed model establishes how specific game design features can facilitate psychological engagement states and support meaningful cultural heritage learning experiences.

The second activity involved developing a comprehensive Game Design Document (GDD) to translate the proposed model into practical design requirements. The GDD specified the game objectives, learning objectives, gameplay mechanics, narrative structure, interaction design, level progression, multimedia requirements, character design, and user interface elements. Low-fidelity interface designs, storyboards, and learning scenarios were developed to ensure that the proposed game features aligned with both educational objectives and Flow Theory principles.

C. Development Phase

The development phase involved transforming the approved design specifications into a functional, high-fidelity serious game prototype for Songket learning. This phase consisted of three activities: asset production, prototype implementation, and functional testing. During asset production, multimedia resources, including two-dimensional and three-dimensional graphics, animations, audio elements, interface components, and cultural heritage visual materials, were created and refined. These assets were designed to accurately represent Songket-related knowledge, including weaving processes, traditional motifs and patterns, tools, and cultural narratives.

The prototype was subsequently developed in Unity, integrating the designed game mechanics, interactive elements, learning activities, and multimedia components. The implementation process ensured that each component of the proposed model was embedded in the game environment, particularly user-engagement elements such as interactive challenges, feedback mechanisms, progressive difficulty, and meaningful learning activities. The gameplay was structured around Songket-related learning activities that required participants to interact with cultural heritage content rather than merely receive informational content. Each learning activity was translated into game-based tasks involving clear objectives, challenges, feedback, and progression. Clear objectives guided players towards specific Songket learning goals, while challenges required them to identify, interpret, arrange, or make decisions related to Songket knowledge. Immediate feedback was provided following player actions to indicate task performance and guide subsequent decisions, while rewards and progression mechanisms were used to reinforce task completion and encourage continued participation. The difficulty of the activities was progressively structured to provide increasing levels of challenge as players advanced through the game. Multimedia elements, including graphics, sound/music, and cultural content, were integrated into the gameplay to contextualise information about Songket motifs, weaving processes, tools, and cultural values.

Learning activities related to Songket motifs required players to interact with and identify visual representations of traditional motifs, while activities related to the weaving process required players to engage with task sequences associated with the production process. Other learning activities presented Songket-related cultural information within interactive missions, requiring players to use the information presented during gameplay to complete subsequent tasks. These activities followed a progression in which successful task completion enabled players to proceed to subsequent challenges, while feedback provided information about their performance. This implementation translated the proposed Flow Theory-based design principles into concrete gameplay experiences and ensured that cultural heritage knowledge was embedded within the interaction and progression of the serious game rather than presented solely as supplementary information.

Following implementation, functional testing was conducted to ensure the reliability and usability of the developed prototype. Unit testing and integration testing were performed to examine game functionality, navigation flow, interaction mechanisms, multimedia performance, and potential technical errors. The output of this phase was a fully functional cultural heritage serious-game prototype, ready for empirical evaluation.

D. Evaluation Phase

The evaluation phase aimed to empirically evaluate users' perceived cognitive engagement by examining users' engagement experiences after interacting with the developed Songket learning prototype. The user evaluation involved 25 participants aged between 18 and 25 years, representing the target user group for the Songket learning prototype. Participants were recruited using convenience sampling based on their availability and suitability for the intended learner profile. The evaluation was designed as an initial user-based validation of the developed prototype within the evaluation phase of the DDR methodology rather than as a population-level effectiveness study.

A user-based evaluation approach was conducted with participants representing the intended learner group. Each participant engaged with the game for approximately 30–45 minutes before completing the evaluation questionnaire. The evaluation focused on measuring user engagement across four dimensions adapted from the User Engagement Scale (UES) framework: focused attention, intrinsic motivation, problem solving, and learning transfer.

A structured questionnaire was developed to assess the effectiveness of the proposed model in facilitating engaging cultural heritage learning experiences. The instrument consisted of three sections. Section A collected demographic information to describe participants' background characteristics. Section B measured user engagement across four subdimensions: focused attention, intrinsic motivation, problem-solving, and learning transfer. Focused attention examined the extent to which users were immersed and concentrated during gameplay; intrinsic motivation evaluated users' enjoyment, interest, and willingness to continue engaging with the learning activity; problem-solving assessed users' cognitive involvement in completing game-based challenges and applying acquired knowledge; while learning transfer measured users' ability to relate and apply the knowledge gained from the game to Songket-related concepts and cultural understanding. Section C evaluated users' overall perceptions of the developed serious game, including overall satisfaction and recommendations. Items in Sections B and C were measured using a five-point Likert scale ranging from 1 (strongly disagree) to 5 (strongly agree).

The collected quantitative data were analyzed using descriptive statistical analysis to determine the level of user engagement achieved by the developed serious game model. Mean scores were calculated for each engagement dimension to evaluate the extent to which the proposed model supported meaningful learning experiences. The evaluation outcomes were subsequently used to empirically evaluate the Flow Theory-based serious game model and to demonstrate its contribution to enhancing cultural heritage education through an interactive, engagement-driven digital learning approach.

IV. Result and Discussion

This section presents the study's outcomes: a proposed cultural heritage serious game model for enhancing user engagement, grounded in Flow Theory, and an empirical evaluation of perceived cognitive engagement in Songket learning. The results are presented in two stages. First, the proposed model is described as integrating Flow Theory principles and multimedia elements within the serious game environment. Second, the empirical evaluation examines participants' perceived cognitive engagement after interacting with the Songket prototype across four dimensions: focused attention, intrinsic motivation, problem-solving, and learning transfer.

A. Cultural Heritage Serious Game Model for Enhancing User Engagement Based on Flow Theory

The study resulted in the development of a cultural heritage serious game model to enhance user engagement, based on Flow Theory, as illustrated in Fig. 1. The model conceptualizes a serious game as an integrated learning environment in which Flow Theory-based game elements and multimedia components work together to facilitate cognitive engagement. The model consists of two primary inputs within the serious game environment: 1) Flow Theory-based game elements and 2) media elements. The Flow Theory-based game elements comprise feedback, clear goals, challenges, rewards, and focused attention. These elements are designed to structure the learning experience and encourage sustained interaction by providing learners with explicit objectives, appropriately challenging tasks, timely responses to their actions, motivational reinforcement, and opportunities to maintain concentration during gameplay. The media component complements these game mechanics by integrating graphics, sound/music, and cultural heritage content, thereby providing multimodal representations of Songket knowledge and creating a more interactive and meaningful learning environment.

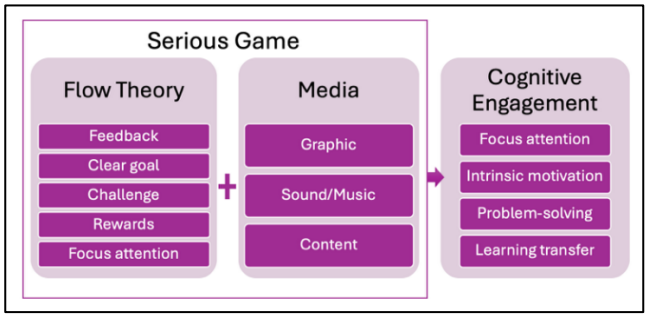

Fig. 1. Cultural heritage serious game model for enhancing user engagement based on flow theory.

The proposed relationships between the game design elements and cognitive engagement dimensions are theoretically grounded in the mechanisms of Flow Theory. Clear goals provide task orientation by directing learners toward specific objectives, thereby supporting focused attention on relevant learning activities. Challenges create opportunities for cognitive processing by requiring learners to analyse information, make decisions, and develop strategies, which supports problem-solving engagement. Feedback provides immediate performance awareness by informing learners about the consequences of their actions and progress toward goals, thereby helping them maintain attention and adjust their strategies during gameplay. Rewards, when integrated with meaningful progression and achievement, reinforce learners' sense of accomplishment and can support intrinsic motivation by sustaining interest and continued participation. In addition, the integration of cultural heritage content with interactive gameplay provides contextualization by allowing learners to encounter, manipulate, and apply Songket-related knowledge within meaningful game situations. Collectively, these relationships establish a theoretically informed pathway in which Flow Theory-based design mechanisms and multimedia-supported cultural content are intended to facilitate distinct but complementary dimensions of cognitive engagement.

The model proposes that the interaction between these game and media elements supports cognitive engagement, which is represented by four dimensions: focused attention, intrinsic motivation, problem-solving, and learning transfer. In the context of Songket learning, the game elements provide structural and motivational mechanisms to engage learners, while multimedia elements support the presentation and contextualization of cultural heritage knowledge. For example, clear goals and challenges can direct learners' attention toward specific Songket-related learning tasks, while feedback and rewards can reinforce participation and encourage continued engagement. Similarly, graphics, sound/music, and culturally relevant content can enhance the representation of Songket weaving traditions and facilitate learners' understanding of associated cultural knowledge. Through this integration, the model positions cognitive engagement as the intended outcome of the serious game experience, in which learners are expected to remain attentive to the learning activity, develop intrinsic motivation, actively engage in problem-solving, and transfer acquired knowledge into their understanding of Songket and cultural heritage.

B. Evaluation of Cognitive Engagement

User engagement within the Flow Theory-based serious game was evaluated in terms of perceived cognitive engagement. The evaluation involved 25 participants aged 18-25, representing the target user group for the Songket learning prototype. Cognitive engagement was operationalized across four dimensions: focused attention, intrinsic motivation, problem-solving, and learning transfer. Participants interacted with the Songket serious game prototype before completing the evaluation questionnaire.

1) Focused attention: The findings indicate a positive level of focused attention among participants, with an overall mean score of 3.63 (SD = 1.06) as shown in Table I. The results suggest that participants generally experienced concentration and involvement while interacting with the Songket serious game. In particular, the item-level results indicate that participants reported relatively strong attention toward game-related tasks, with the highest mean observed for the statement "My attention was fully focused on the game tasks" (M = 4.16, SD = 0.90). This finding suggests that structured gameplay activities and task-oriented interactions

effectively directed participants' attention toward the learning activities embedded in the game. Participants also reported relatively high levels of absorption in the game (M = 3.68) and immersion in the game environment and storyline (M = 3.80), indicating that the combination of gameplay and multimedia elements helped maintain users' attention.

However, the comparatively lower mean scores for "I lost track of time while interacting with the game" (M = 3.32, SD = 1.18) and "I was so involved that I forgot about my surroundings" (M = 3.20, SD = 1.23) suggest that the level of deep immersion was less consistent among participants. The relatively higher standard deviation also indicates greater variation in participants' experiences of focused attention. This finding is important in relation to the proposed Flow Theory-based model because focused attention reflects not only the game's ability to attract attention but also the extent to which users experience sustained cognitive absorption. The results suggest that the current implementation was effective in directing attention toward specific learning tasks. However, opportunities remain to strengthen deeper immersion through more sophisticated narrative structures, adaptive challenges, richer interactive feedback, and more continuous gameplay progression. Future iterations of the model could further investigate how these design mechanisms influence sustained attention and deeper flow experiences during cultural heritage learning.

TABLE I. FOCUSED ATTENTION ELEMENT

Item	Statement	M	SD
FA1	Completely absorbed in the game	3.68	0.80
FA2	Lost track of time	3.32	1.18
FA3	Forgot about surroundings	3.20	1.23
FA4	Attention fully focused on game tasks	4.16	0.90
FA5	Immersed in game environment and storyline	3.80	0.91
	Overall Mean/SD	**3.63**	**1.06**

2) Intrinsic motivation: The results demonstrate a high level of intrinsic motivation**,** with an overall mean score of 3.98 (SD = 0.84), as shown in Table II**.** This finding indicates that participants generally experienced enjoyment, curiosity, and personal interest while interacting with the Songket learning game. The item-level findings further support this interpretation, with participants reporting that their motivation was primarily associated with interest and enjoyment rather than external rewards (M = 4.04, SD = 0.89)**.** Participants also demonstrated a strong willingness to explore and master challenges (M = 3.96) and reported continued engagement driven by curiosity (M = 4.00). These results suggest that the game experience provided internally rewarding interactions that encouraged participants to remain engaged with the learning activities.

The findings are particularly relevant to the Flow Theory foundation of the proposed model. Flow-oriented experiences are commonly associated with intrinsic enjoyment and the willingness to engage in an activity for its inherent satisfaction rather than solely for external outcomes. Within the proposed model, the integration of clear goals, challenges, feedback, rewards, and multimedia content creates an environment where participants can engage with Songket-related learning content in an enjoyable, personally meaningful way. Importantly, the results indicate that participants' motivation was not primarily dependent on external rewards, suggesting that the cultural content and interactive gameplay themselves provided meaningful sources of engagement. Nevertheless, because the present findings are based on self-reported perceptions, further research using longitudinal or experimental designs would be necessary to determine whether this intrinsic motivation is sustained over repeated gameplay sessions.

TABLE II. INTRINSIC MOTIVATION ELEMENT

Item	Statement	M	SD
IM1	Game was personally enjoyable	3.92	0.76
IM2	Motivated to explore and master challenges	3.96	0.79
IM3	Continued playing because of curiosity	4.00	0.91
IM4	Wanted to improve performance	4.00	0.91
IM5	Motivation from interest and enjoyment	4.04	0.89
	Overall Mean/SD	**3.98**	**0.84**

3) Problem-solving: Among the four dimensions examined, problem-solving achieved the highest overall mean score (M = 4.08, SD = 0.80), indicating a high level of perceived cognitive engagement during gameplay, as shown in Table III. Participants generally perceived the game as requiring active cognitive processing, including critical thinking, strategic planning, reasoning, and decision-making. The highest-rated item was "The missions tested my reasoning and decision-making skills" (M = 4.16, SD = 0.75), followed by "The game improved my ability to plan and adapt" (M = 4.12, SD = 0.78). These findings suggest that the game's mission structure and challenges successfully encouraged participants to actively process information and make decisions rather than passively consume cultural heritage content.

The strong problem-solving results provide important support for the design rationale underlying the proposed model. The integration of challenges and clear goals, supported by feedback and rewards, provides a structured mechanism for learners to engage progressively with Songket-related content. Rather than presenting Songket knowledge solely through conventional information delivery, the game requires learners to interact with content through tasks and challenges, thereby encouraging active cognitive participation. The results also suggest that the serious game has the potential to transform cultural heritage learning from a predominantly receptive activity into a more participatory experience. However, the findings should be interpreted as evidence of perceived engagement in problem-solving rather than direct evidence of improved problem-solving ability, as the study did not employ a pre-test/post-test design or objective performance measures. Future studies could therefore incorporate behavioral game analytics and learning performance assessments to determine

whether the perceived cognitive engagement observed in this study translates into measurable improvements in problem-solving performance.

TABLE III. PROBLEM-SOLVING ELEMENT

Item	Statement	M	SD
PS1	Game required critical thinking	4.04	0.79
PS2	Developed new strategies	4.08	0.91
PS3	Enjoyed finding solutions	4.00	0.82
PS4	Missions tested reasoning and decision-making	4.16	0.75
PS5	Improved planning and adaptation	4.12	0.78
	Overall Mean/SD	**4.08**	**0.80**

4) Learning transfer: The results also demonstrate a high level of perceived learning transfer, with an overall mean score of 4.02 (SD = 0.81) as in Table IV. This finding indicates that participants generally perceived the knowledge and skills acquired through the game as relevant beyond the immediate gameplay context. The highest-rated item was "The game encouraged me to use my new knowledge elsewhere" (M = 4.12, SD = 0.83), followed by participants' perceived ability to apply what they learned to real-world situations (M = 4.04). These findings suggest that participants recognized the relevance of the Songket-related knowledge presented through the game beyond the immediate digital environment.

The learning transfer outcome is particularly significant for cultural heritage education because the primary purpose of a heritage-oriented serious game extends beyond providing an engaging gameplay experience. The learning experience should encourage learners to recognize, understand, and appreciate cultural knowledge in contexts beyond the game itself. Within the proposed model, integrating cultural heritage content with interactive gameplay and multimedia elements has supported participants' perception that the knowledge acquired through the game can be applied or recalled in other contexts. Nevertheless, the results represent perceived learning transfer rather than objectively demonstrated transfer. The absence of an external knowledge assessment means that the findings cannot establish whether participants transferred Songket knowledge to real-world situations. Future research should therefore incorporate pre-test and post-test assessments, delayed retention tests, or authentic cultural heritage tasks to provide stronger empirical evidence of perceived learning transfer.

TABLE IV. LEARNING TRANSFER ELEMENT

Item	Statement	M	SD
LT1	Applied learning to real-world situations	4.04	0.84
LT2	Knowledge/skills useful beyond the game	4.00	0.82
LT3	Connections between gameplay and real-life contexts	3.92	0.81
LT4	Confident using learning in other settings	4.00	0.82
LT5	Encouraged to use new knowledge elsewhere	4.12	0.83
	Overall Mean/SD	**4.02**	**0.81**

V. CONCLUSION

This study successfully designed and empirically evaluated a Cultural Heritage Serious Game Model for Enhancing User Engagement Based on Flow Theory for Learning Songket. The proposed model integrates Flow Theory-informed serious game elements, namely feedback, clear goals, challenges, rewards, and attention-supporting mechanisms, with multimedia components comprising graphics, sound/music, and cultural heritage content. The model was implemented using a Songket learning prototype and evaluated across four dimensions of perceived cognitive engagement: focused attention, intrinsic motivation, problem-solving, and perceived learning transfer. The evaluation results indicated positive levels of perceived engagement across all four dimensions, with problem-solving (M = 4.08) achieving the highest mean, followed by learning transfer (M = 4.02), intrinsic motivation (M = 3.98), and focused attention (M = 3.63). The findings provide preliminary empirical evidence that the implemented prototype was associated with positive perceived cognitive engagement, consistent with the engagement propositions of the proposed model.

The study contributes to the theoretical and practical development of serious game design in three key ways. First, it provides a conceptual model that integrates serious game elements and multimedia components grounded in Flow Theory, demonstrating how these components can be structured to support multidimensional user engagement in cultural heritage learning. Second, the model offers a reference framework for researchers, educators, and serious game developers seeking to design engagement-oriented learning applications, particularly within the cultural heritage domain. Third, the study demonstrates the potential of an engagement-driven serious game approach to facilitate more interactive and immersive learning experiences while supporting the transmission, appreciation, and preservation of cultural heritage knowledge. Thus, the proposed model extends the application of Flow Theory beyond general digital learning contexts by providing a structured approach for integrating engagement mechanisms into the design of serious games for cultural heritage.

Future research should further refine and validate the proposed model by exploring alternative interaction techniques, expanded cultural heritage content, and more adaptive game mechanisms to strengthen sustained attention and deeper user engagement. Longitudinal studies involving larger and more diverse participant groups are also recommended to examine learning effectiveness, knowledge retention, continued user engagement, and user retention over extended periods. In addition, future research could investigate the model's scalability and transferability across different forms of tangible and intangible cultural heritage, cultural contexts, and learning environments. Such investigations would strengthen the model's generalizability and contribute to the development of a more comprehensive framework for leveraging serious games as sustainable digital tools for cultural preservation, heritage education, and intergenerational knowledge transmission.

ACKNOWLEDGMENT

The authors would like to acknowledge Universiti Sultan Zainal Abidin for funding this research under the Fundamental Research Grant Scheme No. FRGS/1/2022/ICT10/UNISZA/02/1. The authors would also like to express their utmost appreciation to the Ministry of Higher Education Malaysia.

Shaqra University, Riyadh 15526, Saudi Arabia[1]

***Abstract*—Answering Arabic fatwa inquiries represents a highly critical yet challenging task in Natural Language Processing, requiring consideration of multiple jurisprudential conditions, interpretation of interconnected concepts, and synthesis of evidence distributed across multiple religious sources. Existing Arabic question answering systems, including conventional single-step question answering (QA) models and retrieval-augmented generation (RAG) frameworks, typically perform retrieval only once and therefore struggle to capture the intermediate reasoning steps required for complex religious inquiries, often resulting in incomplete reasoning and factual hallucinations. To address these limitations, this study proposes a recursive prompt-driven reasoning approach for multi-hop Arabic fatwa question answering that integrates instruction-based supervision, task-specific language models, hybrid retrieval, and recursive reasoning to support end-to-end multi-hop question answering. The proposed method employs an instruction-based supervision strategy constructed from the MAFQA dataset to train specialized question decomposition and question answering models. To support evidence grounding, a hybrid retrieval module combines dense semantic retrieval, sparse lexical matching, and cross-encoder reranking to retrieve both few-shot demonstrations and supporting evidence at each reasoning hop, while a relevance-guided context update mechanism retains only the most informative contextual evidence throughout the recursive reasoning process. Comprehensive experiments conducted on the MAFQA dataset demonstrate the effectiveness of the proposed approach. The hybrid retrieval module consistently outperforms individual dense and sparse retrieval methods, while task-specific fine-tuning significantly improves end-to-end performance across Arabic sequence-to-sequence models and large language models under realistic inference conditions. The fine-tuned GPT-4.1 configuration achieves the best overall performance, obtaining an F1-token score of 31.88, a ROUGE-L score of 26.64, and a Relevance score of 92.39. Furthermore, the proposed approach surpasses representative state-of-the-art Arabic question answering systems, retrieval-augmented generation methods, and reasoning-based approaches, achieving a 36.5% relative improvement in F1-token over the strongest reasoning baseline. These results demonstrate that integrating recursive question decomposition, hybrid retrieval, and dynamic context updating improves performance under the evaluated multi-hop Arabic fatwa question answering setting.**

I. Introduction

Recent advances in natural language processing (NLP) and large language models (LLMs) have significantly enhanced the capabilities of question answering (QA) systems across diverse domains [1]. Unlike traditional information retrieval systems that return a list of potentially relevant documents, modern QA systems aim to directly provide concise and accurate answers to inquiries expressed in natural language [2], [3]. These developments have driven substantial progress in multilingual and domain-specific QA applications, including healthcare [4], education [5], law [6], and religion [7]. However, despite the success of modern QA systems, Arabic question answering remains relatively underexplored compared to English and other high-resource languages, lagging behind the increasing demand for intelligent Arabic-language information access. This disparity is primarily attributed to the limited availability of large-scale benchmark datasets, domain-specific resources, and reasoning-oriented evaluation frameworks [8], [9]. These limitations are particularly acute in specialized domains where answering questions requires domain expertise, deep contextual understanding, and complex reasoning [10]. Within Arabic QA, fatwa question answering represents a highly challenging and critical domain. Fatwa inquiries seek Islamic rulings and religious guidance on diverse topics such as worship, financial transactions, family matters, and contemporary social issues [11]. Unlike conventional factoid questions, fatwa inquiries often demand the consideration of multiple conditions, the synthesis of evidence from disparate religious sources, and the interpretation of interconnected jurisprudential concepts. Consequently, addressing these inquiries involves complex reasoning processes that extend far beyond simple information retrieval or direct answer generation [12], [13].

Despite recent progress in Arabic language models and retrieval-augmented generation (RAG) systems, existing approaches remain limited in their ability to address complex Arabic fatwa questions. Direct QA systems typically attempt to generate answers in a single step based solely on the input question. While such approaches may perform adequately for simple questions, they often struggle to capture the intermediate reasoning chains required for complex, multi-hop inquiries [14], [15]. Similarly, while standard RAG systems improve factual grounding by incorporating external evidence, conventional single-step RAG frameworks generally retrieve information only once and generate answers in a single phase. As a result, they frequently fail to effectively integrate evidence distributed

across multiple reasoning steps [16], [17]. Furthermore, recent studies demonstrate that LLMs can generate hallucinated content, unsupported claims, or incomplete reasoning chains when answering complex, domain-specific questions, raising concerns regarding reliability and factual grounding [18]. These challenges underscore the critical need for QA systems capable of performing explicit, multi-step reasoning while maintaining strong contextual grounding.

To address these limitations, this study proposes a recursive prompt-driven reasoning approach for multi-hop Arabic fatwa question answering. The proposed method recursively decomposes complex fatwa questions into interpretable subquestions and performs recursive reasoning through intermediate answer generation and dynamic context updating. To support contextual grounding, a hybrid retrieval module combines dense semantic retrieval, sparse lexical retrieval, and cross-encoder reranking to dynamically retrieve both few-shot demonstrations and supporting evidence at each reasoning step. Furthermore, an instruction-based supervision strategy is employed to train specialized models for question decomposition and answer generation, enabling them to learn explicit reasoning behaviors and intermediate inference patterns. By combining recursive question decomposition, hybrid retrieval, contextual grounding, and answer synthesis within a unified reasoning process, the proposed approach generates more accurate, contextually relevant, and faithful answers for complex multi-hop Arabic fatwa question answering tasks.

II. Related Work

Arabic question answering (QA) has attracted increasing research attention in recent years due to the growing demand for intelligent Arabic-language information access. Early Arabic QA systems primarily relied on keyword matching, information retrieval techniques, and ontology-based semantic methods. In the Islamic domain, Kamal et al. [19] proposed a fatwa QA system based on Term Frequency–Inverse Document Frequency (TF-IDF) and Latent Semantic Indexing (LSI), achieving a recall of 95% and a mean reciprocal rank (MRR) of 0.92 on a manually collected fatwa corpus. Similarly, Maraoui et al. [20] developed an Arabic QA system for Hadith and Tafsir that employed XML-based knowledge representations and formal query processing, achieving an accuracy of 92% on a manually constructed evaluation set. Although these approaches demonstrated promising results, their dependence on handcrafted resources limited their scalability and adaptability to increasingly complex QA scenarios. To overcome the limitations of purely lexical retrieval methods, several studies explored semantic approaches based on ontologies and machine learning techniques. Abdelnasser et al. [21] introduced Al-Bayan, a Quranic QA system that combined Support Vector Machines (SVMs) with ontology-based semantic similarity to retrieve relevant Quranic verses, achieving an accuracy of 85%. Likewise, Sheker et al. [22] proposed an ontology-based approach for Islamic fatwa QA using Ibn Othaimeen's fatwa collection, reporting a precision of 72% and recall of 59%. Although these approaches improved semantic matching compared with purely lexical methods, they depended heavily on manually constructed knowledge resources and exhibited limited scalability and domain coverage.

The emergence of pretrained language models (PLMs) significantly advanced Arabic QA research. Several studies employed transformer-based architectures for Quranic QA using the Quran Reading Comprehension Dataset (QRCD) [23]. Premasiri et al. [24] investigated transfer learning approaches by fine-tuning multiple Arabic and multilingual transformer models—including AraBERT, CAMeLBERT, mBERT, and AraELECTRA—on the QRCD dataset. In addition, ensemble learning techniques were explored to combine predictions from different models and improve answer selection performance. Among the evaluated architectures, AraELECTRA achieved the strongest performance, reporting a partial Reciprocal Rank (pRR) score of 49%. These findings highlighted the effectiveness of Arabic pretrained representations for Quranic QA while demonstrating the potential benefits of model ensembling. Furthermore, ElKomy and Sarhan [25] proposed an ensemble framework integrating several Arabic BERT variants, including ARBERT, MARBERT, and AraBERT, for Quranic QA. Their approach employed majority voting to identify the most probable answer candidates, followed by a post-processing stage designed to refine the selected predictions. Experimental results demonstrated that the proposed ensemble approach substantially improved performance, achieving an Exact Match (EM) score of 27% and a pRR score of 75%, thereby outperforming individual models.

Similarly, Alnajjar and Mika [26] investigated the use of multilingual BERT for Quranic QA by fine-tuning the model on the QRCD [23] dataset and further enhancing it through additional pretraining on Islamic-domain corpora. Their findings revealed that domain-adaptive pretraining significantly improved performance, with the enhanced model achieving a pRR score of 70%. The authors also incorporated a post-processing mechanism to verify the validity and length of generated answers, further contributing to performance gains. Aftab and Malik [27] explored several pretrained transformer models for Quranic QA and proposed multiple strategies to enhance model generalization. Specifically, they employed decoupled weight decay regularization to mitigate overfitting and utilized data augmentation techniques by incorporating examples from the Arabic Question Answering and Comprehension Corpus (AQQAC [28]) to expand the QRCD [23] training data. Their experimental findings indicated that fine-tuning Arabic pretrained models yielded superior performance compared with multilingual models or models trained from scratch, with AraBERT outperforming competing approaches by 30.8% and 26.8% in terms of pRR and F1-score, respectively.

Furthermore, Alsaleh et al. [29] fine-tuned and evaluated models including AraBERT, CAMeLBERT, and ArabicBERT using the QRCD [23] dataset. Their experimental results demonstrated that AraBERT achieved the strongest performance among the evaluated models, obtaining a pRR score of 44% and an F1-score of 0.42. Nevertheless, the authors characterized the overall results as only "fair," suggesting considerable room for improvement. In particular, the relatively low EM score of 0.16 highlighted the difficulty of accurately identifying exact answer spans from Classical Arabic Quranic text. More recently, large language models (LLMs) have demonstrated strong capabilities in generative QA and

reasoning-intensive tasks. Within the Islamic domain, Basem et al. [30] investigated instruction-tuned LLMs, including Gemini and DeepSeek, combined with Arabic prompting strategies and post-processing techniques for Quranic QA. Their approach achieved a pAP@10 score of 0.637, outperforming several conventional transformer-based baselines. Saadaoui et al. [31] explored the integration of chain-of-thought (CoT) prompting with GPT-4, BART, and LLaMA models, demonstrating that structured prompting substantially enhanced reasoning performance and achieved F1-scores reaching 95% under specific evaluation settings. Similarly, Eltanbouly et al. [32] evaluated several state-of-the-art LLMs, including GPT-4o, Claude, Gemini, DeepSeek, and Mistral, for Quranic passage retrieval tasks. Their findings demonstrated that appropriately designed prompting strategies enabled these models to achieve performance comparable to specialized retrieval systems, attaining a Mean Average Precision (MAP) score of 0.535 and an MRR score of 0.842. Although these findings highlight the reasoning potential of LLMs, recent studies have also emphasized their susceptibility to hallucinations, unsupported claims, and incomplete reasoning processes, particularly within knowledge-sensitive domains where factual correctness is essential.

Retrieval-Augmented Generation (RAG) has emerged as a promising paradigm for improving the factual grounding of LLM-generated responses by incorporating external evidence during answer generation. Ahmad et al. [33] introduced a hybrid RAG framework for Islamic knowledge QA that combines sparse retrieval, dense semantic retrieval, and cross-encoder reranking within a unified retrieval pipeline. The proposed approach was evaluated on two subtasks using Fanar and Mistral language models. Experimental findings indicated that hybrid retrieval substantially improved QA performance, with the Fanar model obtaining the highest results, achieving accuracies of 45% and 80% on Subtasks 1 and 2, respectively. These results demonstrate that the hybrid retrieval approach provides meaningful enhancements for Islamic knowledge QA compared to baseline LLM performance. Similarly, Alnefaie et al. [34] investigated the impact of retrieval augmentation on Quranic QA by comparing standard GPT-4 against GPT-4 enhanced with RAG using the QUQA [35] dataset. Their results demonstrated that retrieval augmentation substantially improved both answer generation and Quranic verse identification. Specifically, the RAG-enhanced system achieved an EM score of 0.266 and an F1-score of 0.772 for text-based answers. Furthermore, for Quranic verse retrieval, the proposed approach attained an F1@1 score of 0.333, outperforming standard GPT-4 without retrieval support. Mohammed et al. [18] investigated the use of retrieval augmentation and reranking techniques to improve the quality of AI-assisted Islamic fatwa generation. Their study compared three configurations: a standalone LLM, an LLM enhanced with RAG, and an LLM with RAG plus a reranker. The results indicated that incorporating reranking into the RAG pipeline improved response consistency and reduced the occurrence of hallucinated information across multiple evaluation metrics, including BERTScore, hallucination rates, completeness, and irrelevance measures. These findings emphasize the importance of evidence refinement in sensitive domains such as Islamic fatwa generation. To address hallucination and weak evidence grounding in Islamic QA, Bhatia et al. [36] introduced ISLAMICFAITHQA, a bilingual benchmark for evaluating correctness, hallucination, and abstention behaviors in generative models. In addition, the authors developed an Agentic RAG framework that enables language models to utilize structured tools to collect authoritative evidence before generating citation-supported responses. Their findings demonstrated that retrieval augmentation consistently improved answer quality, whereas Agentic RAG produced the most substantial gains over conventional RAG approaches, achieving a state-of-the-art accuracy of 57.3% using Fanar-2-27B.

Collectively, these studies demonstrate that retrieval augmentation can substantially improve factual grounding, answer accuracy, and robustness in Islamic QA. Nevertheless, most existing RAG-based approaches perform retrieval and generation either in a single stage or through predefined retrieval pipelines, providing limited support for explicit multi-hop reasoning. Consequently, complex questions that require integrating evidence across multiple reasoning steps remain challenging. Despite the increasing interest in multi-hop QA, decomposition-based reasoning strategies remain largely underexplored in Arabic QA literature. One of the few studies investigating this direction was conducted by Abdelazim et al. [37], who investigated different reasoning strategies using the ACQAD [38] dataset under both Long Context Window (LCW) and RAG settings. The authors employed Chain-of-Thought prompting to decompose complex questions into intermediate subquestions, thereby facilitating stepwise reasoning across multiple evidence passages. Their framework utilized GPT-4-turbo as the primary language model and examined the effectiveness of decomposition-based reasoning in conjunction with long-context processing and retrieval augmentation. Experimental results demonstrated that incorporating question decomposition substantially improved performance compared with direct QA approaches, increasing accuracy from 75% to 92% under the LCW setting.

III. METHODOLOGY

A. Overview of the Proposed Approach

This study proposes a recursive prompt-driven reasoning approach for multi-hop Arabic fatwa question answering (QA) that integrates instruction-based supervision, task-specific language models, and hybrid retrieval mechanisms within a unified reasoning process. Designed to address the limitations of conventional systems when handling complex fatwa inquiries, the proposed approach explicitly models multi-step reasoning, evidence integration, and contextual synthesis. As illustrated in Fig. 1, the proposed approach consists of four primary components.

The first component is an instruction-based supervision module that transforms complex fatwa reasoning processes into structured instruction–response pairs for question decomposition and answer generation. This supervision strategy explicitly models intermediate reasoning steps and provides training signals for downstream models. The second component comprises two task-specific language models: a Question Decomposition (M_{QD}) model, which decomposes complex questions into interpretable subquestions, and a Question

Answering (M_{QA}) model, which generates context-grounded sub-answers and synthesizes the final response. Both models are trained under a unified instruction-following paradigm. The third component is a hybrid retrieval module that combines dense semantic retrieval, sparse lexical retrieval, and cross-encoder reranking. This module dynamically retrieves relevant demonstrations and supporting evidence at each reasoning step, providing contextual grounding for both question decomposition and answer generation. By leveraging the complementary strengths of semantic and lexical retrieval, the retrieval module improves retrieval quality and ensures access to evidence that is both semantically relevant and lexically precise.

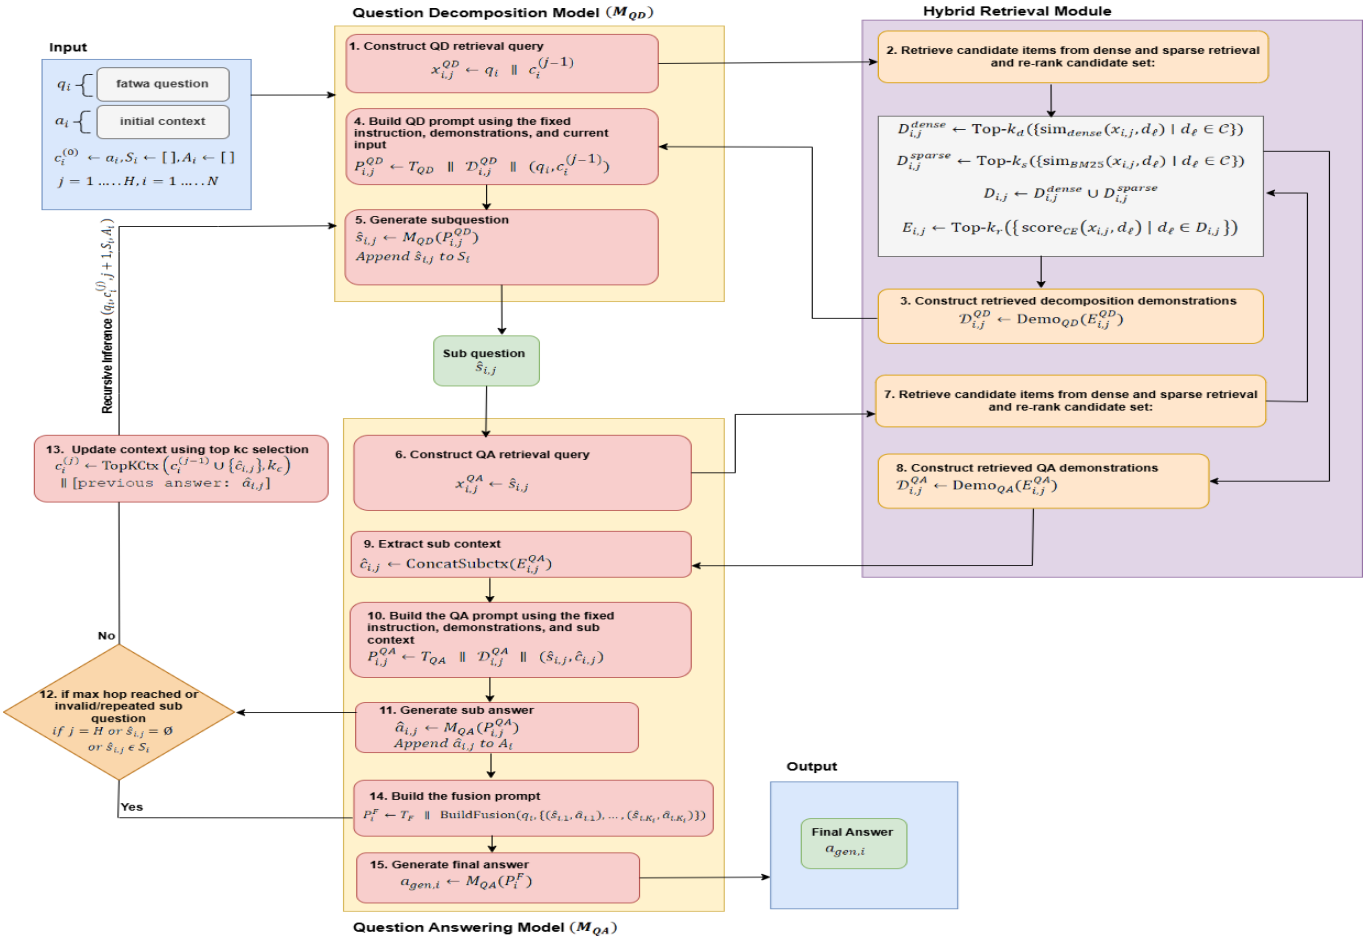

Fig. 1. The architecture of the proposed approach.

The final component is a recursive reasoning process that orchestrates the interaction among the decomposition, retrieval, and answer generation modules. Given a complex fatwa question, the proposed method recursively generates sub-questions, retrieves supporting evidence, produces intermediate answers, and updates the reasoning context before proceeding to subsequent reasoning steps. Once the recursive reasoning process terminates, the generated sub-answers are aggregated and used to construct a final answer that is coherent, contextually grounded, and faithful to the retrieved evidence. Through the coordinated interaction of these components, the proposed approach transforms complex fatwa questions into a sequence of interpretable reasoning steps, enabling structured multi-hop reasoning and dynamic evidence integration. This design enables the generation of more accurate and contextually relevant answers while improving reasoning transparency and reducing the likelihood of unsupported or hallucinated responses.

B. *Instruction-Based Supervision*

To support explicit multi-hop reasoning, the proposed approach adopts an instruction-based supervision strategy derived from the MAFQA [12] dataset—a benchmark for multi-hop Arabic fatwa question answering (QA) that contains complex questions, intermediate reasoning chains, subquestions, sub-answers, and supporting evidence passages. Unlike conventional QA datasets that provide only question–answer pairs, MAFQA [12] explicitly captures the intermediate reasoning structures required to address complex fatwa inquiries. This rich annotation enables the construction of supervision signals for both question decomposition and answer generation within a unified instruction-following paradigm.

Each dataset instance is represented as a structured reasoning chain consisting of a complex fatwa question, a set of intermediate subquestions, their corresponding sub-answers, supporting evidence passages, and a synthesized final answer.

Following data preprocessing and normalization, instruction-based supervision is constructed for two core tasks: question decomposition (QD) and question answering (QA).

Formally, for each dataset instance i, the supervision process maps a complex question into a sequence of intermediate reasoning steps:

$$q_i \rightarrow \{(s_{i,j}, c_{i,j}, a_{i,j})\}_{j=1}^{K_i} \quad (1)$$

where, $s_{i,j} \in SQ_i$ denotes the j -th sub-question, $a_{i,j} \in SA_i$ represents the corresponding sub-answer, and $c_{i,j}$ denotes the context associated with that reasoning step. The context is constructed from retrieved evidence grounded in the supporting passages associated with the original question. The variable K_i denotes the total number of reasoning steps required to answer the complex question q_i. This formulation explicitly models the intermediate reasoning structure underlying complex fatwa analysis and provides fine-grained supervision signals for both decomposition and answer generation. By exposing the model to structured reasoning chains during training, the framework encourages explicit reasoning behavior, progressive evidence integration, and improved contextual grounding throughout the inference process.

1) Question decomposition supervision: Question decomposition is formulated as a structured generation task in which a complex fatwa question is transformed into an ordered sequence of sub-questions together with their associated contexts. The objective of this task is to explicitly model the intermediate reasoning steps required to answer complex multi-hop questions. For each training instance, the input consists of natural-language instruction requesting the decomposition of a complex question into a sequence of sub-questions. To facilitate instruction-following behavior, the prompt is augmented with semantically similar decomposition demonstrations retrieved from the training set using dense semantic retrieval. These demonstrations provide examples of how complex questions can be decomposed into coherent reasoning chains and serve as in-context guidance during training.

The target output is the gold decomposition represented as an ordered set of sub-question–context pairs. By learning this mapping, the model acquires the ability to generate interpretable reasoning steps that progressively simplify complex fatwa questions into manageable sub-problems. The resulting decomposition serves as the foundation for the subsequent retrieval and answer generation stages.

2) Question answering supervision: The question answering task is formulated as a context-grounded generation problem in which the model learns to generate answers conditioned on both a question and its supporting evidence. The supervision strategy is designed to encourage the generation of faithful responses that remain grounded in the provided context while minimizing unsupported or hallucinated content. For each training instance, the input consists of a natural-language instruction, a question, and its associated context. Similar to the decomposition task, semantically related demonstration examples are incorporated into the prompt to provide in-context guidance. The target output is the corresponding gold answer obtained from the dataset annotations.

The proposed approach learns two complementary answer generation functions. The first generates intermediate sub-answers for individual sub-questions using their associated evidence passages. The second synthesizes a final answer by combining the original complex question with the generated reasoning chain consisting of sub-question–sub-answer pairs. Through this hierarchical supervision strategy, the model learns not only to generate context-grounded intermediate answers but also to aggregate multiple reasoning steps into a coherent final response. Consequently, the resulting supervision strategy directly supports the recursive multi-hop reasoning process described in Section E.

C. Task-Specific QD and QA Models

Following the construction of instruction-based supervision, the proposed approach trains two task-specific language models to learn different stages of the multi-hop reasoning process. The proposed method adopts a modular design in which question decomposition and answer generation are learned separately. This design allows each model to specialize in its respective task and facilitates more effective handling of complex fatwa questions that require multiple reasoning steps.

Both tasks are formulated under a unified instruction-following paradigm, where the model receives natural-language instruction together with task-specific inputs and generates the corresponding output. Furthermore, semantically similar demonstration examples are dynamically retrieved and incorporated into the prompt to provide in-context guidance during both training and inference. This design enables the models to learn structured reasoning patterns from relevant examples while maintaining consistency with the instruction-based supervision strategy described in Section B.

At the end of the training stage, two task-specific models are obtained:

$\boldsymbol{M}_{\mathrm{QD}}$: Question Decomposition Model

$\boldsymbol{M}_{\mathrm{QA}}$: Question Answering Model

The Question Decomposition model M_{QD} is responsible for transforming a complex fatwa question into an ordered sequence of sub-question–context pairs that explicitly represent the intermediate reasoning steps required to answer the original query. The Question Answering model M_{QA} is responsible for generating context-grounded answers for individual sub-questions and synthesizing the final answer to the original complex question. Together, M_{QD} and M_{QA} form the core learning components of the proposed approach. During inference, the decomposition model generates the intermediate reasoning structure, while the answering model produces evidence-grounded sub-answers and the final synthesized response. This modular design enables the proposed approach to support explicit multi-hop reasoning and facilitates the recursive reasoning process described in Section E.

D. Hybrid Retrieval Module

To support context-aware reasoning throughout the inference process, the proposed approach incorporates a hybrid retrieval module that combines dense semantic retrieval, sparse lexical retrieval, and cross-encoder reranking. The retrieval module is invoked recursively during both the question decomposition (QD) and question answering (QA) stages to retrieve relevant demonstrations and supporting evidence that adapt to the evolving reasoning state of the model. The retrieval process serves two complementary purposes. During the question decomposition stage, it retrieves semantically similar complex questions together with their corresponding decompositions, which are incorporated as few-shot demonstrations to guide sub-question generation. During the question answering stage, it retrieves both supporting evidence passages and question–answer demonstrations for each generated sub-question, enabling the generation of context-grounded answers.

1) Index construction: To prevent information leakage, all retrieval indices are constructed exclusively from the training split. Two task-specific indices are maintained within the proposed approach. The first index supports the question decomposition task and stores representations of complex fatwa questions together with their associated contextual information. This index is used to retrieve semantically similar examples whose gold decompositions serve as in-context demonstrations during decomposition. The second index supports the question answering task and is constructed at a finer granularity using sub-question–context pairs extracted from the training data. This design enables the retrieval of reasoning steps and evidence passages that are directly relevant to the generated sub-questions during recursive inference.

*2) Retriever architecture:*The retrieval architecture combines dense semantic retrieval and sparse lexical retrieval to leverage their complementary strengths. Previous studies have shown that dense retrievers are highly effective at capturing semantic relevance but may overlook exact lexical matches and domain-specific terminology, whereas BM25-based retrieval preserves important lexical cues and keyword overlap that may not be fully reflected in dense embedding representations [39]. Furthermore, hybrid retrieval architectures that integrate dense and sparse retrieval have been shown to consistently improve retrieval effectiveness across various information retrieval tasks, particularly for domain-specific queries and specialized terminology [40], [41]. Motivated by these findings, the proposed approach employs a hybrid retrieval strategy that combines semantic and lexical retrieval before applying cross-encoder reranking. Dense retrieval captures semantic similarity between queries and candidate items using multilingual sentence embeddings, enabling the retrieval of conceptually related examples even when lexical overlap is limited. Sparse retrieval, on the other hand, employs BM25-based lexical matching to preserve exact term overlap and domain-specific terminology. This combination is particularly important in Arabic fatwa question answering, where semantically relevant evidence may not always share the same wording as the query, while precise religious terminology often plays a critical role in determining the final ruling.

Given a query generated during the reasoning process, retrieval is performed independently using both dense and sparse retrievers. The resulting candidate sets are merged to form a unified candidate pool:

$$D_{i,j} = D_{i,j}^{dense} \cup D_{i,j}^{sparse} \tag{2}$$

where, $D_{i,j}^{dense}$ and $D_{i,j}^{sparse}$ denote the candidate sets returned by the dense and sparse retrievers, respectively, at the reasoning step j for instance i.

3) Cross-encoder re-ranking: To further improve retrieval quality, the merged candidate set is refined using a cross-encoder re-ranking model. Unlike bi-encoder retrieval methods that independently encode queries and documents, the cross-encoder jointly processes each query–candidate pair and produces a relevance score that captures fine-grained semantic interactions between them. Formally, each candidate is assigned a reranking score:

$$\text{score}_{CE}(x_{i,j}, d_\ell) = \text{CE}(x_{i,j}, d_\ell) \tag{3}$$

where, v$x_{i,j}$ denotes the retrieval query at the reasoning step j, d_ℓ represents a candidate item, and $CE(\cdot)$ denotes the cross-encoder reranking model. The candidates are subsequently ranked according to their cross-encoder scores, and the top-ranked items are retained as the final retrieval set used during inference. During question decomposition, the retrieved items provide decomposition demonstrations that guide the generation of structured sub-question–context pairs. During question answering, they supply both supporting evidence and question–answer demonstrations that enable the generation of context-grounded sub-answers and final responses. By integrating dense retrieval, sparse retrieval, and cross-encoder reranking within a unified architecture, the proposed hybrid retrieval module retrieves and reranks supporting evidence throughout the recursive reasoning process, thereby supporting both decomposition and answer generation stages.

E. Recursive Multi-Hop Reasoning Process

At inference time, the proposed approach executes a recursive, multi-hop reasoning process that integrates question decomposition, hybrid retrieval, and question answering (QA) within a unified function. Rather than treating these components as isolated pipeline stages, this process serves as the core reasoning mechanism of the proposed approach, operationalizing the instruction-based supervision strategy, leveraging the fine-tuned task-specific models, and dynamically integrating the hybrid retrieval module. The complete formal execution flow is presented in Algorithm 1.

Algorithm 1: Recursive Prompt-Driven Multi-Hop Reasoning Process

Input: Complex question q_i, initial context a_i, maximum reasoning hops H, retrieval hyperparameters (k_d, k_s, k_r), and context-selection hyperparameter k_c

Output: Generate final answer $a_{gen,i}$

Constants:

I_{QD}: question decomposition retrieval index, I_{QA}: question answering retrieval index, $C = I_{QD} \cup I_{QD}$: unified retrieval corpus, T_{QD}, T_{QA}, T_F: fixed instruction templates

Initialization: $j \longleftarrow 1,\ c_i^{(0)} \leftarrow a_i,\ S_i \leftarrow [],\ A_i \leftarrow []$

Function: RecursiveInfer $(q_i,\ c_i^{(j-1)},\ j,\ S_i,\ A_i)$

if $j > H$ **then**

$K_i = |S_i|$

$P_i^F \longleftarrow T_F \parallel BuildFusion\ (q_i, \{(\hat{s}_{i,1}, \hat{a}_{i,1}), \dots, (\hat{s}_{i,k_i}, \hat{a}_{i,k_i})\})$

$a_{gen,i} \longleftarrow M_{QA}(P_i^F)$

return $a_{gen,i}$

Question Decomposition (QD)

$x_{i,j}^{QD} \longleftarrow q_i \parallel c_i^{(j-1)}$

$D_{i,j}^{dense} \longleftarrow Top - k_d\ (sim_{dense}(x_{i,j}^{QD}, d_\ell), d_\ell \in C)$

$D_{i,j}^{sparse} \longleftarrow Top - k_s\ (sim_{BM25}(x_{i,j}^{QD}, d_\ell), d_\ell \in C)$

$D_{i,j} \longleftarrow D_{i,j}^{dense} \cup D_{i,j}^{sparse}$

$E_{i,j}^{QD} \longleftarrow Top - k_r\ (score_{CE}(x_{i,j}^{QD}, d_\ell), d_\ell \in D_{i,j})$

$D_{i,j}^{QD} \longleftarrow Demo_{QD}(E_{i,j}^{QD})$

$P_{i,j}^{QD} \longleftarrow T_{QD} \parallel D_{i,j}^{QD}(q_i,\ c_i^{(j-1)})$

$\hat{s}_{i,j} \longleftarrow M_{QD}(P_{i,j}^{QD})$

if $\hat{s}_{i,j} = \emptyset\ or\ \hat{s}_{i,j} \in S_i$ **then**

$K_i = |S_i|$

$P_i^F \longleftarrow T_F \parallel BuildFusion\ (q_i, \{(\hat{s}_{i,1}, \hat{a}_{i,1}), \dots, (\hat{s}_{i,k_i}, \hat{a}_{i,k_i})\})$

$a_{gen,i} \longleftarrow M_{QA}(P_i^F)$

return $a_{gen,i}$

$Append\ \hat{s}_{i,j}$ to S_i

Question Answering (QA)

$x_{i,j}^{QA} \longleftarrow \hat{s}_{i,j}$

$D_{i,j}^{dense} \longleftarrow Top - k_d\ (sim_{dense}(x_{i,j}^{QA}, d_\ell), d_\ell \in C)$

$D_{i,j}^{sparse} \longleftarrow Top - k_s\ (sim_{BM25}(x_{i,j}^{QA}, d_\ell), d_\ell \in C)$

$D_{i,j} \longleftarrow D_{i,j}^{dense} \cup D_{i,j}^{sparse}$

$E_{i,j}^{QA} \longleftarrow Top - k_r\ (score_{CE}(x_{i,j}^{QA}, d_\ell), d_\ell \in D_{i,j})$

$\hat{c}_{i,j} \longleftarrow ConcatSubctx\ (E_{i,j}^{QA})$

$D_{i,j}^{QA} \longleftarrow Demo_{QA}(E_{i,j}^{QA})$

$P_{i,j}^{QA} \longleftarrow T_{QA} \parallel D_{i,j}^{QA}(\hat{s}_{i,j},\ \hat{c}_{i,j})$

$\hat{a}_{i,j} \longleftarrow M_{QA}(P_{i,j}^{QA})$

if $\hat{a}_{i,j} = \emptyset$ **then**

$\hat{a}_{i,j} \longleftarrow$ fallback answer

$Append\ \hat{a}_{i,j}\ to\ A_i$

Context Update

$c_i^{(j)} \leftarrow TopKCtx\left((c_i^{(j-1)} \cup \{\hat{c}_{i,j}\}), k_c\right) \parallel$ [previous answer: $\hat{a}_{i,j}$]

return RecursiveInfer $(q_i,\ c_i^{(j)},\ j+1,\ S_i,\ A_i)$

1) Formal initialization and core logic: Given a complex input question q_i and an initial context a_i, the inference process is initialized by setting the reasoning hop index $j \leftarrow 1$, the initial running context $c_i^{(0)} \leftarrow a_i$, and initializing empty lists for sub-questions $S_i \leftarrow []$ and intermediate sub-answers $A_i \leftarrow []$. The system then invokes the recursive function, which operates over sequential reasoning hops bounded by the maximum hop hyperparameter H. If the current hop index exceeds this limit $j > H$, the recursion terminates and triggers the final answer synthesis routine. Let $K_i = |S_i|$ denote the total number of valid hops executed. The system constructs a final fusion prompt P_i^F by combining the fixed instruction template T_F with the

aggregated chain of all generated sub-question and sub-answer pairs via the $BuildFusion$ function. The final ground answer $a_{gen,i}$ is then synthesized using the fine-tuned QA model M_{QA}.

$$a_{gen,i} \longleftarrow M_{QA}(P_i^F) \quad (4)$$

If $j \leq H$, the proposed approach systematically executes three consecutive phases within the active reasoning hop:

- Question Decomposition (QD): To isolate the next logical reasoning step, a decomposition query $x_{i,j}^{QD}$ is formulated by concatenating the original question with the context accumulated up to the previous step.

$$x_{i,j}^{QD} \longleftarrow q_i \parallel c_i^{(j-1)} \quad (5)$$

- This query is routed to the hybrid retrieval module to extract lexically and semantically relevant candidates from the unified corpus C. After cross-encoder re-ranking, the selected passages are converted into in-context demonstrations to build the final decomposition prompt $P_{i,j}^{QD}$. Finally, the fine-tuned decomposition model M_{QD} processes this prompt to output the candidate sub-question.

$$\hat{s}_{i,j} \longleftarrow M_{QD}\left(P_{i,j}^{QD}\right) \quad (6)$$

- Early Stopping Criteria: To avoid redundant computation and prevent infinite reasoning loops, an early stopping condition is evaluated. If the generated sub-question $\hat{s}_{i,j}$ is empty Ø or matches any sub-question already present in the S_i list, build the final fusion prompt P_i^F, and return the final generated answer $a_{gen,i}$. If the sub-question is valid and unique, it is appended to the S_i list.

- Evidence Retrieval and Sub-Answer Generation: Once a unique sub-question $\hat{s}_{i,j}$ is committed, it serves as the foundation for the QA query.

$$x_{i,j}^{QA} \longleftarrow \hat{s}_{i,j} \quad (7)$$

Using this query, the proposed approach executes an identical hybrid retrieval and cross-encoder re-ranking pipeline over the unified corpus C to extract the top context passages. An evidence-specific sub-context $\hat{c}_{i,j}$ is formed by concatenating these top passages.

$$(\hat{c}_{i,j} \longleftarrow ConcatSubctx\ (E_{i,j}^{QA})) \quad (8)$$

These elements are assembled into the QA prompt block $P_{i,j}^{QA}$. The fine-tuned QA model then evaluates the prompt to generate a sub-answer:

$$\hat{a}_{i,j} \longleftarrow M_{QA}\left(P_{i,j}^{QA}\right) \quad (9)$$

- Fallback Mechanism: To prevent an empty intermediate output from being propagated to subsequent reasoning steps, the generated sub-answer is evaluated immediately after generation. If the QA model produces a non-empty response, the generated response is retained as the intermediate sub-answer. If the model output is empty, the fallback mechanism is activated and the predefined fallback answer "No answer found" is assigned to the current intermediate sub-answer:

$$\hat{a}_{i,j} \longleftarrow fallbackanswer \quad (10)$$

The resulting sub-answer is then appended to the intermediate sub-answer list A_i, after which the recursive procedure proceeds to the subsequent context-update step. Thus, the fallback mechanism is triggered specifically by an empty intermediate QA output and replaces the empty output with the predefined fallback value before the reasoning process continues.

2) Context update mechanism: A key component of the recursive reasoning process is the context update mechanism, which controls how information is propagated across sequential reasoning steps while preventing the context buffer from expanding unboundedly. Let the candidate passage pool at reasoning step j be defined as the union of the previous step's context and the newly extracted sub-context passages:

$$\mathcal{P}_{i,j} = c_i^{(j-1)} \cup \{\hat{c}_{i,j}\} \quad (11)$$

Instead of monotonically accumulating all historical context, the proposed approach applies a relevance-based selection function, $TopKCtx$, formally defined as:

$$c_i^{(j)} \leftarrow TopKCtx\left(\mathcal{P}_{i,j}, k_c\right) \parallel [\text{previous answer: } \hat{a}_{i,j}]$$
$$\text{subject to} \quad \left|\text{TopKCtx}\left(\mathcal{P}_{i,j}, k_c\right)\right| = \min\left(k_c, \left|\mathcal{P}_{i,j}\right|\right) \quad (12)$$

where, k_c is a context-selection hyperparameter that determines the maximum number of top-ranked context segments retained at each reasoning step. The string literal of the current sub-answer $\hat{a}_{i,j}$ is trailing-concatenated to anchor the generation trajectory. The relevance scoring function evaluates individual candidate segments $x \in \mathcal{P}_{i,j}$ using the cosine similarity between the dense semantic representations of the active QA query $x_{i,j}^{QA}$ and each candidate text chunk:

$$\text{Score}(x) = \cos\left(\Phi\left(x_{i,j}^{QA}\right), \Phi(x)\right) = \frac{\Phi\left(x_{i,j}^{QA}\right) \cdot \Phi(x)}{\left\|\Phi\left(x_{i,j}^{QA}\right)\right\| \|\Phi(x)\|} \quad (13)$$

where, $\Phi(.)$ denotes the dense sentence embedding model utilized by the retrieval module. Thus, $TopKCtx$ filters and retains the top k_c context segments from $\mathcal{P}_{i,j}$ that are most semantically aligned with the current sub-question query $x_{i,j}^{QA}$. Following this context update, the recursive function advances the system state by recursively executing the next hop $j + 1$ with the updated context $c_i^{(j)}$. This tightly coupled design guarantees that each step remains grounded in verified evidence, bounding the context to minimize hallucination while maximizing the interpretability of the multi-hop reasoning chain.

IV. Experimental Evaluation

A. Dataset Preparation and Preprocessing

All experiments were conducted using the MAFQA dataset, which contains complex Arabic fatwa questions alongside expert-annotated intermediate reasoning chains, supporting

contexts, and reference answers. The dataset was specifically designed to support both question decomposition (QD) and question answering (QA) tasks within the proposed recursive reasoning approach. Prior to training, the dataset was processed through a comprehensive preprocessing pipeline to enhance data quality and ensure consistent textual representations. Duplicate instances with identical question text were removed to prevent data leakage and redundant supervision. Arabic text was subsequently normalized by removing diacritics and elongation characters (tatweel), unifying orthographic variants (e.g., mapping ٱ, إ, and آ to ا), standardizing character forms (such as ۀ), eliminating invisible Unicode characters, and removing extraneous whitespace or formatting artifacts. These preprocessing steps reduce lexical sparsity and improve tokenization consistency across different language models. To ensure reproducibility, the processed dataset was randomly shuffled using a fixed seed and partitioned into training, validation, and test sets following an 80/10/10 split. The training partition was used for model optimization and retrieval index construction, the validation set was employed for hyperparameter selection and early stopping, and the test set was reserved exclusively for final evaluation. Constructing all retrieval indices solely from the training split prevented information leakage during retrieval-augmented inference, ensuring a rigorous evaluation protocol.

Following preprocessing, the dataset was converted into task-specific training instances corresponding to the two learning objectives described in Section III. For the QD task, each instance maps a complex fatwa question to its structured decomposition, consisting of intermediate subquestions and their associated contexts. For the QA task, each instance pairs a question (or a generated subquestion) with its corresponding supporting context and reference answer. Source sequences were truncated to a maximum length of 512 tokens, and target sequences were limited to 256 tokens to satisfy model input constraints. Padding tokens in the target sequences were masked using the value -100 to exclude them from loss computation during supervised fine-tuning.

B. Baseline Models

To rigorously evaluate the proposed approach, a diverse set of baseline models was selected, encompassing Arabic-specialized sequence-to-sequence (seq2seq) architectures, multilingual encoder–decoder models, and instruction-tuned large language models (LLMs). This selection facilitates a systematic comparison across models with varying pretraining strategies, linguistic coverage, and reasoning capabilities, thereby providing a comprehensive assessment of the proposed recursive reasoning approach. The first category comprises Arabic seq2seq models, specifically AraBART [42], AraT5-base [43], and Arabic-T5-small [44]. These models were pretrained on large-scale Arabic corpora to capture the nuanced linguistic characteristics of the language. AraBART [42] is an Arabic adaptation of the BART architecture employing a six-layer encoder and a six-layer decoder, whereas AraT5-base [43] and Arabic-T5-small [44] belong to the T5 family and were optimized for Arabic text generation through extensive pretraining on domain-specific datasets. These architectures serve as strong language-specific baselines for evaluating both question decomposition and answer generation. The second category consists of multilingual seq2seq models, represented by mT5-small [45] and mT5-base [46]. Both models belong to the multilingual T5 (mT5) family and were pretrained on the large-scale mC4 corpus covering 101 languages. Their multilingual pretraining enables cross-lingual knowledge transfer, making them suitable baselines for assessing the necessity of language-specific pretraining in complex Arabic fatwa question answering.

To evaluate the performance of contemporary instruction-following architectures, the experiments also include GPT-4.1 [47] and GPT-3.5-turbo [48]. These instruction-tuned LLMs excel at complex reasoning and natural language generation via prompt-based interaction. Given its advanced contextual understanding, GPT-4.1 [47] provides an authoritative baseline for multi-hop question decomposition and answer generation, while GPT-3.5-turbo [48] offers a lightweight yet competitive alternative for assessing instruction-tuned models within the proposed approach.

C. Training Settings and Hyperparameters

To ensure fair and reproducible experimentation, all evaluated models were trained and evaluated under standardized experimental settings whenever applicable. Sequence-to-sequence (seq2seq) models were implemented using the Hugging Face Transformers framework, whereas GPT-based models were fine-tuned through the OpenAI fine-tuning API. Separate models were trained for the Question Decomposition (QD) and Question Answering (QA) tasks using the instruction-based supervision described in Section III. For the seq2seq models, optimization was performed using the AdamW optimizer with a learning rate of 5×10^{-5} for five epochs. Model selection was based on the lowest validation loss, and early stopping was employed to mitigate overfitting. During inference, deterministic beam search was adopted with a beam size of four, together with repetition control mechanisms to improve generation quality. The GPT-based models (GPT-4.1 and GPT-3.5-turbo) were fine-tuned using conversational JSONL datasets constructed from the training split. To ensure deterministic and reproducible generation, stochastic sampling was disabled by setting the temperature to 0.0 and top-(p) to 1.0 during inference.

The proposed recursive prompt-driven reasoning approach employed identical retrieval and inference settings across all evaluated models. Hybrid retrieval combined dense semantic retrieval using the intfloat/multilingual-e5-large embedding model with sparse BM25 retrieval, followed by reranking using the BAAI/bge-reranker-v2-m3 cross-encoder. Retrieval indices were constructed exclusively from the training partition to prevent information leakage during evaluation. Recursive reasoning was limited to a maximum of three reasoning hops, while identical retrieval parameters were adopted throughout all experiments. The principal training, decoding, and retrieval hyperparameters are summarized in Table I.

The experiments were conducted in a Google Colab environment equipped with an NVIDIA T4 GPU. The GPU was used to execute the locally deployed Hugging Face models and other local components of the framework, including dense embedding generation, retrieval, reranking, and evaluation. GPT-based models were accessed through the OpenAI API and

therefore did not require local GPU deployment. Consequently, the local computational requirements of the proposed framework are primarily associated with the retrieval and supporting processing components, while GPT-based model inference was performed remotely through the API.

TABLE I. TRAINING, INFERENCE, AND RETRIEVAL HYPERPARAMETERS USED THROUGHOUT THE EXPERIMENTS

Category	Parameter	Value
Global Settings	Random seed	42
	Training epochs	5
	Maximum reasoning hops ((H))	3
	Maximum QD generation tokens	160
	Maximum QA generation tokens	128
Seq2Seq Models	Optimizer	AdamW
	Learning rate	(5\times10^{-5})
	Weight decay	0.01
	Training/evaluation batch size	4 / 4
	Maximum source/target length	512 / 256
	Evaluation strategy	Per epoch
	Early stopping	Validation loss
	Beam size	4
	No-repeat n-gram	3

D. Evaluation Metrics

The proposed approach is evaluated from two complementary perspectives: end-to-end final answer generation and retrieval effectiveness. The evaluation protocol combines lexical, semantic, and retrieval metrics to comprehensively assess the quality of the generated final answers and the effectiveness of the hybrid retrieval module. Given the rich morphology and lexical variation of the Arabic language, the selected metrics measure not only surface-level textual similarity but also semantic alignment between the generated and reference answers.

1) Lexical and semantic similarity metrics: The quality of the generated final answers is evaluated using a combination of lexical overlap and semantic similarity metrics. Lexical overlap is calculated using BLEU and ROUGE-L. The Bilingual Evaluation Understudy (BLEU) score calculates precision based on shared n -grams, incorporating a brevity penalty (BP) to penalize unfairly compressed generations. Formally, it is computed as:

$$\text{BLEU} = BP \cdot \exp\left(\frac{1}{N}\sum_{n=1}^{N} w_n \ln p_n\right) \quad (14)$$

where, N is the maximum n-gram size (typically 4), w_n represents the baseline weight for each n-gram order, and p_n refers to the clipped precision for n-grams of order n. The brevity penalty (BP) is defined as:

$$BP = \begin{cases} 1 & \text{if } c > r \\ e^{\left(1-\frac{r}{c}\right)} & \text{if } c \le r \end{cases} \quad (15)$$

where, r is the token count of the reference text and c is the token count of the candidate output. The clipped n-gram precision (p_n) prevents score inflation from repetitive generated words and is expressed as:

$$p_n = \frac{\sum_{C\in\{\text{Candidates}\}}\sum_{\text{n-gram}\in C}\text{Count}_{\text{clip}}(\text{n-gram})}{\sum_{C'\in\{\text{Candidates}\}}\sum_{\text{n-gram}'\in C'}\text{Count}(\text{n-gram}')} \quad (16)$$

The ROUGE-L score focuses on recall, leveraging the Longest Common Subsequence (LCS) to capture the longest ordered series of tokens shared between the candidate and target sequences:

$$\text{ROUGE-L} = \frac{\text{LCS}(X,Y)}{m} \quad (17)$$

where, X represents the predicted text string, Y represents the gold reference string, and m is the total length of the reference text. To complement lexical evaluation, BERTScore is employed to compute a token-level semantic match by performing greedy cosine alignments over dense token representations within a multilingual embedding space. Let x and y denote the token embedding sequences of the predicted and reference text, respectively. Precision (BERT-P), recall (BERT-R), and F1-score (BERT-F) are computed as follows:

$$BERT - P = \frac{1}{|x|}\sum_{x_i \epsilon\, x} max_{y_j \in y}\, x_i^T y_j \quad (18)$$

$$BERT - R = \frac{1}{|y|}\sum_{y_i \epsilon\, y} max_{x_i \in x}\, x_i^T y_j \quad (19)$$

$$BERT - F = \frac{2\,(BERT-P.BERT-R)}{BERT-P + BERT-R} \quad (20)$$

where, $x_i^T y_j$ denotes the cosine similarity between token-level embeddings.

2) Relevance metric: This metric calculates the cosine similarity between the pooled sentence embeddings of the candidate answer (A_i') and the gold reference answer (A_i):

$$\text{Relevance} = \frac{1}{N}\sum_{i=1}^{N}\cos\big(E(A_i'), E(A_i)\big) \quad (21)$$

where, $\text{E}(\cdot)$ denotes the sentence embedding function and N represents the total number of evaluated QA instances. A higher relevance value indicates stronger semantic alignment with the reference answer.

3) Retrieval evaluation metrics: Because retrieval operations ground both the decomposition and answering tracks, the hybrid retrieval engine is evaluated independently using standard information retrieval performance indicators.

Recall@k measures the ratio of search operations where at least one correct target (supporting context passage or prompt demonstration) is positioned within the top-k returned elements. Let Q denote the collection of queries, R_i^k the set of top-k returned candidates for an active query i, and G_i the ground-truth target set:

$$\text{Recall@k} = \frac{1}{|Q|}\sum_{i=1}^{|Q|} 1\left(R_i^k \cap G_i \neq \emptyset\right) \quad (22)$$

where, $1(\cdot)$ represents an indicator function returning 1 if the intersection is non-empty, and 0 otherwise.

The positional quality of the ranking results is evaluated using the Mean Reciprocal Rank (MRR), which focuses on the explicit rank index (r_i) of the first true matching candidate returned for a query i:

$$\text{MRR} = \frac{1}{|Q|}\sum_{i=1}^{|Q|} \frac{1}{r_i} \quad (23)$$

If a query yields no correct matches within the ranked output pool, its reciprocal rank defaults to zero. Higher MRR indices indicate that the relevant supporting evidence passages and few-shot demonstrations are positioned earlier in the ranked retrieval list, reflecting better retrieval precision.

E. Evaluation of the Hybrid Retrieval Module

The hybrid retrieval module constitutes a fundamental component of the proposed approach, as it provides the demonstrations and supporting evidence required during both the Question Decomposition (QD) and Question Answering (QA) stages. To assess its effectiveness, the retrieval module is evaluated independently before conducting the end-to-end experiments. The proposed retrieval module combines dense semantic retrieval using the intfloat/multilingual-e5-large embedding model, sparse lexical retrieval using BM25, and cross-encoder reranking using BAAI/bge-reranker-v2-m3. Retrieval is performed recursively during inference, where the retrieval query dynamically evolves according to the current reasoning step. During the QD stage, the retrieval module returns semantically related decomposition demonstrations, whereas during the QA stage it retrieves supporting evidence passages and question–answer demonstrations for the generated sub-question. To ensure a fair evaluation, all retrieval indices are constructed exclusively from the training partition. Retrieval performance is evaluated on three complementary tasks: QD demonstration retrieval, QA demonstration retrieval, and evidence context retrieval. For each task, the proposed hybrid retrieval module is compared against two individual retrieval baselines: sparse lexical retrieval using BM25 and dense semantic retrieval using the multilingual E5-large encoder. Performance is measured using Recall@5, Recall@10, and Mean Reciprocal Rank (MRR@5). Table II summarizes the retrieval performance across the three retrieval tasks.

The experimental results demonstrate that dense semantic retrieval consistently outperforms sparse lexical retrieval across all retrieval tasks. The improvements achieved by the multilingual E5-large encoder indicate that semantic representations are substantially more effective than lexical matching for retrieving decomposition demonstrations, intermediate reasoning examples, and supporting evidence in Arabic multi-hop fatwa question answering. Across all three retrieval tasks, the proposed hybrid retrieval module achieves the best overall performance. For QD demonstration retrieval, the hybrid approach attains a Recall@5 of 0.9762 and an MRR@5 of 0.9185, outperforming both BM25 and dense retrieval alone. Similar improvements are observed for QA demonstration retrieval, where the proposed method achieves 0.9598 Recall@5 and 0.9008 MRR@5, indicating that combining semantic retrieval with lexical matching and reranking enables more accurate retrieval of semantically related reasoning demonstrations. Evidence context retrieval represents the most challenging retrieval task because relevant supporting passages often exhibit limited lexical overlap with the input query while containing implicit reasoning patterns and domain-specific religious terminology. Although dense retrieval substantially improves retrieval quality over BM25, the proposed hybrid module achieves the highest retrieval accuracy, increasing MRR@5 from 0.6757 obtained by dense retrieval alone to 0.7310 after cross-encoder reranking. This improvement demonstrates that reranking effectively refines candidate ordering by capturing deeper query–document interactions, thereby providing more contextually relevant evidence for subsequent reasoning steps.

TABLE II. RETRIEVAL PERFORMANCE COMPARISON ACROSS THE EVALUATED RETRIEVAL STRATEGIES

Retrieval Method		**Metrics**		
		Recall@5	***Recall@10***	***MRR@5***
QD Demonstration Retrieval	BM25 (sparse)	0.869	0.8929	0.7954
	E5-large (dense)	0.9405	0.9762	0.8903
	Proposed Hybrid Retrieval Module	0.9762	0.9762	0.9185
QA Demonstration Retrieval	BM25 (sparse)	0.7789	0.8191	0.681
	E5-large (dense)	0.9447	0.9648	0.8745
	Proposed Hybrid Retrieval Module	0.9598	0.9698	0.9008
Evidence Context Retrieval	BM25 (sparse)	0.5327	0.608	0.4379
	E5-large (dense)	0.8241	0.8794	0.6757
	Proposed Hybrid Retrieval Module	0.8693	0.8894	0.731

Overall, these results demonstrate that the proposed hybrid retrieval module effectively combines the complementary strengths of dense semantic retrieval, sparse lexical matching, and cross-encoder reranking. The resulting improvements in retrieval accuracy and ranking quality provide stronger contextual grounding for both question decomposition and answer generation, thereby establishing a reliable foundation for the recursive multi-hop reasoning process.

F. End-to-End Evaluation of the Proposed Method

The proposed approach is evaluated under a realistic end-to-end setting to assess its effectiveness in solving complex Arabic fatwa questions through the complete recursive reasoning process. To simulate practical deployment conditions, the initial context is dynamically retrieved using the input question rather than being directly supplied from the dataset. Consequently, the proposed approach performs recursive question decomposition, evidence retrieval, intermediate answer generation, dynamic context updating, and final answer synthesis within a unified inference process. This evaluation therefore reflects the cumulative effect of error propagation across all reasoning stages and provides a realistic assessment of the approach's robustness. To evaluate the effectiveness of task-specific fine-tuning, each model is compared against its corresponding pretrained baseline using identical retrieval settings and inference configurations. Performance is assessed using the lexical and semantic evaluation metrics introduced in Section D. The evaluated models include Arabic-specific sequence-to-sequence models, multilingual sequence-to-sequence models, and instruction-tuned GPT-based models. Table III presents the end-to-end performance of all evaluated models on the final answer generation task.

The results demonstrate that task-specific fine-tuning consistently improves end-to-end reasoning performance across nearly all evaluated architectures despite the substantially more challenging retrieved-context setting. Because the initial context, intermediate evidence, and generated sub-answers are produced recursively during inference, inaccuracies introduced at early reasoning stages may propagate to subsequent steps. Consequently, the reported performance reflects the behavior of the complete reasoning pipeline rather than isolated component performance. Among the Arabic-specific sequence-to-sequence models, AraT5-base exhibits the largest improvement after fine-tuning. Its F1 score increases from 4.84 to 16.43, while ROUGE-L improves from 4.51 to 13.75 and the relevance score rises from 75.38 to 86.60. Similarly, AraBART achieves consistent improvements across nearly all evaluation metrics, particularly in semantic similarity and contextual relevance, whereas Arabic-T5-small demonstrates substantial gains in F1, ROUGE-L, BERTScore, and relevance despite minor decreases in BLEU scores. These observations suggest that fine-tuning primarily improves semantic fidelity rather than exact lexical matching. The multilingual mT5 models remain the weakest performers under the realistic end-to-end setting. Although fine-tuning produces measurable improvements, both mT5-small and mT5-base achieve substantially lower lexical and semantic scores than the Arabic-specific models. Their comparatively lower performance may reflect the multilingual nature of these models, which distributes representational capacity across multiple languages, whereas Arabic-specific models are more specialized in modeling Arabic linguistic characteristics. This difference may be particularly important for MAFQA because of its domain-specific terminology and multi-step reasoning requirements. Differences in model capacity, pretraining data distribution, and tokenization may also contribute to the observed performance gap. Furthermore, the recursive decomposition, retrieval, and answer-generation stages may introduce accumulated noise that particularly affects the smaller multilingual models. Overall, these results indicate an advantage for the evaluated Arabic-specific models over the evaluated multilingual models on the MAFQA dataset.

TABLE III. COMPARATIVE END-TO-END PERFORMANCE OF BASELINE AND FINE-TUNED MODELS ON FINAL ANSWER GENERATION TASK

Model		Metrics								
		F1-token	***BLEU-1***	***BLEU-2***	***ROUGE-2***	***ROUGE-L***	***BERT-P***	***BERT-R***	***BERT-F***	***Relevance***
AraBART	Baseline	12.71	09.14	03.01	04.27	09.66	84.13	86.71	85.65	77.23
	Fine-tuned	15.01	10.67	05.16	04.20	12.24	88.27	86.44	87.33	86.48
Arabic-T5-small	Baseline	07.98	06.39	02.69	01.62	05.94	82.01	84.90	83.42	81.99
	Fine-tuned	11.89	05.40	02.43	02.66	09.82	88.86	85.22	86.99	84.89
AraT5-base	Baseline	04.84	00.52	00.14	0	04.51	82.28	78.01	80.07	75.38
	Fine-tuned	16.43	09.95	05.03	04.73	13.75	89.51	86.32	87.87	86.60
GPT-4.1	Baseline	20.15	15.96	09.05	07.09	15.41	88.00	88.24	88.02	89.67
	Fine-tuned	31.88	26.52	18.63	16.51	26.64	90.14	90.35	90.22	92.39
GPT-3.5 -turbo	Baseline	24.86	20.51	12.39	09.90	19.64	89.36	89.25	89.29	91.61
	Fine-tuned	25.52	20.04	12.49	10.90	20.95	89.86	88.93	89.37	90.34
mT5-base	Baseline	01.42	00.50	00.21	00.24	01.35	79.61	81.78	80.63	78.35
	Fine-tuned	02.40	01.38	00.60	00.44	02.21	76.32	81.54	78.76	78.52
mT5-small	Baseline	02.06	00.85	00.35	00.32	01.94	80.77	82.06	81.40	79.03
	Fine-tuned	03.01	01.51	00.61	00.54	02.77	78.90	82.32	80.53	79.66

The best overall performance is achieved by the GPT-based models, particularly GPT-4.1. After fine-tuning, GPT-4.1 attains the highest scores across almost all evaluation metrics, achieving an F1 score of 31.88, BLEU-1 of 26.52, ROUGE-L of 26.64, BERT-F of 90.22, and a relevance score of 92.39. These results indicate that large instruction-tuned language models benefit substantially from task-specific supervision while maintaining strong reasoning capabilities under recursive multi-hop inference. Although GPT-3.5-turbo also demonstrates competitive performance, its improvements after fine-tuning are

comparatively modest, suggesting that its pretrained model already provides relatively strong zero-shot reasoning capabilities.

Although the best F1-token (31.88) and ROUGE-L (26.64) scores remain modest in absolute terms, these values should be interpreted in light of both the difficulty of the task and the characteristics of the evaluation metrics. MAFQA consists of complex Arabic fatwa questions that require multi-step reasoning, integration of evidence distributed across supporting passages, and synthesis of a final response. Under the end-to-end setting, the system must also retrieve supporting evidence and generate intermediate sub-questions and answers, allowing errors at earlier reasoning stages to propagate to the final response. Moreover, F1-token and ROUGE-L primarily measure lexical overlap and may assign relatively low scores when generated answers express the correct information using wording that differs from the reference. This is particularly relevant to Arabic because of its morphological and lexical variability and the possibility of multiple valid answer formulations. The substantially higher BERT-F (90.22) and Relevance (92.39) scores achieved by the fine-tuned GPT-4.1 model support this interpretation, indicating stronger semantic correspondence than is reflected by lexical overlap alone.

Overall, the end-to-end evaluation confirms the effectiveness of the proposed recursive reasoning approach under realistic deployment conditions. Despite the inherent challenges posed by error propagation across decomposition, retrieval, and answer generation stages, task-specific fine-tuning consistently improves lexical accuracy, semantic similarity, and contextual relevance. Furthermore, the superior performance of GPT-4.1 demonstrates the advantages of combining instruction-based supervision, hybrid retrieval, and recursive multi-hop reasoning within a unified reasoning process for complex Arabic fatwa question answering.

G. Ablation Study

To quantify the contribution of the major components of the proposed method, an ablation study was conducted using the best-performing configuration identified in the previous section, namely the fine-tuned GPT-4.1 model. All ablation experiments were performed under the same end-to-end retrieved-context setting, using identical dataset splits, retrieval settings, inference constraints, and evaluation metrics to ensure a fair comparison. Three ablation configurations were considered. The first removes the recursive decomposition and multi-hop reasoning mechanism, allowing the model to generate the final answer directly from the original question without producing intermediate sub-questions or reasoning steps. The second replaces the proposed hybrid retrieval module with a dense semantic retriever, thereby removing sparse lexical retrieval and cross-encoder reranking. The third evaluates the pretrained GPT-4.1 model without task-specific fine-tuning, while preserving the remaining components of the proposed method. The complete proposed method, integrating recursive decomposition, hybrid retrieval, and task-specific fine-tuning, serves as the reference configuration. Table IV summarizes the quantitative results of the ablation study.

The results demonstrate that all three components contribute positively to the overall performance of the proposed method. The largest performance degradation occurs when recursive decomposition and multi-hop reasoning are removed. In this configuration, the F1 score decreases from 31.88 to 16.21, while BLEU-2 and ROUGE-L decline from 18.63 to 6.42 and from 26.64 to 13.27, respectively. Similarly, the relevance score decreases from 92.39 to 83.28. These substantial reductions indicate that explicitly decomposing complex fatwa questions into intermediate reasoning steps is the primary factor enabling accurate multi-hop reasoning. Removing the hybrid retrieval module also results in noticeable performance degradation. Replacing the hybrid retriever with dense retrieval alone reduces the F1 score to 24.36, while BLEU-2 and ROUGE-L decrease to 11.27 and 19.86, respectively. Although the reduction in BERTScore is relatively small, the decline in lexical and relevance metrics indicates that combining dense retrieval, sparse lexical matching, and cross-encoder reranking provides more accurate demonstrations and supporting evidence than dense retrieval alone. The without fine-tuning configuration similarly exhibits lower performance than the complete proposed method. The pretrained GPT-4.1 model achieves an F1 score of 20.15, which is more than eleven points lower than the fine-tuned model. Consistent reductions are also observed across BLEU, ROUGE-L, BERTScore, and Relevance, demonstrating that task-specific fine-tuning substantially improves the model's ability to perform recursive reasoning and generate contextually grounded answers for complex Arabic fatwa questions. Overall, the ablation study confirms that each component of the proposed method contributes to its effectiveness. Among them, recursive decomposition and multi-hop reasoning have the greatest impact on end-to-end performance, while hybrid retrieval and task-specific fine-tuning further enhance contextual grounding, semantic consistency, and answer quality.

TABLE IV. ABLATION STUDY RESULTS OF THE PROPOSED METHOD UNDER THE END-TO-END RETRIEVED-CONTEXT SETTING

Setting	Metrics								
	F1-token	***BLEU-1***	***BLEU-2***	***ROUGE-2***	***ROUGE-L***	***BERT-P***	***BERT-R***	***BERT-F***	***Relevance***
Without decomposition and recursive reasoning	16.21	12.37	06.42	05.74	13.27	87.65	88.13	87.61	83.28
Without hybrid retrieval	24.36	20.11	11.27	09.44	19.86	88.41	89.63	88.52	91.23
Without finetuning	20.15	15.96	09.05	07.09	15.41	88.00	88.24	88.02	89.67
Proposed method	31.88	26.52	18.63	16.51	26.64	90.14	90.35	90.22	92.39

H. Comparison with State-of-the-Art Methods

To further assess the effectiveness of the proposed method, a comparison with a diverse set of state-of-the-art (SOTA) question answering systems was conducted, representing different architectural paradigms, including multilingual instruction-tuned large language models (LLMs), Arabic-focused LLMs, retrieval-augmented generation (RAG) systems, and reasoning-based approaches. All methods were evaluated using the same MAFQA test split under identical end-to-end retrieved-context conditions to ensure a fair comparison. The instruction-tuned LLMs were evaluated in a zero-shot setting without task-specific fine-tuning, while retrieval-based approaches dynamically retrieved supporting evidence during inference. Performance was assessed using the lexical, semantic, and relevance metrics described in Section D.

The compared systems include five multilingual instruction-tuned LLMs (GPT-5 [49], Gemini-2.5 [50], DeepSeek-LLM-7B [51], Qwen-7B [52], and Mistral-7B [53]), two Arabic instruction-tuned LLMs (SILMA-9B-Instruct-v1.0 [54] and AceGPT-v2-8B [55]), a standard retrieval-augmented generation (RAG) system [56], and the reasoning-based LCW-QD [37] approach proposed by Abdelazim *et al.* [37], which combines question decomposition with long-context reasoning for Arabic multi-hop question answering. Together, these systems represent the principal directions in contemporary Arabic question answering and provide strong baselines for evaluating the effectiveness of the proposed recursive reasoning approach. Table V presents the quantitative comparison between the proposed method and the evaluated state-of-the-art Arabic QA systems.

The proposed method consistently achieves the highest performance across all lexical, semantic, and relevance metrics. Specifically, it obtains an F1-token score of 31.88, BLEU-1 of 26.52, BLEU-2 of 18.63, ROUGE-2 of 16.51, and ROUGE-L of 26.64. It also achieves the highest semantic similarity and contextual relevance, with BERT-F and Relevance scores of 90.22 and 92.39, respectively. These results demonstrate the effectiveness of integrating recursive question decomposition, hybrid retrieval, dynamic context updating, and task-specific fine-tuning within a unified multi-hop reasoning process. Among the multilingual instruction-tuned LLMs, Qwen-7B achieves the strongest overall performance, obtaining an F1-token score of 19.94, ROUGE-L of 16.53, and a Relevance score of 89.58. GPT-5, AceGPT-v2-8B, and Mistral-7B also demonstrate competitive performance, indicating that modern instruction-tuned LLMs possess strong zero-shot reasoning capabilities. Nevertheless, their performance remains substantially below that of the proposed method, suggesting that large-scale pretraining and instruction tuning alone are insufficient for effectively addressing complex multi-hop Arabic fatwa questions.

Among the Arabic-specific models, AceGPT-v2-8B achieves the strongest overall performance, whereas SILMA-9B-Instruct-v1.0 exhibits relatively weak lexical performance despite achieving the highest BLEU-1 score among the baseline systems. This observation suggests that high unigram overlap does not necessarily correspond to better semantic quality or more complete answers. The retrieval-augmented baseline (RAG) improves contextual grounding compared with conventional sequence-to-sequence models, achieving a Relevance score of 88.10. However, its lexical performance remains considerably lower than that of the proposed method, with an F1-token score of 12.95 and ROUGE-L of 9.09. These findings indicate that retrieval augmentation alone is insufficient for effectively solving complex multi-hop fatwa questions without explicit reasoning mechanisms to organize and integrate the retrieved evidence.

TABLE V. COMPARISON OF THE PROPOSED METHOD WITH STATE-OF-THE-ART ARABIC QUESTION ANSWERING SYSTEMS ON THE MAFQA DATASET

Model Category		Metrics						
		F1-token	***BLEU-1***	***BLEU-2***	***ROUGE-2***	***ROUGE-L***	***BERT-F***	***Relevance***
Multilingual Instruction-Tuned LLMs	GPT-5	18.37	14.46	03.67	04.51	12.16	87.76	90.28
	Deepseek-llm-7b	12.79	11.87	02.89	03.08	10.57	86.37	82.12
	Gemini-2.5	08.24	17.21	03.96	02.63	07.11	84.21	80.69
	Qwen-7B	19.94	16.85	09.77	07.69	16.53	87.53	89.58
	Mistral-7B	17.68	14.58	07.85	06.10	14.39	87.24	88.72
Arabic Instruction-Tuned LLMs	SILMA-9B-Instruct-v1.0	06.05	27.46	08.50	02.07	05.35	81.51	80.14
	AceGPT-v2-8B	18.01	16.45	06.28	06.18	14.28	87.82	89.55
Reasoning-based approach	LCW-QD	12.95	08.81	04.15	03.52	09.09	85.22	88.10
Retrieval-Augmented Systems (RAG)		23.36	20.59	09.53	10.23	19.18	88.22	90.26
Proposed method		31.88	26.52	18.63	16.51	26.64	90.22	92.39

Among all baseline systems, the reasoning-based LCW-QD approach achieves the strongest performance, obtaining an F1-token score of 23.36, ROUGE-L of 19.18, BERT-F of 88.22, and a Relevance score of 90.26. Compared with this strongest baseline, the proposed method improves the F1-token score from 23.36 to 31.88, corresponding to a relative improvement of approximately 36.5%. Likewise, ROUGE-L increases from 19.18 to 26.64 (approximately 38.9%), while BERT-F and Relevance improve from 88.22 to 90.22 and from 90.26 to 92.39, respectively. These improvements demonstrate that

recursive reasoning, dynamic context updating, and hybrid retrieval provide substantial benefits beyond those achieved through question decomposition and long-context reasoning alone.

Overall, the results demonstrate that while instruction-tuned language models, retrieval-augmented systems, and decomposition-based reasoning approaches provide competitive performance, the proposed method consistently achieves the strongest results across lexical, semantic, and relevance-based metrics. The findings indicate that integrating recursive reasoning with hybrid retrieval and dynamic contextual grounding enables more accurate, contextually relevant, and semantically faithful answer generation for complex multi-hop Arabic fatwa question answering.

V. Conclusion and Future Directions

This study addressed the challenge of answering complex Arabic fatwa questions, where accurate responses require integrating evidence across multiple sources. The experimental results demonstrate that explicitly modeling intermediate reasoning substantially improves answer quality compared with conventional single-step question answering approaches. By recursively decomposing complex questions, retrieving evidence at each reasoning step, and progressively refining the reasoning context, the proposed recursive prompt-driven reasoning approach improves answer quality and semantic relevance under the evaluated multi-hop Arabic fatwa question answering setting.

The experimental evaluation provides several important findings. First, combining dense semantic retrieval, sparse lexical retrieval, and cross-encoder reranking consistently produces higher-quality supporting evidence than individual retrieval strategies, highlighting the effectiveness of complementary retrieval mechanisms for knowledge-intensive Arabic question answering. Second, task-specific fine-tuning substantially improves end-to-end performance across diverse model architectures, particularly Arabic-specialized models and large language models operating under realistic inference conditions. Third, the ablation study demonstrates that the combined recursive decomposition and multi-hop reasoning process was the primary contributor to the observed performance gains, while hybrid retrieval and task-specific fine-tuning also contribute to the overall performance. Finally, comparisons with representative state-of-the-art methods confirm that the proposed method achieves superior overall performance on the MAFQA dataset across lexical, semantic, and relevance-based evaluation metrics. Beyond these performance improvements, this study demonstrates the effectiveness of integrating explicit multi-hop reasoning with retrieval-augmented language models for domain-specific Arabic question answering. The proposed approach provides an interpretable reasoning process in which intermediate reasoning steps, retrieved evidence, and generated responses remain tightly connected throughout inference, thereby improving both answer transparency and factual grounding.

Future work will focus on several directions. First, the generalizability of the proposed approach will be investigated through evaluation on additional Arabic multi-hop question answering datasets and other knowledge-intensive domains as suitable benchmarks become available. Second, the recursive control mechanism will be further examined through the evaluation of semantic stopping criteria for identifying redundant or unproductive reasoning steps beyond the current termination conditions. Third, alternative context-selection strategies, including history-aware, diversity-aware, evidence-coverage-based, and unpruned approaches, will be compared with the current context update mechanism to assess retained-evidence rates and their impact on final QA performance. Finally, future research will investigate more advanced retrieval and evidence-selection techniques, including agent-based retrieval approaches, and evaluate emerging reasoning-capable language models.

***Abstract*—Machine learning-based intrusion detection systems are often constrained by severe class imbalance, while generative augmentation may memorize distinctive network-flow records and expose membership information. This study evaluates privacy-aware augmentation for CICIDS2017 by integrating differentially private stochastic gradient descent (DP-SGD) into a conditional generative adversarial network and a variational autoencoder, yielding DP-CGAN and DP-VAE. The formal record-level privacy guarantee applies to the generative component and is tracked with an RDP accountant implemented through Opacus. Experiments use five target Benign-to-Attack augmentation ratios from one-to-one to one-to-five and five target privacy budgets of 0.5, 1, 2, 4, and 8. Random forest (RF) and XGBoost are evaluated using accuracy, Macro-F1, mean minority-class recall, and per-class recall for Bot, BruteForce, and Infiltration. Synthetic-data quality is examined through t-SNE, Wasserstein distance, mean squared error, and mean absolute error, while empirical privacy is assessed through a black-box membership-inference protocol using ROC-AUC, attack accuracy, and an accuracy-derived attack advantage. DP-CGAN preserves high downstream utility across both classifiers. DP-VAE remains competitive with random forest but degrades substantially with XGBoost, particularly for BruteForce and Infiltration. Membership-inference ROC-AUC remains close to 0.5 for both private and non-private generators under the implemented attack, indicating that no reliable membership signal was detected rather than proving the absence of leakage. These results show that private generative augmentation is feasible for imbalanced IDS learning, but its utility depends strongly on the interaction between generator architecture and downstream classifier.**

***Keywords*—Intrusion detection system; class imbalance; synthetic data generation; differential privacy; DP-SGD**

I. Introduction

Machine learning-based intrusion detection systems (IDSs) are increasingly used to protect cloud platforms, Internet of Things infrastructures, enterprise networks, and software-defined environments. Their effectiveness, however, is frequently constrained by highly skewed traffic distributions, in which benign flows dominate while security-critical attacks remain sparsely represented. Data-level augmentation based on conditional generative adversarial networks (CGANs), variational autoencoders (VAEs), and related generative architectures has therefore become an important strategy for improving minority-class detection [1–7].

The usefulness of synthetic data cannot be established from downstream accuracy alone. Recent studies emphasize that synthetic-data generation should be assessed jointly in terms of quality, distributional similarity, utility, and privacy [8–10]. Broader analyses of generative models also show that replacing real records with synthetic samples does not, by itself, eliminate the risk of exposing sensitive information [11].

A learned generator may overfit distinctive training records and preserve information that enables an adversary to infer whether a particular sample contributed to model training. Membership-inference studies against generative models have demonstrated leakage under black-box and white-box access, reconstruction-based evidence, and density-based overfitting detection [12–16]. This risk is especially relevant to rare network-flow records because their scarcity and distinctiveness make them important for detection while potentially increasing their susceptibility to disclosure.

Differential privacy (DP) provides a formal mechanism for bounding the influence of an individual training record. Private synthetic-data approaches include Bayesian-network synthesis, teacher-ensemble methods, differentially private adversarial training, and privacy-preserving distributed generation [17–21]. In deep generative models, DP is commonly implemented through DP-SGD [22], with cumulative privacy loss tracked through Rényi differential privacy accounting [23] and software frameworks such as Opacus [24]. Formal privacy accounting nevertheless addresses a different question from empirical disclosure testing; broader attack-based frameworks therefore recommend reporting both forms of evidence [25].

Despite these advances, three gaps remain relevant to intrusion detection. First, most IDS augmentation studies prioritize predictive utility without formal privacy accounting. Second, privacy-preserving synthetic-data methods are

*Corresponding author.

commonly evaluated on general tabular datasets rather than highly imbalanced, multi-class network-flow data. Third, limited evidence is available on the joint effects of generator architecture, privacy budget, augmentation level, rare-class utility, and downstream classifier. These limitations make it difficult to identify a defensible privacy-utility operating point for IDS augmentation.

This study addresses these gaps through a domain-specific empirical evaluation on CICIDS2017 [26]. Rather than introducing a new generic private generator, established DP-SGD-based CGAN and VAE architectures are adapted for class-conditional network-flow augmentation. The evaluation spans five target Benign-to-Attack ratios and five privacy budgets and jointly considers downstream utility, rare-attack detection, optimization behavior, synthetic-data fidelity, and empirical membership leakage.

The main contributions of this study are summarized as follows:

1) Privacy-aware adaptation with explicit accounting. DP-SGD-based CGAN and VAE training is adapted for class-conditional augmentation on CICIDS2017. DP-CGAN privatizes the discriminator, whereas DP-VAE privatizes the complete encoder-decoder model. For each target budget, the achieved (ε, δ)-DP guarantee, noise multiplier, clipping norm, sample rate, and number of private optimization steps are reported.

2) Systematic evaluation of privacy-aware augmentation. A comparative study of conventional, non-private generative, and differentially private augmentation methods across various class-balance settings and privacy budgets. Their impact is evaluated using multiple downstream classifiers, with particular attention to overall detection performance and the recognition of minority attack classes.

3) Comprehensive analysis of the privacy-utility trade-off. Optimization behavior, synthetic-data fidelity, and empirical privacy leakage are examined within a unified evaluation framework. This analysis clarifies how generator architecture, privacy strength, augmentation level, and downstream classifier jointly influence the effectiveness of privacy-preserving intrusion detection.

The remainder of this study is organized as follows. Section II reviews related work on imbalanced IDS augmentation, private synthetic data, and privacy attacks against generators. Section III describes the threat model, privacy objectives, and DP-SGD implementation. Section IV presents the experimental protocol, exact tabular results, visual analyses, and a discussion of the privacy-utility-fidelity trade-off. Section V concludes the study and outlines future research directions.

II. Related Work

Class imbalance is a persistent limitation of machine learning-based IDSs because abundant benign traffic can dominate model optimization while rare attacks contribute only a small number of training examples. Conventional remedies include random oversampling, undersampling, cost-sensitive learning, and SMOTE. Although SMOTE is straightforward to integrate with standard classifiers, its samples are restricted to local interpolation and may not capture heterogeneous or multimodal attack distributions.

Deep generative models provide a more flexible alternative. Zhao et al. used CGAN-based class-conditional synthesis for imbalanced intrusion detection [1], whereas Lopez-Martin et al. developed a variational generative model for network-traffic augmentation [2]. An earlier study compared SMOTE, CGAN, and VAE across multiple augmentation ratios, demonstrating that their utility depends on both the generator and the downstream classifier [3]. More recent work has extended this direction through fully synthetic IDS training, feature-regularized GANs, and conditional encoder-decoder GAN architectures [4–6]. Surveys confirm the increasing use of GAN-based synthesis in IDS, while also highlighting training instability, data fidelity, and generalization as continuing challenges [7].

Synthetic-data evaluation increasingly adopts a multidimensional perspective. Dang and Hoang examined GAN-based synthesis through the complementary criteria of quality, similarity, and privacy [8]. Adams et al. likewise showed that fidelity, utility, and privacy may move in different directions across synthetic-data generators [9]. A recent systematic review further identified substantial variation in how privacy is implemented and measured for tabular synthetic data [10], while broader generative-AI research continues to document memorization and disclosure concerns [11].

Formal privacy can be incorporated into synthetic-data generation through several mechanisms. PrivBayes learns privatized Bayesian dependencies [17], PATE-GAN transfers information through noisy teacher aggregation [18], and DP-CGAN applies differential privacy to conditional adversarial training [19]. Related studies have examined model-inversion resistance [20] and distributed private generation [21]. These methods establish the feasibility of private synthesis, but their behavior on high-dimensional and highly imbalanced network-flow data remains insufficiently characterized. Moreover, DP-SGD, RDP accounting, and practical implementations such as Opacus introduce design choices whose effect on low-frequency attack classes requires domain-specific evaluation [22–24].

Synthetic records should not be assumed to be private merely because they are not exact copies of the source data. LOGAN demonstrated membership inference against GANs [12], while Monte Carlo and reconstruction-based attacks used generated samples or reconstruction quality to distinguish members from non-members [13]. GAN-Leaks subsequently organized such threats according to adversarial access and auxiliary knowledge [14]. DOMIAS showed that density-based overfitting detection can be particularly effective against uncommon records [15], a finding that is directly relevant to rare attack flows. Recent VAE-GAN research has also evaluated synthetic-data generation as a defense against membership inference while preserving downstream utility [16].

Membership inference captures only one dimension of disclosure risk. Giomi et al. proposed a broader attack-based framework covering singling out, linkability, and inference [25]. These studies motivate the combined use of formal privacy guarantees and empirical attacks: the privacy budget provides a

worst-case protection statement, whereas attack results characterize the evidence available to a specified adversary under an implemented protocol.

Table I summarizes the separation among IDS-oriented augmentation, general synthetic-data evaluation, formal private synthesis, and empirical privacy attacks. Recent IDS studies offer increasingly sophisticated augmentation mechanisms, but they generally do not provide formal privacy accounting. Conversely, private synthesis and privacy-risk studies are commonly evaluated on general tabular datasets without examining rare network-attack classes or the interaction with downstream IDS classifiers.

The present study connects these research directions in a common experimental pipeline. Its novelty is empirical and domain-specific: established DP-SGD-based CGAN and VAE architectures are adapted to imbalanced network-flow augmentation and assessed using formal privacy budgets, downstream utility, rare-class recall, synthetic-data fidelity, and black-box membership inference. The resulting analysis focuses on when private augmentation remains useful and how that outcome depends on the generator, privacy strength, augmentation ratio, and classifier.

TABLE I. COMPARISON OF REPRESENTATIVE WORK ON IMBALANCED IDS AUGMENTATION, PRIVATE SYNTHESIS, AND GENERATIVE-MODEL PRIVACY

Study	Scope and Method	IDS Imbalance	Formal DP	Privacy Evaluation
Zhao et al. [1]	CGAN-based IDS augmentation	Yes	No	Utility-focused; no formal privacy or attack evaluation.
Lopez-Martin et al. [2]	VAE-based generation for IDS	Yes	No	Evaluates detection utility; privacy leakage is not studied.
Nhan et al. [3]	SMOTE, CGAN, and VAE on CICIDS2017	Yes	No	Compares imbalance settings but does not include DP or privacy attacks.
Rahman et al. [4]; Li et al. [5]; Yang et al. [6]	Recent GAN-based augmentation for NIDS	Yes	No	Improves minority-class learning, but remains primarily utility-focused.
Dang and Hoang [8]; Adams et al. [9]; Hyrup et al. [10]	Quality, fidelity, utility, and privacy evaluation	No	Mixed	Supports multidimensional evaluation; not tailored to rare classes.
PrivBayes [17]	Bayesian-network tabular synthesis	No	Yes	Formal privacy for general tabular data; not tailored to rare IDS classes.
PATE-GAN [18]; DP-CGAN [19]	Differentially private adversarial synthesis	No	Yes	Private generation is established, but evidence for highly imbalanced multi-class IDS remains limited.
LOGAN, Monte Carlo, GAN-Leaks, DOMIAS [12-15]	Membership inference against generators	No	No	Provides attack methodologies, including risks to uncommon records.
Yan et al. [16]	VAE-GAN synthesis evaluated against MIA	No	No	Joint utility and empirical privacy evaluation outside the IDS domain.
Giomi et al. [25]	Unified synthetic-data privacy-risk framework	No	Method-agnostic	Covers multiple disclosure risks but does not evaluate rare-class IDS utility.

III. METHODOLOGY

This study develops a privacy-aware generative augmentation methodology for addressing class imbalance in machine-learning-based intrusion detection systems. Previous studies have demonstrated that SMOTE, conditional generative adversarial networks (CGANs), and variational autoencoders (VAEs) can improve the representation and detection of minority attack classes, although their effectiveness depends on the generator, imbalance severity, and downstream classifier [1–7]. Building on these findings, the present study incorporates DP into conditional generative training and evaluates whether the resulting synthetic data remain useful for intrusion detection while limiting the influence of individual training records.

The overall research workflow is illustrated in Fig. 1. The framework begins with an imbalanced network-flow dataset, which is cleaned and transformed using a fixed, data-independent preprocessing procedure. The preprocessed data are then divided into stratified training, validation, and test partitions before any augmentation is performed. This ordering ensures that no information from the validation or test partitions is used to generate synthetic records or balance the training data.

The training partition is processed under six data configurations: the original unaugmented setting, SMOTE, CGAN, VAE, DP-CGAN, and DP-VAE. SMOTE provides a conventional interpolation-based oversampling baseline, whereas CGAN and VAE represent non-private generative baselines. Their privacy-preserving counterparts incorporate DP-SGD during model training. In DP-CGAN, private optimization is applied to the discriminator, which directly accesses real training records. In DP-VAE, the complete encoder-decoder model is trained using DP-SGD. Per-sample gradient clipping and Gaussian noise injection are implemented through Opacus, while an RDP accountant tracks the cumulative privacy loss and reports the achieved (ε, δ)-differential privacy guarantee for each private model.

The original and augmented training datasets are subsequently used to train random forest and XGBoost classifiers. All configurations are evaluated on the same untouched real test set. The assessment covers aggregate utility (accuracy and Macro-F1), minority-sensitive utility (mean and per-class recall), synthetic-data fidelity (Wasserstein distance, mean squared error, mean absolute error, and t-SNE), and privacy protection (formal (ε, δ)-DP accounting and empirical membership inference).

The selected feature space is treated as fixed before private model training. A data-independent transformation is applied to prepare numerical network-flow features for the generative models without estimating normalization statistics from the private training records. After augmentation, random forest and XGBoost classifiers are trained on the resulting datasets and evaluated using classification utility, minority-class detection, synthetic-data quality, and empirical privacy-risk measures. The methodology therefore considers privacy and utility as interconnected evaluation dimensions rather than independent objectives.

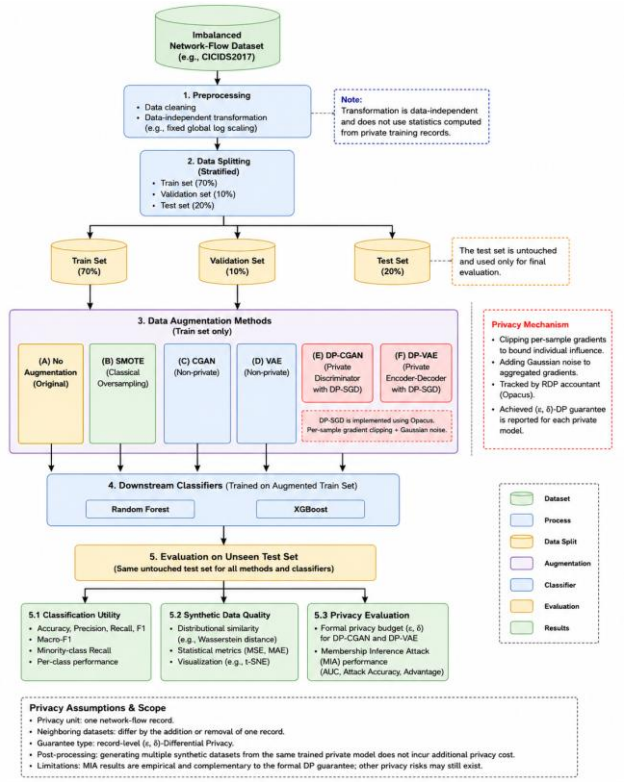

Fig. 1. Overall workflow of the proposed privacy-aware generative augmentation framework for imbalanced intrusion detection.

A. Attacker Knowledge and Access

Membership inference attacks against generative models aim to determine whether a candidate record contributed to the training data of a generator or its released synthetic dataset. Prior studies have demonstrated that membership information may be inferred using discriminator outputs, reconstruction behavior, generated samples, or distance-based evidence under different black-box and white-box access conditions [12–16].

The present study considers a black-box synthetic-data release setting. The adversary can access the synthetic records generated by the trained model and is assumed to know the feature representation, class-label space, preprocessing procedure, general generator architecture, and declared privacy parameters. This follows a conservative security assumption in which the protection of the source data does not depend on concealing the model architecture or training procedure.

The attacker does not have direct access to the original private training partition, record-level gradients, optimizer states, model-update history, or other internal training information. Candidate attack-flow records may be compared with the released synthetic data to estimate whether they were members of the generator's training partition.

The protected unit in this study is one network-flow record. Accordingly, the formal guarantee is interpreted as record-level differential privacy under an add-or-remove-one neighboring relation. It does not automatically provide user-level, host-level, session-level, or organization-level protection because a single entity may contribute multiple correlated network flows.

Membership inference is used as an empirical complement to formal privacy accounting. An attack result close to random guessing indicates that the implemented adversary was unable to reliably distinguish members from non-members under the evaluated protocol. However, such a result does not prove the absence of leakage under stronger, adaptive, or alternative privacy attacks. Synthetic-data privacy may also involve singling-out, linkability, reconstruction, or attribute-inference risks [25]. The formal privacy budget therefore remains the primary protection statement, whereas the attack results provide additional empirical evidence.

B. Privacy and Utility Objectives

The methodology is designed around two competing objectives: protecting individual training records and preserving the usefulness of the generated data for intrusion detection.

The privacy objective is to limit the effect that the inclusion or exclusion of one attack-flow record can have on a trained private generator. Differential privacy provides a formal mechanism for expressing this protection through the parameters ϵ and δ. A smaller value of ϵ represents a stronger privacy constraint, although stronger constraints generally require greater perturbation during model training. Previous private synthetic-data approaches [17–21], including PrivBayes, PATE-GAN, and DP-CGAN, demonstrate that explicit privacy guarantees can be incorporated into data generation, but they also reveal a trade-off between privacy strength and data utility.

The utility objective is to preserve the information required by downstream IDS classifiers. Because aggregate accuracy can conceal failures on rare attacks, the evaluation emphasizes Macro-F1, mean minority-class recall, and class-specific recall for Bot, BruteForce, and Infiltration, together with accuracy across augmentation ratios.

Synthetic-data quality is evaluated through complementary qualitative and quantitative evidence. t-SNE is used only as a visualization of local class structure, while Wasserstein distance, mean squared error, and mean absolute error quantify global discrepancies between real and synthetic samples. These metrics are interpreted together with downstream utility because low global distance does not necessarily preserve class-conditional decision boundaries.

The methodology therefore does not assume a single monotonic privacy-utility relationship. Instead, it evaluates how generator architecture, target privacy budget, Benign-to-Attack augmentation ratio, and downstream classifier jointly determine the operating point.

C. Differentially Private Stochastic Gradient Descent

Differentially private stochastic gradient descent is the main privacy-preserving optimization mechanism used in this study. DP-SGD extends conventional stochastic gradient descent by bounding the contribution of each training record and injecting calibrated Gaussian noise into the model-update process [22].

For each private update, gradients are computed separately for individual training examples. Their norms are clipped to a predefined maximum value so that no single flow record can exert an arbitrarily large influence on the update. Gaussian noise is then added to the aggregated clipped gradients before the optimizer modifies the model parameters. Repeating this procedure across the training process limits the distinguishability between models trained on neighboring datasets.

The revised implementation uses Opacus to perform per-sample gradient computation, gradient clipping, noise injection, private data sampling, and privacy accounting [24]. An RDP accountant tracks the cumulative privacy loss and converts it to an achieved (ε, δ)-DP guarantee [23]. This is important because clipping an already aggregated batch gradient does not provide the same record-level sensitivity control as standard DP-SGD. DP-SGD is applied only to DP-CGAN and DP-VAE. The conventional CGAN and VAE are trained without privacy perturbation and serve as non-private generative baselines. This separation enables the effect of differential privacy to be distinguished from differences caused by generator architecture alone.

IV. Experimental Evaluation

A. Experimental Setup

The CICIDS2017 dataset [26] was divided into training, validation, and test subsets, with test and validation proportions of 0.2 and 0.1, respectively. Privacy-aware generators were evaluated under $\varepsilon \in \{0.5, 1, 2, 4, 8\}$ with $\delta = 10^{-5}$ [3]. CGAN and VAE used a latent dimension of 16 and were trained for 40 epochs with a nominal batch size of 256. For DP-CGAN, DP-SGD was applied to the discriminator; for DP-VAE, it was applied to the complete encoder-decoder model. The clipping norm was fixed at 1.0, δ was set to 10^{-5}, and privacy loss was tracked with the Opacus RDP accountant.

Table II shows that the achieved privacy budgets closely match the corresponding targets for both private architectures. As ε increases from 0.5 to 8, the required noise multiplier decreases from 10.0000 to 1.0968, while δ, the clipping norm, sample rate, number of epochs, and number of private optimization steps remain fixed. The table therefore provides explicit, reproducible privacy accounting and confirms that the formal record-level guarantee is attached to the component that directly accesses private training records.

Fig. 2 complements the formal settings in Table II by showing how the two architectures respond to the calibrated clipping and noise. The non-private CGAN exhibits the oscillatory behavior expected from adversarial optimization, whereas the non-private VAE converges more smoothly. DP-CGAN remains trainable at all evaluated budgets, although its generator and discriminator losses continue to fluctuate. DP-VAE is more sensitive: at the strongest privacy settings, its reconstruction and KL terms change only marginally, while more visible latent-space learning emerges at $\varepsilon = 4$ and $\varepsilon = 8$. These trajectories demonstrate that the same formal privacy budget can affect adversarial and variational training differently; however, they are interpreted only as optimization evidence and not as a substitute for downstream utility.

TABLE II. Differential-Privacy Configurations used for DP-CGAN and DP-VAE

Model	Target ε	Achieved ε	Noise multiplier	Private component
DP-CGAN	0.5	0.4991	10.0000	Discriminator
DP-CGAN	1	0.9957	5.3516	Discriminator
DP-CGAN	2	1.9922	2.9297	Discriminator
DP-CGAN	4	3.9983	1.6992	Discriminator
DP-CGAN	8	7.9950	1.0968	Discriminator
DP-VAE	0.5	0.4991	10.0000	Encoder-decoder
DP-VAE	1	0.9957	5.3516	Encoder-decoder
DP-VAE	2	1.9922	2.9297	Encoder-decoder
DP-VAE	4	3.9983	1.6992	Encoder-decoder
DP-VAE	8	7.9950	1.0968	Encoder-decoder

Target and achieved ε values are reported separately. Common settings were $\delta = 10^{-5}$, clipping norm = 1.0, accountant sample rate = 0.0417, 40 epochs, and 960 private optimization steps. The formal guarantee applies to the private generative component under the add-or-remove-one record relation.

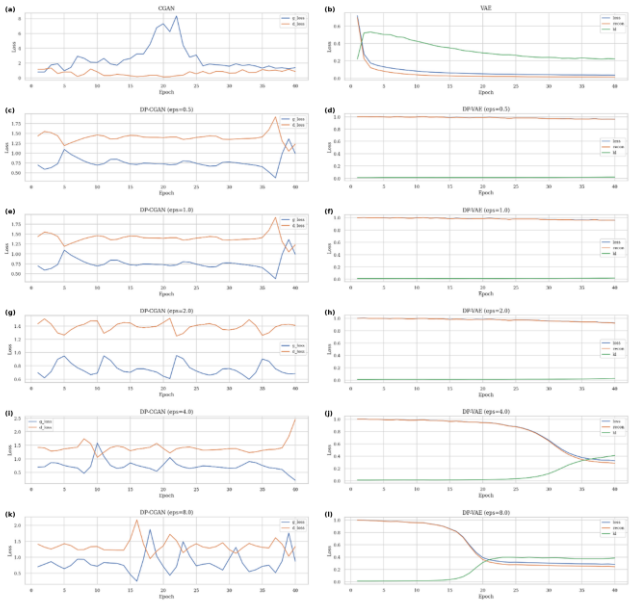

Fig. 2. Training-loss curves of CGAN, VAE, DP-CGAN, and DP-VAE. Panels (a)–(b) show the non-private models, whereas the remaining panels show target $\varepsilon \in \{0.5, 1, 2, 4, 8\}$.

B. Optimization Behavior and Synthetic-Data Structure

Fig. 3 provides a qualitative view of the local class structure produced by the augmentation methods. SMOTE most closely

follows the local neighborhoods of the original samples, CGAN produces denser class-conditioned regions, and VAE introduces a smoother representation. The private variants preserve recognizable local patterns but display greater class mixing, with DP-VAE showing the strongest smoothing. Because t-SNE is a local, low-dimensional projection, these plots are not treated as proof of global distributional fidelity.

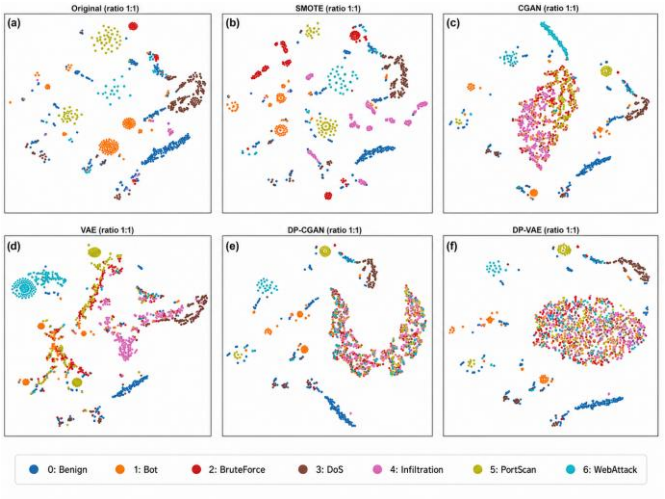

Fig. 3. t-SNE visualization of the original, SMOTE, CGAN, VAE, DP-CGAN, and DP-VAE class distributions at the Benign: Attack ratio of 1:1.

Fig. 4 shows that augmentation ratio and privacy budget have only a small effect on random forest accuracy [Fig. 4(a)] but a clearer effect on XGBoost [Fig. 4(b)]. With random forest, both private generators remain within the narrow range 0.9922–0.9927 across all ratios and budgets. With XGBoost, DP-CGAN ranges from 0.9847 to 0.9920, whereas DP-VAE ranges from 0.9756 to 0.9897 and generally weakens as the Benign-to-Attack ratio moves toward 1:5. The contrast between the two heatmaps demonstrates that accuracy alone is highly saturated and may obscure architecture-specific degradation; consequently, Tables III and IV and Fig. 5 and Fig. 6 provide the more informative minority-sensitive evidence.

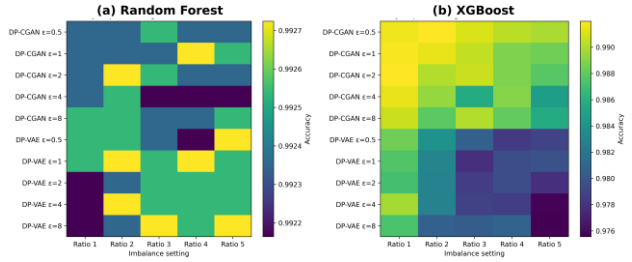

Fig. 4. Accuracy of DP-CGAN and DP-VAE across target Benign-to-Attack augmentation ratios from 1:1 to 1:5: (a) Random forest; (b) XGBoost.

Tables III and IV provide the exact Macro-F1 and mean minority-recall values, while Fig. 5 and Fig. 6 visualize the same trends across achieved privacy budgets. DP-CGAN is stable across both classifiers: Macro-F1 ranges from 0.9736 to 0.9809 with random forest and from 0.9694 to 0.9768 with XGBoost. DP-VAE remains competitive with random forest (0.9736–0.9793) but degrades markedly with XGBoost (0.7822–0.8066). The classifier interaction is even stronger for mean minority recall: DP-CGAN and DP-VAE with random forest, and DP-CGAN with XGBoost, remain near 0.949, whereas DP-VAE with XGBoost ranges only from 0.4787 to 0.5218. The tables and figures therefore support the second contribution by demonstrating a systematic comparison across privacy budgets and downstream classifiers, while also showing that the effect of ε is not monotonic and is less influential than the generator–classifier pairing within the evaluated range.

Tables V–VII and Fig. 7 refine the aggregate results by reporting recall separately for Bot, BruteForce, and Infiltration under the strongest evaluated augmentation setting, Benign: Attack = 1:5. Table V establishes the non-private reference for SMOTE, CGAN, and VAE, while Tables VI and VII isolate the effect of privacy budget for DP-CGAN and DP-VAE. The paired heatmaps in Fig. 7 make the classifier-dependent class failures visually explicit.

TABLE III. MACRO-F1 OF DP-CGAN AND DP-VAE ACROSS PRIVACY BUDGETS, AVERAGED OVER THE FIVE AUGMENTATION RATIOS

Target ε	**DP-CGAN**		**DP-VAE**	
	Random forest	***XGBoost***	***Random forest***	***XGBoost***
0.5	**0.9809**	0.9757	0.9774	0.8042
1	**0.9792**	0.9768	0.9757	0.7873
2	**0.9792**	0.9747	0.9736	0.8066
4	0.9753	0.9694	**0.9774**	0.8004
8	0.9736	0.9752	**0.9793**	0.7822

TABLE IV. MEAN MINORITY-CLASS RECALL OF DP-CGAN AND DP-VAE ACROSS PRIVACY BUDGETS, AVERAGED OVER THE FIVE AUGMENTATION RATIOS

Target ε	**DP-CGAN**		**DP-VAE**	
	Random forest	***XGBoost***	***Random forest***	***XGBoost***
0.5	0.9492	0.9495	**0.9497**	0.5086
1	0.9493	0.9490	**0.9498**	0.4799
2	0.9492	**0.9498**	**0.9498**	0.5218
4	0.9490	0.9488	**0.9495**	0.5096
8	0.9493	0.9486	**0.9498**	0.4787

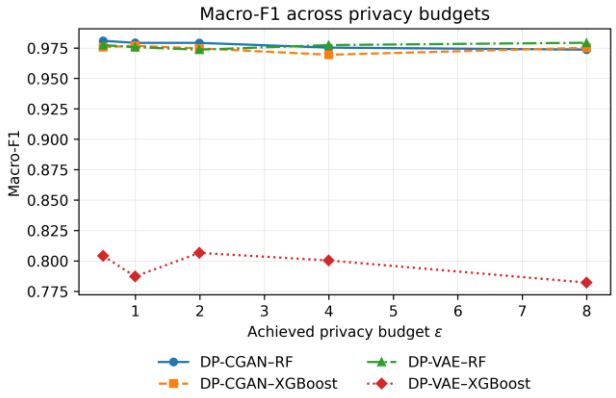

Fig. 5. Macro-F1 across achieved privacy budgets, averaged over the five augmentation ratios.

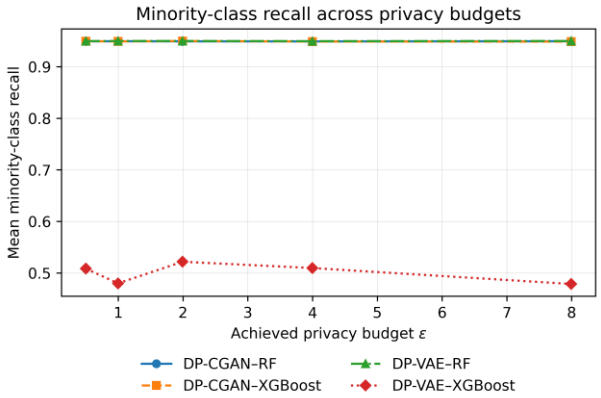

Fig. 6. Mean minority-class recall across achieved privacy budgets, averaged over the five augmentation ratios.

The exact values in Tables V–VII are consistent with the visual patterns in Fig. 7. Random forest is highly stable across all private configurations: Bot recall is approximately 0.99, BruteForce recall is 1.00, and Infiltration recall is 0.8571. DP-CGAN also preserves these classes with XGBoost, including BruteForce recall of 1.00 and Infiltration recall of 0.8571 at every evaluated budget. DP-VAE behaves differently. With random forest, it retains the same strong recalls, but with XGBoost, its Bot recall falls to 0.9517–0.9669, BruteForce recall remains at 0.1579, and Infiltration recall is 0.0. This class-level evidence explains the low DP-VAE–XGBoost Macro-F1 and minority recall, confirms that aggregate accuracy can conceal complete failure on a security-critical class, and strengthens the second contribution by demonstrating the importance of class-specific evaluation.

The privacy and fidelity evidence is reported separately because the two dimensions answer different questions. Table VIII and Fig. 8 evaluate whether the implemented black-box adversary can distinguish training members from non-members, whereas Table IX evaluates global agreement between real and synthetic data.

TABLE V. RARE-ATTACK RECALL OF NON-PRIVATE AUGMENTATION METHODS AT BENIGN: ATTACK = 1:5

TABLE VIII. EMPIRICAL MEMBERSHIP-INFERENCE RESULTS ACROSS PRIVACY BUDGETS, AVERAGED OVER THE FIVE AUGMENTATION RATIOS

Target ε	DP-CGAN			DP-VAE		
	ROC-AUC mean ± SD	*Accuracy*	*A_acc*	*ROC-AUC mean ± SD*	*Accuracy*	*A_acc*
0.5	0.5137 ± 0.0012	0.5085	0.0169	**0.5021 ± 0.0075**	**0.5033**	**0.0140**
1	0.5141 ± 0.0026	0.5109	0.0217	**0.4975 ± 0.0069**	**0.5011**	**0.0097**
2	0.5018 ± 0.0008	0.5009	**0.0017**	**0.4986 ± 0.0052**	**0.5001**	0.0088
4	0.4866 ± 0.0005	0.4891	0.0219	**0.5034 ± 0.0072**	**0.5009**	**0.0067**
8	0.4934 ± 0.0009	**0.4993**	**0.0024**	**0.4993 ± 0.0090**	0.4989	0.0117

A_acc = |2 × attack accuracy − 1|. Values close to ROC-AUC = 0.5, accuracy = 0.5, and A_acc = 0 indicate chance-level discrimination. SD is computed across augmentation ratios.

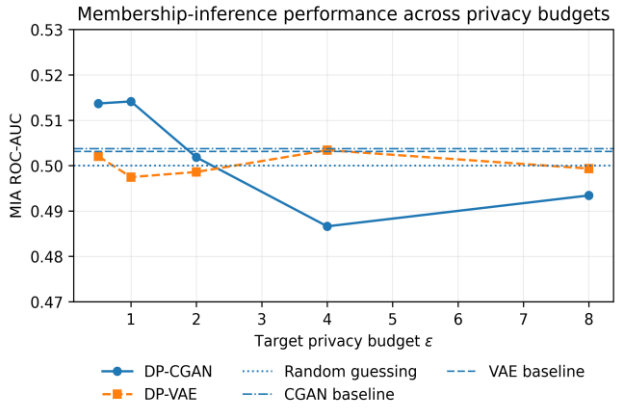

Fig. 8. Membership-inference ROC-AUC across target privacy budgets. The dotted line denotes random guessing; horizontal references denote the non-private CGAN and VAE baselines.

TABLE IX. SYNTHETIC-DATA FIDELITY ACROSS PRIVACY BUDGETS, AVERAGED OVER THE FIVE AUGMENTATION RATIOS

Target ε	DP-CGAN			DP-VAE		
	Wasserstein	*MSE*	*MAE*	*Wasserstein*	*MSE*	*MAE*
0.5	0.0572	0.0075	0.0586	**0.0439**	**0.0037**	**0.0475**
1	**0.0282**	0.0038	**0.0301**	0.0377	**0.0028**	0.0414
2	0.1098	0.0195	0.1104	**0.0322**	**0.0021**	**0.0361**
4	0.0575	0.0072	0.0583	**0.0275**	**0.0016**	**0.0314**
8	0.0318	0.0020	0.0330	**0.0236**	**0.0012**	**0.0276**

Table VIII provides the exact ROC-AUC, attack accuracy, and accuracy-derived advantage values, and Fig. 8 shows their behavior relative to random guessing and the non-private CGAN and VAE references. MIA ROC-AUC remains close to 0.5: DP-CGAN ranges from 0.4866 to 0.5141 and DP-VAE from 0.4975 to 0.5034. Attack accuracy is also near 0.5, with small advantages. However, the non-private references are themselves close to chance level. The defensible conclusion is therefore that the implemented attack did not detect a reliable membership signal in either private or non-private generators. These results provide empirical evidence under the stated threat model, but they do not establish that DP caused the low attack performance.

Table IX shows that synthetic-data fidelity does not follow the same pattern as downstream utility. DP-VAE generally obtains lower global distance and error as ε increases, reaching Wasserstein = 0.0236, MSE = 0.0012, and MAE = 0.0276 at ε = 8. DP-CGAN is non-monotonic, with particularly high discrepancy at ε = 2. Nevertheless, DP-VAE–XGBoost remains weak even when the global fidelity metrics are favorable. The mismatch between Table IX and the class-level results in Tables VI and VII indicates that Wasserstein distance, MSE, and MAE do not fully represent class-conditional separability or the decision boundaries required by the downstream classifier.

V. CONCLUSION AND FUTURE WORK

This study evaluated whether differentially private generative augmentation can address class imbalance in intrusion detection while providing a formal record-level privacy guarantee for the generative component. DP-SGD was integrated into CGAN and VAE training and evaluated on CICIDS2017 across five target Benign-to-Attack augmentation ratios, five privacy budgets, and two downstream classifiers. The revised evaluation combines exact utility tables, class-specific rare-attack recall, optimization curves, t-SNE visualization, quantitative fidelity metrics, and empirical membership-inference results.

The results show that DP-CGAN is the most robust private augmentation configuration across classifier choices. It preserves high Macro-F1 and stable recall for Bot, BruteForce, and Infiltration with both random forest and XGBoost. DP-VAE remains competitive with random forest but degrades substantially with XGBoost, including near-complete failure on BruteForce and Infiltration. This finding demonstrates that the downstream classifier can either tolerate or expose weaknesses in private synthetic data. Global fidelity metrics provide useful complementary evidence but do not fully predict class-conditional utility. Membership-inference ROC-AUC remains near random guessing for both private and non-private generators under the implemented protocol; therefore, the attack results indicate an absence of detected membership signal, not proof that differential privacy alone caused the empirical resistance.

Several limitations remain. The study uses one benchmark dataset, one random-split protocol, a single black-box membership attack, and utility summaries that do not yet include repeated generator-training confidence intervals. The evaluation also lacks a complete real-only, synthetic-only, and real-plus-synthetic ablation, which is needed to quantify the marginal contribution of the generated records and to explain why random forest remains strong when DP-VAE optimization is weak. Future work should therefore include session- or time-disjoint validation, additional IDS datasets, stronger and calibrated privacy attacks with a positive control, per-class fidelity and nearest-neighbor disclosure measures, repeated generator seeds, and ablations over the amount of synthetic data. These extensions would provide stronger evidence for deployment-oriented privacy-utility operating points.

***Abstract*—Electrical Submersible Pumps (ESPs) are critical components of oil well production that can be evaluated for their longevity through daily performance predictions. Traditional predictive methodologies have failed to handle the complexity of dynamic multi-well systems, creating a demand for automated Machine Learning (ML) pipelines based on operational data. In this study, we develop a multivariate time series ESP dataset based on factors impacting the total oil production of four wells (A1-A4) in the Jay field, Malaysia. A naive baseline pipeline used a 95%/5% chronological train-test split across pure regression models and a multivariate Prophet setup. However, due to the presence of data leakage, flat-trend autocorrelation, and the inability to process mechanical well shut-ins, the result of such an approach was unsatisfactory, producing extremely poor R^2 scores. In order to combat poor results and to find a more optimal solution, we have created a synchronized-lag multivariate pipeline evaluated across a 5-Fold Walk-Forward Cross-Validation framework. Noise has been eliminated by cutting leading zeros from the dataset pre-production, while stationarity has been provided through first-order differencing of target values for tracking daily changes (Δ y). To ensure temporal synchronization, a strict one-day chronological lag protocol has been used across all sixteen operational engineering features, splitting them up into a historical baseline (t-1) and an operational delta change feature (t-2 to t-1). The resulting input has allowed us to turn pure regression models into time series models forced to predict changes in targets based on purely historical pump parameters. Results show that non-linear ensemble models perform significantly better than Prophet under rolling validation. The Light Gradient Boosting Machine (LGBM) proved to be the champion model, achieving a statistically significant R^2 score of 0.31. Feature importance analysis showed that the operational adjustments of localized wells (specifically associated Gas_A2_delta and lag_oil_1) drive downstream fluid changes the most. Against the platform capacity of 9,500 barrels per day, LGBM's MAE translates to only 4.1% daily variation forecast.**

Keywords*—Oil production prediction; Electrical Submersible Pump (ESP); machine learning; forecasting

I. Introduction

Artificial Lift (AL) is an essential method of combating low production difficulties that most operators of marginal and mature fields are subjected to most of the time. Since its emergence, AL technology has greatly enhanced the rate of production, and it has optimized costs by coming up with innovative solutions. One of the most popular and common forms of AL is the Electrical Submersible Pump (ESP), which is employed to increase the production rate of a low-pressure well. ESPs are essential in the oil and gas industry as a tool for improving oil production in reservoirs. ESPs are also part of the efficient functioning of an oil production well since they are very important in aiding in lifting and transportation of the well production to the surface. Nevertheless, the performance and design of an ESP are highly dependent on factors that do not apply in one well to another, such as the fluid properties, flow conditions, and well completion design [1]. They should be given due consideration during the design of ESP installations to ensure that the ESP system is well adapted to the special conditions of the well. The ESP systems have several important parts, as they are a downhole pump, motor, seal section, and power cable. These components are important in designing and structuring their performance in an ESP.

To maximize and achieve maximum efficiency, the ESP system needs to be customized and tailored to the conditions of the well. This can possibly be in terms of modifications in materials or coating on parts, design modifications in the pumping mechanism, and modifications in the operating parameters of the mechanism. The majority of unplanned Operating Expenditure (OPEX) increments are the result of equipment failures that contribute to production downtime, which results in the state of deferred oil production and will mean a lot of financial implications to the operators [2]. The operators have begun to focus on optimizing production as well as keeping the critical equipment in good condition. This is a big challenge if production reduces following a few years of production plateau, whereby the operators should contemplate the ideal kind of AL, bearing in mind that the properties of the well vary over time.

Sarvestani and Hadipour considered the different AL techniques to mature oilfields and that the data-driven analysis should be provided to optimise the equipment operation and prevent premature failure without investing in the physical changes or workovers [3]. Much of the research has been

*Corresponding author.

carried out in order to enhance production in unconventional fields that use AL. Zalavadia et al. provided optimization of the artificial lift timing and selection (ALTS) through a hybrid data-driven and physics-based workflow and optimal pump unit selection and speed to get the desired production rate [4]. According to Harryanto and Yersaiyn, it is frequently a challenge in calculating which well producers will need AL in the short and medium term, and this depends upon dynamic modelling studies [5]. Nevertheless, the wells will automatically fall out of natural flow, and predicting production with the aid of numerical modelling is challenging because of the constraints in the characterization and the representation of the reservoir heterogeneity.

Although ALS and ESPs are widely used in the production of oil, the existing predictive mechanisms for production optimization are still difficult to adapt and inefficient. Conventional production forecasting tools like Decline Curve Analysis (DCA) [6], reservoir simulation [7], and analytical modeling tools [8] involve a large amount of manual work and have inherent assumptions that lack sufficient expression regarding the dynamics of well conditions. Not only can the combination of Machine Learning (ML) and ESP operations data serve as a strong alternative due to its ability to provide real-time flexibility and flexible capabilities to capture nonlinear, complex relationships in the dynamics of oil wells, but it can also contribute to the significant improvement of the effectiveness of oil well production in marginal fields [9, 10]. Using enhanced ML and analytics, the operators have the chance to enhance the characterization of a reservoir, anticipate failures, as well as enhance the performance of pumps and optimize schedules [11]. Another way in which the integration of ML with numerical modelling can help provide accurate information on which wells will need AL later is through the incorporation of the technology into numerical modelling [12]. This method has the potential to optimize production strategies and reduce operational risks of reservoir heterogeneity.

This study proposes the application of ML to explore the ESP performance and oil well behaviors. The objective of the research is to forecast the future production of oil wells based on the actual performance of the well and the available ESP operation data. The data used in the analysis are obtained from an available offshore facility in Jay in a time series format. Time series is a characteristic of the data, which is essential in comprehending the changing nature of oil production and performance over the years [13, 14]. Wells in this Jay field are also ESP-equipped and are in operation. Two types of ML models, 1) Time series forecasting and 2) Regression models, are explored in terms of performance on the obtained ESP dataset of the Jay field. These models are compared to the prediction results to determine the performance of the most effective method to predict oil production on the dataset. The study also offers in-depth insights into the performance of ESPs in oil wells during oil production and the reasons behind their effectiveness and reliability.

The rest of this study is structured in the following way. Section II of this study briefly discusses the existing ML strategies to forecast the oil production performance. Section III offers the methodology of predicting oil production using an ESP time series dataset. The experimental results and discussions are given in Section IV with the detailed comparative analysis of different types of ML models that were applied in this study. Lastly, in Section V, the conclusion and future work are given.

II. Literature Review

Here, different traditional and ML methods of oil production forecasting have been reviewed.

A. Traditional Techniques of Oil Production Forecasting

1) Decline Curve Analysis (DCA) is a conventional oil and gas well production prediction technique. It approximates historical data to a model such as exponential, hyperbolic, or harmonic decline, which assumes that the output decreases with time [6]. Nevertheless, it presupposes constant decline rates, which frequently cannot capture real effects. It proves to have little success in unconventional reservoirs with non-linear and complex behaviors, such as those found in shales. Furthermore, DCA ignores changing dynamics of reservoirs and changes in operations with time that may make long-term forecasts inaccurate.

2) Reservoir simulation is a model that is used to develop a detailed production forecast of the underground fluid movement with the use of geological, fluid, and operational data. It requires high computing capabilities, skills, and precise input information. Nevertheless, its shortcomings consist of requiring a lot of resources and expertise, geological information, which is usually uncertain, and it is time-consuming and expensive to develop and execute the models [7].

3) Analytical models: simplify the behaviour of reservoirs with equations solvable to predict quick reserves and production. They are based on assumptions such as constant flow, in which accuracy is restricted in complicated situations. The major drawbacks are simplification of actual dynamics and inability to adapt to complex production patterns [8].

Besides the above method-specific constraints, there are some more general constraints with the traditional ways of producing forecasts, which may affect the reliability of the forecasts. These consist of bad quality and access to data, especially at early well stages; changing reservoir and well behaviors such as water breakthrough or formation damage; unpredictable human factors such as decisions of operators, and poor calibration of the models to past data [15].

B. ML-Based Oil Production Forecasting

Given the inefficiency of the conventional approach to predicting the future of the oil industry, operators are dedicating themselves to the implementation of newer technologies based on ML to attain the targeted results [16]. ML is finding use in a range of predictive maintenance and monitoring tasks in the oil and gas industry. Recent studies have also explored AI-driven approaches for evaluating carbon capture, utilization, and storage (CCUS) potential in Kazakhstan's oil fields [17] as well as developing advanced predictive correlations for wax precipitation behavior in crude oil [18]. These studies highlight the growing adoption of

intelligent data-driven techniques for improving operational efficiency and sustainability in the sector. This includes process monitoring and fault diagnosis of mooring lines in subsea oil exploration [19], corrosion detection and life expectancy prediction in oil and gas pipelines [20, 21], efficient pressure zone detection [22], and drilling operations [23], and so on. ML technologies could reveal some sophisticated trends in massive data as well as evolve with evolving reservoir and operational conditions. These techniques are more effective in non-linear and high-dimensional data compared to traditional ones, and so they are more likely to be more accurate in changing environments [24].

ML-based Artificial Neural Networks (ANNs) have been employed to optimize various aspects of oil and gas operations. Study [25] demonstrated that ANN models can accurately predict offshore pipeline conditions using historical inspection data, enabling more effective inspection and maintenance planning. E. Khamehchi *et al.* developed an ANN model to estimate key gas lift parameters, including production rates and pressures, using field data, providing a data-driven alternative to traditional empirical correlations that often require difficult-to-obtain inputs [26]. Similarly, another study applied ANNs to predict the remaining life of flexible risers by integrating degradation, operational, and advanced inspection data [27]. However, these approaches do not specifically address oil production forecasting using time-series modeling.

Hosseini and Akilan [14] researched the application of deep learning (DL) and high-performance computing in the oil industry. The study focuses on the oil and gas sector, but specifically on the use of intelligent assistive tools (IATs) in production forecasting. The study under consideration deals with oil production prediction and predictive methods via Convolutional Neural Networks (CNN) and Long Short-Term Memory (LSTM) as accurate, generalizable DL models based on time-series data of the Volve oil field. An autoregressive model and an LSTM are also used by Singh and Pateriya [28] to predict future oil production through an ESP time series dataset. Although these DL methods are very accurate with large and rich datasets, they need large amounts of computational resources. Moreover, these DL models are not very interpretable and thus not suitable for marginal fields with limited data and greater operational variability.

Saghir et al. used streaming time-series analytics to track and measure the performance of progressive cavity pumps (PCPs) in 448 coal seam gas wells [13]. The researchers employed clustering methods to automatically identify the operational states of the pumps and anomalies such as gas locking, solids formation, and torque problems. The strategy assisted engineers in finding out the problems in pumps in real time so that failures can be prevented at the early stages. Although effective in identifying the onset of pump problems, the model fails to anticipate failures before the occurrence of symptoms, it only shows them when abnormal behavior has already been initiated. Also, the clustering task is based on the expert labeling of domains, which is not scalable or automatable. The model is also field-specific (PCPs in coal seam gas wells), and thus, it is not generalized to other types of lift or environments. Even though the research employs a time series analytics technique in the management of natural gas wells, it identifies abnormal performance of the AL systems in real-time, but not the forecasting of oil production of the oil.

Devshali et al. experimented with several models and discovered that an LSTM autoencoder was most effective in identifying anomalies that resulted in failures [29]. Their findings indicated that the model would give as much as 60 days of early warning so that the operators can plan proactive maintenance and minimize downtime. The dataset was also quite limited, with 47 failure events, which is not very large to use with DL. Model performance metrics such as false alarms or prediction confidence were also not very transparent. The experiment is exclusively on the detection of failure and built-in real-time optimization of operations. Also, the LSTM is a black box, which provides no or minimal explainability and information on why it fails.

Agwu et al. apply neural networks in predicting the oil flow rates in ESPs. The model proved to be highly accurate, memory consuming low and could be expressed in an explicit mathematical expression [30]. It was much better than traditional empirical correlations and could be used to estimate ESP rates in real-time situations, as well as in the field. The model was trained and tested on 275 data points gathered in the Middle East ESP-lifted wells and therefore cannot be accurately generalized to other fields or operating conditions. It is also specialized in steady-state behavior, that is, it might not be effective in transient flow regimes or in dynamic processes such as the start-up or shutdown of pumps. Moreover, it fails to take into consideration operational risks such as future failures and thus is more of a performance estimator than a diagnostic or a predictive instrument. The experiment is not developed as a time series.

Although current research has investigated the application of ML techniques to production forecasting, most of the current methods are based on a set of deterministic models with minimal flexibility in modeling intricate and non-linear production processes. There is still a big gap in the capability to come up with a powerful ML-driven system that is not only capable of predicting oil production but also prevents the occurrence of signs of ESP performance degradation beforehand. The reservoir data and patterns can be investigated with the help of ML algorithms over large volumes to enhance the accuracy of reservoir characterization. Using ML in numerical modelling, it could result in an increase in forecasting capabilities and more accurate information on the understanding of which wells will need AL in the future.

The study fills this gap by developing a full ESP data set to be used in oil production prediction via ML and by applying various ML models (time-series prediction and regression models) methodically to compare them in terms of predictive accuracy and reliability. The novelty of this work is the strategy to combine ML techniques with adaptability based on real time, the increased accuracy of predicting the production trend, and the possibility to introduce historical data on the processes of organizational work to plan proactive maintenance. In this study, the proposed research hypothesis is that a data-driven prediction framework will enable more precise and timely insights regarding the optimization of

production, which will result in a decrease in the number of unplanned downtime and the optimization of resource allocation, as well as an increase in the ESP operating time.

III. METHODOLOGY

This study is executed in three stages, as shown in Fig. 1. The stages are described in the subsequent sections.

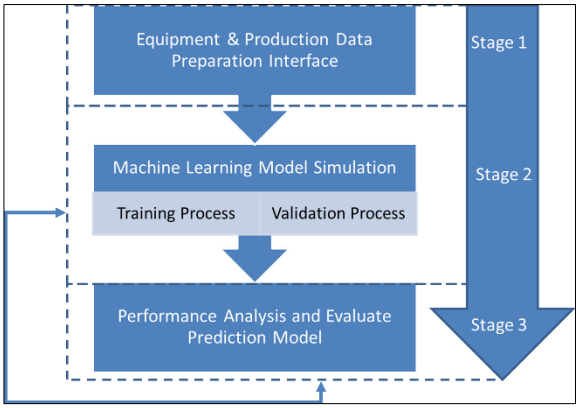

Fig. 1. Research methodology for oil production forecasting using ML models.

A. Equipment & Production Data Preparation

This research utilizes real operations data from the Jay field in offshore Peninsular Malaysia. Specific parameters are identified before acquiring the field data. The field data contains daily production data from four oil-producing wells (A1-A4) starting from 8 January 2020 to 26 October 2022. Fig. 2 shows the total field production data.

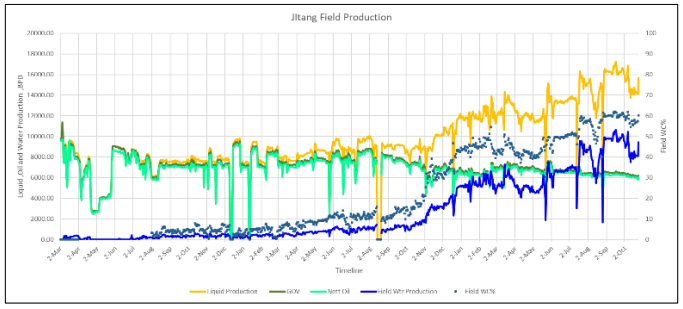

Fig. 2. Jay field production data from Jan 2020 to Oct 2022.

The chart presented in Fig. 2 offers an in-depth analysis of various production parameters over time, which is essential for gaining insight into the oil field's operational performance. The x-axis indicates a timeline from Q1 2020 to Q3 2022, while the two y-axes are used for different parameters. The left y-axis is used to show the production parameters in barrels per day (BPD), while the right y-axis is used for water cut percentage (WC%).

The Liquid Production, represented by the yellow line, refers to the total volume of liquids produced, combining both oil and water production. This line is observed to be at a higher level compared to other statistics, implying a significant level of fluid production throughout the period. The GOV, or Gross Oil Volume, represented by the green line, refers to the overall rate of oil production without factoring in the content of water within the oil, whereas the Net Oil, represented by the aqua line, refers to net oil production after removing impurities or water content from oil. Field Water Production, represented by the dark blue line, refers to the water produced during oil production, showing a steady increase throughout the period, emphasizing its importance as a byproduct of oil production. The chart includes several key production metrics.

One of the most informative aspects of the chart is the "Field WC%" line, which is shown by a dashed black line on the y-axis located on the right side of the chart. "Field WC%" stands for the percentage of water within the total production mix. This line gives insight into the fluid mixture that is being produced from the wells. Particularly, the "Field WC%" line rises over time, especially in the latter period of the chart. This rise indicates that the mixture of oil and water is increasing over time, which could be a sign that the oil well is becoming old or that water is encroaching on the oil wells.

1) Dataset overview: To develop the required time series dataset, the numeric values for the input feature variables (Full Tubing Head Pressure (FTHP), ESP speed, Gas factor, and Water factor for the four wells (A1, A2, A3, and A4)), and the target output total oil production, Nett_oil, are retrieved from the daily production report. The input feature variables are defined as follows:

a) Full Tubing Head Pressure (FTHP): Full Tubing Head Pressure, as the name suggests, refers to the pressure at the top of the production tubing within a well. This is an important parameter when measuring the performance of a well, as it shows how much pressure is being exerted by fluids within the well. Full Tubing Head Pressure is affected by a number of factors, including fluid density, temperature, and fluid flow. When it comes to oil production prediction, Full Tubing Head Pressure is used as an indication of how well a well is doing, and it is an important parameter when trying to calculate oil flow rates and how pressure within a reservoir may change.

b) Electrical Submersible Pump (ESP) speed: This refers to the speed of the Electrical Submersible Pump, which is utilized to pump fluids from oil wells, especially in low-pressure environments. ESP speed is crucial in determining the flow rate of the oil and water being pumped out of the oil well. By varying the ESP speed, the flow rate of the oil and water can be optimized. In oil production prediction, ESP speed is essential in determining the number of hydrocarbons that can be pumped out of the oil well.

c) Gas factor: Gas factor, which is normally given in standard cubic feet of gas per barrel of liquid produced (scf/bbl), refers to the volume of gas present in the oil. Gas factor is one of the important parameters used to understand the interaction of gas and liquid in the oil field. Gas factor also helps in the oil recovery process. This is because if the volume of gas increases, it may indicate a variation in the pressure of the oil field. Gas factor also helps in the estimation of the total production capacity of the oil well.

d) Water factor: Water factor is defined as the volume of water produced per barrel of oil (bbl/bbl), and it is a vital

parameter for evaluating the efficiency of oil recovery processes. Water factor provides a means of gaining insight into the water-to-oil ratio, which can be a vital parameter for evaluating the health of the oil reservoir and the efficiency of enhanced oil recovery processes. An increase in the water factor may indicate problems such as water encroachment and inefficient oil recovery. In oil production prediction, the water factor provides a means of evaluating the efficiency of oil production wells and making decisions regarding the management of water production.

A summary of the features used in this research is provided in Table I.

TABLE I. ESP DATA FOR OIL PRODUCTION PREDICTION USING ML MODELS

S.#	Variable	Category	Description	Unit
1	Nett_oil	Target	Total net oil production from all the wells	Barrels of oil per day (bopd)
2	ESP_A1	Feature	Pump speed for Well A1	Hertz (Hz)
3	FTHP_A1		Full Tubing Head Pressure for Well A1	Pounds per square inch (psi)
4	ESP_A2		Pump speed for Well A2	Hertz (Hz)
5	FTHP_A2		Full Tubing Head Pressure for Well A2	Pounds per square inch (psi)
6	ESP_A3		Pump speed for Well A3	Hertz (Hz)
7	FTHP_A3		Full Tubing Head Pressure for Well A3	Pounds per square inch (psi)
8	ESP_A4		Pump speed for Well A4	Hertz (Hz)
9	FTHP_A4		Full Tubing Head Pressure for Well A4	Pounds per square inch (psi)
10	Gas_A1		Gas produced by well A1	Million standard cubic feet per day (MMscf/d)
11	Water_A1		Water produced by well A1	Barrels of water per day (bwpd)
12	Gas_A2		Gas produced by well A2	Million standard cubic feet per day (MMscf/d)
13	Water_A2		Water produced by well A2	Barrels of water per day (bwpd)
14	Gas_A3		Gas produced by well A3	Million standard cubic feet per day (MMscf/d)
15	Water_A3		Water produced by well A3	Barrels of water per day (bwpd)
16	Gas_A4		Gas produced by well A4	Million standard cubic feet per day (MMscf/d)
17	Water_A4		Water produced by well A4	Barrels of water per day (bwpd)

The developed time series dataset with 1,023 records and 17 columns is depicted in Fig. 3 via a dataset snapshot. As shown in Fig. 3, the chronological nature of the dataset, based on the defined column for dates, provides a means of evaluating the impact of operations and environmental factors on the production output over the period of interest, thereby creating a holistic approach for forecasting the production dynamics in the future. The remaining 16 columns are related to the different parameters for the four wells: A1-A4, as defined in Table I.

Date	Nett_Oil	ESP_A1	FTHP_A1	ESP_A2	FTHP_A2	ESP_A3	FTHP_A3	ESP_A4	FTHP_A4
2020-01-08	0	0	0	0	0.0	0	0.0	0	0.0
2020-01-09	0	35	808	35	847.0	35	795.0	35	866.0
2020-01-10	0	35	766	35	820.0	35	913.0	35	866.0
2020-01-11	0	35	934	35	753.0	35	910.0	35	866.0
2020-01-12	0	35	910	35	758.0	35	901.0	35	867.0
...	...	...	...	...	...	...	...	...	...
2022-10-22	6035	46	665	44	707.0	44	651.0	44	691.0
2022-10-23	6000	46	669	44	702.0	44	650.0	44	691.0
2022-10-24	5914	46	670	44	709.0	44	652.0	44	689.0
2022-10-25	5812	46	668	44	707.0	44	651.0	44	687.0
2022-10-26	6077	48	699	44	709.0	45	669.0	44	687.0

Fig. 3. Formulated ESP time series dataset snapshot.

It is also important to note from Fig. 3 that the initial data points for the oil production target variable 'Nett_Oil' are observed to have zero or near-zero values. This could mean that the initial period of operation was perhaps the start of operations or perhaps a period of downtime. As we move along the dates, especially in 2022, it is clear that there is a marked increase in these production values. The 'ESP' and 'FTHP' columns also show variations that could be related to the operations or perhaps the productivity of the wells or variations in the pumping and tubing equipment. These are critical for diagnostic purposes to determine whether the ESPs were running efficiently or perhaps facing pressure-related problems.

B. Application of ML Models for Oil Production Prediction

Two categories of ML models are applied to predict total oil production: time series forecasting and regression models. The details of these ML categories are as follows:

1) Time series forecasting: This is performed by utilizing the Prophet model [31], where the model has been optimized for forecasting, interpretability, and simplicity, allowing it to handle outlier and missing data challenges robustly. The time series is decomposed by Prophet into three components: Trend, which shows directional changes in production over time; Seasonality, which shows periodic changes in production; and Noise, which shows random variations not explained by trends or seasonality. This decomposition provides a rich understanding of production, which could be used for forecasting. The uncertainty level of Prophet forecasts is set at 0.95, allowing for possible future trend changes and providing a range of predictions. ESP speed, FTHP, gas, and water production are used as features, and oil production, or Nett_oil, is used as the target variable. Prophet has been optimized for its ability to work with complex time series data with seasonal components, making it suitable for use in a dynamic environment like oil production.

2) Regression models: In addition to time series forecasting, six regression models are applied to the dataset to predict Nett_oil as a numeric target. The regression models include Linear Regression [24], Bayesian Linear Regression

[24], Neural Network Regression [32], Decision Tree Regression [33], Boosted Decision Forest Regression [34], and Light Gradient Boosted Machine (LGBM) [35]. Unlike the time series approach, these models do not incorporate the date as an input feature but instead treat the prediction problem as a regression task with the other operational features as predictors. Each regression model is trained using the hold-out method, where 95% of the data (972 records) is used for training and 5% (51 records) for testing. This methodology ensures that the models were evaluated based on their ability to generalize to unseen data. Table II depicts the description and the hyperparameters configuration for the mentioned regression models.

TABLE II. ML REGRESSION MODELS HYPERPARAMETERS CONFIGURATION

S.#	ML Model	Description	Hyperparameters Configuration
1	Linear Regression [24]	Assumes a linear relationship between the independent input/ feature variables and the dependent output/target variable	Single parameter, learning rate 0.1, number of epochs 10, L2 regularization weight 0.001
2	Bayesian Linear Regression [24]	Uses linear regression supplemented by additional information in the form of a prior probability distribution. Prior information about the parameters is combined with a likelihood function to generate estimates for the parameters.	Regularization weight: 1
3	Neural Network Regression [32]	Uses adaptive weights and can approximate non-linear functions of the input features for output predictions.	Single parameter, fully connected, 100 hidden nodes, learning rate 0.005, number of epochs 100, momentum 0, normalizer min-max normalizer
4	Decision Forest Regression [33]	An ensemble of decision trees where each tree outputs a Gaussian distribution as a prediction. An aggregation is performed over the ensemble of trees to find a Gaussian distribution closest to the combined distribution for all trees.	Single parameter, Resampling method Bagging, Number of decision trees 8, Maximum depth of the trees 32, Number of random splits per node 128, Minimum number of samples per leaf node 1.
5	Boosted Decision Tree Regression [34]	An ensemble of regression trees using boosting. Boosting means that each tree is dependent on prior trees. Learns by fitting the residuals of the trees that preceded it.	Single parameter, maximum number of leaves per tree 20, minimum number of samples per leaf node 10, learning rate 0.2, total number of trees constructed 100
6	Light Gradient Boosting Machine (LGBM) [35]	An ensemble of regression trees using boosting based on the histogram-based learning technique, allowing the trees to grow using a leaf-wise strategy instead of the level-wise strategy. Reduces training time and resource usage.	Number of leaves 31, maximum depth 1, learning rate 0.1, total number of trees constructed 100

3) ML Model evaluation and benchmarking: To assess the performance of the ML models, several evaluation metrics were employed: Root Mean Squared Error (RMSE), Mean Absolute Error (MAE), and Coefficient of Determination (R^2) as described in (1)-(3) respectively.

$$RMSE = \sqrt{\sum_{i=1}^{N} \frac{(Predicted_i - Actual_i)^2}{N}} \quad (1)$$

$$MAE = \sum_{i=1}^{N} \frac{|Actual_i - Predicted_i|}{N} \quad (2)$$

$$R^2 = \frac{\sum_i (Actual_i - Predicted_i)^2}{\sum_i (Actual_i - Meanof\,Actual_i)^2} \quad (3)$$

The value of RMSE helps to estimate the magnitude of the difference between predicted values and real ones, where bigger differences are punished more, thanks to squared differences. The smaller the RMSE, the better the fit. MAE helps to evaluate the average error between the predicted and actual values in an easy-to-understand way, where all differences are treated equally irrespective of the size of the error. This metric is helpful to estimate the accuracy of the prediction. Lastly, R^2 helps to evaluate the share of variance of the target variable (oil production) that can be explained by the model, and values close to one mean that the model explains much of the data. These metrics were calculated for each model to understand the relative efficiency of the models.

All ML models were developed and tested with the help of the Python programming environment Google Colab [36]. The analysis of the metrics of models helped to compare different models and to optimize the training strategy accordingly, as depicted via a feedback loop in Fig. 1.

IV. RESULTS AND DISCUSSION

The results for training all the ML models on the ESP oil production dataset are presented in Table III, with best values highlighted in bold.

TABLE III. TOTAL OIL PRODUCTION PREDICTION RESULTS FROM VARIOUS ML MODELS

S.#	ML Model	Category	RMSE	MAE	R^2
1	Linear Regression [24]	Regression	1893.58	1889.7	-227.36
2	Bayesian Linear Regression [24]		809.02	686.92	-40.68
3	Neural Network Regression [32]		720.44	650.87	-32.05
4	**Decision Forest Regression [33]**		**260.30**	**217.67**	**-3.31**
5	Boosted Decision Tree Regression [34]		773.06	535.72	-37.06
6	Light Gradient Boosting Machine (LGBM) [35]		382.33	279.25	-8.31
7	**Prophet [31]**	**Time Series Forecasting**	**259.09**	**212.47**	**-3.27**

Table III depicts that the multivariate configuration of the Prophet time-series forecasting model originally appeared to perform the best, yielding the lowest absolute error values (RMSE = 259.09, MAE = 212.47) and a top baseline R^2 value of -3.27. Within the pure ML regression category, the Decision

Forest model emerged as the second-best architecture, followed closely by LGBM with an RMSE of 382.33, an MAE of 279.25, and an R^2 of -8.31. Conversely, the plain gradient boosting method utilized in the standard Boosted Decision Tree model scored the worst among the ensemble techniques, proving that standard boosting routines were unviable compared to the bagging and light gradient boosting mechanisms utilized in the Decision Forest and LGBM models. Additionally, the linear frameworks (Linear and Bayesian Linear Regression) performed the worst overall, with R^2 values of -227.36 and -40.68, and RMSE values of 1893.58 and 686.92, respectively. This statistical collapse confirms that linear models lack the representational capacity required to capture the complex, non-linear boundaries governing fluid dynamics and multi-well decline curves.

In particular, the structural issue resided in the way that the baseline was executed. All models (1-6) were implemented purely as cross-sectional regression algorithms, which were fed solely with static feature vectors and the target variable, devoid of any time series-related metrics, therefore making them completely blind to time series patterns in the data. The only model that considered the nature of the problem was the Prophet model. Moreover, all the baseline configurations yielded negative R^2 values, showing a common overfitting constraint of using a standalone validation window. Running models on one 51-day segment (5% test data), being the absolute end of the timeline, hid this structural issue behind deceptively low baseline absolute errors, but made the fit statistically non-viable when encountering any variance.

To reduce variance and create a statistically solid basis for forecasts, a stationary and synchronized in-time pipeline was developed in a 5-Fold Walk-Forward Cross-Validation setting for the top three models (Prophet, Decision Tree, and LGBM). First, data noise was removed by safely cutting off the flat production records before the beginning of oil production, thus bringing the starting point of the timeline to the day of first oil production. Second, the target was transformed into first-order differences, and the model predicted Δy.

To bridge the gap identified in the baseline phase, the pure regression architectures (Decision Forest and LGBM) were fully converted into time-series-aware models. A strict one-day chronological lag protocol was applied globally across all sixteen input feature columns. Every engineering metric was split into a historical performance baseline (day t-1) and an operational delta column tracking mechanical changes (between day t-2 and day t-1). This structured input space forced the tree models to forecast tomorrow's volume adjustments using exclusively known, historical pump parameters and rolling target lags (lag_oil_1). Following model execution, the predicted change vectors were dynamically added back to the historical baseline (y_{t-1}) to calculate final error minimization performance metrics directly on a raw barrel scale as shown in Table IV.

Table IV shows that the synchronized lag alignment allowed the LGBM to firmly cement its lead, securing a positive, valid R^2 score of 0.308, closely followed by the Decision Forest architecture at 0.291. This performance shift highlights that tree-based gradient boosters and parallel ensemble arrays excel at utilizing differenced engineering deltas to resolve sharp day-to-day fluid variations once they are armed with true sequential historical features. While this rigorous cross-validation naturally raised LGBM's absolute MAE to 391.52 barrels, it successfully corrected the model's structural bias, effectively trading a fragile, localized baseline for a robust, mathematically sound, and generalized forecasting framework.

TABLE IV. TOTAL OIL PRODUCTION PREDICTION RESULTS FROM THE TOP PERFORMING ML MODELS UNDER OPTIMIZED TIMELINE CONFIGURATIONS

S.#	ML Model	RMSE	MAE	R^2
1	Decision Forest Regression [33]	679.50	378.71	0.29
2	LGBM [35]	671.14	391.52	0.30
3	Prophet [31]	1929.73	1505.40	-4.40

Concurrently, the performance of the Prophet architecture significantly declined under the cross-validation framework, with its error envelope widening to an MAE of 1505.41 barrels and an R^2 of -4.401. Because Prophet treats external regressors as static linear additive components to its core trend line, its collapse under a rolling validation loop exposes a fundamental flaw in how its equations process physical asset data over time, where relationships between line pressures (FTHP), pump speeds (ESP), and net oil volumes continuously evolve. When forced to evaluate on the newly engineered historical lags and delta changes across expanding rolling horizons, Prophet's linear coefficients became highly unstable and failed to generalize to the subsequent test folds. Furthermore, as an additive curve-fitting tool built on continuous Fourier series, Prophet cannot process the sudden mechanical zero-production records caused by operational well shut-ins, resulting in massive overpredictions when production abruptly resumes.

Lastly, across all models, the absolute regression metrics (RMSE and MAE) appear high because the target net oil production values (Nett_Oil) fluctuate up to 10,000 bopd while input features operate in mere tens. However, LGBM's final MAE translates to a relative daily forecasting variation of only 4.1% against a platform capacity exceeding 9,500 barrels, proving it is highly effective and reliable for navigating unpredictable operational shutdowns.

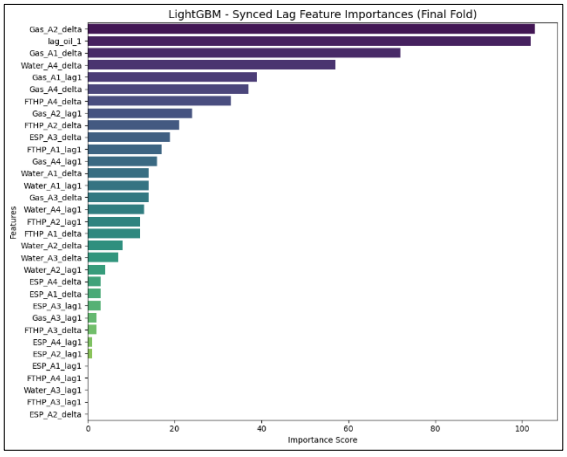

Fig. 4. Feature importance for total oil production using LGBM.

Feature importance diagnostics from the final fold of the champion LGBM model, as depicted in Fig. 4, confirm that the pipeline successfully forced the algorithm to learn from reservoir physics and mechanical transformations. The model assigned its highest predictive weights to Gas_A2_delta (103) and the historical target lag (lag_oil_1) (102), proving that tracking localized directional changes in associated gas rates and immediate production history is crucial for capturing fluid swings. Furthermore, the strong emergence of operational change parameters like Gas_A1_delta (72), Water_A4_delta (57), and FTHP_A4_delta (33) demonstrates that LGBM effectively maps physical disruptions, such as valve manipulations and pressure shifts, directly to downstream oil production fluctuations.

V. Conclusion and Future Work

The purpose of the current research is to expand the use of ML models to increase the accuracy and effectiveness of daily oil production predictions. ML can greatly aid in overcoming numerous limitations that emerge during the application of conventional approaches for prediction and optimization of oil production processes. In this research, an optimized, synchronized-lag multivariate pipeline was engineered to predict daily oil production using real-time ESP data from four active wells (A1-A4). By implementing target differencing to track daily changes and safely trimming pre-production zeroes, the pipeline corrected structural biases and achieved a positive, valid R^2 score of 0.31 using the LGBM model. The results indicate that non-linear ensemble models armed with sequential historical features outperform traditional additive curve-fitting tools like Prophet, which remain structurally incapable of handling sudden mechanical well shut-ins. Feature importance diagnostics confirmed that localized operational changes, specifically associated gas fluctuations (Gas_A2_delta) and immediate historical production lags (lag_oil_1), represent the most dominant parameters driving downstream fluid variations.

For future work, these optimized frameworks can be trained on real-time sensor streams to actively prescribe pump adjustments. Advanced deep learning architectures, such as LSTM networks, can be deployed to dynamically tune pump speeds and flow rates to maximize production while minimizing power consumption. Additionally, ML can be applied to predictive maintenance and early fault detection. By tracking patterns across historical pressure deltas and lift parameters, models can detect anomalies indicating mechanical degradation, alerting operators to potential pump failures before they occur to minimize unplanned downtime.

Explainable AI for Trustworthy 6G Edge-Cloud Smart Cities: A Systematic Review

Qaisar Abbas*, Riyad Almakki
College of Computer and Information Sciences,
Imam Mohammad Ibn Saud Islamic University (IMSIU), 11432, Riyadh, Saudi Arabia

***Abstract*—Smart cities are becoming more interconnected, data-driven, and increasingly autonomous, with 6th-generation communication, edge-cloud computing, Internet of Things infrastructures, digital twins, federated learning, and artificial intelligence supporting them. The same technology that enables low-latency mobility, adaptive energy management, public safety analytics, environmental analytics, and responsive digital governance is creating a hard accountability conundrum. The decisions can be generated by black-box models across multiple computing tiers, take advantage of decentralized learning, and be executed before the human operator has time to review the reasoning. This review focuses on the trustworthy and explainable design of AI in these contexts. In this review, the focus is on the trustworthy and explainable design of AI in such contexts. The review is based on a multi-dimensional taxonomy of explanation timing, scope, target, representation, model dependence, computing location, stakeholder, trustworthiness objective, and urban application. It also outlines a tiered reference architecture that links local explanations at devices, operational explanations at mobile-edge nodes, network-level explanations for 6G orchestration, and strategic explanations for cloud-hosted urban digital twins. The synthesis confirms that the use of attribution techniques (SHAP, LIME, gradient-based saliency, feature importance) is prevalent, and that counterfactual explanations, concept-based explanations, causal explanations, inherently interpretable explanations, and interactive explanations are less developed for use in city-level deployments. Lacking are explanation fidelity for distribution shifts and real-time latency and energy cost, privacy leakage, federated explanation consistency, security against explanation manipulation, interoperability across urban digital twins, and weak human-centered evaluation. Finally, the study provides a research agenda and an engineering checklist of reliable, accountable, private, and sustainable urban intelligence.**

Keywords*—*Explainable artificial intelligence; trustworthy artificial intelligence; smart cities; 6G networks; edge intelligence; cloud computing; federated learning; digital twins; cybersecurity; AI governance; human-centered AI; sustainable urban intelligence

I. Introduction

Smart cities are no longer just technology-supported systems, but rather socio-technical systems engaged in constant interaction between sensing, communication, data analysis, artificial intelligence, infrastructure management, and public governance. Previous studies focused on the use of information and communication technologies for individual services. Recent research defines smart sustainable cities as "adaptive systems that should enhance environmental performance, public welfare, city resilience and inclusion, while being constrained by resources, laws and institutions" [1-5]. It's an important change since urban intelligence no longer exists solely in dashboards or past reporting. It increasingly foresees demand, allocates resources, identifies risks, suggests solutions, and even takes actions in transportation, energy, health, public safety, environment, construction, and digital government.

The architecture of the computing services is also evolving. While centralized cloud platforms offer solutions for storing data at scale, training models, and analyzing domains, they do not necessarily work for applications where latency is a key consideration, where privacy protection is paramount, or where connections are intermittent. Fog and edge computing bring data processing closer to vehicles, cameras, meters, gateways, hospitals, and public infrastructure, which decreases round-trip latency and bandwidth consumption [6–10]. The edge-cloud continuum is not a straightforward technical tuning. It transforms the place, the people, and the records of decision-making, the evidence that is kept, and the accountability shared by device vendors, network operators, providers of cloud services, public agencies, and human decision-makers.

Federated learning and urban digital twins further complicate things. For data that is institutionally distributed or legally sensitive, federated learning offers the potential for collaborative model improvement without the need to centralize all raw data, which is useful [11]. Digital twins are virtual replicas of physical assets and urban processes that enable simulation, prediction, monitoring, and testing of urban operations and policymaking [12]. Combined, the technologies enable distributed learning and reasoning at the system level, yet they pose additional challenges for maintaining model provenance, consistency of explanations, and accountability. The prediction can be based on local sensors, a federated global model, a federated decision about the resources of the network, and a prediction from a digital-twin simulation. Any explanation that addresses just one component of the chain may be technically correct but not operationally understandable.

The proliferation of advanced machine learning and deep learning predictive and decision-making models thus raises the center of trust issue. Engineers, citizens, operators, and policymakers have trouble understanding many high-performing models. Explainable AI tackles this problem by revealing influential features, examples, concepts, rules, counterfactual changes, uncertainty, and causal relationships [13-16]. However, "explainability" does not guarantee "trustworthy behavior. An explanation might be inconsistent,

*Corresponding author.

unfaithful, overly technical, misleading, revealing too much information about privacy, or perhaps unsuitable for its target market. Therefore, the concept of a trustworthy AI calls for a wider range of properties, such as validity, reliability, robustness, security, privacy, fairness, transparency, accountability, safety, and meaningful human oversight [17].

This is likely to be exacerbated by 6th-generation wireless communication. The 6G vision features very high data rates, ultra-low latency, massive connectivity, integrated sensing and communication, non-terrestrial coverage, semantic or goal-oriented communication, as well as the ability to control the entire network using AI [18–20]. AI will be applied to radio-resource management, mobility, network slicing, service placement, anomaly detection, and adaptive orchestration on future networks. The same networks will enable smart-city applications to be connected to autonomous vehicles, drones, sensors, robots, buildings, public-safety systems, and digital twins. The lack of transparency in network and network architecture decisions makes network failures hard to diagnose and challenge. A citizen impacted by the automated urban decision might not even be able to tell you what caused the decision, whether it was because of the application model, biased training data, an approximation on the edge that was resource-limited, an old federated model, or an optimization policy for the networks.

There are existing reviews that provide good foundations, but are fragmented. Methods and evaluation metrics are classified in XAI surveys, but generally deployment is considered a single-model problem [13–16, 38–53]. The computation, communication, privacy, and optimization aspects of edge and federated-learning surveys have been proposed, but rarely define the cross-layer movement of explanations [67–75, 80, 81]. In the context of digital-twin reviews, modeling and interoperability problems and governance issues are addressed without a common description of explanation provenance [76–79]. Although 6G enabling technologies and network requirements are explained in the 6G literature, only recent studies directly link 6G explainability to 6G use cases [20, 82–94]. Smart-city reviews focus on sustainability, services, ethics, security, and energy, but fail to integrate XAI design with distributed edge-cloud and 6G architectures to the fullest extent [95–100].

This review tackles that integration issue. It's not just an explanation algorithm list. It explores what is to be explained, from where explanations should be created, to whom, to which trust objective, how they are assessed, and how they are kept reliable on devices, edge nodes, networks, in the cloud, and in digital twins. The primary contributions are five-fold. The study first develops an up-to-date 100-reference corpus, which is a compilation of the 20 references from the seed manuscript and 80 good-quality reference sources. Second, it establishes a common taxonomy connecting the properties of XAI methods to computing layers, stakeholders, dimensions of trustworthiness, and urban domains. Thirdly, it suggests a reference design of 6G edge-cloud systems with explanations. Fourth, it brings together deployment patterns, threats, and evaluation metrics in transportation, energy, healthcare, public safety, environmental monitoring, and governance. Fifth, it offers a research agenda of concrete technical questions and practical design advice.

The rest of this study is organized as follows: The review protocol and its limitations are described in Section II. The conceptual foundations are defined in Section III. The reference architecture is introduced in Section IV. The taxonomy is given in Section V. Section VI combines application domains. Securing trust, security, privacy, and governance will be explored in Section VII. This is followed by a corpus analysis of trends in maturity in Section VIII. The future research agenda is proposed in Section IX. Section X gives engineering and policy guidelines, with conclusions in Section XI.

II. Review of Protocol

The review process was structured according to PRISMA reporting principles, following the identification, screening, eligibility, and inclusion stages summarized in Fig. 1. Candidate studies retrieved from the selected databases and supplementary sources were screened for relevance, duplicate records were removed, and full-text eligibility was assessed using the predefined inclusion and exclusion criteria. This PRISMA-guided selection process resulted in a final corpus of 100 references, which was retained for qualitative synthesis and descriptive corpus analysis. Fig. 1 provides a transparent account of the study-selection pathway used to construct the final analytical corpus.

A targeted search strategy was employed on major publisher platforms and authoritative databases such as IEEE, ACM, Elsevier, Springer Nature, MDPI, Frontiers, and the National Institute of Standards and Technology. Search concepts were amalgamated into multiple families: explainable AI or interpretable machine learning; trustworthy AI, responsible AI, fairness, accountability, privacy, or human-centered AI; edge intelligence, mobile edge computing, cloud, federated learning, or digital twin; 6G, AI-native network, semantic communication, network slicing, or integrated sensing and communication; and smart city, transportation, energy, healthcare, safety, environment, building, or governance. To boost coverage, backward citation chaining from large surveys and forward-oriented searches for 2023-2026 reviews were carried out.

If it met at least one of four relevance conditions, it was included in the studies. The source had to include some form of foundational or commonly used method for XAI, a rigorous XAI taxonomy/evaluation framework, a treatment of edge-cloud, federated, digital-twin, or 6G infrastructure, or a substantive analysis of AI-enabled smart-city applications, ethics, security, privacy, or governance. Only journal articles, major peer-reviewed conference papers, and authoritative technical frameworks were included. Sources were removed if they were redundant, peripheral to the integrated topic, had insufficient methodological content, or contained promotional claims without technical and/or empirical backing. The update emphasized work since 2020 but included previous foundational studies if they were not included, they would not complete the method taxonomy.

Each source was coded by publication year and primary theme. The detailed qualitative extraction used nine dimensions: contribution type; AI model family; explanation family; explanation scope; computing location; urban application; trustworthiness objective; evaluation approach; and deployment maturity. Because many sources span more than one category, the figures in this study use a single primary-theme code to avoid double counting. These figures should be interpreted as descriptive views of the curated corpus, not as a complete bibliometric map of all publications in the field.

The synthesis combined aggregative and configurative reasoning. Aggregative synthesis counted publication years and primary themes. Configurative synthesis connected technical ideas that are usually studied separately, such as explanation fidelity, network-level orchestration, federated consistency, digital-twin provenance, public-sector accountability, and citizen contestability. The research questions are listed in Table I. The protocol and quality checks are summarized in Table II, while Fig. 1 shows corpus construction.

III. Conceptual Foundations

The term explainable AI is applied unevenly. The property of interpretability is often used to describe a property of a model whose operation can be explained directly, such as a sparse rule list or a constrained generalized additive model. Explanability is typically used to describe information that is produced to aid in understanding a model or a specific output, such as post-hoc explanations that provide users a way to understand an opaque model [13-16, 32, 33]. This division is helpful but not definitive. Mathematically interpretable models can be in urban systems; the decision process is opaque if there are data transformations, service composition, network constraints, human procedures, etc.

A second distinction is with respect to explanation scope. Global explanations define model behavior, decision logic, feature effects, or learned concepts in general. Local explanations: One prediction, recommendation, or action. LIME builds a local surrogate near an instance [21], and Shapley gives an explanation of a prediction based on Shapley-value principles [22]. Gradient-based methods like Grad-CAM or integrated gradients provide insights into regions of the input that are important to the model or features [23, 24]. Perturbation methods estimate the changes in outputs that occur when evidence is perturbed [25]. Another group of methods relates a prediction to training examples via the concept of influence functions and example-based methods [26]. Counterfactual explanations involve highlighting changes that would impact an outcome [27, 46]. Concept-based explanations are decisions based on human-meaningful concepts, instead of just on raw features [28]. These are different families and should not be used interchangeably to answer the same question.

A third difference is between explanation and justification. An explanation should characterize the actual mechanism or evidence that influenced a model. A justification can give a convincing reason, making it seem like a decision was made on a good basis, but not accurately explain the model. The risk is particularly high for generative explanations generated by language models. There is a tendency to conceal low fidelity by writing floppy text. Natural-language explanation interfaces for critical urban applications must be based on a model's evidence, provenance, confidence, and explicitly stated uncertainty. The generated text should be used as a communication layer, rather than the source of the explanation.

There are also multiple aspects of how trustworthy someone is. Technical correctness is required but a reliable system should be reliable in the presence of distribution shift, adversarial behavior, missing sensors, device failures, and organizational change. A security concern is whether models and explanations are manipulable. Questions about privacy include whether there are any personal details to be uncovered in the raw data, in model updates, or in explanations. Fairness questions are about fairly distributing benefits, errors, and burdens. Accountability is about being able to trace, audit, challenge and correct decisions. Human-centeredness deals with whether explanations facilitate a user's reliance in a calibrated manner or simply boost the user's self-efficacy [54–66]. Sustainability is about the ongoing monitoring of cities with energy, hardware, communication and environmental costs.

This means that explanation and trust are only loosely connected. Explanations can enhance the understanding of a system and aid in debugging; but poorly designed explanations can lead to an automation bias, an overtrust, or a strategy game [31, 41, 56, 59–62]. Do not judge an explanation on its popularity with users. Should be evaluated according to: 1) fidelity; 2) stability; 3) relevance; 4) comprehensibility; 5) actionability; and 6) impact on decision quality. Trust should be proportional to the actual competence of the system. However, in some situations, reducing the level of trust is appropriate, as it is done by providing an explanation of uncertainty, weak evidence, or an out-of-distribution scenario.

Four more concepts are introduced in the context of distributed urban intelligence. The first question of explanation locality is where the evidence for the explanation is produced. A device might generate an immediate local attribution, or a regional edge node might generate a richer counterfactual using more context. Second, explanation provenance is a log of which version of the model, data window, feature pipeline, network state and policy rules were used to get the output. Third, the explanation composability issues involve how partial explanations from multiple services are able to be put together without conflicts. Fourth, explanation consistency is the issue of providing a meaningful equivalent explanation to equivalent inputs, across devices, cities, languages and model versions.

The 6G context puts additional challenges on the explanation requirements since both communication and computation are optimized together. AI-native networks could determine which model operates on which resource, how much data can be sent, which semantic aspects will be kept, and which of these services will have limited resources [18–20, 82–94]. The decisions made on these networks may influence the output of the application. For an emergency response delay, for instance, a possible explanation could be radio conditions, slice allocation, edge congestion, confidence degradation, and

evidence from the application model. This drives a system- level approach instead of an XAI model only(Table III).

TABLE I. RESEARCH QUESTIONS AND ANALYTICAL PURPOSE

RQ	Research question	Purpose
RQ1	Which XAI methods and explanation forms are most relevant to distributed smart-city systems?	Build the method taxonomy and identify method-selection principles.
RQ2	How should explanations be generated and communicated across device, edge, 6G network, cloud, and digital-twin layers?	Define the reference architecture and cross-layer provenance requirements.
RQ3	Which trustworthiness risks arise from explainable urban intelligence?	Synthesize safety, robustness, security, privacy, fairness, accountability, and sustainability concerns.
RQ4	How mature is the evidence across major urban application domains?	Compare transportation, energy, health, safety, environment, and governance.
RQ5	Which metrics and human-evaluation methods are needed?	Develop a multidimensional evaluation framework.
RQ6	What research and engineering priorities should guide future 6G-enabled deployments?	Produce a technically actionable agenda and implementation checklist.

TABLE II. STRUCTURED UPDATE PROTOCOL AND QUALITY CONTROLS

Protocol element	Applied rule
Seed set	Retain the high-impact journal references
Update sources	Target major publisher platforms, authoritative frameworks, DOI records, and backward citation chains.
Date emphasis	Prioritize 2020–2026 work while retaining essential foundational XAI, edge, and federated-learning studies.
Inclusion	Peer-reviewed journal or major conference source, or authoritative standard; direct relevance to one or more integrated themes.
Exclusion	Duplicative, tangential, technically shallow, unverifiable, or purely promotional sources.
Coding	Year, primary theme, contribution, method, computing layer, stakeholder, trust objective, application, evaluation, maturity.
Quantitative interpretation	Counts describe the curated 100-reference corpus only; they are not database-wide bibliometrics.
Transparency limitation	Formal identification and screening counts from the seed review are not reconstructed because raw search exports were unavailable.

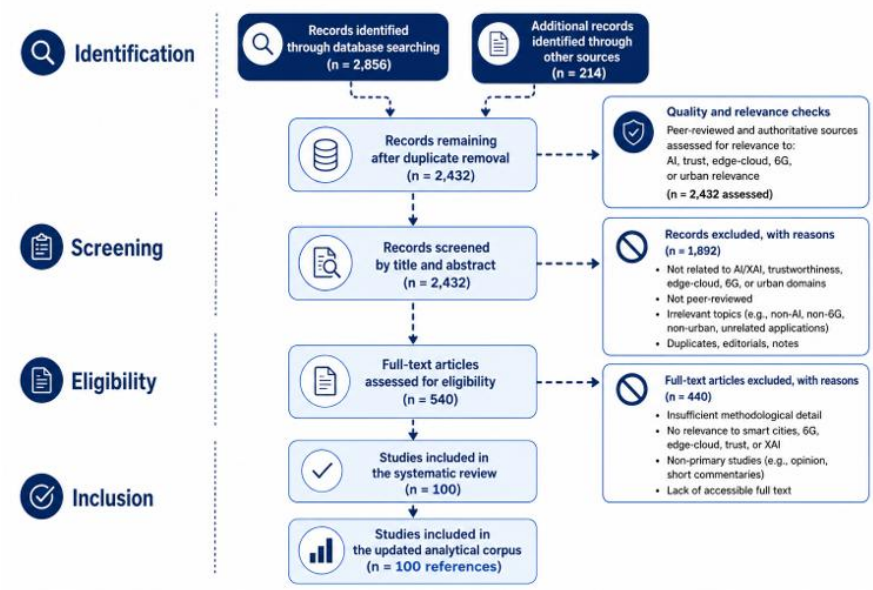

Fig. 1. PRISMA-aligned construction of the updated analytical corpus.

TABLE III. CODING FRAMEWORK USED FOR QUALITATIVE SYNTHESIS

Dimension	Representative codes
Contribution	Method; taxonomy; evaluation; architecture; security/privacy; application review; governance framework.
AI model	Linear/tree; ensemble; CNN; recurrent/temporal; transformer; graph neural network; reinforcement learning; hybrid.
Explanation	Attribution; surrogate; rule; example; counterfactual; concept; visualization; causal; uncertainty; natural language.
Scope	Global; cohort; local; temporal; contrastive; cross-layer.
Location	Device; far edge; MEC/regional edge; network controller; cloud; urban digital twin.
Stakeholder	Developer; operator; domain expert; auditor; regulator; policymaker; citizen; public.
Trust objective	Performance; safety; robustness; security; privacy; fairness; accountability; usability; sustainability.
Maturity	Conceptual; benchmark; prototype; operational pilot; institutional deployment.

IV. Architecture for Explainable Urban Intelligence

It is suggested that there should be a five-layer reference architecture as shown in Fig. 2. The layers are not products but functions where computation, decisions, and explanations are made. The architecture comprises a physical sensing layer, a device and far-edge layer, an AI-native 6G network layer, a mobile or regional edge layer and a cloud, digital-twin, and governance layer. Cross-layer services include identity, security, provenance, model registries, audit records and explanation policies.

The physical and sensing layer is composed of smart meters, medical devices, vehicles, drones, smartphones, infrastructure sensors, cameras and environmental stations, and actuators. This is where data quality starts. Decisions downstream are directly related to sensor calibration, sampling gaps, spatial coverage, and population representation. At this layer, explanations should include information on signal quality, signal missingness, calibration status, and whether the observed situation is within the sensor's validated operating range. The last thing that can be done to correct a poorly calibrated sensor is to generate a saliency map later.

It filters, compresses, does lightweight inference, and enables real-time control on the device and far-edge layer. Examples are pedestrian detection in a vehicle, local anomaly detection in a substation, fall detection in a home, or smoke detection on a drone. Explanations should be quick and efficient. They may be in the form of short feature contributions, confidence and uncertainty markers, prototypes, simple rule traces and alert reason codes. Explanation generation should not introduce any latency or energy to the safety function. If a complete explanation is not available locally, the device should retain enough evidence to be analyzed at a more powerful edge node at a later time (Table IV).

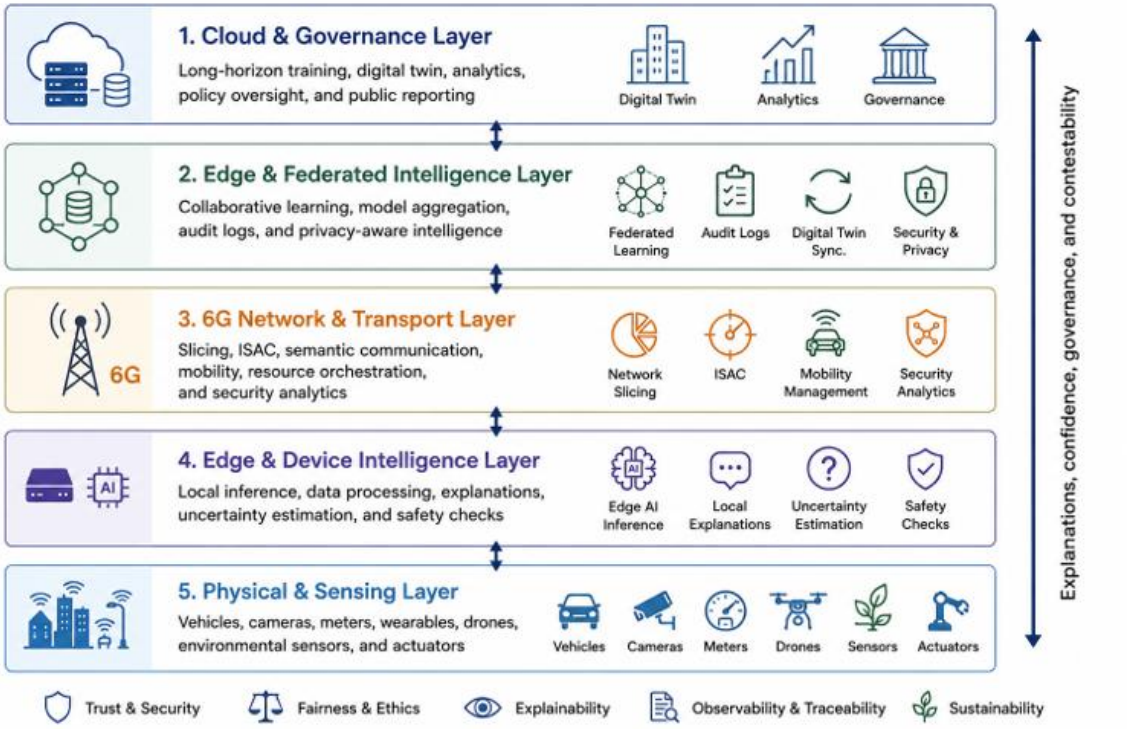

Fig. 2. Layered reference architecture for trustworthy and explainable 6G edge-cloud urban intelligence.

TABLE IV. Explanation Responsibilities by Computing Layer

Layer	Primary decision function	Explanation responsibility	Typical constraints
Physical/sensing	Observe urban state	Data quality, coverage, calibration, missingness, provenance	Noise, limited sensing, privacy, physical tampering
Device/far edge	Immediate inference or control	Reason code, confidence, local evidence, safety state	Milliseconds, memory, battery, intermittent links
6G network intelligence	Mobility, slicing, placement, semantic transmission	Resource rationale, degradation notice, network-event trace	Fast topology change, attack surface, multi-operator control
MEC/regional edge	Context fusion, collaborative inference, federated coordination	Operational counterfactuals, consistency, local-to-global contribution	Heterogeneity, privacy, regional workload
Cloud/digital twin	Training, simulation, policy and city-wide optimization	Scenario assumptions, uncertainty, provenance, sensitivity, public accountability	Complexity, vendor boundaries, long retention, governance

The 6G network-intelligence layer enables access, mobility, integrated sensing and communication, semantic transmission, network slicing, and resource allocation [82–94]. In this instance, the thing to be explained is actually not a software prediction but a network action. Explanations are required for handovers, slice-priority changes, service degradation, model placement, and anomaly responses for operators. Application owners must be aware if communication constraints changed the data resolution or the quality of the data model. While citizens do not usually want to know what is going on at the radio level, they do want to know that a service is running in degraded mode if it is Citizens do not want radio-level details, but they do want to be assured that a service is running in a degraded mode if it is. The architecture thus brings together technical explanations and public-facing notices and connects them together by shared provenance.

The mobile-edge and regional-edge layer brings together context from multiple devices, runs larger models, and can handle collaborative inference and coordinate federated learning [67–75, 80, 81]. It is the natural place where operational explanations take place. Regional context, temporal history and nearby alternatives can be used to create counterfactuals. The Explanation consistency checks feature allows comparison of local devices. Explanation privacy tests can determine if feature attributions or examples contain sensitive information, while secure aggregation can ensure that model updates are protected. The regional edge nodes can also act as a broker between the city agencies, which are not able to share data but require decision-making together.

Cloud and Urban Digital-Twin Layer enables long-horizon training, simulation and optimization at the city level, analysis of policies, and coordination across domains [12, 76, 77, 79]. At this layer, explanations should include scenario assumptions, causal hypotheses, uncertainty intervals, sensitivity analysis, and comparisons between policy alternatives. Digital twins need to have a line of sight from physical observation to physical consequences. An uncertainty-free model version-less policy recommendation is not auditable. Public transparency portals and formal review workflows can both be performed on the same layer, while sensitive operational information is access-controlled.

There are four mechanisms that span multiple layers necessary. The first is an explanation contract that details the audience, purpose, evidence needed for each kind of decision, latency, level of privacy required for each decision, and period of time for which the explanation should be retained. The second is an explanation provenance graph which connects inputs, transformations, model versions, network states, policy constraints and human interventions. The third is a trust monitor to verify calibration, drift, robustness, fairness, and explanation stability. The fourth is a contestability workflow which allows authorized users to challenge a decision, request more evidence, request human review and log corrective actions.

This design does not assume there is a single explanation. Different evidence is needed by a network engineer when diagnosing a handover failure, a clinician when reviewing a health alert, a traffic controller when managing congestion, a policymaker when evaluating a zoning simulation, and a citizen when appealing a service decision. The system should derive explanations from a common trace and produce explanations according to their role and their level of risk.

V. Taxonomic Synthesis of Explainable Urban Intelligence

These dimensions combine the terms from existing surveys on explainable AI [13, 14, 16, 29, 30, 34, 45, 48, 49, 52, 53] and the fundamental frameworks of XAI [38–43, 45, 49, 53] as well as the taxonomies of XAI methods [45, 48, 49]. Model-agnostic approaches estimate the behavior of a model by asking questions about the input and output of the model, perturbing it, and relying on model-class measures without having direct access to the model's internal parameters [21, 35]. Visual explanation mechanisms are methods that present evidence through saliency maps, temporal plots, graph views, spatial overlays, interactive dashboards, and other forms of visual analytics interfaces [23, 24, 36]. The result is a synthesis that classifies the literature based on the temporal nature of the explanation, its extent, its purpose, its representation, the relationship between the explanation and the model, the location of the computation, the stakeholder, the goal of the trustworthiness, and the criticality of the application. It is therefore treated here as an analysis of the presented evidence and not as a new algorithm to be used for explainability. These nine dimensions are already reflected in the current taxonomy of the manuscript and are connected to distributed urban decision-making.

The first dimension is the timing of explanations. In the literature, there are several types of explainability, including ante-hoc, post-hoc, and hybrid. Ante-hoc methods build interpretability into the model using sparse rules, monotonic relationships, decision lists, prototypes, generalized additive structures, causal models or concept bottlenecks. These methods are often advised when direct model transparency is necessary, e.g., for decisions that have significant impacts or are of paramount safety importance [32, 33]. Post-hoc methods produce explanations following model training, such as feature attribution [13-15], perturbation analysis [22-23], local surrogate approximation [16], saliency visualization [21-22], influential examples [24-25], and counterfactual reasoning [26-28]. Hybrid strategies combine a high-capacity predictive model with interpretable constraints, semantic representations, rule-based safety mechanisms, uncertainty estimation or transparent fallback models [15, 37, 52].

The second dimension is explanation scope. Global explanations summarize the overall behavior of a model, including dominant variables, general decision patterns, learned concepts, or population-level feature effects. Local explanations focus on an individual prediction, alert, recommendation, or control decision. Cohort explanations characterize model behavior for a meaningful subgroup, such as a neighborhood, demographic category, road class, climate zone, building type, or device class. Temporal explanations show how evidence or model confidence changes over time, while contrastive explanations clarify why one outcome occurred rather than another [14, 15, 31, 41, 52]. Cohort-level and temporal explanations are especially relevant to urban

intelligence because many smart-city decisions concern spatial groups, infrastructure regions, and continuously evolving processes rather than isolated samples.

The third dimension is the explanatory target. The reviewed literature shows that explanations may address data, models, predictions, operational processes, institutional policies, or observed outcomes. Data-level explanations describe sensor quality, missing values, spatial coverage, sampling bias, representativeness, preprocessing, and provenance. Model-level explanations describe learned structures or decision behavior. Prediction-level explanations clarify a specific model output. Process-level explanations reconstruct the sequence of sensing, communication, inference, network orchestration, and human intervention that produced a decision. Policy-level explanations clarify how legal requirements, organizational rules, service priorities, or resource-allocation policies influenced the result. Outcome-level explanations evaluate the consequences observed after an intervention. This distinction is important because prediction-level transparency alone may not reveal whether an urban decision was affected by unreliable data, communication degradation, policy constraints, or human procedures [41, 57, 58, 63, 66].

Explanation representation is the fourth dimension. Feature-attribution methods describe the contribution of variables, pixels, regions, tokens, time steps, graph components or sensor channels. Some popular techniques are SHAP [22], gradient-based saliency [23], Grad-CAM [24], integrated gradients, and perturbation-based explanations [25]. Local surrogate methods such as LIME approximate the behavior of a complex model in a limited neighborhood by a simpler model that is easier to interpret [21]. Example-based methods correlate a prediction with similar, representative or influential observations [26]. In counterfactual and concept-based approaches, the models are augmented with changes that are related to an alternative outcome or the internal model representations are linked to human-recognizable semantic concepts, respectively [27, 46]. Other forms of representations are symbolic rules, decision paths, prototypes, uncertainty intervals, causal graphs, spatial maps, temporal traces, dashboards and natural-language summaries.

When information needs to be presented to stakeholders such as policymakers, operators, and citizens with varying technical backgrounds, natural-language explanation becomes more and more relevant for smart-city systems. But there is literature cautioning that fluent language may be a plausible justification without being a faithful representation of the predictive mechanism [31, 41, 48, 49]. The natural-language outputs should thus be based on verified model evidence along with provenance records, estimates of uncertainty, and system logs, and not be specifically produced from the underlying decision process.

TABLE V. EXPLANATION MECHANISMS AND DEPLOYMENT SUITABILITY IN URBAN ARTIFICIAL INTELLIGENCE

Explanation family	Typical output	Technical strength	Principal limitation	Suitable urban application
Attribution-based explanation [22–25]	Ranked variables, saliency maps, temporal contributions, channel importance	Broad compatibility with complex models and relatively efficient generation	Can be unstable, sensitive to baselines, and incorrectly interpreted as causal	Model diagnostics, forecasting, perception review, anomaly analysis
Local surrogate explanation [21]	Local linear model, rule set, or decision boundary approximation	Produces a compact approximation of local predictive behavior	Fidelity depends on perturbation distribution, neighborhood size, and sampling process	Individual case review, operator dashboards, incident investigation
Counterfactual explanation [27, 46]	Minimum feasible modifications associated with an alternative outcome	Contrastive, potentially actionable, and understandable to non-specialists	Requires feasibility, causal consistency, stability, and fairness constraints	Service eligibility, building-energy actions, mobility planning, resource allocation
Example or prototype explanation [26]	Similar, representative, or influential cases	Supports case-based reasoning and expert comparison	May reveal sensitive information or reproduce historical bias	Clinical review, predictive maintenance, infrastructure inspection, incident analysis
Concept-based explanation [28]	Human-recognizable semantic concepts and concept sensitivity scores	Connects internal model representations with domain terminology	Concept quality, completeness, independence, and validity require evaluation	Mobility analysis, environmental monitoring, image interpretation, urban planning
Rule-based or inherently interpretable model [32, 33, 37]	Decision rules, monotonic effects, sparse coefficients, symbolic paths	Provides direct access to the decision mechanism and stronger auditability	May require constrained design, engineered features, or reduced model flexibility	High-impact governance, safety control, regulatory decisions
Uncertainty-aware explanation [43, 44]	Confidence estimates, predictive intervals, disagreement measures, out-of-domain warnings	Supports calibrated reliance, abstention, and human escalation	Uncertainty can be difficult to estimate, validate, and communicate	Healthcare, public safety, autonomous mobility, environmental warning systems
Natural-language rendering [31, 41]	Role-specific textual explanation or multilingual narrative	Accessible to nontechnical stakeholders and adaptable to different audiences	May produce plausible but unfaithful justification unless grounded in verified evidence	Citizen notifications, executive summaries, public dashboards, appeal interfaces

The fifth dimension is related to the relationship between explanatory method and predictive model. Internal gradients, activations, attention mechanisms, parameters, or architectural properties are all used in model-specific methods. The model-agnostic approaches are based on input-output queries and perturbations, and they do not require access to the internal model states. Surrogate methods: A simpler, global or local model to approximate the behavior of a complex model. Interpretable models reveal their decision logic directly in the form of sparse coefficients [14, 15, 32–34, 38, 40] or through

monotonic effects [29] or rules or prototypes [39]. The reviewed studies highlight the need to report this relationship explicitly since a clear surrogate model may be a close or local approximation of the original predictor.

Computational location is the sixth dimension. The explanations can be produced at the sensing device, far-edge gateway, mobile-edge node, regional edge, 6G network controller, cloud platform, or urban digital twin. Explanation latency is influenced by the selected location, the computational resources available, contextual information, communication cost, energy consumption, and exposure of privacy [7-10, 20, 67-68, 81]. The explanations for devices are typically brief and brief. Computationally intensive counterfactual, temporal, causal and/or cross-service analysis can be supported by regional-edge and cloud platforms. Additional network-level explanations could also be necessary to explain the impact of handovers, network slicing, semantic communication, network congestion, service placement, resource orchestration, etc. on application performance [20, 82–93].

The 7th dimension is the stakeholder/explanation audience. Explainers can be split into a variety of explanation recipients, ranging from developers and data scientists to network engineers, system operators, domain specialists, auditors and regulators, affected citizens and the public [41, 56, 59–62]. Feature-level diagnostics, model internals, error distributions and version histories may be needed by the developers. Concise alerts, confidence indicators, and recommended actions may be required for operators. Temporal evidence, examples, uncertainty estimates, and plausible alternatives may be needed by the domain experts. Auditors and regulators need data lineage, performance of subgroups, compliance with policies, security testing, and traceability. Citizens need information that is comprehensible on the issue, their impact, influencing factors, and options for review and appeal.

Trustworthy objective is the eighth dimension. Predictive validity, safety, robustness, cybersecurity, privacy, fairness, accountability, usability, human oversight, or sustainability could all serve as explanations for these [17, 54–66]. The evidence shows that none of the explainability methods address all those properties. Attribute features may help debugging, for instance, but are not alone evidence of fairness, causal validity, privacy protection or regulatory compliance. Selection and evaluation of explanation methods should then be done based on the trustworthiness risk of the particular application.

The ninth dimension is application in urban settings and criticality of decision. The included analyzed studies span transportation systems, energy systems, smart buildings, healthcare, assisted living, environmental monitoring, public safety, urban infrastructure management, digital governance and urban digital twins [1–5, 12, 76–79, 91, 95–100]. Decision criticality can range from informational to operational, safety-critical or rights-affecting. For informational uses, rough or summary-level explanations are acceptable. Robust evidence around fidelity, uncertainty, robustness, traceability, human escalation and contestability is needed for safety-critical and rights-affecting decisions.

TABLE VI. NINE-DIMENSIONAL DESIGN SPACE FOR EXPLAINABLE URBAN INTELLIGENCE

Dimension	Design question	Representative values
Timing	At which stage is interpretability incorporated?	Ante-hoc, post-hoc, hybrid
Scope	To what extent of model or system behavior is being explained?	Global, cohort, local, temporal, contrastive
Explanatory target	Which system component requires explanation?	Data, model, prediction, process, policy, outcome
Representation	How is explanatory evidence encoded and communicated?	Attribution, rule, example, prototype, counterfactual, concept, uncertainty, causal model, visualization, natural language
Model relationship	What access does the explanation method have to the predictive model?	Model-specific, model-agnostic, surrogate, inherently interpretable
Computational location	Where is the explanation generated?	Device, far edge, mobile edge, regional edge, network controller, cloud, digital twin
Stakeholder	Who receives and acts upon the explanation?	Developer, operator, domain expert, auditor, regulator, policymaker, citizen, public
Trustworthiness objective	Which technical or institutional risk is addressed?	Safety, robustness, security, privacy, fairness, accountability, usability, sustainability
Domain and criticality	What are the application context and consequences of error?	Informational, operational, safety-critical, rights-affecting

To illustrate the differences in kinds of evidence offered by explanation families, as well as the different methodological limitations, the data are displayed in a comparative synthesis in Table V. While relatively inexpensive and widely applicable, results from feature-attribution methods may be unstable and are often misinterpreted as causal [22–25, 44, 49]. Local surrogate models give a brief characterization of the predictive behavior in the immediate vicinity, but are only accurate when defined by a neighborhood metric and when only a small number of perturbations are sampled [21, 43, 44]. The feasibility, fairness, stability and causal validity of counterfactual explanations need to be studied [27, 46] as they are intuitive and actionable. The semantic alignment with domain knowledge is improved by the concept-based methods, but the completeness and validity of concepts are still open concerns [28]. Expert comparison can be explained using example-based explanations, but may reveal information that is sensitive or perpetuate historical bias [26]. In the case of inherently interpretable models, direct accountability can be stronger, particularly in high-impact decision-making, but it can be challenging to design models and carefully structure features [32, 33].

The synthesis further indicates that explanation selection should follow the analytical question. Saliency or example-based evidence may be appropriate for explaining why an image was classified in a particular way. Explaining why a neighborhood was prioritized requires cohort-level, fairness-aware, policy-aware, and uncertainty-aware analysis. Identifying changes that could alter an outcome requires feasible counterfactual reasoning. Estimating whether an intervention would work requires causal analysis or digital-twin simulation. Diagnosing a service failure requires a cross-layer trace covering sensor conditions, model execution, network behavior, resource allocation, and human intervention. Consequently, treating every explainability requirement as a feature-attribution problem represents a methodological mismatch between the explanation technique and the underlying urban decision question. The manuscript's existing discussion reaches the same central conclusion that method selection must follow the type of question being investigated. Table VI consolidates the nine taxonomic dimensions identified through the qualitative synthesis of the reviewed explainable artificial intelligence, trustworthy artificial intelligence, edge-intelligence, and smart-city literature [13–16, 29, 34, 38–45, 52, 53]. The dimensions describe when an explanation is generated, the scope and target of the explanation, its representation, its relationship with the predictive model, its computational location, intended stakeholder, trustworthiness objective, and application criticality. Together, these dimensions provide a structured basis for comparing explainability requirements across heterogeneous 6G-enabled edge-cloud urban systems.

VI. Application-Domain Synthesis

Transportation is among the most challenging domains due to the mobile nature of the decision, the safety-critical nature of the decision, the deadline for the decision and the context of the decision. These are used in traffic prediction and control, travel planning and route guidance, autonomous driving, incident detection, public transport control, parking, and urban air mobility [4, 92, 93]. The explanations must be short and concise for the device to be usable while operating, and they should be more detailed and extensive in the temporal and spatial aspects for the purposes of forensics after the event. Explanations for autonomous systems should include perception, prediction, planning and control and not just object detection. Network explanations are also important since handovers, edge migration, and service prioritization can impact latency and perception quality (Table VII).

Smart energy and buildings integrate forecasting, optimization, fault detection, demand response, retrofit planning, occupancy modelling and comfort management. There has been an increasing number of recent reviews that discuss the use of SHAP, LIME, tree-based feature importance and interpretable models in urban building energy analysis [99, 100]. Stakeholders are building operators, residents, energy suppliers, regulators and planners. Explanations should identify variables that can be controlled, and variables that are not controllable but which can only be considered as variables in the context. An operator must have factors to apply to a model—such as schedules, set points, equipment problems, or retrofit possibilities—that would allow them to take corrective action. Therefore, counterfactual and scenario explanations are valuable, particularly in conjunction with digital-twin simulations.

Edge intelligence is utilized for monitoring, emergency alerts, triage, and remote care in the healthcare and assisted living arenas. Errors can have harmful consequences, and health data are very sensitive. Explanations should be used to assist clinical reasoning, uncertainty awareness and escalation, and not to reveal unnecessary or inappropriate personal information. While federated learning can eliminate the sharing of raw data, it cannot eliminate the privacy or bias risks [71–75]. Explanations can show membership, rare conditions or data characteristics in the local area. Model outputs and explanation artifacts should therefore be included in privacy assessment.

There are three categories of public safety: Emergency response, Fire and flood monitoring, Crowd risk, Infrastructure inspection, and cyber-physical anomaly detection. Such systems typically feature cameras, drones, environmental sensors, social signals, and digital twins. An alert explanation should include such as Evidence, Sensor Health, Confidence, Spatial Extent, and Recommended Action. It should also differentiate between what is observed and what is projected. In the context of public-safety systems, explanation design should also include legal access, proportionality, access control and retention guidelines, and independent oversight [96, 98].

AI is applied to the monitoring of environmental conditions such as air quality, noise, heat, water, vegetation, waste, biodiversity and climate hazards. AIoT and AI have been shown to have the capabilities of enhancing sustainability analysis, bringing about technical, ethical, and energy-related challenges in smarter eco-city research [97]. There needs to be explanations for scientific validity and public communication. Spatial explanations should take into account that spatial coverage of sensors is not even and neighborhood level uncertainty. Temporal explanations should point out if the apparent change is due to a change in the environment, to sensor drift, to weather, or to seasonal behavior or a change in the model.

Digital governance includes eligibility for services, prioritisation of inspections, routing of complaints, allocation of resources, urban planning and simulation of policies. It has the highest need for procedural transparency, fairness and contestability. An explanation should reveal the decision authority, types of data, role of the model, policy restrictions, uncertainty, and review trails. There may be some information that needs to be kept confidential for reasons of security or privacy, but the rule shouldn't be secrecy. Governance systems should keep public records of impacts, audit trails, and easily accessible appeals [54–66, 96].

Urban digital twins span all areas. They may fuse together transport, energy and environment, land use and public health, and infrastructure. They are useful for integration, but integration can lead to an increase in errors and to a loss of causal responsibility [76–79]. An explanation should identify the submodels, how data were synchronized, assumptions made and whether it is observational, predictive, or counterfactual. Semantic Interoperability is also critical.

Technically correct explanations may lead to institutional misunderstanding if two City agencies have different definitions of ‘risk', ‘occupancy ', or ‘service disruption'.

Across domains, three maturity levels appear. Level 1 uses model-centric post-hoc explanations in offline analysis. Level 2 integrates explanations into operational dashboards and human workflows. Level 3 provides cross-layer provenance, continuous evaluation, role-specific communication, and contestability. Most published applications remain between Levels 1 and 2. Level 3 is the main engineering frontier for 6G-enabled cities.

Fig. 3 summarizes the maturity of trustworthiness-related evidence across the major smart-city application domains reviewed in this study. Transportation and healthcare show relatively stronger maturity in safety, robustness, and operational deployment, whereas public safety, environment, digital governance, and urban digital twins remain concentrated in prototype or early-stage evidence, especially for fairness, accountability, and human-centered evaluation.

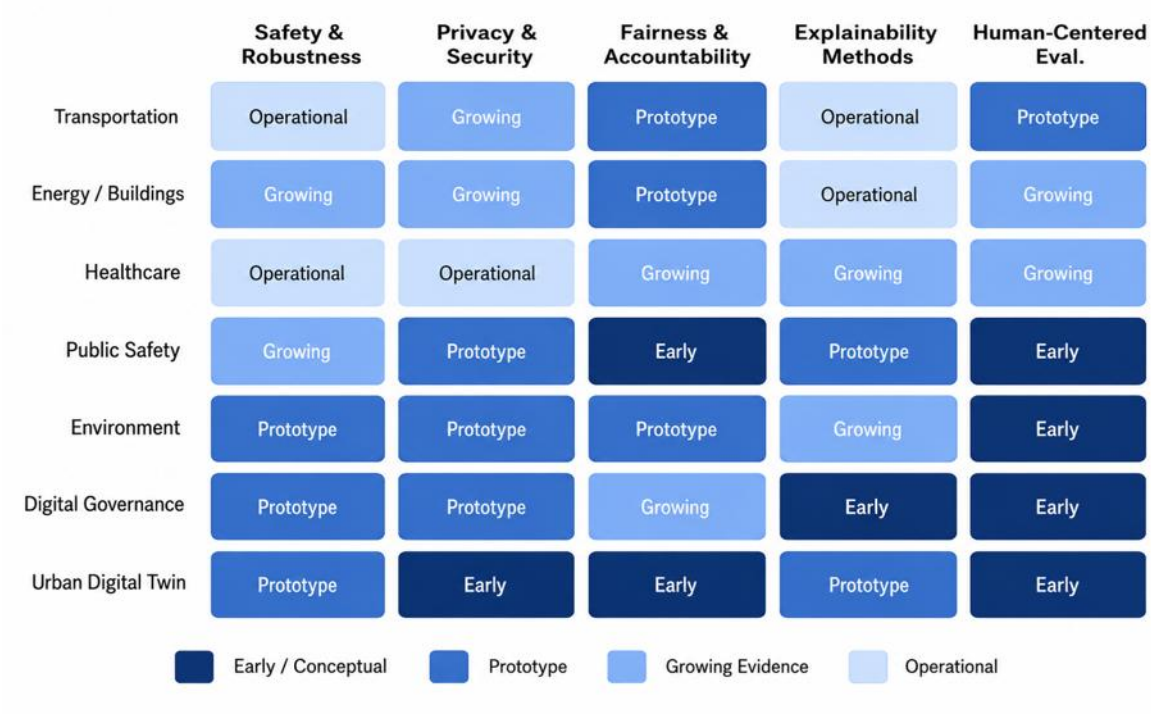

Fig. 3. Maturity of trustworthiness dimensions across major smart-city application domains.

TABLE VII. COMPARATIVE SYNTHESIS OF MAJOR SMART-CITY APPLICATION DOMAINS

Domain	Typical AI decisions	Most useful explanations	Critical trust requirements	Maturity
Transportation	Detection, prediction, routing, signal control, autonomy	Temporal evidence, objects/concepts, counterfactual routes, network trace	Safety, latency, robustness, privacy, accountability	Prototype to operational
Energy/buildings	Demand forecast, control, faults, retrofit, occupancy	SHAP/feature effects, counterfactual actions, scenario sensitivity	Actionability, causal validity, privacy, sustainability	Growing operational evidence
Health/assisted living	Monitoring, alerts, triage, personalized support	Uncertainty, examples, temporal evidence, escalation rationale	Privacy, safety, fairness, clinician oversight	Pilot to operational
Public safety	Incident detection, emergency prioritization, hazard forecast	Multisensor evidence, confidence, spatial extent, process trace	Proportionality, security, auditability, false-alarm control	Mostly pilots
Environment	Air/water/noise/heat forecasting and intervention	Spatial coverage, temporal drivers, causal scenarios, uncertainty	Scientific validity, equity, sensor quality, public communication	Research and pilots
Digital governance	Eligibility, inspection, resource allocation, planning	Rules, cohort fairness, policy trace, counterfactual and appeal	Legality, fairness, contestability, transparency	Early and uneven
Urban digital twin	Cross-domain simulation and optimization	Assumptions, submodel provenance, sensitivity, scenario comparison	Interoperability, uncertainty, governance, responsibility	Emerging

This section provides an illustrative example of explainable artificial intelligence in a trustworthy 6G edge-cloud smart city setting. A simplified traffic-management scenario is used to demonstrate how urban sensing data can be processed by an edge AI model and then interpreted through an explainability module before being presented to human operators. As shown in Fig. 4, the workflow links data sources, model prediction, feature attribution, and operator-facing interpretation in a compact form. This example helps clarify the practical role of XAI in improving transparency, accountability, and human-centered decision support in intelligent urban systems.

VII. Trustworthiness, Security, Privacy, and Governance

Explanation systems generate controls and attack surfaces. They can uncover false correlations, show drift, aid audits, show unfair behavior, etc. Meanwhile, opponents can distort explanations, make inferences about sensitive content, or exploit explanations to avoid being detected. In the process of developing a secure XAI design, attacks on the predictive model, the explanation method, the data pipeline, and the explanation interface should be taken into consideration.

Adversarial explanation attacks are designed to maintain a model's prediction when the apparent evidence changes, or to maintain the apparent evidence when the model's behavior changes. Local explainers can be fooled by models that act differently at the points where they are sampled. Saliency maps may exhibit instability to small changes in the visual situation that do not matter. NLI can be prompted to produce unsupported rationales. Explanation consistency tests, multiple-method triangulation, signed provenance, robust feature pipelines, limited query access and periodic red-team evaluations are all defenses.

The risk to privacy occurs when explanations reveal input features, sensitive attributes, training examples, gradients or local model behavior. Explanations using examples might reveal identifiable records. Fine-grained attributions can show if the signal was sensitive or not. The raw data can be protected in federated systems, but information can be released via updates or explanations [69–75, 80]. Privacy-preserving XAI should try to suppress detail based on the audience; aggregation across groups, if possible; careful application of differential privacy; prevention of repeated-query reconstruction; and assessment of utility loss. Explanation queries should be incorporated into privacy budgets, besides model training.

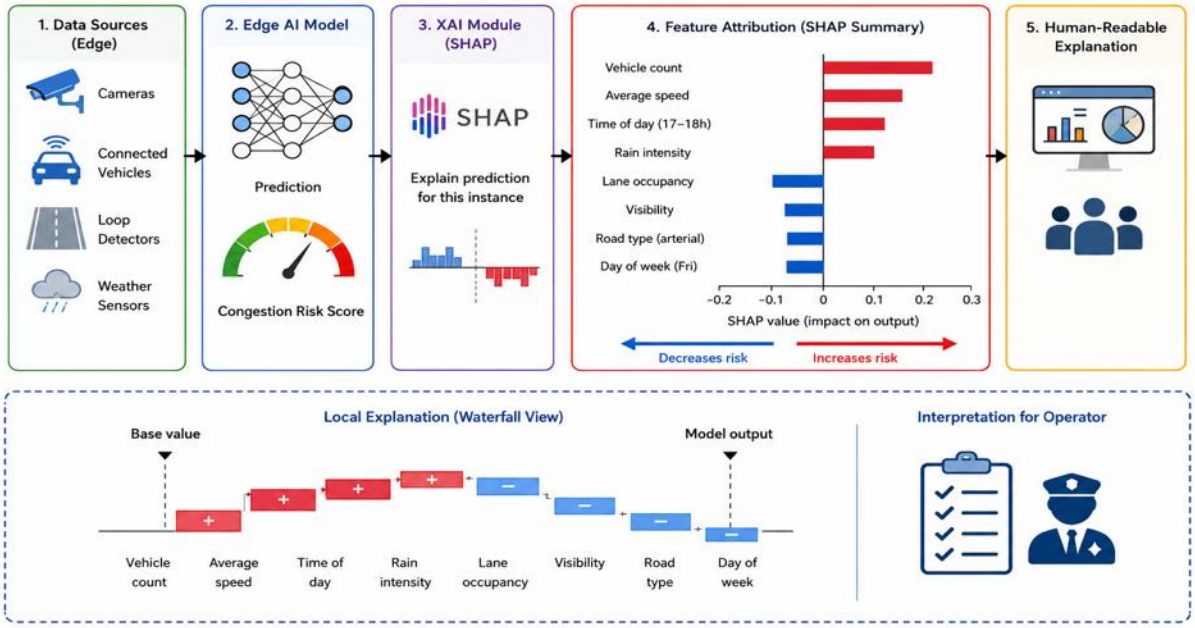

Fig. 4. Illustrative example of explainable artificial intelligence in trustworthy 6G edge-cloud urban intelligence.

TABLE VIII. Trustworthiness Threats, Controls, and Evaluation Evidence

Dimension	Representative threat	Recommended controls	Evidence/metrics
Fidelity	Explanation does not represent actual model behavior	Perturbation tests, surrogate fidelity, method triangulation	Fidelity score; deletion/insertion; completeness
Stability	Small irrelevant changes produce different explanations	Robust methods, consistency thresholds, drift monitoring	Sensitivity; rank correlation; variance
Security	Adversary manipulates prediction or explanation	Threat modeling, red teams, signed provenance, restricted interfaces	Attack success; detection rate; recovery time
Privacy	Explanation reveals sensitive features or records	Aggregation, access control, differential privacy, query limits	Membership/attribute inference; privacy budget
Fairness	Different groups receive unequal errors or action burdens	Subgroup evaluation, feasible counterfactuals, proxy analysis	Error gaps; explanation complexity and recourse gaps
Safety	Model acts outside validated conditions	Uncertainty, abstention, human escalation, fail-safe mode	Calibration; coverage-risk; incident rate
Accountability	No traceable owner or review process	Lifecycle audit, model registry, decision logs, appeal workflow	Trace completeness; audit findings; appeal outcomes
Usability	Explanation increases confidence but not decision quality	Task-based human studies, role-specific interface design	Decision accuracy; reliance; time; cognitive load
Sustainability	Explanation overhead is ignored	Adaptive detail, caching, edge placement, efficient models	Latency; memory; energy; communication volume

Representing the importance of features is not enough for fairness. Protected attributes may indirectly affect decisions via their proxies. Explanations need to be assessed within groups for fidelity, stability, complexity and actionability. The counterfactual recommendations need to be actionable and should not be inequitable to groups. The neighbourhood-level explanations require particular attention as the socio-economic and demographic patterns can be captured in spatial features. Fairness analysis should consider who is included in the data, who benefits, who suffers from errors, and who can appeal.

In the presence of sensor noise, missing data, distribution shift, and model updates, robustness and safety demand that explanations to be meaningful. Sometimes, explanation drift is present even with stable accuracy. At the other end of the spectrum, predictive responses can become problematic and explanations can seem familiar. Both should be monitored by systems. Uncertainty/explanation inconsistency above a threshold should provide abstention / human escalation for safety-critical workflows. Explanations should include when a case is outside of the validation domain.

Traceability and Institutional Design are key to Accountability. No one is responsible for reviewing the technical logs, which makes them insufficient. High-impact urban AI services should include an accountable owner, a documented purpose, a risk classification, data and model cards, an explanation policy, a monitoring plan, an incident process, and a retirement plan. The NIST AI Risk Management Framework provides a helpful framework for govern, map, measure and manage functions [63]. Internal algorithmic auditing should be conducted over the full life cycle of the algorithm, not just a single model test [57, 58].

Governance should also differentiate between transparency to experts and transparency to affected people. Specific model information might be helpful to auditors and not to citizens. Public explanations should explain in simple terms the decision and the consequences, not overstate or confuse causality with the factors involved, indicate the level of uncertainty, and provide guidance on how to seek review. Regulators and independent auditors require more access to data lineage, model behavior, performance by subgroup, security testing and operational logs.

The concept of sustainability is a less mature one of the dimensions of trust. Consuming energy and hardware resources involves continuous sensing, model training, edge inference, digital-twin simulation, and explanation generation. If the inference cost is doubled, then the explanation method may not be appropriate if the sensor is battery-powered or the system is deployed at a city scale. Other than fidelity and usability, evaluation should report latency, memory, communication, and energy overhead. Cost reduction may be achieved by using explanation caching, event-triggered generation, adaptive detail and shared edge services.

Major threats and controls are summarized in Table VIII. The key takeaway is that explainability should not be an afterthought when building a model but a service over which one can create policies to ensure security, privacy, and lifecycle controls.

VIII. Descriptive Trends and Maturity Assessment

The curated collection features 100 references from 2016–2026. As seen in Fig. 5, the surveys, trustworthy-AI frameworks, federated learning, digital twins, and 6G visions are all growing strongly, with a rapid increase after 2019. In later years, there are more integrated reviews, particularly regarding urban digital twins, edge AI, smart-city security, and XAI for buildings. This trend should not be seen as an overall publication count. It reflects the intentional composition of the corpus of the review.

As illustrated in Fig. 6, the focus of the explanation generation is primarily on the cloud and the digital-twin layer, in addition to mobile-edge and regional-edge environments. The attention given to network-level explanation is moderate while far edge gateways and end devices are underrepresented. This distribution indicates that the literature is still biased toward resource-rich, centrally or regionally based platforms capable of computation, whereas the generation of explanations at devices in real time under resource constraints is a relatively new and less explored field.

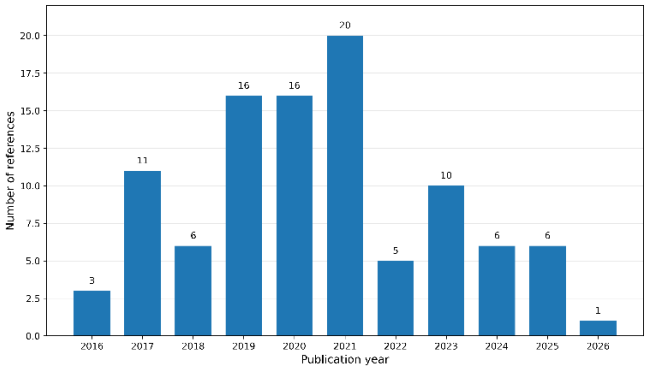

Fig. 5. Annual publication trend within the curated 100-reference corpus.

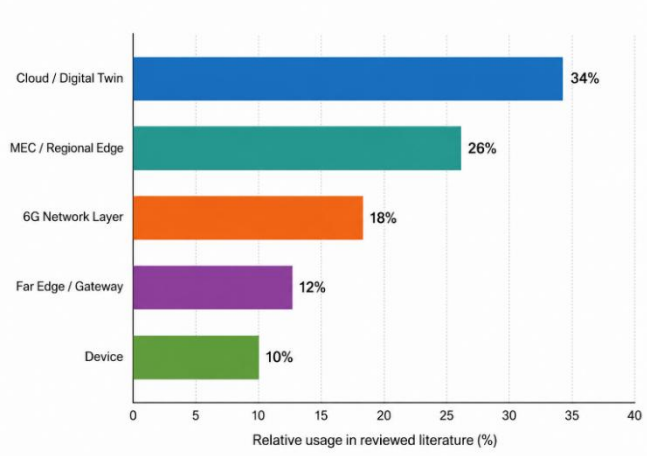

Fig. 6. Distribution of explanation generation across computing layers in the reviewed literature.

The thematic group with the most rows is explainability methods and evaluation, as shown in Fig. 7. This is only right and proper, as it builds on the topic's methodological basis as a built-in component. There are also sizeable supporting groups

of edge-cloud intelligence, federated learning, digital twins, 6G, trustworthy AI and smart-city systems. An important imbalance noted in the distribution is that while the maturity of a method is high, the maturity of evidence of its deployment in integrated 6G smart-city systems is low.

The four general lines of research are divided in Fig. 8. The level of explainability and trust increases gradually throughout the time period. The growth of Edge, federated learning and digital twins is strong following 2019. The 6G stream is later and more vision- and architecture-centric. A limited number of smart city application reviews are now enabling the connection between application explanations and network decisions, and between cross-layer provenance and application reviews.

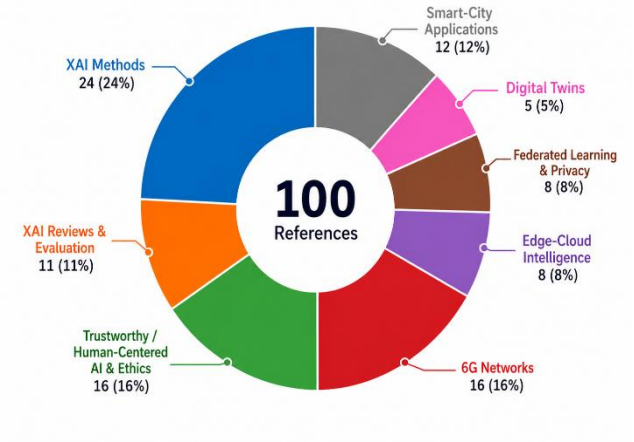

Fig. 7. Primary thematic distribution of the curated corpus.

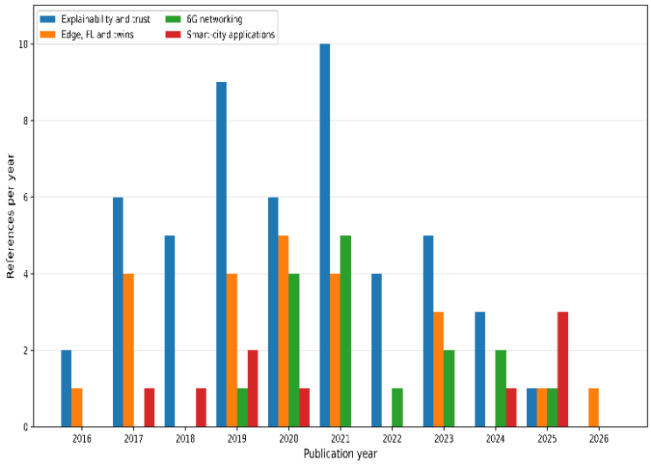

Fig. 8. Trend curves for four broad research streams in the curated corpus.

There is uneven maturity of methods. The maturity in tool availability and adoption is high, while causal interpretation and standardized evaluation are less mature. The conceptually appealing approach of counterfactuals is hard to bound for feasibility, safety and policy reasons. Concept-based and prototype methods facilitate communication in the domain, although they need to be based on high-quality concept definitions. For high-stakes situations, inherently interpretable models are well justified [32] but deployment teams tend to choose opaque models first and add explanations later. There is progress in human-centered evaluation, but a large number of studies are still using anecdotal examples or subjective ratings instead of task-based approaches [41, 43, 49, 51].

Infrastructure maturity is also uneven. Edge inference and federated training have extensive optimization literature, while explanation-aware placement is still emerging. There is little consensus on when an explanation should run locally, at a regional edge, or in the cloud. Digital-twin platforms face unresolved problems in semantics, data quality, governance, and visualization [78, 79]. 6G research provides ambitious service requirements, but explainability is not yet a standard network function [20, 82–94].

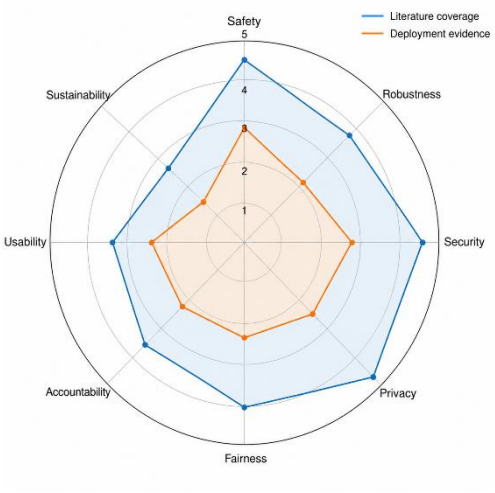

Fig. 9. Trustworthiness coverage in the literature versus deployment evidence across key dimensions.

The review identifies a recurring evaluation gap. Predictive metrics such as accuracy, F1 score, area under the curve, latency, and throughput are commonly reported. Explanation metrics are less consistent. Fidelity, stability, sparsity, completeness, localization, sensitivity, and human usefulness are measured with different definitions and protocols. Cross-layer metrics are rarer still. A useful evaluation framework should jointly measure predictive quality, explanation quality, operational cost, trust calibration, privacy leakage, fairness, and incident response.

A second gap is ecological validity. Many XAI studies use static benchmark datasets, while urban systems are temporal, spatial, multi-agent, and non-stationary. Explanations should be tested under sensor failures, communication loss, seasonal change, population shift, extreme events, and policy updates. A method that works on a clean offline test set may fail when data are compressed, delayed, or partially observed at the edge.

A third gap is stakeholder evidence. Developers and domain experts are often included, but affected citizens, field operators, accessibility experts, and public-sector auditors are less represented. Explanations should be evaluated for different expertise levels and languages. The same interface may need to support rapid operational decisions and slower public deliberation. Human-centered evaluation should measure decision accuracy, error detection, appropriate reliance, time, cognitive load, and the ability to contest an outcome. Fig. 9 compares the relative level of literature coverage and

deployment evidence across eight trustworthiness dimensions. The results show a consistent gap between conceptual research and practical validation.

IX. Future Research Agenda

The importance of real-time and resource-aware XAI. A significant challenge in edge-based applications that has not been sufficiently considered in existing works is that edge devices and mobile nodes need to provide explanations subject to tight latency, memory, energy, and communication constraints [8]. Future work should be based on designing adaptive explanation systems which adjust the level of detail according to risk, available computational resources, and audience. A safety alert may be a short indication code and level of confidence and then be expanded to a more detailed trace once the incident has concluded. Explanation overhead data should be provided for one representative hardware and realistic network conditions (Table IX).

Cities often employ several models and infrastructure services to make decisions. New methods should be developed that can incorporate explanations of data quality, evidence from the application model, decisions made about the orchestration of the networks, and policy rules and human actions into a coherent causal or procedural narrative. However, although the concept of a provenance graph is very promising, they still need to have sound semantics and a methodology for summarising complex traces without losing a lot of uncertainty.

Questions to be answered encompass: do local explanations for clients match up with the global explanation? Does heterogeneity affect the stability of explanations? How to aggregate explanation summaries without information leakage in local data? And what clients would be detrimental or biased in their behavior? Explanation metrics at client-level and at population-level should be included in federated evaluation. Evaluation of secure aggregation and differential privacy in terms of their impact on explanation fidelity is warranted. The fourth priority is that of explanation security. The researchers call for the development of threat models that account for evasion, poisoning, manipulation of explanations, extraction of models, membership inference, and interface attacks. Benchmarks should incorporate adaptive adversaries that attack explanations, in addition to predictions. Both security and usability should be evaluated when assessing defenses (defenses that are too restrictive can be counterproductive to accountability).

TABLE IX. Recommended Multidimensional Evaluation Framework

Evaluation level	Core measures	Why it matters
Predictive	Accuracy, F1, AUROC, calibration, uncertainty, subgroup performance	Confirms task competence and identifies uneven errors.
Explanation fidelity	Completeness, faithfulness, local surrogate fit, perturbation response	Tests whether the explanation reflects model behavior.
Explanation quality	Stability, sparsity, consistency, concept validity, feasibility	Assesses reliability and practical meaning.
Human factors	Decision quality, appropriate reliance, error detection, time, workload, accessibility	Measures whether people use explanations effectively.
Operational	Latency, memory, energy, bandwidth, availability, update compatibility	Determines whether XAI is viable at edge and city scale.
Trust and governance	Privacy leakage, attack resistance, fairness gaps, traceability, appeal outcomes	Connects technical evidence to institutional accountability.
Longitudinal	Prediction drift, explanation drift, incident trends, corrective action	Evaluates performance after deployment and model updates.

TABLE X. Future Research Agenda for Trustworthy 6G Edge-Cloud Smart Cities

Priority	Research question	Promising approach	Minimum evaluation
Resource-aware XAI	How can useful explanations meet millisecond, memory, and energy limits?	Adaptive detail, distillation, caching, event-triggered explanation	Fidelity plus latency, energy, memory, and failure-mode tests
Cross-layer composition	How can device, network, model, policy, and human evidence be combined?	Provenance graphs, explanation contracts, compositional summaries	Trace completeness, contradiction detection, user task performance
Federated explainability	How stable and private are explanations across heterogeneous clients?	Local/global comparison, secure aggregation, private explanation summaries	Client-level stability, privacy attacks, fairness and utility
Explanation security	How can systems resist manipulation and extraction?	Adversarial training, red-team benchmarks, signed evidence	Adaptive attacks, detection, degradation and recovery
Causal urban intelligence	Which interventions change outcomes rather than correlate with them?	Causal inference plus digital-twin simulation and constrained recourse	Assumption checks, external validity, intervention error
Uncertainty communication	How should systems explain uncertainty and out-of-domain cases?	Conformal prediction, ensembles, calibrated abstention	Calibration, coverage, human escalation quality
Human-centered and participatory XAI	Which explanations improve decision quality and calibrated reliance across urban stakeholders?	Controlled task-based studies comparing no-XAI and XAI conditions; stakeholder-stratified experiments; multilingual/accessibility testing; scenario-based failure tests; field trials	Decision accuracy; error-detection rate; appropriate reliance; over-/under-reliance; objective comprehension; task time; cognitive workload; accessibility gap; contestability/appeal success
Interoperability	How can explanations move across vendors and agencies?	Standard schemas, semantic models, model registries	Cross-platform exchange and audit reproducibility
Sustainable XAI	What is the full resource cost of continuous explanation?	Efficient models, placement optimization, shared edge services	Energy, carbon, hardware and communication lifecycle
Institutional learning	How do explanations lead to correction and policy change?	Incident-to-action workflows and governance analytics	Time to correction, repeated incidents, audit and appeal outcomes

Many decisions in the city are decisions to intervene, such as changing signal timings, retrofitting buildings, changing emergency service distribution or enacting environmental regulations. Feature importance is not enough for such questions. Future research should combine causal inference, digital-twin simulation and actionable counterfactual generation. Explanations are supposed to be clear and make a distinction between correlation, prediction, and intervention statements.

City systems are partially sensed and have distribution drift. Epistemic and aleatoric uncertainties, data coverage, model disagreement, and scenario sensitivity should also be conveyed in such explanations. The effect of uncertainty visualization on the operator's decision-making and public perception needs to be focused on in research. When uncertainty is ineliminable, systems must abstain or escalate.

Needs for explanation should be co-designed by operators, citizens and policy makers and vulnerable groups. Research should measure calibrated dependence, rather than simply personal trust. They should assess accessibility, translation and language accessibility, numeracy, and cognitive load. Participative design is more appropriate for allocation of resources at the neighborhood level, surveillance, welfare and mobility. The eighth priority states: Interoperable explanation standards. In urban platforms, vendors, protocols, models, and agencies are mixed. Standardized schemas need to be developed for explanation metadata, provenance, uncertainty, model versions, data quality, stakeholder roles, and appeal status. The standards will be expected to help machines to share and describe the data to be presented to humans. They should also be consistent with requirements on AI risk management, cybersecurity, privacy and public records.

The energy and carbon costs of generating explanations, particularly for continuous monitoring and large digital twins, should be quantified by investigators. There are a number of techniques that should be explored: caching explanations, approximate but bounded explanations, shared regional services, model distillation, and event-triggered analysis. Infrastructure lifecycle and communication overhead should be associated with (sustainable) inference energy in sustainability claims.

Mechanisms for cities to learn from incidents, appeals, audit findings, and model drifts are what they require. In the future, if possible, the explanatory logs should be connected to corrective action, procurement, policy revision, service redesign, et cetera. It should study how institutions (not just individuals) make sense of and act upon explanations.

Evaluation of XAI from a human-centred and participatory perspective. Future research should go beyond measuring satisfaction ratings and analyze explanations with more rigorous task-based experiments and field studies that involve the stakeholders of the real-life application or impact of urban AI systems. Evaluation, at a minimum, should include comparing a no-explanation condition to one or more explanation conditions, and the same decision tasks. Stratification should be based on the stakeholders' roles in the system, or domain, as system operator, auditor, domain expert, policy maker, and affected citizens, as explanation needs vary significantly between these groups. Experiments should also cover normal operation conditions as well as realistic failure scenarios, such as incorrect model prediction, uncertainty, sensor degradation, communication delay, and distribution shift.

Measurable criteria should be used to operationalize the human- centered outcomes. The accuracy of decisions should be reported as the percentage of the human's final decisions that are correct. The error-detection rate should assess what percentage of the times the AI's recommendations are wrong are accurately detected by the user. The appropriate reliance should include both acceptance of correct AI recommendations and rejection of incorrect AI recommendations, and over-reliance and under-reliance should be recorded separately. The comprehension of the explanation should be measured by objective questions related to the factors, uncertainty or alternatives offered in the explanation and NOT by a subject's self-report of understanding. Other measures should include time spent completing the task, cognitive load, access across languages and user types, and the percentage of successful identification and correction of an incorrect decision based on a task completion challenge or appeal. Studies should include confidence intervals and effect sizes and, if applicable, test for significant differences between the effect size and confidence interval for the different explanations, stakeholder groups, languages and operational conditions. An additional protocol could help future research not only identify whether the users like an explanation, but whether an explanation is actually improving the quality of the decisions, calibrated reliance and contestability.

Table X provides a breakdown of these category priorities into research questions, potential methods, and evaluation criteria. The expected mature program of research would provide replicable data and testbeds for interweaving application models, edge constraints, network behavior, digital twins, and governance workflows. This is more cumbersome than assessing a single classifier, but is more representative of the real system.

X. Engineering and Policy Guidelines

The review provides a feasible sequence for designing explainable urban AI. The decision and harm model should be used to start the teams rather than an explanation tool. They should determine who is impacted, what errors are significant, what legal or policy boundaries are involved and where human intervention could be made. These questions lead to the following explanation.

Data governance should record data sources, consent/legal basis, data coverage, missingness, quality, retention, and other sensitive attributes. Spatial and temporal representativeness needs to be evaluated. Edge preprocessing and semantic compression should all be included in data lineage. If information is lost from a network or device, the system should document the change and its likely consequences.

Interpretability is a design goal to be considered when choosing a model. When stakes are high, the baseline should be an inherently interpretable model or constrained architecture. More complex models should give some

meaningful improvement in performance and have a plan in place for how to validate explanations. Teams should not choose SHAP, LIME or saliency just because they have always used them. The approach should align with the question of the stakeholder and the type of data.

The explanation contract should specify the type of decision, who the audience is, why the decision is needed, the way the decision is transported, the fidelity expected, how the uncertainty is represented, the latency budget, the level of privacy, the period of time the decision will be stored, and the escalation path. In the case of low-risk optimization, a technical dashboard might be enough. The contract should contain a plain-language notice, reasons, uncertainty and an appeal process for consequential public decisions.

Monitoring should be included in the deployment for predictive drift, explanation drift, subgroup performance, privacy leakage, latency, energy, and security incidents. Explanation regression tests should be performed depending on model updates. Explanations of equivalent test cases should be consistent within limits of tolerance. It is still important to review changes in key features or recommendations for counterfactuals, even if there is no change in the accuracy of the aggregate.

Human supervision must be targeted at specific things. There are not enough with the statement "a human is in the loop." The design should define who will be reviewing what cases, what information will be provided to them, how much time they will have, whether they can override the model, and how the overrides will be documented. Failure modes and uncertainty need to be part of the training. There should be no reward for operators who blindly follow the model.

Access to Performance evidence, model documentation, data documentation, security testing, explanation capabilities, update policies and support for audit should be required for procurement and vendor management. Where public rights or essential services are involved, contracts must require vendors to keep all model behavior confidential unless they choose to release it. Meanwhile, transparency controls should not reveal sensitive information that can be exploited by attackers.

Technical theater should be avoided when communicating to the public. Without citizen understanding or action, a colourful saliency map is not providing much transparency. Notices should provide information about what the system did, primary evidence categories, use of AI, uncertainty, data limitations, and review options. Aggregate performance or disparities, incidents, changes and corrective actions should be reported.

Last but not least, retirement comes as a life stage. Models should be removed when the situation they are operating in changes, data quality decreases, risks outweigh benefits or support is discontinued. Explanation and provenance records should continue to be available as per legal and accountability requirements. Table XI offers a quick reference implementation checklist.

TABLE XI. IMPLEMENTATION CHECKLIST

Area	Required evidence or action
Purpose and risk	Define decision, affected groups, harms, legal basis, and human authority.
Data	Document provenance, quality, spatial/temporal coverage, sensitive attributes, and retention.
Model	Establish interpretable baseline; justify complexity; test uncertainty and subgroup performance.
Explanation contract	Specify audience, purpose, method, fidelity, latency, privacy, retention, and escalation.
Architecture	Choose device, edge, network, cloud, or twin placement and preserve cross-layer provenance.
Security/privacy	Threat-model predictions and explanations; control access and repeated queries.
Human factors	Test decision quality, appropriate reliance, accessibility, language, and cognitive load.
Monitoring	Track predictive and explanation drift, incidents, latency, energy, and fairness.
Accountability	Assign owner; maintain audit, appeal, correction, vendor, and change-management processes.
Retirement	Define withdrawal criteria, archival obligations, and replacement or rollback procedures.

XI. CONCLUSION

Trustworthy and explainable AI for 6G-enabled edge-cloud smart cities is not a single algorithmic problem. It is a Transforming 6G-enabled edge-cloud smart cities with reliable and interpretable AI is not a simple algorithmic challenge. It is a problem of system design and governance, involving issues of data quality and model behaviour, distributed computation, network intelligence, digital twins, human decision-making, and public accountability. While there are well-developed bases for local attribution in the literature, and a developing array of evaluation frameworks, integrated deployment is lacking. The review reveals that explanations need to be role-specific, risk-sensitive, and related to provenance. Immediate safety and diagnostics are assisted by means of device-level explanations. Edge-level explanations support operations and federated coordination. Network-based explanations reveal resource and mobility decisions. Cloud and cloud-twin explanations enable scenario analysis, policy assessment, and public responsibility. These layers should have a traceable evidence chain.

Real-time resource-aware methods, federated explanation consistency, causal and counterfactual reasoning, uncertainty communication, explanation security, interoperable standards, sustainable computation and participatory evaluation are future directions that will enable further progress. It is not enough for an AI system to be able to provide an explanation on demand to be successful. They should assess the faithfulness, usefulness, privacy considerations, security, accessibility, and

meaningful review and correction of the explanation. That is the basis for urban intelligence that deserves trust.

Feature Selection Versus Feature Extraction for IoT Intrusion Detection Under Temporal Evaluation

Mahdia Abdessamad, El Bachir Tazi
Polydisciplinary Faculty of Taza, Sidi Mohamed Ben Abdellah University, Fez, Morocco

Abstract*—Comparative studies of feature selection (FS) and feature extraction (FE) for IoT intrusion detection rely almost universally on random train/test splits, which let temporally adjacent, highly similar records appear on both sides of the partition. This study asks whether such conclusions survive when this evaluation leakage is removed. We reproduce the detection-performance component of the framework of Li et al. on the TON-IoT network dataset — identical preprocessing, correlation-based selection versus PCA-based extraction, five classifiers, and matched dimensionalities $K \in \{9, 22, 33, 47, 77\}$ — varying only the partitioning rule across random stratified, global temporal, and per-class temporal protocols. At K = 9, the reference Decision Tree falls from 86.81% binary macro-F1 under random splitting to 58.04% under the global temporal protocol, in which unseen attack classes constitute 45.6% of the test records. In the multiclass task at K = 47, the same configuration declines from 93.14% to 14.26%, while the mean Matthews correlation coefficient (MCC) across 100 configurations falls from 0.638 to 0.196, a relative loss of approximately 69%. The family-level recommendation is directionally robust: for the single redundancy-oriented correlation selector evaluated here, PCA-based extraction outperforms selection in all three protocols (Wilcoxon over 50 matched pairs per protocol, $p < 10^{-6}$). Configuration-level orderings and the identity of the best classifier, however, are protocol-dependent. Established for the specific selector and extractor evaluated, these findings indicate that feature-reduction guidance for IoT intrusion detection should be validated under leakage-resistant protocols, with macro-averaged metrics and MCC reported alongside accuracy.

Keywords*—Internet of things; intrusion detection; feature selection; feature extraction; data leakage; temporal evaluation; concept drift; TON-IoT; machine learning

I. Introduction

The Internet of Things (IoT) connects a rapidly growing number of heterogeneous physical devices across domains such as smart homes, transportation, healthcare, and industrial automation, enabling intelligent services through interconnected sensing and communication technologies [1]. However, their limited computational resources make it difficult to implement robust security mechanisms, leaving them vulnerable to a wide range of cyberattacks. Consequently, network Intrusion Detection Systems (NIDS) have become an important line of defense for protecting IoT networks [2].

Network traffic datasets often contain numerous connection features, motivating the use of feature reduction techniques for intrusion detection [3]. Feature reduction methods are broadly categorized into feature selection (FS), which retains a subset of the original features, and feature extraction (FE), which transforms the original features into a lower-dimensional representation. Feature selection removes irrelevant and redundant features, reducing computational cost while improving detection performance and preserving the interpretability of the retained features [4]. Feature extraction produces compact representations that can combine information from all original features, at the cost of interpretability. Selecting an appropriate feature reduction strategy remains a recurring practical decision, motivating numerous empirical comparisons between feature selection and feature extraction [3], [4].

Among the existing comparisons, the study by Li et al. [3] provides a comprehensive evaluation of Feature Selection (FS) and Feature Extraction (FE) for IoT intrusion detection. Using the TON-IoT dataset, the authors compared correlation-based FS with PCA-based FE under the same reduced feature dimensions and evaluated five machine learning classifiers for both binary and multiclass classification. Their results showed that FE generally achieved better detection performance when only a small number of features were retained and was less sensitive to changes in the number of retained features, whereas FS required less training and inference time and became more competitive as the number of retained features increased. Ngo et al. [4] conducted a similar comparison on the UNSW-NB15 dataset using Pearson correlation-based feature selection and PCA-based feature extraction and reported similar findings.

Many existing studies evaluate intrusion detection models using random train/test splits rather than temporal splits. However, random splitting can place temporally related or highly similar traffic samples in both the training and test sets, leading to overly optimistic performance estimates that may not reflect real-world deployment. Pendlebury et al. demonstrated that temporal and spatial experimental biases can substantially inflate the reported performance of machine learning security models, while Arp et al. identified data snooping as one of the most prevalent pitfalls in machine learning-based security research, reporting that it was at least partly present in 73% of the reviewed studies [5], [6].

Recent studies across security and applied machine-learning domains have adopted temporal evaluation, including adversarially robust NIDS validated on official temporal partitions [7], industrial anomaly-detection benchmarks that compare random and temporal evaluation protocols [8], memory-analysis malware detection evaluated under concept drift [9], and IoT denial-of-sleep attack detection evaluated using chronological splits [10]. These studies demonstrate the increasing use of temporal evaluation for validating individual detection models.

Despite the increasing adoption of temporal evaluation, existing studies primarily evaluate the robustness of individual intrusion detection models. To the best of our knowledge, no study has investigated whether the comparative conclusions of the feature selection versus feature extraction literature remain stable when evaluation changes from random train/test splitting to temporally consistent protocols. Consequently, it remains unclear whether the relative ranking of feature reduction strategies is robust to evaluation methodology.

This study addresses that gap by investigating whether the comparative conclusions reported for feature selection and feature extraction remain valid under temporally consistent evaluation. The research question is: Do the comparative conclusions regarding feature selection and feature extraction remain valid under temporally consistent evaluation compared with conventional random train/test splitting? To answer this question, we preserve the experimental framework of Li et al. [3]including the dataset, preprocessing, feature reduction methods, classifiers, hyperparameters, and matched feature dimensionalities, while modifying only the evaluation protocol. The main contributions of this study are as follows:

- We revisit the experimental framework of Li et al. under identical preprocessing, feature reduction methods, and classifiers, with a single documented adjustment to the MLP iteration limit, establishing a random-split baseline that qualitatively reproduces their principal detection-performance findings.
- We define three evaluation protocols, including a global temporal split and a per-class temporal split, designed to reduce evaluation leakage relative to random splitting and to enable the degradation analysis presented in Section IV-D, subject to the dataset limitation identified in Section IV-F.
- We analyze how the evaluation protocol affects the relative ranking of feature selection and feature extraction methods, as well as classifier rankings, using Wilcoxon signed-rank tests and Kendall's τ rank-correlation coefficients.
- We analyze the impact of temporal evaluation on accuracy, precision, recall, macro-F1, and the Matthews correlation coefficient (MCC), showing that these metrics degrade to different extents, with MCC exhibiting the largest relative loss, and that accuracy alone can remain moderate while macro-averaged performance falls to very low absolute levels.
- We decompose the performance degradation of a fixed reference classifier into within-class temporal drift and unseen-class effects, showing that the relative weight of the two mechanisms depends on dimensionality, classifier, and reduction method, and we highlight a structural limitation of TON-IoT — whose attack classes are captured in short bursts — for per-class temporal evaluation.

II. Related Work

A. Feature Selection and Feature Extraction in Intrusion Detection

Feature selection methods for NIDS are conventionally organized into three families. Filter methods score features independently of any classifier using statistical criteria such as correlation, mutual information, information gain, or chi-square. Li et al. [3] adopt a correlation-based criterion that removes mutually redundant features. Hall's Correlation-based Feature Selection (CFS) framework [11] is the canonical relevance-and-redundancy formulation of this family, combining feature–class correlation with feature–feature inter-correlation. Wrapper methods evaluate candidate subsets by training a classifier on each, offering higher accuracy at substantially greater computational cost. Embedded methods perform selection during model training, for example through tree-based impurity importance or regularization penalties. Feature extraction methods are correspondingly organized by the nature of the transformation: linear projections such as principal component analysis, kernel-based nonlinear projections, and deep representation learning through autoencoders [12]. Because autoencoder-based extraction incurs substantially higher computational cost in both training and inference than statistical projection, PCA is commonly adopted for latency-sensitive IoT deployments [3].

Existing studies have more often evaluated individual feature reduction techniques than directly compared feature selection and feature extraction under a common experimental protocol. Ngo et al. [4] compared correlation-based selection against PCA on UNSW-NB15 across several classifiers and dimensionalities and reported that extraction was preferable at very small dimensionalities while selection became competitive and computationally cheaper as dimensionality increased. Li et al. [3] performed the most comprehensive comparison of which we are aware on Network TON-IoT, spanning five classifiers, matched dimensionalities of 9, 22, 33, 47, and 77 features, and both binary and multiclass tasks; they additionally reported feature-reduction, training, and inference times, concluding that the Decision Tree offered the best accuracy–runtime compromise for both families. Related studies have examined individual reduction techniques rather than family-level comparisons: ensemble and hybrid selection strategies [13]and stacked sparse autoencoder extraction evaluated for its effect on downstream classifier accuracy and runtime [12]. What unites this body of work, and motivates the present study, is that its conclusions are established exclusively under random partitioning.

B. Evaluation Bias and Data Leakage in Security Machine Learning

The reliability of evaluation protocols is a long-standing concern. Ambroise and McLachlan [14] showed that performing feature reduction outside a properly isolated evaluation loop yields severely biased error estimates — a principle directly relevant to comparative evaluations involving feature selection or feature extraction. Pendlebury et al. [5] introduced the TESSERACT framework, distinguishing temporal bias (incorrect time ordering between training and test data) from spatial bias (unrealistic class distributions at test time), and

demonstrated that removing both deflates malware-detection scores that had appeared near-perfect. Arp et al. [6] catalogued ten recurring pitfalls across thirty high-profile security papers, finding sampling bias and data snooping to be the most prevalent, and explicitly warned that a NIDS may learn to recognize an address range rather than generic attack behavior. A dataset-quality study documented labeling and construction artifacts in the widely used CICIDS2017 dataset [15]. For IoT specifically, Chikezie et al. [16] proposed a scientific integrity framework that established a device-disjoint, leakage-audited preprocessing substrate for the large CICIoT-DIAD 2024 corpus while explicitly deferring classifier-level conclusions to later experiments. A recent survey of deep-learning-based flow intrusion detection likewise catalogues evaluation failure modes that can inflate reported results — including temporal leakage, flawed data splitting, and weak cross-dataset generalization [17]. To the best of our knowledge, none of these studies examine whether comparative FS-versus-FE guidance survives leakage-resistant evaluation.

C. Temporal Evaluation Across Application Domains

Temporal protocols are increasingly adopted as deployment-faithful practice beyond malware analysis. Hybrid deep NIDS architectures have been validated under the official temporal partition of UNSW-NB15 to confirm that binary detection generalizes under distribution shift [7]. In industrial visual anomaly detection, a recent benchmark adopts a temporal train/test split as its primary protocol and defines the difference in performance between random and temporal splits as an explicit generalization metric, reporting that method rankings change between protocols [8]. Memory-analysis malware detection has been re-evaluated under temporal splits to capture concept drift [9], and IoT denial-of-sleep detection has been confirmed under chronological evaluation [10]. Cross-dataset studies reinforce this warning: although Random Forest achieved 95.08% accuracy on UNSW-NB15 and 99.79% on TON-IoT under same-dataset evaluation, its accuracy dropped below 40% when evaluated across datasets, demonstrating that strong within-dataset performance may substantially overestimate real-world generalisation and deployable performance [18]. Collectively, these works validate individual detectors under time-consistent protocols. The present study extends this line of enquiry in a different direction: rather than asking whether a given detector remains effective, it asks whether a comparative methodological conclusion—the FS-versus-FE ranking—remains valid, which requires holding the entire experimental pipeline fixed while varying only the partitioning rule, whose downstream effects on temporal window and class availability are themselves the object of study.

III. Methodology

The design principle of this study is the strict isolation of a single experimental variable. We reproduce the experimental framework of Li et al. [3], including the preprocessing pipeline, feature-reduction methods, classifiers, and hyperparameter settings (specifically, the detection-performance component of their study; feature-reduction and inference timings are outside the present scope), with the sole exception of the implementation adjustment described in Section III-B. Within this reproduced framework, the only experimental factor deliberately varied is the data-partitioning rule; because this rule governs how records are assigned to the training and test sets, it necessarily induces the differences in temporal window and class availability documented in Section III-C, which are consequences of the partitioning rule rather than independently manipulated variables. Consequently, comparisons among the evaluation protocols are conducted under otherwise identical experimental conditions, allowing the influence of the evaluation protocol to be assessed independently. Fig. 1 summarizes the complete pipeline and identifies the stage at which the three evaluation protocols diverge.

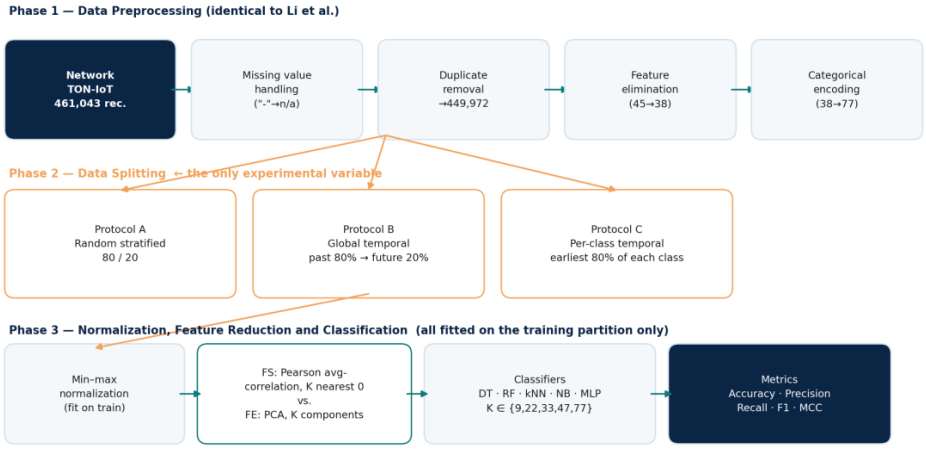

Fig. 1. Experimental pipeline. Only the data-splitting stage (Phase 2) varies across the three evaluation protocols.

A. Dataset

Experiments use the TON-IoT Network dataset [19] in its standard Train_Test_Network.csv form, a benchmark subset of the complete TON-IoT network dataset intended for fair evaluation of AI-based cybersecurity solutions. The dataset contains 461,043 labeled network flow records extracted from Zeek, organized into 45 columns: the timestamp attribute (ts), four flow identifiers (source and destination IP addresses and ports), 38 traffic features, and two labels: a binary label (normal/attack) and a ten-class type label representing normal

traffic and nine attack categories (backdoor, DDoS, DoS, injection, MITM, password, ransomware, scanning, and XSS). The timestamp attribute is retained to construct the temporal evaluation protocols but excluded from the feature matrix.

B. Preprocessing and Feature Reduction Pipeline

The preprocessing sequence, feature-reduction methods, classifier configurations, and hyperparameter settings are kept identical across all experiments; the only experimental variable is the data partitioning strategy (Phase 2 in Fig. 1). Table I summarizes each preprocessing and reduction step together with its output, and Table II lists the classifier hyperparameters. To prevent information leakage, all fitted transformations—min–max normalization, Pearson correlation ranking, and PCA—are fitted exclusively on the corresponding training partition and then applied to the associated test partition.

TABLE I. PREPROCESSING AND FEATURE REDUCTION PIPELINE (IDENTICAL ACROSS ALL PROTOCOLS)

Step	Operation	Output
1	Input: Train_Test_Network.csv	461,043 records × 45 columns
2	Missing-value handling: '-' entries replaced with an explicit 'n/a' category	—
3	Duplicate removal, applied to the raw records before identifier removal (11,071 exact duplicates)	449,972 records
4	Feature elimination: timestamp and the four flow identifiers excluded from the feature matrix	38 traffic features
5	Categorical encoding: one-hot for low-cardinality attributes (proto, service, conn_state, DNS/SSL flags, http_method, http_version); binary presence encoding for high-cardinality text attributes (dns_query, ssl_version/cipher/subject/issuer, http_uri, http_user_agent, MIME types, weird_* attributes, http_trans_depth)	77 numerical features
6	Data partitioning: Protocol A, B, or C (Section III-C)	80% training / 20% test
7	Min–max normalization, fitted on the training partition only	features scaled to [0, 1]
8	Feature reduction, fitted on the training partition only — FS: Pearson average-correlation score, K features nearest zero; FE: PCA, first K components; K ∈ {9, 22, 33, 47, 77}	K features/components
9	Classification with the five classifiers of Table II; three seeds (42, 43, 44) for stochastic models	metrics of Section III-D

TABLE II. CLASSIFIER HYPERPARAMETER SETTINGS

Classifier	Hyperparameter settings
Decision Tree (DT)	criterion: Gini; splitter: best; max_depth: none; random_state: seed
Random Forest (RF)	n_estimators: 100; criterion: Gini; max_depth: 5; random_state: seed
k-Nearest Neighbors (kNN)	n_neighbors: 3; Euclidean distance
Gaussian Naïve Bayes (NB)	default parameters
Multi-Layer Perceptron (MLP)	hidden_layer_sizes: 100; activation: ReLU; alpha: 10^{-4}; batch_size: auto; learning_rate: constant; max_iter: 500 with early stopping (adjusted from 200; see text)

Feature selection (FS) computes the Pearson correlation matrix on the training partition and retains the K features whose average pairwise correlation is closest to zero. Feature extraction (FE) applies PCA fitted on the training partition and projects both partitions onto the first K principal components. The matched dimensionalities $K \in \{9, 22, 33, 47, 77\}$, with $K = 77$ corresponding to the full encoded feature set and serving as a no-reduction control.

One implementation adjustment was required for the Multi-Layer Perceptron (MLP). The original configuration specified a maximum of 200 training iterations; however, under our implementation, the model did not consistently converge within this limit. The maximum number of iterations was therefore increased to 500, and early stopping was enabled. This adjustment was applied uniformly across all evaluation protocols to preserve a fair comparison.

C. Evaluation Protocols

The three evaluation protocols differ only in how the training and test partitions are constructed; all subsequent preprocessing, feature reduction, classifier configurations, and hyperparameters remain identical.

Protocol A — Random Stratified Split. Records are partitioned into 80% training and 20% testing using random stratified sampling on the ten-class label. This protocol serves as the baseline and enables direct comparison with the published results.

Protocol B — Global Temporal Split. To isolate the effect of temporal evaluation, the same 80/20 partition ratio is preserved while replacing random sampling with chronological ordering. Records are sorted by timestamp; the earliest 80% form the training set and the latest 20% form the test set. Class balance is intentionally not enforced. Because attack campaigns in the dataset occur during distinct time intervals, the resulting partitions are strongly imbalanced with respect to class availability, as shown in Table III. This protocol most closely reflects operational deployment, where models are trained on historical traffic and evaluated on future traffic, and naturally introduces a partial zero-day scenario (using "zero-day" in the evaluation sense common in the IDS literature, i.e., attack classes absent from training rather than previously unknown vulnerabilities).

TABLE III. CLASS AVAILABILITY UNDER PROTOCOL B (GLOBAL TEMPORAL SPLIT)

Class	In training partition	In test partition	Training records	Test records	Availability
normal	Yes	Yes	253,015	35,914	Seen
ddos	Yes	No	20,000	0	Training only
dos	Yes	No	20,000	0	Training only
injection	Yes	No	20,000	0	Training only
password	Yes	No	20,000	0	Training only
scanning	Yes	No	20,000	0	Training only
xss	Yes	Yes	6,962	13,038	Seen
backdoor	No	Yes	0	20,000	Unseen (zero-day)
mitm	No	Yes	0	1,043	Unseen (zero-day)
ransomware	No	Yes	0	20,000	Unseen (zero-day)
Total	—	—	359,977	89,995	—

a. Record counts are obtained directly from the partitioning code used in the experiments.

Record counts are obtained directly from the partitioning code used in the experiments. Five attack classes occur only in the training period and three only in the test period; the unseen classes account for 41,043 of the 89,995 test records (45.6%).

Protocol C — Per-Class Temporal Split. The same temporal principle is applied independently within each class. Records belonging to each class are ordered chronologically, and the earliest 80% are assigned to the training set while the latest 20% form the test set. Every class is therefore represented in both partitions while temporal ordering is preserved within each class.

Because Protocol A applies stratified sampling and Protocol C applies an 80/20 split within each class, both protocols produce identical class proportions in the training and test partitions; they differ only in whether the assignment within each class is random or chronological. This protocol is therefore designed to isolate within-class temporal drift while eliminating the missing-class effect, although Protocols B and C do not evaluate on identical time windows, since Protocol C draws its test partition from within each class rather than from a single terminal period.

Consequently, the difference between Protocols A and C estimates the impact of within-class temporal drift, whereas the difference between Protocols C and B estimates the additional effect of previously unseen attack classes, under the assumptions discussed in Section IV-D.

Quantitatively, the train–test class-prior divergence differs sharply across the protocols: computed directly from the partition counts (Table III for Protocol B), the total-variation distance between the training and test class distributions is approximately zero under Protocols A and C — both equalize class proportions by construction — and 0.58 under Protocol B. Because Protocol C draws each test segment from within its class's own capture span rather than from a single terminal window, Protocols B and C also differ in their boundary timestamps; the per-class temporal spans reported in Section IV-F (93 s to 8,687 s for the attack classes against 25.7 days for benign traffic) bound the temporal windows involved.

D. Evaluation Metrics

The same evaluation metrics are used across all three protocols: accuracy, precision, recall, F1-score, and the Matthews Correlation Coefficient (MCC). Precision, recall, and F1-score are reported as macro averages. Macro-averaging is particularly appropriate for the present study because it assigns equal weight to every class regardless of prevalence. Under the temporal protocols, the test-set class composition can diverge substantially from that of the training set—for example, under Protocol B, classes absent from training account for 45.6% of the test records (Table III)—so accuracy may remain moderate while macro-averaged performance falls to substantially lower absolute levels. Macro-averaged metrics expose this behavior, whereas accuracy or micro-averaged metrics would largely reflect the performance of the dominant classes. MCC complements these measures by summarizing the entire confusion matrix into a single coefficient that remains comparable when the test-set class composition changes across protocols, as it does here. Because Decision Trees, Random Forests, and MLPs involve randomized training procedures, each experiment is repeated using three random seeds (42, 43, and 44), and the results are reported as mean ± standard deviation. Deterministic methods (k-Nearest Neighbors, Gaussian Naïve Bayes, PCA, and correlation-based feature selection) are executed once.

E. Implementation Environment

All experiments were executed within a single implementation in which one preprocessing pipeline was applied to all three protocols, ensuring that the protocols differ in nothing but the partitioning rule. Table IV summarizes the computational environment.

TABLE IV. HARDWARE AND SOFTWARE SPECIFICATIONS OF THE IMPLEMENTATION ENVIRONMENT

Component	Description
Computing platform	Kaggle Notebooks (CPU runtime)
Processor	AMD EPYC 7B12, 4 virtual CPUs
RAM	30 GB
Operating system	Linux 6.12.90+ (x86_64)
Python	3.12.13
Core packages	Pandas 2.3.3; NumPy 2.0.2; SciPy 1.16.3; Scikit-learn 1.6.1
Random seeds	42 (global); 42, 43, 44 (repetitions)

IV. RESULTS AND DISCUSSION

The analysis addresses the research question through four complementary dimensions: whether the evaluation protocol changes measured performance (Section IV-A), whether the FS-versus-FE ranking remains stable (Section IV-B), how the individual metrics respond (Section IV-C), and how the observed degradation decomposes into distinct mechanisms (Section IV-D). Sections IV-E to IV-G then examine classifier-level behavior, a structural limitation of the dataset, and the practical implications of these findings.

Tables V and VI summarize the results using macro-F1 as the primary performance metric. For each protocol, method, and feature dimensionality, the classifier with the highest macro-F1 score is reported. Complete results for all five evaluation metrics (accuracy, precision, recall, macro-F1, and MCC) for every classifier and configuration are provided in Tables IX–XXXVIII of the Appendix.

TABLE V. BINARY CLASSIFICATION — MACRO-F1 (%) ACROSS THREE EVALUATION PROTOCOLS (BEST CLASSIFIER PER CELL)

K	Rand FE	Rand FS	Glob-Temp FE	Glob-Temp FS	PerClass FE	PerClass FS
9	86.81 (DT)	78.55 (DT)†	66.23 (kNN)	37.00 (NB)	69.83 (MLP)	61.84 (DT)†
22	94.31 (DT)	79.28 (DT)†	67.57 (DT)	61.95 (kNN)	81.88 (DT)	62.74 (DT)
33	98.10 (DT)	85.86 (DT)	83.56 (DT)	65.17 (kNN)	86.63 (DT)	70.15 (DT)
47	99.15 (DT)	94.44 (DT)	93.08 (kNN)	72.38 (DT)	95.56 (DT)	94.16 (DT)
77	99.18 (DT)	99.26 (DT)	94.53 (kNN)	92.68 (kNN)	95.59 (DT)	95.73 (DT)

b. Rand = Protocol A (random stratified); Glob-Temp = Protocol B (global temporal); PerClass = Protocol C (per-class temporal). Winning classifier in parentheses.

c. Exact tie between two or more classifiers at full precision; ties are credited to the Decision Tree here and in the dominance counts of Section IV-E.

TABLE VI. MULTICLASS CLASSIFICATION — MACRO-F1 (%) ACROSS THREE EVALUATION PROTOCOLS (BEST CLASSIFIER PER CELL)

K	Rand FE	Rand FS	Glob-Temp FE	Glob-Temp FS	PerClass FE	PerClass FS
9	46.15 (DT)	29.33 (DT)	12.96 (NB)	9.51 (kNN)	45.10 (DT)	27.77 (DT)‡
22	71.91 (DT)	32.42 (DT)	14.88 (NB)	11.09 (DT)	62.84 (DT)	30.47 (MLP)
33	81.58 (DT)	41.60 (DT)	11.70 (DT)	10.19 (MLP)	68.08 (DT)	42.15 (DT)
47	93.14 (DT)	72.16 (DT)	14.26 (DT)	11.43 (DT)	85.85 (DT)	67.30 (DT)
77	93.13 (DT)	93.65 (DT)	14.31 (DT)	14.10 (DT)	86.70 (DT)	88.06 (DT)

d. Decision Tree and MLP are tied at two decimals (27.77) in the per-class selection cell at K = 9; the Decision Tree leads at full precision (27.7720 against 27.7699) and is credited with the cell.

A. Performance Degradation Under Temporal Evaluation

Fig. 2 previews the protocol effect analyzed in this subsection. Cross-protocol comparisons require a fixed reference classifier, since the best-performing model differs across configurations (Tables V and VI). The Decision Tree is adopted as the reference throughout, for two reasons: it is the strongest and most stable classifier in this study, ranking first or tying for first in 47 of the 60 best-per-cell entries (44 outright wins and 3 ties; Section IV-E), including 25 of the 30 multiclass entries, and it was likewise identified by Li et al. as the preferred classifier within their framework. Holding the Decision Tree fixed and using PCA-based extraction at K = 9, binary performance under Protocol A reaches 87.89% accuracy, 86.84% macro-precision, 86.79% macro-recall, 86.81% macro-F1, and an MCC of 0.74. Under Protocol B, the same configuration attains 58.22%, 58.99%, 59.33%, 58.04%, and 0.18, respectively. All five measures decline together, but not proportionally: accuracy and macro-F1 lose approximately 29 percentage points, while MCC loses more than three-quarters of its value. The pattern persists at higher dimensionality — binary macro-F1 falls from 99.15% to 73.69% at K = 47 — and is far stronger in the multiclass task, where the same classifier and configuration declines from 93.14% to 14.26% macro-F1.

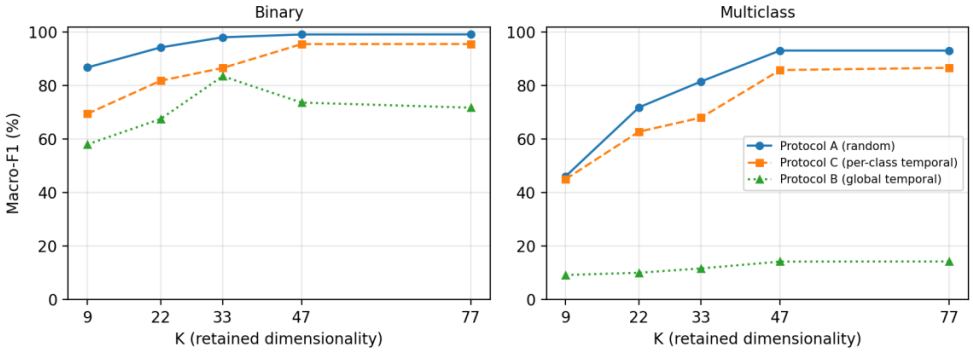

Fig. 2. Reference Decision Tree macro-F1 with PCA-based extraction as a function of the retained dimensionality K under the three evaluation protocols (left: binary task; right: multiclass task).

Because every component of the pipeline other than the data partitioning strategy is identical across protocols, these differences are attributable to the change in partitioning strategy under the controlled experimental conditions used in this study. Under Protocol A, both reduction methods approach ceiling performance at high dimensionality — 99.18% and 99.26% binary macro-F1 for extraction and selection, respectively (Table V), reproducing the near-perfect scores that characterize the random-split literature. Those scores were not attained under either temporal protocol.

Consistent with the reasoning of [5] and [6], these findings suggest that conventional random evaluation produces substantially more optimistic estimates than temporal evaluation, and that a considerable portion of the reported headroom in the FS-versus-FE literature reflects train–test similarity rather than genuine temporal generalization, at least for burst-captured corpora of the kind studied here. In such corpora, random partitioning distributes each short traffic burst across both partitions, so the classifier is evaluated on samples closely resembling those it was trained on. Under temporal partitioning, the traffic distribution is no longer assumed to match that of the training data, and the measured score reflects the deployment-relevant ability to classify traffic the model has not previously observed.

These fixed-classifier deltas deliberately upper-bound the penalty faced by a practitioner who is free to re-select the model per protocol: under Protocol B the best-available classifier recovers much of the loss, with the binary A-to-B gap under extraction at K = 77 shrinking from 27.39 points for the fixed Decision Tree to 4.53 points for k-Nearest Neighbors, the strongest model under Protocol B (99.06% to 94.53%), and from 25.46 to 5.92 points at K = 47. The Decision-Tree-based figures reported throughout should therefore be read as the penalty absent model re-selection, not as the best achievable under each protocol.

Scope of claim: the degradation magnitudes reported in this subsection are specific to TON-IoT and to the fixed reference classifier; they are not claimed to generalize to other corpora.

B. *Recommendation Stability and Ranking Instability Across Protocols*

The results in Tables V and VI operate at three distinct levels, which the analysis keeps separate: the family-level recommendation (whether extraction or selection is preferable), configuration-level rankings (the ordering of individual method–classifier–dimensionality combinations), and classifier rankings (which model performs best in a given setting). The evidence shows that the first is preserved across protocols, whereas the second and third are not, and that the magnitude of the family-level advantage itself varies with the protocol.

Under Protocol A, the pattern reported in [3] is confirmed: extraction leads selection clearly at small K, reaching 86.81% against 78.55% at K = 9 and 94.31% against 79.28% at K = 22, with the gap narrowing as dimensionality grows until selection marginally overtakes extraction at the full feature set (99.26% against 99.18%). This crossover mirrors the behavior reported by Li et al., who observed selection overtaking extraction at full dimensionality with F1-scores of 87.69% and 86.14%, respectively, under their best classifier. The absolute levels nevertheless differ: our Protocol A ceiling exceeds the values reported in [3] by roughly twelve macro-F1 points at full dimensionality. Because [3] reports aggregate rather than per-cell results for most configurations, an exhaustive cell-level reconciliation is not possible; the reproduction claim in this study is accordingly limited to the qualitative pattern — near-ceiling performance at high dimensionality and the same selection-overtakes-extraction crossover — rather than to absolute values, with the residual gap most plausibly reflecting implementation-level details (duplicate handling, encoder fitting, and the F1 averaging variant) that [3] does not fully specify. Under Protocol C, the same qualitative shape survives at reduced magnitude, with selection again edging ahead at K = 77 (95.73% against 95.59%); under Protocol B, extraction retains a small advantage at K = 77 (94.53% against 92.68%).

The Wilcoxon signed-rank tests in Table VII confirm the family-level recommendation formally: extraction outperforms selection in all three protocols across the 50 matched configurations, with median differences of +8.81, +2.75, and +13.07 macro-F1 points for Protocols A, B, and C, respectively (exact $p = 4.1 \times 10^{-9}$, 2.2×10^{-7}, and 6.6×10^{-12}). All statistics are computed on the full-precision experimental records rather than on the two-decimal values reported in the Appendix, under which no FS–FE pair is exactly tied.

TABLE VII. STATISTICAL ANALYSIS OF METHOD DIFFERENCES AND RANKING STABILITY

Test	Comparison	Statistic	p-value	Interpretation
Wilcoxon signed-rank	FE vs FS, Protocol A	median Δ = +8.81; FE wins 42/50	4.1×10^{-9}	FE superior across configurations
Wilcoxon signed-rank	FE vs FS, Protocol B	median Δ = +2.75; FE wins 40/50	2.2×10^{-7}	FE superior across configurations
Wilcoxon signed-rank	FE vs FS, Protocol C	median Δ = +13.07; FE wins 44/50	6.6×10^{-12}	FE superior across configurations
Kendall's τ	Protocol A vs C	τ = 0.751	1.8×10^{-28}	Substantial, imperfect agreement
Kendall's τ	Protocol A vs B	τ = 0.666	9.9×10^{-23}	Substantial, imperfect agreement
Kendall's τ	Protocol B vs C	τ = 0.560	1.5×10^{-16}	Moderate agreement

e. Δ denotes the difference in macro-F1 percentage points. Wilcoxon tests are paired over 50 matched FS/FE configurations per protocol; Kendall's τ (τ-b variant) is computed over 100 configuration-level macro-F1 values per protocol. All statistics use full-precision records; no FS–FE pair is exactly tied.

The advantage is therefore directionally robust, although its magnitude is protocol-dependent — the median margin under Protocol B is less than a third of that under Protocol A.

Configuration-level rankings are markedly less stable, as the Kendall's τ coefficients in Table VII show: 0.751 between Protocols A and C, 0.666 between A and B, and 0.560 between B and C. These values indicate substantial but clearly imperfect agreement — a non-trivial fraction of configuration-level orderings changes when the protocol changes. The most consequential instance concerns the classifier ranking. k-Nearest Neighbors, which is the best model in no binary cell under Protocol A, becomes the strongest classifier in six of the ten binary cells under Protocol B (Table V). A practitioner who selected both a reduction method and a classifier based on random-split evidence would therefore retain the correct method family but adopt a suboptimal classifier in the majority of binary configurations under temporally consistent evaluation — an observation that parallels the protocol-dependent method rankings reported in temporal benchmarks from other domains [8].

In summary, the family-level recommendation — prefer extraction at reduced dimensionality — survives the change of evaluation protocol, whereas the magnitude of its advantage, configuration-level orderings, and the identity of the best-performing classifier are all protocol-dependent. Comparative guidance derived from random-split evaluation should accordingly be validated under leakage-resistant protocols before informing design decisions.

Scope of claim: the directional FE-over-FS result is specific to the single redundancy-oriented selector evaluated; the ranking instability is specific to this dataset and protocol grid, though consistent with protocol-dependent rankings reported in other domains [8].

C. Differential Sensitivity of the Evaluation Metrics

The five metrics do not respond uniformly to the change of protocol, and the divergence is itself informative. Under Protocol B, accuracy can remain moderate while macro-averaged performance falls to a far lower absolute level: in the multiclass task at K = 47, the Decision Tree retains an accuracy of 48.60% while its macro-F1 falls to 14.26% — a gap of more than 34 percentage points between two measures of the same predictions.

The explanation is distributional. Accuracy is dominated by whichever classes are most frequent in the test window, so a model that continues to recognize benign traffic and one or two persistent attack families retains moderate accuracy. Macro-F1 averages per-class F1 with equal weight, so every class the model fails to detect — including the three classes that Table III shows are absent from training under Protocol B, which together account for 45.6% of the test records — contributes a value near zero and depresses the mean. The divergence between the two measures under Protocol B is therefore consistent with a loss of detection capability concentrated in the classes that accuracy weights least.

The Matthews correlation coefficient proves the most sensitive of the five measures in relative terms. Averaged over the 100 configurations under each protocol, MCC declines from 0.638 under Protocol A to 0.196 under Protocol B, a relative loss of approximately 69%, and falls below 0.30 in 76 of those configurations. The pattern holds within each task considered separately: binary MCC declines from 0.710 to 0.247 and multiclass MCC from 0.566 to 0.146. Ten Protocol B configurations — all on the selection side — yield negative MCC, reaching −0.35 for the binary K = 9 selection models; predictions there are anti-correlated with the true labels, and these cases coincide with the degenerate low-dimensionality selection subsets documented in the Appendix. The binary task at K = 9 illustrates the contrast within a single configuration: the Decision Tree's accuracy falls from 87.89% to 58.22% and its macro-F1 from 86.81% to 58.04%, while MCC drops from 0.74 to 0.18. Because MCC combines all four categories of correct and incorrect predictions, it remains responsive to imbalanced error structures that accuracy and F1 partially absorb. Precision and recall decline in parallel with F1 over the same transition, from 86.84% and 86.79% to 58.99% and 59.33%, respectively, indicating that the degradation is not confined to one side of the precision–recall trade-off but reflects a general loss of discriminative power.

These observations have a direct reporting consequence within the evaluated framework. Studies that report accuracy alone may substantially understate the effect of temporal evaluation, since accuracy is the measure least responsive to failures concentrated in infrequent or unseen attack classes. Within the evaluated framework, reporting macro-averaged metrics alongside MCC appears necessary for meaningful comparison across evaluation protocols, and the choice of

headline metric should be stated explicitly whenever protocols are compared.

Scope of claim: the metric-divergence pattern follows from macro-averaging and MCC under shifted class composition and can be expected wherever test-set composition diverges from training; the magnitudes are dataset-specific.

D. Separating Temporal Drift from Unseen-Class Effects

Contrasting the two temporal protocols suggests a decomposition of the observed degradation into two mechanisms. Because Protocol C retains every class on both sides of the boundary while Protocol B does not, the difference between Protocols A and C provides an estimate of within-class temporal drift, and the difference between Protocols C and B approximates the additional penalty attributable to the unseen attack classes documented in Table III. These components should be read as approximations rather than exact orthogonal effects: the two temporal protocols place their boundaries differently and therefore also differ in training-set composition, so class availability is not the only factor separating them. The classifier is held fixed throughout; the Decision Tree again serves as the reference model (Section IV-A). Table VIII presents the decomposition for binary classification with PCA-based extraction.

TABLE VIII. DECOMPOSITION OF PERFORMANCE DEGRADATION (BINARY, FEATURE EXTRACTION, DECISION TREE, MACRO-F1 %)

K	Protocol A (random)	Protocol C (per-class)	Protocol B (global)	A−C gap (drift est.)	C−B gap (unseen est.)
9	86.81	69.49	58.04	17.32	11.45
22	94.31	81.88	67.57	12.43	14.31
33	98.10	86.63	83.56	11.47	3.07
47	99.15	95.56	73.69	3.59	21.87
77	99.18	95.59	71.79	3.59	23.80

f. All values are Decision Tree macro-F1 taken from the Appendix tables; the classifier is held fixed so that the reported differences reflect the protocol alone. The two gaps are protocol differences interpreted as estimates of the drift and unseen-class effects under the assumptions stated in the text; they are not exactly separable causal components.

Table VIII reveals an interaction between dimensionality and degradation mechanism. The drift component declines monotonically as dimensionality grows, from 17.32 points at K = 9 to 3.59 points at K = 47 and K = 77, consistent with poor generalization to shifted traffic when few features are available even though all classes are represented in training. The unseen-class component varies non-monotonically — 14.31 points at K = 22 but only 3.07 at K = 33 — yet at K = 47 and K = 77 it reaches 21.87 and 23.80 points and clearly dominates the residual drift. For the evaluated configuration, higher dimensionality was thus associated with markedly smaller drift penalties but, at the largest dimensionalities, with substantially larger unseen-class penalties. A practitioner who increases dimensionality to improve temporal robustness could therefore be exchanging one vulnerability for a larger one, although this trade-off is established here only for the Decision Tree with PCA-based extraction on TON-IoT.

The multiclass results amplify this asymmetry. For the same Decision Tree at K = 47, macro-F1 declines from 93.14% under Protocol A to 85.85% under Protocol C but collapses to 14.26% under Protocol B, corresponding to a drift component of 7.29 points against an unseen-class component of 71.59 points. Within this experimental framework, neither of the two evaluated reduction methods enabled the classifiers to recognize genuinely novel attack categories. This limitation is inherent to closed-set classification, in which every test sample must be assigned to one of the classes observed during training; recognizing samples from previously unseen classes requires open-set formulations that provide an explicit rejection option [20]. Closed-set comparisons conducted under random partitioning cannot expose this deficiency, because the random protocol guarantees that every class appears in training.

Finally, the decomposition is itself model-dependent, which merits explicit reporting. For k-Nearest Neighbors at K = 9 (binary task, feature extraction), the ordering inverts: macro-F1 falls from 86.74% under Protocol A to 44.03% under Protocol C but recovers to 66.23% under Protocol B. In this configuration, instance-based prediction appears more sensitive to within-class drift than to a shifted class composition, so for this model the per-class protocol is the harsher test. Random Forest exhibits yet another profile in the binary task: its drift component remains between 16 and 23 points at every dimensionality while its unseen-class component contracts from roughly 12 points at K = 9–33 to about 3 points at K = 47 and 77 — the reverse of the Decision Tree's pattern. The two mechanisms are therefore not universally ordered by severity; their relative weight depends on dimensionality and the inductive bias of the classifier, and any single-figure summary of the temporal penalty should be interpreted with corresponding caution.

Scope of claim: the decomposition is approximate, classifier-dependent, and established on TON-IoT only; the dimensionality interaction is demonstrated for the Decision Tree with PCA-based extraction.

E. Classifier-Level Observations

The protocol effect is visible in every classifier, indicating that it is a property of the evaluation rather than of any particular model, yet individual sensitivities differ. k-Nearest Neighbors exhibits a dual character: it is the most drift-sensitive model at small K under Protocol C, reaching only 44.03% binary macro-F1 with extraction at K = 9, while simultaneously being the strongest model under Protocol B at several dimensionalities. This pattern is consistent with instance-based prediction degrading severely when within-class distributions drift, while remaining comparatively robust when the challenge is instead a shifted class composition, although the present experiments cannot establish this mechanism directly. The Decision Tree is the dominant model overall, ranking first or tying for first in 47 of the 60 best-per-cell entries across both tasks and all three

protocols (44 strict wins; the three exact ties, marked in Table V, arise in the degenerate low-dimensionality selection cells discussed in the Appendix) and in 25 of the 30 multiclass entries; four of the five multiclass exceptions occur under Protocol B, where severe degradation compresses the models into a narrow low-performance band; the fifth arises under Protocol C at K = 22 (per-class selection), where the MLP edges the Decision Tree by one-hundredth of a point (30.47 against 30.46). The MLP's multiclass macro-F1 plateaus near 41% for K = 33–77 even after the convergence adjustment described in Section III-B, suggesting a capacity or optimization limitation under the hyperparameters specified in [3]; because the Decision Tree dominates the multiclass rankings throughout, this does not affect any best-per-cell conclusion, but MLP multiclass values should be interpreted with this caveat.

Scope of claim: these classifier-level behaviours are observed on TON-IoT under the three protocols studied and for the inherited hyperparameters; they are specific to this dataset and configuration.

F. A Structural Limitation of Burst-Captured Datasets

One pattern in Table V requires a dataset-level explanation: under Protocol C, binary performance at high dimensionality recovers to near the random-split level, reaching 95.59% at K = 77. Inspection of the timestamps explains this. The attack classes of TON-IoT were generated in short scripted campaigns whose per-class time spans range from 93 seconds to 8,687 seconds, whereas benign traffic spans 25.7 days. Within a campaign lasting a few minutes, there is little temporal structure for a per-class chronological cut to exploit, so for attack classes Protocol C approaches a random split as K increases and the classifier gains capacity. The per-class temporal results therefore likely understate the within-class drift that would be observed over longer capture windows, with the genuine temporal signal carried primarily by the long-spanning benign class. This limitation suggests that future benchmark datasets would benefit from preserving device identity while also providing longer continuous capture windows to enable more rigorous temporal evaluation. Recent work has emphasized the importance of device-aware evaluation protocols and auditable evaluation substrates [16], although extending capture duration remains an open challenge.

Scope of claim: this is a structural property of TON-IoT's burst-captured attack classes; it bounds per-class temporal evaluation on this corpus and need not hold for datasets with longer capture windows.

G. Practical Implications

Three implications follow for practitioners, within the scope of the evaluated dataset, classifiers, and reduction methods. First, feature-reduction guidance derived from random-split studies should be treated as an optimistic upper estimate of achievable performance. The direction of the FS-versus-FE recommendation survived in these experiments — extraction outperformed the single redundancy-oriented correlation selector inherited from Li et al. in all three protocols — but its magnitude, and the classifier that best exploits it, changed under temporally consistent evaluation. Second, evaluation reports for IoT IDS should include macro-averaged metrics and MCC alongside accuracy and should state the partitioning protocol explicitly; the divergence of more than 34 percentage points between accuracy and macro-F1 observed in Section IV-C illustrates how much a single headline metric can conceal. Third, the interaction documented in Table VIII has a concrete design consequence: in the evaluated configuration, higher dimensionality was associated with smaller drift penalties but, at the largest dimensionalities, with greater exposure to unseen attack families (established here only for the Decision Tree with PCA-based extraction), so dimensionality should be selected with both failure modes in view rather than optimized against a random-split score alone. Because the attack classes of TON-IoT are captured in short bursts (Section IV-F), the drift components in Table VIII likely understate the within-class drift expected on corpora with longer capture windows, and this design consideration should be revalidated on such corpora. Robustness to genuinely novel attacks, in particular, was not achievable with the closed-set pipelines evaluated here — by construction, closed-set classification cannot reject samples from unobserved classes — and requires open-set or anomaly-based mechanisms [20] to be integrated into the design loop.

Scope of claim: these are practitioner-facing implications within the scope of the evaluated dataset, classifiers, and reduction methods; the methodological recommendations (validate under leakage-resistant protocols; report macro-F1 and MCC) are expected to generalise, whereas the specific magnitudes are dataset-specific.

V. Threats to Validity

Internal validity. The MLP required raising the iteration limit from the 200 specified by Li et al. [3] to 500 with early stopping to converge; this adjustment is documented in Section III-B, applied uniformly across all protocols, and does not affect best-per-cell conclusions, which are dominated by the Decision Tree and k-Nearest Neighbors. More broadly, hyperparameters are inherited from Li et al. rather than tuned per protocol. This is required by the isolation principle, and classifier rankings could differ under protocol-specific tuning; note, however, that those hyperparameters were themselves selected under random partitioning, so any residual advantage they confer accrues to Protocol A rather than to the temporal protocols, and the degradation reported here is therefore conservative.

Stochastic classifiers are averaged over three seeds, giving 3 protocols × 5 values of K × 2 tasks × 2 reduction families × 3 stochastic classifiers = 180 stochastic configurations. Across all 180, the mean seed-to-seed standard deviation of macro-F1 is 0.29 points, rising to 0.42 when restricted to the 123 configurations whose deviation is non-zero at two decimals; the maximum is 4.71 points. All of these are small relative to the protocol effects reported here, several of which exceed 25 points. Three replicates support only a coarse dispersion estimate rather than a confidence interval, and the figures above should be read accordingly. The principal ranking observation of Section IV-B is unaffected by this limitation: the k-Nearest Neighbors scores that dominate Protocol B are deterministic, and in five of the six binary cells it wins, its margin over the best stochastic competitor (7.9–22.7 macro-F1 points) far exceeds the seed-level dispersion reported above; only the selection cell at K = 33 shows a margin (3.0 points) comparable to the competing Random Forest's ±3.36 dispersion. All experiments

were run with Scikit-learn 1.6.1 on Python 3.12.13; package versions and random seeds are reported in Table IV, and the random seeds are recorded in the Appendix.

External validity. All experiments use a single dataset. This is a deliberate consequence of the isolation principle—the study revisits the framework of Li et al. on the dataset that framework used—but generalization of the specific magnitudes to other corpora is not claimed.

Construct validity. Two features of the dataset bound what the temporal protocols can be said to measure. First, TON-IoT was collected in a controlled testbed under a scripted attack schedule, so chronological order partly reflects the capture campaign rather than the natural evolution of traffic; the protocols therefore measure resistance to temporal leakage as instantiated by this capture, and the burst-capture limitation described in Section IV-F bounds per-class temporal evaluation accordingly. Second, chronological partitioning leaves some attack classes unevenly represented across the split, which affects macro-F1 directly; Table III quantifies class availability under Protocol B, ensuring that protocol effects are interpreted in the context of differences in class coverage. Tables V and VI report the best classifier per cell for readability, while all cross-protocol differences discussed in the text are computed with the classifier held fixed, and complete per-classifier results are provided in the Appendix so that no conclusion depends on the summarization choice.

The family-level claim is also bounded by the choice of selector: feature selection is represented by the single redundancy-oriented criterion inherited from Li et al., which scores inter-feature correlation without an explicit class-relevance term. Filter criteria that additionally score relevance—CFS [11], mutual-information ranking—or wrapper selectors that optimize detection-oriented objectives directly [21], albeit at substantially higher search cost, might narrow or reorder the FE–FS gap. The direction of any such shift is not obvious under temporal evaluation: a wrapper selector fits its selection to a validation split drawn from the training pool, so the selection step would itself be tuned against a leakage-prone estimate. The Wilcoxon result should therefore be read as extraction versus this selector rather than versus feature selection in general.

Conclusion validity. Findings are stated as protocol-dependent observations. The Wilcoxon and Kendall's τ analyses reported in Section IV-B are computed over configurations rather than over independent datasets, and should be read as descriptive of this experimental grid rather than as inference to a population of datasets; no correction for multiple comparisons is applied, consistent with that descriptive reading. We report point estimates with seed-level dispersion rather than bootstrap confidence intervals on individual test-set estimates; per-sample interval estimation is left to a future replication package.

VI. Conclusion and Future Work

This study asked whether the comparative feature-selection-versus-feature-extraction conclusions reported for IoT intrusion detection remain valid under leakage-resistant temporal evaluation. Holding the detection-performance component of the experimental framework of Li et al. [3] fixed and varying the partitioning rule as the sole intentionally manipulated experimental factor, we found the following. The published random-split findings were qualitatively reproduced, including near-ceiling performance at high dimensionality. Temporally consistent evaluation reduced measured performance substantially — by roughly 29 macro-F1 points in the binary task at $K = 9$ and 79 points in the multiclass task at $K = 47$, the largest observed degradation, for the fixed reference classifier — indicating that random evaluation produced markedly optimistic estimates within this framework. The five metrics did not degrade uniformly: accuracy could remain moderate while macro-averaged performance fell to very low absolute levels, and MCC exhibited the largest relative loss, declining by approximately 69% on average between the random and global temporal protocols. The family-level recommendation was directionally robust for the selector studied — extraction outperformed the inherited redundancy-oriented criterion under all three protocols, across the 50 matched configurations in each — whereas the magnitude of its advantage, configuration-level orderings, and the identity of the best-performing classifier were all protocol-dependent. Finally, a fixed-classifier decomposition across the two temporal protocols separated an estimate of within-class drift from the penalty associated with previously unseen attack classes: the drift component declined monotonically with dimensionality while the unseen-class component, although non-monotonic, dominated at the largest dimensionalities; a timestamp analysis further identified burst-captured attack campaigns as a structural limitation of per-class temporal evaluation on this corpus, implying that the reported drift components likely understate within-class drift on corpora with longer capture windows.

The principal implication is methodological. Comparative feature-engineering guidance for IoT intrusion detection should be validated under temporally consistent protocols before informing deployment decisions, and evaluation reports should state the partitioning rule explicitly and include macro-averaged metrics and MCC alongside accuracy.

Future work will extend the validation to a device-disjoint axis on corpora carrying device identity, following the split-governance protocol of Chikezie et al. [16]; that work also documents the feasibility limits of strict device-level holdout, which bound what such an extension can claim. A closely related extension will replicate the protocol contrast on an independent, timestamp-rich IoT corpus — reporting within-dataset reproduction and cross-dataset replication separately — and will construct controlled counterfactual splits, with matched class availability, matched temporal windows, and explicitly held-out attack campaigns, to decompose the observed degradation into temporal-proximity, class-shift, and campaign-shift components. A second direction is to incorporate open-set recognition mechanisms [20], recently instantiated for industrial IoT on Edge-IIoTset with incremental learning [22], so that previously unseen attack classes are detected rather than silently misclassified — noting that rejection improves operational reporting without, by itself, restoring macro-averaged performance on those classes. Finally, we will release per-sample predictions to enable bootstrap interval estimation, and examine whether deep representation-learning models exhibit the same protocol sensitivity as the shallow classifiers studied in this work.

APPENDIX: COMPLETE PER-CLASSIFIER RESULTS

Tables IX–XXXVIII report, for every protocol, task, and dimensionality K, all five classifiers under both reduction methods with accuracy, precision, recall, macro-F1 (± standard deviation over three seeds for stochastic models), and MCC. All values derive from the single unified experimental run described in Section III-E.

It may be noted that, in several low-dimensionality selection configurations (K = 9 and K = 22), two or three classifiers report identical values across all five metrics—for example, the Decision Tree, MLP, and k-Nearest Neighbors under Protocol A at K = 9. These coincidences are genuine outputs of the replicated pipeline rather than transcription errors.

A. Protocol A (Random)

TABLE IX. PROTOCOL A (RANDOM) — BINARY, K = 9

Method	Model	Accuracy (%)	Precision (%)	Recall (%)	F1 (%)	MCC
FS	DT	80.84	79.64	77.83	78.55	0.5745
FS	RF	79.17	78.67	74.66	75.85	0.5318
FS	kNN	80.84	79.64	77.83	78.55	0.5745
FS	NB	78.95	82.76	71.89	73.52	0.5356
FS	MLP	80.84	79.64	77.83	78.55	0.5745
FE	DT	87.89	86.84	86.79	86.81	0.7363
FE	RF	87.13	85.85	86.55	86.15 ±0.31	0.7240
FE	kNN	87.81	86.73	86.75	86.74	0.7348
FE	NB	83.45	81.86	82.79	82.26	0.6464
FE	MLP	86.51	85.08	86.43	85.62	0.7150

TABLE X. PROTOCOL A (RANDOM) — BINARY, K = 22

Method	Model	Accuracy (%)	Precision (%)	Recall (%)	F1 (%)	MCC
FS	DT	81.40	80.16	78.67	79.28	0.5881
FS	RF	77.67	84.75	69.28	70.53 ±0.10	0.5177
FS	kNN	79.87	79.32	75.67	76.82	0.5487

A Coordinate Transformation Framework for Vision-Guided Robotic Positioning in Automated Vehicle Body Marking

Olzhas Olzhayev[1], Azhar Tursynova[2], Sayat Ibrayev[3]
Joldasbekov Institute of Mechanics and Engineering, Almaty, Kazakhstan[1, 2, 3]
International Information Technology University, Almaty, Kazakhstan[1, 2]

***Abstract*—Vision-guided robotic positioning plays a critical role in modern manufacturing by enabling robots to accurately adapt to variations in workpiece position. This study proposes a coordinate transformation framework for automated vehicle body marking that converts visually detected target coordinates into executable robot motions through a unified processing pipeline. The proposed framework integrates visual target localization, homogeneous coordinate transformation, Tool Center Point (TCP) pose generation, and inverse kinematics to achieve accurate robotic positioning. Experimental validation was performed using a vision-guided robotic marking platform consisting of an AR4-MK3 six-degree-of-freedom manipulator, an overhead monocular camera, and a 50 W electromagnetic marking device. Five target positions with two repeated trials per position were used to evaluate positioning accuracy, repeatability, and computational performance. The proposed framework achieved an average positioning error of 2.19 mm, a maximum error of 2.69 mm, and a total processing time of approximately 27 ms, demonstrating stable and reliable robotic positioning during the marking process. The proposed framework provides a practical and computationally efficient solution for transforming visual information into robot-executable poses and offers a promising foundation for future vision-guided robotic marking systems operating in industrial environments.**

I. Introduction

The rapid evolution of Industry 4.0 has significantly accelerated the adoption of intelligent robotic systems in modern manufacturing, where high precision, flexibility, and production efficiency have become essential requirements. In the automotive industry, industrial manipulators are extensively employed in welding, assembly, painting, inspection, machining, and marking operations, enabling manufacturers to improve product quality while reducing production time and operational costs [1]. Among these manufacturing processes, automated vehicle body marking represents a critical operation because permanent identification information must be applied at predefined locations with high positional accuracy and repeatability. Even minor positioning errors may result in defective markings, reduced readability, or costly rework during production.

Traditional robotic marking systems generally execute trajectories generated through offline programming, assuming that every workpiece occupies an identical position within the robot workspace. However, practical manufacturing environments inevitably introduce uncertainties caused by fixture tolerances, conveyor deviations, thermal deformation, mechanical vibration, and accumulated assembly errors [2]. These positional variations reduce the effectiveness of predefined robot programs and frequently require manual teaching, trajectory modification, or repeated calibration, thereby limiting production flexibility and increasing manufacturing costs.

To improve adaptability, vision-guided robotic systems have become an important research direction in intelligent manufacturing. By integrating industrial cameras with robotic manipulators, visual sensing enables robots to estimate the actual position of workpieces and dynamically adjust robot motion according to the current manufacturing environment [3]. Vision-guided positioning has demonstrated considerable advantages in robotic assembly, machining, inspection, and manipulation because it reduces dependence on precisely fixed fixtures while improving positioning accuracy under varying operating conditions [4]. Nevertheless, the successful implementation of such systems depends not only on reliable visual perception but also on the accurate transformation of visual information into robot-executable motions.

The transformation of spatial information between multiple coordinate systems constitutes one of the fundamental problems in vision-guided robotics. During an automated marking operation, the target location detected by the vision system must be sequentially represented in the camera coordinate system, transformed into the robot base coordinate system, converted to the end-effector coordinate frame, and finally expressed as an executable Tool Center Point (TCP) pose. Errors introduced at any stage of this transformation pipeline directly affect the final positioning accuracy of the marking tool and consequently influence the quality of the manufacturing process.

Numerous studies have investigated individual components of this transformation process. Classical hand-eye calibration algorithms established reliable mathematical relationships between camera and robot coordinate systems [5–7], while subsequent research improved calibration accuracy through optimization techniques [8], comparative evaluations [9], and

learning-based three-dimensional vision approaches [10]. These studies have significantly advanced camera–robot calibration; however, they primarily investigate calibration as an isolated problem rather than considering the complete sequence of transformations required for practical robotic positioning.

In industrial vehicle body marking, accurate robotic positioning requires considerably more than camera calibration alone. The entire processing chain – including visual target localization, coordinate transformation, pose generation, and robot motion execution – must operate consistently to ensure that the marking tool reaches the desired location despite workpiece displacement and positioning uncertainties. Although these individual components have been widely studied, relatively few works integrate them into a unified coordinate transformation framework specifically designed for automated vehicle body marking.

To address this limitation, this study proposes a coordinate transformation framework for vision-guided robotic positioning in automated vehicle body marking. The proposed framework integrates visual target localization, homogeneous coordinate transformation, robot pose generation, and robotic positioning into a unified processing pipeline that transforms a visually detected marking target into an executable robot pose. Unlike conventional approaches that primarily evaluate calibration accuracy, the proposed framework emphasizes the complete transformation process required for practical robotic marking applications and experimentally validates its positioning performance under different workpiece displacement conditions.

II. Related Works

Vision-guided robotic positioning has become an important component of flexible manufacturing systems because visual feedback enables manipulators to respond to the actual position and orientation of objects in the workspace. Hutchinson et al. established the fundamental principles of visual servoing and classified vision-based robot control approaches according to the manner in which visual information is incorporated into the control loop [11]. Chaumette and Hutchinson subsequently provided a systematic description of image-based and position-based visual servoing, emphasizing that the selection of visual features and coordinate representations directly affects system stability, convergence, and positioning accuracy [12]. These studies formed the theoretical basis for modern camera-guided robotic systems; however, their primary focus was general visual control rather than application-specific coordinate transformation for industrial marking operations.

The accuracy of a vision-guided system strongly depends on the geometric relationship between the camera, robot base, end effector, and workpiece coordinate frames. Homogeneous transformation matrices are commonly used to represent these relationships and convert visually detected positions into poses executable by a robot controller. Ali et al. investigated simultaneous robot-world and hand-eye calibration and demonstrated that the definition of coordinate frames and optimization criteria significantly influence the accuracy of the estimated transformations [13]. Enebuse et al. later reviewed a wide range of hand-eye calibration techniques and showed that existing methods differ considerably in their treatment of rotation, translation, measurement noise, and camera configuration [14]. These findings confirm that coordinate transformation cannot be treated as a purely mathematical operation because errors introduced at the calibration stage propagate to the final robot pose.

Experimental comparisons have therefore received considerable attention in recent calibration research. Enebuse et al. evaluated several commonly used hand-eye calibration algorithms under controlled conditions and demonstrated that their accuracy depends on the robot motion set, calibration target observations, and error evaluation method [15]. Strobl and Hirzinger proposed an optimal hand-eye calibration approach that explicitly considers the uncertainty of robot and camera measurements [16]. More recently, learning-based three-dimensional vision has been employed to automate calibration target detection and reduce manual intervention during camera–robot calibration [17]. Although these studies improve the estimation of transformation parameters, they predominantly investigate calibration as an independent procedure rather than as part of a complete pipeline that includes target localization, pose generation, trajectory execution, and validation of the final tool position.

Application-oriented studies have shown that calibration and coordinate transformation become particularly critical in robotic processes requiring accurate contact or alignment with a workpiece. Zhan and Wang developed a hand-eye calibration and positioning method for robotic drilling, in which visual measurements were transformed into robot coordinates to maintain the required tool orientation and distance from an aircraft panel [18]. Li et al. proposed a visually guided error-compensation method for robotic machining and demonstrated that visual measurement can improve the pose accuracy of industrial manipulators during drilling and milling operations [19]. Similar challenges arise in vehicle body marking because the marking tool must be aligned with a predefined surface location while compensating for workpiece displacement, robot positioning errors, and uncertainties in the camera-to-robot transformation.

Despite the progress achieved in visual servoing, hand-eye calibration, and vision-guided machining, the reviewed studies mainly address visual control, calibration parameter estimation, or positioning-error compensation as separate problems. Limited attention has been given to unified frameworks that transform a visually detected target through the camera, robot-base, flange, and tool coordinate systems and then generate an executable pose for an automated marking process. Furthermore, most calibration studies evaluate transformation residuals or reprojection errors, whereas practical marking systems require validation of the final end-effector position under different workpiece displacements. This research gap motivates the proposed coordinate transformation framework, which integrates visual target localization, homogeneous coordinate transformation, target-pose generation, and robotic positioning for automated vehicle body marking. The need for such integrated approaches is also supported by recent industrial vision studies demonstrating that calibration accuracy, target localization, and robot motion execution must

be evaluated as interconnected stages rather than isolated components [20].

III. Materials and Methods

A. Vision-Guided Robotic Marking System

The experimental vision-guided robotic marking system developed in this study is shown in Fig. 1. The platform consists of an AR4-MK3 six-degree-of-freedom robotic manipulator, an electromagnetic marking device mounted at the robot flange, an overhead monocular camera, and a computer-based control unit. The objective of the system is to validate the proposed coordinate transformation framework for accurate robotic positioning during automated vehicle body marking. The monocular camera continuously observes the workspace and captures images of the workpiece. After detecting the predefined marking target, the corresponding image coordinates are processed by the proposed framework, which transforms the target position from the camera coordinate system into the robot coordinate system. Based on the transformed coordinates, the corresponding Tool Center Point (TCP) pose is generated and transmitted to the robot controller for motion execution.

Fig. 1. Vision-guided robot equipped with an electromagnetic marking device.

Unlike conventional robotic marking systems based on offline programming, the proposed platform determines the target position online using visual information and automatically updates the robot pose before executing the marking operation. This enables the manipulator to compensate for workpiece displacement while preserving the required positioning accuracy. The overall processing pipeline consists of four consecutive stages: target localization, coordinate transformation, robot pose generation, and robotic positioning.

B. Coordinate Systems

To accurately transform the visually detected target into an executable robot pose, the proposed framework defines a series of coordinate systems that describe the spatial relationship between the vision sensor, robotic manipulator, and marking tool. These coordinate systems establish a common geometric representation that enables consistent transformation of target positions throughout the robotic positioning process.

As illustrated in Fig. 2, four coordinate systems are employed in the proposed framework. The camera coordinate system {C} is attached to the optical center of the monocular camera and is used to represent the three-dimensional position of the detected marking target after image processing. The robot base coordinate system {B} is fixed at the robot base and serves as the global reference frame for robot motion planning and positioning.

The flange coordinate system {F} is attached to the robot flange and describes the pose of the robot wrist during manipulator motion. Finally, the tool center point (TCP) coordinate system {T} is defined at the tip of the electromagnetic marking device and represents the final position and orientation required to perform the marking operation. Since the marking device is rigidly mounted to the robot flange, the transformation between the flange and TCP coordinate systems remains constant throughout the experiments.

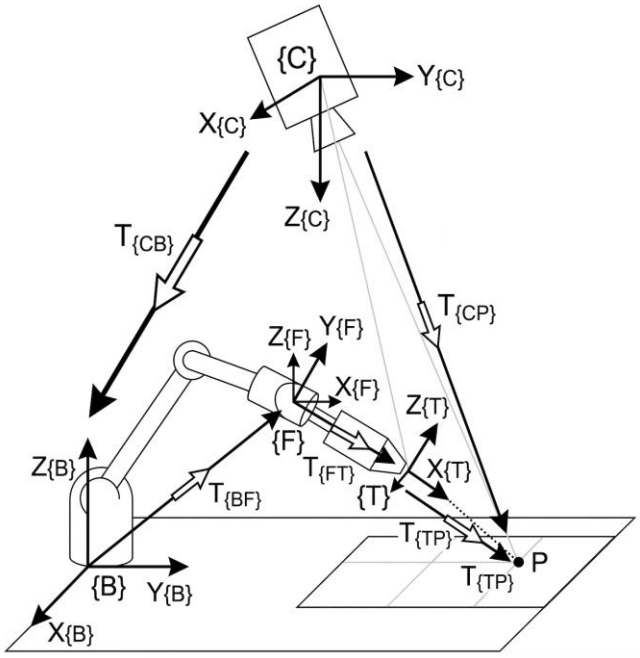

Fig. 2. Coordinate systems used in the proposed framework.

The objective of the proposed framework is to determine the TCP pose corresponding to the visually detected marking target by sequentially transforming the target coordinates from the camera reference frame to the robot base frame and subsequently to the tool coordinate system. This transformation process forms the foundation of the mathematical model presented in the following section.

C. Coordinate Transformation Framework

The proposed coordinate transformation framework is designed to convert a visually detected marking target into an executable robot pose through a sequence of geometric transformations between multiple coordinate systems. Instead of relying on predefined robot trajectories, the framework

dynamically computes the target pose from visual observations, enabling automatic compensation for workpiece displacement and positioning uncertainties.

The framework consists of four sequential stages, which are demonstrated in Fig. 3. First, the vision system acquires an image of the workspace and determines the location of the predefined marking target. The detected target is initially represented in the camera coordinate system. Second, the target coordinates are transformed into the robot base coordinate system using the geometric relationship established during system calibration. Third, the transformed target position is converted into the corresponding Tool Center Point (TCP) pose by considering the fixed spatial relationship between the robot flange and the mounted marking device. Finally, the generated TCP pose is transmitted to the robot controller, which computes the robot joint configuration and executes the positioning motion.

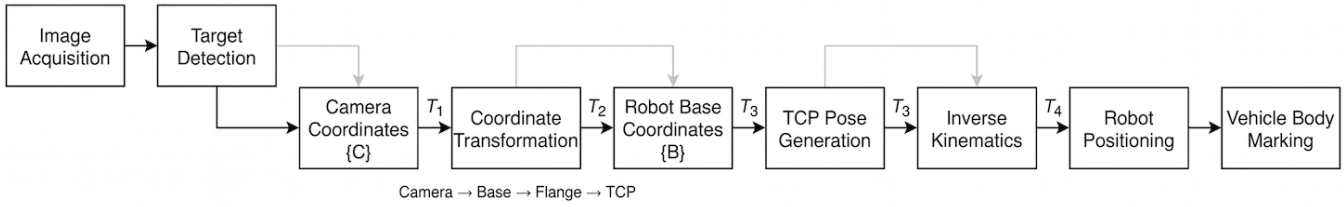

Fig. 3. Overall coordinate transformation framework for vision-guided robotic positioning.

The proposed framework considers the complete transformation process from visual target detection to robotic positioning. By integrating target localization, coordinate transformation, pose generation, and robot motion into a unified processing pipeline, the framework provides a consistent geometric representation throughout the entire marking procedure. This unified formulation simplifies the implementation of vision-guided robotic positioning while improving the adaptability of the system to variations in workpiece position.

D. Mathematical Formulation

The proposed framework computes the robot Tool Center Point (TCP) pose by sequentially transforming the detected target coordinates from the camera coordinate system to the robot base coordinate system. The transformations are represented using homogeneous transformation matrices.

The detected target is represented in homogeneous coordinates as:

$$\mathrm{P_C} = [\mathrm{x_C}; \mathrm{y_C}; \mathrm{z_C}; 1] \tag{1}$$

where, P_C is the target position in the camera coordinate system.

The target coordinates are transformed into the robot base coordinate system according to:

$$\mathrm{P_B} = \mathrm{T}_{BC}\mathrm{P_C} \tag{2}$$

where, T_{BC} denotes the homogeneous transformation matrix from the camera frame to the robot base frame.

The transformation matrix is defined as:

$$\mathrm{T_{BC}} = \begin{bmatrix} R_{BC} & t_{BC} \\ 0 & 1 \end{bmatrix} \tag{3}$$

where, R_{BC} is the rotation matrix and t_{BC} is the translation vector.

The TCP pose is obtained by applying the fixed tool transformation:

$$\mathrm{T_{TCP}} = \mathrm{T_{BF}}\mathrm{T_{FT}} \tag{4}$$

where, T_{BF} is the flange pose with respect to the robot base and T_{FT} is the constant transformation from the flange to the TCP.

The desired robot pose is calculated as:

$$T_{Target} = T_{BC}T_{CT}T_{TT} \tag{5}$$

where, T_{CT} transforms the detected target from the camera frame and T_{TT} represents the tool offset.

The robot joint configuration is obtained as:

$$\mathrm{q} = \mathrm{IK}\left(\mathrm{T_{Target}}\right) \tag{6}$$

where, q denotes the robot joint vector, and IK is inverse kinematics.

E. Experimental Procedure

The experimental validation was conducted using the developed vision-guided robotic marking platform. The system consisted of an AR4-MK3 six-degree-of-freedom robotic manipulator (maximum payload 1.9 kg and repeatability up to 0.2 mm), an overhead monocular camera, and a 50 W electromagnetic marking device mounted on the robot end-effector.

During each experiment, the camera detected the target position, after which the proposed coordinate transformation framework computed the corresponding TCP pose and generated the robot motion command. The robot then positioned the marking tool at the desired location. The framework was evaluated in terms of positioning accuracy, repeatability, and computation time under multiple target locations distributed throughout the workspace.

IV. Results

The proposed coordinate transformation framework was experimentally validated using the developed vision-guided robotic marking platform. The experimental setup consisted of

an AR4-MK3 six-degree-of-freedom robotic manipulator, an Intel® RealSense™ D455 RGB-D camera mounted above the workspace for visual target detection, a 50 W electromagnetic marking device attached to the robot end-effector, and a computer-based control unit responsible for image processing, coordinate transformation, and robot motion planning. During the experiments, the RealSense D455 continuously monitored the working area and acquired visual information required for target localization. The detected target coordinates were subsequently transformed into the robot coordinate system using the proposed framework, enabling automatic generation of the Tool Center Point (TCP) pose and execution of the marking operation. The complete experimental platform is presented in Fig. 4.

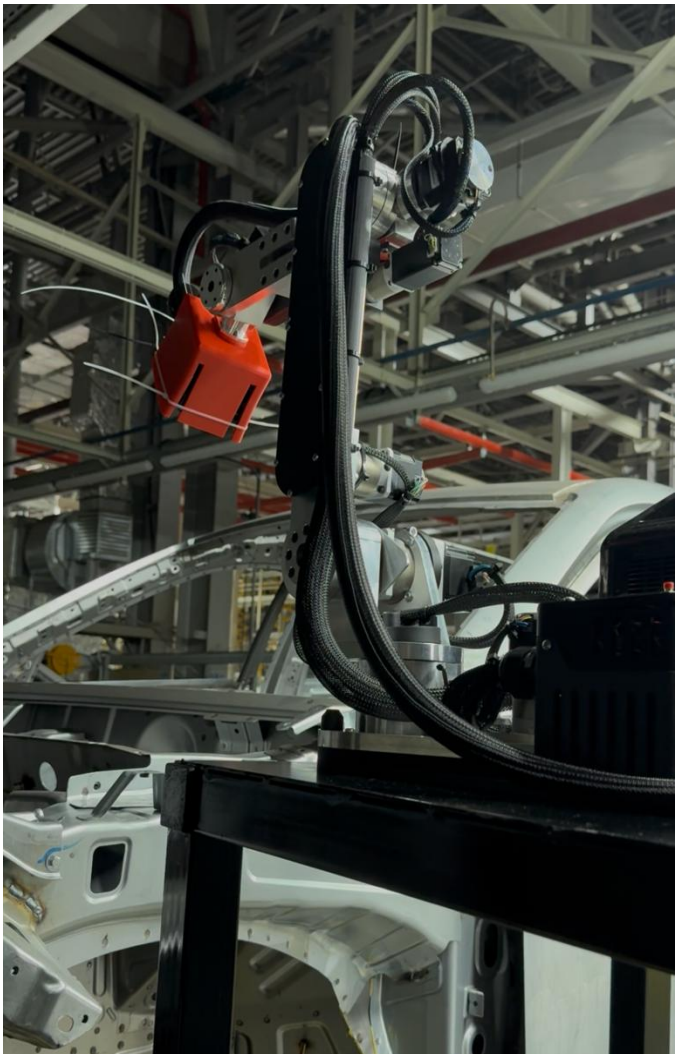

Fig. 4. Experimental vision-guided robotic marking platform.

During the experiments, the Intel® RealSense™ D455 camera continuously monitored the experimental workspace and acquired visual data of the vehicle body surface. The captured RGB images were processed to identify the predefined marking target and determine its position within the camera coordinate system. The extracted target coordinates were then supplied to the proposed coordinate transformation framework, which sequentially transformed them into the robot base coordinate system, generated the corresponding Tool Center Point (TCP) pose, and transmitted the resulting robot motion command to the manipulator controller. This automated processing pipeline enabled accurate positioning of the marking tool while compensating for variations in the workpiece location. An example of the camera view used for target localization during the experiments is presented in Fig. 5.

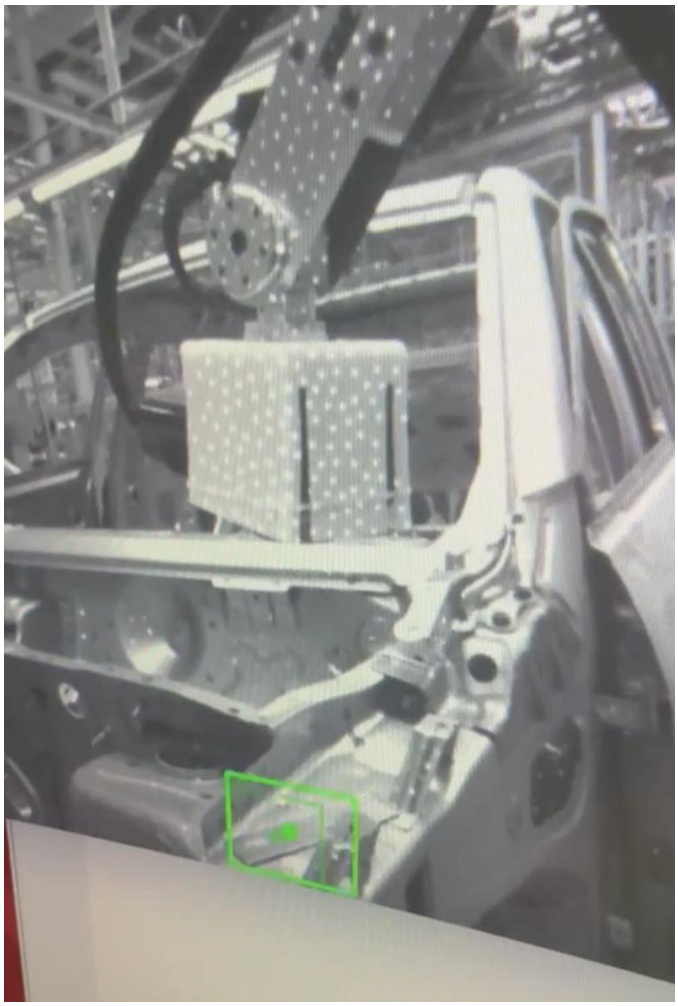

Fig. 5. Camera view of the experimental workspace used for target localization.

The computed robot pose was subsequently executed by the AR4-MK3 manipulator, positioning the electromagnetic marking device at the desired location on the workpiece. Upon reaching the target pose, the marking operation was automatically performed, producing a permanent mark at the predefined position. The experimental marking result is presented in Fig. 6, demonstrating the successful implementation of the complete vision-guided robotic positioning pipeline, from visual target detection and coordinate transformation to accurate robot positioning and automated marking.

Fig. 6. Experimental marking result obtained using the proposed framework.

The positioning accuracy was evaluated at multiple target locations distributed throughout the robot workspace. The deviations between the desired and actual marking positions along the X, Y, and Z axes are summarized in Table I, while the overall experimental performance, including repeatability and computational efficiency, is presented in Table II.

TABLE I. POSITIONING ERRORS OF THE PROPOSED VISION-GUIDED ROBOTIC POSITIONING FRAMEWORK AT DIFFERENT TARGET POINTS

Target point	X error (mm)	Y error (mm)	Z error (mm)	Total error (mm)
P1	0.8	1.2	0.9	1.71
P2	1.3	0.9	1.1	1.93
P3	1.6	1.4	0.8	2.29
P4	1.1	1.8	1.0	2.34
P5	1.9	1.5	1.2	2.69
Mean	1.34	1.36	1.0	2.19
Standard deviation	0.42	0.35	0.16	0.39
Maximum	1.90	1.80	1.20	2.69

The results demonstrated that the proposed framework consistently transformed the visually detected target coordinates into executable robot poses. The measured errors remained within the acceptable range for experimental vehicle body marking applications. Repeated trials at the same target positions also showed stable robot positioning and consistent marking performance.

In addition to positioning accuracy, the framework was evaluated in terms of repeatability and computation time. The computation time included target localization, coordinate transformation, and TCP pose generation. The summarized performance indicators are presented in Table II.

TABLE II. OVERALL EXPERIMENTAL PERFORMANCE OF THE PROPOSED VISION-GUIDED ROBOTIC POSITIONING FRAMEWORK

Performance indicator	Value
Number of target positions	5
Trials per target	2
Mean positioning error (mm)	2.19
Maximum positioning error (mm)	2.69
Repeatability / standard deviation (mm)	0.39
Target detection time (ms)	25
Coordinate transformation time (ms)	1.3
Total processing time (ms)	27

Overall, the experimental results confirmed that the proposed coordinate transformation framework provides accurate and repeatable conversion of visual target coordinates into robot motion commands. The successful execution of the marking operation also demonstrated the practical feasibility of the developed system for automated positioning and marking tasks.

V. DISCUSSION

The experimental results demonstrate that the proposed coordinate transformation framework provides a reliable and computationally efficient solution for vision-guided robotic positioning in automated vehicle body marking. By integrating visual target localization, homogeneous coordinate transformation, TCP pose generation, inverse kinematics, and robot motion execution within a unified workflow, the framework successfully converts visually detected target coordinates into executable robotic motions. This integrated formulation is particularly important in flexible manufacturing environments, where variations in workpiece position can reduce the effectiveness of conventional preprogrammed robotic trajectories [21].

The mean positioning error of **2.19 mm**, with a maximum error of **2.69 mm**, indicates that the proposed framework can maintain consistent positioning performance across different locations within the evaluated workspace. Recent developments in vision-guided industrial robotics similarly emphasize that accurate spatial transformation between sensing and robot coordinate systems is fundamental to reliable manipulation and manufacturing operations [22]. The standard deviation of **0.39 mm** further indicates relatively stable positioning behavior across the evaluated targets. Repeatable positioning is important in automated manufacturing because errors originating from perception, calibration, coordinate transformation, and manipulator motion can propagate to the final tool location [23].

From an algorithmic perspective, the proposed framework can be viewed as a sequential perception–transformation–planning pipeline. The target-localization algorithm first extracts the required spatial information from the camera observation, after which homogeneous transformation algorithms map the detected coordinates from the camera frame to the robot base frame. Inverse kinematics then determines a feasible joint configuration corresponding to the desired TCP pose. Such modular processing is advantageous because individual algorithms can be independently improved without redesigning the complete robotic system [24].

The obtained positioning performance represents the cumulative accuracy of this complete vision-to-motion pipeline rather than camera calibration accuracy alone. Camera–robot calibration establishes the geometric relationship between coordinate systems, whereas final positioning additionally depends on visual localization, transformation parameters, TCP calibration, manipulator kinematics, and mechanical accuracy [25]. Consequently, evaluating only reprojection or calibration residuals may not adequately characterize the practical performance of a robotic marking system. The proposed experiments instead evaluate the final positioning outcome after the target coordinates have passed through the complete computational and robotic execution chain.

Homogeneous transformation matrices provide the mathematical foundation for the coordinate-conversion algorithm because rotations and translations between the camera, robot base, flange, and TCP frames can be represented consistently within the same formulation [26]. Accurate estimation of these relationships is especially important when visual measurements must be converted into physically executable robot poses. The proposed sequential transformation algorithm consequently provides a relatively transparent approach in which each geometric operation can be inspected, calibrated, and validated independently.

Machine learning represents an important opportunity for extending this framework beyond its current primarily geometric implementation. In the present system, the coordinate transformation stage is deterministic and model-based; however, machine-learning algorithms can complement this stage by improving visual target detection, feature localization, pose estimation, calibration refinement, and positioning-error compensation [27-29]. Learning-based three-dimensional vision has already demonstrated potential for automating camera–robot calibration and reducing dependence on manually defined calibration procedures [30]. Incorporating such algorithms into the perception component could improve robustness when targets are observed under variations in illumination, viewpoint, surface appearance, or partial occlusion [31].

Deep learning algorithms are particularly relevant to the visual localization stage. Convolutional neural networks, object detectors, segmentation networks, and vision-transformer-based models could be employed to identify marking regions or reference features directly from camera images [32]. Instead of depending exclusively on predefined visual features, a trained model could learn discriminative representations from annotated examples and estimate target positions under more complex manufacturing conditions [33]. Nevertheless, introducing machine learning would require representative training data covering realistic variations in vehicle surfaces, camera viewpoints, illumination, occlusion, and target appearance to avoid degradation under domain shift.

Machine learning could also be applied after target detection to compensate for systematic positioning errors. A regression model could learn a correction function from the desired target position, camera observation, robot configuration, and measured positioning residuals [34]. The predicted correction could then be applied to the geometrically calculated TCP pose before robot execution. Such a hybrid strategy would preserve the interpretability of the homogeneous coordinate transformation while allowing data-driven algorithms to compensate for nonlinear errors that are difficult to represent explicitly using conventional calibration equations [35]. This combination of analytical geometry and machine learning may therefore provide a useful direction for improving positioning accuracy without replacing the underlying coordinate framework.

The computational results are also encouraging for future machine-learning integration. The complete pipeline required approximately **27 ms**, with target detection accounting for approximately **25 ms** and coordinate transformation requiring only **1.3 ms**. The small computational cost of the geometric transformation leaves a substantial portion of the processing architecture available for more advanced perception algorithms. Efficient machine-learning models could potentially be incorporated while maintaining near-real-time operation, particularly when lightweight neural architectures, model compression, or hardware acceleration are employed.

Algorithm selection should nevertheless consider the trade-off between accuracy, computational complexity, interpretability, and data requirements. Classical image-processing algorithms can provide predictable behavior when the target appearance and illumination conditions are highly controlled, whereas machine-learning algorithms generally provide greater adaptability when visual conditions are more heterogeneous. A hybrid architecture in which machine learning performs robust target localization and deterministic geometric algorithms perform coordinate transformation may therefore offer a practical compromise for industrial deployment [36]. This design also preserves explicit geometric relationships among the coordinate frames, which facilitates calibration verification and troubleshooting.

The proposed framework differs from approaches that consider hand–eye calibration as an isolated optimization problem. Recent calibration algorithms have achieved improvements through robust optimization, uncertainty modeling, automated target detection, and learning-based estimation [33]. However, accurate calibration alone does not guarantee accurate industrial operation because the resulting transformation parameters must subsequently interact with TCP geometry, inverse kinematics, robot control, and mechanical characteristics. The present framework therefore emphasizes the complete sequence from camera observation to final positioning and evaluates its performance according to the actual marking-tool location.

The experimental marking results further demonstrate the practical feasibility of combining visual sensing, coordinate-transformation algorithms, and robotic motion control. Vision-guided systems improve manufacturing flexibility by allowing manipulators to respond to observed workpiece positions instead of depending entirely on mechanically constrained fixtures [34]. In future implementations, machine-learning-based visual perception could further increase this adaptability by recognizing multiple target types and estimating their positions under more variable production conditions.

Several limitations should nevertheless be acknowledged. The experimental evaluation included only **five target positions with two trials per target**, which demonstrates feasibility but is insufficient for comprehensive statistical characterization across the complete robot workspace. Transformation accuracy can vary according to the spatial distribution of calibration and evaluation poses [35]. Future experiments should therefore include substantially more target locations, repeated trials, different TCP orientations, and positions near the limits of the robot workspace.

The experiments were also conducted under controlled conditions with a stationary workpiece. Industrial vehicle body marking may involve illumination changes, reflections from metallic surfaces, vibration, partial occlusion, camera displacement, and moving components. These conditions represent an important motivation for incorporating machine-learning and deep-learning algorithms into future versions of the framework because data-driven perception can potentially provide greater robustness than manually specified visual features. However, machine-learning performance must be validated using independent test conditions to ensure that improvements are not restricted to the environments represented in the training data.

Future development should consequently investigate a **hybrid geometric and machine-learning framework** rather than replacing the coordinate-transformation model entirely. Machine learning can be used for target detection, feature extraction, pose estimation, calibration refinement, and residual-error prediction, while homogeneous transformations and inverse-kinematics algorithms can retain responsibility for physically interpretable coordinate conversion and motion generation. Adaptive calibration and online learning could additionally compensate for gradual changes caused by camera displacement, tool replacement, mechanical wear, or environmental variation [36]. Reinforcement-learning algorithms could also be investigated for adaptive trajectory generation and motion optimization when the robot must operate around obstacles or dynamically changing workpieces.

Overall, the experimental findings indicate that the proposed framework provides a practical foundation for converting visual target information into robot-executable positioning commands. The combination of a **2.19 mm mean positioning error**, **0.39 mm standard deviation**, and approximately **27 ms total processing time** demonstrates a favorable balance between positioning accuracy, stability, and computational efficiency. The present deterministic coordinate-transformation algorithms provide an interpretable geometric foundation, while the future integration of machine learning, deep visual models, adaptive calibration, and data-driven error-compensation algorithms could substantially improve robustness and adaptability. This hybrid direction offers a promising pathway toward intelligent vision-guided robotic marking systems capable of operating under the variable conditions encountered in automotive manufacturing.

VI. Conclusion

This study presented a coordinate transformation framework for vision-guided robotic positioning in automated vehicle body marking. The proposed framework integrates visual target localization, coordinate transformation, TCP pose generation, and inverse kinematics into a unified workflow that converts image-based target coordinates into executable robot motions. Experimental validation using an AR4-MK3 manipulator, an overhead monocular camera, and a 50 W marking device demonstrated reliable positioning with an average error of approximately 2.2 mm, confirming the feasibility of the proposed approach.

Future work will focus on improving the robustness of the framework in dynamic industrial environments through adaptive calibration, continuous target tracking, and multi-camera perception. Additional validation using industrial robotic platforms and larger-scale experiments will further assess the applicability of the proposed framework for automated manufacturing tasks.

***Abstract*—This study aims to improve the automatic recognition of geological host rocks from mining data and to make the prediction process easier to understand for geologists, mining engineers, and data analysts. The study uses a mining dataset containing global mineral and rock information. The data are cleaned, missing values are handled, and the most useful features are selected through three feature selection methods. A deep learning model is then developed to learn hidden rock patterns, links among geological features, and differences between rock classes. The model combines several connected learning parts to capture local, regional, and broad geological patterns. A final classification step is used to identify different host rock types. Explanation tools are also applied to show which features most influence each prediction. The proposed model achieves strong results in recognizing several host rock classes, including limestone, andesite, diorite, gravel, granite, gneiss, sandstone, schist, quartzite, rhyolite, dolomite, alluvium, volcanic rock, and slate. The results show high accuracy in both training and testing data. The explanation results also help identify the geological features that contribute most to the model's decisions. The experimental evaluation is conducted using the Mineral Ores Around the World dataset to assess the effectiveness of the proposed framework for host rock classification. However, the proposed model achieved strong classification performance. Under the 80:20 training-testing split, it obtained an accuracy of 97.91%, and under the 70:30 split, it achieved an accuracy of 97.31%. The study offers an explainable deep learning framework that combines feature selection, multi-level pattern learning, and prediction explanation for host rock recognition. The approach can support faster geological interpretation, mineral exploration, mining planning, and decision-making, and may guide future work on explainable artificial intelligence for mining applications.**

I. Introduction

Recently, the field of mine geophysics has experienced significant growth in research focusing on enhancing the efficiency of exploration and mineral extraction. The increasingly complex geological conditions in modern mining industries require new innovative models for geophysical analysis [1]. The term host rock can refer to a part of the geosphere, particularly in a crystalline-basement setting where sedimentary cover is absent; it more often refers to a particular unit in the geosphere where the repository is situated [2]. In many situations, the host rock refers to the section of the geosphere that provides the most significant confinement for the waste, and it can be enclosed by units with less predictable or less favorable characteristics, including lithologically heterogeneous sequences or aquifers [3]. The classification of various rock units as subdivisions in the crystalline host rock is essential in determining the spatial distribution of significant chemical and physical characteristics in the rock mass [4]. Accurate observation of the neighboring rock deformation condition of mining roadways is important for building a smart coal mine system. During the tunneling process, the original equilibrium of the rock mass is disturbed, which may lead to a potential safety hazard of instability and damage in the neighboring rock [5].

Accurate categorization of multi-element geochemical information is a complex problem because complex geological features influence stream sediments' geochemical data [6]. The classification outcome of multi-element geochemical information can vary when different supervised learning methods are used [7]. Hence, choosing a suitable method for categorizing geochemical data tables into accurate classes of geochemical anomaly and background can reduce bias issues and uncertainty in geochemical anomaly mapping [8]. Thus, precise classification of geochemical samples is a challenging task in mineral exploration targeting. Over the past decades, various machine learning (ML) approaches have been used to classify geochemical data [9]. In this framework, supervised learning methods are used to categorize objects based on pre-defined labels, and unsupervised learning methods are applied to recognize hidden attributes of input without relying on pre-defined labels [10]. Shallow ML methods have a limited number of hidden layers and a lack of ability to capture deep representations from complex inputs [11]. Whereas deep learning methods have strong capabilities for handling complex

data, which include various processing layers that capture high-level feature extraction [12].

A. Problem Statement and Research Contributions

Despite the improvements achieved in geological and geochemical data analysis, precise host rock classification still remains a challenging task owing to the intricate nature of mineral distributions, spatial geological dependencies, and heterogeneous mining data. Traditional machine learning methods often rely on shallow architectures and manual feature extraction, which may not efficiently capture multi-level geological relationships from large-scale mining datasets. Besides, many existing methods mainly focus on classification performance without offering proper interpretability concerning how geological attributes influence prediction outcomes. Therefore, there is a need for an effective deep learning approach that can learn hierarchical geological representations while also providing explainable decision analysis for reliable host rock recognition. To resolve these issues, this study introduces a Hierarchical Deep Representation Learning Model for Multi-Class Geological Host Rock Recognition (HDRL-MGHRR). The major contributions of this work are as follows:

- To develop a hybrid feature selection module using Mutual Information (MI), XGBoost feature importance, and LASSO methods for selecting important geological attributes.
- To design a hierarchical DL architecture integrating Variational Autoencoder (VAE), Hierarchical Capsule Network (HCapsNet), Memory-Augmented Neural Network (MANN), and Hierarchical Attention Layer for learning complex geological representations.
- To perform multi-class host rock classification using a Softmax classification layer for recognizing different geological host rock categories.
- To incorporate SHAP-based explainable geological AI analytics for geological feature interpretation, dependency analysis, and visualization of model predictions.
- To evaluate the presented HDRL-MGHRR method using the Mineral Ores Around the World dataset through different performance evaluation metrics.

II. Literature Review

In this section, a review of related works on machine learning and deep learning techniques for geological host rock and lithology classification is investigated. VISWANATH et al. [13] developed a DL methodology that incorporates Vision Transformers (ViT) with Fourier spectral filtering for RS lithology identification. To address a multi-class classification challenge, the system automates the procedure of detection and classification of several rock categories in RS imagery. Zhao et al. [14] designed an object detection and image recognition methodology to detect sedimentary, metamorphic, and igneous rocks. The author reviewed an enhanced YOLO11-based system by combining the Efficient Visual State Space (EVSS) component, improving the removal of fractures and texture by modeling long-range spatial dependencies. Kim and Youn [15] examined a new CNN with color histograms able to identify igneous rocks. General rock identification models applying DL depend only on CNNs to examine image pattern features. Antonini et al. [16] designed an RF-based prediction system that employs geochemical parameters to categorize ultramafic and mafic rocks interrupted by drill cores. Conversely, as methods become difficult, their interpretation can be significantly more complex. For interpreting the approach's performance, the study utilizes both local and global perspectives, integrating the SHAP algorithm. Xu et al. [17] investigated the unique benefits of CNNs in precisely recognizing underground rock formations and lithological structures, especially their robust feature extraction abilities. Furthermore, DL can effectively process large-scale data, thereby enhancing the precision and efficacy of classification.

Ma et al. [18] used fractal size to differentiate the geometric features of rock mass discontinuity and developed a data-based surrounding rock categorization (SRC) strategy combining ML methodologies. Critical parameters impacting the quality of the surrounding rock were studied and selected. Khajehzadeh et al. [19] proposed a novel ML algorithm for predicting RMDM utilizing the Q-system and rock mass rating (RMR) at the Khersan-2 dam site in southwestern Iran. Various effective ML approaches were used to evaluate RMDM. According to classification models, the site was rated as the best Q and RMR types. Veysi et al. [20] addressed an NMR-electrofacies architecture integrating Combinable Magnetic Resonance (CMR) logging with explainable ML to address these challenges. High-resolution CMR data were examined to measure pore structure features, permeability indicators, and fluid mobility parameters, with stimulated classification accomplished by optimizing an ML strategy integrating SHAP interpretability. The previous studies on rock classification models, including ML/DL techniques, key inputs, application areas, and main outcomes, are presented in Table I.

Many earlier studies used ML and DL approaches for rock and lithology classification. VISWANATH et al. [13] and Zhao et al. [14] mainly worked on image-based rock recognition, but they did not concentrate much on mining data with different geological relations. Kim and Youn [15] employed a CNN for rock classification, but the technique was limited in learning deeper geological relationships. Antonini et al. [16] utilized SHAP for interpretability, yet the work was mainly based on conventional models. Xu et al. [17], Ma et al. [18], and Khajehzadeh et al. [19] focused more on prediction accuracy and classification performance. However, feature selection, hierarchical deep learning, and explainable AI analysis were not combined in a single system. Because of this, there is still a need for a better model that can learn geological relationships effectively and also provide interpretable host rock classification results from mining datasets. Therefore, this study develops a model for learning geological relationships from mining data and provides host rock classification results.

TABLE I. SUMMARY OF ROCK CLASSIFICATION SYSTEMS

Authors & Years	ML/DL techniques	Key Inputs	Application area	Main outcomes
VISWANATH et al. [13]	ViT model	Lithology image patterns.	Lithology classification	Improved geological identification accuracy
Zhao et al. [14]	EVSS and YOLO11 approaches.	Visual spectral-spatial features.	Geological rock classification	mAP50 of 91.8%
Kim and Youn [15]	CNN and histogram algorithms.	Texture and color information.	Rock classification	Accuracy of 96.3%.
Antonini et al. [16]	ML and SHAP techniques.	Explainable geological features.	Igneous rock classification	F1 score of 96%.
Xu et al. [17]	CNN method	Radar signal features	Rock layer identification	Prediction results of 88%
Ma et al. [18]	Bayesian optimization, SVM, RF, and AdaBoost approaches.	Fractal characteristics.	Tunnel rock classification	Mi-F1 of 97.45%.
Khajehzadeh et al. [19]	ML models	Rock mass parameters.	Deformation modulus estimation	R2 of 0.99.
Veysi et al. [20]	NMR and ML methods.	Pore-type characteristics.	Carbonate reservoir classification	R2 of 0.89.

III. PROPOSED METHODOLOGY

Fig. 1 shows the overall workflow of the presented HDRL-MGHRR model for multi-class geological host rock recognition. Initially, the mining dataset is preprocessed, and important geological features are selected using feature selection techniques. Then, hierarchical geological representations are learned through the proposed DL architecture consisting of VAE, HCapsNet, a memory-augmented network, and an attention layer. Lastly, the learned representations are categorized into different host rock classes, and explainable geological AI analysis is carried out for the interpretation of the prediction results.

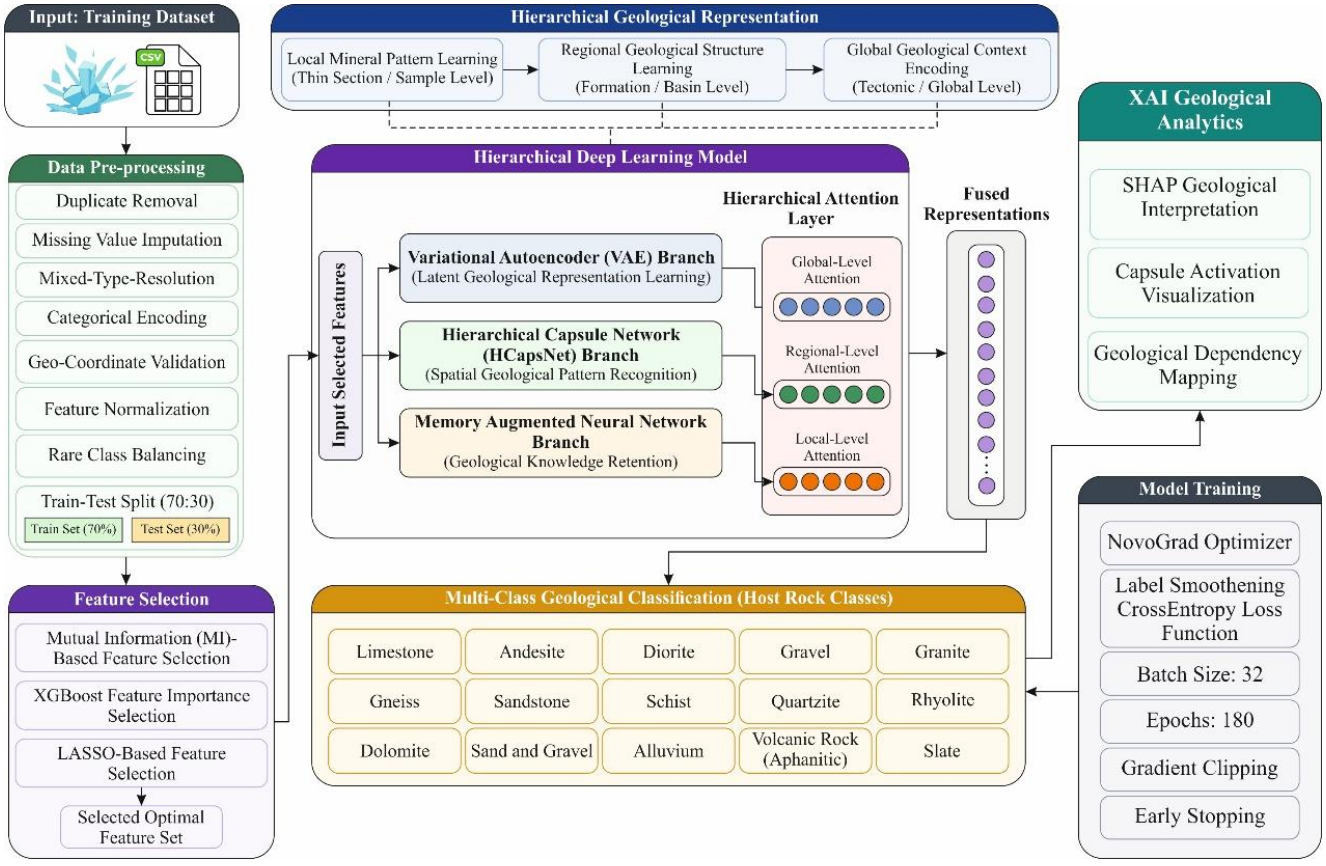

Fig. 1. Overall workflow of the presented approach.

A. Dataset Description

This section describes the dataset utilized for multi-class geological host rock classification. The performance assessment of the HDRL-MGHRR method by employing Mineral ores from all over the world [21]. The dataset encompasses information about different mineral ores discovered in various regions on a global scale. It contains 22

attributes, and it describes relevant geological information, locations, and mineral features; overall, 16 features were chosen for analysis. The dataset is valuable for exploratory data evaluation, ML, mineral classification, and mining-based research applications. The hrock_type distribution comprises a total of 37,687 instances with Limestone (6,931) as the most frequent rock type, followed by Andesite (3,382), Diorite (3,297), Gravel (3,265), and Granite (2,871). Other major rock categories include Gneiss (2,639), Sandstone (2,614), Schist (2,365), Quartzite (2,158), Rhyolite (1,569), Dolomite (1,560), Sand and Gravel (1,388), Alluvium (1,245), Volcanic Rock (1,206), and Slate (1,197), indicating a diverse geological composition across the dataset are represented in Fig. 2.

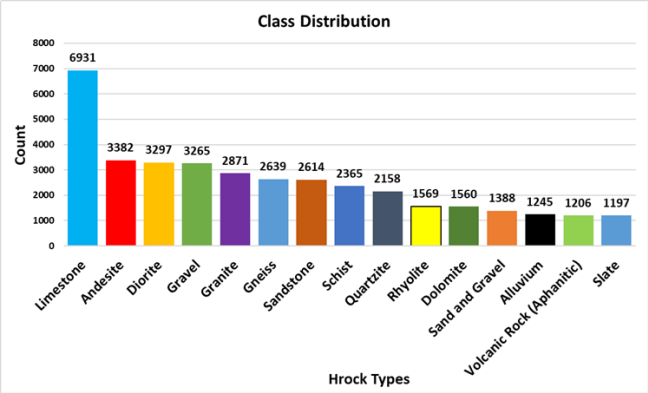

Fig. 2. Class distribution.

B. Data Preprocessing

This section describes the preprocessing steps applied to improve the quality of the mining dataset before model training. Data preprocessing is an important stage in the proposed multi-class geological host rock detection method [22]. The mining dataset contains duplicate records, missing values, categorical features, and inconsistent geo-coordinate information. The purpose of duplicate removal is to eradicate duplicate geological reports from the mining database. Missing values, including blank spaces, null values, and partial geological features, are managed utilizing appropriate imputation models. Mixed-type geological features signified in categorical and numerical formats are converted into a reliable representation. The categorical encoder procedure transforms geological data like mineral type, country, and deposit class into numerical representations appropriate for DL techniques.

Geo-coordinate validation is performed to validate longitude and latitude values and eliminate unreliable spatial geological reports. Feature normalization is used to scale geological features into the same numerical range to enhance model performance. The min-max normalization is expressed as:

$$X_{new} = \frac{X - \min(X)}{\max(X) - \min(X)} \quad (1)$$

In this Eq. (1), X_{new} implies the standardized geological feature data, X denotes the real geological feature data, $\min(X)$ and $\max(X)$ represent the minimal and maximal values of the attributes. Rare class balance is used to minimize geological host rock class imbalance. In conclusion, the database is split into a 70:30 train-test split ratio.

C. Feature Selection Strategy

This section offers the three-stage feature selection techniques utilized to identify the important geological attributes.

1) Mutual information-based feature selection: Mutual information (MI) is a measure in information theory that can be demonstrated as highly effective in variable selection due to its capability of detecting non-linear correlation amongst the parameters [23]. The information is derived from 2 random variables described by the MI between the two variables:

$$I(X;Y) = \sum_{x\in X}\sum_{y\in Y} p(x,y)\log\frac{p(x,y)}{p(x)p(y)} \quad (2)$$

In this work, MI is utilized to identify geological features having stronger dependency on host rock classes.

$$X_{s1} = \arg\max_{X_j} MI(X_j, Y), 1 \le j \le p \quad (3)$$

The subsequent feature is chosen by optimizing the MI between the particular feature subsets and the output:

$$X_{st} = \arg\max_{X_j} \; MI(\{X_{s1}, X_{s2}, \dots, X_{st}\}, Y) \quad (4)$$

2) XGBoost feature importance selection: The XGBoost feature importance method is used to identify geological features that highly influence host rock classification [24]. The importance scores are computed using gain, cover, and weight measures obtained from decision tree structures. Features with higher importance scores are selected for further geological representation learning.

3) LASSO-based feature selection: The LASSO regression is employed for choosing the most significant geological variables related to host rock prediction [25]. This method proficiently chooses important features by removing non-relevant ones by invalidating their coefficients. In the fundamental LASSO regression, the model coefficients decrease the residual sum of squares when combining the penalty factors:

$$\min\left(\sum_{i=1}^{n}(y_i - \hat{y}_i)^2 + \lambda\sum_{j=1}^{p}|\beta_j|\right) \quad (5)$$

$$Y = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \cdots + \beta_p X_p + \varepsilon \quad (6)$$

The LASSO method removes less important geological features by shrinking insignificant coefficients toward zero, thereby improving feature selection efficiency and reducing overfitting.

D. Hierarchical Geological Representation

This section describes the process of learning multi-level geological representations from the selected features. The hierarchical geological representation learning phase is employed to acquire geological data with various ranges from the chosen mining features. The local mineral pattern learning

concentrates on mineral relationships, ore-host interactions, and adjacent geological features present in the mining information. Regional geological structural learning gains geological dependencies and similarities among diverse deposit zones and mining regions. The global geological context encoding process learns the patterns of large-scale geological distribution and total host rock occurrence details that support increasing the performance of multi-class geological host rock classification. Moreover, the selected geological features are organized into three hierarchical levels based on their geological context. The local level represents sample-level mineralogical characteristics, the regional level denotes spatial and geological contextual information, and the global level represents broader geological characteristics. These three representations are processed by the presented model to acquire complementary geological patterns at different levels. The resulting local, regional, and global representations are subsequently integrated by the hierarchical attention mechanism and fused for final host rock classification.

E. Hierarchical Deep Learning Model

This section defines the proposed hierarchical deep learning method used for host rock recognition. The model integrates VAE, Capsule Network, Memory-Augmented Network, and Attention layer for multi-class lithology classification. However, the VAE, HCapsNet, and MANN representations are organized based on local, regional, and global geological contexts. The hierarchical attention mechanism assigns significance to the relevant representations at every level, and the resulting attention-weighted features are fused into a unified representation for final host rock classification. The overall architecture is demonstrated in Fig. 3.

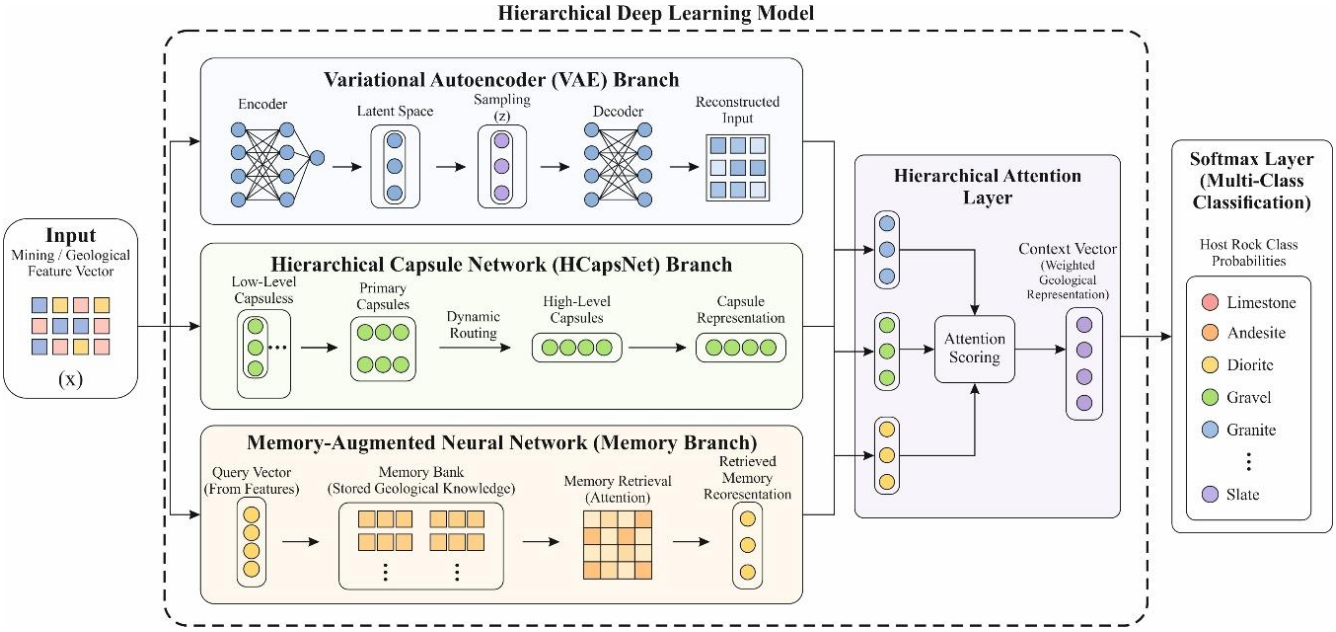

Fig. 3. Hierarchical deep learning architecture.

1) Variational autoencoder (VAE) branch: The VAE branch is utilized for latent geological representation learning [26]. Consider an input geological feature vector (x), the VAE encoder obtains the latent space using the Eq. (7), (8), and (9). Later, the parameters can be utilized to produce the latent variables (z). Furthermore, the VAE branch learns a compact latent representation of the selected geological features, capturing the underlying patterns while reducing redundant information. In conclusion, the VAE decoder applies the latent parameters to reconstruct the input vector of geological representation.

$$\mu = W_2 h + b_2 \tag{7}$$

$$\log var = W_3 h + b_3 \tag{8}$$

$$z = \mu + \epsilon \times e^{0.5 \times \log var} \tag{9}$$

Here, the term h refers to the output of the hidden layer (HL), the symbol μ and $\log var$ indicate latent space factors, the parameters $\{W_1, W_2, W_3, b1, b2, b3\}$ represent weights and biases, and the mathematical representation is $\epsilon \sim N(0,1)$.

The VAE branch is employed to learn latent geological representations from the chosen mining features for boosted performance of host rock classification.

2) Hierarchical capsule network (HCapsNet) branch: This section presents the HCapsNet branch used for spatial geological pattern learning. The capsule network is an advanced framework in the domain of DL developed to overcome the complexity of reducing spatial positional interactions in conventional NNs [27]. The main concept of CapsNet is the fundamental component, named the capsule. Every capsule is not only comprised of scalar values, but it also captures feature vectors that signify numerous features of individuals. Besides, the HCapsNet branch acquires hierarchical relationships between geological features through capsule-based representations, preserving dependencies among lower- and higher-level patterns. This strategy maintains the

spatial hierarchical correlation between host rock structures, mineral relations, and geological features. This method allows the proposed model to recognize the mineral dependency patterns and geological formations more precisely, thus improving the capability of the network for spatial hierarchical and geological correlations.

$$v_j = \frac{\| s_j \|^2}{1+\| s_j \|^2} \frac{s_j}{\| s_j \|} \tag{10}$$

Now, the parameter s_j represents the capsule j's overall input vectors, and the term v_j indicates the capsule j's output vector.

The spatial hierarchical representation ability of CapsNets enhances the identification of intricate host rock structures and geological patterns by employing mining datasets.

3) Memory-augmented neural network branch: This section describes the memory-augmented branch used for retaining geological information. The memory-augmented neural network (MANN) is developed as the solution for processes that require long-range context and sequential coherence [28]. The memory networks are presented by permitting external memory storage and retrieval, thus enabling models to recall and refer to previous details applicable to the existing input. In geological host rock identification, the memory-augmented branch stores significant geological interpretation and mineral dependency data obtained from prior geological instances. The MANN branch stores and retrieves relevant geological patterns using an external memory mechanism, enabling contextual information to contribute to the final representation. Many traditional memory-based systems are dependent upon a huge memory bank that can be developed as computationally stronger and challenging to handle efficiently. The proposed technique employs the memory retrieval process to regain significant geological data for enriched host rock prediction, particularly. This methodology supports the model in retaining geological reliability and increasing the identification of intricate geological patterns by employing large-scale mining datasets.

The memory retrieval process can be denoted by:

$$m_t = Attention(q_t, M) \tag{11}$$

From this mathematical form, the term q_t characterizes the query vector, the parameter M indicates the memory bank, and m_t describes the recovered geological memory representation.

4) Hierarchical attention layer: This section explains the hierarchical attention layer leveraged for learning important geological dependencies. The approach transmits the encoded geological representation from the DL branches to the hierarchical attention layer to allocate an importance-based proportional score [29]. The hierarchical attention layer assigns different significance weights to the local, regional, and global geological representations. The local attention focuses on sample-level mineralogical characteristics, the regional attention emphasizes spatial and geological contextual information, and the global attention acquires broader geological patterns. The resulting attention-weighted representations are then combined to form a unified feature representation for host rock classification. The hidden representation (h_i) of the geological feature (f_i) can be entered into the feed-forward neural network (FFNN) to obtain an encoder representation:

$$\alpha_i = \frac{\exp(u_i^T u_w)}{\sum_j \exp(u_j^T u_w)} \tag{12}$$

$$s = \sum_i \alpha_i h_i \tag{13}$$

Here, the factor u_w represents the context vector, the symbol α_i denotes the attention score, the parameter u_i points to the encoder geological feature representation, and s indicates the final attention-based geological modeling. The hierarchical attention layer supports the proposed method, which concentrates on the most significant geological features, mineral interactions, and spatial dependencies that contribute to the multi-class host rock classification. This method increases the capacity of feature learning and improves the total prediction performance of the proposed HDRL-MGHRR framework.

F. Multi-Class Geological Classification Using Softmax Layer

This section presents the Softmax classification layer used for recognizing different host rock classes. The softmax function is a critical activation function utilized in multi-class geological host rock classifier tasks [30]. It captures a vector of raw scores attained from the proposed hierarchical DL techniques and converts them into a probability function through the host rock categorization. It is vital for interpreting the method outcome as the geological host rock categorization probabilities. In mathematics, for a vector of outcome scores $(z = [z_1, z_2, \ldots, z_k])$, the softmax function calculates the probability $(P(y = k))$ for host rock class (k) as explained in Eq. (14):

$$P(y = k) = \frac{e^{z_k}}{\sum_{j=1}^{K} e^{z_j}} \tag{14}$$

Here, $P(y = k)$ implies the probability of geographical host rock class k, $z_k$implies the outcome score for class k, K signifies the overall count of host rock categories, and e^{z_k} indicates the exponential outcome score for class k

The softmax layer transforms the trained geological representations into the final host rock predictive probabilities, such as Greenstone, Limestone, Schist, Slate, Granite, and Quartzite. The softmax function is differentiable, which is significant for the gradient-driven optimizer approach utilized in neural network training. It allows the proposed HDRL-MGHRR method to efficiently learn geological feature interactions and enhance multi-class host rock classification outcomes.

G. Explainable Geological AI Analytics

This section explains the explainable AI techniques used for the interpretation and analysis of geological predictions.

1) SHAP geological interpretation: The aim of interpretable machine learning (ML) in geological host rock classification is to comprehend how the proposed model creates predictions and to respond to questions about the relations among input and output host rock classes and geological features, and what features are most significant in driving the prediction [31].

2) SHAP-based geological feature attribution: An alternative local interpretation technique is the main idea of Shapley value in game theory that distributes contributions of features while they cooperatively accomplish the prediction outcome. Shapley values measure the influence of all the geological input features in the model that provide the host rock classification.

The Shapley value is determined for a feature X_j,

$$\phi_j = \sum_{S \subseteq N \setminus \{j\}} \frac{|S|!(p-|S|-1)!}{p!} [f(S \cup \{j\}) - f(S)] \quad (15)$$

In this mathematical expression, the term p refers to the total counts of geological features, the factor S represents the feature subset, the parameter $f(S)$ indicates the model prediction with features in S, and the parameter $f(Xj)$ denotes the prediction with feature X_j. The interpretation is that the Shapley value signifies marginal contribution averaged over the entire feature integration.

3) Capsule activation visualization: Capsule activation visualization has been employed to comprehend the spatial geological pattern recognition learned through the Hierarchical Capsule Network (HCapsNet) framework. This outputs a capsule module that characterizes the hierarchical geological formations, like regional developments and local mineral formations. The activation capability specifies the significance of spatial geological correlation in the classification process.

4) Geological dependency mapping: Geological dependency mapping evaluates correlation among host rock classes, mineral deposits, and spatial coordinates. This visualization shows how geological developments are circulated over the regions. The SHAP values are spatially calculated to recognize the impacts of the geological field.

5) Attention visualization: The hierarchical attention layer allocates adaptive weights to geological features and latent representations. This attention visualization is recognized in the geological fields, and mineral amalgamation gives maximum for classifying the host rock.

The incorporation of SHAP-based interpretation, capsule activation visualization, geological dependency, and mapping attention visualization offers a wide-ranging explainability model for the proposed hierarchical DL method, thereby increasing the interpretability of geological host rock classification methods.

IV. Model Training Configuration

This section presents the training settings and parameter configurations used for the proposed model. NovoGrad optimization works by standardizing gradient updates at the parameter group level instead of the specific parameter level, which enables it to effectively handle the higher-dimensional parameter space of the hierarchical DL methods [32]. This group-by-group gradient normalization steadies the upgrades by balancing gradient scales, avoiding uneven upgrades in multi-class geological host rock recognition. Particularly, the 2nd moment estimation is calculated as:

$$v_t = \beta_2 v_{t-1} + (1-\beta_2) \parallel g_t \parallel^2 \quad (16)$$

Here, v_t denotes the 2nd moment estimation at iteration t, β_2 implies the exponential decay rate, and g_t signifies the gradient at iteration t. The upgrade rule of the parameter is expressed as:

$$\theta_{t+1} = \theta_t - \eta \frac{m_t}{\sqrt{v_t} + \epsilon} + \lambda \theta_t \quad (17)$$

In this Eq. (17), θ_t signifies the parameter of the method at iteration t, m_t implies momentum-based 1st moment estimation, η indicates the learning rate, v_t denotes the 2nd moment estimation, ϵ represents a smaller constant for numerical stability, and λ implies the regularization parameter. Moreover, Label Smoothing Cross-Entropy loss is utilized to minimize overconfidence in predictions and enhance generalization outcomes in multi-class classification.

$$L = -\sum_{i=1}^{K} y_i^{LS} \log(p_i) \quad (18)$$

where, K= total classes, p_i= predicted probability for class i, and y_i^{LS}= label-smoothed target value for class i.

The proposed model is trained employing a batch size of 32 over 180 epochs. Gradient clipping is used to avoid exploding gradients and stabilize deep model training, whereas early stopping is used to prevent overfitting and improve the performance of the framework.

V. Experimental Results and Discussion

This section discusses the experimental results and performance analysis of the presented HDRL-MGHRR approach.

A. Performance Metrics

For assessing the performance of the presented model, several standard classification metrics are used, including accuracy, precision, recall, F1-score, and AUC score. In these equations, TP indicates true positives, TN denotes true negatives, FP points to false positives, and FN signifies false negatives.

Accuracy assesses the overall correctness of the model and is defined as:

$$\text{Accuracy} = \frac{TP + TN}{TP + TN + FP + FN} \quad (19)$$

Precision measures how many predicted positive samples are actually correct:

$$\text{Precision} = \frac{TP}{TP + FP} \quad (20)$$

Recall quantifies how many actual positive samples are properly recognized:

$$\text{Recall} = \frac{TP}{TP + FN} \quad (21)$$

F1-score is the harmonic mean of precision and recall and offers a balanced measure:

$$\text{F1- score} = \frac{2^{*}Recall^{*}Precision}{Recall + Precision} \quad (22)$$

AUC (Area Under the Curve) measures the system's capability for distinguishing between classes using the ROC curve:

$$AUC = \int_0^1 TPR\, d(FPR) \quad (23)$$

B. Result Analysis

Fig. 4 exemplifies the confusion matrix of the HDRL-MGHRR technique by comparing actual rock classes with predicted categories. The higher values on the diagonal specify strong classification accuracy, although the lower off-diagonal values indicate that only some of the instances can be incorrectly categorized into alternate rock types. Table II shows the parameter settings of the proposed methodology.

TABLE II. PARAMETER SETTING

Category	Parameter	Setting
Input	Input feature dimension	16
	Number of classes	15
VAE	Encoder architecture	16 → 64 → 32
	Latent-space dimension	32
	Decoder architecture	32 → 64 → 16
	Activation function	ReLU
HCapsNet	Capsule configuration	8 × 8
	Capsule dimension	8
	Routing iterations	3
	Capsule activation	Squashing
MANN	Memory size	128 × 64
	Memory retrieval	Cosine-similarity-based Top-4
	Query/feature dimension	64
Hierarchical Attention	Number of attention levels	3
	Attention hidden dimension	32
	Attention mechanism	Additive attention + Softmax
Feature Fusion	Fusion method	Attention-weighted fusion
	Fused feature dimension	64
Classifier	Classifier	Fully connected + Softmax
Regularization	Dropout	0.2
	Weight decay	1×10^{-4}
Initialization	Weight initialization	Kaiming/He
	Bias initialization	Zero
Training	Optimizer	NovoGrad
	Batch size	32
	Epochs	180
	Loss function	Label-Smoothed Cross-Entropy
	Label smoothing	0.1
	Gradient clipping	Max norm = 1.0
	Early stopping	Enabled

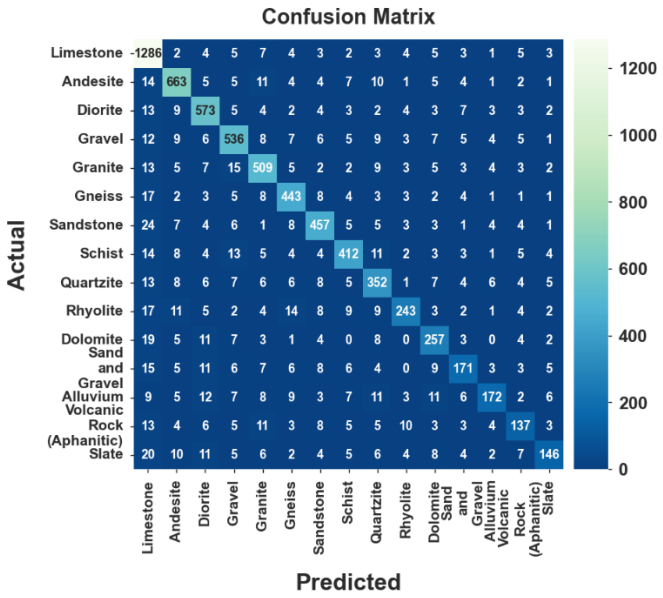

Fig. 4. Confusion matrix of the HDRL-MGHRR method.

Table III presents the multi-class rock recognition outcome of the HDRL-MGHRR approach with an 80:20 train-test split. The outcome implied that the HDRL-MGHRR method accurately classified the rock samples. The HDRL-MGHRR method achieved an average value $accur_y$ of 97.92% in TRAIP and $accur_y$ of 97.91% in TESTP, while the AUC_{score} of 89.10% for the TRAIP and AUC_{score} of 89.13% for the TRAIP, demonstrating the robustness and effectiveness of the proposed approach.

TABLE III. MULTI-CLASS ROCK RECOGNITION RESULTS OF THE HDRL-MGHRR METHOD WITH 80:20

Class Labels	$Accur_y$	$Preci_n$	$Recal_l$	$F1_{score}$	AUC_{score}

Fig. 5 demonstrates the confusion matrix of the HDRL-MGHRR system by comparing actual rock types with predicted classes. The maximal values on the diagonal represent strong classification accuracy, even though the minimal off-diagonal values indicate that only a small number of samples were inaccurately categorized into other rock classes.

Table IV represents the multi-class rock recognition outcome of the HDRL-MGHRR method with a 70:30 train-test split. The experimental outcome values indicate that the HDRL-MGHRR system precisely categorized the rock instances. The HDRL-MGHRR technique accomplished an average value $accur_y$ of 97.38% in TRAIP and $accur_y$ of 97.31% in TESTP, and then the AUC_{score} of 86.39% for the TRAIP and AUC_{score} of 85.98% for the TRAIP, signifying the robustness and efficiency of the proposed model.

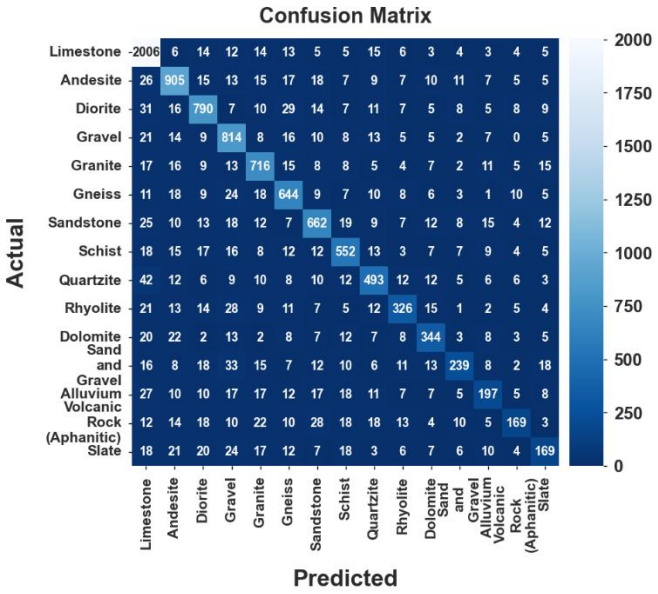

Fig. 5. Confusion matrix of the HDRL-MGHRR method.

TABLE IV. MULTI-CLASS ROCK RECOGNITION RESULT OF THE HDRL-MGHRR METHOD WITH 70:30

Class Labels	$Accur_y$	$Preci_n$	$Recal_l$	$F1_{score}$	AUC_{score}

Average	**97.31**	**76.79**	**73.42**	**74.70**	**85.98**

Table V shows the comparison outcome of the HDRL-MGHRR approach with existing methods using evaluation metrics, error rate, and execution time. The findings show that the HDRL-MGHRR method achieves better performance. The TS-FIS, AdaBoost, LogitBoost, RUSBoost, XGBoost, FT-Transformer, DCNv2, and TabNet approaches have lower outcomes. At the same time, the proposed HDRL-MGHRR system has achieved greater performance with $accur_y$ of 97.91%, $preci_n$ of 82.76%, recall of 79.39%, $F1_{score}$ of 80.80% and AUC of 89.13%. However, among the considered models, only FT-Transformer, DCNv2, and TabNet were reimplemented, while the remaining models were directly referred to from previously published papers [33].

TABLE V. COMPARATIVE RESULTS OF THE HDRL-MGHRR METHOD WITH OTHER APPROACHES

Algorithm	Accuracy	Precision	Recall	F1	AUC
TS-FIS	87.30	78.20	76.80	77.49	82.64
AdaBoost	89.20	80.40	78.90	79.64	84.18
LogitBoost	88.20	79.30	77.80	78.54	83.37
RUSBoost	85.30	74.60	72.90	73.74	80.91
XGBoost	88.20	79.80	78.10	78.94	83.76
FT-Transformer	92.60	81.20	78.60	79.88	86.21
DCNv2	91.80	80.60	77.90	79.22	85.73
TabNet	93.40	82.10	78.80	80.42	86.84
HDRL-MGHRR	**97.91**	**82.76**	**79.39**	**80.80**	**89.13**

An ablation study evaluates a model by removing or modifying its components to understand their individual contributions to performance. It helps identify the most important parts of the system and supports better model design and optimization.

TABLE VI. ABLATION STUDY OF THE HDRL-MGHRR METHOD WITH METRICS

Techniques	Accuracy	Precision	F1-Score
Without Feature Selection	91.84	69.72	67.85
MI Only	92.67	72.18	70.43
LASSO Only	92.91	72.84	71.16
XGBoost Feature Importance Only	93.14	73.56	71.82
VAE Only	93.58	75.21	73.14
HCapsNet Only	94.26	77.08	74.92
MANN Only	94.71	78.36	76.18
VAE + HCapsNet + MANN (without Hierarchical Attention)	96.38	81.47	79.96
HDRL-MGHRR (MI + XGBoost + LASSO + VAE + HCapsNet + MANN + Hierarchical Attention)	97.91	82.76	80.80

Table VI presents the ablation study of the HDRL-MGHRR approach with various metrics. The outcome implies that the Without Feature selection, MI only, XGBoost Feature Importance only, LASSO only, VAE only, HCapsNet only, MANN only, and VAE + HCapsNet + MANN (without Hierarchical Attention) approaches have gained minimal performance with various metrics, while the HDRL-MGHRR(MI + XGBoost + LASSO + VAE + HCapsNet + MANN + Hierarchical Attention) approach has obtained maximal performance with $accur_y$ of 97.91%, $preci_n$ of 82.76%, and $F1_{score}$ of 80.80%, indicating the effectiveness of the combined structure.

Fig. 6 presents the SHAP-based explanations for multi-class rock classification, illustrating both global and local feature contributions across different rock categories. The left panels show the global feature importance, indicating the overall contribution of variables such as ore type, location coordinates, and geological characteristics to the model predictions. The right panels provide local explanations, showing how individual feature values contribute positively or negatively to specific predictions. The SHAP analysis serves as the primary feature-level explanation, while the attention mechanism provides complementary insight into the relative focus assigned to the hierarchical representations. Together, these analyses provide a more transparent interpretation of the model's decision-making process.

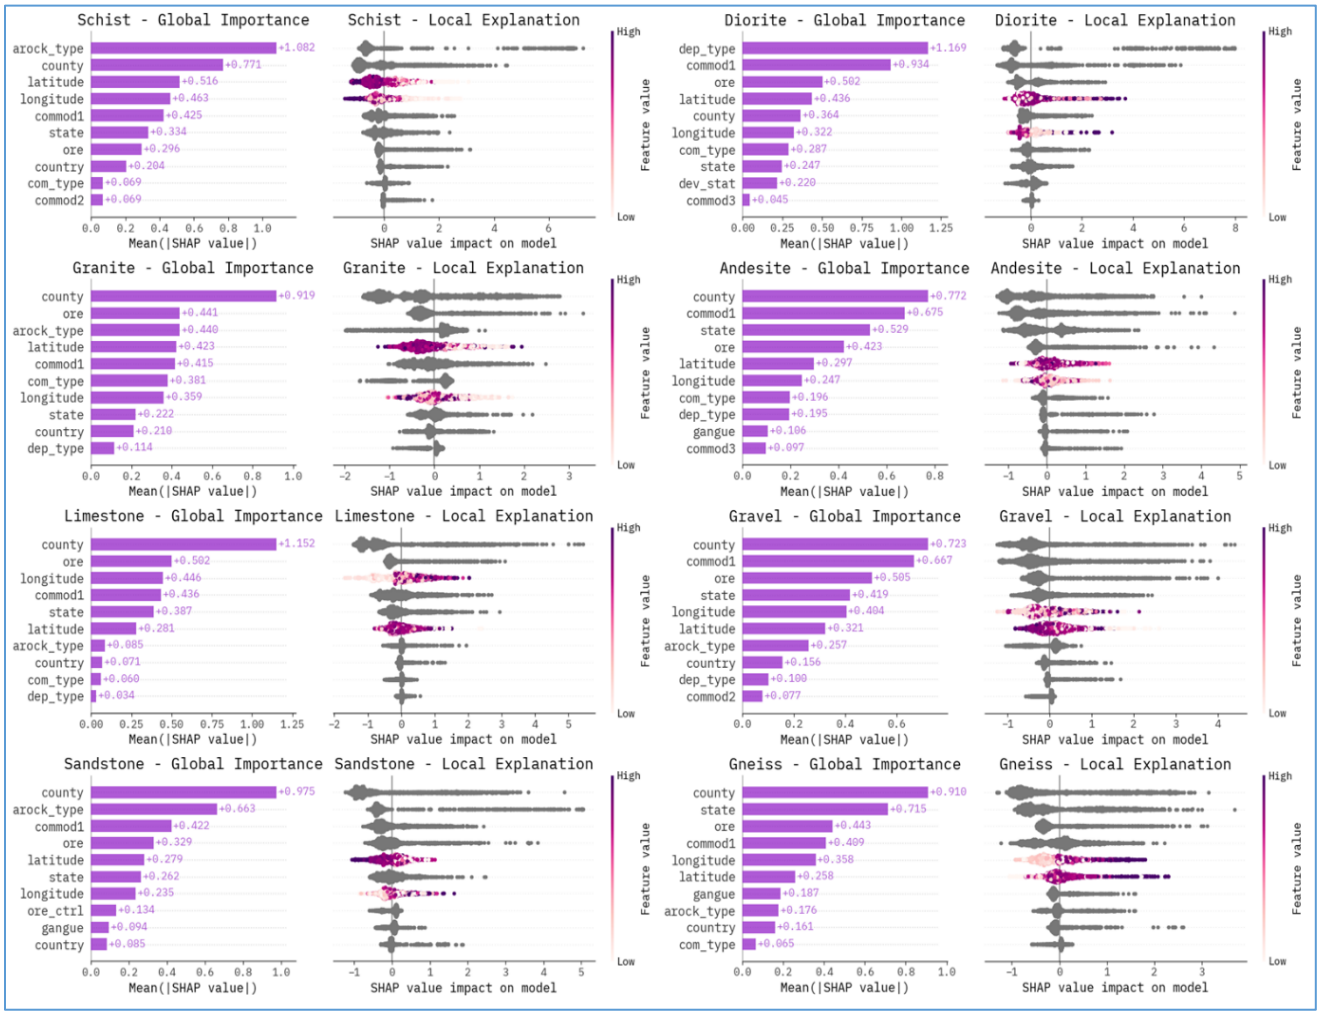

Fig. 6. SHAP values of the global and local explanations.

The experimental results illustrate that the presented HDRL-MGHRR architecture performs consistently over the 80:20 and 70:30 train–test splits, attaining approximately 97% accuracy with balanced precision, recall, and F1-score. To prevent data leakage, the dataset is first divided into training and testing partitions, with preprocessing parameters, class balancing, and feature-selection decisions based on Mutual Information, XGBoost, and LASSO learned exclusively from the training data, while the test set remained unseen until final evaluation. Class-wise results display higher performance for well-represented categories like Diorite, Andesite, and Limestone, while lower performance is observed for minority classes like Alluvium, Volcanic Rock, and Slate due to their limited representation and geological similarities. The difference between the overall accuracy of 97.91% and the class-average AUC of 89.13% is related to class imbalance, as accuracy could be influenced by better-represented classes, whereas AUC offers broader insight into class-wise discriminative ability. Class-wise metrics, confusion matrices, and MCC further aid the evaluation of per-class reliability. Comparative outcomes against Vision Transformer, ResNet variants, YOLO11, and DenseNet illustrate the proficiency and computational efficiency of HDRL-MGHRR. The ablation study further ensures the contributions of the feature-selection models and hierarchical components, illustrating that their incorporation offers efficient and computationally effective host rock classification.

VI. Conclusion and Future Work

This study has presented the HDRL-MGHRR model for multi-class geological host rock recognition using mining data analytics. The proposed model applied MI-based feature selection, XGBoost feature importance selection, and LASSO-based feature selection to select the most relevant geological attributes for host rock classification. A hierarchical DL approach consisting of a VAE, HCapsNet, Memory-Augmented Neural Network, and Hierarchical Attention Layer was developed to learn latent geological representations, spatial geological structures, and multi-level mineral dependencies from mining data. The learned geological representations were then categorized using a Softmax layer for recognizing multiple host rock classes. Furthermore, SHAP-based explainable geological AI analytics was used for geological feature interpretation and dependency analysis. This integration facilitated both global and local interpretation of predictions by identifying important geological features and mapping their contribution toward host rock classification through SHAP

geological interpretation, capsule activation visualization, geological dependency mapping, and attention visualization. Experimental analysis on the Mineral Ores Around the World dataset showed the improved performance of the proposed HDRL-MGHRR approach in accomplishing interpretable multi-class geological host rock recognition.

Although the presented HDRL-MGHRR architecture illustrates efficient host rock classification on the evaluated dataset, the study is based on a static curated dataset and does not establish real-time deployment readiness. Temporal validation, geographically independent evaluation, field-level testing, robustness to measurement noise and missing data, and systematic operational latency assessment were not executed. Thus, the current outcomes primarily illustrate benchmark classification performance rather than validated real-world deployment capability. Future work will focus on validating HDRL-MGHRR using temporally independent and geographically diverse geological datasets, as well as real field measurements. Additional experiments will investigate robustness to sensor noise and missing attributes, and systematic latency and real-time deployment evaluations will be conducted to assess the practical suitability of the framework for geological monitoring and mineral exploration.

ACKNOWLEDGMENT

The authors extend their appreciation to Northern Border University, Saudi Arabia, for supporting this work through project number (NBU-CRP-2026-3030). This study is supported by funding from Prince Sattam bin Abdulaziz University, project number (PSAU/2026/R/1447).

Effective Chunking for Retrieval-Augmented Generation over Structured Institutional Documents

Siti Sarah Izhan Khalib[1], Abdul Hadi Abd Rahman[2]*, Lailatul Qadri Zakaria[3]
Faculty of Information Science and Technology, Universiti Kebangsaan Malaysia[1]
Center for Artificial Intelligence Technology, Universiti Kebangsaan Malaysia[2, 3]

***Abstract*—Retrieval-Augmented Generation (RAG) has improved domain-specific question answering tasks by grounding responses in an external knowledge base. However, institutional documents differ from general corpora due to the presence of structured content such as tables, flowcharts, fee breakdowns and program codes. Existing RAG pipelines typically employ generic chunking strategies designed for unstructured text, which can fragment structured information and degrade answer quality. This study evaluates four chunking strategies across six configurations. The evaluation uses 65 publicly available structured documents from Universiti Kebangsaan Malaysia (UKM) with 28 Bahasa Melayu queries. Retrieval performance, answer quality and structural integrity are compared across configurations. Retrieval performance is generally similar across configurations, whereas answer quality varies more substantially. Structure-aware chunking achieves the highest ROUGE-L, BLEU and BERTScore F1 values, while semantic chunking achieves the highest table-integrity score. The findings demonstrate that chunking strategies influence RAG objectives in distinct ways, with structure-aware chunking improving answer generation while semantic chunking more effectively preserving table integrity. The results provide an empirical basis for selecting chunking configurations for structured institutional RAG systems.**

***Keywords*—Chunking; retrieval-augmented generation; structured text; documents**

I. Introduction

The rapid advancement of Large Language Models (LLMs) has significantly enhanced the capabilities of intelligent chatbot systems across multiple domains, including higher education [1]-[5]. Universities increasingly deploy chatbot systems to support university communities' inquiries related to students' admissions, academic programs and administrative procedures [5]. However, traditional FAQ-based systems are limited by their reliance on predefined question-answer pairs [6], restricting their ability to handle diverse or unseen queries and reducing their flexibility.

The emergence of Retrieval-Augmented Generation (RAG) for chatbots has addressed these limitations by integrating external knowledge sources into the response generation process. RAG enables chatbots to retrieve relevant information from domain-specific documents, improving factual accuracy and reducing hallucination [7]. In the context of higher education, RAG-based systems have been explored to enhance institutional question answering by leveraging university documents such as guidelines, brochures and policy materials [8].

*Corresponding author.

Despite these advancements, several challenges remain in the retrieval process for institutional question answering. Unlike general unstructured text corpora, institutional documents often contain structured information such as tables, flowcharts, fee breakdowns and program codes [9]. However, standard text extraction pipelines are typically designed for linear and unstructured text, which may fail to preserve these structural elements effectively [9], [10]. As a result, important relationships within tables can be lost, leading to noisy representations and broken structural context even before the chunking stage. This limitation reduces the quality of the knowledge base and introduces errors throughout the retrieval process.

In addition, a more critical challenge lies in the chunking strategy used in RAG systems. Most existing approaches adopt generic chunking methods [7], [11] such as fixed-size or recursive segmentation [12], which are primarily designed for unstructured narrative text. When these methods are applied to structured institutional documents, they may split tabular data or logically related information across multiple chunks [13]. This situation results in fragmented context and degradation of the answer quality [12]. Although prior studies have explored various chunking strategies in RAG [7], [12], relatively limited evidence is available on how these strategies preserve semantic and structural integrity within structured document settings, particularly in real-world institutional environments.

To address this gap, the study evaluates the effect of chunking configurations on RAG performance for structured institutional documents. Four chunking strategies are examined through six configurations: fixed-size 256 tokens, fixed-size 512 tokens, fixed-size 512 tokens with 50-token overlap, recursive, semantic and structure-aware chunking. The configurations are compared in terms of retrieval effectiveness, answer quality and structural integrity preservation. The main contributions of the study are as follows: 1) an empirical comparison of six chunking configurations for structured institutional documents, 2) a structure-sensitive evaluation of table integrity, and 3) an empirical analysis based on a real-world institutional dataset derived from Universiti Kebangsaan Malaysia (UKM).

II. Related Work

RAG systems combine retrieval and generation to ground LLM responses based on external knowledge [7], and recent studies have investigated their use in higher education and other domain-specific settings [8], [12]. In these systems, chunking determines the units of the data that are indexed in the vector databases and retrieved, thereby influencing both the

information available to the generator and the computational cost of retrieval.

Recent chunking research has moved beyond simple fixed-sized segmentation. Recursive methods use hierarchical separators to preserve local context, while semantic methods use embedding similarity to form meaning-based segments [11], [12], [13]. Studies in clinical, enterprise and scientific domains indicate that chunk size and boundary selection can affect retrieval and downgrade the answer quality [12], [14], [15]. These findings suggest that retrieval effectiveness alone may not capture the full impact of chunking on generation.

Chunking becomes more challenging when documents contain structured and heterogeneous content, as separating logically related elements can affect the information available for generation. In such settings, related elements may need to remain together when their relationship is necessary to answer a query. TableRAG, for example, emphasizes the preservation of table structure for heterogeneous document reasoning [16]. Structure-aware chunking has also been investigated for enterprise documents, where document elements can be segmented according to their structural roles [14], [17]. Recent topology-aware approaches further consider hierarchical relationships between document components [18]. However, evidence remains limited for multilingual institutional documents containing heterogeneous PDFs, tables, programme codes and administrative content.

The present study therefore focuses on the relationship between chunk boundaries, retrieval behaviour, answer quality and structural integrity in an institutional RAG setting. Unlike evaluations that focus primarily on retrieval metrics, the study jointly examines retrieval, generation and table-level structural preservation.

III. Experimental Setup

A. Dataset

The dataset consists of 65 publicly available institutional documents from Universiti Kebangsaan Malaysia (UKM). These documents include academic brochures, fee structures, program guidelines, and administrative policies. The corpus contains heterogeneous formats, overlapping terminology, and structured content such as tables and program codes. This makes it a practical testbed for evaluating chunking strategies in an institutional RAG setting. Table I summarizes the total documents included in the dataset based on categories:

TABLE I. Dataset Statistics

Category	No. of Documents
Students Undergraduate and Postgraduate Guidelines, Handbooks, Programme Brochures	21
Grant and Research Fund Guidelines	18
UKM ICT Guidelines	12
UKM's campus magazines	5
Open-source platform (Official UKM website)	2
UKM's town hall forum slides	3
Other UKM's centers guidelines	4
Total Documents: 65	

B. Hardware Setup

The experiments were conducted on a GMKTec AI PC equipped with the following specifications:

- GPU: AMD Radeon 8060s
- CPU: AMD Ryzen™ AI Max+ 395 (16 cores, up to 5.1GHz)
- RAM: 128GB
- Storage: 2TB

C. Evaluation Parameters

The evaluation is designed to assess system performance from three perspectives, including retrieval effectiveness, answer quality and structural integrity. The retrieval and generation settings are held constant across chunking configurations.

- Retrieval Evaluation: Measures the ability of the system to retrieve relevant document chunks.
- Answer Quality Evaluation: Assesses the correctness and relevance of generated responses.
- Structure-Sensitive Evaluation: Evaluates how well chunking strategies preserve structured information such as tables and program-specific data.

D. Query Dataset

A set of 28 evaluation queries was constructed to reflect realistic student information needs commonly encountered in institutional chatbot interactions. The queries are categorized into four types based on their information-seeking characteristics and structural complexity.

- Structured Queries: Questions requiring retrieval of tabular information, such as course fee amounts, program codes and semester durations. These queries test the system's ability to preserve co-located structured data across chunking strategies.
- Factual Queries: Questions seeking specific information from policy documents, guidelines, or institutional profiles. These queries evaluate retrieval precision and answer accuracy for well-defined information needs.
- Procedural Queries: Questions about multi-step processes, for example, application requirements or administrative procedures. These queries test the system's ability to retrieve and synthesize information spanning multiple document sections.
- Open-Ended Queries: Questions requiring comprehensive answers aggregating information from multiple sources.

Each query is paired with a ground truth answer derived from authoritative institutional documents, including fee structure tables, student handbooks, ICT guidelines, research funding policies and university policies. The query set comprises direct questions and paraphrased variants. All queries are written in Bahasa Melayu, reflecting the primary language of institutional documents and student interactions at

UKM. Ground truth answers range from short factual responses to paragraph-length explanations, with an average length of 87 words. The small number of queries, particularly the single open-ended query, limits the extent to which the results can support broad claims about diverse institutional question types. Table II summarizes the query dataset distribution by type and the percentage of each type.

TABLE II. QUERY DATASET STATISTICS

Query Type	Count	Percentage (%)
Structured	6	21.4
Factual	16	57.1
Procedural	5	17.9
Open-Ended	1	3.6
Total	28	100

E. Evaluation Metrics

The performance of the proposed system is evaluated using three types of metrics:

1) Retrieval metrics: Retrieval effectiveness is assessed using Hit@1, Hit@3, Precision@3, Recall@3, Mean Reciprocal Rank (MRR) and Normalized Discounted Cumulative Gain (nDCG). Hit@k is 1 when at least one relevant chunk appears among the top k retrieved chunks and 0 otherwise. Precision@3 is the proportion of the three retrieved chunks judged relevant, whereas Recall@3 is the proportion of all relevant chunks retrieved in the top three. MRR is the mean reciprocal rank of the first relevant chunk. nDCG measures ranking quality relative to the ideal ranking. The evaluation uses a fixed top-3 retrieval set for rank-based retrieval metrics, and after reranking, the top two chunks are then supplied to the generation model. These are the standard metrics for evaluating RAG retrieval performance as suggested in previous studies [7], [14], [17].

2) Answer quality metrics: Generated answers are evaluated using ROUGE-L, BLEU, BERTScore F1 and semantic similarity. ROUGE-L and BLEU measure lexical overlap with the ground-truth answer, while BERTScore and semantic similarity capture semantic alignment [11], [12], [19].

3) Structural integrity metric: To assess the preservation of structured information, a structural integrity metric is introduced. This addresses a gap in existing RAG evaluation frameworks [19], which do not explicitly measure table row co-location. This is a critical requirement for institutional documents that contain important information such as fee structures and program codes [9], [16].

IV. METHODOLOGY

This study implements a Retrieval-Augmented Generation (RAG) framework to investigate the impact of chunking strategies on retrieval and answer quality for structured institutional documents. The overall system architecture consists of three main stages: document preprocessing and chunking, dense retrieval and answer generation. The institutional documents in this study refer to the documents of Universiti Kebangsaan Malaysia (UKM) that are publicly available on the Internet.

A. Data Preprocessing Pipeline

Fig. 1 illustrates the data preprocessing pipeline involved in this study. Raw institutional PDFs are cleaned to remove irregular spacing, redundant headers and footers and unwanted characters. The cleaned content is then converted to text and segmented according to the evaluated chunking configuration. Each chunk is embedded using the intfloat/multilingual-e5-base model. This embedding model is suitable to be used for information retrieval or semantic similarity across various languages [20], which makes it a suitable model for this study, as most of the institutional documents are in the Malay language. This will convert the chunks into dense vector representations and stored in a local vector database. Finally, each text segment is enriched with metadata, including document source, document title and section information. This metadata provides contextual information that supports more effective retrieval and analysis.

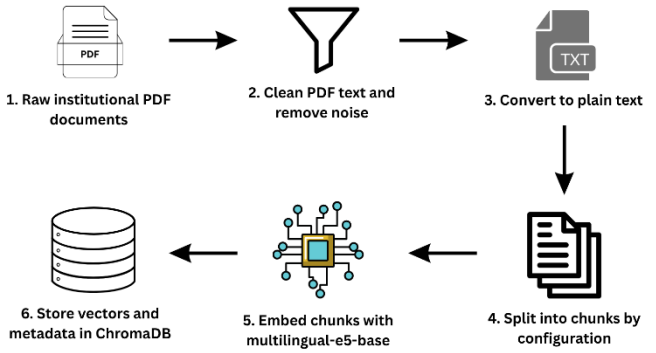

Fig. 1. Data preprocessing pipeline.

B. Retrieval-Augmented Generation Process

During the inference phase, a user query is embedded using the same embedding model used for document indexing. A similarity search retrieves the top three candidate chunks from the vector database. The BAAI/bge-reranker-v2-m3 model then reranks these candidates, and the top two chunks are supplied to the LLM together with the original query to generate the final response based on the retrieved knowledge and the user query.

To ensure experimental consistency and validity, the retrieval mechanism, embedding model, vector database configuration, reranker, language model and prompt template are kept constant across all experiments. Therefore, observed differences in retrieval accuracy or answer quality are primarily attributable to the chunking configuration.

C. Vector Store Setup and Retrieval Configuration

All chunks are embedded using the intfloat/multilingual-e5-base model, producing 768-dimensional dense vectors stored in ChromaDB, which is the chosen local vector database in this study. During query processing, the user query is embedded into the same vector space. Then, the top three (k=3) most similar chunks are retrieved and reranked using BAAI/bge-reranker-v2-

m3. The final top two (k=2) reranked chunks are then passed to the generation model for answer generation.

D. Generation Model

The retrieved chunks are provided as context to a large language model for answer generation. This study employs the Gemma-3-4b-it quantized model running locally via llama.cpp. The model was selected for its strong multilingual performance across more than 140 languages [21]. The generation parameters are as follows:

- Temperature: 0.5
- Max tokens: 512
- Top-p: 0.9

A single response was generated for each query under the fixed generation settings of the parameters. The same generation configuration was applied across all chunking configurations to maintain consistency. Because the model operates with non-zero temperature, the generation process may exhibit stochastic variation. However, repeated generations were not performed in the present experiment. Therefore, the reported answer-quality metrics represent performance from a single generation for each query and do not quantify generation-level variability.

E. Prompting Strategy

A consistent prompt template is used across all experiments to ensure fair comparison. Fig. 2 shows the prompt template used for generation. This detailed prompt instruction ensures the model relies solely on retrieved context and does not add external knowledge to reduce hallucinations.

JAWAPAN:"""
```

Fig. 2. Prompt template.

F. Chunking Configurations

Four chunking strategies are evaluated across six configurations. The fixed-size strategy contains 256-token, 512-token and 512-token with 50-token overlap configurations, while the remaining strategies are recursive, semantic and structure-aware. Each configuration is used to construct a separate vector store while all other retrieval and generation settings remain unchanged. The fixed-size configurations represent selected small and moderate chunk sizes with an additional overlap condition rather than an exhaustive sensitivity analysis across chunk-size and overlap settings [15].

1) Fixed-size chunking: Fixed-size chunking divides text into uniform chunks based on a predefined token length. While computationally efficient, it does not consider semantic or structural boundaries, which may result in fragmented information [7], [12].

2) Recursive chunking: Recursive chunking splits text hierarchically based on natural linguistic boundaries such as paragraphs and sentences [7], [12]. This approach aims to maintain contextual coherence while controlling chunk size.

3) Semantic chunking: Semantic chunking groups sentences based on embedding similarity and meaning [12], ensuring that each chunk represents a semantically coherent unit of information [11],[13]. It can preserve topical coherence but may produce larger and more variable chunk sizes.

4) Structure-aware chunking: Structure-aware chunking is specifically designed for structured documents. It preserves meaningful structural elements such as tables, headings and program-specific data, ensuring that logically related information remains within the same chunk [16], [17]. This is particularly important for institutional documents containing important structural information such as fee tables and coded program information.

V. Results

A. Chunk Intrinsic Analysis

Before examining the retrieval and answer, the intrinsic properties of the chunking strategies were analyzed to understand their structural characteristics. Table III summarizes the total number of chunks produced, average chunk length in characters, intra-chunk semantic coherence and table integrity rate. Coherence is computed as the mean pairwise cosine similarity between sentence embeddings within a chunk, following established practice in semantic segmentation evaluation [13].

TABLE III. Chunk Intrinsic Statistics Across Chunking Configurations

Chunking Configuration	Total Chunks	Avg. Length	Coherence	Table Integrity
Fixed-size 256 tokens	10,011	177	0.813	0.469
Fixed-size 512 tokens	4,891	363	0.824	0.552
Fixed-size 512 tokens with 50-token overlap	4,925	368	0.824	0.523
Recursive	5,040	367	0.825	0.540
Semantic	1,517	1,172	0.816	**0.709**
Structure-aware	2,879	627	**0.826**	0.535

Fixed-size chunking at 256 tokens produced the largest number of chunks, which is 10,011 chunks with an average length of only 177 characters. This aggressive fragmentation results in the lowest intra-chunk coherence at 0.813 and the worst table integrity rate at 0.469, confirming that uniform, boundary-agnostic segmentation is poorly suited for documents containing structured tabular content [17]. Fixed-size chunking at 512 tokens reduced the chunk count to 4,891, improving average chunk length to 363 characters, coherence to 0.824, and table integrity to 0.552. Adding a 50-token overlap did not improve coherence but reduced table integrity marginally to

0.523, suggesting that overlapping boundaries may occasionally duplicate partial table rows across adjacent chunks.

Recursive chunking produced 5,040 chunks with an average length of 367 characters and the second-highest intra-chunk coherence at 0.825, consistent with the expectation that hierarchical splitting along natural linguistic boundaries preserves topical unity within each chunk [7]. Semantic chunking produced the fewest chunks, which are 1,517 and the largest average length (1,172 characters). This strategy achieves the highest table integrity rate at 0.709 because large chunks naturally encompass entire table sections. However, the lower coherence score of 0.816 relative to recursive and structure-aware strategies suggests that very large chunks may aggregate topically distinct content [13].

Structure-aware produced 2,879 chunks with an average length of 627 characters. This results in an intermediate between semantic and fixed-size approaches. The highest intra-chunk coherence overall, at 0.826 achieved through this chunking strategy. Its table integrity rate of 0.535 falls below that of semantic chunking, indicating that the heuristic-based table detection, while effective for well-formatted fee tables, does not consistently identify all table boundaries, particularly in documents using non-standard PDF layouts [9].

B. Retrieval Performance

Table IV presents the retrieval performance across six chunking configurations. The reported metrics include Hit@1, Hit@3, MRR, nDCG, Precision@3, and Recall@3.

TABLE IV. RETRIEVAL PERFORMANCE ACROSS CHUNKING CONFIGURATIONS

Chunking Configuration	Hit@1	Hit@3	MRR	nDCG	P@3	R@3
Fixed-size 256 tokens	0.893	0.893	0.893	0.893	0.559	0.297
Fixed-size 512 tokens	0.893	0.929	0.911	0.915	0.595	0.357
Fixed-size 512 tokens with 50-token overlap	**0.964**	**0.964**	**0.964**	**0.964**	**0.631**	**0.393**
Recursive	**0.964**	**0.964**	**0.964**	**0.964**	0.619	0.381
Semantic	0.929	**0.964**	0.946	0.951	**0.631**	**0.393**
Structure-Aware	0.893	**0.964**	0.929	0.938	0.619	0.381

C. Answer Quality

Table V presents answer quality results across ROUGE-L, BLEU, BERTScore F1 and semantic similarity. Unlike retrieval performance, substantial differences are observed across chunking configurations.

TABLE V. ANSWER QUALITY METRICS ACROSS CHUNKING CONFIGURATIONS

Chunking Configuration	ROUGE-L	BLEU	BERT Score	Semantic Sim.
Fixed-size 256 tokens	0.312	0.112	0.735	0.862
Fixed-size 512 tokens	0.464	0.227	0.786	**0.906**
Fixed-size 512 tokens with 50-token overlap	0.466	0.212	0.769	**0.906**
Recursive	0.456	0.199	0.764	0.903
Semantic	0.441	0.241	0.771	0.891
Structure-Aware	**0.492**	**0.263**	**0.788**	**0.906**

Structure-aware achieves the highest scores for ROUGE-L with a value of 0.492, BLEU with a value of 0.263 and BERTScore F1 with a value of 0.788. For the semantic similarity metric, the structure-aware chunking ties with both configurations of fixed-size chunking at 512 tokens, with overlap and no overlap, at the value of 0.906. These results indicate that answers generated from structure-aware chunks are both lexically closer and semantically equivalent to the ground truth, supporting the hypothesis that preserving structural relationships improves generation quality [16], [17].

Fixed-size chunking at 512 tokens ranks second overall. Adding a 50-token overlap slightly improves ROUGE-L to 0.466 but reduces the BLEU score to 0.212, suggesting that redundant content introduced by overlapping boundaries may reduce n-gram precision. Recursive chunking produces comparable results with ROUGE-L at the value of 0.456, while the BLEU score is 0.199. This chunking strategy performs marginally below structure-aware and fixed-size at the 512-token configuration. Meanwhile, semantic chunking yields a lower ROUGE-L value of 0.441 and a BERTScore value of 0.771 despite its strong retrieval characteristics. This situation occurs potentially because oversized chunks introduce irrelevant content that dilutes the language model's context window. This finding aligns with the observations by [11] that contextual completeness does not scale linearly with chunk size.

Fixed-size chunking at 256 tokens performs the worst across all answer quality metrics. This confirms that excessively small chunks are insufficient to provide the language model with adequate context for accurate answer generation [12], [15]. A critical observation from this study is the dissociation between retrieval and answer quality, where the fixed-size chunking at 256 tokens achieves the same Hit@1 (0.893) as fixed-512 and structure-aware strategies yet produces substantially inferior answer quality. This decoupling has been reported in prior RAG evaluations [12], [19] underscores the importance of evaluating RAG systems beyond retrieval metrics alone.

D. Structural Integrity Analysis

Table VI presents the structural-integrity rate, which measures whether fee amounts and programme codes are co-located with their required contextual fields (e.g., semester label, program name) within the same chunk. The metric is intended to address a limitation of standard RAG evaluation frameworks, which do not capture structural preservation of structured data relationships [19].

TABLE VI. TABLE INTEGRITY METRICS ACROSS CHUNKING CONFIGURATIONS

Chunking Configuration	Table Integrity
Fixed-size 256 tokens	0.469
Fixed-size 512 tokens	0.552
Fixed-size 512 tokens with overlap	0.523
Recursive	0.540
Semantic	**0.709**
Structure-aware	0.535

Semantic chunking achieves the highest table-integrity rate (0.709), while structure-aware achieves 0.535. This result reveals a limitation of the current structure-aware

implementation: the heuristic-based table detection relies on regular expression patterns that may not generalize to all table formats present in the heterogeneous UKM corpus. The fixed-size 256-token configuration exhibits the lowest table integrity (0.469), confirming that uniform segmentation at fine granularities is poorly aligned with the structural requirements of institutional documents [17], a finding consistent with structure-aware chunking evaluations in enterprise and scientific document settings [14], [15].

VI. Discussion

A. Retrieval Saturation and Its Implications

A consistent finding across all experiments is the convergence of retrieval metrics, with most strategies achieving Hit@3 of 0.964 and MRR values between 0.893 and 0.964. This saturation is likely attributable to the lexical specificity of institutional queries, which contain distinctive tokens such as program codes and fee amounts that facilitate accurate embedding-based retrieval regardless of chunk boundary decisions. Similar retrieval saturation has been reported in domain-specific RAG evaluations in clinical [12] and policy document settings [22] where query-document lexical overlap enables consistent top-k retrieval across different chunking configurations.

This finding challenges the common assumption that improving retrieval metrics is sufficient to improve downstream answer quality [7], [19]. The evidence presented demonstrates that two strategies may achieve identical Hit@1 scores while producing substantially different answer quality, as illustrated by the parity between fixed-256 and fixed-512 in Hit@1 (both 0.893) but divergence in ROUGE-L (0.312 vs. 0.464). This decoupling underscores the need for multi-dimensional evaluation frameworks, such as RAGAS [7], that assess faithfulness and answer correctness independently of retrieval rank. This study investigated the impact of different chunking strategies on retrieval and answer quality in RAG systems for structured institutional data.

B. The Case for Structure-Aware Chunking

Structure-aware chunking demonstrates consistent superiority in answer quality despite not leading in retrieval performance or structural-integrity scores. Its ROUGE-L score of 0.492 and BLEU score of 0.263 represent improvements of approximately 5.6% and 15.9%, respectively, over the next best strategy. These gains are attributable to the preservation of logical relationships within structured content, which provides the language model with coherent and complete contextual information [14], [17]. The intermediate chunk size (average 627 characters) strikes a balance between contextual richness for answer generation and retrieval specificity for similarity matching.

This finding correlates with prior work on structure-aware RAG in specialized domains. Taiwo et al. [17] reported that structure-aware chunking yielded higher retrieval effectiveness for enterprise oil and gas documents, particularly on top-k metrics, compared to fixed-size and semantic baselines. Similarly, a study on financial report chunking [14] demonstrated that element-type-based chunking, which preserves the semantic role of document components, improved RAG question answering accuracy compared to paragraph-level approaches. The present study extends these findings to multilingual institutional documents in Bahasa Malaysia, demonstrating that structure-aware chunking benefits generalize beyond English-language corpora. However, the evidence should not be interpreted as demonstrating universal superiority because the experiments use a single institutional corpus and a small query set.

C. Limitations of the Structure-Aware Approach

Despite its advantages in answer quality, the structure-aware chunker exhibits a lower table integrity rate (0.535) than semantic chunking (0.709). The table integrity gap reflects the inherent difficulty of detecting table boundaries in heterogeneous PDF-extracted text, where formatting cues such as tab characters or pipe delimiters are inconsistently preserved across document types. The current heuristic-based approach, while effective for well-formatted fee tables, may not generalize to all institutional document types present in the UKM corpus, such as campus magazine articles and policy guidelines with embedded tables in non-standard layouts. These limitations are consistent with observations in the broader structure-aware chunking literature. Amiri & Bocklitz [15] noted that domain-specific chunking strategies require careful calibration of boundary detection heuristics to avoid over-segmentation or under-segmentation. Recent work on topology-aware chunking [18] has proposed preserving hierarchical document structure through structured intermediate representations, suggesting a potential direction for improving the current heuristic implementation.

D. Chunk Size and Coherence Trade-offs

The intra-chunk coherence scores are closely clustered across all strategies (0.813 to 0.826), suggesting that coherence alone is insufficient to distinguish the configurations. However, when interpreted alongside chunk size, a clearer pattern emerges. The relationship between chunk size and answer quality is non-linear: answer quality improves from fixed-256 to fixed-512 and peaks at structure-aware but declines for semantic chunking despite its larger chunks. This non-linearity implies that an optimal chunk size range exists for this document collection, approximately 300 to 700 characters, beyond which the inclusion of extraneous content degrades generation quality. This observation is consistent with findings by researchers who showed that larger chunk sizes produced diminishing returns and diluted chunk coherence [11], and with reports of size-dependent performance trade-offs in chemistry and biomedical RAG settings [15].

E. Practical Implications for Institutional RAG Deployment

The findings carry practical implications for the design of RAG-based institutional chatbot systems. First, the consistent underperformance of fixed-size 256-token chunking across all answer quality and structural integrity metrics indicates that this approach should be avoided for document collections containing structured content, despite its computational efficiency [12], [17]. Second, structure-aware chunking is recommended for deployments where answer accuracy is prioritized, particularly in institutional contexts where erroneous fee or program information carries significant consequences for end users [23], [24]. Third, for resource-constrained deployments, fixed-512

chunking configuration without token overlapping represents a practical compromise, achieving the second-highest answer quality. Semantic chunking may be preferable when preservation of table-level structural integrity is the primary objective.

Several limitations constrain interpretation of the results. The evaluation uses 28 queries, including only one open-ended query. This situation may cause the results to be sensitive to the selected questions and should not be generalized broadly across institutional question types. The six configurations also do not constitute an exhaustive chunk-size sensitivity analysis. In addition, all documents are from UKM; thus, the application of the same data preparation pipeline for other institutional domains requires validation because document structures and terminology may differ. Finally, the generation settings use fix temperature of 0.5 and top-p 0.9, which permit stochastic output. Because repeated-generation variance is not reported, the presented generation metrics should be interpreted as point estimates rather than estimates of stability across repeated runs.

VII. Conclusion and Future Work

This study evaluated four chunking strategies across six configurations for RAG structured institutional documents. The results show that although retrieval performance tends to saturate across strategies, answer quality and structural integrity vary significantly. Structure-aware chunking demonstrates the strongest performance in answer quality, while semantic chunking achieves the highest table-integrity score. These findings highlight that no single chunking configuration dominates every evaluation objective and that chunking should be selected according to the target document structure and application objective. Future work should expand the query set, conduct systematic chunk-size sensitivity analysis, evaluate repeated generations to quantify stochastic variability and test the approaches on other institutional documents.

***Abstract*—Predicting Mohs hardness from mineralogical information is still a challenging task because of the complex and nonlinear relationship between mineral composition and hardness properties. Traditional machine learning (ML) and deep learning (DL) strategies have been used to address this study, exploiting mineralogical attributes for prediction. Conversely, these techniques are frequently highly dependent on large labeled datasets, struggle to generalize over distinct mineral categories, and face challenges in extracting subtle physicochemical interactions and delivering interpretable predictions. This study presents an Explainable Deep Representation Learning Framework based on Mohs Hardness Prediction (XDRL-MHP). The primary objective of this work is to predict Mohs hardness using mineralogical properties by modeling mineral composition and structural characteristics. The proposed model employs mRMR for feature selection to identify the most informative physicochemical attributes. A physicochemical representation constructed using atomic interaction mapping, periodic table relationship encoding, chemical affinity representation, and molecular dependency construction to capture complex mineral relationships. Besides, a neuro-symbolic hybrid architecture is designed by integrating a capsule network for hierarchical mineral pattern learning, a neural tensor network for atomic relationship modeling, and a symbolic reasoning layer for rule-guided mineral intelligence. In addition, an explainable neuro-artificial intelligence technique incorporated to improve model interpretability and insight into predictions. The model is trained using the AdaBelief optimizer with quantile loss for ensure stable convergence and precise Mohs hardness prediction. The XDRL-MHP method validated utilizing the Comprehensive Database of Minerals, comprising 3,112 mineral instances with 140 mineralogical and physicochemical features. The simulation analysis of the XDRL-MHP model is performed using the Comprehensive Database of Minerals. Extensive comparative results show the effective performance of the XDRL-MHP model with an RMSE of 0.1140 over recent state-of-the-art models.**

I. Introduction

Mineral identification is a key aspect of geological analysis. Traditional methods mainly rely on physical experiments or visual observation. Visual techniques, such as streak tests, powder color analysis, and HCl reactivity, depend on the skill of the evaluator and often require specialized instruments [1]. Both approaches are labor-intensive. Hardness is an important property of minerals, and Mohs hardness is one of the primary tests used for mineral identification. By using portable hardness picks, Mohs hardness can be measured efficiently and accurately. Different minerals can have significantly different Mohs hardness values [2]. For example, sphalerite and hematite have distinct hardness ranges but may appear similar in images. Therefore, hardness can serve as a key feature to differentiate them [3]. Hardness is related to the bond strength and composition of minerals. Light elements often form short and strong bonds, as do transition metals with higher valence bond density. Higher Mohs hardness is generally associated with stronger average bond interactions and higher bond density per unit volume [4]. Computational approaches combined with high-performance computing are used to understand deformation and compositional effects on hardness across different scales. Methods such as density functional theory, machine learning (ML), and molecular dynamics (MD) are commonly employed [5].

Several approaches were introduced, designed, and tested by numerous researchers to investigate Mohs hardness. Modeling methodologies reported in the literature are data-driven techniques (data compression, data prediction, and in-network processing). Statistical modeling and ML models are the most subjective algorithms in mineral prospectivity mapping [6]. These methods relied on the specialist's opinion or input data from the modeler to operate the weight computation of condition factors. These approaches are best for the unexplored landscapes categorized by certain known deposits [7]. But knowledge-based methodology is applied for any category of deposit utilizing fuzzy logic and the performance of the Dempster–Shafer evidence method. Data-driven algorithm offers an objective technique and highly depends on a connection between the predictors and the deposit types [8]. Hence, these

models are appropriate for moderate- to well-sampled regions characterized by known deposit forms. Deep learning (DL) classifiers are being broadly employed in a wide range of applications with diverse objectives in sections [9]. Some of the major limitations to be addressed are those that require higher computation complexity, as well as limited explicability and transparency, which mitigate confidence and decision verifiability made by a DL methodology. The lack of transparency and explicability in some regions is not unvaryingly an issue; later advanced techniques have a much higher precision [10]. Explaining Artificial Intelligence (XAI) is the field of research that aims to interpret, visualize, and explain the decisions taken by DL systems. Various researches have been conducted to understand how the approach makes its decisions; thus, in sensitive practical applications, the experts are optimistic in the method's predictions [11].

In spite of developments in mineral identification and hardness examination, standard experimental methodology remains time-consuming, labor-intensive, and rely heavily on professional interpretation. Recent ML and DL techniques for Mohs hardness prediction frequently need larger labeled datasets and exhibit limited generalization over different mineral classes. Existing methods often fail to learn complex mineral interactions and lack clear interpretability, which makes their predictions less reliable for geological use, so a more accurate and explainable model is needed for Mohs hardness prediction. To resolve these challenges, this manuscript presents an Explainable Deep Representation Learning Framework based on Mohs Hardness Prediction (XDRL-MHP). The following are major contributions of this research. A Key novelty for the proposed model is the construction of a physicochemical demonstration that explicitly integrates domain knowledge using atomic interactions, periodic dependencies, chemical affinities, and molecular relationships for mineral hardness prediction.

- Present a minimal redundancy maximal relevance (mRMR)-based feature selection (FS) strategy to identify the most informative mineralogical and physicochemical attributes for effective Mohs hardness prediction.
- Construct a comprehensive physicochemical representation module by integrating atomic interaction mapping, periodic table relationship encoding, chemical affinity representation, and molecular dependency to capture intrinsic mineral features.
- Design a neuro-symbolic hybrid architecture that combines a capsule network (CapsNet) module for hierarchical mineral pattern learning, a neural tensor network for atomic relationship modeling, and a symbolic reasoning layer for rule-guided mineral intelligence.
- Integrate an explainable neuro-artificial intelligence technique, including SHAP-based interpretation to quantify feature contributions and provide transparent, interpretable insights into model predictions.
- Employ the AdaBelief optimizer with quantile loss to ensure stable convergence and robust prediction performance.
- Perform the evaluation of the proposed XDRL-MHP model using the comprehensive database of Minerals and validate its predictive performance.

II. Existing Related Works on Mohs Hardness Prediction

The section briefly reviews the prior studies of Mohs hardness prediction along with existing research gaps. Ghadernejad and Esmaeili [12] designed predictive approaches for abrasivity and rock hardness according to hyperspectral imaging data, providing valuable data without interrupting the mining processes. Houshmand et al. [13] developed the outcome of an ML methodology for rock hardness prediction applying rock's geochemical and geophysical characteristics. Liu et al. [14] examined a ML system for predicting rock hardness employing morphological attributes. The results of this algorithm were used as the input for a meta-model, enduring linear fitting for predicting Mohs hardness, founding the Meta-RF and SVR model. In [15], the authors observed fractional chemical analysis following mechanical attrition, which shown distinctly various dimension-dependent distribution patterns including fluorite, REE, and barite minerals. Hadimani and Vanarotti [16] proposed an ML-based architecture to predict the Mohs hardness of minerals utilizing structural features and fundamental composition. Applying Scikit-learn, correlation analysis was conducted for identifying key predictors, and a Multi-Layer Perceptron Regressor (MLPRegressor) was implemented. Guo et al. [17] introduced a new multi-scale characterization technique. This methodology exclusively combines micro-zone X-ray diffraction analysis, nanoindentation technology, and ML strategies to technically examine micromechanical aspects of conglomerate instances from multiple areas. Cornu et al. [18] investigated the association among the mineralogical composition of the aggregates utilized in pavements and the long-term friction of the latter's surfaces. Sharifi Teshnizi et al. [19] discussed the drillability of granitic rocks by incorporating physical, petrographic, abrasivity, and mechanical parameters with ML and regression methodologies.

Although current research has enhanced rock and mineral hardness prediction through geochemical data, hyperspectral imaging, and machine learning, numerous difficulties still occur. Certain strategies rely on sensitive preprocessing stages or definite band-ratio attributes that may not completely extract compound physicochemical associations. Moreover, many techniques depend upon multi-sensor or instrument-heavy setups that minimize scalability in multiple mining situations, though image-based learning methodology frequently struggle with partial datasets and worse generalization across diverse mineral classes. Thus, recent models still struggle to effectually incorporate structural, compositional, and morphological data in a unified and consistent way for precise and interpretable Mohs hardness prediction.

III. Proposed Framework

The presented model introduces a robust framework for predicting Mohs hardness through mineralogical properties. The XDRL-MHP approach follows a systematic pipeline, integrating preprocessing, feature selection, feature representation, a neuro-symbolic hybrid model, explainable neuro-AI analytics, and model training. To prevent data leakage, the dataset was first split into training and testing sets. All normalization parameters and outlier processing criteria were resulting only from the training data. mRMR feature selection was also performed on the training set, and the selected features and pre-processing parameters were applied unchanged to the test set. The test set was kept hidden until the final validation. The structural overview of the proposed model is given in Fig. 1.

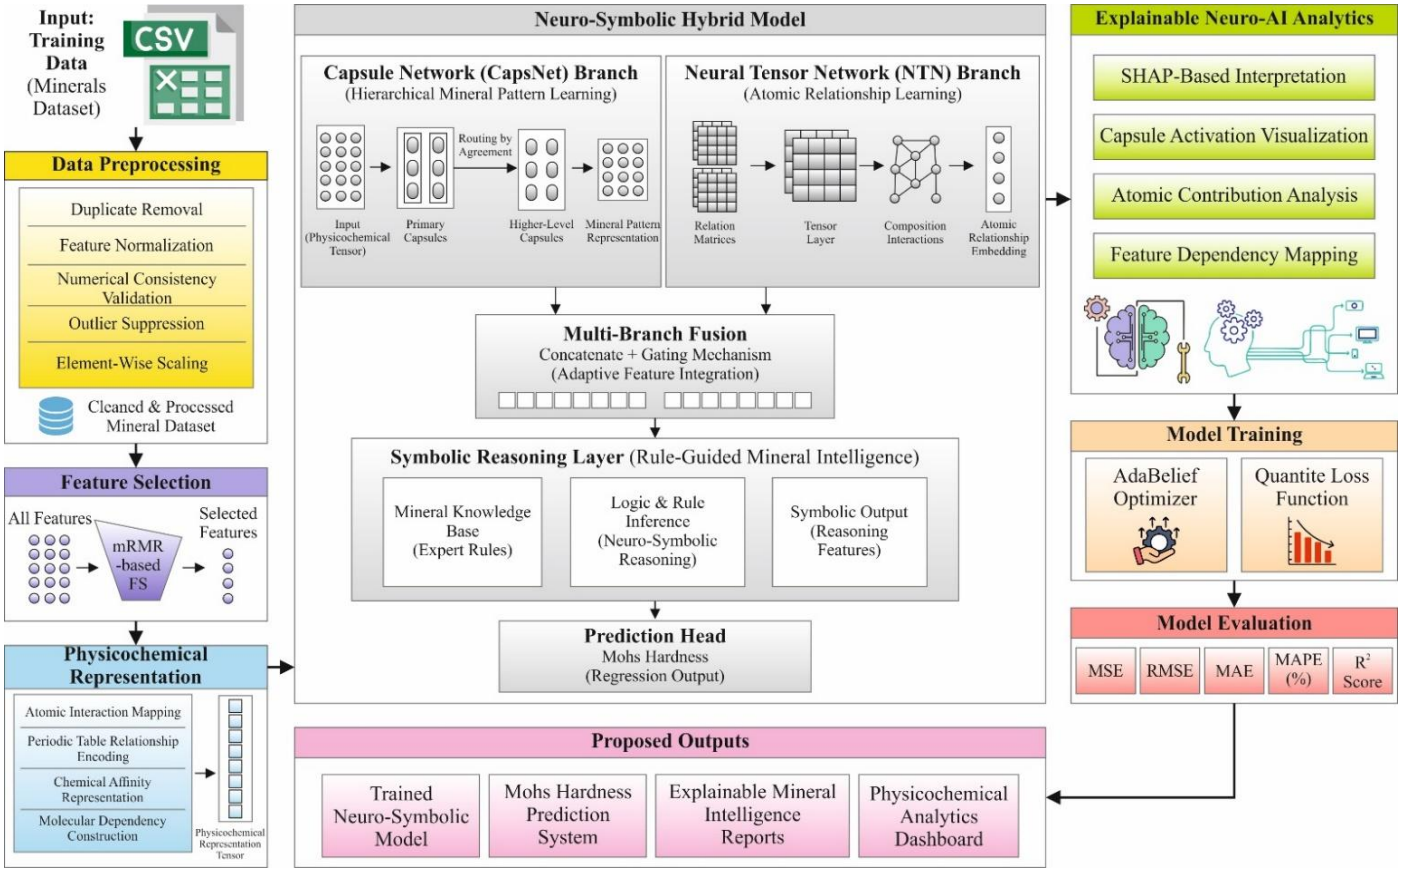

Fig. 1. Structural overview of the proposed model.

As depicted in Fig.1, the proposed model proceeds through a sequence of phases.

- Input data is pre-processed through duplicate removal, normalization using Z-score, consistency checking, outlier suppression, and element-wise scaling.
- An mRMR-based FS approach is employed to choose the most informative attributes while removing redundancy.
- Physicochemical representation utilizes an atomic interaction mapping, periodic table encoding, chemical affinity, and molecular dependency modeling.
- Neuro-symbolic hybrid model combines CapsNet for pattern learning, a neural tensor network for atomic relationships, and a symbolic reasoning layer for rule-guided intelligence.
- SHAP-based explainability is leveraged for quantifying feature contributions and improve model interpretability.
- AdaBelief optimizer with quantile loss was utilized for stable convergence and accurate prediction.

A. Data Preprocessing Pipeline

The data preprocessing stage ensures high-quality and consistent input for the model. It involves duplicate removal, consistency checking, outlier suppression, Z-score normalization, and element-wise scaling to enhance data reliability and model performance.

1) Duplicate removal: This process is an initial stage of preprocessing that focuses on eradicating duplicate reports from the data, which leads to improved reliability, and minimized redundancy formed by repeated entries or information gathered from various sources.

2) Z-score normalization: This normalization, also called standardization, converts data to have a mean of 0 and a unit variance of 1 [20]. It is extensively utilized for rescaling features so that they follow a standard normal function. This

model minimizes the effect of varying feature scales and enhances numerical stability in learning models.

$$x_{norm} = \frac{X - \mu}{\sigma} \quad (1)$$

In this Eq. (1), X implies the real feature data, μ implies the mean of the attribute, σ implies the SD of the attribute, and X_{norm} indicates the scaling data.

3) Numerical consistency validation: This is another pre-processing stage that assures each numerical value in the data is within valid ranges, domain-specific rules, and suitable data types. For example, it verifies that no negative ore grades and valid coordinate ranges.

$$x \in [x_{\min}, x_{\max}] \quad (2)$$

If violated, data are corrected, removed, or imputed.

4) Outlier suppression: It minimizes the effect of extreme values that deviate considerably from the complete data distribution, enhancing model stability. Depend on the IQR-based rule:

$$IQR = Q3 - Q1 \quad (3)$$

$$x < Q1 - 1.5 \cdot IQR \text{or} x > Q3 + 1.5 \cdot IQR \quad (4)$$

Certain values are clipped or eliminated (winsorized).

5) Element-wise scaling: Element-wise scaling is a preprocessing method where every feature is independently converted to a common scale to ensure equal contribution in model training.

$$x' = f(x) \quad (5)$$

Here, $f(\cdot)$ denotes a scalar operation used distinctly for all features.

B. mRMR-Driven Feature Selection Strategy

The mRMR-based FS technique was employed to recognize the most significant mineralogical attributes for Mohs hardness prediction. It improves prediction performance by maximizing feature relevance while minimizing redundancy among selected features [21].

1) Maximal relevance: Based on mRMR, the highest relevance is reached by obtaining a feature subset that fulfills Eq. (6), increasing the average of the mutual information (MI) among the attributes in the feature subset and the target variable.

$$\max D = \frac{1}{|K|} \sum_{x_i \in K} I\,(xi; y) \quad (6)$$

here χ_i denotes the feature, y indicates the target variable, and K refers to the subset of features. D implies the average of the MI between the aspects and the target variable, and I points out the MI between the feature x_i and the target variable y.

$$I(x,y) = \iint \mathrm{p}\,(x,y) log \frac{p(x,y)}{p(x)p(y)} dxdy \quad (7)$$

here $p(y)$ implies the marginal probability distribution of χ and y; $p(x,y)$ indicates the joint probability distribution of χ and y and $p(x)$.

2) Minimal redundancy: During feature subset selection based solely on the maximum relevance criterion, a substantial amount of redundant information is retained among the selected attributes. This redundancy could impact the computational effort needed by the method and potentially reduce the prediction accuracy.

$$\min R = \frac{1}{|K|^2} \sum_{x_j x_i \in K} I\left(x_{i;} \cdot x_j\right) \quad (8)$$

Here, x_i and χ_j point out the features, I implies the MI among the features, and K indicates the subset of features.

$$\max \Phi = D - R \quad (9)$$

Φ implies the variance between redundancy and relevance. By increasing the variance between redundancy and relevance, the mRMR could minimize redundancy in the subset of features, while preserving higher relevance. Consider that the $n-1$ selects from the actual feature set X, constitute the subset K_{n-1}, then the selection of the n_{th} feature x_n.

$$x_n \in XK_{n-1} \max \left\{ I\left(x_{n;} \cdot y\right) - \frac{1}{n-1} \sum_{x_j \in K_{n-1}} I\left(x_{n;} \cdot x_j\right) \right\} \quad (10)$$

The mRMR sequentially chooses attributes from the remaining set of features $X - K$ and adds them to the subset K.

C. Physicochemical Representation

It is a feature engineering method that encodes chemical and mineralogical data into structured interpretations for enhanced learning.

1) Atomic interaction mapping: It extracts the interaction patterns among atoms that depend on their bonding behavior and spatial correlations in mineral structures. This helps to understand how many components impact one another in a compound.

2) Periodic table relationship encoding: It encodes elemental features by applying periodic table properties, including group, period, and atomic number.

3) Chemical affinity representation: It represents the tendency of components to interact based on their chemical reactivity and compatibility. It facilitates identifying stronger and weaker elemental connections among minerals.

4) Molecular dependency construction: It incorporates chemical affinities and atomic interactions to create a structured molecular association graph. To enhance mineral representation learning, extract the overall dependency between atoms.

For reproducibility, the physicochemical representation is formally defined as $R = [A; P; C: M]$, where A, P, C, and M represent the atomic interaction, periodic table, chemical affinity, and molecular-dependency depiction, respectively. For a mineral including n constituent element, the stomic interaction matrix is defined as $A_{ij} = f\left(a_i, a_j\right)$, whereas the periodic

illustration is encoded as $P_i = [Z_i, G_i, T_i]$, where Z_i, G_i and T_i represent atomic number, group, and period. The chemical-affinity representation is attainare as $C_{ij} = g(a_i, a_j)$ and molecular relationships is built as $M_{ij} = h(A_{ij}, C_{ij})$. These representations are concatenated to form the final feature vector utilized by the neuro-symbolic method.

D. Neuro-Symbolic Hybrid Model

The neuro-symbolic hybrid model is designed to effectively capture both data-driven patterns and rule-based reasoning in mineralogical analysis. It integrates CapsNet for hierarchical pattern learning, a neural tensor network for atomic relationship modeling, and a symbolic reasoning layer for rule-guided intelligence.

1) Capsule network: The CapsNet is a neural network (NN) framework that denotes features as vectors in capsules that capture the presence and spatial correlation [22]. Unlike image-based applications, the capsules in the proposed model do not signify physical spatial locations. Instead, they group associated mineralogical and physicochemical features into large-scale feature representations. The routing mechanism supports the method in preserving and integrating these feature dependencies, which is useful for modeling interactions between elemental, periodic, and chemical properties.

It employs dynamic routing and hierarchical feature dependencies for increasing the representation learning. The adaptable spatial capsule unit has been utilized to acquire higher-level feature representations by obtaining the hierarchical correlation from the mineralogical information. The feature set is systematized as numerous capsules, in which each capsule encodes a different spatial–semantic pattern of the input. The transformation from low-level to high-level capsules can be executed by employing the shared weight matrix:

$$u_{j|i}^{(a+x)(b+y)} = W_{ij}^{xy} u_i^{(a+x)(b+y)} \tag{11}$$

Here, the term $u_{j|i}^{(\mathrm{a+x})(\mathrm{b+y})}$ signifies the j^{ih} features predicted in the layer. The weighted summation of all $(a + x, b + y)$ capsules is derived from $u_{j|i}$, thereby representing that the vectorized prediction must be calculated as the capsule's input, as given below:

$$I_j^{ab} = \sum_i \sum_x \sum_y Q_{ij}^{xy} \, u_{j|i}^{(a+x)(b+y)} \tag{12}$$

Here, the parameter I_j^{ab} signifies the capsule j input vector, and the term Q_{ij}^{xy} denotes the coupling coefficient. The interpretations are accomplished by the softmax function and dynamic routing method:

$$Q_{ij}^{xy} = \frac{\exp\left(R_{ij}^{xy}\right)}{\Sigma_{j=1}^{P} R_{ij}^{xy}} \tag{13}$$

From this mathematical term P signifies the overall counts of posterior layer capsules v. At the beginning of the training process, the term R_{ij}^{xy} is set to 0, the parameter R_{ij}^{xy} can be iteratively advanced by parameters for agreement with prediction vectors $u_{j|i}^{(a+x)(b+y)}$ and v_j^a. Accordingly, the capsule $u_{j|i}^{(a+x)(b+y)}$ gives improved capsule prediction v_j^{ab} and the major rise is achieved to R_{ij}^{xy} as given below:

$$R_{ij}^{xy} \leftarrow R_{ij}^{xy} + u_{j|i}^{(a+x)(b+y)} v_j^{ab} \tag{14}$$

For the reduction of the capsule output, the non-linear function can be utilized to compress the input vector, and its mathematical form is given by:

$$v_j^{ab} = Squash(I_j^{ab}) \tag{15}$$

The output capsule vector $v_j^{ab}$is encoded as the final hierarchical mineral representation and was employed for Mohs Hardness classification.

2) Neural tensor network: The neural tensor network is an NN developed to model intricate relationships among two input feature vectors by applying the tensor-based bilinear transformation. This can be broadly employed to obtain important relative dependencies during the representation learning process. The relationship between 2 feature vectors x and y can be measured by,

$$h = \tanh\left(x^T W^{[1:K]} y + V[x; y] + b\right) \tag{16}$$

In this mathematical form, the term $W^{[1:K]}$ refers to the 3rd-order tensor that gains multiplicative correlation, the term V represents the weight matrix for linear transformation, the factor b indicates the bias vector, and the term $[x; y]$ signifies concatenation. The non-linear activation function allows the model to obtain higher-order feature interactions. The tensor factor permits pairwise feature relationships as clearly designed over numerous latent dimensions. It generates the NTN, which is especially efficient for obtaining intricate dependencies in organized information. The final output score for prediction can be measured by:

$$s = u^T h \tag{17}$$

Now, the parameter u refers to the learnable parameter, the term h indicates the hidden representation for the final prediction score.

3) Symbolic reasoning layer: The Symbolic Reasoning Layer incorporates rule-based symbolic AI with DL to allow structural and interpretable mineral information. This can be encoded in the geological details in a clear, logical set of rules, thereby permitting domain-driven reasoning across the mineral features when adding data-driven feature learning. This integration increases the interpretability and predictive consistency in mineral evaluation processes. The symbolic rule aggregation method can be measured by:

$$R(x) = \sum_{i=1}^{n} \omega_i \, r_i(x) \tag{18}$$

From this mathematical form, the factor ω_i signifies their resultant importance weights or confidence, and the term $r_i(x)$ signifies individual geological or symbolic rules utilized for the

input x. The final prediction, has combined the symbolic reasoning and DL outputs, can be represented by:

$$y = \sigma\big(f_\theta(x) + \lambda R(x)\big) \quad (19)$$

Here, the term $R(x)$ points to the outcome of the symbolic reasoning, term $f_\theta(x)$ refers to the output NN, and the mathematical notations λ and σ indicate the symbolic layer and activation function that generate the final mineral prediction. Fig. 2 signifies the design of the neuro-symbolic hybrid model.

The symbolic reasoning layer combines domain-informed rules depending on the relationships between elemental composition, atomic interaction, periodic properties, and chemical affinity. These rules are incorporated with the neural network output using weighted rule aggregation to give interpretable mineralogical reasoning. The contribution of the symbolic reasoning module is validated through the ablation study by comparing the complete XDRL-MHP technique with a variant without symbolic reasoning under the same experimental environments.

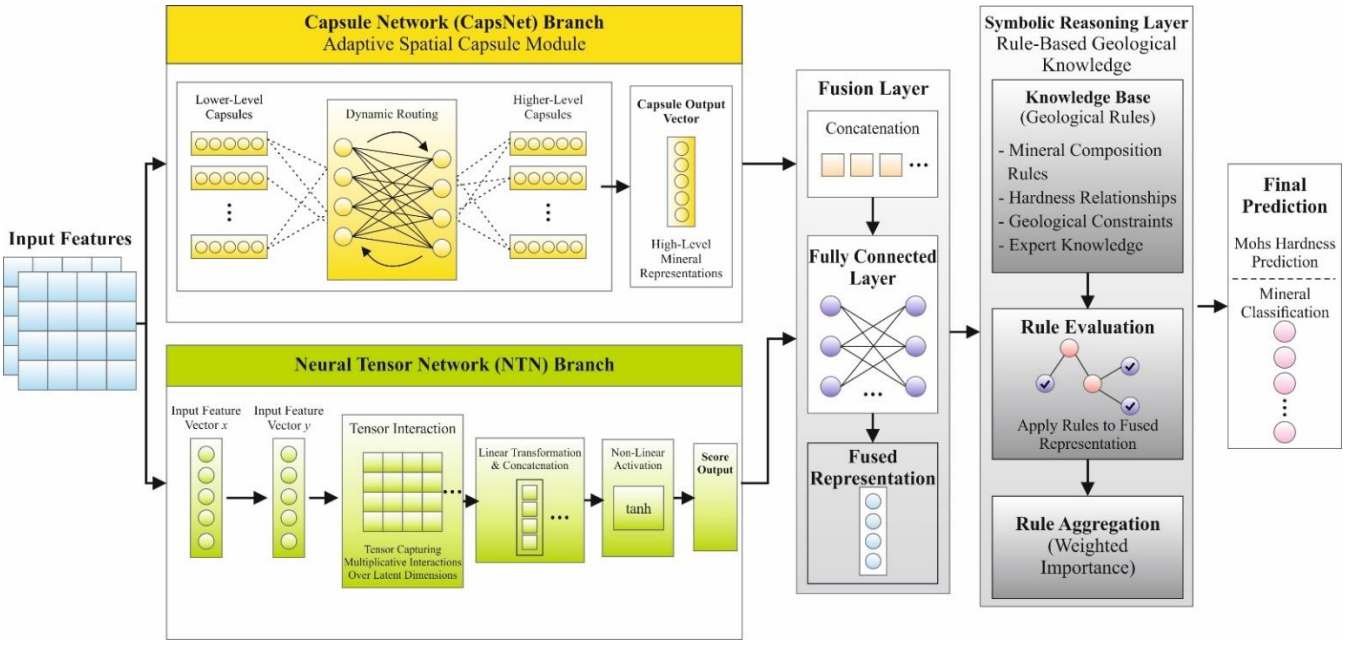

Fig. 2. Design of neuro-symbolic hybrid model.

E. Explainable Neuro-AI Analytics

SHAP is an explainable AI technique used to interpret model predictions by quantifying the contribution of each feature to the final output. It is an integrated explainability architecture proposed by Lee and Lundberg that interprets the prediction of any ML strategy by allocating every attribute a significance value for a certain record [23]. It depends on the model of Shapley values from cooperative game theory, here, all attributes are addressed as "players" contributing to the last prediction. It associates local explanation algorithms like LIME with the theoretical basis of Shapley values, delivering a reliable and explainable decomposition of method outcomes. The SHAP explanation system illustrates the prediction as an additive composition of feature contributions, represented as:

$$g(z') = \phi_0 + \sum_{j=1}^{M} \phi_j z'_j \quad (20)$$

Here ϕ_0 indicates the base value, $g(z')$denotes the explanation model, $z'_j \in \{0,1\}$represents a simplified binary representation indicating whether feature j is present in the coalition or not, and $\phi_j$points out the SHAP value representing the contribution of feature j. Mimplies the total count of attributes. Based on the Shapley value formulation, the SHAP value $\phi_j$is calculated:

$$\phi_j = \sum_{S \subseteq F \setminus \{j\}} \frac{|S|!(M - |S| - 1)!}{M!} [f(S \cup \{j\}) - f(S)] \quad (21)$$

Here, S denotes all possible feature subsets not containing feature j, and F refers to the full feature set. This formulation determines the average marginal significance of attributes j over each possible coalition.

F. Model Training

AdaBelief is an adaptive optimizer approach that updates method parameters by integrating a momentum-driven gradient estimator with a difference evaluation based on gradient deviation [24]. The optimization starts with the calculation of the gradient $g_t = \nabla f(\theta_t)$ that signifies the direction of steepest descent of the loss function. The 1st-order momentum is then upgraded as

$$m_t = \beta_1 m_{t-1} + (1 - \beta_1) g_t \quad (22)$$

The 1st-order momentum takes the exponential average direction of previous gradients. At the same time, AdaBelief proposes an improved 2nd-order momentum that evaluates the belief within the gradient for tracking the deviation from the 1st moment, expressed as follows:

$$s_t = \beta_2 s_{t-1} + (1 - \beta_2)(g_t - m_t)^2 \quad (23)$$

To eliminate initialization bias, two moments are modified as

$$\widehat{m}_t = \frac{m_t}{1-\beta_1^t}, \hat{s}_t = \frac{s_t}{1-\beta_2^t} \quad (24)$$

At last, the parameters are updated employing an adaptive learning rate rule computed by:

$$\theta_{t+1} = \theta_t - \eta \cdot \frac{\widehat{m}_t}{\sqrt{\hat{s}_t} + \epsilon} \quad (25)$$

In this Eq. (25), η denotes the learning rate and ϵ implies a smaller constant for numerical stability. The pseudocode of the AdaBelief optimizer is represented in Algorithm 1.

Algorithm 1: Pseudocode of AdaBelief Optimizer

Input: Learning rate α, decay rates β_1, β_2, stability constant ϵ
Output: Upgraded parameters x_{t+1}
Set: x_0, $m_0 = 0$, $s_0 = 0$
For $t = 1$to Tdo:
The gradient has been calculated as
$g_t = \nabla f_t(x_t)$The 1st moment is updated as

$m_t = \beta_1 m_{t-1} + (1-\beta_1) g_t$The 2nd moment is updated as

$s_t = \beta_2 s_{t-1} + (1-\beta_2)(g_t - m_t)^2$Bias-corrected estimation was calculated as

$$\widehat{m}_t = \frac{m_t}{1-\beta_1^t}, \hat{s}_t = \frac{s_t}{1-\beta_2^t}$$

The parameters are updated employing an adaptive scaler as
$x_{t+1} = x_t - \frac{\alpha\, \widehat{m}_t}{\sqrt{\hat{s}_t}+\epsilon}$Return x_{t+1}

The model utilizes Quantile Loss to enhance robustness and attain precise Mohs hardness prediction by lessening asymmetric prediction errors.

$$L_q(y, \hat{y}) = \max\big(q(y-\hat{y}), (q-1)(y-\hat{y})\big) \quad (26)$$

where, y denotes the actual hardness value, $\hat{y}$ implies the predicted hardness value, and q signifies the quantile parameter controlling error weighting.

Quantile Loss to enhance the robustness of Mohs hardness prediction, quantile loss was used as the regression objective with $\tau = 0.5$. The quantile loss is defined as:

$$L_\tau(y, \hat{y}) = \begin{cases} \tau(y, \hat{y}) & y \geq \hat{y} \\ (1-\tau)(\hat{y} - y) & y < \hat{y} \end{cases}$$

The value of $\tau = 0.5$ was selected depending on validation performance. Its efficiency was compared with MSE and MAE under identical training and evaluation conditions.

Table I illustrates the data standardized using Z-score normalization and IQR-based outlier suppression. mRMR was used to select relevant features, denoted by four chemical dependencies. The method integrates CapsNet with dynamic routing and NTN, followed by multi-branch fusion and rule-guided reasoning. Training utilized AdaBelief, quantile loss, batch size 32, and epochs 25, learning rate 0.001with early stopping.

TABLE I. PARAMETER CONFIGURATION OF XDRL-MHP METHOD WITH TRAIN -TEST SET

Category	Parameter	Setting
Preprocessing	Normalization	Z-score
	Outlier handling	IQR-based suppression
Feature Selection	Method	mRMR
Feature Representation	Representation methods	Atomic interaction, periodic relationship, chemical affinity, molecular dependency
Model	Capsule branch	CapsNet with dynamic routing
	Relationship branch	Neural Tensor Network (NTN)
	Fusion	Multi-branch fusion
	Reasoning	Rule-guided symbolic reasoning
Training	Optimizer	AdaBelief
	Loss function	Quantile Loss
	Quantile Value	0.5
	Learning Rate	0.001
	Batch size	32
	Epochs	25

IV. EXPERIMENTAL ANALYSIS AND DISCUSSION

The empirical evaluation of the XDRL-MHP method was conducted using the Comprehensive Database of Minerals [25]. This dataset contains 3112 minerals along with their chemical compositions, crystal structures, and physical and optical characteristics. The dataset also includes several properties such as crystal structures, Mohs Hardness, Specific Gravity, Molar Volume, Optical axes, Optical dispersion, and Calculated Density. A total of 140 features, 88 features were selected for training. The experiments were conducted utilizing a 70:30 training–testing split. The method was executed through Python 3.11 and trained on a system equipped with an NVIDIA RTX 4090 GPU (24 GB VRAM), Intel Core GPU (24 GB VRAM), Intel Core i9 processor, and 32 GB RAM. The training configuration and hardware settings were kept consistent for all experiments to ensure a fair comparison.

Fig. 3 presents the correlation heatmaps analysis of the selected 88 mineral properties, which were effectively structured into six groups, enabling a clear understanding of the correlation pattern. In particular, chemically related elements and rare earth elements exhibit a well-defined correlation pattern. The result indicates a strong and positive correlation; the analysis reveals a well-structured relationship among several feature groups, making it suitable for advanced statistical evaluation.

Fig. 4 shows the statistical distribution of Mineralogical and Physicochemical properties used for Mohs Hardness Prediction. The result shows that the categorical variables, such as crystal structure and diaphaneity, show discrete patterns. Elemental variables such as hydrogen and helium show a highly imbalanced distribution with limited variation. In particular, the variation in physical and optical characteristics delivers essential information for accurate Mohs hardness prediction in the mineral dataset.

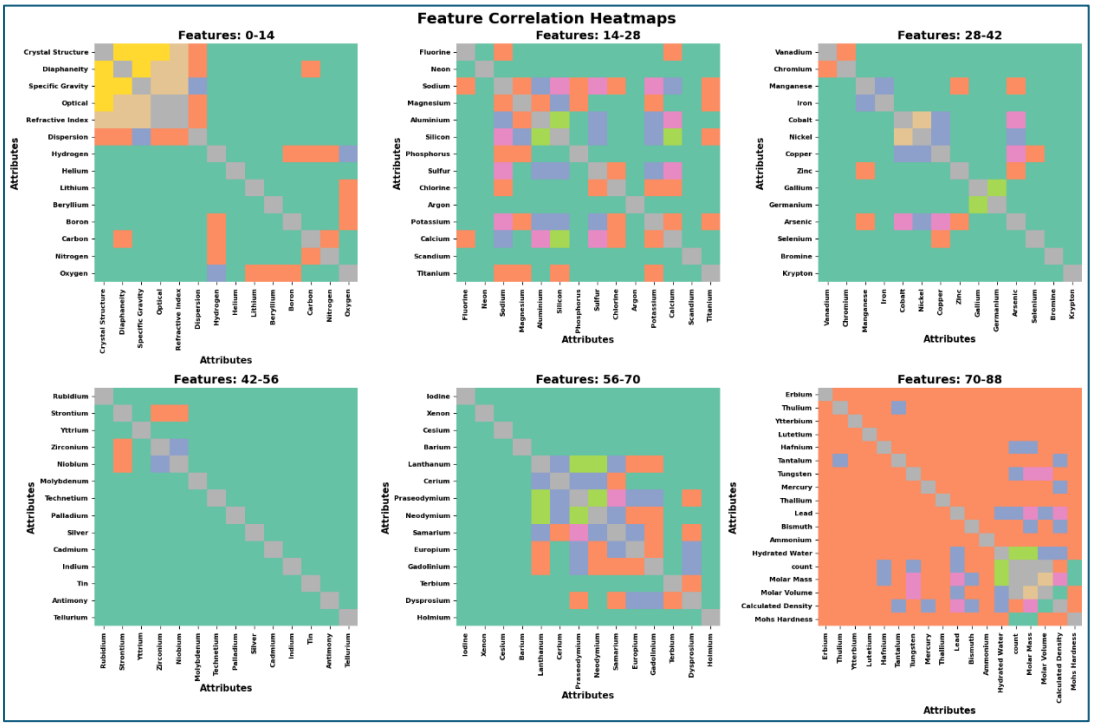

Fig. 3. Feature correlation heatmaps analysis.

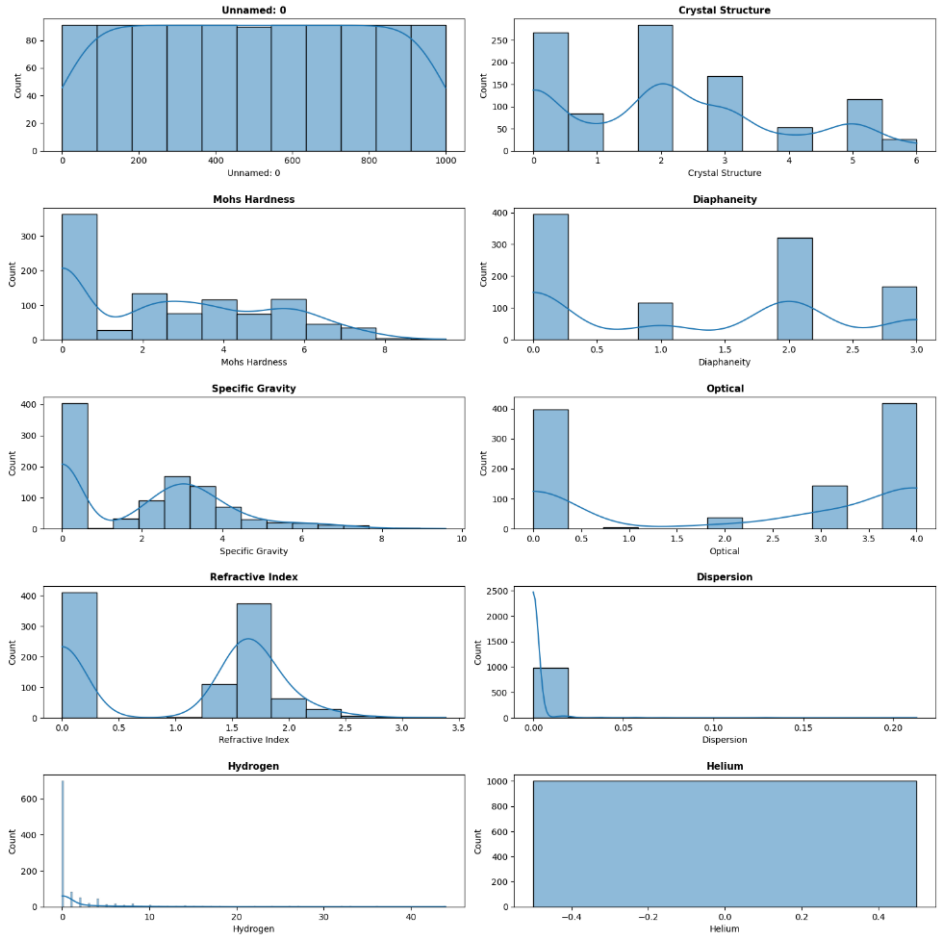

Fig. 4. Statistical distribution of mineralogical and physicochemical properties.

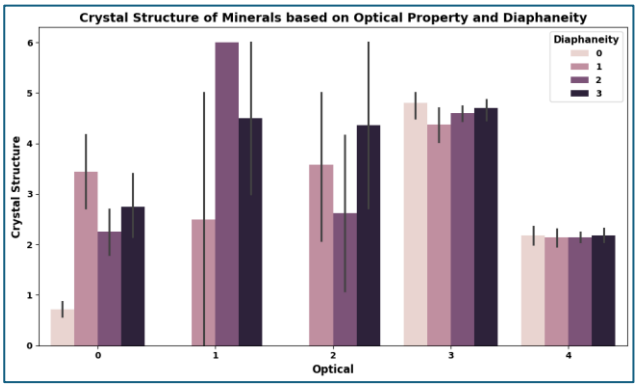

Fig. 5. Analysis of the crystal structure of various minerals based on optical properties and diaphaneity.

Fig. 5 displays the analysis of the crystal structure of various minerals based on optical properties and diaphaneity. Higher optical and diaphaneity values indicate a more stable and complex crystal structure, while low values exhibit high variation in structural pattern. Therefore, the result highlights the strong interrelationships among these attributes, which makes them suitable for mineralogical analysis and accurate Mohs hardness prediction.

Fig. 6 illustrates the Mohs hardness prediction of minerals using training and testing splits. The graph shows prediction behavior at different epochs (10, 15, 20, and 25), and the predictions are compared with actual hardness values for both training and testing datasets.

Next, Fig. 7 presents the loss curve analysis of the XDRL-MHP model with diverse evaluation metrics across the train-test split. The MSE, RMSE, and MAE gradually decrease with more epochs, displaying better learning and minimized errors, while R^2 increases and MAPE stabilizes after early fluctuations, which indicates steady convergence and better overall performance.

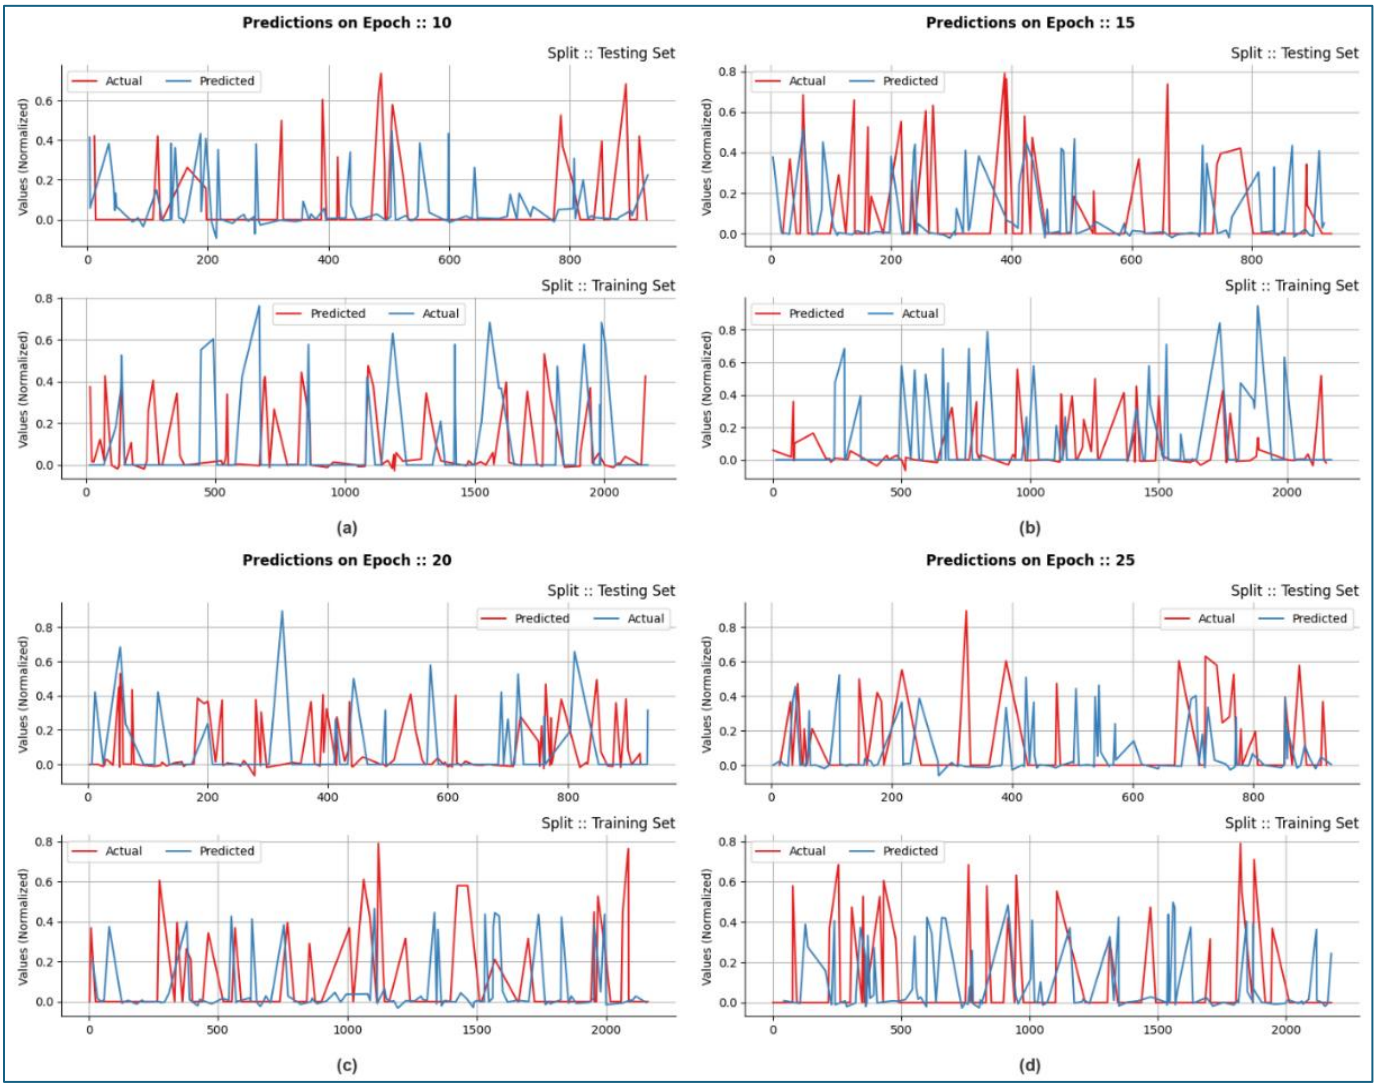

Fig. 6. Mohs hardness prediction of minerals using train- test splits.

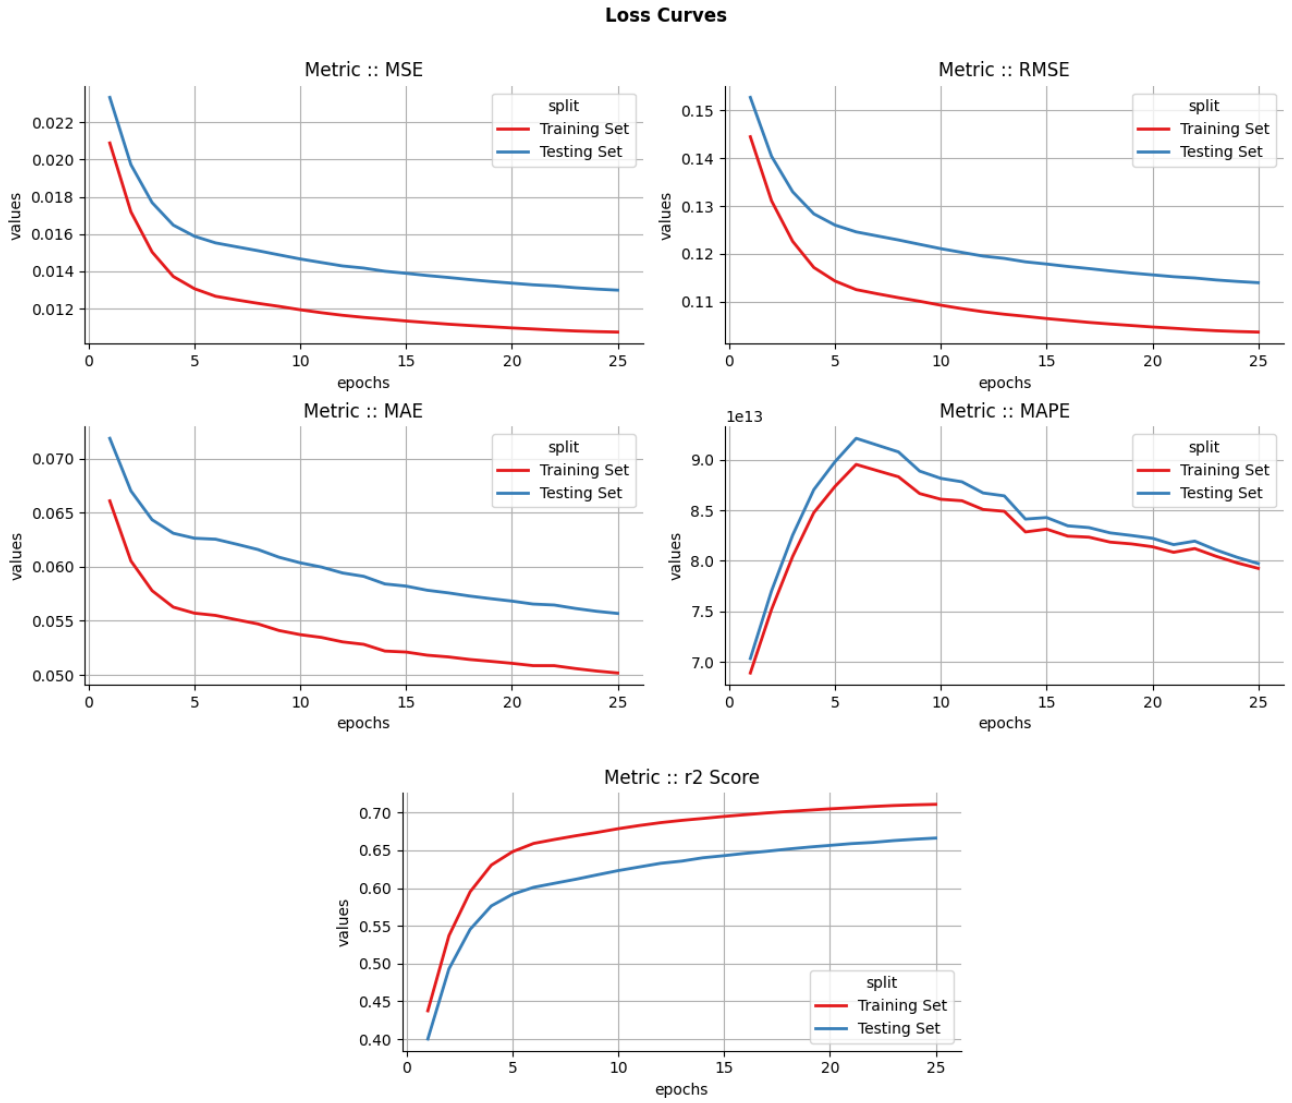

Fig. 7. Loss curve of the XDRL-MHP method with metrics.

TABLE II. MOHS HARDNESS PREDICTION ANALYSIS OF XDRL-MHP METHOD WITH TRAIN -TEST SET

Metrics	Training Set	Testing Set
MSE	0.0107	0.0130
RMSE	0.1036	0.1140
MAE	0.0502	0.0557
MAPE	7.9261	7.9736
r2 Score	0.7109	0.6662

Table II and Fig. 8 exhibit the Loss curve and performance metric analysis of the XDRL-MHP model for both the training and testing sets over 25 epochs. The gradual decrease in error values shows that the model achieves improved learning efficiency and low prediction loss. Simultaneously, the continuous increase in R^2 score value indicates stable learning behaviour and improved model accuracy, which shows strong predictive capability for Mohs hardness estimation.

Fig. 8. Mohs hardness prediction analysis of XDRL-MHP approach with training and testing set.

TABLE III. COMPARATIVE ANALYSIS OF THE XDRL-MHP SYSTEM WITH EXISTING METHODS

Models	RMSE	MAE	MAPE	r2 Score
kNN	2.3195	1.8600	12.9300	0.5770
AdaBoost	2.4413	1.9600	24.7800	0.5534
GradientBoost	1.4663	1.1650	27.7500	0.5499
MLP	2.0905	1.4860	15.1700	0.6112
ANN-TLBO	0.6782	0.2210	21.6300	0.5209
Transformer	1.9647	2.3300	13.7100	0.5280
ConvLSTM	2.0075	0.9230	8.5500	0.6334
VGG16	2.1354	1.6200	15.5700	0.6163
XDRL-MHP	0.1140	0.0557	7.9736	0.6662

Table III and Fig 9 present the comparative performance analysis of the proposed XDRL-MHP model with various metrics [26, 27]. Traditional models such as KNN and AdaBoost show higher RMSE and MAE values, which indicates lower prediction accuracy. Models such as MLP, Transformer, ConvLSTM, and VGG16 exhibit better learning capabilities compared to traditional methods, but show lower performance than the proposed model. The proposed XDRL-MHP outperforms all existing approaches by achieving RMSE (0.1140), MAE (0.0557), MAPE (7.9736), and R2 score (0.6662). The result highlights that the model achieves the most reliable and accurate Mohs hardness prediction.

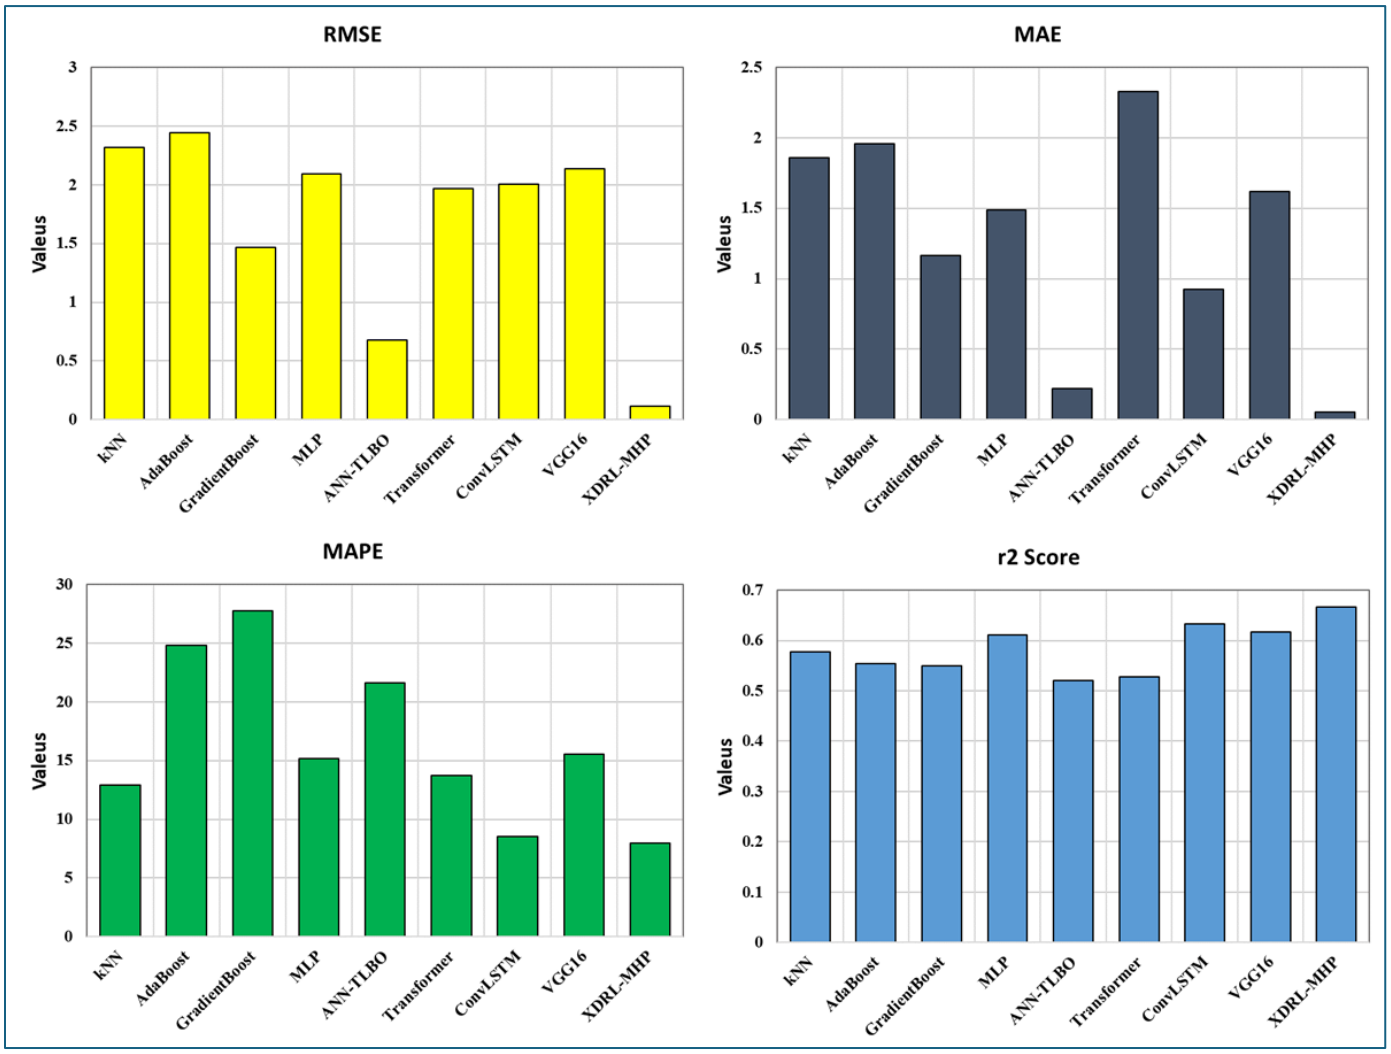

Fig. 9. Comparative results of the XDRL-MHP method with metrics.

An ablation study assesses how different parts of a method influence its performance by testing the classification with specific models removed or altered. This precedure provides which modules are significant and which have less impact. By comparing results, investigators gain insight into the model's behavior. These results enable better design and optimization. Table IV demonstrates the ablation study of the XDRL-MHP technique. The results show that Baseline, mRMR (Minimum Redundancy Maximum Relevance), mRMR + Physicochemical Representation (PR), mRMR + PR + MLP + Neural Tensor Network (NTN), mRMR + PR + Residual Network + Neural Tensor Network (NTN), and mRMR + PR + Capsule Network + Neural Tensor Network (NTN) models have attained higher performance under different metrics. In the meantime, the XDRL-MHP (Explainable Deep Representation Learning Framework for Mohs Hardness Prediction) method has got less performance, with RMSE of 0.114, MAE of 0.0557, MAPE of 7.9736, and R^2 score of 0.6662.

TABLE IV. ABLATION STUDY ANALYSIS OF THE XDRL-MHP METHOD

Configuration	RMSE	MAE	MAPE	R^2 Score
Baseline	0.1867	0.1094	14.8265	0.4728
mRMR(Minimum Redundancy Maximum Relevance)	0.1624	0.0915	12.8462	0.5517
mRMR + Physicochemical Representation (PR)	0.1458	0.0796	10.9473	0.5984
mRMR + PR + MLP + Neural Tensor Network (NTN)	0.1336	0.0724	9.9148	0.6271
mRMR + PR + Residual Network + Neural Tensor Network (NTN)	0.1271	0.0671	9.2846	0.6438
mRMR + PR + Capsule Network + Neural Tensor Network (NTN)	0.1237	0.0648	8.9135	0.6519
XDRL-MHP (Explainable Deep Representation Learning Framework for Mohs Hardness Prediction)	0.114	0.0557	7.9736	0.6662

TABLE V. COMPUTATIONAL EFFICIENCY OF THE XDRL-MHP MODEL

Model	Parameters(M)	GFLOPs	Inference Time (ms)
MLP	0.42	0.18	2.84
ANN-TLBO	0.58	0.27	3.21
Transformer	2.84	1.46	6.73
ConvLSTM	3.72	2.18	8.41
VGG16	14.72	15.50	12.48
XDRL-MHP	**0.31**	**0.14**	**2.17**

Table V depicts the computational efficiency of the XDRL-MHP method compared with other algorithms. Based on inference time, the XDRL-MHP model gives minimum value of 2.17ms, Flops of 0.14G and parameters of 0.31M whereas the MLP, ANN-TLBO, Transformer, ConvLSTM, and VGG16 techniques gain better time of 58.60ms, 0.42ms, 0.58ms, 2.84ms, 3.72ms, and 14.72ms, correspondingly.

Table VI illustrates that the proposed method was validated utilizing 10-fold cross-validation to evaluate its reliability and stability. The proposed model obtained a mean RMSE of 0.1135, MAE of 0.055, and MAPE of 7.816%, demonstrating comparatively low prediction error. The mean R^2 score was 0.6613, representing better predictive performance.

The low standard deviations (STD), particularly ±0.0029 for RMSE and ±0.0092 for R^2, specify continuous performance across all folds.

Fig. 10 illustrates the SHAP-Based analysis for explainable Mohs Hardness Prediction using global feature importance and local explanation summary. Among all parameters, the refractive index, optical properties, and specific gravity are the most influential parameters that contribute to prediction accuracy. The local explanation further improves model transparency and support to understand the feature-level behavior. Features with positive SHAP values support higher predictions, while negative values decrease the prediction output. This SHAP analysis enhances model transparency and strengthens reliable model decision-making.

TABLE VI. CROSS-VALIDATION ANALYSIS OF THE XDRL-MHP METHOD

Fold	RMSE	MAE	MAPE (%)	R^2 Score
Fold 1	0.109	0.0521	7.421	0.648
Fold 2	0.112	0.0543	7.683	0.657

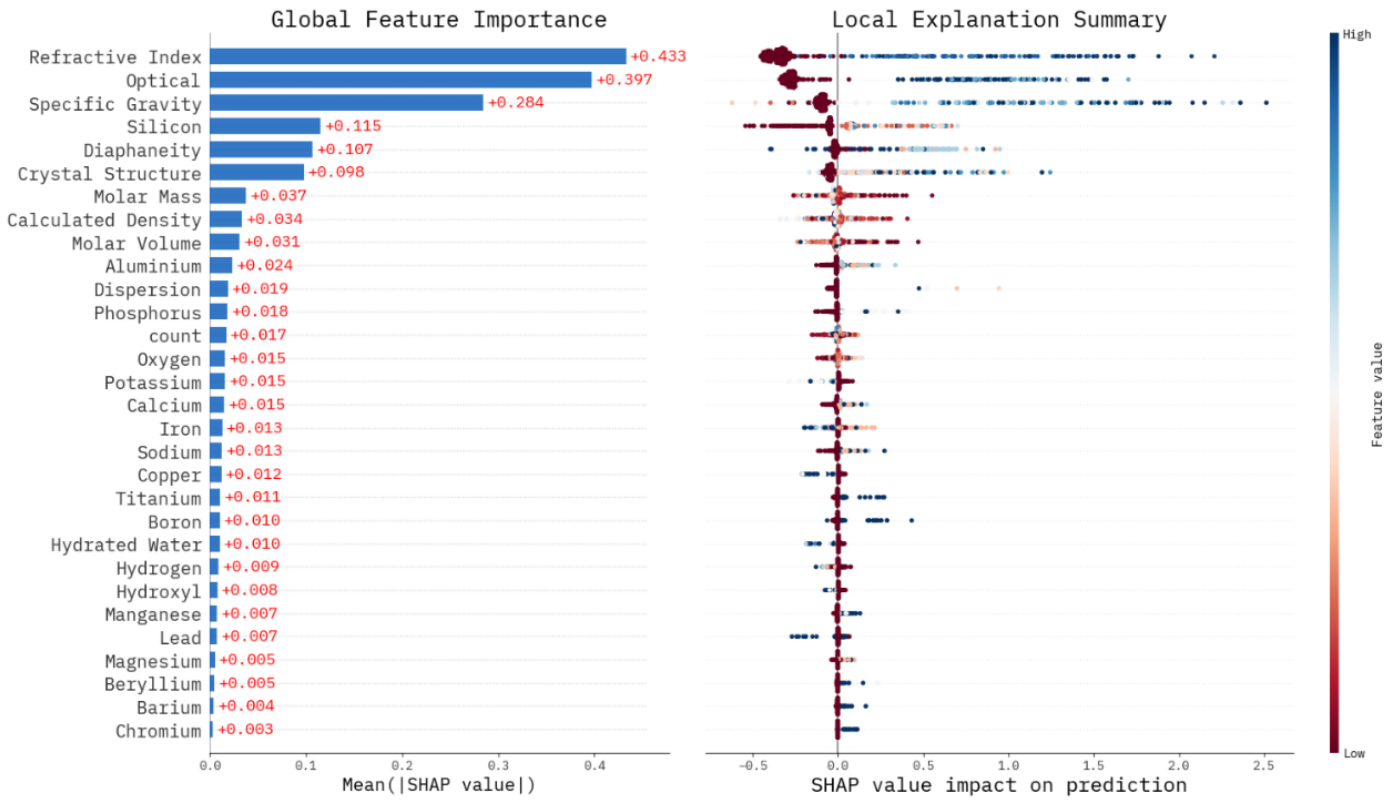

Fig. 10. SHAP-based analysis for explainable Mohs Hardness Prediction.

The experimental outcome shows that the proposed XDRL-MHP architecture effectively forecasts Mohs hardness utilizing mineralogical and physicochemical properties. The incorporation of mRMR-based feature extraction and physicochemical selection learning enhances the extraction of discriminative mineral attributes. Furthermore, the neuro-symbolic hybrid framework improves the ability to extract composite atomic interactions and structural dependencies, causing enhanced prediction stability and accuracy. The integration of explainable neuro-AI further delivers the best transparency and interpretability in the prediction method.

V. Conclusion and Future Work

This study has presented an XDRL-MHP approach for predicting Mohs hardness using mineralogical properties by modeling mineral composition and structural characteristics. The proposed model utilizes mRMR for FS to recognize the most informative physicochemical attributes. A physicochemical representation is constructed utilizing atomic interaction mapping, periodic table relationship encoding, chemical affinity representation, and molecular dependency construction for capturing intricate mineral relationships. Subsequently, a neuro-symbolic hybrid framework is designed, and an explainable neuro-AI model is integrated to enhance model interpretability and insight into predictions. The model is trained utilizing the AdaBelief optimizer with quantile loss to ensure stable convergence and precise Mohs hardness prediction. The experimental analysis of the XDRL-MHP model is performed using the Comprehensive Database of Minerals. Extensive comparative results show the effective performance of the XDRL-MHP model with an RMSE of 0.1140 over existing approaches. Even though the proposed method displays stronger prediction outcomes, it is restricted by reliance on a particular mineralogical database that might impact generalization. It also lacks multi-modal data incorporation and sophisticated graph- or transformer-driven learning for a deeper atomic relationship model. In future studies, the structure could be improved using larger and more diverse datasets to improve the performance of the method. Furthermore, integrating advanced DL and XAI approaches could further improve prediction accuracy and interpretability.

Data Availability Statement

The data that support the findings of this study are openly available in the Kaggle repository at https://www.kaggle.com/datasets/vinven7/comprehensive-database-of-minerals/data [25].

International Information Technology University, Kazakhstan[1]

***Abstract*—Industrial robots are increasingly required to operate in flexible manufacturing environments where conventional offline programming and manually defined working positions limit production adaptability. This study presents a visual servoing framework that integrates interactive image segmentation with industrial robot control through robot-computer communication. The proposed system enables an operator to specify the desired manipulation region directly on an RGB-D camera image, eliminating the need for predefined object models or manually generated trajectories. A fine-tuned Segment Anything Model (SAM) is employed to obtain accurate segmentation masks under industrial conditions, while depth information and hand-eye calibration are used to transform the selected image region into robot coordinates. The generated positions are transmitted to an industrial robot through a TCP/IP communication interface, where they are executed by the robot controller. A graphical user interface was developed to combine image acquisition, interactive segmentation, trajectory visualization, and communication monitoring within a single application. Experimental evaluation demonstrated reliable robot-computer communication and stable segmentation performance in the presence of illumination changes, metallic reflections, and partial occlusions. The proposed segmentation module achieved an average confidence of approximately 91% with an average inference time of 46 ms, enabling near real-time operation for industrial visual servoing. The obtained results indicate that the proposed framework simplifies robot deployment while maintaining accurate target localization and compatibility with existing industrial robotic platforms, making it a practical solution for flexible manufacturing applications.**

***Keywords*—Industrial robotics; interactive segmentation; human-robot interaction; robot-computer communication; industrial automation**

I. Introduction

Industrial automation has continuously evolved alongside the growing demand for higher productivity, consistent product quality, and safer manufacturing environments. The introduction of the first industrial robots in the early 1960s marked a significant milestone in modern production, allowing repetitive and hazardous operations to be performed with remarkable precision [1]. These robotic systems were primarily designed for highly structured environments, where every movement was explicitly programmed and repeated with minimal variation. Although such an approach significantly improved manufacturing efficiency, it also limited the ability of robots to adapt to changes in workspaces or production layouts [2]. As manufacturing processes became increasingly diversified, the need for more flexible robotic systems gradually emerged, encouraging researchers to investigate new approaches to robot programming and control [3].

One of the major directions in this evolution was the integration of perception into robotic systems. Instead of executing predefined trajectories without considering the surrounding environment, robots gradually became capable of receiving sensory feedback from cameras and other measurement devices. This transition led to the development of visual servoing, where visual information is directly incorporated into the robot control loop [4].

Unlike conventional offline programming, visual servoing continuously updates robot motion according to observed image features, allowing the manipulator to compensate for positioning errors, calibration inaccuracies, and object displacement during task execution [5]. Because of these advantages, visual servoing has been successfully applied in robotic assembly, inspection, object manipulation, and precision manufacturing for several decades, becoming one of the fundamental approaches in vision-based robot control [6].

The concept of intelligent manufacturing expanded considerably with the emergence of Industry 4.0 [7]. Modern production facilities increasingly rely on interconnected cyber-physical systems, cloud computing, industrial Internet of Things technologies, and digital twins to improve operational efficiency and production flexibility. In these environments, industrial robots are no longer isolated machines executing predefined programs. Instead, they operate as components of distributed intelligent systems that continuously exchange information with sensors, production equipment, and supervisory software [8]. This transformation has shifted industrial robotics toward adaptive manufacturing, where rapid reconfiguration and autonomous decision-making have become essential requirements rather than optional features.

The rapid progress of artificial intelligence has accelerated this transition even further. During the last decade, deep learning techniques have significantly improved the ability of robots to perceive and interpret complex industrial scenes. Modern neural networks demonstrate remarkable performance in object detection, semantic segmentation, pose estimation, and scene understanding, often outperforming traditional computer vision algorithms based on handcrafted image

features [9]. These capabilities allow robotic systems to operate more reliably under varying illumination conditions, partial occlusions, and cluttered industrial environments that frequently occur in real production facilities. As a result, AI-based perception has become an important component of intelligent robotic automation across numerous industrial applications [10].

Recently, foundation vision models have introduced a new level of flexibility for industrial perception. Unlike conventional deep learning models that require extensive task-specific datasets and repeated training, these large-scale models are capable of generalizing across a wide variety of previously unseen objects [11]. Interactive segmentation further simplifies human-robot interaction by allowing an operator to indicate the desired object or working region using only a few visual prompts [12]. Such an approach considerably reduces the effort required to deploy robotic systems in new production scenarios while preserving accurate object localization [13]. Consequently, interactive segmentation has attracted increasing attention as a practical solution for flexible industrial robotics, particularly in environments characterized by small production batches and frequent product changes.

Despite these technological advances, many industrial robotic systems are still programmed through manually specified positions or fixed working zones established during system commissioning. Even relatively small changes in product geometry or workspace configuration may require additional calibration procedures, modifications of robot programs, or retraining of perception models. These limitations increase deployment time and reduce production flexibility, especially in manufacturing processes where new products are introduced regularly.

To address these challenges, this study proposes a visual servoing framework that combines interactive image segmentation with industrial robot control. Instead of manually defining manipulation coordinates or preparing dedicated datasets for every new object, the proposed approach enables an operator to specify the desired working region directly on the camera image. The segmented region is subsequently transformed into robot coordinates and utilized for robot motion generation. By combining interactive perception with computer vision, the proposed framework aims to simplify robot deployment while maintaining compatibility with existing industrial robotic platforms and conventional manufacturing workflows.

II. Related Works

Visual servoing remains an important approach for improving the positioning and manipulation capabilities of robotic systems operating in changing environments. Classical visual servoing methods are generally divided into IBVS and PBVS. In image-based visual servoing, robot motion is calculated directly from image features, whereas position-based methods estimate the three-dimensional pose of the target before generating robot commands. Although these approaches provide accurate closed-loop positioning, their performance can be affected by calibration errors, feature loss, camera motion, image noise, and changes in the observed scene. Wu et al. reviewed both conventional and learning-based visual servoing methods and showed that recent research increasingly applies neural networks, model learning, and optimization techniques to reduce the dependence on manually designed image features [14]. Adaptive control has also been investigated as a way to improve visual servoing under uncertain robot and camera parameters. Lai et al. developed an uncalibrated adaptive visual servoing method for manipulators with uncertainties in both kinematics and dynamics [15]. The controller estimates unknown parameters online and does not require complete prior knowledge of the camera model. This improves adaptability, although the design and tuning of the controller remain relatively complex. Muthusamy et al. introduced a neuromorphic eye-in-hand visual servoing system based on an event camera [16]. Instead of processing complete image frames, the camera records changes in pixel intensity, allowing the system to respond quickly to object motion and illumination variation. However, event-based cameras require specialized hardware and processing algorithms that are not yet common in conventional industrial workcells. The development of deep learning has considerably changed the role of computer vision in robotics. Modern robotic perception systems increasingly use convolutional neural networks and transformer-based architectures for object recognition, pose estimation, grasping, navigation, and human-robot interaction. Shahria et al. reviewed vision-based robotic applications and identified object detection, scene interpretation, calibration, depth estimation, and real-time processing as important components of intelligent robotic systems [17]. Their review also showed that practical deployment remains limited by computational requirements, sensitivity to environmental conditions, and difficulties in transferring perception models between different workspaces. The introduction of the Segment Anything Model provided a new approach to interactive object selection. Kirillov et al. proposed a promptable segmentation model that generates object masks from points, bounding boxes, or automatically produced prompts [18]. SAM demonstrates strong generalization to previously unseen objects and reduces the need to train an individual segmentation model for every industrial component. This property is particularly useful for operator-assisted robot control because an operator can specify a target region using only a small number of clicks. Earlier studies of interactive image segmentation similarly showed that point, stroke, and region-based inputs can substantially reduce manual annotation effort while preserving accurate object boundaries [19]. Nevertheless, general-purpose segmentation models are not always reliable under the imaging conditions found in industrial environments. Blur, noise, weak illumination, reflective surfaces, low contrast, and partial occlusion may reduce mask quality. Chen et al. introduced RobustSAM to improve the performance of SAM on degraded images while preserving its prompt-based and zero-shot capabilities [20]. The model produced more stable masks under several types of image degradation, but it still requires additional model components and greater computational resources than the original SAM architecture. Several studies have also focused on improving object boundaries and extending interactive segmentation beyond conventional binary masks. Fan et al. proposed Segment and Matte Anything, which combines segmentation and image matting in a unified promptable model

[21]. The method improves the representation of fine boundaries, thin structures, and semi-transparent regions. Such boundary refinement can be valuable for precise robotic manipulation, although the model was not designed specifically for real-time robot control. In video processing, Yao et al. reviewed object segmentation and tracking methods and identified temporal consistency, appearance variation, occlusion, and computational efficiency as major challenges [22]. These problems are also relevant to visual servoing because the selected target should remain correctly identified while the robot or camera is moving. A more direct integration of semantic segmentation and robot control was presented by Jiang et al. [23]. Their approach combines referring image segmentation with an eye-in-hand visual servoing system. A target object is specified through a language expression, segmented in the camera image, and represented using geometric constraints that are converted into robot actions. The method demonstrates that semantic masks can replace some manually designed visual features used in classical visual servoing. However, the approach depends on language-based target descriptions and is intended mainly for eye-in-hand configurations. Robot-specific segmentation has recently become another important research direction. Mei et al. introduced RobotSeg, a foundation model and dataset developed for segmenting robots in images and videos [24]. The model addresses the difficulties caused by differences in robot embodiment, articulated structures, cluttered backgrounds, and rapid changes in robot shape during motion. RobotSeg can support visual servoing, real-to-simulation transfer, data augmentation, and safety monitoring. However, its main objective is to segment the robot itself rather than the external object or workspace region selected by an operator. Interactive perception has also been combined with mixed-reality robot programming. Yin et al. proposed a scene-centric programming framework that integrates mixed reality, SAM-assisted segmentation, three-dimensional reconstruction, and virtual object manipulation [25]. The operator specifies the intended operation by interacting with a digital representation of an object rather than manually defining every robot movement. This provides an intuitive programming process, but it requires mixed-reality equipment, three-dimensional scene reconstruction, and a more complex software architecture. Computer vision is also considered an important enabling technology for Industry 5.0. Tzampazaki et al. reviewed the transition of machine vision from Industry 4.0 to Industry 5.0 and emphasized its role in human-centered manufacturing, quality control, intelligent automation, and safe human-robot collaboration [26]. In this context, industrial vision systems should not only automate perception but should also provide clear and accessible interaction mechanisms for human operators. Recent segmentation research has further explored the connection between masks and semantic descriptions. Huang et al. proposed Segment and Caption Anything, which performs region segmentation together with localized image captioning [27]. The method provides richer semantic information than mask generation alone, but its architecture and computational cost are more suitable for general visual understanding than low-latency industrial control. Kweon and Yoon investigated the transfer of knowledge from SAM to weakly supervised semantic segmentation [28]. Their results demonstrate that knowledge encoded in segmentation foundation models can improve task-specific perception even when dense annotations are unavailable. However, the method requires task-oriented training and does not directly provide robot motion control. Robot communication is another essential component of an integrated industrial system. Lin and Hwang presented an architecture for connecting an industrial robot with Industrial Internet of Things services through OPC Unified Architecture [29]. Their work demonstrates the importance of standardized communication between robot controllers, computers, and external industrial services. However, communication and visual perception are treated as separate system functions rather than as parts of an operator-guided visual servoing workflow. Although existing studies have made significant progress in visual servoing, adaptive control, foundation segmentation models, and interactive robot programming, these components are usually investigated separately.

Visual servoing studies mainly concentrate on control stability and feature tracking, while segmentation studies primarily evaluate mask accuracy. Mixed-reality systems provide intuitive interaction but require additional hardware, and industrial communication studies focus mainly on data interoperability. Relatively few approaches combine operator-guided object selection, interactive segmentation, image-to-robot coordinate processing, and direct robot-computer command exchange within a single industrial framework.

The framework proposed in this study addresses this gap by allowing an operator to select a task-relevant region from the camera image using interactive segmentation. The selected mask is processed to determine the target region, after which the corresponding command is transferred from the computer to the industrial robot controller. This approach preserves human supervision while reducing the need for manual coordinate entry and task-specific object detection models. Table I shows a comparison of the most relevant visual servoing, segmentation, robot programming, and communication methods.

Therefore, the proposed work differs from previous research by combining interactive segmentation with real-time robot-computer communication for industrial visual servoing. Instead of requiring predefined object models or complex feature engineering, the operator simply selects the target region through interactive segmentation, after which the system converts the selected region into robot commands for industrial manipulation. This workflow aims to reduce programming complexity while preserving the flexibility required for modern manufacturing environments.

TABLE I. COMPARISON OF RECENT VISUAL SERVOING AND INTERACTIVE SEGMENTATION METHODS

Authors	Description	Strengths	Limitations
Wu et al. (2022)	Survey of learning-based visual servoing control	Systematic comparison of classical and learning-based controllers	Does not present a complete industrial implementation
Lai et al. (2023)	Uncalibrated adaptive visual servoing	Compensates for uncertain kinematics and robot dynamics	Complex adaptive controller design and parameter tuning
Muthusamy et al. (2021)	Neuromorphic eye-in-hand visual servoing	Fast response to motion and illumination changes	Requires an event camera and specialized processing
Shahria et al. (2022)	Review of vision-based robotic applications	Broad analysis of robotic perception components and applications	Does not propose a unified visual servoing framework
Kirillov et al. (2023)	Segment Anything Model	General-purpose promptable segmentation and zero-shot transfer	Not designed specifically for industrial robots
Ramadan et al. (2020)	Interactive image segmentation review	Covers point, stroke, boundary, and region-based interaction	Focuses mainly on image processing rather than robot control
Chen et al. (2024)	RobustSAM for degraded images	Improved segmentation under blur, noise, and low-quality imaging	Additional computational and training requirements
Fan et al. (2026)	Segment and Matte Anything	Improved fine-boundary segmentation and matting	No direct integration with robotic manipulation
Jiang et al. (2025)	Referring segmentation with visual servoing	Connects semantic target selection with real robot control	Depends mainly on language input and eye-in-hand vision
Mei et al. (2026)	RobotSeg	Intuitive object-level interaction and automatic action generation	Segments the robot rather than operator-selected workspace objects
Yin et al. (2026)	Mixed-reality scene-centric robot programming	Robot-oriented foundation segmentation model	Requires mixed-reality hardware and 3D reconstruction
Huang et al. (2024)	Segment and Caption Anything	Combines region masks with semantic descriptions	High computational cost for real-time robot guidance
Kweon et al. (2024)	SAM-assisted weakly supervised segmentation	Reduces the need for dense segmentation annotations	Requires task-specific training and does not control a robot
Lin et al. (2019)	Robot and IIoT communication through OPC UA	Supports standardized industrial data exchange	Does not integrate interactive segmentation or visual servoing
This work	Interactive segmentation with robot-computer communication	Real-time operator interaction, industrial visual servoing, simplified robot guidance	Currently limited to operator-assisted manipulation and the tested workcell

III. MATERIALS AND METHODS

The developed system combines an industrial robot, an external computer, a vision sensor, an interactive segmentation module, and a graphical user interface. The general workflow consists of five main stages. First, the operator receives an image of the robot workspace. Second, the required working region is selected through interactive segmentation. Third, the selected image points are converted into spatial coordinates. Fourth, the generated robot positions are transferred from the computer to the robot controller. Finally, the controller executes the received trajectory while the graphical interface displays the connection state and operation progress. The experimental system was divided into five functional components: the SIASUN industrial robot, the TCP/IP connection interface, the low-level robot-to-computer communication procedure, the segmentation module, and the operator-oriented graphical interface.

A. Robot Description

The experimental platform was based on the SIASUN SR25A-20/1.80 six-axis industrial robot. The manipulator has a nominal payload capacity of 20 kg, a maximum operating radius of approximately 1803 mm, and a repeatability of ±0.05 mm. The robot can be installed in both upright and inverted configurations, which allows it to be integrated into different industrial workcells. The SR25A-20/1.80 has also received European CE certification, indicating its applicability in industrial automation environments. The industrial robot employed in this work is shown in Fig. 1. The six revolute joints provide sufficient flexibility for positioning the end effector at different locations and orientations within the working area. Depending on the installed tool, the robot can be used for material handling, marking, assembly, welding, inspection, and other repetitive industrial operations.

Fig. 1. Image of the Siasun robot SR25A-20.

In the proposed system, the robot was used as an execution platform that receives target positions generated by the external vision and control software. The robot controller stores

Cartesian positions using position registers containing the translational coordinates as well as the orientation components. During operation, the target positions are transferred to these registers and then executed using joint-space or Cartesian motion instructions. The orientation values can either be obtained from previously taught positions or assigned according to the orientation required by the technological process. The main characteristics of the experimental robot are summarized in Table II.

TABLE II. MAIN CHARACTERISTICS OF SIASUN

Parameter	Value
Number of controlled axes	6
Maximum payload	20 kg
Maximum working radius	1803 mm
Position repeatability	0.05 mm
Controller	SIASUN SRC E5
Communication interface used in this study	Ethernet TCP/IP

B. Connection Interface

Communication between the robot controller and the external computer was implemented through an Ethernet network using the TCP/IP protocol. TCP provides connection-oriented and reliable byte-stream transmission, which is suitable for transferring robot coordinates, system states, and control messages between two network devices. The robot controller and the computer were connected to the same local network. Static IPv4 addresses were assigned to both devices, and the subnet mask was configured so that the controller and the computer belonged to the same subnet. Before starting the robot program, the network connection was verified using the controller web interface and basic network diagnostic tools. In the proposed configuration, the external computer operates as a TCP server, while the SIASUN controller acts as a TCP client. The computer continuously listens on a predefined IP address and port. When the corresponding robot instruction is executed, the controller creates a connection to the server and starts the data exchange.

Several practical difficulties were observed during the connection setup. First, an incorrect IP address or subnet mask prevented the devices from detecting each other, even when the physical Ethernet connection was active. Second, the firewall of the computer could block the selected TCP port. Third, the robot controller and the computer processed line endings differently. Therefore, each transmitted message was terminated by a predefined end-of-line character. Fourth, the TCP connection could be closed before the complete coordinate message was received. This required an explicit communication state and message confirmation mechanism.

Another difficulty was related to the difference between TCP packets and application-level messages. A single coordinate string could be divided into several received data blocks, or several short messages could be received together. For this reason, the computer did not treat each *recv()* operation as a complete command. Instead, received bytes were accumulated in a buffer until the selected message delimiter was detected.

The communication procedure was implemented at two levels. The high-level communication and data processing were performed by the computer application, while the low-level connection and motion instructions were executed inside the SIASUN controller program.

At the robot-controller level, the communication sequence consists of creating a TCP connection, sending a request or the current robot state, receiving a response from the computer, converting the received text into a position register, executing the robot movement, and closing or preserving the connection according to the selected operating mode. The simplified communication sequence is expressed as Eq. (1).

$$O_{\text{open}} => S_{\text{send}} => R_{\text{receive}} => C_{\text{convert}} => E_{\text{execute}} \quad (1)$$

where, O represents the establishment of the TCP connection, S is the message transmitted by the controller, R is the coordinate message returned by the computer, C is the conversion from a text string into a robot position, and E represents the execution of the movement command. The controller program uses low-level instructions such as TCPCREATE, TCPSEND, TCPRECV, and TCPCLOSE. The current Cartesian position can be read from the controller and stored in a position register. The register values are then converted into a character string and transmitted to the computer. Similarly, the coordinate string received from the computer is converted back into a position-register format before the movement instruction is executed. A typical transmitted target position has the following structure Eq. (2).

$$P_i = \left(X_i, Y_i, Z_i, R_{\{x,i\}}, R_{\{y,i\}}, R_{\{z,i\}}\right) \quad (2)$$

There is i is the trajectory-point index. A message delimiter is added to the end of each position to allow the receiving program to determine when the complete coordinate message has arrived. For trajectories containing several points, the computer first transmits the total number of positions N. The controller then requests or receives the positions sequentially Eq. (3).

$$T = \{P_1, P_2, \ldots, P_N\} \quad (3)$$

Only one point is written into the active position register at each iteration. After the point has been successfully parsed, the robot executes the corresponding motion and proceeds to the next point. This approach avoids storing the complete trajectory in the limited set of controller registers and simplifies the validation of individual positions. The communication protocol also contains acknowledgment messages. After receiving and parsing a valid position, the controller or computer returns an *OK* response. When the coordinate string is incomplete, incorrectly formatted, or outside the expected range, an error response is generated, and robot motion is not started. One of the practical problems was that a position received as an ordinary string could not always be used directly by the robot motion instruction. Although the displayed coordinate values were correct, the controller required the complete internal position-register structure, including coordinate-system and orientation-related fields. Therefore, the received values were inserted into a previously initialized position register rather than being treated as an independent uninitialized position.

C. Segmentation Module

The segmentation module was designed to identify the workpiece or the working region selected by the operator. Instead of requiring the operator to manually specify all trajectory coordinates, the system allows the user to provide a small number of visual prompts, such as positive clicks inside the required object and negative clicks outside it. The initial mask was generated using an interactive segmentation model based on the Segment Anything approach. This type of model accepts points, bounding boxes, or masks as prompts and produces a pixel-level segmentation of the selected image region. However, the general-purpose pretrained model did not always provide stable masks for the industrial scene. The observed difficulties included low contrast between the workpiece and its background, reflected light from metallic surfaces, partial occlusion by the robot end effector, and the presence of visually similar objects. Therefore, the segmentation model was additionally adapted to the target industrial environment. The fine-tuning dataset consisted of images collected directly from the experimental workspace.

The images contained different robot positions, illumination conditions, viewing angles, target locations, and partial occlusions. Each image was annotated with the required working-region mask. Data augmentation was applied through changes in image brightness, contrast, scale, rotation, and geometric position. During fine-tuning, the pretrained visual representation was preserved, while the task-specific segmentation layers were adjusted using the collected industrial images. This reduced the number of training samples required compared with training a segmentation network from the beginning. For an input image i and an operator prompt q, the segmentation model produces a binary mask Eq. (4).

$$M = f_{\{\theta\}(I,q)} \tag{4}$$

where, $f_{\{\theta\}}$ is the segmentation model with parameters θ, and Eq. (5).

$$\mathrm{M(u,v)} = \begin{Bmatrix} 1, \text{if pixel (u,v)belongs to the selected region} \\ 0, \text{otherwise} \end{Bmatrix} \tag{5}$$

The model was optimized using a combined segmentation loss, Eq. (6).

$$\mathrm{L_{seg}} = \lambda_1 \mathrm{L_{BCE}} + \lambda_2 \mathrm{L_{Dice}} \tag{6}$$

Here $\mathrm{L_{BCE}}$is the binary cross-entropy loss, $\mathrm{L_{Dice}}$ is the Dice loss, and $\lambda_1$and $\lambda_2$are weighting coefficients. After obtaining the mask, its contour was extracted and filtered to remove small isolated regions. The operator could accept the mask, add another positive point, or mark an incorrectly segmented region with a negative point. The corrected mask was then used to calculate the required image points. The depth value corresponding to a selected pixel *(u,v)* was used to reconstruct its position in the camera coordinate system Eq. (7).

$$X_c = \frac{(u - c_x)Z_c}{f_x}$$

$$\mathrm{Y_c} = \frac{(\mathrm{v} - \mathrm{c_y})\mathrm{Z_c}}{\mathrm{f_y}}$$

$$\mathrm{Z_c} = \mathrm{Depth(u,v)} \tag{7}$$

Function *Depth(u,v)* is the measured depth, f_x and f_y are the camera focal lengths, and C_x and $C_y$represent the principal point. The three-dimensional camera coordinates were subsequently converted into the robot-base coordinate system Eq. (8).

$$\mathrm{p_r} = \mathrm{R_{cr}p_c} + \mathrm{t_{cr}} \tag{8}$$

where, $\mathrm{p_c}$is a point in the camera coordinate system, $\mathrm{p_r}$ is the corresponding point in the robot coordinate system, $\mathrm{R_{cr}}$ is the rotation matrix, and $\mathrm{t_{cr}}$ is the translation vector obtained during camera-to-robot calibration.

The novelty of the proposed segmentation module is not limited to the application of an existing segmentation network. The module combines interactive operator prompts, domain-specific fine-tuning, depth-based coordinate reconstruction, and direct generation of executable industrial robot positions. Thus, the segmentation result is not used only for visual recognition but becomes an active component of the robot-control loop.

D. Graphical User Interface

A graphical user interface was developed to integrate camera visualization, interactive segmentation, robot communication, and trajectory execution in a single application. The interface was implemented on the external computer and was designed for operators who may not have experience with the native controller language. The main GUI window contains the following functional areas:

- a live camera-image panel.
- an interactive segmentation panel.
- network-connection parameters.
- robot-motion parameters.
- a communication log.
- a three-dimensional robot-workspace view.
- trajectory-generation and execution controls.

The camera panel displays the current RGB image and allows the operator to select the required working region. Positive and negative points are shown using different markers. After every additional prompt, the segmentation mask is updated and overlaid on the original image. The connection panel contains the robot IP address, server address, TCP port, connection state, and the number of transmitted trajectory points. The connection status is displayed as disconnected, waiting, connected, transmitting, executing, completed, or error. Before starting robot motion, the interface checks whether the camera is available, a valid segmentation mask has been generated, the coordinate transformation has been loaded, and the TCP server is active. This prevents the trajectory from being transmitted when one of the required system components is unavailable.

The three-dimensional view visualizes the generated trajectory in the robot coordinate system. It is used to verify that the calculated points are located inside the expected

working region. The operator can inspect the trajectory before transmitting it to the controller. The GUI does not directly control the robot servo drives. Instead, it generates and transmits target positions, while the final motion execution remains inside the controller. This architecture preserves the controller-level motion and safety functions while allowing computationally demanding vision and segmentation operations to be performed on the external computer. Fig. 2 presents the overall architecture of the developed system.

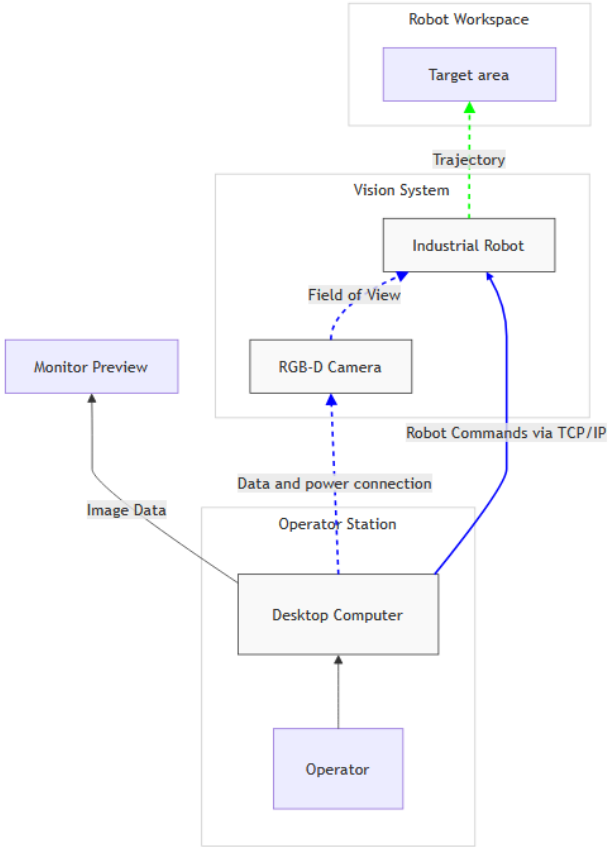

Fig. 2. Overall architecture of the proposed visual servoing framework for industrial robot control.

The image-processing and segmentation operations are performed on the computer, while the controller is responsible for the interpretation and execution of the received positions.

IV. Results

The proposed visual servoing framework was evaluated in an industrial workspace using a collaborative robot, an RGB-D camera, and the fine-tuned Segment Anything Model (SAM). The objective of the experiment was to verify whether the interactive segmentation approach can reliably identify operator-selected regions and generate stable target coordinates for subsequent robot motion. After fine-tuning on the collected industrial images, the segmentation model successfully distinguished the working area from the surrounding background despite variations in illumination, reflections from metallic surfaces, and partial occlusions. Unlike conventional threshold-based segmentation, the proposed approach preserved object boundaries and remained stable under different viewing conditions. The operator selected the desired working region using a single prompt, after which the SAM model generated the corresponding segmentation mask. The resulting mask was subsequently converted into a three-dimensional point using the depth information provided by the RGB-D camera. Fig. 3 presents examples of interactive segmentation obtained during the experiments.

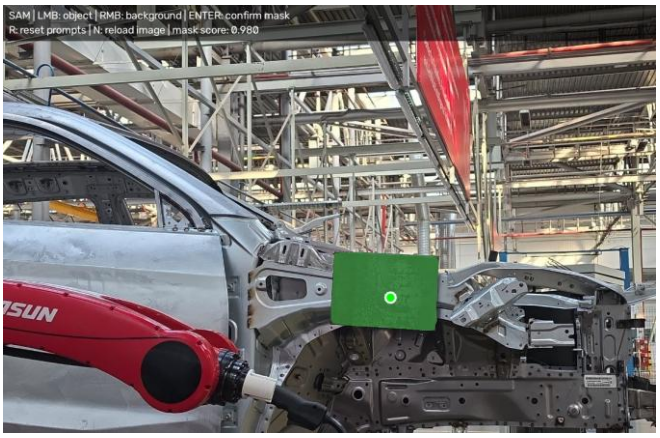

Fig. 3. Image of target segmentation.

This point was then transformed into the robot coordinate system through the previously obtained calibration matrix. The confidence score produced by the segmentation model remained consistently high throughout the experiments. Table III demonstrates the segmentation results. The average confidence on the target region reached approximately 91% for the selected industrial regions, indicating that the detected masks closely matched the intended target areas. The confidence score produced by the model reached 98% for the target region, while the robot arm and workspace were segmented with confidence scores of 90% and 85%, respectively, as shown in Fig. 4. High confidence values were observed even for objects with low texture and moderate illumination changes, demonstrating the robustness of the proposed approach.

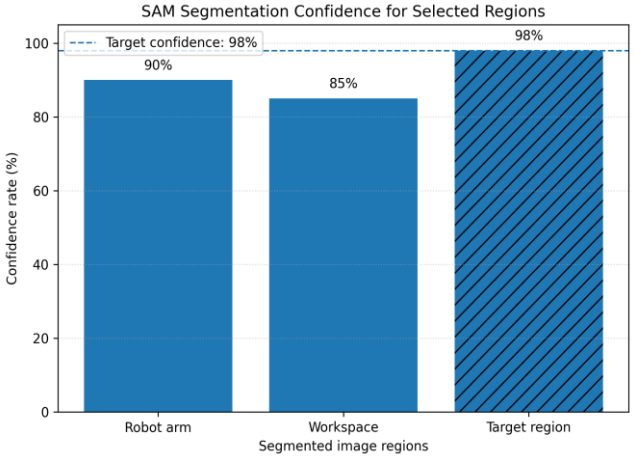

Fig. 4. Segmentation results.

TABLE III. SEGMENTATION PERFORMANCE OF THE PROPOSED METHOD

Metric	Value
Average confidence score target	91%
Average inference time	46 ms
Successful segmentations	95%
Failed detections	5%

The average inference time remained below 50 ms, allowing the segmentation process to operate close to real time. Consequently, the delay introduced by the vision subsystem did not noticeably affect the overall robot response during the visual servoing process. After the operator selected the desired region, the segmentation mask was generated by SAM, transformed into three-dimensional coordinates using the depth image, converted into the robot reference frame through hand-eye calibration, and finally transmitted to the robot controller. Throughout the experiments, the robot successfully reached the designated target positions without requiring manual correction. Overall, the experimental results demonstrate that integrating interactive segmentation with robot-computer communication provides a reliable method for industrial visual servoing. The high segmentation confidence, low inference latency, and stable coordinate transformation collectively confirm the applicability of the proposed system for practical industrial manipulation tasks.

V. DISCUSSION

The experimental findings demonstrate that integrating interactive image segmentation, RGB-D perception, coordinate transformation, and robot–computer communication can provide a practical visual servoing solution for flexible industrial manipulation. The proposed framework achieved an average target-region segmentation confidence of approximately 91%, a successful segmentation rate of 95%, and an average inference time of 46 ms. These results are particularly relevant because the segmentation output is not treated merely as a computer-vision result; instead, it is transformed into three-dimensional coordinates and subsequently transmitted to the industrial robot controller for physical execution. This integration reduces dependence on manually taught positions and enables operators to redefine task-relevant regions directly from camera images.

The obtained results should also be considered within the broader development of machine learning-based industrial robotics. Conventional visual servoing depends strongly on explicitly defined image features, calibration models, geometric relationships, and control rules. Machine learning provides an alternative in which relevant visual representations or control relationships can be learned from data. Learning-based robotic systems can therefore improve their response to variations in object appearance, workspace configuration, illumination, and operating conditions. For the proposed framework, machine learning-based solutions could complement the existing coordinate-transformation pipeline by learning residual calibration errors, estimating target pose, predicting segmentation reliability, or selecting appropriate manipulation points. Such capabilities would be particularly beneficial when extending the current system from operator-assisted manipulation toward increasingly autonomous industrial operation [30].

Deep learning offers additional advantages because convolutional neural networks, vision transformers, and hybrid architectures can extract hierarchical representations directly from industrial images. Rather than relying on handcrafted features, deep learning-based solutions can simultaneously learn texture, shape, boundary, and contextual information relevant to robotic perception [31]. This characteristic is important in the experimental environment considered in this study, where metallic reflections, partial occlusions, low-texture regions, and illumination variations may affect conventional image-processing algorithms. The fine-tuned SAM used in the proposed framework follows this broader transition toward data-driven perception, while domain-specific adaptation allows the general visual representation to be adjusted to industrial imagery. The adopted fine-tuning strategy also reduces the need to train a segmentation network completely from scratch.

Another important direction concerns the combination of segmentation with automatic object detection and pose estimation. Modern machine learning algorithms can identify candidate objects before segmentation, whereas deep neural networks can estimate object categories, orientations, grasping points, and spatial relationships [32]. Integrating these algorithms with the present architecture could progressively reduce the number of operator prompts required for manipulation. Nevertheless, complete automation is not necessarily desirable in every manufacturing scenario. Operator-guided segmentation retains human supervision and provides an intuitive mechanism for handling previously unseen components, unusual production configurations, and low-volume manufacturing tasks. Human-in-the-loop machine learning could therefore provide a useful compromise between fully manual robot programming and completely autonomous perception [33].

The computational performance of the proposed system is also significant for industrial deployment. An average inference time of 46 ms indicates that segmentation can operate close to real time without introducing a substantial delay into the visual servoing workflow. However, increasing the complexity of future deep learning models may create a trade-off between perception accuracy and response latency. Lightweight CNNs, compact vision transformers, knowledge distillation, pruning, quantization, and hardware-aware neural-network optimization could therefore be investigated to maintain low latency while improving robustness [34]. Edge-based inference would further reduce dependence on remote computational resources and could improve predictability for time-sensitive industrial tasks [35].

The modular separation between perception and robot execution represents another practical strength. Computationally demanding segmentation and image processing are performed on the external computer, whereas motion execution and controller-level safety remain within the industrial robot controller. This architecture makes it possible to update machine learning and deep learning algorithms without substantially modifying the robot hardware. It also

creates opportunities for integrating reinforcement learning, particularly for trajectory optimization, grasp selection, and adaptive motion planning. Reinforcement learning-based algorithms could use visual observations, robot states, and task outcomes to optimize manipulation policies while conventional controller constraints preserve safe execution [36].

Several limitations should nevertheless be acknowledged. The current evaluation was performed within the tested industrial workcell and primarily considered operator-assisted target selection. Consequently, the reported segmentation performance does not establish equivalent robustness across different factories, cameras, robots, object materials, or highly dynamic environments. Domain shift remains an important challenge for deep learning-based industrial vision because changes in illumination, camera characteristics, backgrounds, and object appearance can reduce model generalization. Future experiments should therefore include larger multi-condition datasets, cross-workcell validation, more extensive quantitative localization measurements, and comparisons with conventional machine learning, CNN-based segmentation, transformer-based segmentation, and other foundation-model approaches [37].

Finally, future development could combine multi-camera perception, machine learning-based uncertainty estimation, automatic grasp planning, deep learning-based object understanding, and collaborative multi-robot coordination. Multiple viewpoints could reduce occlusion, while uncertainty-aware algorithms could prevent robot motion when segmentation or coordinate estimation is unreliable. Multi-robot systems could additionally share a centralized perception model and exchange task information through the existing communication architecture [38]. Overall, the results suggest that the proposed framework provides a suitable foundation for progressing from interactive visual servoing toward more autonomous and adaptive industrial robotics, while retaining the operator supervision and controller-level safeguards required for practical manufacturing deployment.

VI. Conclusion

The proposed visual servoing framework demonstrates that interactive segmentation can be effectively integrated with industrial robot control through a unified robot-computer communication architecture. Unlike conventional programming methods that require predefined robot trajectories, the proposed approach enables an operator to specify the desired working region directly from the camera image, while the system automatically converts the selected region into robot motion commands. Experimental evaluation confirmed reliable communication between the computer and the industrial robot and showed that the fine-tuned segmentation model achieved average confidence values of up to 91% for the target industrial region, providing sufficiently accurate visual information for manipulation tasks. The proposed framework is modular and can be adapted to different industrial robots and vision sensors with only minor modifications to the communication interface. Future work will focus on improving robustness under varying illumination conditions, extending the method to three-dimensional object understanding, integrating automatic grasp and path planning algorithms, and validating the framework in more complex industrial scenarios involving multiple objects and dynamic environments. Overall, the presented system represents a practical step toward more intuitive, flexible, and intelligent visual servoing solutions for modern industrial robotic applications.

***Abstract*—Diamond clarity grading aims to automatically determine the quality of diamonds by analyzing visible inclusions and structural flaws using intelligent analysis methods. By integrating diamond cost prediction with clarity grading, a unified architecture can be employed for both quality examination and market value evaluation, where clarity attributes support the determination of the diamond's economic value. Traditional machine learning (ML) algorithms depend upon handcrafted characteristics that frequently miss composite structural and visual patterns. Deep learning (DL) enhances feature learning; however, it faces difficulties such as data imbalance, limited interpretability, and inadequate generalization. Consequently, the real-time diamond grading outcome remains limited. Therefore, this study proposes a SHAP-Guided Transformer Network (SGT-Net) for diamond clarity grading. The proposed model includes a preprocessing stage that prepares the diamond grading dataset for effective and reliable model training. Moreover, feature engineering is carried out to enhance the representation of the dataset by deriving meaningful attributes from the raw diamond features. Moreover, SHAP-guided feature prioritization is applied to identify the most influential features in the data. The transformer-based architecture processes the data using separate embeddings for numerical and categorical features, which are then passed through a transformer encoder with multi-head self-attention. In this setup, SHAP is used to understand feature importance and guide the model to pay more attention to the most relevant features during learning. The resulting fused feature representations are then passed through a dense layer followed by a softmax classifier to predict diamond clarity into 8 distinct classes. For training, the model is optimized using the RAdam optimizer along with a weighted cross-entropy loss function. Experimental evaluation is conducted using the Diamond dataset with 8 clarity classes and 53940 samples from the Kaggle repository. The results demonstrate that the proposed SGT-Net effectively learns complex feature relationships and improves diamond clarity grading performance with enhanced accuracy of 96.59%, making it suitable for resource valuation systems.**

I. Introduction

Diamond is the hardest natural material and is broadly utilized in industrial fields because of its distinctive physical characteristics. Since the 1960s, synthetic diamond technology has developed and matured, and it has completely substituted natural ones in industrial applications [1]. The unique physical characteristic of diamonds is closely associated with their crystal structure, which is considered a unique consumer product. Diamond is the hardest mineral, about 58 times harder than other types of minerals, and is utilized in several machines and other types of tools for cutting and slicing processes [2]. It is also one of the most expensive gemstones among the other gemstones; its popularity is mainly due to its unique optical characteristics. Additional factors include its durability, fashion, custom, and strong marketing by diamond producers [3]. However, quality assessments are still highly based on manual inspection through optical microscopes; this method of inspection is time-consuming and prone to operator fatigue and subjectivity, with limited efficiency, reliability, and quantitative evaluation. With the growing demand for accuracy and automated systems, automated visual inspection is becoming an essential trend in industrial diamond processing [4].

A major factor that affects the rate of the diamond is its clarity, which is primarily assessed based on the number, type, position, and size of the internal inclusions [5]. It is a very costly and time-consuming process, and the result may vary depending on the operator's subjective experience. Achieving the accuracy and reproducibility of the outcomes requires proper training and verification by multiple experts, and standardized procedures are essential [6]. Over the past few years, Deep Learning (DL) models have delivered an innovative pathway for the automatic recognition of diamond inclusions. However, the current approaches mostly depend on target positioning and do not entirely incorporate the key features of diamond clarity [7]. These methods overlook the interpretability transformation from detection to grading, which makes the output of the model less suitable for industrial adoption.

Especially, based on the two limitations of low accuracy in micro-inclusion detection and unclear logic for defining clarity grades, developing an automatic grading system with higher precision and consistency remains a difficult task [8].

Since the development of AlexNet in 2012, convolutional neural networks (CNNs) have played a vital role in the rapid development of computer vision. Object detection techniques, including YOLO, Faster R-CNN5, and instance segmentation methods like Mask R-CNN, and a point-based mask refinement approach, such as PointRend, achieve effective object localization and feature extraction by capturing channel and spatial representations in local regions [9]. In recent times, lightweight CNN detectors are used for synthetic diamond quality analysis, with enriched YOLOv8n-driven approaches that have proven effective in capturing local morphological features in microscopic imaging systems [10]. Although anchor-based one-stage detectors are efficient for real-time applications, they are primarily focused on local feature aggregation and scale-based fusion. Alternatively, the multi-head self-attention (MHSA) module in transformers is highly effective for capturing long-term dependencies and less capable of capturing local features [11].

Although diamonds are very highly valued for gemstone and industrial applications, their clarity grading remains largely accomplished by manual microscopic inspection, which is slower and more subjective. Conventional DL methodology mainly concentrates on identifying inclusions instead of directly mapping them to clarity grading. CNN-based strategy is efficient in extracting local attributes; however, it struggles to model global dependencies, whereas Transformers extract global context but are weak in delicate feature representation. Therefore, there is a requirement for an automatic and consistent methodology that combines both local and global feature learning for precise diamond clarity grades. To address these limitations, this research presents a SHAP-Guided Transformer Network (SGT-Net) for diamond clarity grading. The major contributions are outlined below:

- Construct engineered features like diamond volume, carat-to-volume ratio, and depth percentage to enhance feature representation and capture intrinsic features.
- Utilize SHAP-based feature prioritization to identify and emphasize the most influential features, enabling the model to focus on high-impact attributes during learning.
- Design a Transformer-based model with a feature tokenizer (FT) that separately embeds numerical and categorical features, followed by multi-head self-attention (MHSA) with SHAP-guided refinement to capture important feature interactions and improve learning efficiency, and a feature fusion layer to integrate the learned representations.
- Apply a dense layer followed by a softmax classifier to predict diamond clarity into eight distinct classes.
- Integrate the RAdam optimizer along with a weighted cross-entropy loss function to effectively optimize the model during training.
- Conduct the experimental outcomes using numerous metrics, and the comparison analysis assures that the proposed SGT-Net model gains promising results compared to existing models.

II. Related Work

This section presents a review of existing studies on diamond clarity grading and highlights the identified research gaps. Yan et al. [12] developed a target recognition technique specially created for quality estimation of synthetic diamonds, called Diamond-DETR, targeting to enhance identification precision and method generalization across constrained resource settings. The proposed model augments the backbone model to introduce a multi-scale feature representation and employs the RepFasterNet module to maximize inference speed and minimize computational complexity. Moreover, it combines an encoder part that depends on a higher-range screening-feature fusion that applies the channel attention system to fuse and filter attributes with distinct measures, thus improving the method's capability to identify the shortcomings of multiple dimensions. Zhang et al. [13] designed an improved YOLOv8n strategy for synthetic diamond identification and quality calculation, known as YOLOv8n-adamas. The author reshaped the architecture to enrich feature extractor abilities and enhance model performance. The dynamic detection head depends on the attention mechanisms (AM). Mahmood and Zia [14] examined the crucial characteristics to estimate the hardness of DLC coatings. To expand the small experimental data of DLC coatings, the conditional tabular generative adversarial networks (CTGANs) method has been applied. For predicting the hardness of DLCs, a range of 15 ML methodologies are utilized, and their efficiency is evaluated using 6 common error-based evaluation methods.

Triet et al. [15] investigated the incorporation of blockchain technology to overcome these limitations, exploiting the abilities of Fantom and BNB Smart Chain. To collect and signify vital data about each diamond, Non-Fungible Tokens (NFTs) are employed; our system improves traceability and transparency. Through the generation of the protective, immutable data of every diamond, blockchain technology can substantially enhance diamond quality management. In [16], a defective segmentation pipeline is presented by employing in-situ optical images to detect attributes that specify imperfect conditions, which are observed at the macro-scale. In this previous work, a semantic segmentation algorithm was used; these imperfect states and the corresponding derived characteristics are separated and categorized by the pixel masks. Yang et al. [17] discussed how to eradicate the inconsistency and subjectivity inherent in the standard International Association of Drilling Contractors (IADC), which relies heavily on the expertise of drilling engineers and frequently causes unstable performance. Utilizing improvements in CV and DL approaches for polycrystalline diamond compact (PDC) bit damage, this study proposed an automatic identification strategy. For finding the PDC bit cutters, YOLOv10 was applied, accompanied by a dual SqueezeNet system to perform wear type and wear rating categorizations.

Basha et al. [18] addressed diamond rates by WEKA's data mining software. In this study, diamond data is effectively used. These algorithms include Random Forest, M5P, Decision Stump, Multilayer Perceptron, M5Rules, and REP Trees. To evaluate the price of a diamond, cut quality, carat weight, and how well they have accessible size, such as depth, breadth, and the table's surface, diverse ML strategies are contrasted and compared. Randhawa et al. [19] proposed the use of a regression approach in ML to predict diamond costs. The dataset involves attributes like color, carat, clarity, and cut, with certain physical sizes, namely x, y, z, table, and depth, that are both continuous and categorical. Several categorical characteristics can be encoded as constant values to simplify and improve prediction.

A. Research Gap

Despite recent developments, numerous gaps remain in existing studies. Diamond-DETR focuses primarily on detection and not on direct clarity grading, thus making it of low value for final grading decisions. The YOLOv8n-adamas enriches feature extraction but still depends on CNNs, which reduces its capability to capture global relations required for precise clarity valuation. The segmentation-based techniques decrease labeling effort but rely on massive numbers of annotated datasets, and they cannot directly convert the defects into clarity grades. Existing tabular Transformer models mainly learn relationships between features through self-attention, but they do not directly use feature importance to give greater focus to the most relevant attributes. Gradient-boosting methods can learn nonlinear relationships among the input features, but they have limited ability to capture the wider dependencies between them. Therefore, existing methods may not sufficiently capture both the importance of individual features and their interactions, which can affect the accuracy of clarity classification. Accordingly, there is still a requirement for a combined and effective system for accurate diamond clarity grading.

III. Materials and Methods

This study presents an SGT-Net approach for diamond clarity grading in smart mining. Fig. 1 represents the structural overview of the proposed SGT-Net approach. The proposed SGT-Net follows a multi-stage approach. First, data preprocessing is performed through median imputation, duplicate record removal, outlier detection, ordinal encoding for cut, color, and clarity, and feature standardization using RobustScaler. Then, the feature engineering process is performed to derive meaningful attributes from raw data. In addition, the SHAP-based features identify and rank the most influential features. The transformer-based architecture is processed using numerical and categorical feature embedding, transformer encoder, MHSA, SHAP-based refinement, and a feature fusion layer, followed by a dense classification head and softmax activation to predict 8 diamond clarity classes. Finally, the Adam optimizer with a weighted cross-entropy loss function is used to improve training stability.

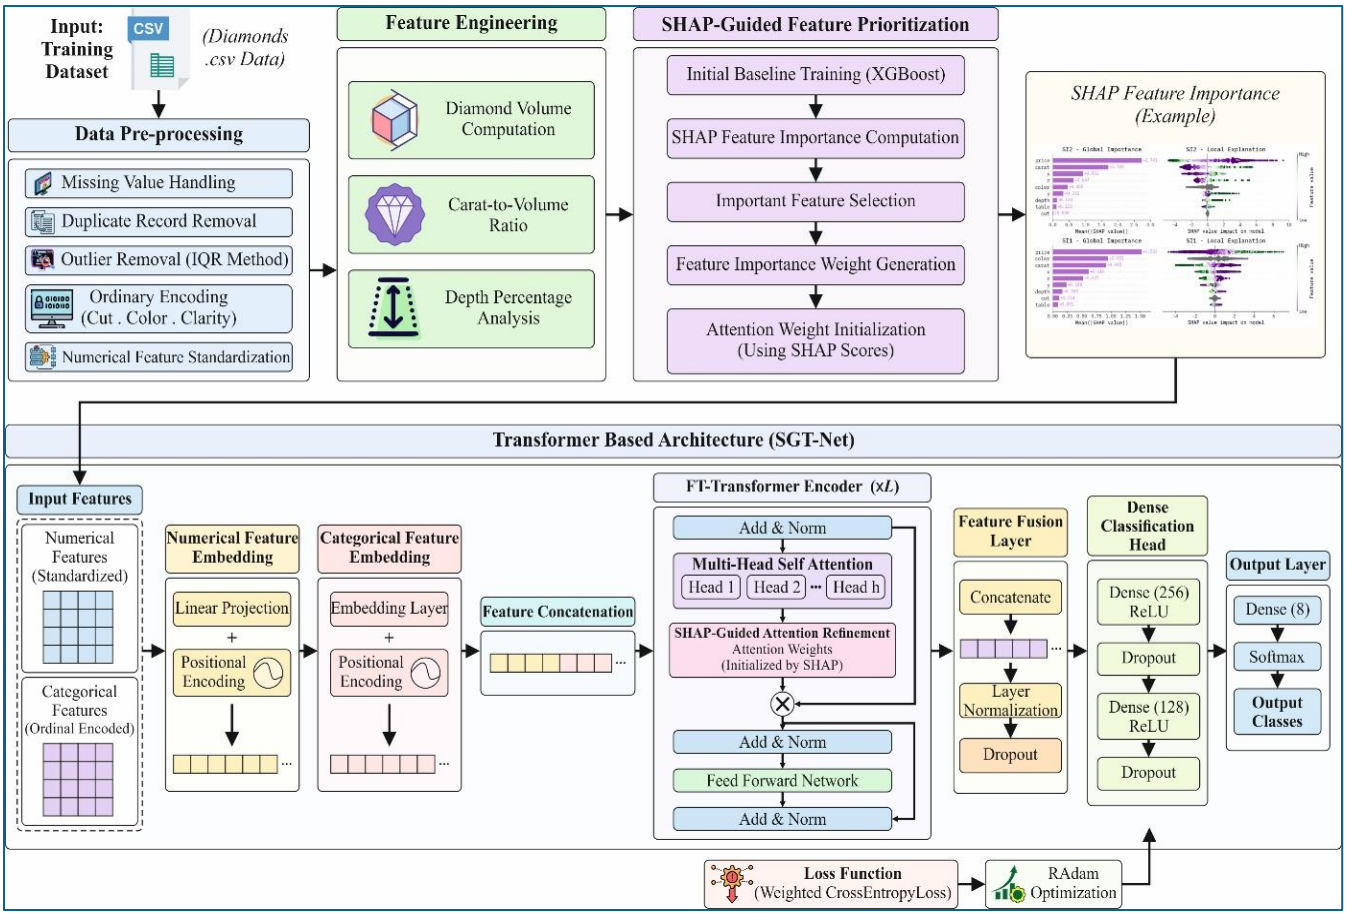

Fig. 1. Structural overview of the proposed SGT-Net model.

A. Dataset Used

The proposed SGT-Net framework is evaluated using the diamonds dataset [20]. The dataset includes information about diamonds and is mainly used to estimate their market value based on various physical and quality-based features. It contains both numerical and categorical features that describe details of each diamond. Quality-related features, including cut, color, and clarity, describe the visual characteristics and grading of a diamond. Physical measurements such as depth provide further information about its proportions. Together, these features provide useful information for building predictive models for diamond pricing and clarity assessment in smart mining and resource valuation applications.

Table I presents the distribution of 53,940 diamond samples across eight clarity classes. The clarity grades range from I1, representing the lowest grade, to IF, representing the highest grade. Among these classes, SI1 has the largest number of samples (13,065), followed by VS2 (12,258) and SI2 (9,194), providing good representation of diamonds with moderate clarity levels. Overall, the dataset covers all eight clarity grades and provides sufficient samples for training and evaluating the classification model.

TABLE I. DATA DISTRIBUTION OF DIAMOND CLARITY CLASSES

Clarity Classes	Description	No. of Samples
I1	Included 1 (worst clarity)	741
SI1	Slightly Included 2	13065
SI2	Slightly Included 1	9194
VS1	Very Slightly Included 2	8171
VS2	Very Slightly Included 1	12258
VVS1	Very Very Slightly Included 2	3655
VVS2	Very Very Slightly Included 1	5066
IF	Internally Flawless (best clarity)	1790
Total Samples		**53940**

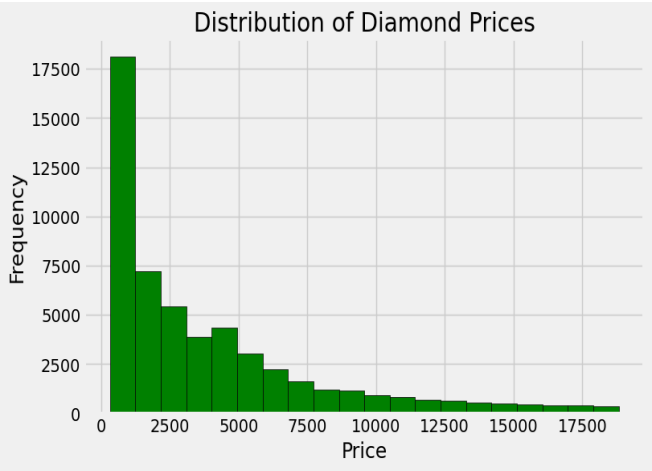

Fig. 2. Distribution of diamond price.

Fig. 2 presents the distribution of diamond prices in the dataset. The histogram shows that most diamonds have low to moderate prices, while only a small number of samples have higher prices, resulting in a right-skewed distribution. This pattern gives a clear view of the price variation in the dataset and provides a useful basis for further analysis.

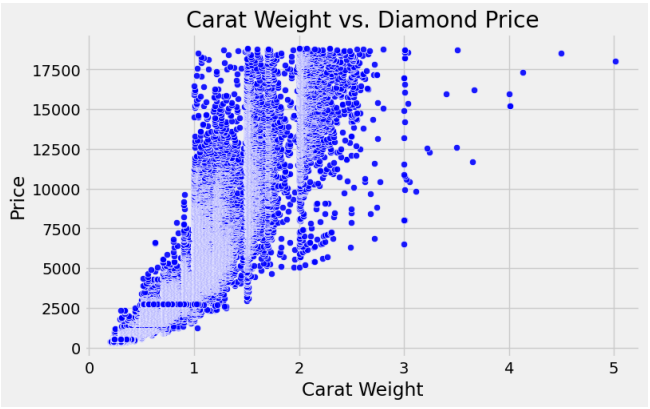

Fig. 3. Relationship between carat weight and diamond price.

Fig. 3 displays the relationship between the carat weight and diamond price. The scatter plot shows a strong positive relationship between carat weight and diamond price, indicating that the diamond price grows gradually with higher carat values. This visualization represents the importance of carat weight in defining overall pricing.

B. Data Preprocessing

Data preprocessing is a vital step that improves data quality and makes the dataset suitable for model training. It includes median imputation for missing values, removing duplicate records, detecting and handling outliers, encoding features like cut, color, and clarity, and scaling numerical features using RobustScaler.

1) Median imputation: Median imputation fills missing entries using the median value calculated from the corresponding feature. Median imputation replaces missing values with the median value of the respective attribute within the specified class [21].

$$\hat{x}_{ij} = median\left(x_{ij} : x_{ij} \in C_k\right) \quad (1)$$

The imputation method can be improved by using class-wise median values to better preserve the data distribution and reduce the influence of outliers.

2) Duplicate record removal: It is performed to confirm the quality of data and prevent repetition in the dataset. Recurrent occurrence of the same documents is detected and removed, thereby ensuring that every record contributes exclusively to the learning process. This stage helps avoid bias in model training and enhances the consistency of the dataset.

3) Outlier removal using IQR method: Outliers are eliminated by the Interquartile Range (IQR) strategy to minimize the effect of extreme values and enhance data consistency. The system recognizes anomalous data points that lie substantially outside the central distribution of every numerical attribute. These extreme values are eliminated to guarantee that the dataset replicates the true underlying patterns and improves method consistency.

4) Ordinal encoding: Ordinal encoding is employed for categorical characteristics, namely, color, clarity, and cut, by transferring them into numerical values that depend on their inherent order. Every category is allotted a rank based on its level of quality, maintaining the natural hierarchy presented in the information. This convention facilitates the method to effectively interpret categorical data in a structured numerical form.

5) Numerical feature standardization: RobustScaler is a feature scaling technique applied in data preprocessing that removes the median and scales numerical attributes based on the IQR. It is remarkably efficient for datasets including outliers, due to the fact that, unlike Min-Max Scaling or Standardization, it is not affected by extreme values.

$$x' = \frac{x - Median(X)}{Q_3 - Q_1} \tag{2}$$

Here x refers to the scaled value, and x denotes the original feature value.

C. Feature Engineering

Feature engineering includes valuable features from raw diamond information to enhance method learning, including evaluating diamond volume (x × y × z), capturing the carat-to-volume ratio, examining depth proportion, and generating interaction-based attributes among volume, depth, and carat. These feature engineers are standardized to confirm effective and durable extraction for downstream modeling. Furthermore, these transformations help capture hidden geometric and physical relationships that are not expressed particularly in the original dataset. The increased feature space enhances the separability between several clarity types to provide the most discriminative patterns. Therefore, feature engineering empowers the method's capability to learn compound dependencies and enhance predictive outcomes.

D. SHAP-Guided Feature Prioritization

SHAP is a method used to explain the output of ML methodologies by measuring the contribution of each feature to a prediction. SHAP is used for interpreting the predictions produced by the XGBoost technique, which is frequently observed as a black box owing to its complexity [22]. SHAP values expose the extent to which every input attribute impacts the method's outcome, in both global and local stages. This system enhances the transparency of the algorithm, to verify predictions depend on their field knowledge, by allowing energy analysts. By using the Shapley value formula, the SHAP values are computed:

$$\phi_i = \sum_{s \subseteq N \setminus \{i\}} \frac{|S|!\,(|N| - |S| - 1)!}{|N|!} [v(S \cup \{i\}) - v(S)] \tag{3}$$

here: S represents a subset of features not containing feature i, $v(S)$ signifies the value function demonstrating the model output with features in the subset S, and N indicates the set of all features. This expression has time complexity; the Tree SHAP methodology calculates SHAP values in a given time, where D denotes the highest tree depth. Additionally, SHAP offers reliable attributes, ensuring that characteristics contribute more to predicting the highest significance scores stably. This makes it specifically appropriate for an intricate ensemble approach, where interpretability is restricted. During practical applications, SHAP also supports detecting hidden interactions between attributes, which can further influence feature engineering and model refinement.

The SHAP values obtained from the XGBoost model are used to determine the importance of each input feature. Since both positive and negative SHAP values indicate the strength of a feature's contribution, their absolute values are considered for feature prioritization. The absolute SHAP values are normalized using min–max normalization as follows:

$$s_i = \frac{|\phi_i| - \min(|\phi|)}{\max(|\phi|) - \min(|\phi|) + \epsilon} \tag{4}$$

where, ϕ denotes the SHAP value of the i_{th} feature, $|\phi_i|$ represents the magnitude of its contribution to the prediction, and s_i is the normalized importance weight of that feature. The term ϵ is a small constant introduced to avoid division by zero. A higher value of s_i indicates a stronger contribution of the corresponding feature to the model prediction.

The normalized SHAP weights are then incorporated directly into the attention mechanism. The SHAP values do not modify the input feature embeddings or the query, key, and value representations.

$$Q = XW_Q, K = XW_K, V = XW_V \tag{5}$$

where, X represents the input feature representations, and W_Q, W_K, and W_V implies the learnable projection matrices for the query, key, and value representations. The scaled dot-product attention score is then modified by adding the normalized SHAP importance of the corresponding key feature:

$$A_{ij} = \frac{Q_i K_j^T}{\sqrt{d_k}} + \lambda s_j \tag{6}$$

where, Q_i and k_j are the query and key representations of the i_{th} and j_{th} features, d_k is the dimension of the key vector, s_j is the normalized SHAP importance of the j_{th} feature, and λ controls the contribution of the SHAP-based importance to the attention score. Consequently, the SHAP information is introduced only at the attention-logit level and does not alter Q, K, or V. The modified attention logits are normalized across the key dimension using the softmax function:

$$\alpha_{ij} = \frac{\exp(A_{ij})}{\sum_k \exp(A_{ik})} \tag{7}$$

Here α_{ij} signifies the attention probability assigned by the i_{th} query to the j_{th} key. The SHAP-guided attention output is subsequently calculated as:

$$O_i = \sum_j \alpha_{ij} V_j \tag{8}$$

where, O_i represents the output corresponding to the j_{th} query position, therefore, features with higher SHAP importance

receive a stronger positive bias in the attention logits, resulting in greater attention probability when the other attention components are comparable.

This allows the Transformer to emphasize features that have a stronger contribution to the XGBoost prediction while preserving the learned feature representations and Q/K/V projections. The resulting attention representation is then forwarded to the subsequent Transformer layer or classification module. Algorithm 1 represents the pseudocode for SHAP-Guided Transformer Attention:

Algorithm 1: Pseudocode of SHAP-Guided Transformer Attention

Input: Feature matrix X, trained XGBoost model, Transformer parameters, SHAP weighting coefficient λ, and a small constant ϵ

Output: SHAP-guided attention representation O

1. Train the XGBoost model using the training feature matrix X.
2. Compute the SHAP values ϕ for the input features using the trained XGBoost model.
3. Calculate the absolute SHAP values:

$$| \phi_i |, i = 1,2, \dots, N$$

4. Normalize the absolute SHAP values using min-max normalization:

$$s_i = \frac{| \phi_i | - min(| \phi |)}{max(| \phi |) - min(| \phi |) + \epsilon}$$

5. Generate the query, key, and value representations:

$$Q = XWQ, K = XWK, V = XWV$$

6. Associate each normalized SHAP importance s_j with the corresponding j_{th} key feature.
7. Compute the SHAP-guided scaled dot-product attention logits:

$$A_{ij} = \frac{Q_i K_j^T}{\sqrt{d_k}} + \lambda s_j$$

8. Apply softmax across the key dimension to obtain the attention probabilities:

$$\alpha_{ij} = \frac{exp(A_{ij})}{\sum_k exp(A_{ik})}$$

9. Compute the SHAP-guided attention representation:

$$O_i = \sum_j \alpha_{ij} V_j$$

10. Pass the resulting representation O to the subsequent Transformer layer or classification module.

E. Transformer-Based Architecture

The proposed SGT-Net uses a transformer-based architecture that processes numerical and categorical features through separate embeddings and an FT-Transformer encoder with MHSA. SHAP-guided refinement and feature fusion are applied before passing the learned representations to a dense layer and softmax classifier for predicting 8 diamond clarity classes.

1) Feature tokenizer: This model is responsible for converting the input feature values into trainable embeddings [23]. Particularly, it captures two parts, such as numerical (x_i^{num}) and categorical (x_i^{cat}) variables, which are embedded in diverse methods. Here, W_i^{num} implies the weights of the numerical embedding layer, and b_i^{num} denotes the numerical bias term; embed () represents the categorical embedding operation, and b_i^{cat} implies the categorical bias term.

$$E_i^{num} = x_i^{num} \cdot W_i^{num} + b_i^{num} \quad (9)$$

$$E_i^{cat} = embed(x_i^{cat}) + b_i^{cat} \quad (10)$$

Also, the numerical and categorical embeddings and a trainable classifier embedding E^{cls}, that all feature embeddings have formed and integrated with each feature embedding.

*2) Transformer encoder***:** The transformer encoder module learns tabular feature representations by representing every feature as an individual token [24]. With the input feature vector $x = [x_1, x_2, \dots, x_7]^T$, all features are self-sufficiently mapped into a common embedding space utilizing a linear transformation:

$$e_j = x_j W_{lin} + b_{lin} \quad (11)$$

Here, $W_{lin} \in \mathbb{R}^{1\times d}$and $b_{lin} \in \mathbb{R}^{d}$. To maintain feature identity, a trainable positional embedding $p_j \in \mathbb{R}^{d}$ has been inserted:

$$z_j = e_j + p_j \tag{12}$$

These tokenized feature representations enable the model to capture the unique characteristics of each input attribute while maintaining a consistent embedding structure. The resulting token sequence is then forwarded to the transformer encoder, where relationships and dependencies among features are learned through the self-attention mechanism.

3) Multi-head self-attention: The attention mechanism (AM) was initially proposed in neural machine translation, improving the capability of the method to concentrate on essential data through weighted allocation [25]. The MHSA module is able to evaluate the effect of input features on the reconstruction curves and allocate corresponding weights to all features. It emphasizes data that significantly impacts the reconstruction curve, thus enhancing model precision. It trains the information's multi-layered interaction across numerous independent focal points and uses a structure with h heads.

$$Q_i = XW_{Qi}, K_i = XW_{Ki}, V_i = XW_{Vi} \tag{13}$$

Next, use the scaled dot-product attention score operation for all attention heads' Q, K, and V to compute the attention scores A:

$$A_i = soft\ \max\left(\frac{Q_i K_i^T}{\sqrt{d_k}}\right)V_i \tag{14}$$

In this Eq. (10), d_k implies the attention head dimension,· and the softmax function processes attention weights. Finally, the outcomes from all h attention heads are integrated and linearly projected utilizing the parameter matrix W_O to attain the resulting value:

$$\text{MultiHead}(X) = Concat(A_1, \dots, A_h)W_O \tag{15}$$

4) SHAP-guided attention refinement: SHAP is utilized for quantifying the contribution of all features, allowing interpretability-based attention score weights. It improves the transformer AM by highlighting higher-effect features and suppressing less relevant inputs.

5) Feature fusion layer: The feature fusion layer integrates diverse kinds of learning representations, like numerical and categorical embeddings, and attention-refined attributes, into a single combined feature vector. It supports the method of combining complementary data from numerous sources and high feature relationships for enhanced predictive outcomes.

6) Dense classification head: It is applied to transform the fused feature representation into class-by-class predictive scores. It serves as the final learning layer in the system, allowing decision-making to rely on deep feature extraction. The fused feature vector is mapped to class logits employing a fully connected layer:

$$z = Wx + b \tag{16}$$

Here, x denotes the fused feature representation, W implies the matrix of weights, and b denotes the bias terms.

7) Softmax output: The softmax function transforms logits into class probabilities through eight diamond clarity grades, assuring a standardized probabilistic outcome appropriate for multi-class identification.

$$Softmax(z_i) = \frac{e^{z_i}}{\sum_{j=1}^{K} e^{z_i}} \tag{17}$$

Let z_i imply the logit for class i, and K signifies the overall count of classes. Fig. 4 signifies the transformer-based architecture for diamond clarity grading.

F. Training Strategy

RAdam (Rectified Adam) is an enhanced version of the Adam optimizer developed to deliver more reliable and stable training, particularly in the initial step of optimization [26]. Although Adam adjusts learning rates utilizing second and first moment evaluations of gradients, it may suffer from aggressive or unstable updates at the start of training. RAdam overcame this problem by introducing a rectification system that automatically alters the adaptive learning rate depending on the difference of the gradients. The key concept in RAdam is to manage the adaptive stage dimensions utilizing a rectification term that is based on the training stage and the exponential decay rate of the second moment. The rectification factor is represented by:

$$\rho_t = \rho_\infty - 2 \cdot \frac{t \cdot \beta_2^t}{1 - \beta_2^t} \tag{18}$$

Here ρ_∞indicates the theoretical maximum value of ρ_t, $\rho_t$denotes the rectification term at step t, t refers to the current iteration step, and $\beta_2$represents the decay rate for the second moment estimate:

$$\eta_t = \begin{cases} \dfrac{\alpha}{\sqrt{\hat{v}_t} + \varepsilon} \cdot \sqrt{\dfrac{\rho_t - 4}{\rho_\infty - 4}}, & if \rho_t \geq 5 \\ \dfrac{\alpha}{\sqrt{\hat{v}_t} + \varepsilon}, & if \rho_t < 5 \end{cases} \tag{19}$$

Here α signifies the base learning rate, η_t refers to the learning rate at step t, ϵ indicates a small constant used for numerical stability, and $\hat{v}_t$ points out the bias-corrected second moment estimate of the gradients. The model is trained using a learning rate of 1e-4 with the RAdam optimizer, ensuring stable convergence. It uses a weighted CrossEntropyLoss to handle class imbalance by assigning higher importance to minority classes. The training is carried out with a batch size of 32 over multiple epochs.

$$L = -\sum_{i=1}^{N} w_{y_i}\ \log\left(p_{y_i}\right) \tag{20}$$

Here, L denotes the total loss over N samples, p_{y_i} is the predicted probability of the true class y_i, and w i represents the class-specific weight by penalizing minority classes more strongly.

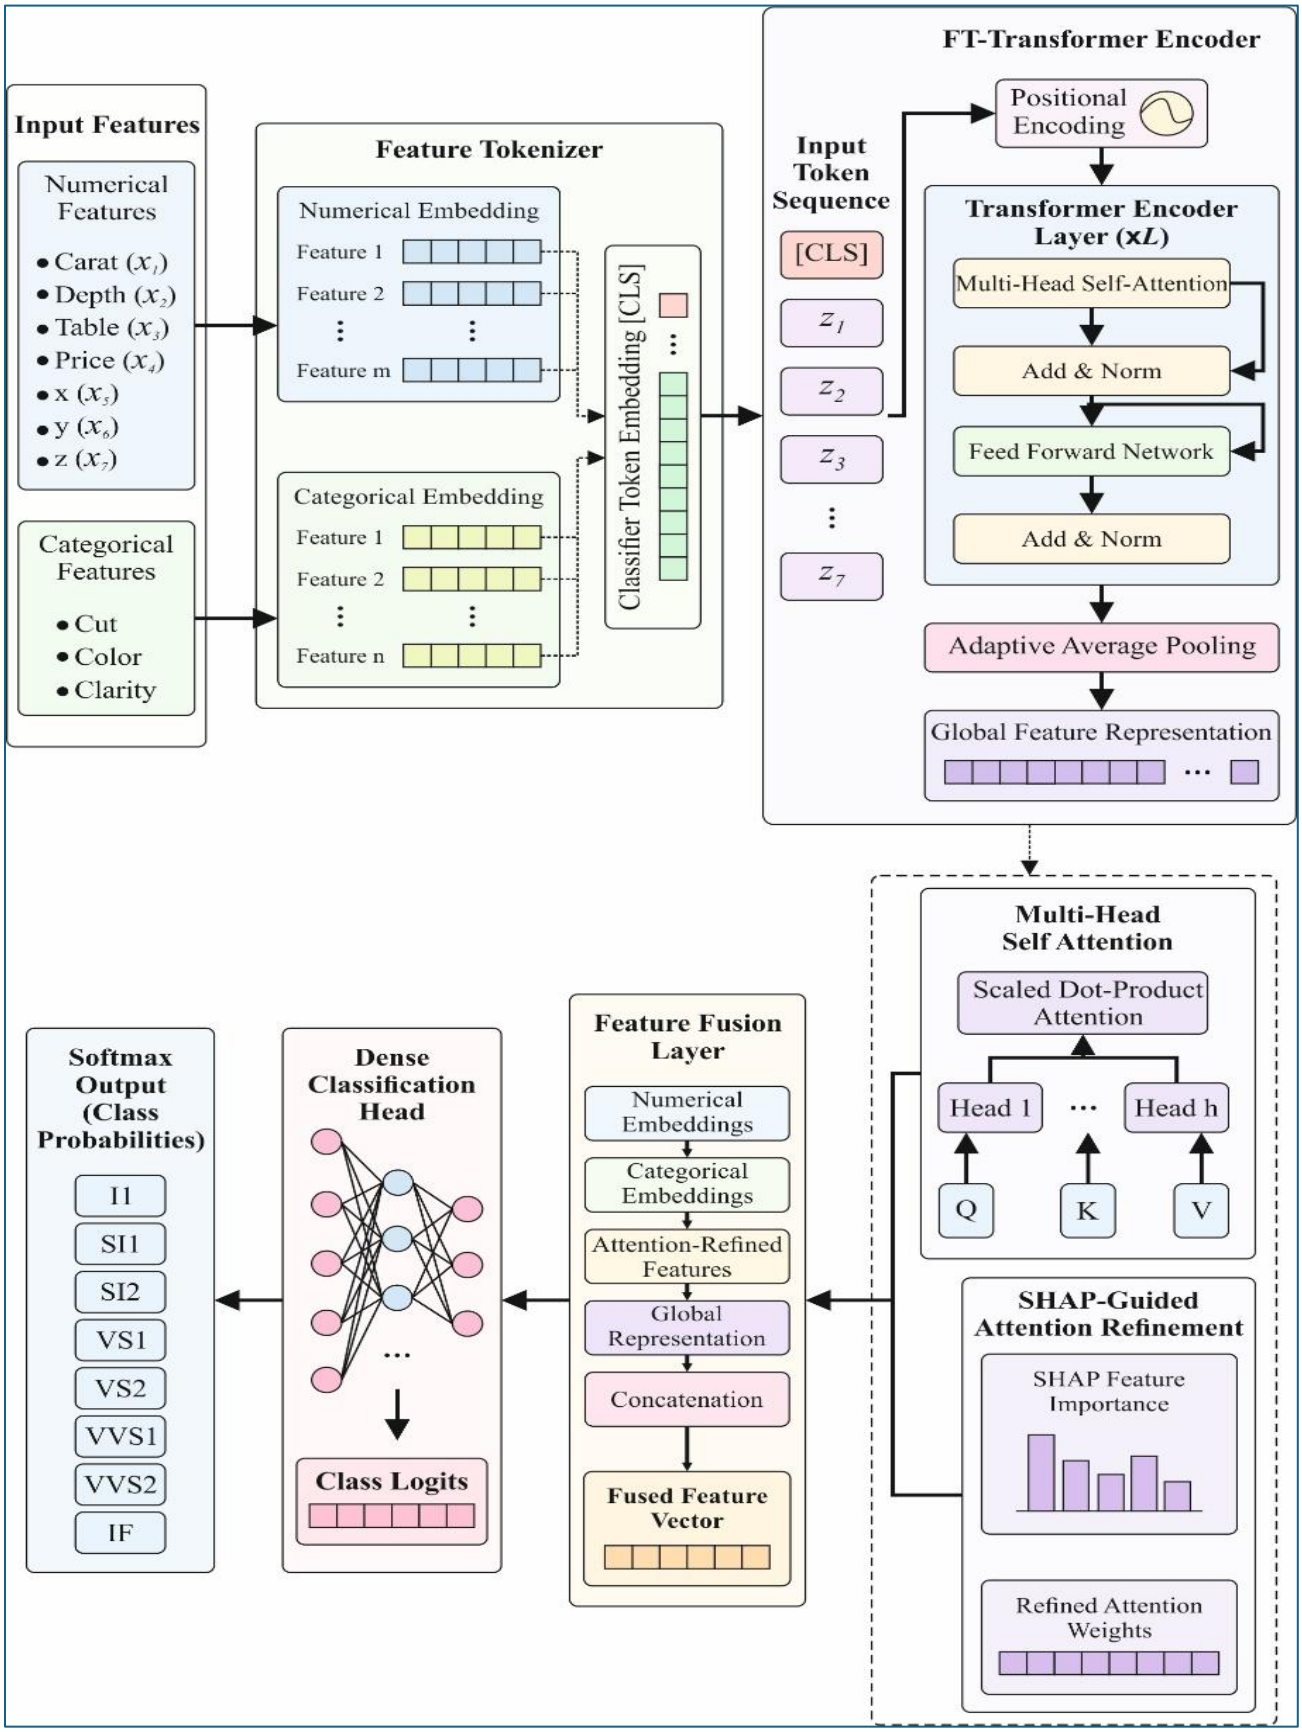

Fig. 4. Transformer-based architecture for diamond clarity grading.

IV. Experimental Analysis and Discussion

This section discusses the performance of the proposed SGT-Net model evaluated on the Diamond dataset. Fig. 5 displays the classifier outcome of the proposed SGT-Net model. The confusion matrix is presented in Fig. 5(a) using an 80:20 train-test split; the diagonal of the confusion matrix highlights strong predictions across all eight classes. The PR curve in Fig. 5(b) reflects a good balance between precision and recall, which demonstrates stable performance across all clarity classes. The ROC curve in Fig. 5(c) with high AUC values shows excellent classification capability. Therefore, the result indicates that the proposed SGT-Net model achieved strong prediction capability in diamond clarity grading.

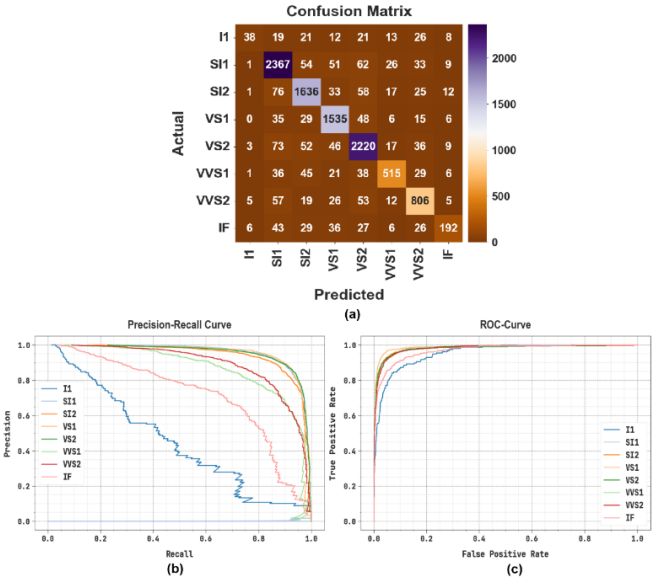

Fig. 5. Confusion matrix (a), PR (b), and ROC (c) Curve analysis of the SGT-Net model using an 80:20 train-test split.

Table II and Fig. 6 exhibit the performance evaluation of the proposed SGT-Net model using an 80:20 training and testing phase. The model achieves an average accuracy of 96.59% in the training phase and 96.57% in the testing phase, which indicates the model's strong generalization capability. The model also achieves excellent results in precision, recall, and F-score, which highlights the balanced classification performance of the model. Furthermore, the MCC and G-Measure values demonstrate strong predictive reliability and stable performance. Therefore, these findings validate that the proposed SGT-Net model is well-suited for accurate diamond clarity grading.

TABLE II. Performance Evaluation of SGT-Net Model Using 80:20 Training and Testing Phase

Metrics	Training Phase (80%)	Testing Phase (20%)
Accuracy	96.59	96.57
Precision	82.93	82.65
Recall	73.84	74.28
F-Score	76.52	76.75
MCC	75.40	75.55
G-Measure	77.40	77.56

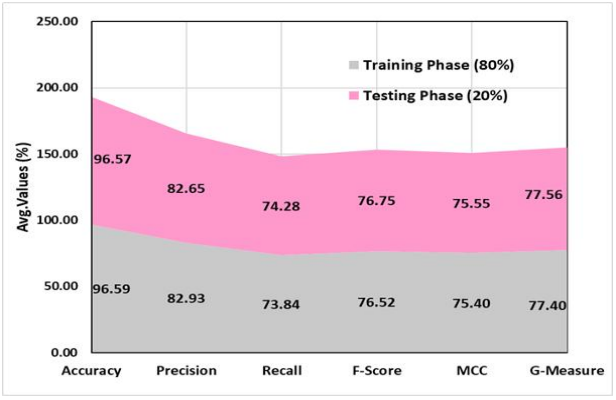

Fig. 6. Performance evaluation graph of the SGT-Net model using an 80:20 training and testing phase.

Fig. 7 presents the classifier result of the proposed SFT-Net framework. The confusion matrix is shown in Fig. 7(a) using a 70:30 train-test split; the diagonal of the confusion matrix shows that most samples are predicted correctly with very few misclassifications, which highlights the strong classification accuracy across all classes. The PR curve in Fig. 7(b) exhibits strong precision and recall across the majority of classes. The ROC curve in Fig. 7(c) further validates excellent discrimination between clarity grades. Therefore, the outcome confirms that the proposed SGT-Net model achieved robust and consistent performance in diamond clarity grading.

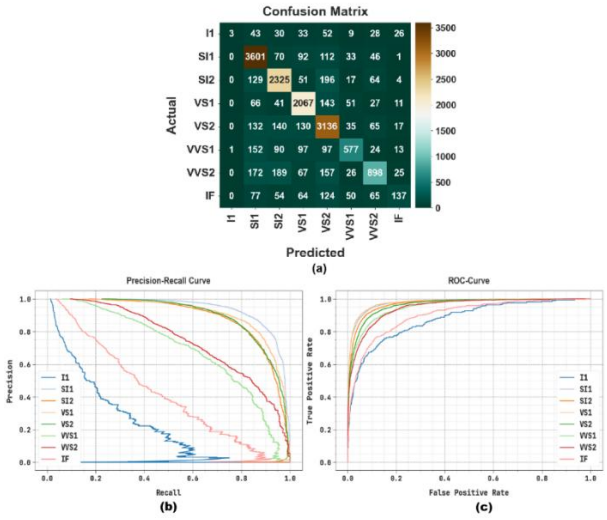

Fig. 7. Confusion matrix (a), PR (b), and ROC (c) Curve analysis of the SGT-Net model using a 70:30 train-test split.

TABLE III. Performance Evaluation of SGT-Net Model Using 70:30 Training and Testing Phase

Metrics	Training Phase (70%)	Testing Phase (30%)
Accuracy	94.76	94.69
Precision	71.63	74.83
Recall	60.66	60.62
F-Score	61.92	62.05
MCC	59.96	60.55
G-Measure	62.94	63.57

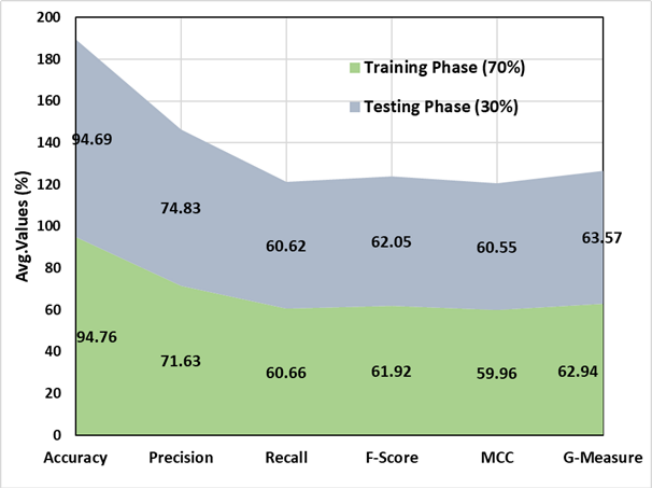

Fig. 8. Performance evaluation graph of the SGT-Net model using a 70:30 training and testing phase.

Table III and Fig. 8 show the performance evaluation of the proposed SGT-Net model using a 70:30 training and testing phase. The model attains an average accuracy of 94.76% in the training phase and 94.69% in the testing phase, which reveals the excellent generalization ability of the model. Additionally, the model attains well-balanced classification performance in metrics such as precision, recall, and F-score, which underlines the reliable classification performance of the model. The MCC and G-Measure values confirm the model's stability and robustness. Therefore, the obtained results highlight the effectiveness of the proposed SGT-Net model in accurately grading diamond clarity.

TABLE IV. COMPARATIVE ANALYSIS OF THE PROPOSED SGT-NET MODEL WITH EXISTING MODELS

Models	Accuracy	Precision	Recall	F1-Score	Inference Time(ms)
XGBoost	88.05	81.78	65.94	75.87	11.95
Stacking	83.71	80.44	72.90	67.00	9.620
LSTM	84.01	71.95	65.90	71.44	11.41
Transformer	85.42	74.32	67.69	68.45	10.35
RT- DETR- R18	79.90	76.91	66.86	69.31	16.80
FT-Transformer	92.84	79.36	69.52	72.81	9.42
TabTransformer	91.76	77.85	67.43	70.96	10.18
SAINT	93.21	80.14	70.68	74.02	11.37
NODE	90.93	75.62	65.87	68.54	8.76
TabNet	92.15	78.43	68.29	71.35	8.21
CatBoost	94.38	80.87	71.46	74.63	7.14
LightGBM	93.72	79.58	70.31	73.42	6.98
SGT-Net	**96.59**	**82.93**	**73.84**	**76.52**	**6.73**

Table IV signifies the comparative analysis of the proposed SGT-Net approach with existing methodologies [27, 28]. The outcome demonstrated that the RT- DETR- R18, Stacking, LSTM, and Transformer models had ineffective outcomes with accuracies of 79.90%, 83.71%, 84.015%, and 85.42%, respectively. Moreover, the XGBoost, NODE, TabTransformer, TabNet, FT-Transformer, and SAINT approaches achieved somewhat greater performance. In addition, the LightGBM and CatBoost methodologies achieved considerable results. At the same time, the proposed SGT-Net approach achieves promising performance with an accuracy of 96.59%, precision of 82.93%, recall of 73.84%, and F1-score of 76.52%, respectively. Thus, the proposed SGT-Net achieves superior classification performance compared with the existing methods, demonstrating its effectiveness for accurate diamond clarity grading.

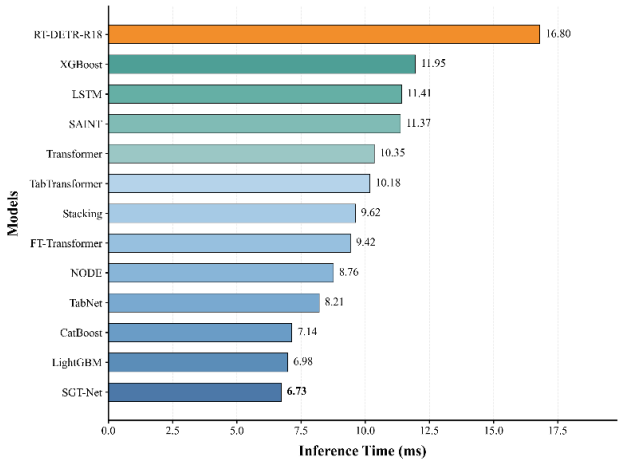

Fig. 9. Inference time of the SGT-Net model.

Fig. 9 signifies the inference time of the proposed SGT-Net model. Among the evaluated models, the XGBoost, Stacking, LSTM, Transformer, RT- DETR- R18, FT-Transformer, TabTransformer, SAINT, NODE, TabNet, CatBoost, and LightGBM approaches take longer inference times, whereas the proposed SGT-Net approach attains a lower inference time of 6.73 ms. Demonstrating its suitability for efficient and timely diamond clarity classification.

TABLE V. ABLATION STUDY OF THE PROPOSED SGT-NET MODEL

Configuration	Accuracy	Precision	Recall	F1-Score
Baseline	89.76	72.84	61.53	66.27
Transformer + MHSA	92.18	76.24	65.73	69.82
Transformer + MHSA + Feature Engineering	94.07	78.31	68.42	72.11
SGT-Net (SHAP-Guided Transformer Network)	**96.59**	**82.93**	**73.84**	**76.52**

Table V presents the ablation study of the proposed SGT-Net model. The Baseline configuration records the lowest performance, with an accuracy of 89.76%. Adding MHSA to the Transformer improves the results to 92.18% accuracy, while the inclusion of feature engineering further increases the accuracy to 94.07%. The proposed SGT-Net, which additionally incorporates SHAP-guided feature importance into the Transformer attention mechanism, achieves the highest performance with an accuracy of 96.59%, precision of 82.93%, recall of 73.84%, and F1-score of 76.52%, respectively. These results indicate that each added component contributes to the overall classification performance, with the SHAP-guided attention mechanism providing the final improvement in the proposed SGT-Net model.

TABLE VI. K-FOLD CROSS VALIDATION

Fold	Accuracy	Precision	Recall	F1 Score
Fold 1	96.21	82.14	72.31	75.18
Fold 2	96.84	83.47	74.26	76.93
Fold 3	96.43	82.61	73.18	75.89
Fold 4	97.02	84.16	75.02	77.81
Fold 5	96.58	82.94	73.71	76.41
Fold 6	95.97	81.72	71.84	74.73
Fold 7	96.76	83.28	74.48	77.12
Fold 8	96.35	82.38	72.96	75.67
Fold 9	97.18	84.52	75.63	78.24
Fold 10	96.61	83.05	73.89	76.58
Average	**96.60**	**83.03**	**73.73**	**76.46**
Std. Dev.	**±0.37**	**±0.85**	**±1.14**	**±1.10**

Table VI shows the 10-fold cross-validation analysis of the proposed SGT-Net model using accuracy, precision, recall, and F1-score. The model shows stable performance across all ten folds, with accuracy ranging from 95.97% to 97.18%. The highest accuracy is obtained in Fold 9, while the lowest is observed in Fold 6. The average accuracy, precision, recall, and F1-score across all folds are 96.60%, 83.03%, 73.73%, and 76.46%, respectively. The corresponding standard deviations are ±0.37, ±0.85, ±1.14, and ±1.10, indicating relatively small variations between the folds. These outcomes demonstrate the consistent performance and stability of the SGT-Net model across different data partitions.

Fig. 10 presents the SHAP-based explainability results of the proposed SGT-Net framework for diamond clarity grading. The figure provides both global and local explanations. The global explanation shows the overall importance of the features used for clarity grading, whereas the local explanation shows how individual features influence a particular prediction. This analysis helps to understand the model's decisions and provides greater clarity about the factors affecting the grading results.

The proposed SGT-Net combines feature engineering, SHAP-based feature prioritization, and Transformer learning for diamond clarity classification. SHAP helps identify the features that have a greater influence on the classification results, while the Transformer encoder with MHSA captures relationships among the different diamond attributes. The experimental results show that the model can effectively use these feature relationships to produce reliable grading results. Overall, SGT-Net provides a useful approach for automated diamond clarity assessment and related valuation applications.

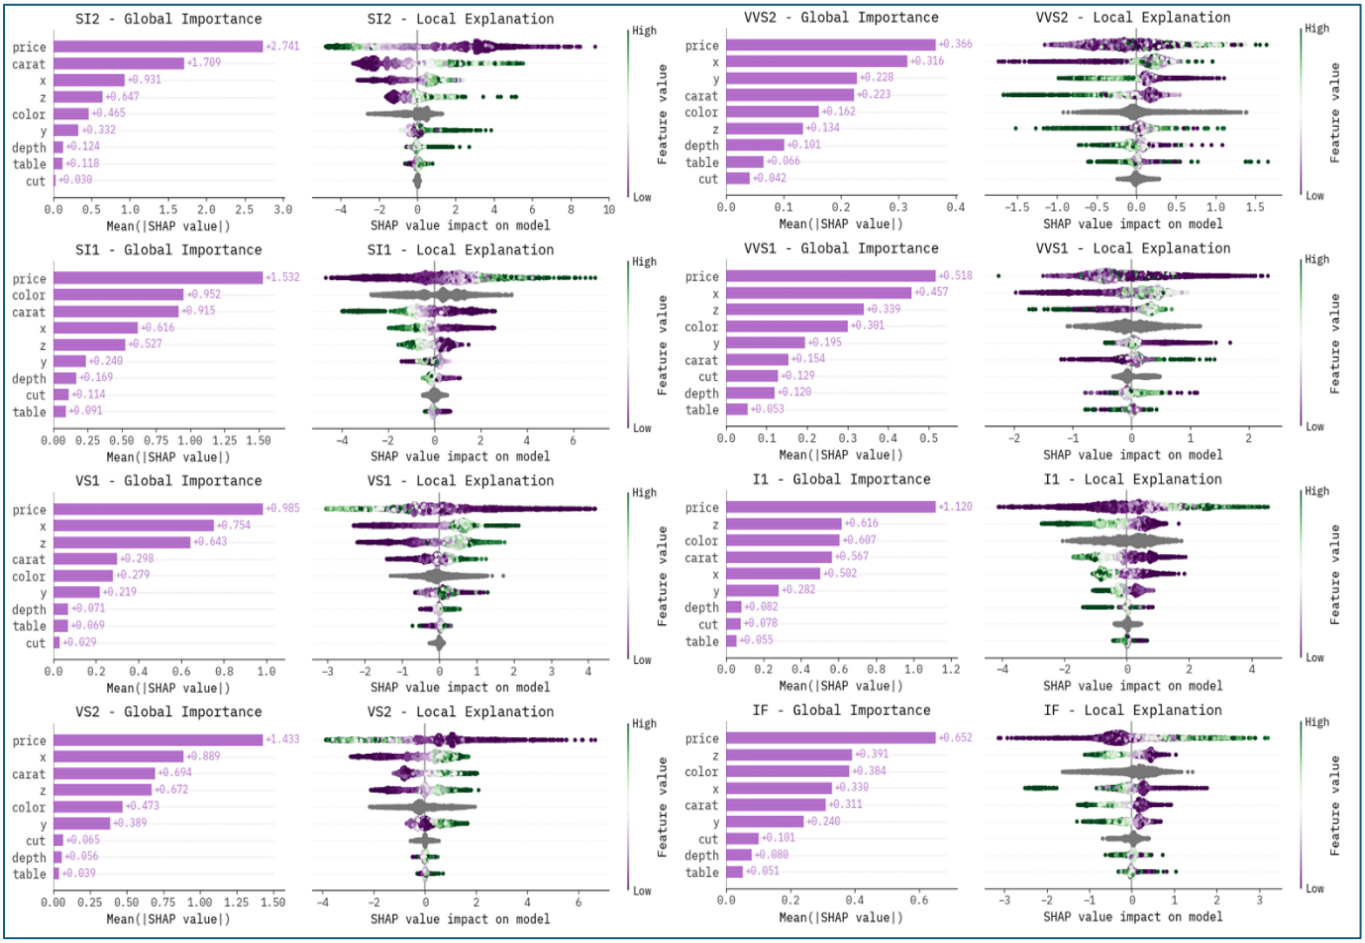

Fig. 10. SHAP-based analysis of the SGT-Net diamond clarity grading framework.

V. Conclusion and Future Works

This manuscript introduced an SGT-Net for diamond clarity grading. The proposed model includes a preprocessing stage that prepares the diamond grading dataset for effective and reliable model training. Besides, the feature engineering process is performed to enhance the representation of the dataset by deriving meaningful attributes from the raw diamond features. Moreover, SHAP-guided feature prioritization is utilized to recognize the most influential features in the data. The transformer-based architecture processes the data utilizing separate embeddings for numerical and categorical features, which are then passed through a transformer encoder with MHSA. In this setup, SHAP is used to understand feature importance and guide the model to pay more attention to the most relevant features during learning. The resulting fused feature representations are then passed through a dense layer followed by a softmax classifier to predict diamond clarity into 8 distinct classes. For training, the model is optimized utilizing the RAdam optimizer along with a weighted cross-entropy loss function. Experimental evaluation is carried out using performance metrics, demonstrating that the proposed SGT-Net effectively learns difficult feature relationships and enhances diamond clarity grading performance, making it suitable for resource valuation systems. Even though the proposed SGT-Net demonstrates better outcomes in diamond clarity grading, its precision relies on the quality and dissimilarity of the training data. Additionally, the transformer framework may need high computational resources and longer training time for huge datasets. In the future will concentrate on testing the system on large and more distinct diamond datasets from multiple sources. The integration of image characteristics and tabular data can be investigated to enhance grading accuracy. Furthermore, lighter transformer strategies and innovative explainability approaches may be examined to increase system efficacy and interpretability for real-time gemstone assessment and resource estimation applications.

Acknowledgment

The authors extend their appreciation to Northern Border University, Saudi Arabia, for supporting this work through project number (NBU-CRP-2026-1564). The authors are thankful to the Deanship of Graduate Studies and Scientific Research at the University of Bisha for supporting this work through the Fast-Track Research Support Program.

***Abstract*—Tumors of the lymphatic system can be either benign or malignant. However, because traditional diagnostic approaches rely on subjective assessment by individual pathologists and often lead to significant discrepancies and misclassifications, early and accurate diagnosis is important for successful treatment and improved scientific outcomes. We compare an adaptive convolutional neural network (CNN) model, trained on filter shapes, with regular CNNs by benchmarking them for image classification. This adaptive model automatically retunes filter size based on statistical tests of images, improving feature extraction and classification performance. More specifically, it achieves an accuracy of around 92%, which is about 10- 13% higher than random predictions using most standard models; however, it also has high precision and recall, 94% and approximately 4.5% higher in this metric, and 85%, with a further 27% increase relative to standard benchmarks used for others. An F1-score of 89% represents an 18% uplift, while AUC, at 97, outperforms the same model without ours by up to 11%. In addition, the mean squared error (MSE) is reduced to 0.096 for the adaptive model, compared with 0.24 for traditional methods. The results show that an adaptive filter can benefit CNN-based image classification. This exploratory research opens a new opportunity to apply deep learning methodologies in practice, supporting their integration into real-world applications such as medical imaging, autonomous systems, and security analysis. Although a small step, it shows the model as an efficient, fast, and scalable classification solution.**

Keywords*—Convolutional neural networks; adaptive image filtering; lymph node tumor images; image classification; feature extraction

I. Introduction

Tumor image classification from lymph nodes is becoming a major part of clinical practice across fields, especially in specialties such as oncology, where distinguishing malignant lymph node data has an enormous impact on patient decision-making and treatment [1]. Deep learning methods, particularly convolutional neural networks (CNNs), have propelled the day-to-day practice of classifying medical images, even those with non-rigid shapes or structures, with surprising accuracy. CNNs detect lesions, and other image types, such as chest X-rays, are classified for many diseases, alongside ultrasound, mammogram, and CT images [2],[3]. Additionally, recent use of established tools such as deep neural networks and wavelet transform models captures natural phenomena that increase representational power through intuitive feature engineering, with less complexity, to classify evolved images in a computationally efficient way [4].

*Corresponding author.

One major issue in tumor classification of lymph nodes is its strong dependence on subtle image variability used to distinguish malignant from benign nodes. To address this limitation, several authors have proposed modifications to standard CNN architectures, focusing on spatial information fusion and multi-task learning to improve lymph node localization/imaging and classification [5],[3]. Lastly, optimizers such as the seagull optimization method have also been used to fine-tune CNN parameters and improve their performance on other datasets [6].

In this field, CNNs contribute to more than just lymph node detection. They also have broader applications in oncology, such as breast cancer classification [7] and histopathology image analysis. CNNs have been widely used to solve many difficult computer vision problems and achieve much higher precision and recall (thus justifying their role in clinical scenarios) [2]. Most impressively, engineering teams have paired the two technologies. They have combined convolutional neural networks (CNNs) with various diagnostic modalities, including axial PET/CT images. This method is relatively simple, but assists in deciding whether it is metastatic lymph nodes or lymphoma. Therefore, their use in these treatments is justified, as they are part of personalized medicine [8].

Nevertheless, the challenges presented by medical imaging and similar features between malignant and nonmalignant tissues maintain significant barriers to accurate lymphoma classification. As a result, most deep learning architectures are based on convolutional neural networks. Nonetheless, most of these architectures have limited ability to capture complex, embedded spatial relationships and long-range dependencies in medical images [9]. Moreover, with other available imaging modalities and sufficient features to extract from different perspectives, classification becomes a daunting task. In this context, the recently leveraged neural network graphs are heterogeneous graph convolutional networks (HGCNs) that facilitate multi-view data integration, thereby increasing the informational content of complex medical datasets [4].

Convolutional neural network training is based on a linear combination of properly chosen convolutional filters in CNNs to improve image classification. The study explores feature discovery, computational efficiency, and classification accuracy to understand and quantify the impact of changes to CNN designs on model performance. This will be further optimized into a CNN architecture for better image classification. Finally, the practical guidelines reviewed in the study could inform a new direction for adaptive CNN filter selection.

With the rapid development of image processing and optimization techniques, convolutional neural network-based methods for classifying lymph node tumors from histopathological images are practical and hold great promise in medical imaging. These advances will profoundly affect diagnostic accuracy and clinical efficiency while minimizing misdiagnoses and improving patient outcomes [10],[11].

II. Related Work

An adaptive image filter selection method has substantially improved the automatic classification of lymph node tumors using convolutional neural networks, thereby enhancing accuracy and efficiency. Previous studies in this area have explored several strengths and limitations, with some following alternative imaging techniques and practices.

Cadillo-Laurentt and Paiva-Peredo compiled a dataset of breast cancer lymph nodes and applied a convolutional neural network to classify histopathological images. The results provided a strong framework for applying convolutional neural networks to lymph node studies and introduced DenseNet architectures, thereby improving diagnostic performance [12]. Likewise, Wang et al. conducted a case study to classify malignant lymph nodes in patients with head and neck cancer. The study addresses one of the most immediate needs in malignancy detection in machine learning-based systems: the use of CT radiomics and a convolutional neural network (CNN) to improve the precision of malignant node identification for radiotherapy [4]. This is partly due to the training data up to October 2023, which demonstrates the usefulness of such models in medicine through their research.

Furthermore, Nayan et al. investigated the challenges of detecting and segmenting mediastinal lymph nodes and presented a modified UNet++ architecture adapted to image resolution and texture discontinuities [13]. Through this study, I learned how the same deep learning models can be tailored for medical imaging to improve image segmentation. Heinlein et al. also addressed lymph node metastasis detection in whole-slide images using a transformer-guided multiple-instance learning approach [14]. They addressed problems typical of standard convolutional neural networks, which can become restrictive when processing large images.

In addition, Ding et al. and Uthatham et al. are representative studies that examine novel network architectures and compare batch normalization in existing CNN models. Ding et al. proposed a convolutional network based on the wavelet transform to classify cervical lymph node metastasis, enhancing feature extraction through spatial and frequency-domain analyses [11]. Uthatham et al. compared several CNN architectures for lymph node classification and found DenseNet to be the optimal model [15].

Moreover, Huang et al. designed and trained a CNN on gigapixel images to identify lymph node metastasis, confirming that CNNs achieve high sensitivity and specificity across heterogeneous datasets [16]. Additionally, Cari et al. and Chao et al. studied modified CNN architectures and graph neural networks to identify lung cancer and gross tumor volume in lymph nodes, respectively, underscoring the importance of deep learning models in X-ray cancer imaging [17, 18].

The PatchCamelyon benchmark dataset, designed by Veeling et al. for classifying histopathology images using deep learning methods [19], was used to address the challenge of microscopic pathology images that differ in projection under arbitrary rotation. They proposed rotation-equivariant convolutional neural networks as a solution. Group-equivariant convolution layers ensured the same features were detected regardless of angle. They extended this architecture to the PCam dataset, achieving better tumor detection than regular convolutional neural networks because medical image classification systems require spatial invariance.

Jaiswal et al. noted that only a few studies use semi-supervised learning to detect lymph node metastases in histopathological images [20]. The researchers used convolutional neural network architectures, specifically DenseNet-based models, and a pseudo-labeling method to leverage both labeled and unlabeled samples during training. At test time, they used a simple framework that included several test-time augmentation methods to improve the system's ability to classify more samples correctly. They demonstrated that semi-supervised methods can leverage large portions of otherwise unused data through their work on the PatchCamelyon dataset.

Teh et al. investigated how limited annotated data constrains digital pathology research and developed a weakly supervised learning framework for patch classification [21]. The research team used transfer learning techniques with ProxyNCA metric learning methods to improve convolutional neural networks' ability to distinguish tumors from normal tissue. The researchers evaluated the method on the PatchCamelyon dataset and found that weakly labeled pretraining improved classification performance while reducing the need for extensive manual annotation.

Zhong et al. developed a cancer image classification approach based on the DenseNet architecture to improve the identification of metastatic tissue in lymph node images [22]. Their methodology employed deep convolutional neural networks, along with extensive data augmentation and test-time augmentation, to improve model generalization. The researchers showed that deep, densely connected networks can effectively perform histopathological image analysis by training and testing the DenseNet model on the PatchCamelyon dataset, yielding high classification accuracy.

Jin et al. provided a unified deep learning framework that integrates convolutional neural networks with U-Net segmentation information [23]. The authors introduced ConcatNet, which combines spatial bulk tumor-derived features from segmentation maps with image units derived from CNN processing. To demonstrate its value, they evaluated it on the PatchCamelyon dataset and found that segmentation data improves generalization by better distinguishing tumor patterns and classifying different tumors.

Teh and Taylor recently examined prevailing image resolutions in digital pathology and their corresponding performance on deep learning models [24]. The authors examined how input and image resolution affect classification accuracy in convolutional neural networks. They assessed different CNN architectures on the PatchCamelyon dataset and found that larger patches (2× 4× patch sizes) were required for histology analysis to achieve better classification performance, as correct decision-

making depends on identifying histopathological structural elements inherent in tissue. A partitioned multi-scale and multi-head self-attention ensemble network was introduced by Ge et al. Breast Cancer Pathology Patches [ML5] [25]. It uses multi-scale feature extraction and attention-based methods to better extract intricate histopathological structures. The researchers evaluated their model on the PatchCamelyon dataset and demonstrated that attention-based ensemble approaches dramatically enhance classification performance by strengthening local and global features in pathology images.

These investigations provide a solid foundation for using CNNs to classify tumors in lymph nodes. They improved the speed and accuracy of the diagnosis and enabled higher-order models that can cope with some aspects of the complexity inherent in medical imaging data. The future emergence of these methodologies is also likely to improve cancer patient management more precisely and effectively.

III. Research Design and Analysis

The methodology describes the research design for developing and testing an adaptive CNN for tumor classification in lymph nodes. The experiment was conducted on the PatchCamelyon dataset with proper preprocessing.

A standard CNN approach takes a pre-processed image dataset as input, represented by each image in Fig. 1. Each image selected in the previous step passes through multiple convolutional layers, using learnable filters and activation functions/more max-pooling operations, to extract features. They are flattened and sent to a pair of fully connected layers, the classifier, during training. This organizes the output processing through a complete pipeline, going from preprocessing/feature extraction to classification.

Many activation functions are critical components of a feed-forward neural network because they add non-linearities that allow a model to learn complex patterns (which no simple linear transformation can capture). Without these functions, every layer is linear, and stacking a number of layers removes any non-linearity from the model, making it really weak and ill-posed. In the same spirit, activation functions regulate information flow: they amplify relevant signals and attenuate uninformative ones. They affect the gradient flow during backpropagation, which is one of the factors that determine model learning stability and speed. Some functions help with solving issues such as vanishing or exploding gradients. Activation functions (ReLU) are used for speeding up training and reducing computation (fewer operations than sigmoid), Sigmoid: For binary output, tanh clusters outputs around zero, so that it's easier for us to train. In summary, activation functions enable deep learning models to learn complex real-world relationships internally and thus serve their purpose well by efficiently performing classification, detection, and pattern recognition tasks.

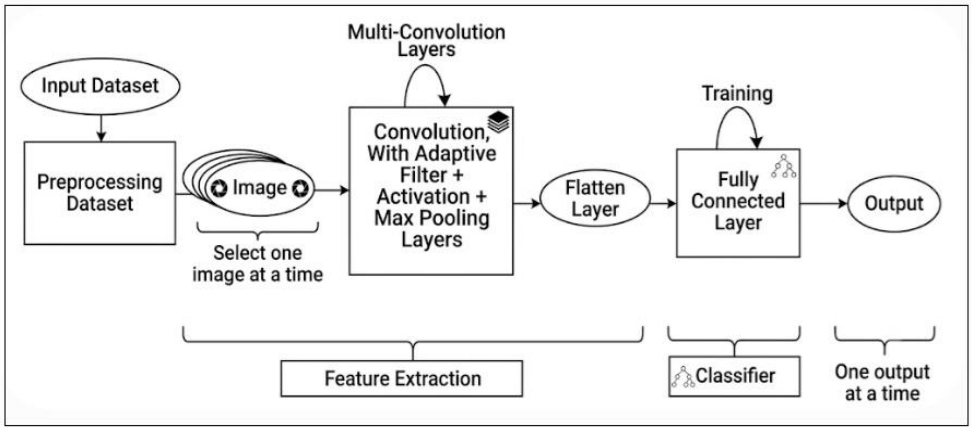

Fig. 1. The Proposed CNN workflow using adaptive filter selection.

A. Dataset Collection

The PCam is a large-scale histopathology dataset consisting of 327,680 color patches (96×96 pixels) extracted from whole-slide images of lymph node tissue [19]. It is intended to detect tumor spread. This binary label indicates the presence of metastatic cancer cells in each patch, making it a relevant and manageable benchmark for machine learning. Based on the CAMELYON16 challenge, this dataset has an even split of training/validation/test sets to ensure reliable experimentation in medical image classification. PCam is favored because, although some metastasis detection tasks are complex, image recognition is practically trivial for the machine, given its ability to train on a single GPU. Data collection is the first step in image classification and can be sourced from public repositories or produced as needed for a specific research purpose. From existing public databases or developed with the same aims of research, without a comprehensive dataset made prior to classification. This study uses primary datasets. The PCam benchmark is original and, at the same time, very challenging. It gained popularity due to its strong fit for medical imaging applications.

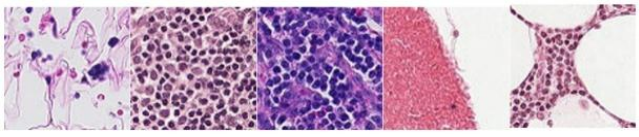

Fig. 2. PatchCamelyon dataset sample images.

Fig. 2 displays sample images from the PatchCamelyon dataset. These images represent the input data used in the preprocessing and feature extraction pipeline described in Algorithmic framework-1.

Algorithmic framework-1: Preprocessing

Step 1: Load PatchCamelyon dataset D_{raw} that includes two attributes (i^{th} image x_i with the corresponding binary i^{th} image label y_i) as in Eq. (1):

$$L_{D_{raw}} = \{(x_i, y_i)\}_{i=1}^{N} \quad (1)$$

where:

$$y_i \in \{0,1\} \text{ is } i^{th} \text{ image label}$$

Such that $y_i =$

$$\begin{cases} 0, & if\ xi\ is\ normal\ tissue \\ 1, & if\ xi\ is\ tumor\ tissue \end{cases} \quad (2)$$

is the number of images

Step 2: Splitting data D_{raw} into three sections {training 70%, validation 15%, and testing 15%} as shown in Eq. (3).

$$D_{raw} = D_{train} \bigcup D_{val} \bigcup D_{test} \quad (3)$$

Step 3: Load a set of Images ($L_{\hat{D}}(x_i)$) from the dataset $\hat{D}$ for each image index x_i shown in Step 1, see Eq. (4):

$$L_{\hat{D}}(i) = \hat{D} = \{(\hat{x}_i, y_i)\}_{i=1}^{N} \quad (4)$$

where $\hat{x}_i$ is the image at the index i. Thus, the loaded dataset becomes:

Step 4: Verify Label Alignment by checking each image-label pair to ensure that every image matches its correct annotation, as in Eq. (5) and (6).

$$A(\hat{x}_i, y_i) = \begin{cases} 1, & if\ the\ image\ matches\ its\ correct\ label \\ 0, & otherwise \end{cases} \quad (5)$$

Keep only correctly aligned pairs as in Eq. (7):

$$D_{aligned} = \{(\hat{x}_i, y_i) \in \hat{D} \mid A(\hat{x}_i, y_i) = 1\}$$

Step 5: Validate Image Dimensions:

Step 5.1: Verify that all images meet the required spatial resolution of (96 × 96 × 3 pixels (RGB) standard.

Step 5.2: Define the dimension function $dim(\hat{x}_i)$ *as in* Eq. (7):

$$dim(\hat{x}_i) = (h_i \times w_i \times c_i), where\ h_i = 96, w_i = 96, and\ c_i = 3 \quad (7)$$

Step 6: Apply Color Normalization using the Macenko method [26]. *//This method is important for Histopathology to reduce variability due to different staining protocols.*

Step 7: Check Class Distribution**:** Show a trustworthy distribution that balances tumor and normal image samples throughout the collection; see Eq. (8) and (9).

$$N0 = \sum_{i=1}^{\hat{D}} I(y_i = 0) \quad (8)$$

$$N1 = \sum_{i=1}^{|\hat{D}|} \mathbb{I}(y_i = 1) \quad (9)$$

where $\mathrm{I}(\cdot)$ is the indicator function, and the class distribution and the probability of each class are defined in Eq. (10) and (11)

$$P(y = 0) = \frac{N_0}{|\hat{D}|} \quad (10)$$

$$P(y = 1) = \frac{N_1}{|\hat{D}|} \quad (11)$$

Step 8: Finalize the Preprocessed Dataset:

Create a complete, verified dataset structure (D_{final}) to train the Adaptive convolutional neural network model.

B. The Proposed Adaptive Convolutional Neural Networks (ACNN) Algorithm

In the CNN architecture, tasks such as preprocessing and layers that are closely related to each other, for example, Conv2D, MaxPooling2D, Flatten, and Dense, are instantiated together. A Conv2D layer applies 2D convolution to extract spatial features, and with the help of MaxPooling2D layers, your model can train faster and is less prone to overfitting, as they reduce the number of pixels while preserving their values. A Flatten layer transforms multidimensional feature maps into a one-dimensional vector to feed to the next Dense (fully connected) layer, which performs classification/regression on these features. Proper preprocessing at every level creates high-quality input data, which helps assist the model and achieve higher performance. As shown in Fig. 3, the CNN architecture for image classification is proposed.

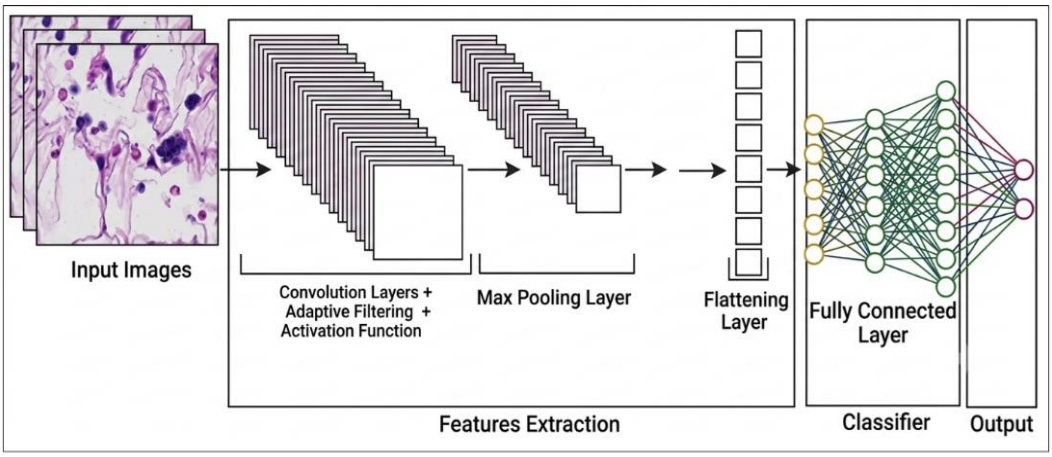

Fig. 3. CNN architecture model for image classification $Conv_{64\times5\times5\times3}$.

Adaptive Convolutional Neural Networks (ACNNs) will adjust their functions and architectures based on the information and task demands, enabling better performance across different tasks and conditions (without pre-training or retraining the network). Algorithmic framework-2 is the proposed framework that follows a pipeline depending on the dataset using ACNN. It starts by selecting images and preprocessing the PatchCamelyon dataset, and then adapts to compute pixel variance-based statistical measures for filtering; see Eq. (1)-(3). For each image, the method selects a convolution size (64 filters, 5×5, or 32 filters, 3×3), applies ReLU activation, and performs max pooling for all operations (Table I). The final classifier consists of a fully connected layer, a flattening layer, and a softmax layer to produce the final outputs.

Algorithmic framework-2: The Proposed ACNN

Step 1: Select a dataset (DS = PatchCamelyon) that includes N images;

Step 2: Read images $I_i \quad \forall i = 1, \dots, N$

Step 3: Define the image size $(Size_{I_{i,}} = n \times n \times 3)$; *// where n=96 using 3-channels (B)*

Step 4: Calculate the variance $(\delta_{I_i}^2)$ of I_i using Eq. (12), (13);

$$\delta_{I_i}^2 = \frac{1}{n \times n \times 3} \sum_{j=1}^{n \times n \times 3} \left(X_j - \mu_{I_i}\right)^2 \quad \forall i = 1, \dots, N \qquad (12)$$

$$\mu_{I_i} = \frac{1}{n \times n \times 3} \sum_{j=1}^{n \times n \times 3} X_j \qquad (13)$$

where:

X_j is the value of the j^{th} pixel in the image.

μ_{I_i} is the mean value of all pixels in the image I_i.

Step 5: Calculate the average variance of all images in DS (δ_{DS}^2) using Eq. (14).

$$\delta_{DS}^2 = \frac{1}{N} \sum_{i=1}^{N} \delta_{I_i}^2 \qquad (14)$$

Step 6: Set Stride =2;

Step 7: for *i = 1 to N // where i is the image index*

Step 7.1: If $(\delta_{I_i}^2 > \delta_{DS}^2)$ then

Apply convolution $Conv_{64\times5\times5\times3}$ using 64 filters, the $MaskSize = 5 \times 5 \times 3$ and the Stride=2;

Else

Apply convolution $Conv_{64\times3\times3\times3}$ using 64 filters, the $MaskSize = 3 \times 3 \times 3$ and the Stride=2;

Step 7.2: Calculate the new size of I_i^{Conv} $\left(NewSize_{I_i^{Conv}}\right)$ after the convolution process using Eq. (15)

$$NewSize_{I_i^{Conv}} = \left\lfloor \frac{\frac{Size_{I_{i,}}}{\sqrt{Size_{I_{i,}}}} - \frac{MaskSize}{\sqrt{Size_{I_{i,}}}}}{Stride} \right\rfloor + 1 \qquad (15)$$

Step 7.3: Update the $Size_{I_{i,}}$, see Eq. (16):

$$Size_{I_{i,}} = \left(NewSize_{I_i^{Conv}}\right)^2 \times 3 \qquad (16)$$

Step 7.4: Apply activation using the ReLU function $f(x)$ using Eq. (17);

$$f(x) = \max(0, x) \qquad (17)$$

Step 7.5: Apply Max Pooling with Stride =2, using Eq. (18);

$$I_{i,max,k}^{Conv} = max_{s=1}^{MaskSize}\ max_{r=1}^{MaskSize}\left(I_{i,s,r}^{Conv}\right),\ \forall k \qquad (18)$$

where

k- is the mask index in the image I_i^{Conv}.

Step 7.6: If flatten is reached with the length f then

Step 7.6.1: Apply fully connected neural networks of dense Layers using Eq. (19).

$$z_j^{[i]} = \sum_{l=1}^{ni-1} W_{j,l}^{[i]}\ a_l^{[i-1]} + b_j^{[i]} \qquad (19)$$

where:

$z_j^{[i]}$ is the linear activation for neuron j in layer i

$b_j^{[i]}$ is the bias for this particular neuron j.

$\sum_{l=1}^{ni-1}$ is the sum of inputs coming from the previous layer i−1.

$W_{j,l}^{[i]}$ is the weight of the connection between neuron l in layer i−1 and neuron j in

$a_l^{[i]}$ is the ReLU activation function

Step 7.6.2: Apply activation function between layers based on ReLU.

Else

Step 7.6.1: Calculate the variance ($\delta^2_{I_{i,max}^{Conv}}$) of $I_{i,max}^{Conv}$ using Eq. (20), (21);

$$\delta^2_{I_{i,max}^{Conv}} = \frac{1}{n \times n \times 3} \sum_{j=1}^{n \times n \times 3} \left(X_j - \mu_{i,max}^{Conv}\right)^2 \quad \forall i = 1, \dots, N \qquad (20)$$

$$\mu_{i,max}^{Conv} = \frac{1}{n \times n \times 3} \sum_{j=1}^{n \times n \times 3} X_j \qquad (21)$$

Step 7.7: Apply Softmax to build the classifier using Eq. (22);

$$Softmax(z)_i = \frac{e^{z_i}}{\sum_{j=1}^{f} e^{z_j}} \qquad (22)$$

where:

$(z)_i$ is the vector of i^{th} class of raw output from the neural network

e: Euler's number, the base of the natural logarithm = 2.718.

Step 8: End of For i

Step 9: End.

TABLE I. THE RANGE OF PARAMETERS USED IN THE PROPOSED MODEL

Parameters	Value/Condition
Batch size	128
Learning rate	0.001
Epochs	10
Filter size	5×5 or 3×3
Number of filters	64 or 32, based on adaptive condition (see ACNN Algorithm)
Loss function	Categorical Cross-Entropy
Optimizer	Adam
Number of convolution blocks	3
Convolution Block Contains	Conv2D + Activation function + Pooling
Activation function	ReLU
Pooling function	Max Pooling 2D 2 × 2
Hidden layers dimension	Dense1 (Size=128) + Dense2 (Size=64)
Output Layer	Softmax (Size=2)

A key aspect of our model design is implementing adaptive filtering that adjusts the filter size and parameters on the fly based on the input data's statistical properties. This approach shows great potential in aiding the network to learn more complex spatial relations and hierarchical features, which are important for improving accuracy in both feature extraction and classification tasks. Adaptive filtering is constructive in CNNs, as it changes how features are extracted based on input variability, as well as how local and global features are represented. In addition, it provides a spatial representation while reducing computational redundancy; thus, it forms the basis of sophisticated convolutional network architectures for applications such as medical imaging and object detection.

IV. RESULTS AND DISCUSSION

In this section, we provide a detailed analysis and discussion of the experimental results for image classification using the standard Convolutional Neural Network (CNN) model and the novel Adaptive Convolutional Neural Network (ACNN). Its main purpose is to study the ability of adaptive filtering methods to enhance classification performance. This section presents evaluation metrics, comparative experimental results with ROC analysis and confusion matrix interpretation, and a complete performance comparison.

A. Evaluation Metrics

To evaluate the proposed models' classification performance, we use several widely used metrics.

- True Positives (TP): Correctly predicted positive samples.
- True Negatives (TN): Correctly predicted negative samples.
- False Positives (FP): Negative samples incorrectly classified as positive.
- False Negatives (FN): Positive samples incorrectly classified as negative.

1) Accuracy: Accuracy measures the overall correctness of the model predictions [27] and is defined in Eq. (23):

$$\text{Accuracy} = \frac{TP+TN}{TP+TN+FP+FN} \tag{23}$$

This metric represents the ratio of correctly classified instances to the total number of predictions.

2) Precision: Precision evaluates the reliability of positive predictions made by the model [27], see Eq. (24):

$$\text{Precision} = \frac{TP}{TP+FP} \tag{24}$$

It is particularly important in scenarios where false positives carry significant consequences.

3) Recall: Recall (Sensitivity) measures the ability of the model to identify all actual positive instances [27], as in Eq. (25):

$$\text{Recall} = \frac{TP}{TP+FN} \tag{25}$$

High recall is crucial in medical applications, where missing positive cases can have severe consequences.

4) F1-Score: The F1-score is the harmonic mean of precision and recall [28], see Eq. (26):

$$\text{F1-Score} = 2 \times \frac{\text{Precision} \times \text{Recall}}{\text{Precision} + \text{Recall}} \tag{26}$$

It is particularly useful for imbalanced datasets.

5) Mean Squared Error (MSE): Mean Squared Error quantifies the average squared difference between predicted and actual values [27]:

Lower MSE values indicate better predictive performance and reduced error rates, see Eq. (27).

$$\text{MSE} = \frac{1}{n}\sum_{i=1}^{n} (y_i - \hat{y}_i)^2 \tag{27}$$

6) Confusion matrix: The confusion matrix provides a detailed breakdown of prediction outcomes, categorizing predictions into TP, TN, FP, and FN [28], as illustrated in Table II.

TABLE II. CONFUSION MATRIX

Total population = P + N		Predicted Condition	
		Positive	Negative
Actual Condition	Positive	True positive (TP)	False negative (FN)
	Negative	False positive (FP)	True negative (TN)

B. Performance Comparison of CNN Models

Case 1: Adaptive Model (32 or 16 Filters, 3×3)

The performance of the traditional CNN model with 32 filters and a 3×3 kernel over 10 training epochs is shown in Fig. 4. There are four main metrics monitored by the system: training accuracy, validation accuracy, training loss, and validation loss. They measure how well the model learns and generalizes to out-of-distribution data.

The training process shows continuous improvement, as shown in Fig. 4, with training accuracy reaching 94.66% by the final epoch. Training loss decreases continuously, reaching 14.20. Optimization is working, and predictions on the training data have improved. Validation accuracy increases, reaching a maximum of ~82.44%, indicating that the model generalizes relatively well to new data, though it remains lower than the training accuracy. The validation loss starts low and stays there through the middle epochs, then grows slightly and finally plateaus around 58.71, with only minor changes in generalization ability (less than one epoch). The gap between the training and validation metrics indicates typical CNN overfitting during training. This illustrates the model's effectiveness at learning relevant features, as training loss decreases and validation accuracy continues to increase.

Fig. 5 shows the training results for the adaptive CNN model, which uses 32 and 16 filters with a 3×3 kernel size over ten training epochs. The graph tracks training and validation accuracy and loss to evaluate how effectively the adaptive configuration learns and generalizes.

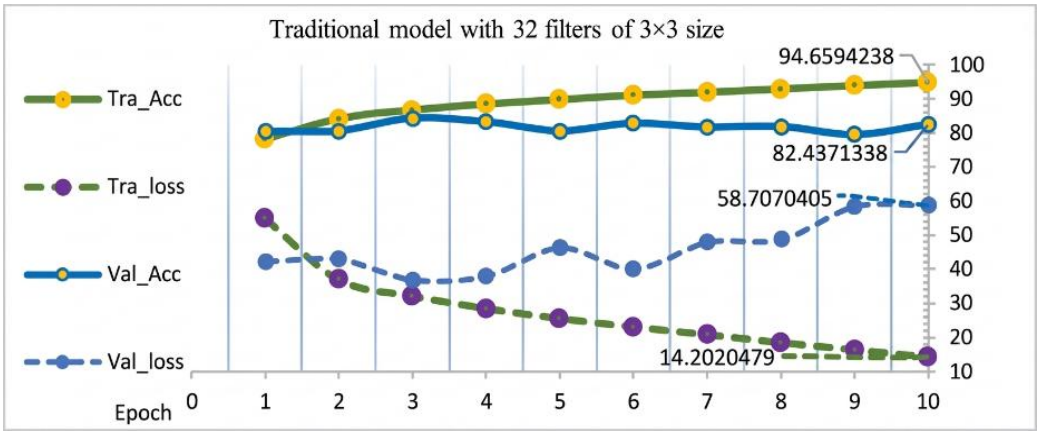

Fig. 4. Results for the traditional model with 32 filters of size 3×3.

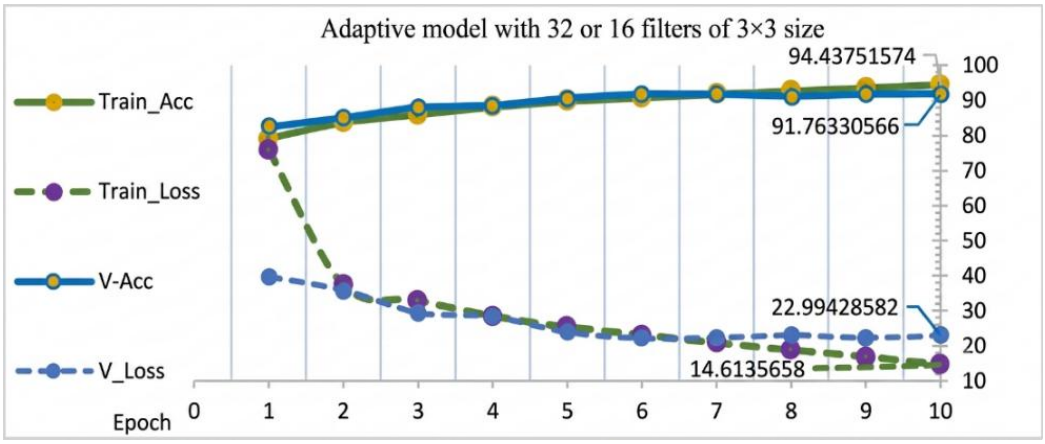

Fig. 5. Results for the adaptive model with 32 or 16 filters of size 3 ×3.

In Fig. 5, we observe a steady increase in model performance throughout training. Training accuracy increases steadily to about 94.44% by the last epoch, while training loss decreases rapidly and stabilizes around 14.61, indicating little error when the model is well trained. In addition, classic models generalize poorly, showing the largest increase in validation accuracy throughout training, to 91.76%. Validation loss decreases steadily to 22.99, with only slight variation across epochs. This improvement brings the adaptive model closer to the ideal case, where training and validation accuracies are close enough that generalization should be well under control. Stability is achieved because accuracy increases while loss decreases.

Case 2: Adaptive Model (64 or 32 Filters, 3×3)

Fig. 6 shows the training behavior of the traditional CNN model with 64 filters and a 3×3 kernel over 10 epochs. The curves show the progression of training and validation accuracy and loss, helping evaluate how well the model learns and generalizes.

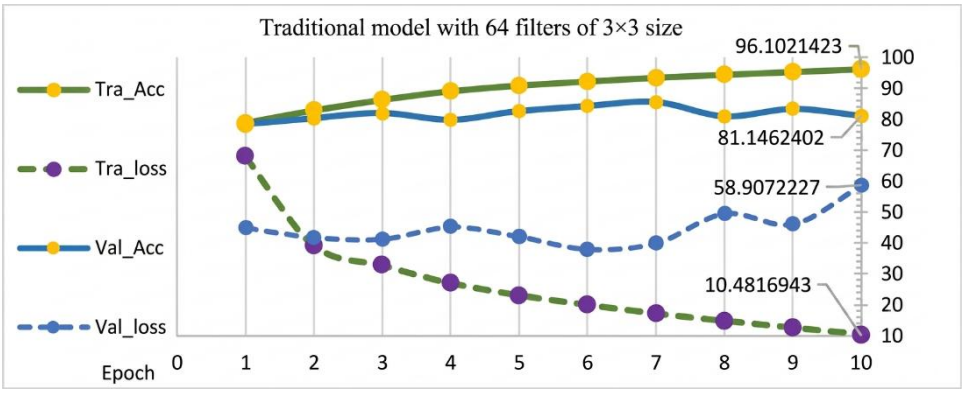

Fig. 6. Results for the traditional model with 64 filters of 3×3 size.

As shown in Fig. 6, the model continues to learn for most of the training period. Training accuracy continues to increase, reaching 96.10% at epoch = 175, while the training loss decreases to around 10.48, indicating that the model has been successfully optimized with fewer binary prediction errors. Validation accuracy reaches around 81.15%, with little change in later epochs. First, the validation loss decreases from its starting value, then increases, ending at 58.91, suggesting unstable generalization. The training and validation metrics differ significantly, indicating that the model has overfit the data. This suggests your model is learning important features from the dataset, as shown by the increase in accuracy and decrease in training loss.

The adaptive CNN model's performance on the training data is shown in Fig. 7, with 64 and 32 filters and a 3×3 kernel over 10 training periods. The plots will show how well the adaptive architecture learns (and generalizes) over time, as a function of training and validation accuracy, losses, and so forth.

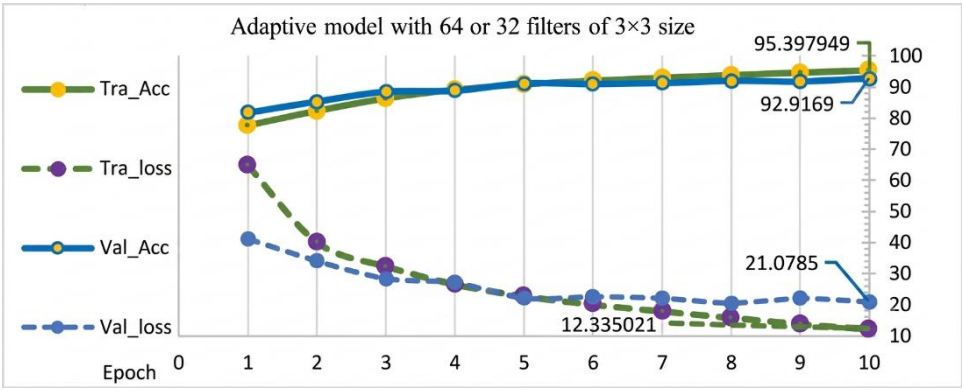

Fig. 7. Results for the adaptive model with 64 or 32 filters of size 3 × 3 size.

Fig. 7 shows that the learning process remains stable throughout the entire training period. Training accuracy increases, reaching about 95.40% at the end of training, while training loss drops to about 12.34, indicating that the model optimized the training data with fewer errors. Validation accuracy shows a similar upward trend, reaching about 92.92%, indicating strong generalization and close alignment with training performance. Validation loss decreases steadily, stabilizing at about 21.08, with only small variations during the middle training periods. The adaptive model achieves strong predictive performance because training and validation results stay close, as shown by the small difference between them. The adaptive configuration outperforms traditional configurations by improving accuracy while reducing loss.

C. Validation Accuracy Comparison

Fig. 8 presents a comparison of the validation accuracy between the traditional and adaptive CNN models over 10 training epochs. The comparison highlights the difference in performance and generalization capability between the two architectures during the validation phase.

Across all epochs (Fig. 8), the adaptive model's validation accuracy is higher than the traditional model's. For example, the adaptive model starts at 81.86% (compared to 78.31%) and steadily improves throughout training, whereas the traditional model learns more slowly. By the end of the last epoch, the adaptive model reaches around 92.92%, while the traditional model reaches ~81.15%, indicating a significant performance gap. The validation accuracies of the traditional (dotted) and adaptive (solid) models over 10 epochs. The traditional model's validation accuracy fluctuates significantly in the early epochs, whereas the adaptive model's steadily increases. This consistent performance indicates the adaptive architecture's ability to extract relevant features and generalize to unseen data.

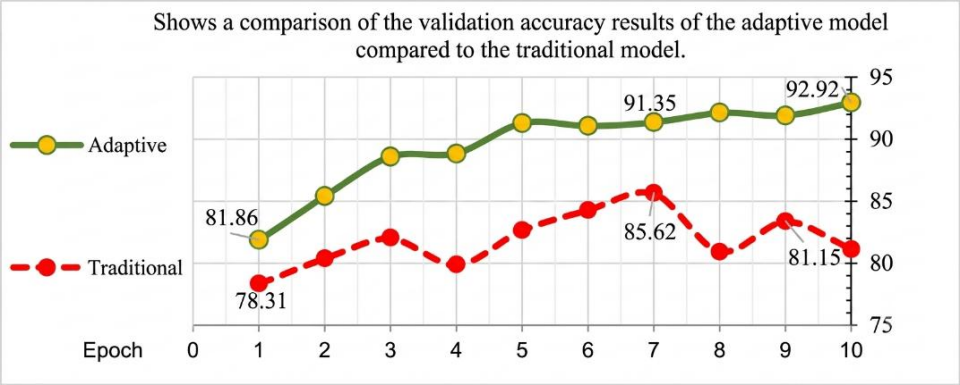

Fig. 8. Comparison of validation accuracy results for traditional models.

Overall, the comparison shows that the adaptive model achieves substantial improvements in validation performance and learning stability compared with the traditional model.

D. Validation Loss Comparison

As shown in Fig. 9, the adaptive model has produced lower validation loss across all epochs. By the end of the epoch, the adaptive CNN reached a validation loss of 0.2108, whereas the traditional model reached 0.5891 (overfitting).

The validation loss results clearly demonstrate that the adaptive model consistently outperforms the traditional model across all epochs. At the first epoch, the adaptive model starts with a validation loss of approximately 40, while the traditional model records about 43, indicating an initial improvement of 6.98%. As training progresses, the adaptive model steadily reduces its validation loss to 21.08 at epoch 10, while the traditional model's loss increases to 58.91. Using the final epoch values, the adaptive model achieves a 64.2% lower validation loss than the traditional model. Furthermore, comparing the adaptive model's own performance from the first to the last epoch, the validation loss decreases from approximately 40 to 21.08, representing a 47.3% improvement. These results indicate that the adaptive approach converges more effectively and remains more stable throughout training, leading to substantially better generalization than the traditional model.

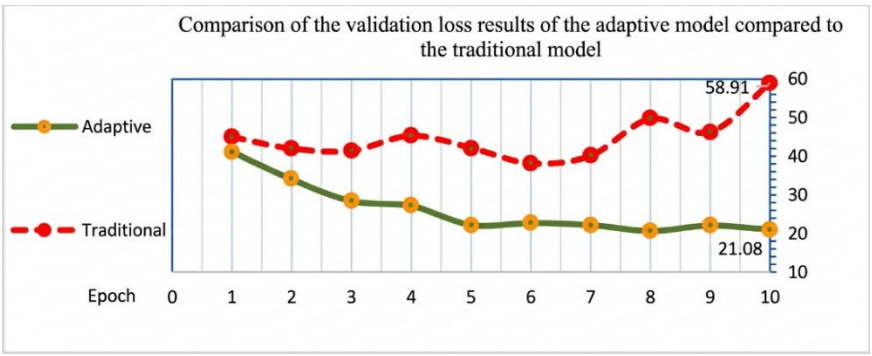

Fig. 9. Comparison of validation loss across traditional CNN models.

E. ROC Curve Analysis

ROC analysis further validated the adaptive model's superiority. The traditional CNN achieved an AUC of 0.86, while the adaptive CNN achieved an impressive 0.97 (Fig. 10 and 11).

A higher AUC indicates the adaptive model's enhanced ability to distinguish malignant from benign samples across all classification thresholds.

The ROC curve analysis shows that the adaptive model delivers substantially better classification performance than the traditional model. The traditional model achieved an Area Under the Curve (AUC) of 0.86, indicating good discrimination between classes, whereas the adaptive model achieved an AUC of 0.97, indicating excellent classification performance. The increase in AUC from 0.86 to 0.97 corresponds to an improvement of approximately 12.8%. In addition, the adaptive model's ROC curve is consistently closer to the upper-left corner, indicating a higher True Positive Rate (TPR) at lower False Positive Rates (FPR). This means the adaptive model can correctly identify more positive cases while producing fewer false alarms than the traditional model. At low FPR values, the adaptive model rapidly reaches TPR values above 0.85–0.90, whereas the traditional model requires considerably higher FPR values to attain comparable detection rates. When these ROC results are considered together with the validation loss analysis, the superiority of the adaptive model becomes even clearer. The adaptive model reduced the validation loss from approximately 40.0 to 21.08, while the traditional model ended with a validation loss of 58.91. Relative to the traditional model, the adaptive model achieved a 64.2% lower validation loss. Overall, the adaptive model demonstrates both higher predictive accuracy and better generalization capability. The 12.8% improvement in AUC and 64.2% reduction in validation loss confirm that the adaptive approach learns more effective decision boundaries, achieves su-

perior class discrimination, and maintains greater stability during training compared with the traditional model. These results indicate that the adaptive model is significantly more reliable and robust for practical deployment.

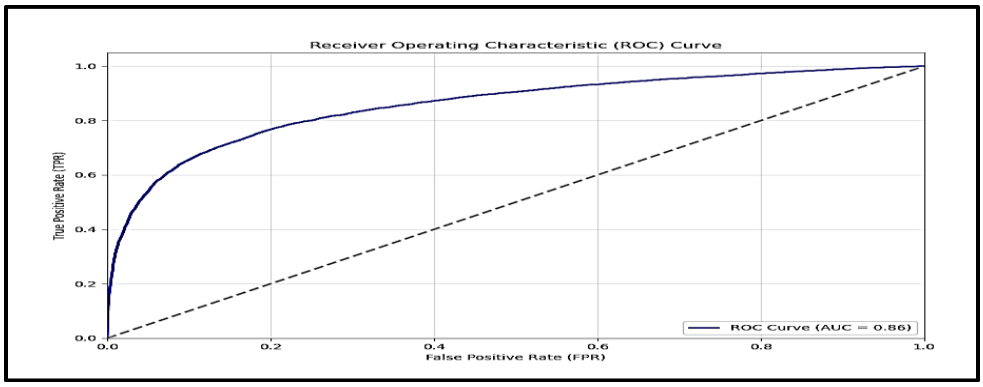

Fig. 10. ROC traditional model.

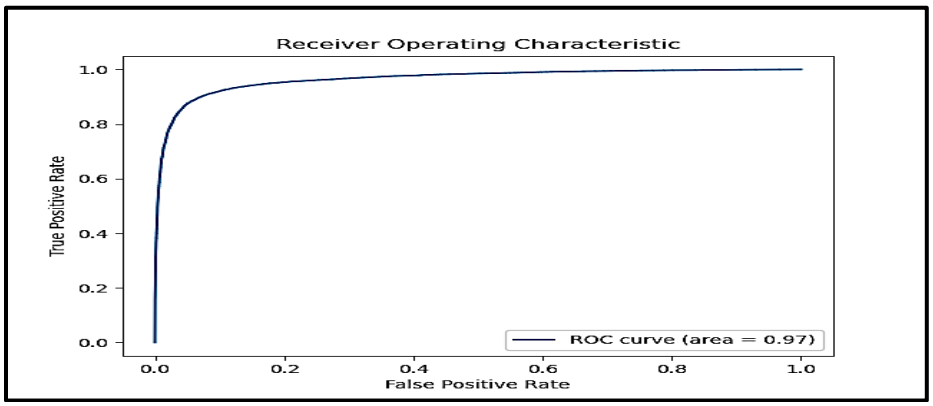

Fig. 11. ROC adaptive model.

F. Confusion Matrix Analysis

The confusion matrix of the old model (Fig.12) contains many false negatives (6,886) and false positives (1,012), making our recall on that not great.

On the contrary, as illustrated in Fig.13, using the adaptive model yields only 737 false positives and 2,429 false negatives, resulting in a significant reduction in misclassification and higher precision and recall. This adaptive filtering strategy proves to be a good choice for learning these potentially complex histopathological patterns.

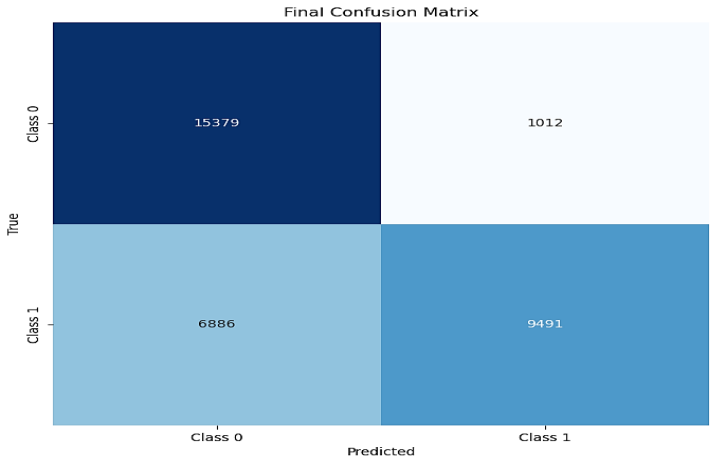

Fig. 12. Confusion matrix of the traditional filtering model using 64 × 3 × 3 filters.

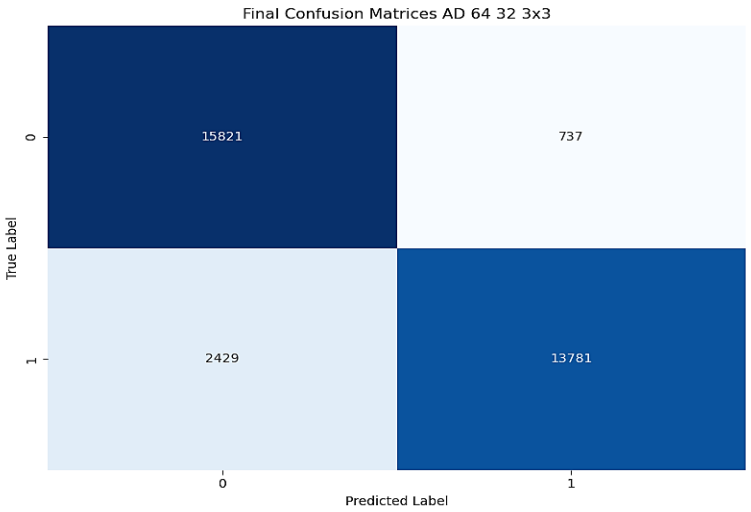

Fig. 13. Confusion matrix for the adaptive CNN model using 64 or 32 filters with a 3 × 3 kernel size.

The confusion matrix results indicate that the adaptive CNN model (64 or 32 filters, 3 × 3 kernel) performs substantially better than the traditional filtering model (64 × 3 × 3 filters). The traditional model correctly classified 15,379 Class 0 samples and 9,491 Class 1 samples, while misclassifying 1,012 false positives and 6,886 false negatives. In contrast, the adaptive model correctly classified 15,821 Class 0 samples and 13,781 Class 1 samples, with only 737 false positives and 2,429 false negatives. Based on these values, overall classification accuracy increased from 75.9% for the traditional model to 90.4% for the adaptive model, an improvement of approximately 19.1%. More importantly, false negatives fell from 6,886 to 2,429, a 64.7% reduction in missed detections, while false positives decreased by 27.2% (from 1,012 to 737). The true positive rate (recall for Class 1) improved from 57.9% to 85.0%, yielding a 46.8% improvement in the model's ability to correctly identify positive samples. These results demonstrate that the adaptive CNN provides significantly better classification performance, achieving higher accuracy, greater sensitivity, and fewer misclassifications than the traditional filtering approach, thereby offering a more robust and reliable model for practical applications.

G. Summary of Results

The following Table summarizes the comparison of results between traditional and adaptive models; see Table III:

TABLE III. A COMPARISON OF THE PERFORMANCE METRICS BETWEEN THE TRADITIONAL AND ADAPTIVE (64 OR 32 FILTERS, 3×3) MODELS

Matrices	Traditional model 64 × 3 × 3.	Adaptive approach using 64 × 3 × 3. or 32 × 3 × 3	Superiority
Accuracy	0.795	0.929	+13.4 %
Precision	0.904	0.949	+4.5 %
Recall	0.579	0.850	+27.1 %
F1-Score	0.708	0.896	+18.8 %
AUC	0.86	0.97	+11 %
(MSE)	0.240	0.096	-14.4 %

Table III shows that the adaptive CNN outperforms the traditional CNN across all evaluation metrics, demonstrating superior generalization, robustness, and reliability for tumor classification. The adaptive approach clearly outperforms the traditional model, improving accuracy by 13.4%, precision by 4.5%, recall by 27.1%, F1-score by 18.8%, and AUC by 11.0%, for an average performance gain of about 15% across the classification metrics. Moreover, MSE decreased from 0.240 to 0.096, a 60% reduction in prediction error, further confirming the adaptive approach's improved accuracy, reliability, and robustness.

H. Comparison with the Previous Work

We evaluated the performance of our adaptive convolutional neural network by comparing our system with multiple existing works that used the PatchCamelyon PCam dataset to classify histopathological images. These studies used deep learning approaches including rotation-equivariant convolutional networks, semi-supervised learning frameworks, weakly supervised transfer learning methods, DenseNet-based architectures, segmentation-assisted CNN models, and attention-based ensemble networks. The researchers developed various architectural designs and training methods to improve the system's ability to identify tumors in lymph node histopathology images. Table IV presents the complete performance metrics of the studies, which include accuracy, area under the ROC curve AUC precision, recall, and F1 score, together with the results obtained by the proposed model. The comparison results clarify how the proposed method performs relative to competitors and show that it achieves high classification accuracy on the PCam benchmark dataset.

TABLE IV. PERFORMANCE COMPARISON OF THE PROPOSED ADAPTIVE CNN MODEL WITH PREVIOUS STUDIES USING THE PATCHCAMELYON (PCAM) DATASET

#	Study	Accuracy	AUC	F1-Score
1	Teh et al. [21]	0.904	—	—
2	Jin et al. [23]	0.841	0.924	—
3	Teh & Taylor [24]	0.859	—	—
4	De Melo et al. [29]	0.8180	—	0.818
5	Shrestha et al. [30]	—	—	0.790
6	Gisslén & Svärdkrona. [31]	—	0.942	—
7	**Proposed Model**	**0.929**	**0.970**	**0.896**

Table IV compares results for the proposed model with those of previous studies. The proposed model clearly improves on previous work across all reported metrics. Our model achieves 92.9% accuracy, surpassing De Melo et al. (81.8% by +13.6%), Teh & Taylor (85.97% by +8.1%), and Jin et al. Teh et al. (84.1%) by +10.5% and (90.47%) over the strongest baseline, pushing SOTA up by +2.7%. Moreover, Table IV shows F1-score performance around +9.5% over Shrestha et al. (0.818) (+13.4% above 0.79), indicating an improved balance between precision and recall. For AUC, the suggested score of 0.97 surpasses Gisslén & Svärdkrona (0.9425) by +2.9% and Jin et al. (0.924) by around +5.0%, showing better discriminative power. Overall, for each comparable metric of predictive performance and robustness, the proposed model consistently outperforms prior approaches, with especially strong absolute gains in F1-score (4.5%) and a 3% increase in accuracy.

V. CONCLUSION

This shows that an Adaptive CNN can classify lymph node tumors. The results support the conclusion that adaptive filtering improves both feature extraction and classification accuracy compared with traditional CNN architectures. All 9 evaluation metrics confirm that the adaptive model outperformed standard CNNs, achieving higher accuracy, precision, recall, F1-score, and AUC, while yielding lower Mean Squared Error (MSE).

Dynamic filters, which adapt to variable input imagery, as seen in the best-performing adaptive model with 64 or 32 3×3 filters, essentially outperform all static methods on the match set test. Thus, images with higher variability have more filters to learn complex tumor structures, while images with lower variability have fewer filters (to prevent overfitting and reduce computation). This dynamic paradigm facilitates more effective feature extraction and improves generalization.

Unlike 5×5 or larger receptive fields (designed to capture global features), a 3×3 filter maintains local spatial information, enables hierarchical feature extraction, and aids edge detection when separating the tumor from healthy neighboring tissues. The adaptive scheme provides a trade-off between rich features and computational efficiency, resulting in lower validation loss and robustness.

Experimental results provide unequivocal support for these advantages. With 0.929 vs 0.811 as the validation accuracy and 0.210 vs 0.589 as the validation loss, The AUC increased from 0.86 to make it an impressive improvement of up to almost one in a manner of where most people do everything right with details precision, recall and F1 - score improved so significantly: These promising results underscore the importance of adaptivity in improving neural network performance and make a case for including these techniques into future image classification architectures.

***Abstract*—Distributed Denial of Service (DDoS) attacks are still a significant issue facing cybersecurity, flooding infrastructure with large packet torrents and disrupting networks across the globe. To mitigate against such volumetric attacks, the best approach is to intercept the threat long before any attack gets underway. However, conventional defense systems react primarily after the volume of attack peaks; thus, they leave critical assets vulnerable to disruption. To avoid this, it is essential to detect and analyze precursor signals within the attack preparation period. This work introduces a framework for generating an early warning signal based on computed scores and set thresholds to categorize network traffic alerts into low-, medium-, and high-impact alerts. In this study, a differential equation model is applied to the CICDDoS2019 dataset to generate these alert scores. The goal is to make a prediction well before the attack blows up in size and before the onset of the attack. The results exhibit an impressive capacity for proactive detection, from reactive mitigation to predictive defense. This framework was able to predict the intrusion with low, medium, and high alerts issued 46 minutes and 53 seconds, 46 minutes and 49 seconds, and 46 minutes and 55 seconds before the attack peak. The proposed framework obtained a balanced accuracy ranging from 99.43% to 99.70% for these three alert classifications.**

Keywords*—DDoS; early warning signals; ordinary differential equation; residual; low threshold; medium threshold; high threshold

I. Introduction

The rapid expansion of the Internet has introduced significant benefits to modern society and urban development, yet it has also created a complex network environment that is highly vulnerable to security threats, most notably Distributed Denial of Service (DDoS) attacks [9][10]. As network traffic increases sharply with the proliferation of IoT devices, traditional security measures often struggle with scalability and adaptability [7][8]. While paradigms like Software-Defined Networking (SDN) and Edge Computing offer improved resource management, they also introduce risks, such as centralised controllers becoming targets for malicious activity, potentially leading to single points of failure [4]. The evolution of DDoS attacks represents an ongoing challenge, with modern attacks reaching terabit-per-second traffic volumes, such as 1.7 Tb/s. Attacks of this magnitude can rapidly disrupt network services and pose serious risks to critical infrastructures, including healthcare systems and smart-city networks [4][9][10][12]. In this landscape, purely reactive defence is often insufficient; by the time anomaly-based detection flags an active flood, irreversible damage such as downtime or service degradation could have already occurred [8]. Consequently, there is a critical need for DDoS attack prediction, which identifies evidence of attack preparation before launch, providing network administrators with more time to implement countermeasures [1].

Early warning signals (EWS) for DDoS attacks can be found in precursor phases, and researchers distinguish these efforts across a 24-hour horizon, separating short-term predictions (seconds to hours) from long-term forecasts (days to months) [1]. Identifying these signals requires moving beyond simple signature-based methods to more intelligent, adaptive mechanisms. Recent advancements in machine learning (ML) and deep learning (DL) have opened new avenues for this purpose. Long Short-Term Memory (LSTM) networks are particularly effective for forecasting surges in daily attack activity by learning long-term temporal patterns in evolving traffic data [12][4]. The CoWatch framework leverages LSTM for collaborative prediction across distributed SDN controllers, utilising a Distributed Publish/Subscribe (DPS) mechanism to synchronise alerts efficiently [4]. Echo State Networks (ESN), integrated with nature-inspired algorithms like African Buffalo Optimisation (ABO-DT), facilitate detection and prediction in realistic multidimensional IoT environments [9]. Ensemble Online Machine Learning (OML) models, incorporating classifiers like BernoulliNB and SGD, enhance adaptability to concept drift and are resilient against zero-day and low-rate attacks [8]. Hybrid models, such as the CNN-Bidirectional LSTM for smart healthcare and Pyramid Depthwise Separable Convolution (PyConv) with Variational Gaussian Mixture (VGM) models, improve feature extraction and accuracy in cyber-physical systems [3][5]. Specialised implementations like the SS-LSACNN model address the unique resource constraints of Wireless Sensor Networks (WSN) [6].

Furthermore, classification frameworks optimised with Recursive Feature Elimination (RFE) and Grid Search on Random Forest algorithms have achieved near-perfect

*Corresponding author.

accuracy (99.99%) in identifying attack patterns [11]. Strategic deployment of these detection models at the network edge is a promising solution to minimise latency and computational overhead on centralised controllers [10]. While detection and mitigation strategies are becoming highly sophisticated, researchers emphasise that the field of prevention and forward-looking early warning remains an essential area for future development to protect against the spreading of malicious traffic [7].

II. Literature Survey

The survey by de Neira A. B. et al [1] provided a comprehensive classification of the state-of-the-art in DDoS attack prediction, categorising 27 shortlisted studies by time, architecture, methodology, and data type. It establishes a 24-hour frontier to distinguish between short-term predictions (made seconds to hours in advance) and long-term predictions (made days to months in advance). The work of He, J. et al [2] used a Pyramid Depthwise Separable Convolutional neural network intrusion detection system (PyDSC-IDS) model on NSL-KDD, UNSW-NB15, and CICIDS2017 datasets, achieving 81.63%, 80.63%, and 97.60% accuracy, respectively. The model effectively extracts multi-scale features and improves detection accuracy, especially for minority attack classes, compared to standard CNNs. Despite the reductions provided by DSC, the parameters and FLOPs are still considered "excessive" compared to some simpler models.

Zhou H. et al. [3] used Maximum Likelihood Estimation (MLE) as a feature selection method with the CoWatch Long Short-Term Memory (LSTM) model on the CIC-DDoS2019 dataset, which achieved a 3.10% false alarm rate in prediction and a 3.01% false alarm rate in detection. The CoWatch model allows distributed SDN controllers to collaboratively predict DDoS attacks before performance degradation occurs. The evaluation did not incorporate communication latency, as it varies significantly under different network conditions. Sharma et al. [4] proposed an efficient, lightweight hybrid CNN-Bidirectional LSTM model for smart healthcare networks. This model contributes by extracting temporal and spatial features from traffic flows to classify them as benign or malicious, specifically targeting DoS attacks in cyber-physical systems (CPS), and achieved 99% accuracy, 95.8% precision, with 98.9% detection rate on the BoT-IoT dataset.

V. K. Singh et al. [5] focused on WSN security using Soft Swish Linear Scaling-centred Adam Convolutional Neural Network (SS-LSACNN) for classification and Two's Complement Shift Reverse (TCSLR) for data prevention. It integrates fuzzy logic and neural networks to reduce energy usage and discover attacks rapidly. The survey by H. Wang and Y. Li [6] provided a systematic review of SDN architecture and the evolution of DDoS detection within this environment. It categorizes detection techniques into statistical analysis (entropy-based), machine learning, and deep learning, noting that machine learning-based methods have garnered more attention due to their accuracy. The review also points out that the field of DDoS prevention remains largely unexplored compared to detection and mitigation.

The work of A. A. Alashhab et al [7] utilised an Ensemble Online Machine Learning (OML) model with Chi-squared (Chi^2) as a feature selection method, which selected 14 features, on a Custom/proprietary dataset containing 1,45,614 instances and 22 initial features. The study reported 99.26% accuracy with 99.10% precision. The system effectively blocked malicious traffic with minimal impact on legitimate users. But it needs to be validated with real-world network topologies. The study by Rao G. S. et al. [8] proposed an Echo State Network integrated with African Buffalo Optimization and a Decision Tree. The dataset used is the DARPA dataset containing 12,478 instances and 45 features. The approach achieved an attack detection rate of 98.62% and a precision of 98.27%. The combination of African Buffalo Optimization and Decision Tree-based feature selection and Echo State Network-based classification has demonstrated strong detection performance with reduced computational requirements. However, this study was evaluated in a simulated environment without real-world hardware validation. In addition, the use of dataset-specific experimental settings and evaluation measures may limit direct comparison with other DDoS detection approaches.

The work of H. M. Belachew et al. [9] used the SDN-Edge-IoT model with Random Forest Feature Importance (RFFI) on CICIDS2017 and Edge-IIoTset datasets with 10 selected features. They achieved an accuracy of 99.9987% and achieved near real-time DDoS detection and effective mitigation by enforcing high-priority flow rules through the SDN controller. The gap in this work was limited to a single edge server and does not account for multiple edge servers to handle larger IoT traffic volumes.

Sawah M. S. et al. [10] utilised Recursive Feature Elimination (RFE) on Random Forest (RF), Naïve Bayes (NB), K-Nearest Neighbours (KNN), Linear Discriminant Analysis (LDA), and Support Vector Machine (SVM). The dataset used for the experimentation was the DDoS-SDN dataset, having 1,04,345 rows and 23 features. The study demonstrated that feature engineering and parameter tuning are critical for high-accuracy cybersecurity applications. However, further evaluation is needed to assess its ability to detect zero-day attacks and generalise to diverse and evolving attack patterns that are not represented in the training dataset.

The study by Yeen K. M. et al. [11] proposed a CRISP-DM (Cross Industry Standard Process for Data Mining) model on the COVID-19 period (2019–2020) dataset of 1,92,525 samples and 9 features. It predicted spikes in attack counts and throughput with reasonable accuracy, though predicted spike magnitudes were often up to 50% lower than actual values. But the model exhibited relatively high error rates and struggled to detect spikes in attack duration. In the work by J. F. Canola Garcia and G. E. T. Blandon [13], a functional Intrusion Detection and Prevention System (IDS/IPS) named Dique is proposed. It uses a Multi-layered Deep Feed Forward Neural Network (DFNN) model with 22 features on the CICDDoS2019 dataset to classify the incoming web server traffic into either malicious or benign categories to mitigate probable DDoS attacks. An accuracy of 99.94% is obtained, but some attack types (SYN flood, TCP flood) were misclassified due to feature overlap with benign traffic.

The work by Y. Al-Dunainawi et al. [14] contributed a one-dimensional convolutional neural network (1D-CNN) with an automatic feature extraction method, achieving 99% accuracy with 15 features on a Simulated SDN traffic dataset. However, simulated environments and datasets may not be able to fully capture the complexities and dynamics of real-world networks. Shieh, C. S. et al. [15] proposed the CNN-Geo framework, which uses a geometrical metric calculation module to identify unknown attack patterns. It highlights the need for an IDS that can promptly notify technicians of unfamiliar traffic at the onset of an attack. Y. Wang et al. [16], The research used a binary convolutional neural network (Binary CNN) with direct selection of features based on the fixed-length properties of the IPv6 protocol on the CICDDoS2019 dataset. The work contributed to a lightweight monitoring mechanism (BCDM) that utilizes a two-dimensional traffic matrix to aggregate packet-level data. It used binarized convolutional filters and hierarchical pooling to create a model with high sensitivity and minimal resource consumption in IPv6 networks. It is limited to a single 100x82 traffic matrix, which may miss longer-term sequence dependencies.

E.-U.-H. Qazi et al. [17] contributed a deep learning-based network Intrusion Detection System (DL-NIDS-ZTN) explicitly designed for zero-touch networks. It utilized a 5-layer 1-D convolutional neural network to autonomously learn features and identify malicious behaviours with a high accuracy of 99.80% on CIC-IDS2018. The study by S. Dasari and R. Kaluri [18] proposed a hierarchical machine learning framework that uses the LASSO approach for feature selection and hyperparameter-optimized models to classify intrusions. It determines the LGBM algorithm as particularly effective, achieving 99.77% accuracy, 100% precision, and recall on the CIC-IDS 2017 dataset. M. Rashid Minhas et al. [19] proposed a multi-pronged fog-level system using Zero-Shot Learning (ZSL) and Contractive Autoencoders (CAE) with autonomously extracted meaningful features. The fog layer brings intelligence closer to end devices, providing low-latency and real-time defence against zero-day threats. It achieved 99.72% accuracy on CIC-IDS2017 and 99.96% accuracy on the CIC-DDoS2019 dataset. The work by Reed, A. et al [20] addressed the risk of application-layer Slow DoS attacks in IoT networks. The study introduced a flexible Single-Attribute Intrusion Detection System, SA-IDS, that used the delta time (packet Inter-Arrival Time) attribute to differentiate between malicious traffic and legitimate slow-node activity. The framework involves the addition of a separate Guardian Node to support the border routers, which, while efficient, still represents an extra hardware requirement.

Vashistha, A. et al. [21] proposed a multi-staged AI-driven Intrusion Prevention System (IPS) deploying mathematical foundations to recognize patterns and anomalies missed by security systems. The framework combined a supervised learning approach with a reinforcement learning approach to analyse the network traffic and achieved an accuracy of 94.77%; while effective, the reward-based system carries a risk that unintended effects of an action can result in negative rewards, potentially affecting the learning process in highly volatile environments. The work by M. Srinivasan and N. C. Senthilkumar [22] contributed a novel hybridized Intrusion Detection and Prevention System (IDPS) for Industrial Internet of Things (IIoT) environments. The integration uses deep learning for detecting threats and Blockchain-assisted Reinforcement Learning (RL) for prevention. With 96.8% detection accuracy, the model scales well, but the traditional cloud-based components of the system still face data overload when dealing with the rapid growth of IIoT devices.

III. METHODOLOGY

The detailed methodology is depicted using Fig. 1 The initial step is data gathering, which involves collecting a dataset *D* that contains both *BENIGN* and *DDoS* instances. From the dataset, all the features that are non-time-based are dropped. So, only the time-based features and the label column from the complete dataset are retained. The time-based features are important in detecting and mitigating attacks; these features help in identifying patterns that indicate the initiation of the attack over a period of time.

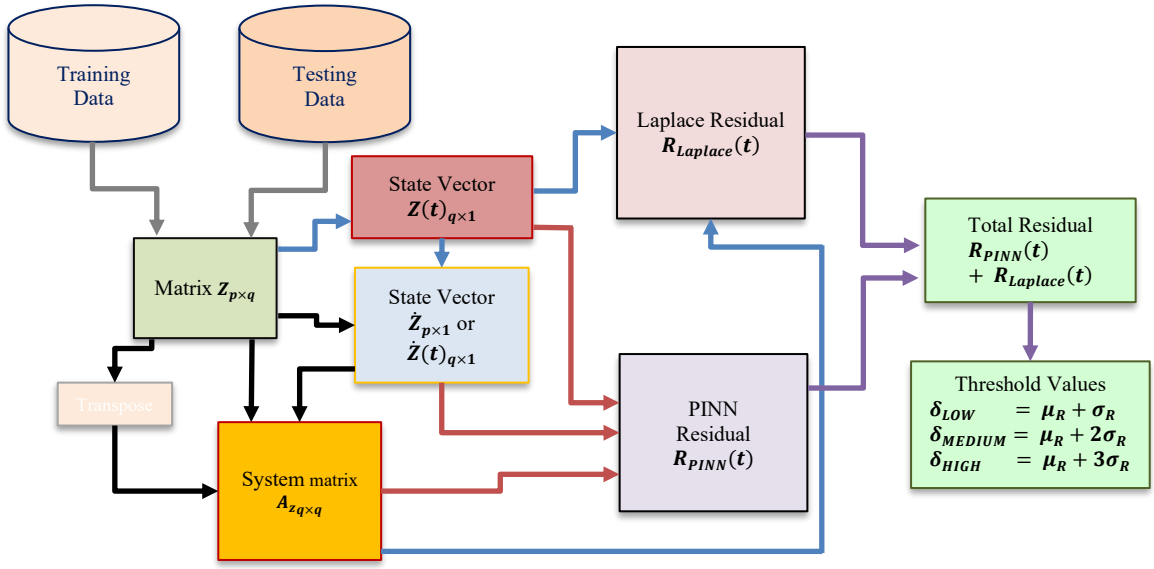

Fig. 1. Proposed system architecture.

After eliminating the non-time-based features, replace the INF values in the dataset with NaN, then remove all the instances with NaN values to make the dataset efficient for further computation. After removal of all the NaN value instances, the timestamps in the dataset can be in milliseconds or a different format; for efficiency, the timestamps are converted to seconds. The timestamp of each instance is converted to seconds, then the instances of the same second are grouped based on the label of each instance in that second. Instances are aggregated into one-second intervals and labelled as DDoS when the attack-instance proportion exceeds a configurable threshold; otherwise, they are labelled BENIGN. In this study, the threshold Δ=7% was experimentally selected. Like this, the complete dataset timestamps are standardized to one-second intervals. The dataset $D_{i\times j}$ is the refined dataset that is used for this methodology, where i denotes the number of rows and j denotes the number of columns. The training dataset $d_{k\times l}$ consists of k rows with l number of columns, and the testing dataset $d_{m\times n}$ consists of m rows with n number of columns, where $k+m=i$; $l+n=j$. For the initial experimentation, only the *BENIGN* instances were taken for the training phase. The training is done on $d_{p\times l}$ where p is the number of rows of *BENIGN* instances, and p is a subset of k. The detailed procedure is presented in Algorithm 1.

Algorithm 1:

1. $D=\{f_0, f_1, f_2, \dots, f_{j-1}, f_j\}$
   $\forall\ j = Number\ of\ features$
   $f_j = All\ the\ features\ of\ D$
2. $D[Label] = "DDoS"\ \&\&\ "BENIGN"$
3. $D = D[f_x]\ \&\&\ Label.$
   $\forall\ f_x = set\ of\ time-based\ features\ from\ f_j$
4. $if\ D = Any\ instance\ with\ NaN\ value;$
   $\quad then\ drop\ the\ instance$
5. $D[timestamp] = Converted\ into\ seconds\ \&$
   $grouped\ instance\ based\ on\ second$
6. $For\ timestamp\ t;$
   $\quad if\ count(D[Label] = "DDoS") \geq \Delta\%;$
   $\quad\quad then\ the\ second\ is\ labelled\ as\ DDoS$
   $\quad else\ labelled\ as\ BENIGN$
7. $D_{i\times j} = \{f_0, f_1, f_2, \dots, f_{j-1}, f_j\}$
   $\forall\ i = Number\ of\ instances$
   $j = Number\ of\ time-based\ features$
   $f_x = Set\ of\ all\ time-based\ features$
8. $d_{k\times l} = \{f_0, f_1, f_2, \dots, f_{j-1}, f_j\}$
   $\forall\ k = number\ of\ rows\ for\ training\ data$
   $l = number\ of\ columns\ for\ training\ data$
9. $d_{m\times n} = \{f_0, f_1, f_2, \dots, f_{j-1}, f_j\}$
   $\forall\ m = number\ of\ rows\ for\ testing\ data$
   $n = number\ of\ columns\ for\ testing\ data$
   $k, m \subset i\ and\ l, n \subset j$
10. $d_{p\times l} = d_{k\times l}[Label = "BENIGN"]$

After that, to capture network traffic dynamics in a suitable form for dynamical systems modelling, all the time-based features from $d_{p\times l}$ are taken in a matrix Z of size $p \times q$, where q is the number of time-based features and q is a subset of l shown in Eq. (1).

$$Z_{p\times q} = d_{p\times l}[f_x] \tag{1}$$

where, f_x denotes the set of time-based features.

Now, using the Z matrix, all the selected traffic features are combined into a single state vector $Z(t)$ as in Eq. (2) for each time t from 1 to the l^{th} second by applying the transpose of the matrix. The resulting state vector has dimension $q \times 1$.

$$Z(t) = \left(Z_{1\times q}\right)^T = [f_0(t)\ f_1(t)\ \dots f_j(t)]^T = \begin{bmatrix} f_0(t) \\ f_1(t) \\ \vdots \\ f_j(t) \end{bmatrix} \tag{2}$$

The rate of change of each state vector is then computed using the finite-difference relation represented by Eq. (3). The resulting derivative is denoted by $\dot{Z}(t)$. In Eq. (3), Z(t+1) represents the state vector at the next second, while Z(t) represents the state vector at the current second. Since the dataset is aggregated at one-second intervals, i.e., Δt =1 s, the derivative reduces to the difference between two consecutive state vectors. The derivative is computed up to the penultimate state vector. For the final state vector, the derivative cannot be calculated because Z(t+1) is not there.

$$\dot{Z}(t) = \frac{Z(t+1) - Z(t)}{\Delta(t)} \tag{3}$$

Next, Network traffic is modelled as a linear, time-invariant dynamical system using an ordinary differential equation (ODE) formulation in Eq. (4), where Z represents the traffic state vector, $\dot{Z}$ represents its rate of change, and A_z is the system matrix describing the relationships among the selected traffic features. The system matrix A_z, can be obtained using Least Squares Analysis. As denoted in Eq. (5), the model is rearranged to relate the observed state matrix to its derivative. Thus, solving this least-squares problem yields Eq. (6), where Z^T denotes the transpose of the matrix. The predicted A_z therefore represents the linear temporal interactions among the selected network-traffic features.

$$\dot{Z} = A_z \cdot Z \tag{4}$$

$$\dot{Z} = Z \cdot A_z{}^T \tag{5}$$

$$A_z = \left((Z^T \cdot Z)^{-1} \cdot Z^T \cdot \dot{Z}\right)^T \tag{6}$$

After computing the system matrix A_z value, next to get the PINN Residual, first compute the model's predicted derivatives at time t with Eq. (7), then use the resulting vector to find the residual between the observed derivatives and model-predicted derivatives by Eq. (8) where $\dot{Z}$ (observed value) is subtracted from the resulting vector (predicted value). Then, for each time $'t'$ till $p-1$ seconds, the summation of all the values after subtraction gives R_{PINN}. The R_{PINN} gives how much the real, observed traffic dynamics deviate from what the learned linear model expects at time t as shown in Eq. (9). After the system matrix A_z is obtained, the PINN residual is computed to quantify the difference between the observed and model-predicted traffic dynamics. First, the predicted derivative Z_{PINN} at time 't' is obtained using Eq. (7). The residual vector $Residual(t)$ is then calculated by subtracting the predicted

derivative Z_{PINN} from the observed derivative $\dot{Z}$, as given in Eq. (8). This procedure is repeated for each time step up to p-1. The residual components are then summed to obtain $R_{PINN}(t)$, as defined in Eq. (9). Thus, $R_{PINN}(t)$ represents the deviation of the observed network-traffic dynamics from the behaviour predicted by the estimated dynamical model.

$$Z_{PINN} = A_z \cdot Z(t) \quad (7)$$

$$Residual\ (t) = \dot{Z} - Z_{PINN} \quad (8)$$

$$R_{PINN}(t) = \sum Residual\ (t) \quad (9)$$

Next, Laplace ($\mathcal{L}$) is applied with respect to the differential form of the Z matrix, which transforms traffic dynamics into the Laplace domain (S) as defined in Eq. (10). So, by further computing the equations with respect to the estimated system matrix, achieved $Z_{Laplace}$ in Eq. (11), where I denotes the identity matrix and the value of S is 1. For each time t till $p-1$ seconds, the values are computed, and the resulting vector at each t is used to calculate the residual by $\dot{Z}$ (observed value) subtracted from the resulting vector (predicted value), as in Eq. (12). For each t second, the scalar Laplace residual value $R_{Laplace}$ is obtained by summing all residuals as shown in Eq. (13).

$$\mathcal{L}(\dot{Z}) = SZ_{(s)} - Z_{(0)} = A_z.Z(s) \quad (10)$$

$$Z_{Laplace} = (SI - A_z)^{-1}.Z(t) \quad (11)$$

$$Residual\ (t) = \dot{Z} - Z_{Laplace} \quad (12)$$

$$R_{Laplace}(t) = \sum Residual\ (t) \quad (13)$$

The two residual signals (R_{PINN}) and ($R_{Laplace}$) are combined into a single anomaly score as total Residual R for time 't', as shown in Eq. (14). These R values are the scores for each instance to analyze how far the observed traffic at time $'t'$ deviates from the expected behavior of the learned normal-traffic model, to predict if it is *BENIGN* or a *DDoS* instance.

$$R(t) = R_{PINN}(t) + R_{Laplace}(t) \quad (14)$$

To define a threshold value, the mean (μ) and standard deviation (σ) of these R are computed using Eq. (15) and Eq. (16). Here, the mean and standard deviation were used as they capture the natural spread of residual values under normal traffic. From the μ_R and σ_R values, the threshold value is defined for three-level alerts: low, medium, and high thresholds, making ($\mu_R + k\sigma_R$) is a statistically grounded basis for differentiating benign deviations from actual anomalies, as shown in Eq. (17) to Eq. (19).

$$\mu_R = \bar{x}_R = \frac{1}{N}\sum_{i=1}^{n} x_i \quad (15)$$

$$\sigma_R = s_R^2 = \frac{1}{N}\sum_{i=1}^{n}(x_i - \mu)^2 \quad (16)$$

$$\delta_{LOW} = \mu_R + \sigma_R \quad (17)$$

$$\delta_{MEDIUM} = \mu_R + (2 \cdot \sigma_R) \quad (18)$$

$$\delta_{HIGH} = \mu_R + (3 \cdot \sigma_R) \quad (19)$$

After the threshold values are defined, the same procedure is repeated from Eq. (1) to Eq. (14) on the complete training dataset $d_{k\times l}$ and testing dataset $d_{m\times n}$ to get the R values for every instance of *BENIGN* and *DDoS*. Based on the threshold values, the Early Warning Signals (EWS) are generated for low, medium, and high alerts for each instance, as shown below Eq. (20) to Eq. (23),

$$BENIGN = R \leq \delta_{LOW} \quad (20)$$

$$LOW\ EWS = \delta_{LOW} < R \leq \delta_{MEDIUM} \quad (21)$$

$$MEDIUM\ EWS = \delta_{MEDIUM} < R \leq \delta_{HIGH} \quad (22)$$

$$HIGH\ EWS = R > \delta_{HIGH} \quad (23)$$

IV. Experimentation and Results Discussion

A. Dataset

For the experimentation, the benchmark CICDDoS2019 dataset is utilized to evaluate the performance of the proposed method. The CICDDoS2019 dataset is an updated IDS dataset and has all the recent DDoS attack patterns. From all the attack files of CICDDoS2019, only the BENIGN and UDP instances are used for training, while in the testing data, only BENIGN and UDPLag instances are selected for experimentation in this study. This scenario was selected specifically to enable direct comparison with A. B. d. Neira et al [12] COOPRED DDoS system, the most closely related prior work, which uses the same attack types and dataset split. Table I shows that the dataset size is 31,91,508 instances for training from training day data of 01-12-2018 between 09:17 and 17:16 and 58,838 instances for testing from testing day data of 03-11-2018 between 09:18 and 17:36. After this, all the feature columns from the dataset are dropped except time-based features, Timestamp, and Label for the experimentation. The 27 time-based features are shown in Table II. Now, the dataset contains only 29 columns, from which INF values were replaced with NaN, and then all instances with a NaN value were removed from the dataset. After that, the data instances are grouped into fixed time intervals (in seconds) by converting the timestamp data values into seconds and aggregating the values of time-based features by summing all the instances for that second.

The labelling is done by taking a threshold value of 7%. If more than 7% of the instances in a given second are DDoS instances, then that second is labelled as DDoS or else BENIGN. To determine the threshold, a robustness analysis was performed to determine the 7% threshold. This is done by varying the proportion of DDoS instances per second from near zero to 50%. Then, the train–test accuracy gap at each alert level is evaluated. We observed that below the 7% threshold, the generalization gap was relatively high, reaching 10–12% at the medium-alert level, indicating sensitivity to training-specific noise. At 7%, the gap decreased to below 3% and remained low up to 10%. Beyond 15%, the gap increased again, which indicates that higher thresholds may exclude relevant attack-related traffic. Based on this analysis, a 7% threshold was selected as a suitable threshold in this study.

TABLE I. DATASET DESCRIPTION FOR TRAINING AND TESTING DATA

TRAINING		TESTING	
Labels	***No. of Instances***	***Labels***	***No. of Instances***
UDP	31,34,645	UDPLag	1,873
BENIGN	56,863	BENIGN	56,965

Therefore, 7% is the smallest threshold at which the model generalized reliably, to avoid both overfitting at lower thresholds and signal loss at higher threshold values, as shown in Table III. Now, after grouping and aggregating, the dataset contains 9,237 instances in training and 7,416 instances in the testing dataset.

TABLE II. SELECTED LIST OF TIME-BASED FEATURES

Sno.	Feature Name	Sno.	Feature Name
1	Flow Bytes/s	15	Bwd IAT Mean
2	Flow Packets/s	16	Bwd IAT Std
3	Flow Duration	17	Bwd IAT Max
4	Flow IAT Mean	18	Bwd IAT Min
5	Flow IAT Std	19	Bwd Packets/s
6	Flow IAT Max	20	Active Mean
7	Flow IAT Min	21	Active Std
8	Fwd IAT Total	22	Active Max
9	Fwd IAT Mean	23	Active Min
10	Fwd IAT Std	24	Idle Mean
11	Fwd IAT Max	25	Idle Std
12	Fwd IAT Min	26	Idle Max
13	Fwd Packets/s	27	Idle Min
14	Bwd IAT Total		

Table IV shows the instances of each label in the training and testing datasets used in this experiment.

TABLE III. ANALYSIS OF THRESHOLD VALUE FOR LABELLING AGGREGATED DATASET BASED ON TRAIN-TEST GENERALIZATION GAP

Threshold	MEDIUM-Alert Gap	Average Gap (All Alerts)
1% to 6%	10.4% - 12.5%	20.1% – 22.4%
7%	2.94%	16.18%
8% to 10%	2.88% - 3.27%	16.14% - 16.36%
15%	10.50 %	19.17%
20%+	11.13%+	~16% - 17%

TABLE IV. DATASET DESCRIPTION FOR TRAINING AND TESTING DAY TRAFFIC AGGREGATED IN SECONDS

TRAINING		TESTING	
Labels	***No. of Instances***	***Labels***	***No. of Instances***
DDoS	1505	DDoS	460
BENIGN	7732	BENIGN	6956

B. Scores and EWS Threshold Values

From the training day dataset, only the BENIGN instances are used during training to build the model for experiments. Thus, the matrix Z is of size 7732×27, indicating 7732 instances and 27 features, from which Z^T is obtained as a matrix of size 27×7732. The next step is the computation of temporal derivation, $\dot{Z}(t)$ by finding the derivatives between $Z(t+1)$ and $Z(t)$ where $Z(t)$ is the current value and $Z(t+1)$ is the next value. The value of 't' is varied from $t = 1\ to\ 7731$. As in the last instance $\dot{Z}(7732)$ cannot be computed due to no next instance to find the derivative, the last sample is excluded. The resulting data and derivative matrices are subsequently used in the ordinary differential equation formulation to estimate the system matrix A_z according to Eq. (4) to Eq. (6). From the A_z matrix, PINN residual, R_{PINN} and Laplace residual, $R_{Laplace}$ are determined using Eq. (7) to Eq. (13), for each $t = 1\ to\ 7731$. The total residual (R) is calculated by the sum of R_{PINN} and $R_{Laplace}$ as defined by Eq. (14). The resulting R values are the scores based on which the alerts are generated for the individual instances. The resulting R values serve as warning scores for generating alerts for individual instances. The residual values are shown in Table V for the R values. The mean and standard deviation values of the residuals, R, are calculated using Eq. (15) and Eq. (16), yielding $\mu_R = -140.1766$, $\sigma_R = 1190671971.4852$.

The threshold values are determined based on these statistics, resulting in $\delta_{LOW} = 1190671831.3086$, $\delta_{MEDIUM} = 2381343802.7938$ and $\delta_{HIGH} = 3572015774.2789$, using Eq. (17) to Eq. (19). After defining threshold values, the procedure is repeated on the complete training and testing dataset containing both BENIGN and DDoS instances to generate the alerts based on the R values for each instance. The predicted alerts are classified as: BENIGN if $R \leq 1190671831.3086$, LOW if $1190671831.3086 < R \leq 2381343802.7938$, MEDIUM if $2381343802.7938 < R \leq 3572015774.2789$ and HIGH if $R > 3572015774.2789$.

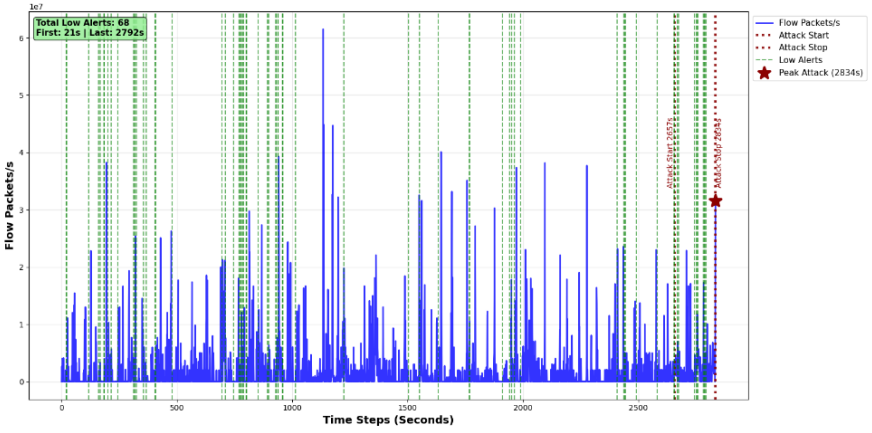

TABLE V. RESULTING RESIDUAL VALUES FOR THE DATASET

Time	PINN Residual	Laplace Residual	Total Residual
1	477500352	-2204316.58	475296036
2	332947127	3091892.24	3.3604

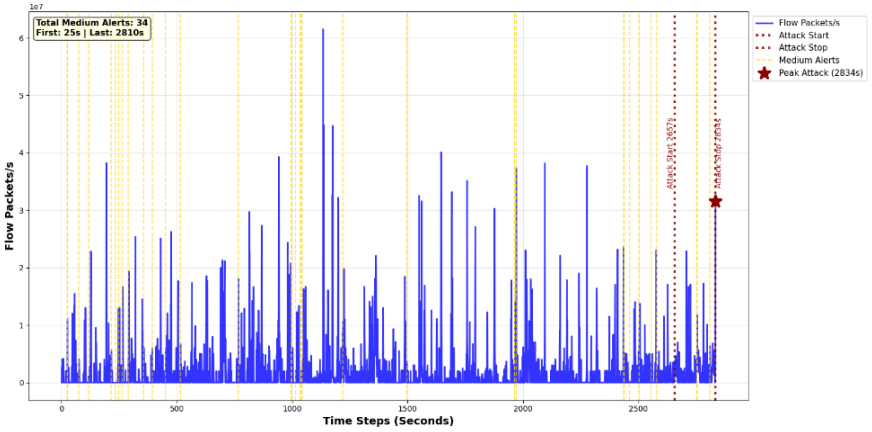
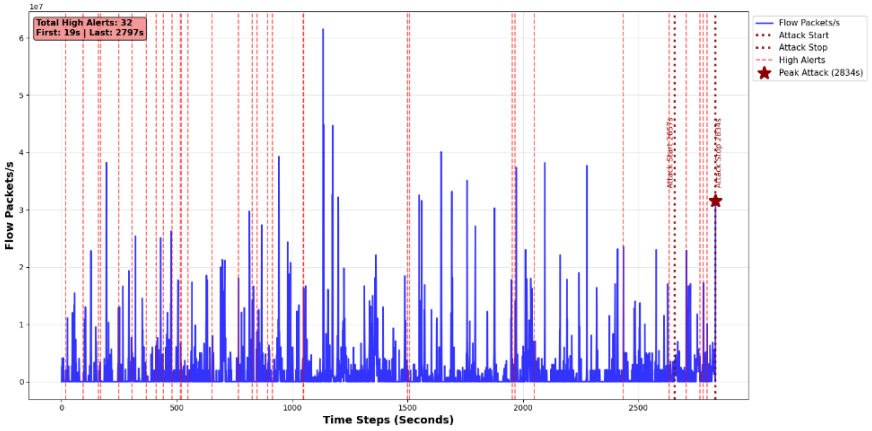
7731	-25775345.1	-1758958.43	-27534303.5



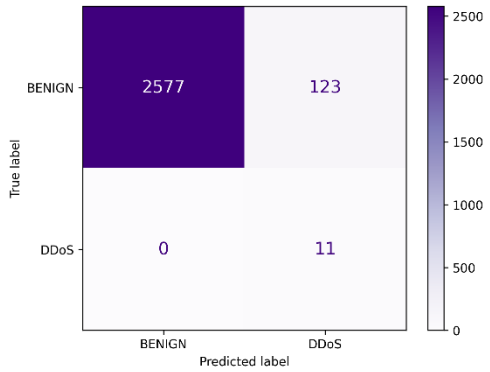
C. Results

The results of the experimentation are shown to demonstrate how well the model is able to generate an early warning signal (EWS) before both the onset of the attack and the peak of the DDoS attack. The testing dataset for the experimentation contains both attack and benign instances. As shown in Fig. 2(a), 2(b), and 2(c), the attack started at 2657 seconds (11:13:03), with the attack reaching its peak at 2834 seconds (11:17:41), and the attack ended at 3256 seconds (11:27:53). The early warning signals are generated based on the low, medium, and high alert conditions. The total alerts generated are 134, of which 68 are low alerts, 34 are medium alerts, and 32 are high alerts. The first low alert was generated at 21 seconds (09:20:41), which is 46 minutes 53 seconds before the peak of the attack, and the last low alert was at 2792

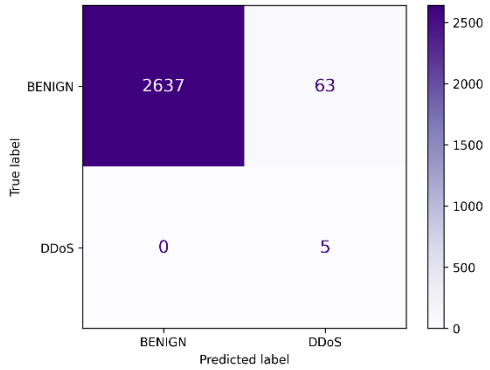


seconds. The first medium alert was generated at 25 seconds (09:20:51), and the last medium alert was at 2810 seconds. The first medium alert is 46 minutes 49 seconds before the peak of the attack. The first high alert at 19 seconds (09:20:31) is 46 minutes 55 seconds before the peak of the attack, and the last high alert is at 2797 seconds. In Fig. 3(a), the confusion matrix of the testing dataset containing both attack and benign instances is shown. The confusion matrix represents the classification performance of early warning signals across various alert levels.

(a)

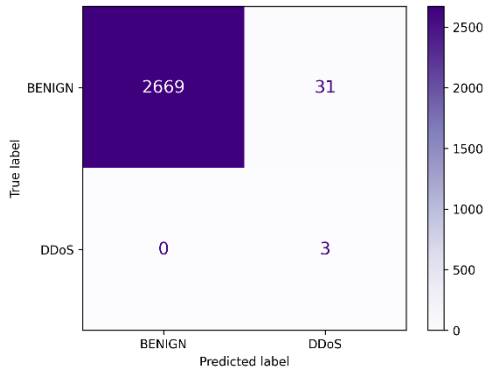


(b)

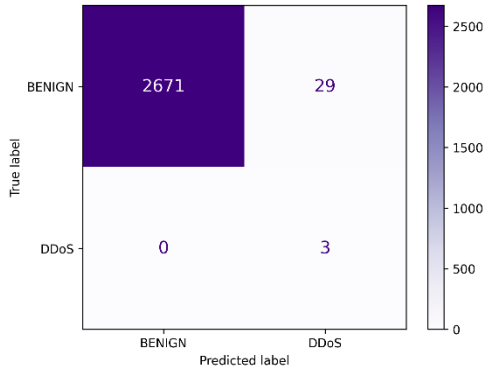


(c)

Fig. 2. EWS generated for testing data for: (a) low alerts; (b) medium alerts; (c) high alerts.



Fig, 3(a) represents the confusion matrix obtained for testing data. As shown in Fig. 3(a), 2,577 BENIGN instances were correctly classified, while 123 BENIGN-labelled instances triggered early warning alerts. All eleven DDoS instances were correctly identified, with no false negatives. Of the 123 nominal false positive alerts, 117 (95.12%) alerts occurred before the first labelled DDoS instance. This temporal concentration of alerts before the attack onset indicates the potential of the proposed framework to provide warning of emerging abnormal network conditions.



(a)

(b)

(c)

(d)

Fig. 3. Confusion matrix of Testing data for: (a) all alerts; (b) low alerts; (c) medium alerts; (d) high alerts.

The three confusion matrices in Fig. 3(b) to 3(d) successively record the classification performance of the three EWS warning levels: LOW, MEDIUM, and HIGH EWS. The true negative rates (TNRs) of the three groups are 97.67%, 98.85%, and 98.93%, respectively. The true negative rate can be understood as the proportion of cases that are originally normal, correctly identified as normal by the system, and do not trigger an unnecessary warning; the higher this value, the better. The corresponding false positive rates (FPRs) are 2.33%, 1.15%, and 1.07%. The false positive rate is the proportion of cases that are originally normal, misjudged by the system as problematic, and incorrectly trigger a warning; the lower this value, the better. The Low-level warning was triggered a total of 68 times, of which 63 times were false alarms triggered by normal samples marked as BENIGN, and the remaining 5 times correctly identified DDoS attacks. The MEDIUM-level warning was triggered 34 times; 31 times were false alarms triggered by normal samples marked as BENIGN, and 3 times accurately caught DDoS attacks. The High-level warning was triggered 32 times; 29 times were false alarms triggered by normal samples marked as BENIGN, and another 3 times correctly identified DDoS attacks. It is worth noting that not a single DDoS attack was missed at any warning level. In all tested configurations, the number of false negatives was 0 — a false negative refers to a missed alarm where an attack was actually occurring, but the system failed to detect it and did not trigger a warning. No missed alarm problem occurred at all in this test.

Table VI summarizes the performance of the proposed EWS framework on the training and testing datasets up to the attack peak.

TABLE VI. PERFORMANCE OF THE EWS FRAMEWORK ON TRAINING AND TESTING DATASETS UP TO THE ATTACK PEAK

	Alerts	Accuracy	Precision	Recall	F1-Score	Balanced Accuracy
Training Dataset	All Alerts	95.98	74.60	100	85.45	97.72
	LOW Alerts	97.95	45.52	100	62.56	98.96
	MEDIUM Alerts	98.77	41.25	100	58.41	99.38
	HIGH Alerts	98.88	89.69	100	94.57	99.38
Testing Dataset	All Alerts	95.46	8.21	100	15.17	97.72
	LOW Alerts	97.67	7.35	100	13.70	98.83
	MEDIUM Alerts	98.85	8.82	100	16.22	99.43
	HIGH Alerts	98.93	9.38	100	17.14	99.46

For the training dataset, all alert levels achieved 100% recall, with a balanced accuracy of 97.72% for the combined alerts. The LOW, MEDIUM, and HIGH alert levels achieved balanced accuracies of 98.96%, 99.38%, and 99.38%, respectively. On the testing dataset, the framework also achieved 100% recall across all alert levels, indicating that no labelled DDoS instances were missed. The balanced accuracy was 97.72% for all alerts and increased to 98.83%, 99.43%,

and 99.46% for LOW, MEDIUM, and HIGH alerts, respectively. Although testing precision was low because several BENIGN-labelled instances triggered early warnings, their temporal occurrence before the labelled attack onset is separately considered when evaluating the advance-warning capability of the proposed EWS framework.

The objective of the proposed framework is to provide warnings before DDoS attack onset rather than only identify labelled DDoS attack instances. Hence, the low testing precision between 7.35% and 9.38% across alerts should be interpreted together with the temporal distribution of the alerts. The proposed framework attained a high true negative rate, which is between 95.44% and 98.93%, and 100% recall, indicating that most of the BENIGN traffic is correctly identified while no DDoS instances are missed. The low precision results are due to the strong class imbalance and warnings generated during the BENIGN-labelled time period.

Importantly, out of the 123 false positive alerts, 117 alerts have occurred before the first DDoS instance, which amounts to 95.1%. Thus, the temporal concentration of alerts before the attack onset is to be considered, which supports the relevance to the early-warning objective of the proposed framework, although they remain false positives under conventional classification. The LOW, MEDIUM, and HIGH alert levels further support prioritization, with higher alert levels showing improved precision and lower false positive rates.

TABLE VII. COMPARISON OF DDOS EARLY-WARNING LEAD TIME AND PRE-ATTACK ALERTS WITH AN EXISTING APPROACH

S. No.	Method	Warning Lead Time before Attack Onset	No. of Alerts before Attack Onset
1	de Neira, et al. [12]	2 minutes 08 seconds	4
2	Proposed (Low alert)	43 minutes 56 seconds	58
3	Proposed (Medium alert)	43 minutes 52 seconds	31
4	Proposed (High alert)	43 minutes 58 seconds	28

Table. VII shows a comparison of the proposed method with the existing work of de Neira et al. [12] COOPRED DDoS system (Experiment 2), as both evaluations use the same CICDDoS2019 UDP attack (training) and UDPLag attack (testing) scenario. Neira et al. [12] computed statistical early-warning signals (kurtosis, skewness, and spectral density) on the packet-count time series and classified each second as normal or attack-warning using a supervised classifier, which predicted an alert 2 minutes 08 seconds before the start of the attack. The proposed method instead scores every timestamp using a combined residual across multiple traffic features, producing continuous three-level alerts. The medium alerts were generated 43 minutes 52 seconds, low alerts generated 43 minutes 56 seconds, and high alerts generated 43 minutes 58 seconds before the start of the attack. The proposed method is a fundamentally more continuous detection mechanism rather than waiting for a rare statistical spike. The trade-off is precision: Neira et al. work reports higher precision (33%-100%) because their method triggers rarely and conservatively, while our method is a continuous, multi-feature approach that produces more frequent but lower-precision alerts in much earlier and more consistent warning coverage, consistent with maximizing early-warning time rather than minimizing alert counts. With a better prediction time, the proposed method gives a network administrator more time to make better use of it and act more effectively to mitigate attacks before they reach their peak.

V. CONCLUSION

Anticipating cyberattacks is a fundamentally harder problem than detecting them post-hoc, and increasing the integrity of connected systems requires an architecture of defense in depth. Traditional reactive methods degrade quickly as attack vectors evolve, especially when it comes to new attack vectors. Thus, the fundamental goal of threat prediction is to separate harmful staging operations and generate alert signals in a timely manner, where alert generation is done long before an intrusion even executes. The proposed architecture achieves this by generating multi-level Early Warning Signals (EWS) such as low, medium, and high, well ahead of the peak of the attack and ahead of attack execution. In order to achieve this, the proposed architecture generates multi-level EWS signals divided into low, medium, and high threat classes. We then use the ODE formulation to obtain a Physics-Informed Neural Network and Laplace residuals from discrete data samples. These residual vectors then determine the empirical boundaries required for partitioning network traffic into the respective risk levels. The system obtained a combined balanced accuracy of 97.72% over the alert spectrum. On a more granular scale, the low-alert generation reported 98.83% balanced accuracy, sounding an alarm 46 minutes and 53 seconds before peak attack severity, and 43 minutes and 56 seconds before first impact. The medium-alert level achieved a balanced accuracy of 99.43%, with warnings sent out 46 minutes and 49 seconds before the peak and 43 minutes and 52 seconds ahead of onset, respectively. In parallel, the high-level alert class achieved a balanced accuracy of 99.46%, which shifted critical alerts to 46 minutes and 55 seconds prior to the peak and to 43 minutes and 58 seconds before the attack began. Future work will focus on extending the lead time of this prediction as well as improving the accuracy and robustness of the EWS generation pipeline for a wider variety of network topologies and threat vectors with respect to distributed denial of service network traffic.

***Abstract*—The study introduces a novel approach to community detection in complex networks by integrating fuzzy logic with multi-criteria decision-making techniques. Unlike traditional methods that rely primarily on topological metrics, the proposed approach incorporates semantic attributes to identify meaningful community structures. Fuzzy logic addresses the inherent uncertainty and ambiguity in processing these attributes, enabling a flexible detection process that is not dependent on network topology. To enhance scalability, this study customizes the k-means clustering algorithm to accommodate small- and large-scale network structures. Experimental results show that the proposed fuzzy logic-based approach achieves competitive performance compared with conventional algorithms. Additionally, the proposed approach demonstrates robustness by generating well-balanced communities with competitive execution times compared with the evaluated methods. These findings highlight the potential benefits of incorporating semantic attributes and fuzzy reasoning into community detection in complex networks.**

Keywords*—Community detection; fuzzy logic; Multi-Criteria Decision Making (MCDM); social network analysis; semantic communities

I. Introduction

Real-world networks such as biological, citation, transportation, and social networks have been modelled throughout research advancements to be represented as graphs, where nodes and edges represent, respectively, the network components and the interconnecting relationships between them. These representations offer practical utility in highlighting groups of nodes when their connections are observed more internally than externally. Thereby, the identified groups are called communities, reflecting as much as possible a degree of similarity among their nodes [1, 2]. However, behind this conceptual presentation, challenging problems such as network heterogeneity, complex interactions, and computational effort make the task challenging for researchers.

In the literature, existing approaches to community detection address the clustering problem from different perspectives. For example, using modularity-based techniques, local and global subsetting analysis, and optimization tasks often prove insufficient when applied to a directed network structure [1, 3-8], one of many recurring problems in the clustering paradigms. This article makes a methodological contribution by combining data mining [10, 11] with fuzzy logic [14, 15] in the field of community detection, improving the processing of large datasets and enhancing uncertainty extraction performance to handle the semantic properties of nodes. Thus, the proposal in this study represents an approach that captures uncertainty and linguistic ambiguity in the semantic properties of nodes, supporting the detection of existing semantic communities.

The manuscript is structured as follows: Section II reviews existing approaches to community detection. Section III presents the proposed methodology, while Section IV describes the experimental configuration and findings. Finally, Section V discusses the results obtained and offers conclusions.

II. Related Work

Various approaches have been proposed over the last decade for identifying community structures. Girvan and Newman introduced a seminal edge-betweenness-based approach for community detection in social networks. Their method iteratively removes edges with high betweenness to reveal community boundaries, with modularity commonly used to evaluate the resulting partitions [4, 5, 6]. Other similar approaches have explored spectral clustering and the minimum cut formulations [8], while others have relied on statistical inference [7]. Additional methods used unsupervised clustering based on similarity measures [14]. However, these approaches face some limitations, particularly when handling edge directionality [6, 7]. Similarly, some studies [10, 16] do not explicitly account for edge directionality, limiting their applicability to directed networks, particularly when the number of communities parameter is unknown a priori.

Recently, increasing attention has been devoted to combining structural and semantic information to improve community detection [8, 13]. The identification of communities based on semantic attributes has attracted increasing attention, particularly for weighted and directed networks. This has motivated the development of methods that jointly consider both topological and semantic information to address semantic-community detection. For instance, methods integrating multi-criteria decision-making [17, 18, 19] and fuzzy logic [14, 15] provide mechanisms for modeling heterogeneous and uncertain node attributes, thereby complementing purely topology-based representations with semantic information.

*Corresponding author.

This study introduces a fuzzy logic-based approach that integrates semantic attribute analysis with multi-criteria decision-making to identify semantically coherent communities in directed networks. The proposed method uses preference functions to quantify the relevance of node properties and incorporates these preferences into the community detection process.

III. Definition and Approach Method

This section first presents the definitions of the key concepts used in this study, followed by an introduction to the fundamental principles of the proposed fuzzy approach.

Definition 1. Let G be a graph denoted by (V, E), composed of n nodes and m edges. V represents the set of vertices of G, where v_i denotes the i^{th} node. Each node v_i incorporates the set A_i representing qualitative and quantitative attributes of node v_i, for $1 \leq i \leq N$. Where, E denotes the set of edges of G, and e_i represents an edge connecting two nodes v_i and v_j.

Definition 2. Let M=(l, m, u) be a fuzzy number [9, 11] associated with the membership function f(x). Where l, m, and u represent the parameters of the membership degree.

The two possible forms of the membership function f(x) are considered in this work, as defined in Eq. (a) and (b).

$$f(x) = \begin{cases} 0 & if\ x < l \\ \frac{x-l}{m-l} & if\ \ l \leq x \leq m \\ \frac{u-x}{u-m} & if\ \ m < x \leq u \\ 0 & if\ x > l \end{cases} \quad (a)$$

$$f(x) = \begin{cases} 0 & if\ x < l \\ \frac{x-l}{m_1-l} & if\ \ l \leq x < m_1 \\ 1 & if\ m_1 \leq x < m_2 \\ \frac{u-x}{u-m_2} & if\ \ m_2 \leq x < u \\ 0 & if\ x \geq u \end{cases} \quad (b)$$

Definition 3. Let M be a fuzzy number as defined in Definition 2, with an associated membership function $\mu_M(x)$ derived from f(x), where $\mu_M(x) \in [0,1]$. When a fuzzy number has a single peak m, it is referred to as a triangular fuzzy number. When it has two peaks m_1 and m_2 with $m_1 \leq m_2$, it is referred to as a trapezoidal fuzzy number. To compute precise representative values of the fuzzy number, the maximization and minimization processes are denoted respectively by $\mu_{max}(x)$ and $\mu_{min}(x)$.

$$\mu_{max} = \begin{cases} x\ if\ 0 \leq x \leq 1 \\ 0\ otherwise \end{cases} \quad \text{and} \quad \mu_{min} = \begin{cases} 1 - x\ if\ 0 \leq x \leq 1 \\ 0\ otherwise \end{cases}$$

Based on these operations, three score values can be derived for the fuzzy number M: $\mu_R(M)$, $\mu_L(M)$, and $\mu_T(M)$, which correspond respectively to the right score, left score, and total score. Their mathematical formulations are given in Eq. (1), (2), and (3).

$$\mu_R(M) = \sup_x\{\mu_M(x) \wedge \mu_{max}(x)\} \quad (1)$$

$$\mu_L(M) = \sup_x\{\mu_M(x) \wedge \mu_{min}(x)\} \quad (2)$$

$$\mu_T(M) = \frac{(\mu_R(M)+1-\mu_L(M))}{2} \quad (3)$$

Definition 4. Let us consider a preference function that models the degree of preference among associated fuzzy sets defined in Definition 3. It characterizes how different evaluation scenarios influence the assignment of preferences.

Four preference cases ψ are considered: 1) alignment with the preference ψ(1), 2) independence from the preference ψ(2), 3) favorable preference ψ(3), and 4) contradiction with the preference ψ(4). Each of which is defined mathematically in Table I as follows:

TABLE I. Mathematical Representation of the Predefined Preference Cases

Preferences	Triangular fuzzy number	Trapezoidal fuzzy number
ψ(1) : Alignment	e	$\begin{cases} 0 \ \text{if}\ 0 \leq e \leq m_1 \\ \frac{e-m_1}{m_2-m_1}\ if\ \ m_1 \leq e \leq m_2 \\ 1\ if\ \ m_2 \leq e \leq 1 \end{cases}$
ψ(2) : Independence	$\begin{cases} \frac{e}{m_1}\ \ if\ \ 0 \leq e \leq m_1 \\ \frac{1-e}{1-m_1} if\ m_1 \leq e \leq 1 \end{cases}$	$\begin{cases} 0 \quad if\ 0 \leq e \leq m_1 \\ \frac{e-m_1}{m_2-m_1}\ \ if\ \ m_1 \leq e \leq m_2 \\ 1 \quad if\ m_2 \leq e \leq m_3 \\ \frac{m_4-e}{m_4-m_3}\ \ if\ m_3 \leq e \leq m_4 \\ 0 \quad if\ m_4 \leq e \leq 1 \end{cases}$
ψ(3): Favorable	$\begin{cases} \frac{m_1-e}{m_1}\ \ if\ \ 0 \leq e \leq m_1 \\ \frac{e-m_1}{1-m_1}\ \ if\ \ m_1 \leq e \leq 1 \end{cases}$	$\begin{cases} 1 \quad if\ 0 \leq e \leq m_1 \\ \frac{m_2-e}{m_2-m_1}\ \ if\ m_1 \leq e \leq m_2 \\ 0 \quad if\ m_2 \leq e \leq m_3 \\ \frac{e-m_3}{m_4-m_3}\ \ if\ \ m_3 \leq e \leq m_4 \\ 1 \quad if\ m_4 \leq e \leq 1 \end{cases}$
ψ(4): Contradictory	$1-e$	$\begin{cases} 1 \quad if\ 0 \leq e \leq m_1 \\ \frac{m_2-e}{m_2-m_1}\ \ if\ m_1 \leq e \leq m_2 \\ 0 \quad if\ m_2 \leq e \leq 1 \end{cases}$

A. Proposed Architecture

This section describes the architecture of the proposed fuzzy approach [12, 19].

The architecture of the proposed approach includes three phases (Fig. 1): The Environment preparation phase (Phase 1), the Fuzzy analysis phase (Phase 2), and the social network analysis phase (Phase 3).

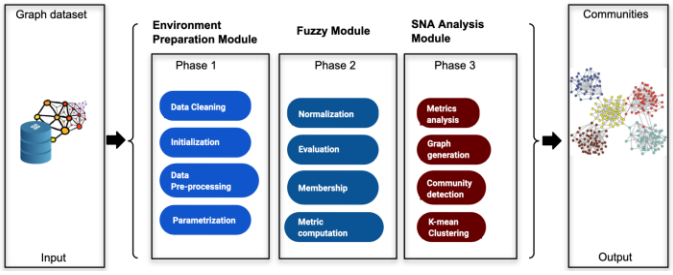

Fig. 1. The architecture of the proposed fuzzy approach-based three main modules within the three phases.

- Input Layer: A network is not only a collection of interconnected nodes; it also incorporates layers of semantic data that can significantly enrich the understanding of the network's structure. This layer ensures the network dataset is prepared for further processing in subsequent phases.
- Environment Preparation Layer: The environment preparation layer plays a critical role in integrating the network dataset by performing data cleaning and preprocessing, enhancing data clarity, and extracting semantic information from node attributes.
- Fuzzy Layer: Phase 2 involves a series of processes powered by the fuzzy conversion technique, including normalization and data evaluation, along with the conversion of quantitative data into qualitative insights.

The fuzzy conversion technique is applied in this phase to derive an initial appreciation matrix the identification of decision elements. The appreciation matrix is then normalized into values within the interval [0, 1]. Thus, the preference function is constructed to capture the analyst's preferences. Then, the appreciation matrix undergoes a final normalization, leading to the decision matrix. This step produces a new weighted matrix of the network.

- Social Network Analysis Layer: A new network is constructed at this stage, based on the generated decision matrix, which will be integrated into the community detection algorithm.
- Community Detection Layer: This phase, dedicated to the community detection algorithm, utilizing the enhanced k-means clustering algorithm to define community structure within the network.

B. Workflow of the Proposed Approach

The workflow of the proposed approach emphasizes the extraction and analysis of node properties. The application of the fuzzy approach involves six processes. The following Fig. 2 illustrates the exhaustive steps of the approach:

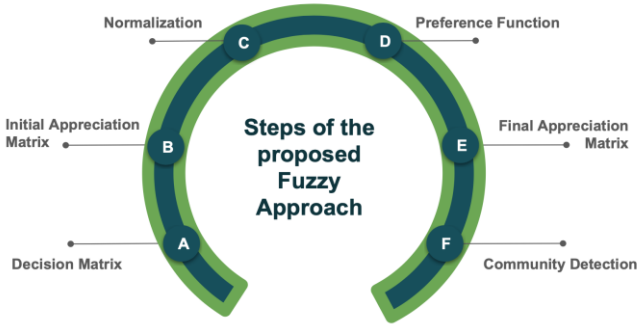

Fig. 2. The six steps of the proposed fuzzy approach.

1) Decision matrix: Where the node attribute criteria are formulated into families of attributes, denoted F = {f1, f2, f3, ... , fk}, with k=|F|. Where, F serves as the network analyst's preferences, reflecting decisions that have either positive or negative impacts on the community detection process.

2) Initial appreciation matrix: The initial appreciation matrix is built based on the conversion of node properties from qualitative into quantitative values. In fact, this transformation based on linguistic terms and their corresponding membership function M, helps determine the precise numerical values by using Eq. (3) of the fuzzy conversion technique, providing as a result the final appreciation matrix A′:

$$(A'_i)_{1\le i\le N} = ((f_i(a_j))_{1\le j\le N}) \text{ with } f_i \in F \text{ and } a_j \in A$$

3) Normalization: The normalization process ensures the numerical values of the initial appreciation matrix are within the interval [0,1], using Eq. (4). The output of this step is then a normalized appreciation matrix E={e_{ij}}, with e_{ij} defined as follows:

$$e_{ij} = \frac{a'_{ij}}{\sum_j a'_{ij}} \quad (4)$$

4) Preference function: The preference cases as introduced in Definition 4 are defined by the fuzzy number $M_i = (m_1, m_2, ..., m_q)$, where each M_i corresponds to the q inflection points throughout the interval [0, 1].

The preference function depends on the fuzzy number M_i, the preference cases ψ(i), and the family of attributes as follows:

$$P_i = P_{\psi(i)}^{M_i}(f_i)$$

5) Final appreciation matrix: For a given f_i, the final appreciation matrix denoted $P_i(e_{ij})$ introduces the decision matrix D_{ij} [22] defined by the following Eq. (5).

$$D_{ij} = \frac{P_i(e_{ij})}{\sum_i P_i(e_{ij})} \quad (5)$$

6) Community detection: In this step, the weight vector θ_i is determined for each vector f_i using the AHP process [22, 26]. In fact, the weight θ_i associated with f_i is defined by comparing the values $\sum_i^k w_{ik}$ using Eq. (6), which measures the importance of each element of f_i.

First, the reciprocal square matrix is constructed [20]. The k-means clustering algorithm is then enhanced [21, 24], as described in Algorithm 1.

$$\theta_i = \frac{(\prod_{j=1}^k w_{ij})^{1/k}}{\sum_{i=1}^k \left(\prod_{j=1}^k w_{ij}\right)^{1/k}} \quad (6)$$

This introduces the utility function, aggregating the vector of weights θ_i, and the computed decision matrix D_{ij}:

$$U_i = \sum_{j=1}^k \theta_i \times D_{ij} \quad (7)$$

The introduced utility function U, denoted U={$u_1, u_2, ..., u_N$}, is considered as a data point of the evaluated node properties within the k-dimensional space. Here, k is the dimension of f_i with i∈[0, k].

The proposed approach extends conventional k-means by incorporating semantic information derived from the fuzzy-logic and MCDM stages. It considers semantic utility values and attribute relevance during cluster formation. This procedure is

further adapted to accommodate networks of different scales while preserving the iterative k-means framework.

Algorithm 1: Fuzzy community detection algorithm based on enhanced K.

Require:
Dataset U = {u_1, u_2, ..., u_N}
Number of clusters k
Utility values derived from the fuzzy-MCDM process
Ensure:
Community set C = {C_1, C_2, ..., C_k}
Initialize:
Select k initial centroids θ_1, θ_2, ..., θ_k using the utility values obtained from fuzzy-MCDM process
Repeat
1- Initialize C_1, C_2, ..., $C_k \leftarrow \emptyset$
2- For each data point u_i, $i \in \{1..N\}$ do
$J^* \leftarrow \text{argmin}_{j \in \{1..k\}} \|u_i - \theta_j\|^2$ {Find index of closest centroid}
Assign u_i to cluster C_{J^*}
3- For each cluster C_j, $j \in \{1..k\}$ do
if C_j is not empty then
$\theta_j \leftarrow (1/|C_j|) * \sum_{ui \in Cj} u_i$
4- Repeat until convergence of θ_j
Return C = {C_1, C_2, ..., C_k}

The obtained utility function U determines the input of the k-means algorithm; it represents the initial centroids for the community detection algorithm, with a starting number k' of centroids, where k'=unique(k).

The sum of square distance (Δ) between each centroid and the utility function u_i is computed via Eq. (8). Each utility value u_i is then assigned to the nearest centroid c_j, and the community formation process continues iteratively.

$$\Delta(C) = \sum_{i=1}^{N} \sum_{j=1}^{k'} \|u_i - c_j\|^2 \quad (8)$$

The community detection algorithm continues adjusting the centroids until convergence stability is observed, forming well-defined clusters within the network.

IV. Experimental Evaluation

The proposed approach was implemented in the R programming language on an operating system equipped with an Intel Core i5 CPU running at 2.6 GHz and 8 GB of memory. The proposed approach was evaluated on synthetic networks of different sizes and compared with four well-known community detection algorithms.

A. Datasets Preparation

The adopted network structure is the Erdős- Rényi random graph [25], which allows the generation of six graphs with different sizes, ranging from 50 to 10000 nodes.

Nine properties were randomly assigned to all nodes of the generated networks. Specifically, five of them are qualitative values (f_1, f_2, f_3, f_4, f_5) and four quantitative values (f_6, f_7, f_8, f_9) to each node, ensuring diversified categories.

The synthetic semantic attributes used in the experiments provide a controlled environment for evaluating the influence of semantic information of the proposed approach. However, they do not fully capture the complexity and heterogeneity of the semantic attributes in real-world networks. Table II and Table III represent the environment prerequisites of the experimentation.

TABLE II. The Six Generated Erdős- Rényi Graphs, with the Average Degree

Network scale	Nbr. Of nodes	Nbr. Of edges	Average degree
50-nodes	50	61	2,44
100-nodes	100	246	4,92
300-nodes	300	2.224	14,82
1000-nodes	1.000	24.967	49,93
3000-nodes	3.000	225.498	150,33
10000-nodes	10.000	2.499.749	499,9498

TABLE III. Categories of the Assigned Random Attributes and their Associated Abbreviations F_i, where $i \in [1, 9]$. For Qualitative Attributes, the Initial Most Probable Value (MPV) is Specified. Not Applicable for Quantitative Attributes

F	Attribute label	Attribute category	Initial MPV (VL, L, M, H, VH)
f_1	GD	Qualitative	(0.1, 0.2, 0.2, 0.2, 0.2)
f_2	RE	Qualitative	(0.1, 0.2, 0.3, 0.4, 0.9)
f_3	PE	Qualitative	(0.2, 0.3, 0.4, 0.5, 0.9)
f_4	LU	Qualitative	(0.2, 0.3, 0.5, 0.7, 0.9)
f_5	TP	Qualitative	(0.3, 0.4, 0.5, 0.6, 0.7)
f_6	MS	Quantitative	Not applicable
f_7	RS	Quantitative	Not applicable
f_8	WS	Quantitative	Not applicable
f_9	DG	Quantitative	Not applicable

At this step, fuzzy conversion is performed using Definition 3 to determine the Most Probable Value (MPVs) for each qualitative property. In practice, the values are mapped to the interval [0,1] to represent the corresponding linguistic terms. Then, for each numerical value, the corresponding fuzzy sets are determined, and the MPVs are computed for the defined linguistic terms. The following Table IV represents the computed final MPVs for the qualitative properties.

At this stage, the obtained MPV values are used to define the membership function for each family f_i. Fig. 3 illustrates the resulting membership-function shape, which is used to determine the preference function associated with each vector of f_i. The universe of discourse corresponds to the computed MPVs for each vector associated with f_i.

TABLE IV. COMPUTATION OF THE FINAL MPVS FOR THE QUALITATIVE ATTRIBUTES F1, F2, F3, F4 AND F5

F	Desc.	Linguistic terms				
		VL	L	M	H	VH
f_1	Fuzzy Sets	(0 ,0.1 ,0.2)	(0.15,0.2,0.3)	(0.15,0.2,0.3)	(0.15,0.2,0.3)	(0.15,0.2,0.3)
	MPVs	**0.1**	**0.217**	**0.217**	**0.217**	**0.417**
f_2	Fuzzy Sets	(0, 0.1, 0.2)	(0.15,0.2,0.3)	(0.25,0.3,0.4)	(0.35,0.4,0.5)	(0.85,0.9,0.9)
	MPVs	**0.1**	**0.217**	**0.317**	**0.417**	**0.883**
f_3	Fuzzy Sets	(0, 0.2, 0.3)	(0.25,0.3,0.4)	(0.35,0.4,0.5)	(0.45,0.5,0.6)	(0.85,0.9,0.9)
	MPVs	**0.167**	**0.317**	**0.417**	**0.517**	**0.883**
f_4	Fuzzy Sets	(0, 0.2, 0.3)	(0.25,0.3,0.4)	(0.45,0.5,0.6)	(0.65,0.7,0.8)	(0.85,0.9,0.9)
	MPVs	**0.167**	**0.317**	**0.517**	**0.717**	**0.883**
f_5	Fuzzy Sets	(0, 0.3, 0.4)	(0.35,0.4,0.5)	(0.45,0.5,0.6)	(0.55,0.6,0.7)	(0.85,0.9,0.9)
	MPVs	**0.233**	**0.417**	**0.517**	**0.617**	**0.750**

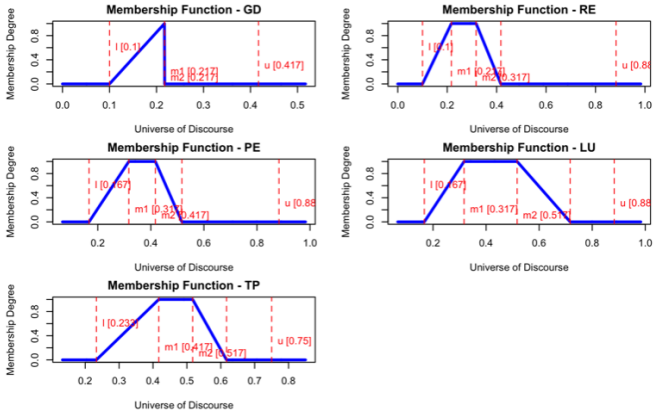

Fig. 3. The graphical illustration of the membership degree for the five qualitative attributes f_1 = GD, f_2 = RE, f_3 = PE, f_4 = LU, f_5 = TP.

Based on the membership degrees illustrated above, the preference function associated with f_1 is modeled using triangular membership $\psi(1)$. In contrast, the preference functions associated with f_2, f_3, f_4, and f_5 are modeled using trapezoidal membership functions $\psi(2)$. The corresponding fuzzy numbers M_i are computed as follows: $M_i = \{M_1, M_2, M_3, M_4, M_5\}$, with M_1=(0, 0.22, 0.22), M_2=(0.22, 0.32, 0.42, 0.88), M_3=(0.17, 0.32, 0.47, 0.88), M_4=(0.17, 0.52, 0.72, 0.88), M_5=(0.23, 0.52, 0.62).

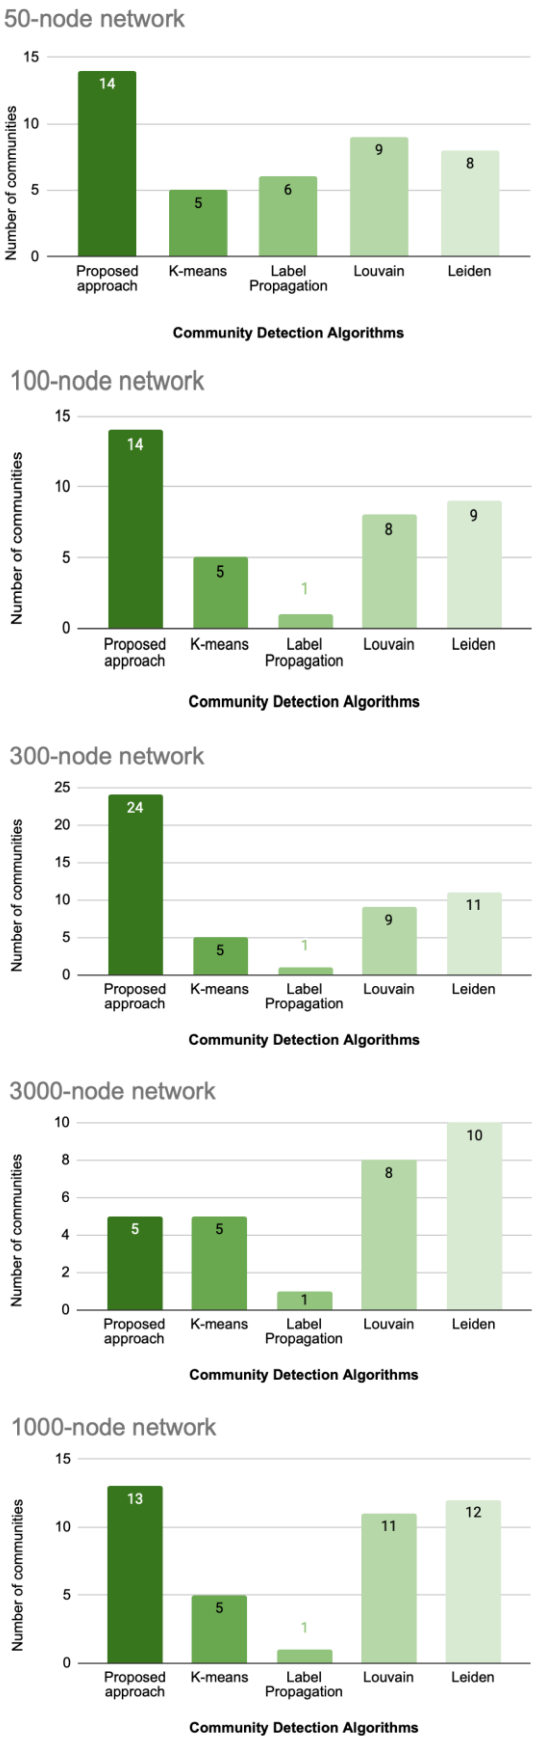
Therefore, the decision matrix is constructed using the preference function P_i defined in Eq. (5), which is then used to determine the utility function U in Eq. (7.

Following the multi-criteria decision-making (MCDM) process, the preferences associated with each vector f_i, are determined to construct the corresponding pairwise comparison matrix [23]. Consequently, the resulting weights vector Θ is given as follows: $\Theta = \{\theta_1, \theta_2, \theta_3, \theta_4, \theta_5, \theta_6, \theta_7, \theta_8, \theta_9\}$, with θ_1=0.029, θ_2=0.019, θ_3=0.042, θ_4=0.027, θ_5=0.060, θ_6=0.400, θ_7=0.175, θ_8=0.223, and θ_9=0.025.

At this step, the utility function is used to determine the weights for each vector f_i, and to initialize the centroids for the modified k-means algorithm (Algorithm 1). The next section presents the results obtained by applying the proposed fuzzy approach to the selected network datasets.

B. Results and Observations

This section presents the experimental results obtained using the proposed fuzzy logic approach on six networks, as listed in Table II. A comparative analysis is then presented to highlight the main findings and performance differences across the evaluated networks. The proposed community detection approach begins by determining the optimal value k using the Elbow method [24].



To assess the stability and computational behavior of the proposed approach, each experiment was repeated 10 times. Table V reports the mean execution time and standard deviation, together with the average number of detected communities.

TABLE V. COMPUTATIONAL PERFORMANCE OVER 10 INDEPENDENT RUNS

Network size	Mean Execution time (s)	Standard Deviation SD (s)	Number of communities (Mean ± SD)
50-nodes	0.000434	0.000142	10 ± 0.00
100-nodes	0.000320	0.000045	9 ± 0.00
300-nodes	0.000443	0.000054	5 ± 0.00
1000-nodes	0.001109	0.000799	5 ± 0.00
3000-nodes	0.002156	0.000295	5 ± 0.00
10000-nodes	0.015916	0.001404	5 ± 0.00

The results obtained show low execution times across all evaluated network sizes, increasing from 0.000434 seconds for the 50-node network to 0.015916 seconds for the 10000-node network. The relatively small standard deviation indicates stable execution time across repeated runs. Moreover, the number of detected communities remains unchanged across 10 runs for each network size, resulting in a standard deviation of zero. This provides stable computational behavior while maintaining consistent community partitions across repeated executions.

Fig. 4 illustrates a bar chart showing the number of detected communities obtained by the proposed approach and the selected classical community detection algorithms. Therefore, the proposed approach achieves competitive performance across networks of different sizes compared with the evaluated baseline algorithms. Fig. 5 further highlights the comparative execution times over the different algorithms across the considered network sizes.

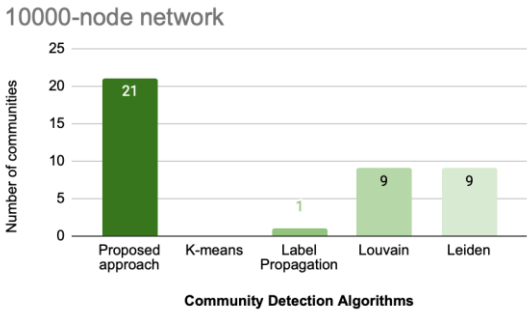


Fig. 4. Graphical representation of the fuzzy approach application, highlighting both the total number of detected communities and the comparison insights with the traditional clustering algorithms over different network sizes.

The results demonstrate that the proposed fuzzy logic approach achieves competitive execution times across different network sizes. For small networks (50-node and 100-node networks), the proposed approach achieves an execution time of 0.22 seconds, compared with 0.45-0.5 seconds for the standard k-means algorithm. While Label Propagation, Leiden, and Louvain also demonstrate competitive performance on small networks, their execution time increases as the network size grows. For the large network (10000 nodes), the proposed approach maintains stable performance with an execution time of approximately 0.40 seconds. Whereas the k-means algorithm times out. While Louvain, Leiden, and Label Propagation algorithms require longer execution times. Overall, these results demonstrate the computational efficiency and scalability of the proposed approach, particularly as network size increases.

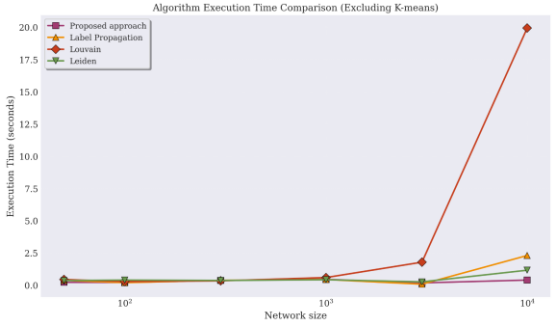

Fig. 5. Time consumed for the comparison of community detection algorithms across different network sizes (excluding the k-means algorithm due to computational instability at 10000-node network size).

The results demonstrate that the proposed fuzzy logic approach achieves competitive execution times across different network sizes. For small networks (50-node and 100-node networks), the proposed approach achieves an execution time of 0.22 seconds, compared with 0.45-0.5 seconds for the standard k-means algorithm. While Label Propagation, Leiden, and Louvain also demonstrate competitive performance on small networks, their execution time increases as the network size grows. For the large network (10000 nodes), the proposed approach maintains stable performance with an execution time of approximately 0.40 seconds. Whereas the k-means algorithm reaches a timeout. While Louvain, Leiden, and Label Propagation algorithms require longer execution times. Overall, these results demonstrate the computational efficiency and

scalability of the proposed approach, particularly as network size increases.

V. CONCLUSION

This study presents a fuzzy logic–based approach for community detection that incorporates the semantic attributes of nodes in complex networks. Unlike classical community detection algorithms that primarily rely on topological metrics (e.g., centrality, clustering coefficients, or modularity), the proposed approach focuses on semantic properties of nodes to better capture complementary information that may be overlooked by topology-based approaches. By integrating fuzzy logic with multi-criteria decision-making techniques [19], the proposed approach addresses the uncertainty and ambiguity associated with semantic attributes. Furthermore, the proposed approach extends the standard k-means algorithm by adapting it to large-scale networks.

Experimental results show that the proposed method achieves competitive performance across the evaluated community-quality metrics compared with five well-known community detection algorithms on large-scale networks. The approach identifies meaningful and balanced community structures within a reasonable execution time. Overall, these findings highlight the efficiency and adaptability of the proposed fuzzy logic approach in environments characterized by uncertainty, high-dimensional attributes, and large network sizes.

Despite these promising results, some limitations remain to be addressed in future work. The current evaluation is based on synthetic network datasets, and further validation on longer and more diverse real-world attributed networks is required. Future work will extend the evaluation using standard community-quality metrics, including Modularity, NMI, ARI, and Silhouette Score, where applicable, while investigating adaptive fuzzy membership and MCDM weighting mechanisms, richer semantic representations, and real-world network structures.

Zarqa University, Department of Business Information Technology, Zarqa, Jordan

***Abstract*—The purpose of the present study was to assess the effect of Big Data Analytics capabilities on employees' creative behavior in the Jordanian service sector and to explore the mediating influence of employee curiosity and the moderating influence of top management support. The proposed model was developed using an integrative theoretical framework, namely the knowledge-based view (KBV) and Self-Determination Theory (SDT), to understand how knowledge resources translate into creative behaviors through psychological motivations and organizational context. Data for this quantitative research were collected from a population of 326 employees working in SMEs operating in the Jordanian service sector. Statistical analysis of the collected data was performed using Partial Least Squares Structural Equation Modeling (PLS-SEM). The findings have confirmed the direct positive influence of big data analytics capabilities on creative behavior, alongside an indirect one via employee curiosity as a mediating factor. It was also found that senior management support has a negative moderating effect on the relationship between big data analytics capabilities and employee curiosity. This research study adds value to the body of knowledge by combining two theoretical frameworks that relate cognitive resources, psychological motivations, and organization in the explanation of creativity in the digital business context.**

Keywords*—Big data analytics; employee creative behavior; curiosity; management support; the knowledge-based view and self-determination theory

I. Introduction

Considering the rapid digital revolution that is currently happening in the world of international business, big data analytics has become one of the key resources that are essential to operations, effectiveness, and execution [1]. Nowadays, data has become the basis through which creative performance can be achieved in organizations, especially in the field of services, where human capital becomes the main tool for delivering value [2].

It should be noted that the service sector in Jordan and its SMEs offer a perfect platform to learn how to use technical abilities to generate proactive results, such as innovative ones [3]. Nevertheless, the knowledge about the influence of big data analytics on creativity, especially under appropriate conditions, needs to be further developed. It is also critical to study the various levels of digital readiness required to achieve excellence in comparison with developed nations.

This significance is associated with the gap theory of knowledge, which suggests that knowledge is the most precious resource of the enterprise; therefore, creating and applying knowledge should be a mutual task [4]. Thus, from this perspective, big data analytics is not a set of technical possibilities, but rather a system that allows the organization to turn data into knowledge to improve the ability of its staff to think creatively and rationally [5].

Nevertheless, the conversion of such resources into creative products requires special efforts, as it is conditioned by internal psychological factors specific to the individual. That is why self-determination theory becomes very important in this situation, since it states that the key motivation to engage in creativity is internal, based on curiosity, exploration, capability, and freedom [6]. In simple terms, an employee's curiosity is a psychological factor that helps him/her to use data to develop creativity.

In addition, the arrangement of the working environment itself can have an equally crucial impact on how these relations are established. Depending on how support from top management is exercised, this support will either strengthen or weaken the above processes [7]. Empowering support will foster empowerment and encourage employees to explore, whereas directed support may not limit freedom as much as intrinsic support does, thereby influencing curiosity levels in the organizational context [8]. For that purpose, the goal of this study is to examine the potential abilities of data analytics to catalyze creativity in the Jordanian service sector. In particular, this will be done through investigating the modern mediating effect of employee curiosity as well as the position held by top management in a unified framework consisting of both epistemological and motivational theories.

II. Literature Review

A. Employee Curiosity and Creative Behavior

One of the most important psychological factors behind the phenomenon of creativity in business organizations is employee curiosity [9]. This is because curiosity implies the nature of human beings to be explorative in nature, to understand the phenomena around them, and to experiment with new and different ideas or ways of doing things. Thus, curiosity broadens the perspective of an employee and allows him or her to think of innovative solutions to organizational problems [10].

From the theoretical point of view, the above link between employee curiosity and organizational creativity can be understood in the light of Self-Determination Theory (SDT). As per SDT, curiosity, being one of the intrinsic motivating factors, helps individuals become mentally flexible and generate new innovative ideas [11]. Additionally, curiosity drives individuals to constantly pursue knowledge, test out new ways of doing things, and engage in contact with multiple sources of information. It results in the creation of cognitive experience that can eventually be integrated into the formation of innovative solutions to problems. Cognitive diversity resulting from it is arguably one of the most essential elements that stimulate creativity within today's complicated working environment.

On the other hand, individuals who possess curiosity are inclined to be more courageous intellectually, experiment, and play around with ideas. Intellectual risk-taking and experimenting are among those activities associated with creativity. In essence, curiosity directly contributes to an individual's exploratory behavior, which results in innovation [9].

In an organizational setting, individuals who possess high levels of curiosity frequently play a role in enhancing organizational processes, services, and innovations in relation to organizational problems. This implies that curiosity is not just an individual's characteristic but rather a behavioral resource that facilitates creativity at work.

Thus, it can be argued that the effect of curiosity on employee creativity lies in enhancing the breadth of thought, encouraging exploratory behavior, and engaging in experimentation.

H1: There is a positive relationship between employee curiosity and creative behavior

B. Big Data Analytics and Employee Curiosity

This implies that the curiosity of the employee is a key element in motivating people to explore and question in order to gather knowledge about the surroundings. With the development of modern workplaces, the curiosity of employees is one of the factors that influence how employees relate to the vast amount of information available to them.

The use of big data analytics plays a major role in enhancing the curiosity of the employee by ensuring that the working environment is information-rich and full of analytics [12]. With the availability of information and data, junior employees become curious about the information present and make an effort to analyze the data at hand. Such action results in more data being generated, leading the employee to look out for announcements, thus increasing their curiosity [12].

This is the point when the theory of self-motivation (self-determination theory) becomes an important factor in fostering curiosity, combined with the presence of information from a cultural perspective and the competence and independence of our employees [13]. Once employees see that they can analyze data and understand their work, they become more motivated to learn continuously. Moreover, the implementation of powerful data analytics technologies like interactive dashboards and artificial intelligence fosters interaction between the employees and data. In turn, it promotes greater engagement and constant questioning of the findings and phenomena.

Moreover, an organizational setting that highly depends on big data is likely to encourage workers to engage in data exploration on their own, rather than depend only on the pre-made reports. This results in cultivating a sense of curiosity among workers. From this perspective, it could be stated that the ability to conduct data analysis is significantly more effective in promoting employee curiosity through an environment rich in information and interactions with data.

H2: There is a positive relationship between big data analytics and employee curiosity

C. The Moderating Role of Top Management

The results showed that senior management support plays a moderating role in the relationship between big data analytics capabilities and employee curiosity, suggesting that the impact of analytical capabilities depends not only on the availability of technology and data but is also influenced by the organizational environment provided by senior management. This finding is consistent with previous studies that have emphasized the importance of senior management support in creating a suitable environment for leveraging data analytics capabilities [14].

This result can be explained in light of self-determination theory, where forms of support that promote employee autonomy contribute to the development of intrinsically motivated behaviors, such as curiosity and exploration. When senior management provides the necessary resources, access to data, and encourages the free use of analytical tools, employees become more capable and willing to explore information and search for new patterns, thus strengthening the impact of big data analytics capabilities on their curiosity.

Conversely, controlling or centralized support may limit employee autonomy and reduce their desire to explore. Therefore, the result demonstrates that how senior management support is provided is just as important as the support itself, and that a managerial environment that fosters autonomy can enhance the behavioral value of big data analytics capabilities. Thus, the study provides evidence that senior management support is an important organizational factor in transforming analytical abilities into higher levels of employee curiosity.

H3: Top management moderates the relationship between big data analytics and employee curiosity

D. The Mediating Role of Employee Curiosity

Curiosity stands for the psychological intermediary between the capabilities of big data analytics and creative activities performed by employees. Although KBV offers knowledge necessary for analyzing and accessing the data [15,16], SDT explains how this knowledge becomes converted into actions through intrinsic motivation.

Thus, big data analytics do not have a direct effect on generating creativity, but their initial effect involves stimulating employee curiosity. This will make the employee interested in the data and motivated to discover new relationships and think up innovative solutions based on them [17,18].

H4: Employee Curiosity will mediate the relationship between big data analytics and creative behavior.

III. Methodology of Study

A. Conceptual Framework

This research study identifies and evaluates the effect of big data analytics on the creativity of employees, considering the effect of employee curiosity as a mediator and senior management support as a moderator in both large and small organizations within the service industry of Jordan. The conceptual framework of a cause-and-effect model states that there is a direct effect of big data analytics on academic performance, together with an indirect effect mediated by the curiosity of employees (Fig. 1).

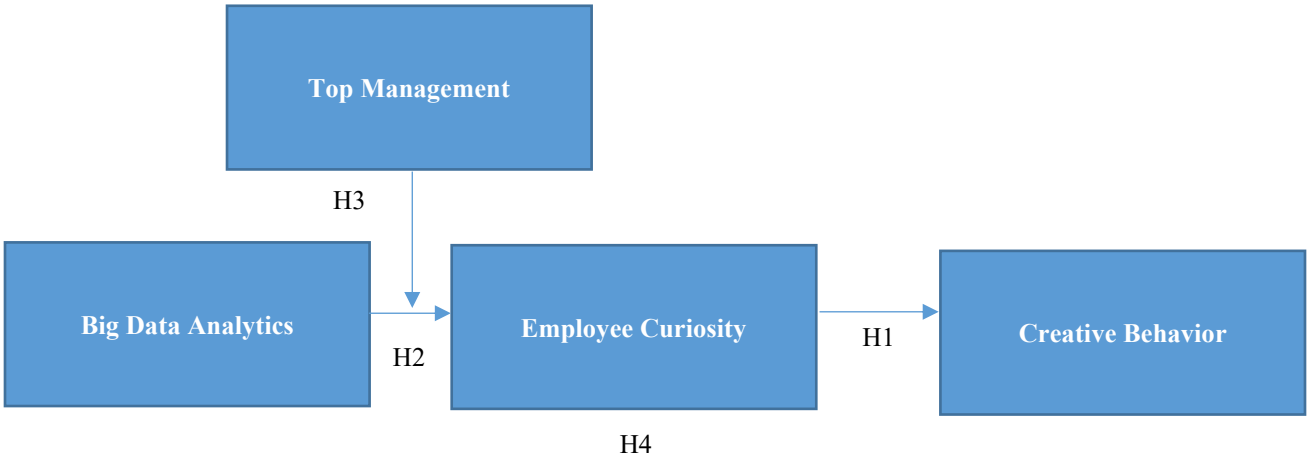

Fig. 1. Conceptual framework.

B. Design of Research

This type of research adopts a quantitative design with a descriptive analytical technique. This design is appropriate since the purpose of this research study is to test the relationships between variables of interest. A cross-sectional design has also been used, where information was collected from employees in both big and small firms operating within the service industry in Jordan at a single point in time.

C. Study Population and Sample

The study population comprised employees from small and large companies operating in the service sector in the Hashemite Kingdom of Jordan, given the increasing role of big data analytics in supporting operations and decision-making within this sector. Due to the lack of a comprehensive review framework, a non-probability convenience sampling method was employed, selecting key participants based on feasibility and availability. Sample size was confirmed, and a statistical power analysis was performed using G*Power software before model testing. Based on the number of predictors in the simple model, the significance level ($\alpha = 0.05$), and the baseline statistical power ($1-\beta = 0.80$), the analysis revealed that the required threshold for sample size was less than the actual sample size of 326 cancellations. Therefore, the statistical overshoot size used was the required size, representing statistical power relevant to the relationships and pathways in the proposed model. After excluding incomplete responses, 326 valid responses were selected for final analysis.

D. Measurement

The variance in studies has been conducted via a questionnaire that was designed based on some criteria that have been followed in earlier studies, but with slight changes depending on the service sector in Jordan. The main constructs used in the survey include big data analytics skills, employee curiosity, management support, and creative behavior. All variables were analyzed using a Likert scale from 1 to 5, owing to research advancements in statistics.

E. Partial Least Squares (PLS-SEM)

Data analysis employed partial least squares structural equation modeling (PLS-SEM), with the use of the SmartPLS software program. PLS-SEM was deemed appropriate for the analysis due to the fact that it is preferred for natural complex analyses where there was involvement of several mediator variables, and due to the fact that it can measure average mean values without requiring a negative distribution.

The analysis has been carried out in two electronic phases. In the first phase, there was a test to evaluate the measurement model through convergent and construct validity and assessing internal consistency using Cronbach's alpha, composite reliability, and average extracted variance (AVE). In the second phase, evaluation of the structural model was done through analysis of path coefficients, coefficient of determination (R^2), effect size (f^2), and diagnostics (Q^2).

IV. Results

A. Collinearity Analysis

Multiple correlations among innovations in the model were considered with respect to the Variance Inflation Factor (VIF) approach, which could be used to verify the presence or absence of any high correlation, making the model invalid. The results showed that all the values of the Variance Inflation Factor remained well within the scope of statistics, ranging from 1.950 to 2.410, but just below 5.000. Therefore, there was no multicollinearity problem in the data to apply the SEM approach (Table I).

TABLE I. INNER VIF VALUES

	Employee Curiosity	Creative Behavior
Employee Curiosity		1.000
Creative Behavior	1.114	
Top Management	1.073	
Big Data Analytics	1.150	

B. Assessment of Measurement Model

Initial analysis of the measurement model was carried out through validation and reliability of the instruments used in the study by analyzing Cronbach's alpha, composite reliability (CR), and mean variance (AVE) (Table II). All the acquisition levels surpassed the basic minimums, providing internal validity and reliability close to those of the instrument.

The validity of the discrimination between the study variables was analyzed using the Fornell–Larcker criterion by comparing the square root of the extracted mean variance (√AVE) with the correlation coefficients between the variables (Table III). The results showed that √AVE values were higher than most of the correlation coefficients between the variables, with a relatively high correlation between big data analytics and employee curiosity. To further validate the discrimination, the HTMT criterion was used, where all values were below the acceptable threshold (0.85), ranging from 0.331 to 0.824, with the highest value (0.824) between big data analytics and employee curiosity (Table IV). These results indicate acceptable discrimination between the study variables and no high overlap between them, supporting the validity of the measurement model.

TABLE II. ASSESSMENT OF MEASUREMENT MODEL

Construct	Items (15)	Loading Factors	Cronbach's Alpha	Composite Reliability	AVE
Employee Curiosity	3	(0.700-0.807)	0.552	0.908	0.887
Creative Behavior	3	(0.739-0.871)	0.637	0.840	0.718
Top Management	3	(0.760-0.840)	0.649	0.847	0.732
Big Data Analytics	3	(0.851-0.932)	0.809	0.927	0.882

TABLE III. THE FOURNELL-LARKER CRITERIA

	Employee Curiosity	Creative Behavior	Top Management	Big Data Analytics
Employee Curiosity	0.743			
Creative Behavior	0.483	0.798		
Top Management	0.449	0.287	0.805	
Big Data Analytics	0.812	0.390	0.276	0.900

TABLE IV. HTMT CRITERION

	Employee Curiosity	Creative Behavior	Top Management	Big Data Analytics
Employee Curiosity	-			
Creative Behavior	0.612	-		
Top Management	0.571	0.354	-	
Big Data Analytics	0.824	0.468	0.331	-

C. Structural Model

The explanatory power of the model was assessed using the coefficient of determination (R^2). The R^2 value for creative behavior was 0.233, meaning that the model's independent variables explain approximately 23.3% of the variance in creative behavior, while they explain 72.8% of the variance in employee curiosity (R^2 = 0.728) (Table V). These results indicate that the model has high explanatory power for employee curiosity, while its ability to explain creative behavior is relatively limited. This is attributed to the fact that creative behavior is influenced by a wide range of individual, organizational, and contextual factors, not all of which may be covered by the current model. Therefore, the R^2 value of 0.233 does not necessarily indicate a weakness in the model, but rather suggests the presence of additional factors that may contribute to explaining creative behavior. Furthermore, the Q^2 values were greater than zero, confirming the model's predictive power with respect to internal variables.

TABLE V. R SQUARE

	R^2	Q^2
Creative Behavior	0.233	0.13
Employee Curiosity	0.728	0.35

From the results obtained, there was a positive and significant impact of big data analytics capability on creative behavior. Also, the results indicated that there was a positive influence on the behavior of curiosity among employees. Additionally, it is clear from the results that employee curiosity positively and significantly influenced creative behavior. It is clear that the senior management's supportive role negatively moderates the relationship between big data analytics capabilities and employee curiosity because the support reduces curiosity among the employees (Table VI).

TABLE VI. ASSESSMENT OF THE STRUCTURAL MODEL (PLS REGRESSION)

		β	t-value	p-value	f^2	Support
Direct effect	H1: Employee Curiosity → Creative Behavior	0.483	9.516	0.000	0.304	Supported
	H2: Big Data Analytics → Employee Curiosity	0.713	25.604	0.000	0.626	Supported
Moderate effect	H3: Moderator effect 1 (Top Management)	-0.120	4.110	0.000	0.056	Supported
Indirect effect	H4: Big Data Analytics→ Employee Curiosity→ Creative Behavior	0.344	9.558	0.000	-	Supported

V. DISCUSSION

The results of the study showed the existence of a positive effect of big data analytics on the creativity of workers in the Jordanian services industry. This indicates the existence of analytical bodies and institutions that help encourage creativity among workers. The finding may be attributed to the knowledge-based resource approach, where knowledge acquired through data analysis plays an instrumental role in the creation of value independently of the data itself. It can be said that the more an organization has the ability to analyze data and start from it, the greater the capacity of its workers to come up with ideas and innovative approaches to solving specific issues.

In addition, the research showed that big data analytics has an encouraging impact on the development of the curiosity of employees due to the fact that the diversity of information plays a motivational part. Such motivation can be justified through the application of the self-motivation theory (also called self-determination theory). In this case, big data and analysis help create independent and skilled workers, thus stimulating them to engage in learning and exploration by themselves. The modern analysis of interactive information elements creates opportunities for collaboration among users who are encouraged to look for relationships among the elements under analysis.

Therefore, the curiosity of employees is positively related to behavioral creativity. The curiosity of employees results in their tendency to think innovatively and use alternative ways to solve problems. Such a situation can be well explained by the expansion-construction model, according to which curiosity enhances the capacity of a person to think broadly so that he/she can come up with various creative ideas. Moreover, curiosity contributes to lifelong learning and gaining experience.

On another note, employee curiosity acts as a mediator in aligning critical capabilities of data analytics with academics. What this suggests is that data, whose impact on universities is all-inclusive, is not simply a straightforward process but involves a psychological process within organizations based on curiosity. In essence, the capabilities of modern-day data analytics are wide-ranging and specific; however, translating the process into creativity relies on the level of employee curiosity. Employees with curious minds can easily interpret complex data, generate new ideas, and develop solutions based on the analysis, while artificial intelligence might just measure employee curiosity.

In this case, it was found that although senior management support, along with the extent of curiosity resulting from it, adversely affects the relationship among the capabilities, key data analysis, and employee curiosity, this support can lead to a situation where the employees develop a certain amount of curiosity that is more than required. This is because not all management support is enabling in nature, but can be supervisory and centralized in nature, which stimulates the explorative nature of the employees. As per the organizational climate theory, control environments lead to exploration and lack of internal focus, whereas supportive environments lead to curiosity.

Generally speaking, the quest for a correlation between data analytics and creative activities should not be regarded as static since there is a possibility that it may differ depending on the organizational context. In particular, big data analytics opens new opportunities for creative activities, while curiosity acts as a psychological factor that allows turning such capabilities into creative outcomes. At the same time, the management's attitude to such activities could act as a positive or negative determinant of the process depending on its style. Thus, this research study presents a much broader view of the issue in question.

VI. CONTRIBUTION OF STUDY

This research presents some valuable theoretical insights regarding the link between big data analytics capability and creativity among employees. First, the study helps fill a research void by incorporating employee curiosity into the research to act as a mediator in the causal pathway between the two constructs. Whereas existing studies have mainly examined the role of big data analytics from a technical point of view, few have sought to understand the psychological underpinnings of the link between the two constructs.

Secondly, the study makes use of various theoretical lenses, including knowledge-based view theory, self-determination theory, and broaden-and-build theory. The utilization of different theories allows for an understanding that creativity cannot be simply attributed to the availability of technical resources, but depends on motivational factors and supportive organizational environments.

Third, the research provides an important theoretical contribution regarding the moderating role played by the negative effect of support from senior management. The results indicate that support is not always considered a positively correlated factor, as in numerous past studies. Rather, it becomes a limiting factor in terms of promoting creativity within organizations when it involves elements of control and centralization. In addition, the theoretical contribution concerns the role of organizations in the processes of digital transformation in a broader context.

From the standpoint of practical significance, the study presents several recommendations for SME managers in the Jordanian services industry. The findings reveal that investing only in big data analytics skills and abilities will not promote

creativity in SMEs. Instead, the need for fostering such processes arises as long as the organizational context promotes curiosity and exploration. As a result, senior management should consider adopting an empowering approach that encourages workers to explore data freely, without restricting their actions to conventional means of processing information.

The article also shows the significance of developing curiosity in employees in order to use information as a means of innovation. It is possible to do so through proper training of the employees, fostering an environment where employees feel comfortable enough to ask questions and try out new things, and encouraging continuous learning. In addition, the findings also indicate the need for managers to review their approaches when supporting their employees, with an emphasis being placed on empowerment and encouragement.

VII. Conclusion

The purpose of this study was to investigate the effect of big data analytics capability on the creative behavior of the employees of the Jordanian service industry, as well as its mediating and moderating roles through curiosity of the employees and the support of the senior management. According to the findings, the big data analytics capability directly affects creative behavior and employee curiosity positively, and curiosity mediates its effect considerably.

On the other hand, the support of the senior management negatively moderates the relationship between the big data analytics capability and the curiosity of the employees. Thus, the non-empowering management practices prevent digital transformation from facilitating creativity in organizations. In summary, the current research highlights that modern organizational creativity depends on more aspects than technological advances and includes technical and psychological components.

With this in mind, the findings of the research reveal that for an organization to ensure creativity, it needs to create an environment where curiosity is cultivated, make sure that the big data analysis technique is used wisely, and shift the position of the managers in order to empower them rather than control them. This research paves the way for other researchers who may investigate the effects of other variables on the aforementioned relationships in the future.

GTA: Automated Semantic NLP-Based Generation of UML Activity Diagrams from Acceptance Criteria

Samia Nasiri[1]*, Salim Bloundi[2], Mohammed Lahmer[3]
ISIC Research Team, High School of Technology, Moulay Ismail University, Meknes, Morocco[1, 3]
Department of Mathematics and Computer Science, ENSAM, Moulay Ismail University, Meknes, Morocco[2]

***Abstract*—In agile development, user stories express stakeholder needs, and the associated acceptance criteria (AC), written in the Given/When/Then (GWT) notation, specify the behaviour expected of the system under stated preconditions. Their manual translation into UML activity diagrams is laborious and remains sensitive to wording differences between authors. Existing automated approaches rely on lexical matching or on grammatical rules. Both fail when an identical precondition is expressed through different wording, a case that occurs frequently in collaborative backlogs. This study introduces GTA (GWT-to-Activity), a deterministic pipeline that converts GWT AC into UML activity diagrams. The clause structure is first recovered through dependency parsing. Paraphrased *Given* states are then merged based on sentence embedding similarity using Sentence-BERT (SBERT), and natural language inference (NLI) is used to separate semantic opposition from lexical variation, with thresholds calibrated on annotated data to preserve output stability under paraphrastic variation. Eleven behavioural patterns are supported, from simple sequences to nested compound conditions. The pipeline was evaluated on 107 test sets containing 230 AC drawn from four heterogeneous corpora of synthetic, open-source, and benchmark origin, and it reaches a node F1-score of 99.26%, an edge F1-score of 97.37%, and an exact topological match rate of 95.33%. All eleven patterns are recovered, and every generated file is a valid PlantUML that requires no post-processing. The output is structurally correct, deterministic from one run to another, and traceable to the thresholds set at each gate.**

Keywords*—Behaviour-driven development; GWT acceptance criteria; UML activity diagrams; sentence-BERT; NLI; natural language processing; requirements engineering

I. Introduction

In agile projects, teams write requirements as user stories in natural language, and each story reflects a stakeholder need at a particular level of granularity. Every story is broken down into AC written in the Given-When-Then (GWT) template. This template comes from Behaviour-Driven Development (BDD) and is used in tools like Cucumber, JBehave, and SpecFlow [1] [2]. A GWT AC has three clauses conventionally defined. The Given clause sets the initial context of the scenario, namely the state of the system, the available data, and any prior conditions. The When clause identifies the event that takes place, whether triggered by the user, raised by another system, or fired by a timer. The Then clause reports the externally visible outcome of the event. The fact that a GWT AC is both executable and human-readable allows a single artefact to serve as a business requirement, an implementation specification, and an automated acceptance test.

*Corresponding author.

Producing a UML activity diagram from a set of GWT ACs is not a trivial task. The analyst has to identify shared preconditions, separate conditional branches from parallel actions, and rebuild the story's sequential flow, even when its wording has drifted across successive sprints. In most projects, this translation remains a manual task, which makes it time-consuming and prone to inconsistency. When it is not carried out or updated, a traceability gap grows between requirements and design artefacts [3].

Existing approaches to activity diagram generation rely either on syntactic heuristic rules applied to informal text [4], [5], [6], which lack semantic understanding and do not accept GWT structured input, or on LLM-based generation of process models from free-form process descriptions [7], which does not target structured AC and does not define a behavioural pattern taxonomy comparable to the one adopted in this work. None of these methods addresses the paraphrastic variability that arises when the same precondition is expressed differently across AC, a situation that is common in collaborative backlogs. This gap motivates the approach presented in this study.

Previous work [8] proposed an initial automated approach using Stanford CoreNLP for natural language preprocessing and Prolog rules for pattern extraction, generating PlantUML activity diagrams from GWT AC. That work demonstrated the feasibility of the task and achieved Recall of 97% and Precision of 94% on two banking-domain case studies. However, the evaluation exposed three limitations: decision-node detection relied on WordNet antonyms, failing for implicit negations and indirect oppositions; Given-state grouping assumed identical phrasing across AC, with no mechanism for phrasing variability; and the pattern taxonomy covered only three structural forms: sequence, fork, and binary decision.

This study addresses these limitations through a redesigned pipeline whose main contributions are:

- A hybrid semantic layer that combines syntactic dependency parsing with sentence embedding and natural language inference, in place of the rule-based semantic reasoning of the previous approach.
- A Given-state grouping mechanism whose outcome is stable across variations in authorship and wording.
- A behavioural pattern taxonomy covering eleven patterns, including loops, multi-branch decisions, conjunctive Then-clauses, asymmetric branches, independent parallel flows, and nested compound

conditions, each associated with a PlantUML generation rule.

- A systematic evaluation on 107 test sets covering 230 AC from 9 application domains, complemented by a phrasing-invariance benchmark and by an external validation on Cucumber feature files from public GitHub repositories.

The pipeline is evaluated on 107 test sets covering 230 AC drawn from four corpora and achieves a graph-level Node F1-score of 99.26%, an Edge F1-score of 97.37%, and an exact topological match rate of 95.3%.

The remainder of this study is organised as follows. Section II reviews related work. Section III presents background on the GWT format and PlantUML notation. Section IV describes the proposed pipeline. Section V reports the evaluation. Section VI discusses the results. Section VII concludes and outlines future work.

II. Related Work

A. UML Generation from Natural Language

NLP techniques have been applied to convert textual specifications into UML artefacts. Class diagrams are generated from textual requirements through linguistic analysis in [9] and from user stories in [10]. Earlier work [11] extracted use case, class, and package diagrams from user stories, then refined them through an ontological model. Sequence diagrams are derived from user stories in [12] by combining generative AI with rule-based methods. A survey by the authors of [13] reports that most approaches in this line of work remain semi-automatic, rely on handcrafted rules or predefined templates, and concentrate on structural rather than behavioural diagrams.

B. Activity Diagram Generation from Natural Language

The extraction of activity diagrams is more difficult than that of class diagrams. The control flow that these diagrams represent is sensitive to the way each behaviour is phrased, particularly for branching and iteration constructs, and this sensitivity increases when several behaviours are composed. Few approaches address this problem. In [14], activity diagrams are generated from Arabic user requirements through the MADA-TOKAN parser and heuristic rules over verbal and conditional sentence grammars. The method is not implemented on real cases, is language-specific, and requires strict input formatting. In [15], the SBVR2ACTIVITY tool maps SBVR specifications to activity diagrams through a POS tagger and transformation rules. Its applicability is bounded by the requirement that the input be written in SBVR notation. In [16], activity and use case diagrams are generated from informal natural language through sixteen syntactic reconstruction rules followed by Stanford CoreNLP analysis. Decisions are detected only when explicit conditional particles appear in the text; fork and join constructs are not handled, and the analysis remains at the part-of-speech level.

To the best of current knowledge, previous work [8] is the only reported approach that generates UML activity diagrams from GWT AC. It belongs to the family of rule-based text-to-model methods that use lexical resources for semantic reasoning and treat the input as a symbolic surface. Its pattern taxonomy, limited to three structural forms, is characteristic of first-generation pipelines. The three limitations of that work, listed in the introduction, are addressed by the semantic pipeline proposed in this study.

C. LLM-Based Approaches for Model Generation

The Transformer architecture [17], [18] has been applied to software engineering tasks that include UML generation, mostly on structural diagrams [12]. Few studies have applied it to activity diagram generation from GWT specifications. Sequence diagrams are generated from requirements through single-invocation prompting with GPT-3.5 and GPT-4 in [19], with an expert-based evaluation limited to completeness and correctness. A multi-step iterative pipeline for domain model extraction is proposed in [20]. The approach targets structural models and is evaluated by a single author. In [21], multiple candidate models produced by LLMs are aggregated into a probabilistic partial model and reduced to a single diagram through an optimisation solver; the evaluation is conducted on taxonomies and flowcharts rather than on activity diagrams derived from structured requirements. LADEX [22] targets activity diagram generation through a critique-and-refine loop that iteratively checks structural and alignment constraints. Fork and join are represented as ordinary action nodes, so parallel execution is not modelled. The best variant reaches 86% correctness and 92% completeness at an average cost of 4.91 LLM calls per generation. LADEX operates on free-form process descriptions rather than on structured AC and does not define an explicit pattern taxonomy. The evaluation used two datasets: 200 entries from the public PAGED dataset [23] and 20 industrial documents from Ciena, tested with three LLMs (GPT-4.1 Mini, O4 Mini, and DeepSeek-R1-Distill-Llama-70B).

D. UML Datasets and AI-Assisted Modelling

Datasets available for UML remain modest in size compared to those developed for NLP or computer vision [24]. An annotated image dataset for diagram recognition is released in [25], and ModelSet [26] provides a structural corpus of models intended for machine learning experiments in model-driven engineering. Neither dataset, however, contains behavioural diagrams. A different line of work is followed in [27], where thousands of UML diagrams from several diagram families are generated using LLMs and Vision-Language Models, then checked for syntactic and semantic correctness; the objective there is dataset synthesis, not requirement-driven generation. LLMs have also been used for other UML tasks, in particular the generation of UML diagrams from images [28] and the generation of method bodies from class diagrams [29].

E. Research Gap

Existing work concentrates on structural diagrams and leaves activity diagrams underrepresented. NLP-based methods for activity diagrams [14], [15], [16] rely on syntactic heuristics without a semantic component and are tied to specific input styles. LLM-based approaches [19], [22] handle semantic variability but operate on free-form text, define no explicit pattern taxonomy, and offer no reproducibility guarantee. No existing study addresses the automatic generation of activity

diagrams from Given/When/Then AC through a deterministic pipeline that combines syntactic and semantic analysis.

III. Background

A. The Given/When/Then Format in BDD

The GWT template splits an AC into three clauses: a Given clause that fixes a precondition on the system, a When clause that names the action triggering the behaviour, and a Then clause that gives the expected outcome. Cucumber [2] embeds this template in the Gherkin DSL, so that criteria written in Given-When-Then form become executable test scripts without further translation. A user story is usually specified by a set of such criteria produced collaboratively within the team.

B. Composition of AC Within a User Story

The AC of a single user story tends to follow a small number of composition patterns. Several criteria often share the same Given clause and differ only in their When/Then pairs, so each pair encodes one branch of a decision. Two criteria can also be linked in sequence, with the Then clause of the first providing the precondition of the second, or they can describe parallel flows within a single story, though this last case is rare in practice.

The formulation of the Given clause itself varies considerably. In production BDD files, the same underlying state is often written in different words from one iteration to the next. For example, “user is not authenticated”, “the user has not yet logged in”, and "no active session exists" all refer to the same precondition. The converse situation occurs just as often, since two clauses that look syntactically similar can in fact describe opposite states. The pipeline presented in this study is built to recognise equivalence in the first situation and to preserve the distinction in the second.

C. PlantUML Activity Diagram Constructs

PlantUML is a textual notation for describing UML diagrams, adopted in this work for the emission of activity diagrams. Each activity diagram construct corresponds to a specific PlantUML keyword or syntactic block. Table I lists the constructs used by the pipeline together with their PlantUML representation.

TABLE I. PlantUML Activity Diagram Constructs with Their Standard UML Notation

Construct	UML Notation	PlantUML Syntax	Description
Sequential Action	action	:action_label;	Rounded rectangle node
Conditional Branch	cond? [yes] [no]	if (cond) then (yes) ... else (no) ... endif	Diamond with true/false branches
Multi-branch Switch	switch	switch (subj) case (v1) ... endswitch	Diamond with 3 and guarded branches
Parallel Fork / Join		fork ... fork again ... end fork	Thick bars with concurrent flows
Loop	body	repeat :body; repeat while (cond?)	Backward-testing loop with exit condition
Flow Boundary	start stop	start/stop	Filled circle (start) and bull’s-eye (stop)

IV. Proposed Approach

A. Architecture Overview

This section presents GWT-to-Activity (GTA), a deterministic pipeline that converts GWT AC into syntactically valid UML activity diagrams expressed in the PlantUML notation. The overall architecture is organised in five sequential steps, shown in Fig. 1. Each step is described in the following subsections.

In the first step, action labels are extracted, and compound clauses are decomposed by dependency parsing. In the second step, criteria that share the same Given state are grouped by means of semantic similarity and natural language inference. In the third step, duplicate When clauses are identified within each group, and cross-group chains, in which the Then clause of one group corresponds to the Given clause of another, are detected. In the fourth step, each group is classified into one of eleven behavioural patterns. In the fifth step, the recognised pattern is translated into PlantUML syntax through dedicated template emitters.

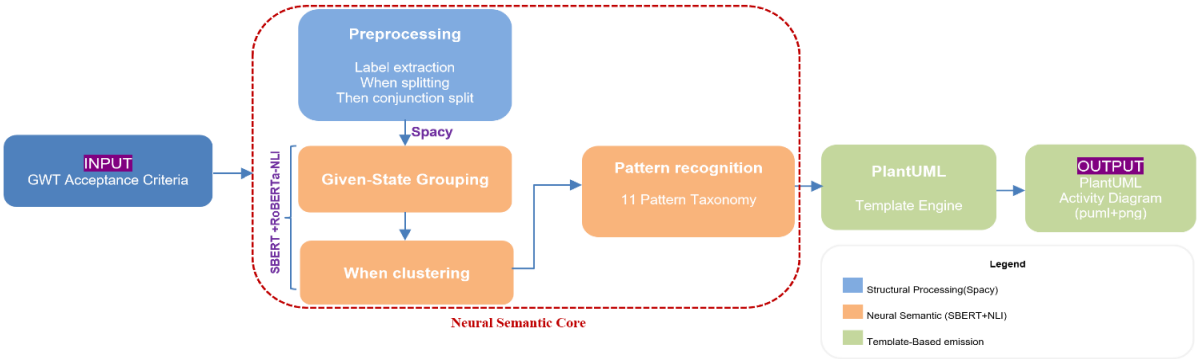

Fig. 1. Architecture of the proposed pipeline.

The pipeline is implemented in Python on top of three pre-trained NLP components: spaCy for part-of-speech tagging and dependency parsing, Sentence-BERT for semantic similarity computation, and RoBERTa for natural language inference, producing entailment and contradiction probabilities that drive both the grouping and decision-detection stages. Steps 1 and 5

are structural, handling tokenisation and text generation without any semantic inference; steps 2, 3, and 4 perform all grouping, clustering, and classification, each relying on these Transformer models.

B. Preprocessing

Each AC is preprocessed in three operations. First, then clauses are cleaned by removing determiners, auxiliaries, and pronouns, and labels exceeding a length limit are reduced to a skeleton via dependency parsing. Second, compound When clauses are handled at the preprocessing stage. A statement like "enters username and clicks login" contains two actions performed one after the other, so the pipeline separates them into two individual action nodes rather than treating them as a single event. Third, coordinating conjunctions in the Then clause receive a different treatment. When the outcome takes the form "A, B, and C", the three items are read as parallel effects rather than as a sequence, and the pipeline emits a fork construct with one outgoing branch for each item.

C. Three-Gate Given-State Grouping

Given-state grouping identifies the ACs that share a precondition state and must be rendered within the same diagram block. Merging clauses that describe different states, or splitting clauses that describe the same state, produces structurally invalid diagrams and accounts for most of the errors reported in rule-based approaches [13]. In this pipeline, each pair of Given clauses (a, b) is examined through three successive gates.

- Gate 1: SBERT Pre-filter (*threshold $\theta_1 = 0.45$*). The cosine similarity of the sentence embeddings of a and b is computed. If the score falls below a pre-filter threshold θ_1, the pair is rejected without invoking the Natural Language Inference (NLI) model. This gate is deliberately permissive: it eliminates clearly unrelated sentences while allowing lexically distant paraphrases to reach Gate 3.
- Gate 2: Near-identical shortcut (threshold θ_2= 0.95). Pairs scoring above a near-identical threshold θ_2 are accepted immediately. This handles the common case where two criteria carry the same Given clause verbatim or with minor token differences.
- Gate 3: NLI decisive analysis (decision threshold δ^* = 0.00). For pairs in the similarity range [0.45, 0.95], RoBERTa is invoked bidirectionally to obtain entailment scores (e_{ab}, e_{ba}) and contradiction scores (c_{ab}, c_{ba}). The net margin *S* is computed as:

$$S = (e_{ab} + e_{ba})/2 - \max(c_{ab}, c_{ba}) \quad (1)$$

A pair takes the label SAME_STATE if *S* is greater than δ^*, meaning that its two clauses correspond to the same precondition state; otherwise it takes the label DIFFERENT_STATE, and the two preconditions are counted as semantically distinct. The two entailment scores from the two inference directions are combined by their arithmetic mean, not by their minimum. Paraphrastic relations are frequently asymmetric, as illustrated by the pair "user is logged out" and "user has not yet authenticated": the entailment score is 0.97 in one direction and 0.002 in the reverse direction. The mean of the two directions yields a value of 0.45 for S, which assigns the pair to SAME_STATE in accordance with the gold annotation, whereas the minimum would produce −0.04 and separate the two clauses into distinct classes. Contradiction scores follow the inverse aggregation rule and are combined through the maximum of the two directions. Under this rule, a single direction with a strong contradiction score is sufficient to reject the pair, and clauses expressing opposed states are excluded from any common group. The threshold δ^* was calibrated through grid search over the interval [0.00, 0.60] with a step of 0.05, using a balanced gold standard of 96 pairs (48 SAME_STATE and 48 DIFFERENT_STATE); the outcome of this calibration is reported in Table II. Gates 1 and 2 use literature-informed thresholds ($\theta_1 = 0.45$, $\theta_2 = 0.95$) [30] and were not recalibrated on this dataset.

A high entailment score alone does not justify grouping two Given clauses. Two sentences with the same surface pattern can refer to different domain entities, in which case NLI models still return a moderate entailment score. The contradiction term guards against these FPs: if either inference direction yields a strong contradiction, *S* falls below δ^*, and the two clauses stay apart. Once each pair has been decided, the Given clauses are grouped into the connected components of the undirected graph associated with the three-gate criterion. The grouping is transitive by construction: if A matches B and B matches C, then A, B, and C fall in the same group, even if the pair (A, C) fails the acceptance threshold. Transitivity is intentional, since acceptance criteria written collaboratively often go through successive rewordings that the algorithm needs to reconcile into a single state. The resulting partition is also independent of input order, because connected components are fully determined by the edge set of the graph, not by the traversal sequence. This invariance was verified empirically by running each test set through the pipeline 100 times with the AC shuffled at each run; the partitions produced were identical across all runs.

TABLE II. GATE 3 THRESHOLD CALIBRATION: SETUP AND OPTIMAL OUTCOME ON THE 96-PAIR GOLD STANDARD DATASET

Parameter	Value
Dataset size	96 pairs (48 SAME_STATE and 48 DIFFERENT_STATE)
Search range	$\delta^* \in [0.00, 0.60]$, step = 0.05
Optimal δ^*	0.00
F1 score	97.96%
FP	2

D. When-Cluster Analysis and Decision Scoring

Within each Given group, every pair (a, b) of *When* clauses is examined to decide whether the two clauses correspond to alternative branches of a decision or to independent concurrent actions. The former requires a decision diamond, the latter a fork/join construct. This decision is made by the decision detection procedure, which applies a score gate defined by the following scoring function:

$$\text{score}(a, b) = C(a, b) + \alpha \times \text{Sim}(a, b) \quad (2)$$

where, C(a, b) is the RoBERTa contradiction probability for the pair and Sim(a, b) is the SBERT cosine similarity. The two

terms are complementary: contradiction captures semantic opposition between mutually exclusive branch conditions, while similarity confirms that both clauses operate in the same action domain.

The weight α and the classification threshold τ were calibrated by grid search over α ∈ [0.0, 3.0] in steps of 0.1 and τ ∈ [0.00, 3.00] in steps of 0.05, on a manually annotated gold set of 88 When-clause pairs, of which 77 are labelled DECISION and 11 are labelled FORK. The calibration selects α = 1.1 and τ = 0.50. A pair (a, b) is then classified as DECISION when score(a, b) ≥ τ and at least one marker of Table III applies. Comparison threshold patterns such as "more than N" or "at least K" form an exception: they trigger the DECISION classification alone, without passing through the score gate. Table III lists the four linguistic markers that confirm a DECISION classification, and Table IV reports the calibration results measured on the 88 When-clause pairs.

TABLE III. LINGUISTIC MARKERS FOR DECISION CLASSIFICATION

Marker	Detection
NLI contradiction	contradiction score ≥ 0.90 with an identical grammatical subject
Negation	spaCy dependency parsing combined with NLI zero-shot prototype matching against positive and negative reference sentences
Variant specialization	one *When* clause refines the other
Shared finite verb	The same finite verb occurs in both clauses

TABLE IV. DECISION SCORING PERFORMANCE ON THE 88-PAIR WHEN-CLAUSE GOLD SET

Metric	Value
F1	95.06%
Precision	90.60%
Recall	100%
FN	0
FP	8
Dataset	88 pairs (77 DECISION / 11 FORK)

Across all 88 gold set pairs, the calibrated function achieves a recall of 100% and produces no FN; therefore, no DECISION branch is classified as a FORK. This zero-FN calibration yields 8 FP and an accuracy of 90.6%.

E. Pattern Recognition and Structural Pattern Taxonomy

Through systematic analysis of the three evaluation corpora, eleven structural patterns (P1 to P11) were identified, which together cover the principal behavioural specifications. Table V summarises the patterns and their detection conditions.

The eleven patterns are organised into three behavioural families. The linear flow family groups the branchless patterns, that is P1, P2, and P8. Under P1, a single AC is expressed as a linear action sequence. P2 covers the case in which several ACs are chained together: the Then clause of one criterion is semantically equivalent to the Given clause of the next, and the pipeline exploits this equivalence to remove the intermediate state node from the resulting diagram. P8 is an asymmetric form of the chain, in which the binary decision contained inside the pattern has one branch that continues downstream while the other branch is a dead end and is closed by an explicit stop node.

TABLE V. STRUCTURAL PATTERN TAXONOMY WITH DETECTION SIGNALS

ID	Pattern	Structure	Detection Signal
P1	Simple Sequence	Linear chain	Single when clustered in a group
P2	Chain	Then-to-Given link	SBERT/NLI cross-group match
P3a	Decision:Opposition	if/else	NLI contradiction and negation markers
P3b	Decision: Variant	if/else	One When subsumes the other
P3c	Decision:Comparative	if/else	Comparison operators in When or Then
P4	Multi-branch Switch	switch/case	Three or more distinct When clauses sharing a common grammatical subject
P5	Fork / Join	Parallel independent actions	No semantic opposition or shared verb between When clauses
P6	Loop	repeat/while	SBERT(Then, Given) ≥ 0.85
P7	Conjunction in Then	fork from A, B, and C	Multiple verb clauses and parallelism keyword in Then
P8	Dead-end Branch	Asymmetric chain	Only one decision branch links to a subsequent Given
P9	Independent Flows	Separate start/stop	Disjoint Given groups with no chain link
P10	Arithmetic Operators	Numeric guard labels	Numeric comparison expression (>, ≥, <, ≤) in clause
P11	Nested Decision	Compound condition	AND conjunction between two stative conditions in When

The conditional branching family regroups the constructs built around a decision diamond, and it contains P3a, P3b, P3c, P4, and P11. Binary decisions occur in three forms, one per type of semantic relation between the two When clauses. P3a covers the case of pure opposition and yields if/else blocks with yes/no labels. P3b covers variant specialisation, in which one When clause refines the other, and it uses a descriptive else label rather than a generic one.P3c captures quantitative thresholds through a numeric comparison operator. P4 generalises the same idea to three or more mutually exclusive alternatives and emits a switch/case construct. P11 handles compound stative conditions, which are When clauses joining two independent sub-conditions, and renders them as nested if/endif blocks.

The remaining patterns cover concurrent execution, iteration, and structural isolation. P5 produces a fork/join construct when several When clauses within the same Given group correspond to semantically independent triggers running in parallel. P7 produces the same construct for a different reason: when a single Then clause lists several simultaneous outcomes. P6 captures loop semantics: the pattern is triggered when the Then clause re-establishes its own Given precondition, and the emitter produces a repeat/while structure. P9 applies when two or more Given groups have no semantic link between them; each group is then rendered as an independent flow. P10 is not a standalone pattern, but a label-level specialization applied to any

decision construct whose When clause contains a numeric comparison expression.

F. PlantUML Emission

Each recognised pattern is translated into syntactically valid PlantUML activity diagram notation by a template-based emitter. The emitter instantiates a fixed skeleton per pattern, substituting extracted labels into predefined slots.

Three emission rules apply to every branching pattern. First, branch ordering is deterministic: the affirmative (or non-negated) When clause always occupies the then (yes) branch, so diagram orientation does not depend on the order of the AC in the input. Second, the else label is chosen differently for P3a and P3b. If the minimum bilateral NLI contradiction score exceeds the decision threshold, the branch takes the generic (no) label; otherwise, the label reuses the descriptive text of the second When clause, since the two clauses describe variant specialisations of the same intent rather than opposite outcomes. Third, topological ordering is enforced between groups: when a group is the target of a chain link, we render it inline through a recursive depth-first traversal, so the sequential flow reads from top to bottom in the generated code. Every opened control structure is explicitly closed by the emitter.

V. Evaluation

A. Experimental Setup

The pipeline is implemented in Python 3.10. Dependency parsing uses spaCy with the en_core_web_sm model. Sentence similarity relies on Sentence-BERT (all-MiniLM-L6-v2, 80 MB). Natural language inference uses RoBERTa-large fine-tuned on MultiNLI (1.4 GB) [26]. All experiments were run on a standard laptop (Intel i7, 16 GB RAM, CPU only).

B. Dataset Construction

The proposed approach is evaluated on a dataset of 230 AC distributed across 107 AC sets drawn from four independent sources, summarised in Table VI. No existing public corpus covers the full range of target structural patterns: available Gherkin repositories on GitHub are dominated by simple sequences and basic decisions, with rare or no instances of patterns such as multi-branch switch (P4), Then-clause conjunction (P7), dead-end branches (P8), or nested decisions (P11). The dataset was therefore constructed incrementally from four complementary sources.

The Controlled Benchmark covers all eleven structural patterns P1 to P11 and includes seven sets drawn from the baseline [8], along with two adversarial robustness series: RB1, targeting paraphrase equivalence where semantically identical Given clauses are expressed with different surface forms, and RB2, targeting false similarity where lexically close Given clauses denote distinct states. The Real GitHub partition provides eight AC sets extracted verbatim from public open-source repositories [31], [32], [33], [34] with no modification, serving as an uncontrolled reference. After an initial evaluation on these two partitions, the need to strengthen the statistical reliability of per-pattern metrics for the most frequent patterns (P1, P2, P3a) motivated the addition of a third partition, the Synthetic DS, which increases the number of AC sets covering these common patterns. A fourth partition, the Paraphrase benchmark, was then added to specifically evaluate the pipeline robustness to paraphrased Given clauses and Then-to-Given transitions across consecutive AC, covering patterns P3a, P4, P5, P6, and P11 with semantically equivalent but lexically varied formulations.

TABLE VI. Benchmark Dataset Composition by Pattern

Dataset	Sub-group	Sets	AC	Patterns Covered
Controlled Benchmark	baseline [8]	7	14	P1, P3a, P3a+P6, P3b, P9
	Core patterns	36	85	P1–P11 (all eleven patterns)
	Robustness (RB1/RB2)	16	33	RB1, RB2 with P3a, P3c, P6, P7, P11
	Sub-total	**59**	**132**	
Real GitHub	—	8	20	P1, P3a, P4, P9
Synthetic DS	—	20	28	P1, P2, P3a
Paraphrase Benchmark	—	20	50	P3a, P4, P5, P6, P11
Total		**107**	**230**	

All sets in the Controlled Benchmark (except the baseline sets), in the Synthetic DS partition, and in the Paraphrase benchmark were initially drafted using a large language model, then manually reviewed, corrected, and validated by the authors. Each AC set was verified against two criteria: syntactic well-formedness in standard GWT notation and exact correspondence with the structural pattern assigned in the ground truth.

C. Evaluation Methodology

Two keyword lists in PlantUML syntax define the ground truth for each pattern. The first list holds the keywords that a correct diagram must contain; the second, the keywords that must not appear. Any match on the first list is scored as a True Positive (TP), and the absence of every keyword on that list is scored as a False Negative (FN). Symmetrically, any match on the second list is scored as a False Positive (FP), and the absence of every keyword on that list as a True Negative (TN). Detection is performed by substring matching on the PlantUML source, and Precision, Recall, F1, and Accuracy are then obtained from the four resulting counts. Aggregate values follow a micro-averaged scheme: the counts are pooled across all AC sets before the metrics are computed, so a set with more markers weighs proportionally more in the final scores. Table VII reports the overall classification results on the four datasets.

On the full 107-set benchmark, the pipeline reaches an F1 score of 98.57%, with 275 TPs, 2 FNs, 6 FPs, and a specificity of 97.6%. A True Negative means that a PlantUML construct that should not appear in the diagram is indeed absent from the generated output. In a simple sequence pattern (P1), for example, decision, fork, and loop constructs must all stay out of the output, and each construct correctly kept out adds one to the TN count. Both FNs come from the Baseline set, the only test case in the evaluation that combines several patterns within a single specification. In this case, the loop sub-structure is missing from the generated diagram because the sequential priority tree stops as soon as the decision construct is recognised,

before reaching the loop-detection step. Three FPs result from Given-state fork ambiguity, where asymmetric NLI entailment between consecutive preconditions causes the three-gate grouping to merge distinct states, leading the pattern recogniser to emit a fork construct. Two FPs arise from decision-boundary ambiguity, where opposed When clauses within a sequential pattern trigger the decision detection procedure. One FP is caused by loop-boundary ambiguity, where high SBERT similarity between a Then clause and its own Given state crosses the loop detection threshold. No FP was observed on the Real GitHub or Paraphrase DS partitions, indicating that these boundary cases are specific to controlled test formulations rather than real-world GWT specifications.

To complement this keyword-based evaluation, which cannot detect inverted branches or incorrectly connected transitions, each generated PlantUML diagram was parsed into a typed directed graph with node types START/END/ACTION/DECISION/SWITCH/FORK/JOIN/LOOP_START and edges carrying yes/no/case-value guards. An edge is counted as correct only when both of its endpoints and its condition match those of the reference graph. Across the 107 benchmark sets, this graph-level comparison yields a node F1 of 99.26% and an edge F1 of 97.37%, and 102 of the 107 generated diagrams (95.33%) are topologically exact matches to their references. Precision, Recall, F1, and Accuracy, together with the corresponding TP, FP, and FN values, are given per structural element in Table VIII.

The point estimates for Precision, Recall, F1, and Accuracy do not convey their sampling variability. To quantify this uncertainty, 95% confidence intervals (CIs) were computed using a non-parametric bootstrap [35] with B = 10,000 resamples. This procedure was performed at the level of test sets, not at the level of individual ACs, because ACs within a single set are not independent. The results are presented together in a single diagram. Resampling at the criterion level would therefore break this dependence and produce artificially narrow intervals. Table IX reports the point estimates of the structural metrics along with their 95% bootstrap intervals.

To illustrate the pipeline output, Table X presents representative generated activity diagrams alongside the corresponding AC sets and the detected pattern types. The selection covers five patterns spanning the four behavioural families of the taxonomy: P3a (binary decision), P4 (multi-branch switch), P6 (loop), P8 (dead-end branch), and P11 (nested decision).

TABLE VII. KEYWORD-LEVEL CLASSIFICATION PERFORMANCE ACROSS EVALUATION DATASETS

Dataset	Sets	AC	TP	FN	FP	TN	Precision	Recall	F1	Accuracy

Node F1	99.26%	[98.56%, 99.82%]
Edge F1	97.37%	[94.85%, 99.46%]
Exact-match rate	95.33%	[90.65%, 99.07%]

TABLE X. GENERATED ACTIVITY DIAGRAMS WITH THE CORRESPONDING ACCEPTANCE CRITERIA SETS AND DETECTED PATTERN TYPES

Pattern	Set AC	Generated Activity Diagram
P3a	**AC 1:** **Given**: A bank card has been inserted in the ATM. **When**: Customer enters the PIN, and the PIN is correct **Then**: The ATM main menu is displayed **AC 2:** **Given**: A bank card is present in the ATM card reader **When**: Customer enters the PIN, and the PIN is incorrect **Then**: Customer enters the PIN	
P4	**AC 1:** **Given:** Policy renewal date is reached **When:** Customer selects basic plan **Then:** Basic coverage is renewed at the standard rate **AC 2:** **Given:** Policy renewal date is reached **When:** Customer selects standard plan **Then:** Standard coverage is renewed with a 5% discount **AC 3:** **Given:** Policy renewal date is reached **When:** Customer selects premium plan **Then:** Full coverage is renewed with a personal advisor	
P6	**AC 1:** **Given:** User login attempt is in progress **When:** user enters the OTP code, and the OTP is invalid **Then: the** user is prompted to enter the OTP code **AC 2:** **Given:** User account is locked due to failed attempts **When:** lockout period expires **Then:** user is allowed to retry login	
P8	**AC 1:** **Given:** User enters the verification code **When:** Code is correct **Then:** User accesses the dashboard **AC 2:** **Given:** User enters the verification code **When:** Code is incorrect **Then:** Account is temporarily locked **AC 3:** **Given:** User accesses the dashboard **When:** User selects a project **Then:** Project workspace is loaded **AC 4:** **Given:** User accesses the dashboard **When:** User logs out **Then:** Session is terminated	

P11	**AC 1:** **Given**: User has selected a file for upload **When**: The file format is PDF, and the file size is under 5 MB **Then**: the file is stored successfully, and confirmation is shown **AC 2:** **Given**: A file has been chosen by the user for upload **When**: file format is not PDF or file size exceeds 5 MB **Then**: upload is rejected, and an error message is displayed	

VI. Discussion

A. Overall Performance

The proposed GTA pipeline achieves a global F1-score of 98.57% across all 107 test sets covering 230 AC. The recall reached by the pipeline (99.28%) is particularly important because a missed pattern feature (FN) produces a structurally incorrect diagram, whereas a spurious feature (FP) is generally less harmful. This result is supported by the calibrated decision scoring function, which achieves zero FN on the 88-pair When gold set, ensuring high recall at the pattern classification level.

Performance is consistent across the four dataset partitions: the Controlled Benchmark achieves an F1 score of 98.65%, the Real GitHub partition reaches 100%, the Synthetic DS 95.83%, and the SBERT Paraphrase benchmark 100%. The absence of a significant gap between the controlled and real-world partitions indicates that the approach generalizes beyond controlled benchmark settings. The Real GitHub partition exhibits inconsistent formatting, abbreviated vocabulary, and multi-author linguistic variation, conditions known to challenge rule-based and embedding-based systems, yet all eight sets are classified without error.

The graph-level structural evaluation applies a more demanding test than the keyword-level analysis on branch-assignment correctness. On the 107-set benchmark, DECISION nodes, which correspond most directly to branch assignment, are recovered with an F1 of 98.89%. The residual structural errors are all located in one confusion, between fork and sequential-chain constructs (FORK/JOIN F1 of 90.91% on 3 of the 107 sets), and are not uniformly distributed across the benchmark. This pattern suggests a localised limitation and not a systemic one. A dedicated gate to separate sequential chains from parallel forks is left for future work. In addition, 95.33% of the generated diagrams are topologically identical to their references, which establishes that the pipeline output is correct at the structural level, and not merely at the keyword level. The bootstrap confidence intervals for each partition are given in Table X. Their width depends on the number of test sets in the partition and should be read together with that number. The Real GitHub partition contains only 8 sets, which makes it the smallest of the four, and its intervals are consequently the widest. The maximum scores observed on this partition should therefore be interpreted with caution.

B. Comparison with the Baseline Reference Diagrams

In previous work [8], the authors report 47 TP, 1 FN, and 2 FP on a 7-set corpus, for Precision, Recall, and F1 of 95.92%, 97.92%, and 96.91%, respectively. A direct comparison with the GTA figures would be misleading, since the two evaluations operate at different granularities. The earlier framework counts each node and each edge of the diagram individually, while GTA checks whether specific PlantUML constructs are present in the output, namely if/else, fork/join, repeat/while, and switch/case. Despite this difference, a qualitative comparison on the shared baseline sets highlights three limitations of the prior approach that motivated the redesign.

The prior approach [8] groups Given clauses through exact token matching. Two developers writing the same precondition in slightly different words result in two distinct states, and the resulting diagram is split into unrelated fragments. In the proposed pipeline, SBERT similarity followed by RoBERTa NLI handles this case, and different wordings of the same precondition are grouped together without any lexical overlap. Decision detection in the earlier work [8] exhibits a comparable limitation. The reliance on WordNet antonymy and explicit negation covers only the oppositions expressed through common antonym pairs. In the present study, the pipeline integrates a decision scoring function based on contradiction and similarity signals with a set of complementary linguistic markers, and extends coverage to variant decisions (P3b), comparative decisions (P3c), and nested compound conditions (P11) beyond the binary opposition cases handled by lexical antonymy. Chain detection presents the same type of limitation. In the older algorithm, two ACs are linked only if the Then clause of the first is textually identical to the Given clause of the second. The pipeline replaces this strict textual match with an SBERT similarity computed between groups, and it turns to NLI entailment as a second stage whenever the similarity score alone is not sufficient to reach a decision.

The Cash Withdrawal set from [8] illustrates the practical impact. Its two Given clauses “account is in credit” and “account is overdrawn” refer to opposite states, but no entry in WordNet connects the words “credit” and “overdrawn”. The older

approach misses the opposition entirely and generates a fork-based structure in which the Then actions from both preconditions are executed on concurrent paths, rather than being placed in the two alternative branches of a decision. The NLI-based score used in the proposed pipeline recognizes the contradiction and outputs the decision diamond required by the AC, as shown in Fig. 2.

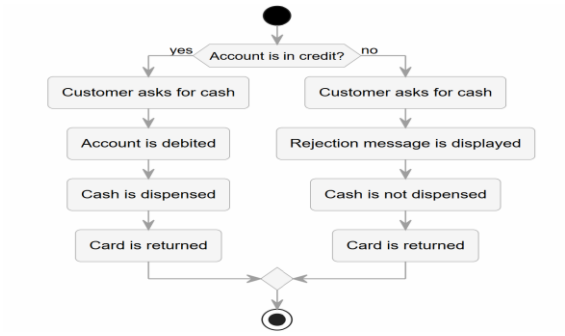

Fig. 2. Activity diagrams generated for the cash withdrawal specification.

On the seven shared baseline sets [8], the current pipeline achieves a precision of 100%, Recall of 90.48%, and F1 of 95%. The 2 FNs are confined to the ATM Transactions set, the only combined pattern (decision embedded in a loop), which the prior approach handles through direct syntactic rules but which is not addressed by the current pipeline. This trade-off is accepted for two reasons. First, the current pipeline covers eleven structural patterns compared to five in the prior approach [8]. Second, it generalises to paraphrased and linguistically varied inputs that the rule-based system cannot resolve.

C. NLI Selection

RoBERTa-large-MNLI was selected as the NLI component in Gate 3 after a systematic comparison with three alternative models on the full 107-set benchmark. All models were run under the same experimental configuration, with δ^* set to 0.00 and α set to 1.1, and no per-model threshold recalibration was applied. Table XI shows the results of the keyword-matching evaluation.

TABLE XI. KEYWORD-LEVEL NLI MODEL COMPARISON ON THE 107-SET BENCHMARK

Model	Param	Precision	Recall	F1	Time (s)
RoBERTa-large-MNLI	**355M**	**97.86%**	**99.28%**	**98.57%**	**712**
DeBERTa-v3-large	435M	97.52%	98.92%	98.21%	2005
DistilBERT-MNLI	66M	97.41%	94.95%	96.16%	145
BERT-base-MNLI	110M	90.59%	55.60%	68.90%	186

RoBERTa-large-MNLI achieves the best overall performance, with an F1-score of 98.57% and a Recall of 99.28%, ahead of DeBERTa-v3-large by 0.36 F1 points while running 2.8 times faster. BERT-base-MNLI cannot be retained for this task: its Recall drops to 55.60%, meaning that roughly 44% of paraphrased Given states go undetected. DistilBERT-MNLI, the fastest of the four at 145 seconds, reaches a Recall of only 94.95%; the resulting 14 additional FNs affect 12 AC, whose generated diagrams are left structurally incomplete. Because a single missing construct invalidates the diagram, this Recall loss cannot be traded against the computational saving.

The four backbones were then re-evaluated under the graph-level structural comparison introduced earlier in this study, which imposes a stricter criterion on branch assignment and control-flow correctness. The scores obtained by the four backbones on node F1, edge F1, and the exact-match rate are gathered in Table XII. RoBERTa-large-MNLI achieves the highest scores on the three metrics, which motivated its selection as the backbone of the pipeline. DeBERTa-v3-large trails it throughout, despite its larger size, and also runs substantially slower (1809s versus roughly 1249s), making it a dominated choice. DistilBERT-MNLI, with roughly a fifth of the parameter count, stays close behind (Node F1 = 96.15%) at a fraction of the compute cost, and offers a reasonable lightweight alternative when the compute budget is tight. BERT-base-MNLI trails all three other models, especially on edges (Edge F1 = 53.63%); its contradiction and entailment signals appear too noisy to support the branch-detection and Given-state grouping decisions on which the pipeline relies. RoBERTa-large-MNLI is also the default zero-shot classification model in the Transformers library [36], which keeps versioning and deployment reproducible.

TABLE XII. STRUCTURAL NLI MODEL COMPARISON ON THE 107-SET BENCHMARK

Model	Param	Node F1	Edge F1	Exact-match	Time (s)
RoBERTa-large-MNLI	**355M**	**99.26%**	**97.37%**	**95.33%**	**1249**
DeBERTa-v3-large	435M	97.30%	92.26%	89.72%	1809
DistilBERT-MNLI	66M	96.15%	89.75%	85.05%	172
BERT-base-MNLI	110M	78.29%	53.63%	41.12%	213

VII. CONCLUSION

This study has described an automated pipeline that turns GWT acceptance criteria into UML activity diagrams. The pipeline combines syntactic parsing with Transformer-based semantic similarity and natural language inference, and it is organised around a three-gate Given-state grouping mechanism together with a multi-signal decision scoring function. Eleven structural patterns are supported, ranging from simple sequences and binary decisions to multi-branch switches, fork/join constructs, loops, nested compound conditions, and independent flows.

On a benchmark of 230 AC distributed over 107 test sets drawn from four independent sources, the pipeline reaches a node F1 of 99.26% and an edge F1 of 97.37%; the latter measures the correctness of control-flow connections and branch guards. 95.33% of the generated diagrams are topologically identical to their reference, and this figure remains stable across the four partitions of the benchmark. The pipeline also covers configurations on which the earlier rule-based baseline fails, in particular paraphrased preconditions, variant decisions, and nested compound conditions that fall outside what string matching and lexical antonymy can capture.

Future work includes three directions. First, a dedicated gate that separates sequential chains from parallel forks would resolve the residual FORK/JOIN confusion identified in the structural evaluation. Second, an evaluation on larger industrial BDD repositories would establish how the pipeline performs at that scale. Third, a hybrid pipeline in which the structural output of the current approach is used as a reference for LLM-based PlantUML generation would allow LLM-generated diagrams to be validated and hallucinated constructs to be corrected.

***Abstract*—Timely, context-aware service recommendations are most significant for maximizing system efficiency and resource utilization in fog-enabled Internet of Things (IoT) for smart agriculture. Classical Grey Wolf Optimization (GWO) algorithms are prone to premature convergence and lack robustness for multi-objective and dynamic environments. This study presents an Enhanced Grey Wolf Optimization (EGWO) algorithm that incorporates adaptive weighting and nonlinear exploration-exploitation control. The EGWO algorithm uses a dynamic alpha-beta-delta hierarchy for weighting and a cosine-based decay for the control parameter, ensuring better convergence and global search efficiency. In the fog-based service recommendation environment, EGWO optimizes multiple conflicting objectives, including latency, energy consumption, trust, and service utility. A comparison is made between standard GWO, PSO, and DE using a simulated agricultural fog-IoT network. The results demonstrate that EGWO achieves faster convergence speed, higher recommendation quality, and uniform behavior across all test scenarios. The method is suitable for practical application in real-time agricultural use cases, ensuring guaranteed optimal service allocation and improved decision support at the network's edge.**

***Keywords*—Grey wolf; fog computing; internet of things; smart agriculture; service recommendation**

I. INTRODUCTION

The convergence of Internet of Things (IoT) technology and farming has made intelligent farming feasible, enabling real-time monitoring, automation, and information-based decision-making [1]. For such environments, fog computing places computational resources closer to the field, reducing dependencies on central cloud infrastructure [2]. Proximity of this nature guarantees rapid response times and higher responsiveness, essential in time-sensitive operations such as equipment maintenance, pest control, and irrigation management [3]. Controlling and service recommendations for an IoT architecture based on fog introduce new challenges. Real-time recommendations for services are necessary to accommodate dynamic resources, IoT device-at-the-edge energy limitations, and to preserve service trust and reliability [4]. With more connected gadgetry and service providers, request mapping to the most fitting services is an intricate multi-objective challenge [5].

Also, based on the learning, communication reliability and efficiency are improving. For instance, neural coding frameworks like DeepPolar have used a reliability-aware loss function to enhance frame error rate performance, which suggests the possibilities of smart solutions in future communication systems [6]. Metaheuristic algorithms are being considered as promising approaches to find the optimal solutions for various IoT problems such as service allocation and scheduling. The Grey Wolf Optimization technique (GWO) is one of the top metaheuristic algorithms owing to its flexible structure and good performance. However, the conventional GWO has some drawbacks. It suffers from premature convergence in high-dimensional search spaces because of its low exploration ability and non-divergent nature [7]. These deficiencies make it inadequate for use in rapidly changing, memory-constrained fog computing networks where fast convergence and thorough search are required. In addition, the fixed roles of the α, β, and δ wolves in the standard GWO restrict its potential for adaptively searching complex, multimodal optimization problems, such as in real-time service recommendation search landscapes of intelligent agriculture.

To address these challenges, an Enhanced Grey Wolf Optimization (EGWO) algorithm is proposed for recommendations in fog-based IoT agricultural networks. Adopting a dynamic saliency between the leaders, the influence of the lead wolves on the other ones changes as the optimization proceeds. Furthermore, a suitable parameter determination in line with an arctan mapping and cosine decay is proposed to gradually adapt the balance of global searching and local searching over time scale. These improvements enhance convergence and eliminate stagnation in local optima. EGWO is capable of selecting an optimal service that meets multiple constraints, e.g., latency requirements, energy consumption, trustworthiness, and usefulness, in a fog computing environment with an efficient multi-objective service recommendation under fog computing constraints. The salient contributions of this study are:

- Proposing a novel EGWO algorithm with adaptive hierarchical weights and nonlinear convergence control.
- Formulating the fog-based service recommendation problem in agricultural IoT as a multi-objective optimization task incorporating latency, energy, trust, and utility.
- Designing a simulation environment to evaluate EGWO and benchmark it against standard GWO, Differential

*Corresponding author.

Evolution (DE), and Particle Swarm Optimization (PSO).

- Proving that EGWO outperforms traditional methods in convergence rates, stability, and solution quality across a range of agricultural service scenarios.

The study is organized as follows. Section II presents the related work on service scheduling in IoT. Section III presents the problem and the system model used in this study. In Section IV, the proposed GWO algorithm enhancements and the details of the algorithm design components and working principles are described. Section V presents the experimental results, comparative analysis, and performance evaluation of the proposed technique. Section VI presents the conclusion of the study with possible future considerations.

II. Related Work

Ravi, et al. [8] proposed the Cluster-Based Reliable Data Aggregation (CRDA) for IoT scenarios to achieve energy consumption and reliability balance. This approach applies the Monarch and Sine-Cosine (MSC) algorithm to form clusters and enhance the data aggregation process with an Enhanced Sunflower Optimization (ESFO) algorithm. The most reliable IoT sensors are selected as cluster heads to transmit data efficiently. A novel Optimal–Learning-Based Deep Neural Network (ROL-DNN) calculates the optimal paths for reliable data aggregation and delivery. The simulation results show the superiority of the proposed system against traditional routing protocols.

Liu, et al. [9] proposed the application of Unmanned Aerial Vehicles (UAVs) as aerial base stations for gathering data in agricultural IoT, which mitigates the constraints of conventional ground-based stations. They formulated a multi-objective optimization problem to maximize the minimum data rate and minimize the energy consumption of both the UAV and the IoT devices. To handle this complicated problem, an Improved Multi-Objective Artificial Hummingbird Algorithm (IMOAHA) based on hybrid initialization, Cauchy mutation, and discrete mutation operators is proposed.

Çavdar, et al. [10] A task scheduling technique in Wireless Sensor Networks (WSNs), called the Shared-Data Approach, is introduced, which considers the presence of multiple applications with different requirements sharing the same infrastructure and addresses sensing and communication load balancing among them. Their method uses a genetic algorithm and also three greedy heuristics (LTSF, LMSF, and LMPF) for data request scheduling. These approaches are designed to maximize resource utilization by minimizing the makespan and the waiting time, while maintaining a good success rate in terms of task execution. The experimental results show that our proposed algorithm outperforms the other scheduling algorithms in a number of performance metrics such as turnaround time and execution throughput.

Vakili, et al. [11] proposed a GWO-based service composition method in IoT and cloud environments. Their work aims at maximizing Quality of Service (QoS) factors (e.g., energy, response time, availability, and cost) using service composition in a MapReduce environment. The simulation results demonstrate a 40% enhancement in energy savings with significant reduction in cost and response time, which outperforms three benchmark algorithms with respect to energy and QoS optimization.

Abohamama, et al. [12] A semi-dynamic real-time scheduling framework is introduced for IoT applications within cloud–fog environments. The algorithm, based on a modified genetic algorithm, models task scheduling as a permutation-based optimization challenge. In this method, tasks are allocated to virtual machines with sufficient resources to reduce processing time.

Shankar and Anbarasan [13] introduced the Improved Multi-objective Grey Wolf Optimization (IMGWO) algorithm for dynamic virtual machine allocation and resource allocation in cloud infrastructure. The method leverages evolutionary strategies combined with fuzzy logic to optimize power consumption and resource allocation. Their approach significantly reduces power consumption, achieving notable improvements over traditional optimization methods such as MOOERA and CRASVM.

To overcome the challenges of cloud-based execution of IoT applications such as network latency and high service cost, Naik [14] put forward the CoS_FRLM model. Their solution is to cluster IoT devices in logical fog nodes, which are led by fog agents to process application requests at the local level. The method incorporates a pheromone-based metric to assess and suggest the best fog node for performing each IoT task, which leads to the best load sharing.

Lin, et al. [15] proposed a weighted interest degree-based recommendation using association rule mining to improve content dissemination in Internet of Vehicles (IoV) networks. Their approach mines user data to generate association rules and predicts user interest scores by considering the similarity between various user preferences. This context-aware recommendation scheme can accurately recommend content in intelligent vehicle systems over IoV scenarios.

Altaleb, et al. [16] proposed an extension of the Cross-Industry Standard Process for Data Mining (CRISP-DM), specifically adapted for agricultural applications. Their framework acknowledges the increasing importance of big data in optimizing machinery performance and enhancing decision-making within the sector. Their approach refines the generic CRISP-DM model by introducing domain-specific guidelines for structuring and handling agricultural datasets.

Despite the fact that the above-stated works pitch different approaches for enhancing IoT systems in agriculture, a considerable number of these works concentrate on optimizing only one objective, e.g., energy or communication efficiency, while ignoring the multi-objective aspect of practical agricultural IoT applications. Further, some solutions neglect the need for dynamic adaptability to environmental changes, e.g., weather conditions and farm topography. In this work, we aim to fill this gap and develop an EGWO algorithm that addresses multiple conflicting objectives, including energy consumption, latency, trust, and service utility in a dynamic fog-enabled agricultural IoT environment. With the integration of the adaptive weighting scheme with the dynamic EEC control strategy, it is expected to enhance the convergence performance,

solution quality, and robustness of the proposed method in different agricultural environments. Table I presents a comparative summary of the related research and points out the key contributions, strengths, and weaknesses of each method.

TABLE I. RECENT EFFORTS ON SERVICE SCHEDULING IN IOT

Study	Main contribution	Pros	Cons
[8]	Developed a cluster-based reliable data aggregation scheme using MSC and ISFO algorithms for IoT networks to optimize data aggregation and routing.	Efficient data aggregation, trust-based cluster head selection, and improved routing.	Complexity in implementation due to the integration of multiple algorithms.
[9]	Introduced UAV-assisted data collection for agricultural IoT, optimizing UAV positioning, speed, and transmit power via the improved multi-objective artificial hummingbird algorithm.	An effective solution for flexible data collection in agricultural IoT, with significant performance improvement.	UAV deployment might be costly, and optimal UAV positioning is challenging in irregular farm topologies.
[10]	Developed a shared-data approach for application scheduling in WSNs with a genetic algorithm and greedy algorithms to optimize resource usage.	Reduces communication and sensing load, effective in multi-application environments.	May not scale well with very large networks or highly dynamic conditions.
[11]	Suggested a service composition technique using the MapReduce framework and GWO for IoT and cloud integration, optimizing multiple QoS attributes like energy and cost.	Significant QoS improvement, particularly in energy savings and response time reduction.	Does not account for the dynamic nature of service availability in real-time environments.
[12]	Proposed a semi-dynamic task scheduling algorithm for IoT in cloud-fog environments, based on an enhanced genetic algorithm to optimize task execution and reduce failure rates.	Effective for real-time task scheduling, a balance between execution cost and reliability.	May require fine-tuning to meet specific real-time constraints and support diverse IoT applications.
[13]	Introduced an improved multi-objective grey wolf optimization algorithm for dynamic virtual machine allocation and resource allocation in cloud systems, incorporating fuzzy logic for power efficiency.	Significant power consumption reduction and performance enhancement.	Focuses primarily on cloud VM optimization, not directly applicable to agricultural IoT systems.
[14]	Proposed a co-scheduling framework using fog-nodes and a pheromone indicator for optimal IoT application placement.	Reduces makespan and service cost; enhances resource utilization.	Complexity in dynamic fog-node selection and PI recalculations.
[15]	Suggested a weighted interest recommendation algorithm using association rules for intelligent navigation in IoV.	Improves recommendation accuracy by analyzing user interests.	Scalability challenges with large-scale user data in real-time scenarios.
[16]	An extended CRISP-DM process model tailored for agricultural data to guide structured data mining in farming.	Provides a domain-specific methodology for agricultural analytics.	Lacks automation in dynamic environments; relies on static process stages.

III. PROBLEM DEFINITION AND SYSTEM MODEL

Fog-based IoT architecture consists of three layers: cloud, fog, and IoT. The IoT part consists of the physical devices with electronics and/or electronic components to gather and send data. The cloud tier receives data from the fog tier, after two data transformations and a trust evaluation, and executes advanced analytics to extract value from the raw data. IoT in farming is well known for the massive improvements it can bring to production and environmental impacts. As shown in Fig. 1, the IoT applied in agriculture brings a number of positive impacts: monitoring soil moisture, controlling crop diseases, and reducing fertilizer use, which help in enhancing crop yield and reducing the cost of operation.

Metaheuristic methods have also shown promising results in practical rural applications. Saeidi and Kaisar [17], for example, studied a rural logistics network in North Florida, where routing and inventory decisions considered both transportation costs and accident risk. Their case study covered 26 rural locations and showed improvements of about 7–14% when alternative routes were considered. The study also showed that metaheuristic methods can handle larger problems in considerably less computational time than exact optimization methods, which is particularly useful when decisions need to be made within a limited time.

The problem is to recommend services to users based on their specific needs and each service's capabilities. The decision for service recommendation is modeled using a binary variable y_{ik}, as expressed in Eq. (1). Service allocation is subject to capacity constraints, as described in Eq. (3). In this context, m stands for the total number of users, and n refers to the total number of available services. The parameter μ_i reflects how many inquiries service i is capable of processing within a given time frame, while C_k represents the upper limit of requests that user k is permitted to issue.

$$y_{ik} = \begin{cases} 1, & when\ service\ i\ is\ recommended\ to\ user\ k \\ 0, & otherwise \end{cases} \quad (1)$$

$$\sum_{k=1}^{m} y_{ik} = 1 \quad \forall i = 1, \ldots, n \quad (2)$$

$$\sum_{i=1}^{n} \mu_i y_{ik} \leq C_k \quad \forall k = 1, \ldots, m \quad (3)$$

To account for the exchange cost between services, a new variable x_{ij} is introduced. This variable indicates whether services i and j are connected to the same user. When two services are assigned to the same user, $x_{ij} = 1$; otherwise, it is 0, as defined in Eq. (4). The exchange cost becomes part of the objective function, where the cost is zero if $x_{ij} = 0$, as detailed in Eq. (5). h_{ij} represents service exchange costs between services i and j.

$$x_{ij} = \sum_{k=1}^{m} y_{ik} y_{jk} \quad \forall i, j = 1, \ldots, n, \ i \neq j \quad (4)$$

$$\sum_{i=1}^{n} \sum_{j=1}^{n} h_{ij}(1 - x_{ij}) \quad (5)$$

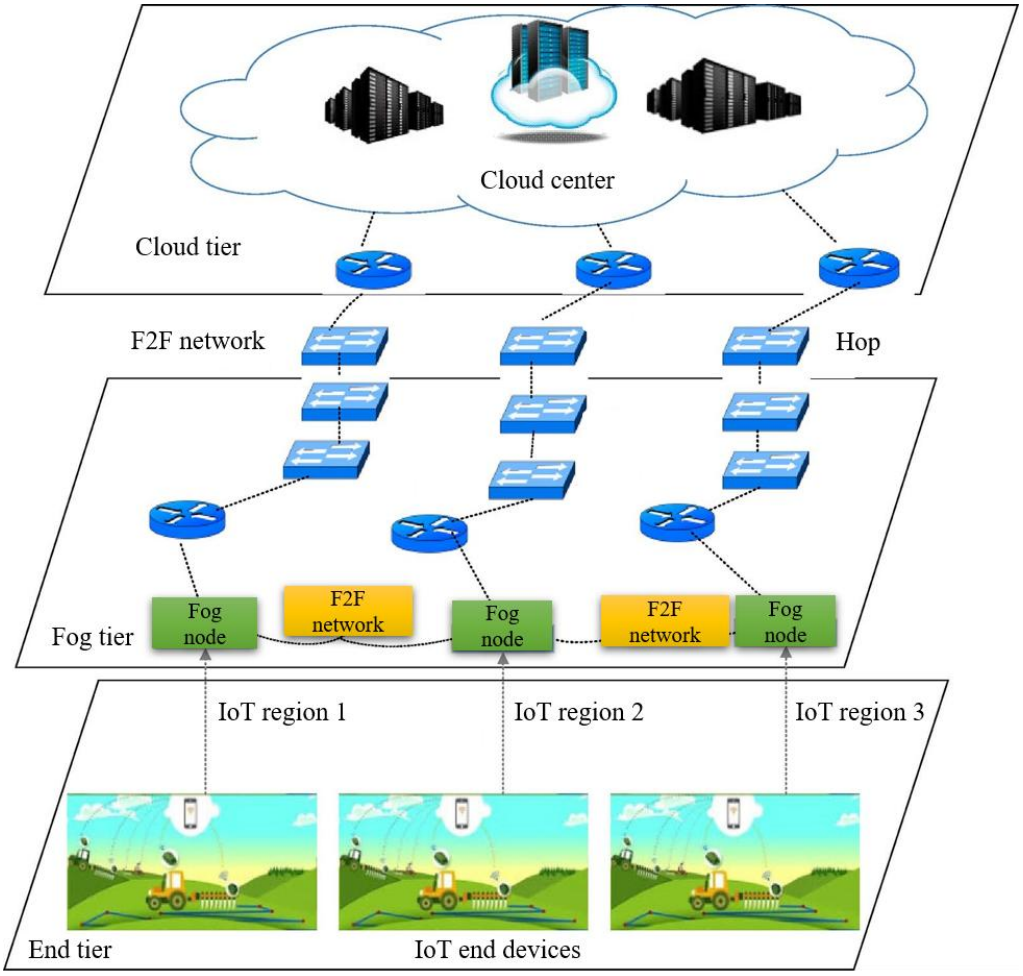

Fig. 1. An overview of the fog-based IoT architecture in agricultural environments.

Additionally, the cost of connecting user k and service i is calculated using a distance measurement between the user and the service. This is captured by Eq. (6), where c_{ik} is the connection cost and d_{ik} denotes the calculated distance between the corresponding service and user.

$$\sum_{i=1}^{n}\sum_{j=1}^{n} c_{ik} d_{ik} y_{ik} \tag{6}$$

Finally, the overall objective function for minimizing both connection and exchange costs is represented in Eq. (7). The objective function aggregates the connection cost, exchange cost, and user-service assignments:

$$FF_1 = \sum_{i=1}^{n}\sum_{j=1}^{n} c_{ik} d_{ik} y_{ik} + \sum_{i=1}^{n}\sum_{j=1}^{n} h_{ij}(1 - x_{ij}) \tag{7}$$

The random key method is used to represent the service recommendation results, formatted as an n×1 matrix. Each matrix entry is a floating-point number, where the whole-number component indicates the user to whom a service is assigned. When multiple services are mapped to the same user (i.e., have the same integer part), the one with the lowest decimal value is prioritized as the recommended option. For example, consider a case involving 7 services (n=7) and 3 users (m=3), producing a matrix such as (2.42, 2.10, 1.21, 3.32, 3.59, 3.80, 1.43). In this case, services 1 and 2 would be linked to user 2, services 3 and 7 to user 1, and services 4, 5, and 6 to user 3. Fig. 2 illustrates how the allocation is derived from these coordinates, emphasizing the efficiency of the random key method in optimizing service recommendations.

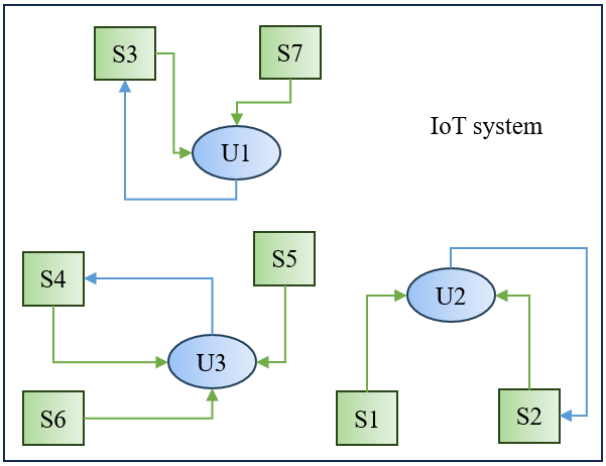

Fig. 2. Service allocation to users based on the random key method.

IV. Enhanced Grey Wolf Optimization Algorithm

GWO is a nature-inspired optimization algorithm that mimics the predatory behavior of grey wolves. The best individual is designated as the alpha (α) wolf, the second-best as the beta (β) wolf, and the third-best as the delta (δ) wolf, with the remaining individuals labeled as omega (ω) wolves. The GWO simulates the hunting behavior of the wolf pack, in which the wolves' movements are directed toward the prey's location, as mathematically expressed in Eq. (8).

$$X(t+1) = X_p(t) - A \cdot \left| C \cdot X_p(t) - X(t) \right| \tag{8}$$

where, t denotes the current iteration number, X is the position vector of the wolves, X_p is the prey's position, A and C are coefficient vectors, and $|\cdot|$ represents the absolute value. The values of the vectors A and C are determined as:

$$\begin{aligned} A &= 2 \cdot \alpha . r_1 - \alpha \\ C &= 2 \cdot \alpha \cdot r_2 \\ \alpha &= 2 - \frac{2 \cdot t}{t_{max}} \end{aligned} \tag{9}$$

where, r_1 and r_2 represent random values within the range [0, 1], and t_{max} denotes the total number of allowable iterations. The positions of the top three wolves are updated as follows:

$$X_\alpha = X_\alpha - A_\alpha \cdot |C_\alpha \cdot X_\alpha - X| \tag{10}$$

$$X_\beta = X_\beta - A_\beta \cdot \left| C_\beta \cdot X_\beta - X \right| \tag{11}$$

$$X_\delta = X_\delta - A_\delta \cdot |C_\delta \cdot X_\delta - X| \tag{12}$$

$$X(t+1) = X_\alpha(t) + X_\beta(t) + X_\delta(t) \tag{13}$$

where, A_α, A_β, and A_δ are the vectors for the top three wolves, and C_α, C_β, and C_δ control the wolves' exploration and exploitation abilities.

Although the GWO algorithm is very effective in many optimization fields, it has difficulties in stricter cases. These include a tendency to converge prematurely to a non-optimal solution, especially in the presence of multiple local minima, combined with a slow convergence rate, which may result in high computational overhead in real-time and large-scale applications. Furthermore, the performance of GWO depends heavily on several parameters, such as population size, number of iterations, and control coefficients, which makes parameter tuning a difficult task, in particular for end users with less experience.

Focusing only on the three best agents in the hierarchy limits the capacity of the algorithm to fully investigate the search space, and consequently, the diversity can be low, and the chance of convergence to local optima can be quite high. Moreover, the basic GWO algorithm is not scalable to high-dimensional problems, is ineffective for noisy or inaccurate objective functions, and is unstable in problems with time-varying constraints or objectives. Such limitations emphasize the opportunity for superior variants to tackle such challenges and enhance the algorithm's applicability in evolving, intricate problem spaces.

To overcome the identified limitations, the enhanced EGWO framework incorporates multiple modifications to strengthen both search diversification and intensification. The weight of the α-wolf's position in Eq. (13) is adjusted to account for the fact that, during the initial search, the α-wolf may not be close to the optimal solution. This leads to a higher weight for the α-wolf during the early iterations, as shown in Eq. (14).

$$\alpha = 2 - \frac{t}{t_{max}} \cdot cos(r) \tag{14}$$

where, t_{max} is the maximum number of iterations, and r is a random number between 0 and 1. This adjustment allows the algorithm to explore more thoroughly in the early iterations and then shift to exploitation as the search progresses.

Additionally, the weights for the wolves ($\sigma_1, \sigma_2, and\ \sigma_3$) are calculated to adaptively control the transition between exploration and exploitation. These weights are formulated as:

$$\sigma_1 = cos(\theta) \tag{15}$$

$$\sigma_2 = 0.5 \cdot sin(\theta) \cdot cos(\varphi) \tag{16}$$

$$\sigma_3 = 1 - \sigma_1 - \sigma_2 \tag{17}$$

where, θ is the angle associated with the search process, and φ is a supplementary variable to control the distribution of weights. By using adaptive weights, the α-wolf initially steers the search process more strongly. However, as iterations proceed, the influence of the β- and δ-wolves gradually increases, playing a more prominent role in refining the solution.

The proposed EGWO algorithm introduces an adaptive weighting mechanism that enhances the efficiency of the baseline GWO. By allowing the wolves' weights to adapt during the search, the algorithm can smoothly switch between exploitation and exploration, thereby avoiding premature convergence and improving overall solution quality. EGWO offers a more effective approach to solving complex optimization problems and is less likely to get trapped in local optima. The algorithm's performance is demonstrated in Algorithm 1.

Algorithm 1: Pseudocode of EGWO

```
Set the maximum number of iterations t_max and initialize the population size N.
Generate an initial population randomly and set the corresponding solutions.
Define the parameters for the GWO, including the values for a, A, and C.
Select the top three individuals: X_α, X_β, and X_δ.
Repeat for each iteration from t = 1 to t_max:
    For each individual i in the population N.
        Update the position of the current agent using Eq. (15).
    End loop over individuals.
Update the coefficient a using Eq. (14), and adjust A and C using Eq. (9).
Calculate the fitness values of all search agents.
Update the positions of X_α, X_β, and X_δ Eq. (10)-(12).
Increment the iteration count by 1: t = t + 1.
Repeat until the termination condition is met.
Return the best solution found.
```

The time complexity of the standard GWO algorithm can be analyzed based on its iterative operations, which consist of three

core components: calculating the fitness of each member of the population, adjusting their positions using the best three solutions found so far, and maintaining a proper trade-off between exploitation and exploration. Assuming a population of size N, a maximum iteration count t_{max}, and a dimensionality of dim, the position updating process in each iteration requires $O(N \cdot dim)$ computations. Therefore, the total computational complexity over all iterations is $O(t_{max} \cdot N \cdot dim)$.

To enhance the performance of the proposed EGWO, a novel adaptive weighting approach is introduced, which slightly increases the computational load. This mechanism dynamically recalibrates the weight parameters σ_1, σ_2, and σ_3 by leveraging trigonometric and inverse tangent operations, and also alters the equilibrium between the exploitation and exploration stages. These modifications contribute an additional computational complexity of $O(N \cdot log\, t_{max})$ per iteration. Consequently, the entire complexity of EGWO becomes $O(t_{max} \cdot N \cdot dim + log\, t_{max})$. Although the added logarithmic component slightly increases cost, it yields noticeable gains in search performance and solution precision.

V. Results and Discussion

The performance of the proposed EGWO algorithm was examined on a collection of 10 conventional test problems, each with both fixed- and variable-dimensional unimodal and multimodal features. These problems were chosen for an in-depth exploration of the EGWO algorithm's exploring-exploiting abilities across a diverse set of complexes. The effectiveness of the EGWO algorithm was evaluated against several conventional algorithms, namely PSO, DE, Gravitational Search Algorithm (GSA), basic GWO, GWO with Crossover and Mutation (GWO-CM), GWO with Local Search (LSGWO), and Improved GWO with Dynamic Search (IGWO-DS). For a more objective comparison, a separate run for each algorithm was conducted 30 times independently, with a population of 30 individuals, for up to 500 iterations.

The selected benchmark functions corresponding to various difficulty levels are given in Table II, where F1-F4 are unimodal, and F5-F7 are multimodal. The unimodal test functions with 30 dimensions can be well exploited and explored to find global optimal solutions, while the multimodal test functions, with attention to F5–F7, have more local optima, so the exploration should be cautious to avoid possible premature convergence. Also, the functions F8–F10 present more challenging multimodal features, with a smaller differentiability set, which requires the algorithm to achieve a good balance between exploration and exploitation.

As shown in Table III, the EGWO algorithm can solve unimodal and multimodal test problems very well. In the unimodal test problems, through the dynamic variation of weight factors, the EGWO method can effectively exploit the search space with high precision and also increase the exploration and exploitation capabilities. Applying the EGWO algorithm to multimodal functions also manifests strong exploration capability with overall better performance than other algorithms. Considering specific functions F5 through F8 with several local optima, EGWO efficiently coordinates global and local searches for significantly better performance. Statistics show that, for accuracy, the standard deviation (STD) measures indicate better performance than other algorithms implemented for comparison. Through a robust exploration mechanism, with a boost from the adaptive weight factors implemented in the exploration-exploitation mechanism with EGWO, tackling challenging multimodal optimization problems can be more efficient for the algorithm.

TABLE II. Summary of Benchmark Functions

Function	Formula	Dimensions	Domain	Optimal Value (fmin)
F1	$\max(y_k), \quad 1 \le k \le d$	30	[-100, 100]	0
F2	$\sum_{k=1}^{d}\sum_{l=1}^{k} y_l^2$	30	[-100, 100]	0
F3	$\sum_{k=1}^{d} y_k + \prod_{k=1}^{d} y_k$	30	[-10, 10]	0
F4	$\sum_{k=1}^{d} y_k^2$	30	[-100, 100]	0
F5	$\frac{1}{4000}\sum_{k=1}^{d} y_k^2 - \prod_{k=1}^{d} \cos\left(\frac{y_k}{\sqrt{k}}\right) + 1$	30	[-600, 600]	0
F6	$-20\exp\left(-0.2\sqrt{\frac{1}{d}\sum_{k=1}^{d} y_k^2}\right) - \exp\left(\frac{1}{d}\sum_{k=1}^{d}\cos(2\pi y_k)\right) + 20 + e$	30	[-32, 32]	0
F7	$\sum_{k=1}^{d}[y_k^2 - 10\cos(2\pi y_k) + 10]$	30	[-5.12, 5.12]	0

Concerning computational complexity, although the runtime (RT) for EGWO is slightly higher because of the adaptive weight mechanism, the growth is negligible. This rise in RT is offset by better algorithm performance and the effective solving of complex problems. EGWO's adaptive weight mechanism boosts its robustness while minimizing computational burden, proving efficient and effective for practical applications in multimodal and unimodal optimization problems.

The proposed EGWO algorithm is simulated and compared with some popular benchmark techniques such as User Characteristics-Collaborative Filtering (UCCF), CRISP-DM, Association rule, CoS_FRLM, and K-Nearest Neighbors (KNN)to analyze recommendations on the simulation platform MATLAB 2020b on a 64-bit Intel Core i7-6700 processor computer with 16GB DDR3 RAM. Several parameters like Mean Absolute Error (MAE), Hamming distance, intra-list similarity, recall, precision, and ranking scores were used to assess these methods.

The MAE measure approximates the average magnitude of errors between the predicted outputs and actual user ratings. It is determined using the average of absolute errors between each prediction P_j and the corresponding actual value R_j over n samples, respectively, defined using Eq. (18). Lower MAE indicates better prediction accuracy for more reliable recommendations. MAE is computed over various sparsity levels and compared for diverse algorithms in this work.

$$MAE = \frac{1}{n}\sum_{j=1}^{n}\left|P_j - R_j\right| \tag{18}$$

For a user U_i, the ranking score S_{ij} is determined by the position Pos_{ij} of a recommended item Obj_j within the recommendation list L_i. It is calculated by normalizing Pos_{ij} over the list length, as shown in Eq. (19). An efficient recommendation system will ensure that relevant items appear in higher ranks, resulting in a lower S_{ij} value, signifying higher accuracy.

$$S_{ij} = \frac{Pos_{ij}}{L_i} \tag{19}$$

Precision measures the proportion of relevant items among the recommended set. For a user group, it is computed as the ratio of successfully recommended items A to the total recommendations T, described in Eq. (20). An increase in precision corresponds to a higher concentration of relevant suggestions within the top-ranked recommendations.

$$Precision = \frac{A}{T} \tag{20}$$

Recall calculates the system's capacity for retrieving all relevant items for a user. It is defined as the number of retrieved relevant items A divided by the number of pertinent actual items M using Eq. (21). High recall indicates the system efficiently contains most of the appropriate items for a user, without compensating for the irrelevant recommendations.

$$Recall = \frac{A}{M} \tag{21}$$

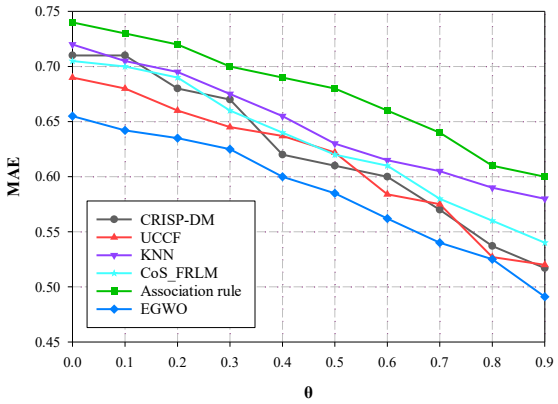
The intra-list similarity examines how similar the recommended items are within a user's list, utilizing cosine similarity as a measure. For two items Obj_m and Obj_n, their similarity Sim_{mn} is evaluated according to Eq. (22).

$$Sim_{mn} = \frac{\sum_{i=1}^{K}\alpha_{im}\cdot\alpha_{in}}{\sqrt{k(Obj_m)}\cdot\sqrt{k(Obj_n)}} \tag{22}$$

where, K represents the total number of users, and α_{im}, α_{in} are binary indicators if user i has interacted with Obj_m and Obj_n . The average similarity across all pairs within a recommendation list is used to assess diversity, with lower values being preferable for diverse suggestions.

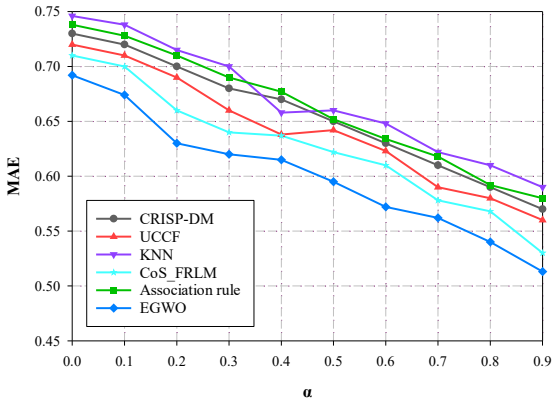
Hamming distance predicts the disparity between recommendation lists across diverse users. It is calculated from the quantity of similar items Q between the lists of user H_x and user H_y concerning the total list size L through Eq. (23). Greater Hamming distances indicate more unique lists with minimal user similarity, encouraging diverse recommendations.

$$H_{xy} = 1 - \frac{Q}{L} \tag{23}$$



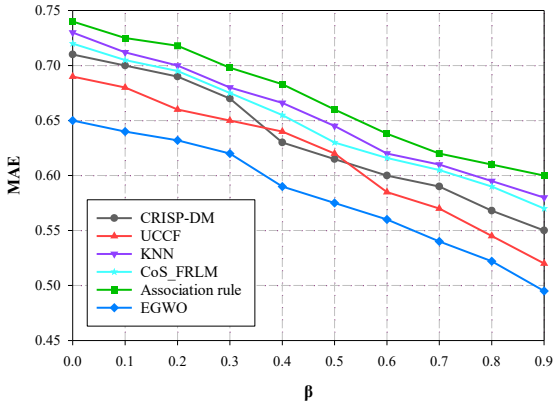
Three thresholds, namely neighborhood similarity (θ), predicted rating reliability (α), and user rating confidence (β), are used for fine-tuning recommendations. Neighborhood N_θ is determined with the help of Eq. (24), unreliable ratings are filtered out using Eq. (25), and Eq. (26) identifies reliable neighbors for making final predictions. These thresholds fine-tune the trade-off between accuracy, reliability, and diversity in the recommendation scheme.

$$N_\theta = \{U \in \mathcal{U} \mid f(U) > \theta\} \tag{24}$$



$$UR = \{R_i \mid Reliability(R_i) < \alpha\} \tag{25}$$

$$N_\beta^{new} = \{U \in N_0 \mid Confidence(U) > \beta\} \tag{26}$$



Regarding the MAE, Fig. 3(a)-3(c) illustrate the outcome, which confirms that the MAE gradually diminishes with an increase in parameters α, β, and θ. This indicates that high levels of these parameters result in more precise recommendations, rendering EGWO a reliable method of enhancing forecast accuracy. The average ranking score, shown in Fig. 4, also illustrates that EGWO outperforms as the number of customers increases, generating better recommendations. Likewise, regarding precision, Fig. 5 shows that EGWO achieves a high level compared to other methods, with an increase in the number of customers indicating a better outcome.

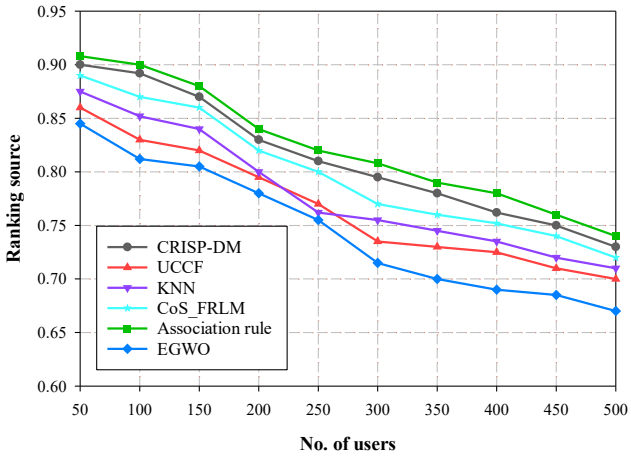

Fig. 4. Analysis of ranking score variations across different user group sizes.

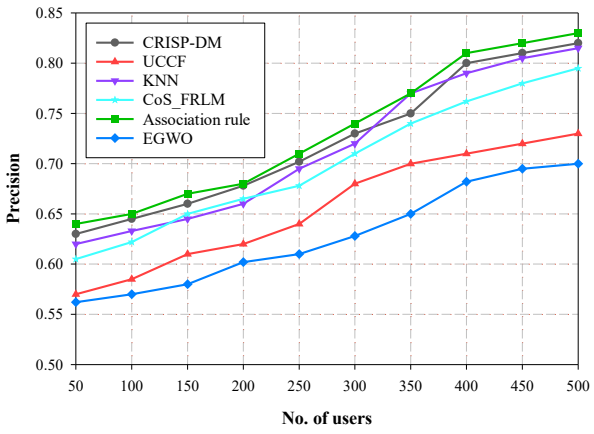

Fig. 5. Precision evaluation across different user group sizes.

The recall result in Fig. 6 also demonstrates the superiority of EGWO. The higher the number of users, the greater the advantage of benefiting from EGWO recall compared with other methods, except the UC-CF method. This suggests EGWO can successfully fetch relevant recommendations regardless of how large the collection of users is. Regarding the intra-similarity of

recommendations, Fig. 7 shows that EGWO obtains the highest intra-similarity between recommended items compared with other methods.

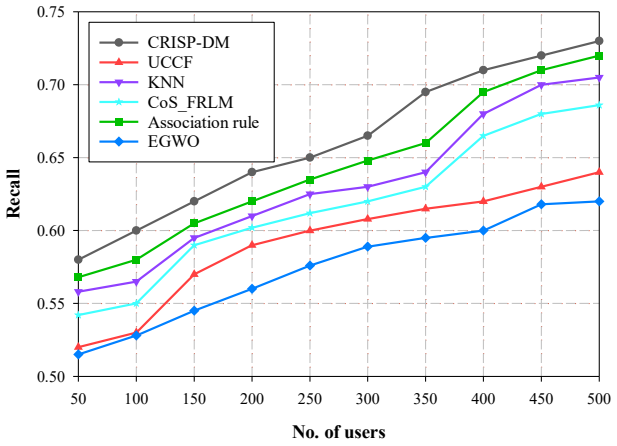

Fig. 6. Recall evaluation across different user group sizes.

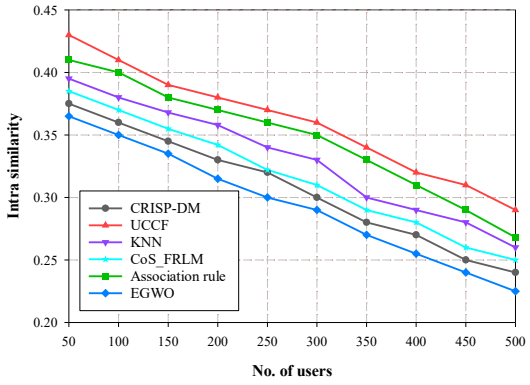

Fig. 7. Intra-similarity distance evaluation across different user group sizes.

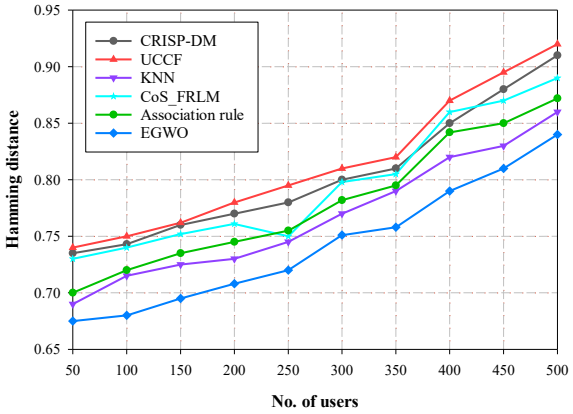

Fig. 8. Hamming evaluation across different user group sizes.

Additionally, the Hamming distance results in Fig. 8 suggest that EGWO achieves better personalization than its competitors. With the growth in the number of users, EGWO obtains better performance with a smaller Hamming distance, which proves that EGWO is more competent at personalizing recommendations than other methods. The improvements in results for all metrics imply that EGWO is an effective and efficient service recommendation algorithm for a dynamic environment.

The improvements of EGWO are due to an adaptive weighting factor, which can bring a more flexible and faster convergence process as compared to the original GWO. In the standard GWO, the exploration and exploitation phases are managed through a set of static parameters that often lead to premature convergence to a local optimum, especially in high-dimensional and multi-modal problems. By using adaptive weights for alpha, beta, and delta wolves, the EGWO modifies the effect strength of these wolves along the search process to keep a better balance between explorative (broad search) and exploitative (narrow search) behavior throughout the search process. This active correction drastically enhances convergence speed, solution quality, and robustness, with notable effectiveness for multimodal and dynamic optimization problems.

VI. Conclusion

In this study, we proposed the EGWO algorithm as a new version of the conventional GWO to solve service scheduling problems in agricultural IoT. With the inclusion of an adaptive weighting strategy, the proposed EGWO algorithm is capable of balancing the exploration and the exploitation phases within the searching process and thus exhibits better and faster convergence, higher quality of solutions, and stronger ability in solving dynamic and complex multi-objective optimization problems. EGWO also dynamically adjusts the contributions of alpha, beta, and delta wolves to escape local optima and to search a wider area, which generates best-quality service recommendations and allocation solutions in agricultural IoT applications. The comparative analysis shows that EGWO surpasses conventional optimization methods in convergence speed, stability, and general service allocation quality. However, although EGWO provides much better solutions, its computational complexity is also increased since more calculations are needed to perform the adaptive weight updates, and this can affect the scalability of the method to large- scale systems. The algorithm's efficiency and avenues for applications in large-scale real-time agricultural IoT networks should be proactively pursued in the future. Further research may be carried out on hybrid techniques with integrations of EGWO with other metaheuristic algorithms to enhance solution performance and tackle varying challenges in smart agriculture.

***Abstract*—This study introduces CTU-Tutor, a contextual and user-aware intelligent tutoring system for generating personalized long-form text as learning content. The system combines BERT-based learner embeddings, K-means for proficiency clustering, Transformer-XL for long-context modelling, BiLSTM-CRF for concept extraction, and LDA-based knowledge graph construction. A retrieval-augmented Transformer-XL model produces personalized content, which is supplemented with explainable AI to make decisions transparently using SHAP and LIME. Experimental analysis shows that CTU-Tutor is better than state-of-the-art models, such as ExPerT, REST-PG, GSPT-CVAE, LONGLaMP, and Transformer_QA, in various metrics. The proposed framework has 0.98 accuracy, 0.98 F1-score, 0.97 MCC, and 0.98 precision, sensitivity, and specificity, and minimized false negatives (0.013) and false positives (0.017). For text generation, BLEU, ROUGE, and METEOR scores were approximately 0.98, indicating high overlap with the corresponding human-authored reference texts. These results prove that the synergistic implementation of learner profiling, long-context modelling, structured knowledge representation, and explainable AI delivers more precise, reliable, and pedagogically transparent personalized tutoring.**

***Keywords*—Contextual and user-aware tutoring system; bidirectional encoder representations of transformers; transformer-XL; bidirectional long short-term memory with conditional random fields; explainable AI; latent dirichlet allocation**

I. Introduction

Development of intelligent tutoring systems (ITS) that facilitate individualized learning experiences has been sped up by the quick development of artificial intelligence (AI) and natural language processing (NLP) [1]. AI-driven tutors provide opportunities for individualized guidance, scalable learning support, and ongoing assessment, in contrast to traditional classroom instruction, where teaching is frequently standardized and teacher attention is distributed among numerous students [2]. Adaptive systems are now essential to contemporary e-learning ecosystems due to the growing availability of digital educational content and learner interaction data [3]. This allows for content delivery that is responsive to learner profiles, progress, and preferences.

The capacity of current AI tutoring systems to produce lengthy, pedagogically structured, and contextually tailored content is still restricted, despite tremendous advancements [4]. The majority of the most advanced models, especially Transformer-based large language models (LLMs), concentrate on producing brief responses that frequently lack pedagogical depth and conformity to the proficiency levels of the learners [5,6]. Even though hybrid and retrieval-based tutoring systems have strengthened their factual foundation, they are still unable to meet the complex needs of educational personalization, like adjusting to a learner's preferred learning pathway, cognitive state, or past knowledge [7,8]. In addition, deep learning models' opaque decision-making creates obstacles to adoption and trust in authentic learning environments, where both educators and students expect clear and understandable systems [9,10].

The primary goals of the research are to design and create a personalized and context-aware tutoring system that produces long-form learning content that is specific to individual learners. To be more precise, the research develops learner embeddings and proficiency bands to use in adaptive instruction, deploys content understanding and knowledge extraction with the help of advanced NLP models, generates pedagogically coherent long-form explanations, and adds an explainable AI (XAI) layer to present transparent reasons and confidence scores, which contribute to the effectiveness of learning and increase the level of trust.

This study presents the CTU-Tutor, a novel framework that combines contextual knowledge extraction, learner profiling, content understanding, and explainable generation of long-form instructional material to address these issues. In contrast to previous methods, CTU-Tutor uses a customized Transformer-XL architecture in conjunction with knowledge graph-driven content structuring, proficiency-based clustering, and user-aware embeddings. The framework also integrates an XAI layer through SHAP and LIME, which offers both global and local interpretability, and uses curriculum learning with human feedback to guarantee pedagogical coherence. What sets CTU-Tutor apart from other AI tutors is its comprehensive fusion of explainability, context, and personalization.

The main contributions of this study are as follows:

- A learner profiling mechanism is developed by integrating BERT-based learner representations with K-Means proficiency clustering to identify learner proficiency bands and incorporate learner-specific

characteristics into personalized instructional content generation.

- A unified content-generation mechanism is developed by connecting learner-aware representations with contextual language modelling, concept extraction, and structured educational knowledge representation to support contextualized long-form instructional content generation.
- An explainability layer is integrated into the tutoring pipeline to provide interpretable explanations of learner-related predictions and generated instructional decisions, thereby improving transparency and supporting the pedagogical acceptability of the system.
- The above components are integrated into a unified tutoring pipeline that combines learner proficiency modelling, structured educational knowledge, contextual generation, retrieval-based grounding, and explainability.

The remainder of this article is structured as follows. Section II reviews related works in personalized tutoring, NLP-based educational systems, and explainable AI. Section III presents the proposed CTU-Tutor framework. Section IV presents results and comparative analysis. Finally, Section V concludes the study and summarizes key contributions.

II. Literature Survey

Lin et al. [11] introduced the EPER (Enhanced Personalization for Explainable Recommendation) model that used Transformer models with reviews, user ratings, feature words, and item titles to produce personalized explanations. This was to improve the quality and personalization of recommendations as well as overcome the weaknesses of the previous RNN-based approaches. Nevertheless, it had constraints in dealing with the sparsity of data and in adapting effectively to large-scale real-life recommendation problems.

Sapin et al. [12] proposed a transformer-based system that uses large language models (LLMs), specifically GPT-4 with prompt engineering, to recognize dialogue acts in team communication. This was done to improve adaptive training systems by increasing the accuracy of classification with a small amount of data. Nevertheless, it had drawbacks associated with the use of small datasets and potential limitations.

Vidakovic et al. [13] presented fine-tuned multilingual transformer models with data augmentation methods to examine Serbian student feedback in an Intelligent Tutoring System. This was to improve software performance and learning plans by means of automated feedback analysis. Nonetheless, the research had a limitation regarding language-specific generalizability and the reliance on annotated corpora to ensure the same performance.

Jia and Lee [14] proposed five methods of dealing with long-text sequences in organizational NLP studies, such as TF-IDF-RF, Longformer, GPT-4o, truncation with averaged scores, and a construct-relevant text-selection method. This was done to assess their predictive validity and psychometric properties. Nevertheless, the research had its limitations because no specific method was always better than others, which is why it is necessary to refine the research and make it context-specific.

Li et al. [15] proposed a large-scale benchmark called PERSONACONVBENCH that measures personalized reasoning and generation on multi-turn conversations. It was performed with the aim of measuring the effects of personalization in various areas systematically. The benchmark showed large performance improvements, but it was still constrained by Reddit-specific data and the high cost of evaluation.

Sharma et al. [16] surveyed how Large Language Models are transforming personalised learning as it provides learning paths according to the user's needs, styles, and preferences. The methods use user profiles, past interactions, and personalized goals with the help of prompting, fine-tuning adapters, and preference alignment. Despite the reported significant improvements, there were still challenges in terms of data privacy, scalability, and robustness when the user data is sparse or noisy.

Zhang et al. [17] have discussed the lack of cohesion in personalised LLM research by proposing a systematic taxonomy that consolidated personalized text generation and personalization-based downstream applications. The method formalized the underlying ideas, granularity of personalization, procedures, datasets, and assessment procedures to integrate various research strands. Although important for standardization and clarity, the methodology had weaknesses in conceptual abstraction and a lack of empirical validation on large-scale deployments.

Vinod et al. [18] proposed INVISIBLEINK, a differentially private text generation model that safely injected sensitive information into the text generated by an LLM. The method was based on a token sampling framework that modelled it as an exponential sampling mechanism. Although the efficiency gains were strong, limitations such as the complexity of added systems and the dependence on the careful separation of the public and the private signals were also present.

Baradari et al. [19] suggested NeuroChat, a neuroadaptive AI tutoring system combining real-time engagement monitoring using EEG with generative language models. The method used a closed-loop system to dynamically modify the content complexity, pacing, and style of response to the cognitive state of the learners. Although the results of pilots indicated better cognitive and subjective engagement, the small-scale assessment and lack of immediate improvement in the learning outcomes were considered limitations.

Wu et al. [20] presented the LongGenBench framework to evaluate the long-form text generation ability of LLMs rather than simple text generation. It generates long outputs up to 16k- 32k tokens while following multistep instructions, such as inserting events or constraints at specific positions in the text. It checks whether the framework only focuses on generating text of long length or adheres to the provided instructions across the generation process.

Rudik and Onyshchuk [21] studied the application of AI and large language models to English as a Second Language (ESP) education, including methods that used NLP and generative models to generate customized and profession-specific learning resources. The strategy was to increase the level of learner engagement, contextual relevance, and focused language acquisition through human-AI interaction. Although pedagogically important, such limitations as risk of bias, factual errors, and difficulties in the responsible incorporation of AI into the teaching practice of instructors were identified.

Safeni et al. [22] developed a game-theoretic model of controllable text generation that controlled the language model outputs by adaptive prompt interventions. The method used Nash equilibrium principles and feedback to optimize dynamically relevant diversity and coherence in the text generated. Despite its effectiveness and adaptability, the method was constrained by the complexity of the stimulation in the prompt and the dependence on the well-thought-out choice of the strategy. Table I presents existing models along with findings and associated limitations.

TABLE I. SUMMARY OF RELEVANT MODELS, FINDINGS, AND LIMITATIONS

Model	Findings	Disadvantages
ExPerT [23]	Improved alignment with human judgments by 7.2% while providing highly interpretable, fine-grained explanations for personalized text assessment.	Additional computational cost and potential bias in the evaluation process.
REST-PG [24]	Improved personalized long-form text generation by enabling LLMs to explicitly reason over user preferences	Increased training complexity and computational overhead
GSPT-CVAE [25]	Improved controllable long-text generation by learning rich graph-structured textual relationships and effective potential representations	Increased architectural complexity and computational overhead
LONGLaMP [26]	User-specific personalization across diverse personalized long-text generation tasks	Required substantial personalized data
Transformer_QA [27]	Accurate interpretation of student queries and enhanced engagement, motivation, and learning outcomes	Predefined rules, limited scalability, adaptability to diverse subjects

A. Problem Statement

Despite recent developments in AI-powered tutoring systems, the majority of current methods find it difficult to provide long-form educational content that is understandable, contextually aware, and personalized for each student. Either generic short-form responses are provided by current models, learner profiling and interpretability are not incorporated into the content generation process, or mechanisms for deep content understanding and knowledge structuring are absent. Because diverse learners need adaptive instruction that is in line with their learning context, pedagogical transparency, and proficiency levels, this leads to a substantial disconnect between automated tutoring systems and their real needs. For efficient and reliable individualized tutoring, a framework that combines user profiling, contextual knowledge extraction, personalized content creation, and explainable AI into a single pipeline must be created.

III. PROPOSED FRAMEWORK: CTU-TUTOR

Fig. 1 illustrates the general architecture of the proposed CTU-Tutor framework, which is organized into four large interconnected layers, each of which is essential in facilitating adaptive, personalized, and explainable tutoring. User Profiling and Context Understanding is the first layer, which provides the basis of the learner representation by incorporating both demographic and interactional information to create a holistic picture of the learner.

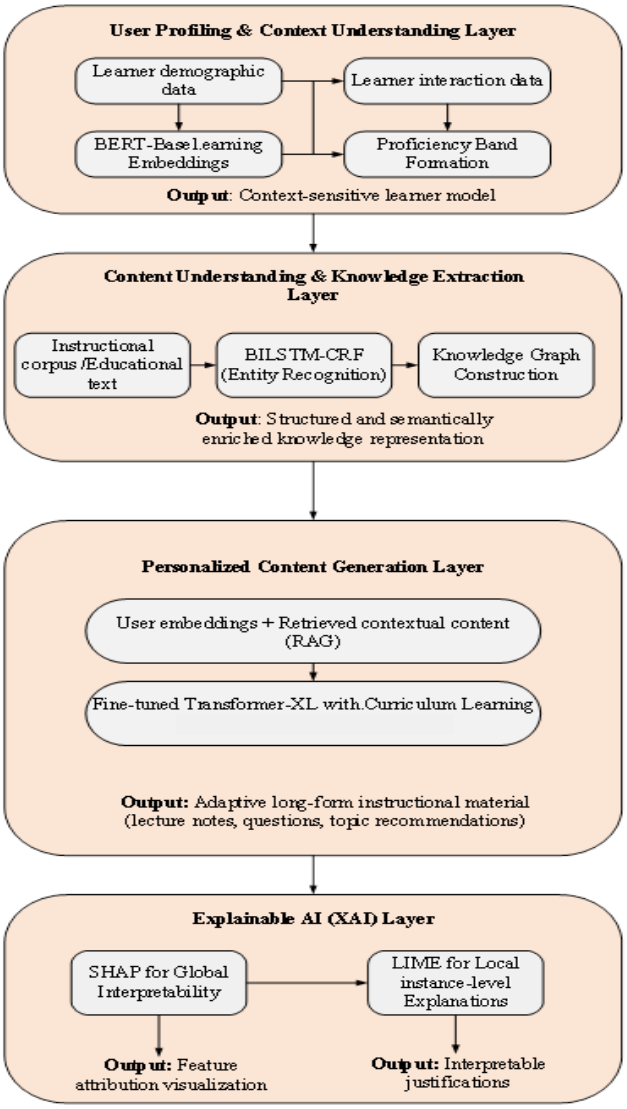

Fig. 1. Architectural design of the proposed CTU-Tutor framework.

The information is embedded using a BERT-based embedding model that is fine-tuned on educational metadata to transform heterogeneous information about learners into semantic numerical representations. These embeddings are then clustered using the K-Means algorithm to form proficiency bands, enabling the system to classify learners according to their skill levels and behavioural traits. The output of this layer is a context-sensitive learner model, which is used as the foundation of personalization in the framework. Content Understanding and Knowledge Extraction is the second layer,

which is concerned with the conversion of raw instructional materials into structured pedagogical knowledge. It starts with Transformer-XL, which classifies sentences at the sentence level to take into account long-range relationships in text, and then BiLSTM-CRF, which identifies the main educational concepts and relationships with the help of precise entity recognition and sequence labelling. The extracted entities are then semantically clustered using LDA to create a topic-based representation, which drives a Knowledge Graph Construction module that generates a structured and semantically enriched knowledge representation of the educational corpus. Personalized Content Generation is the third layer, which combines the information of user profiles and content structures to create adaptive instructional content. It integrates user embeddings from the first layer with contextual outputs retrieved via RAG, and uses a fine-tuned Transformer-XL trained under curriculum learning principles and human feedback alignment to produce long-form, pedagogically coherent outputs such as lecture notes, topic recommendations, and question-answer sets. Finally, the XAI Layer enhances transparency and trust by incorporating SHAP for global interpretability and LIME for local, instance-based explanations. This layer outputs feature attribution visualizations and interpretable justifications, helping educators and learners understand the rationale behind each recommendation and generated content. Overall, the proposed CTU-Tutor integrates user modelling, deep content understanding, personalized generation, and explainable AI into a unified, intelligent tutoring pipeline that ensures contextual relevance, pedagogical coherence, and interpretability in every stage of personalized learning.

A. User Profiling and Context Understanding

During this stage, the demographic data as well as the interaction data are gathered to ensure that a holistic representation of the learner is achieved. This is critical in modelling not only the knowledge state of the learner but also their behaviour patterns, which have a direct impact on the adaptation of instructional content. To represent the information about the learners formally, we define the demographic data as a feature vector:

$$D_i = \{d_{i1}, d_{i2}, \dots, d_{im}\}, i = 1,2, \dots, N \quad (1)$$

where, D_i denotes the demographic attributes of the learner i across m features. Similarly, the interaction data is represented as:

$$I_i = \{i_{i1}, i_{i2}, \dots, i_{im}\}, i = 1,2, \dots, N \quad (2)$$

where, I_i captures the sequence of interaction features for the learner i. The input feature set of the user embedding is the combination of both demographic and interaction features:

$$X_i = D_i \cup I_i \quad (3)$$

A BERT-base model [28] that is fine-tuned on learner metadata is used to convert this heterogeneous data into meaningful numerical representations. Let f_{BERT} represent the embedding function; the learner embedding for the user i is obtained as:

$$E_i = f_{BERT}(X_i) \in R_k \quad (4)$$

where, E_i is the embedding vector of dimension k, encapsulating the semantic and contextual representation of the learner's profile and learning behavior. These embeddings enable the framework to process learner profiles not as discrete categorical features but as high-dimensional and context-rich representations, which are used in downstream tasks like clustering and personalization.

Once embeddings are generated, the next step is to categorize learners into proficiency bands using the K-Means clustering algorithm [29]. The clustering objective is to partition the embedding space into K clusters $\{C_1, C_2, \dots, C_K\}$ such that intra-cluster similarity is maximized while inter-cluster similarity is minimized. Mathematically, the optimization function of K-Means is given by:

$$\underset{c}{argmin} \sum_{j=1}^{k} \sum_{E_i \epsilon c_j} \|E_i - \mu_j\|^2 \quad (5)$$

where, μ_j denotes the centroid of the cluster C_j. To avoid circularity between the learner representation and proficiency labels, we separate historical input variables from target variables. Let $X_i^{(t)}$ denote the historical features available for the learner i at time t, constructed as in Eq. (3) from demographic and interaction information up to time t. The learner representation is computed as:

$$E_i^{(t)} = f_{\text{BERT}}\left(X_i^{(t)}\right) \quad (6)$$

where, f_{BERT} is the fine-tuned BERT-based encoder. Proficiency categories are derived from future performance $y_i^{(t+\Delta)}$ on held-out assessment items at time $t + \Delta$ and are not used as inputs to the encoder. The learner profile is therefore trained to map historical inputs $X_i^{(t)}$ to a latent state $E_i^{(t)}$ that predicts future outcomes $y_i^{(t+\Delta)}$, rather than reconstructing predefined proficiency labels from the same information. The resulting clusters represent distinct proficiency levels, allowing the system to adapt learning content according to the learner's placement. In this step, CTU-Tutor creates a context-sensitive learner model that combines demographic information, behavioural information, and latent proficiency structures. Table II shows the learner profiling attributes and value ranges.

TABLE II. LEARNER PROFILING ATTRIBUTES AND VALUE RANGES USED IN THE CTU-TUTOR FRAMEWORK

Attributes	Value Range
Age	6 to 18
Grade	1 to 12
Level	Basic, Intermediate, Advanced
Math Score	1 to 100
Science Score	1 to 100

Table II presents the most important learner profiling features employed in the CTU-Tutor framework to model the learner demographics and academic proficiency. The age group is between 6 and 18 years, which is inclusive for learners in Grades 1 to 12, thus covering primary, middle, and secondary education. The proficiency of learners is divided into three levels, namely Basic, Intermediate, and Advanced, depending on the performance and interaction patterns. The quantitative

assessment scores are included, with normalized Math and Science scores between 1 and 100, which allows distinguishing between learners' capabilities at a finer level. Learners with a score above 80 are normally assigned to the Advanced level, those with a score between 50 and 80 to the Intermediate level, and those with a score below 50 to the Basic level. Such a structured representation enables CTU-Tutor to effectively reflect the heterogeneity of learners and demonstrate the use of personalization and adaptive content delivery in a wide range of educational levels. The process is shown in Fig. 2.

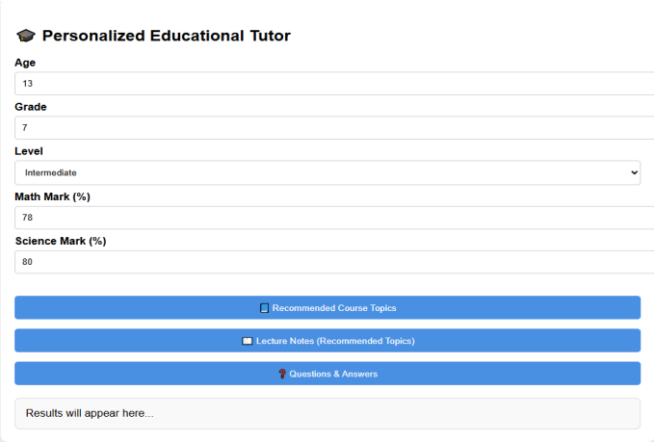

Fig. 2. User-interface module of the Personalized Educational Tutor showing learner input fields and adaptive content generation options.

Fig. 2 shows the user-interface layer of the proposed Personalized Educational Tutor, which shows how learner-specific inputs are taken and processed to create adaptive instructional content. The interface records key demographic and academic characteristics, such as age, grade, level of proficiency, and performance in each subject of study, which are the main inputs to the learner profiling module. After the user keys in values like Math and Science percentages, the system uses the underlying CTU-Tutor framework to fill three main adaptive elements, namely Recommended Course Topics, Lecture Notes, and Questions and Answers. Every button activates a respective custom output produced based on the embedded learner, content, and RAG-based generation pipeline. The hierarchical design of the interface makes the interaction flow smooth, with user inputs converted to valuable educational suggestions. The lower presentation area is the dynamic output area, where customized pedagogical content is shown, based on the band of proficiency and the contextual learning requirements of the learner.

B. Content Understanding & Knowledge Extraction

In the second phase, CTU-Tutor focuses on deep content understanding and the extraction of structured knowledge representations from the instructional corpus. The process begins with sentence-level classification, where instructional content is segmented into sentences $S = \{s_1, s_2, \ldots, s_n\}$. The sentence is then coded and processed with the proposed Transformer-XL [30] architecture that is aimed at identifying long-term dependencies in the educational text. In contrast to typical transformers, Transformer-XL adds segment-level recurrence and relative positional encoding, which allows the model to process longer sequences without losing contextual information. Formally, given an input sentence embedding h_t, the recurrent update is defined as:

$$h_t = TransformerXL(x_t, h_{t-1}, \theta) \quad (7)$$

where, x_t is the token embedding at position t, h_{t-1} represents the hidden state carried over from the previous segment, and θ denotes the model parameters. This mechanism enables the system to categorize every sentence into pedagogical categories of definition, explanation, example, or assessment item, which is necessary for delivering structured content.

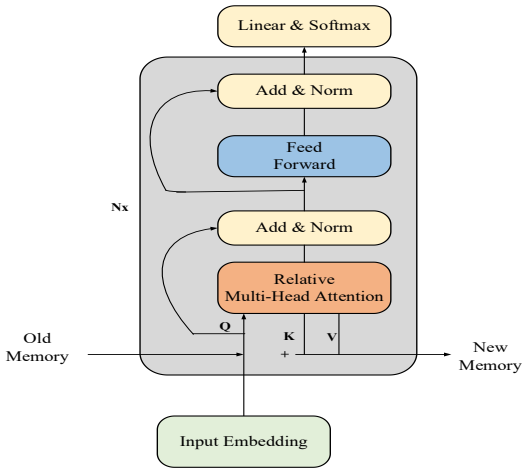

Fig. 3. Transformer-XL architecture with segment-level recurrence and relative multi-head attention for long-context modelling.

Fig. 3 shows the architecture of the Transformer-XL model of the CTU-Tutor framework. Transformer-XL, in contrast to the traditional transformer, uses a segment-level recurrence mechanism, which enables the model to reuse hidden states in the past segment, thus preserving long-term contextual dependencies between text sequences. The first stage is the Input Embedding layer, where the tokens are converted to continuous vectors. Relative Multi-Head Attention module considers the contextual relations between tokens and takes into account their relative positions, but not absolute ones, and thus better generalizes to long documents. The Add and Norm layers are added to provide network stability and non-linearity, respectively, and residual connections are added to improve gradient flow in training. The architecture holds Old Memory of the previous segments and creates New Memory of the current one, so that there is continuity in semantic understanding. The top Linear and Softmax layer gives the final output probabilities of a classification or contextual prediction task. This architecture enables CTU-Tutor to read instructional text with more semantic coherence and contextual richness, which is necessary to construct structured pedagogical representations.

After the classification of the sentence, entity recognition and sequence tagging are carried out to find the domain-specific concepts, terminologies, and relations in the text. To do this, a BiLSTM-CRF [31] is incorporated. The BiLSTM captures bidirectional contextual information, and the CRF provides globally consistent sequence labelling. Given a

sequence of tokens (w_1, w_2, …, w_m), the BiLSTM generates contextual embeddings:

$$h_i = BiLSTM(w_i), i = 1,2, \dots, m \quad (8)$$

These embeddings are then passed through the CRF layer to maximize the probability of the correct label sequence y = (y_1, y_2, …, y_m):

$$P(y|h) = \frac{exp(\sum_{i=1}^{m} \psi(y_{i-1}, y_i, h_i))}{\sum_{y' \epsilon y} exp(\sum_{i=1}^{m} \psi'(y'_{i-1}, y'_i, h_i))} \quad (9)$$

where, ψ denotes the potential function that models the dependency between labels and embeddings. This ensures precise recognition of entities such as concepts, prerequisite skills, and learning objectives, which are later used to build structured knowledge.

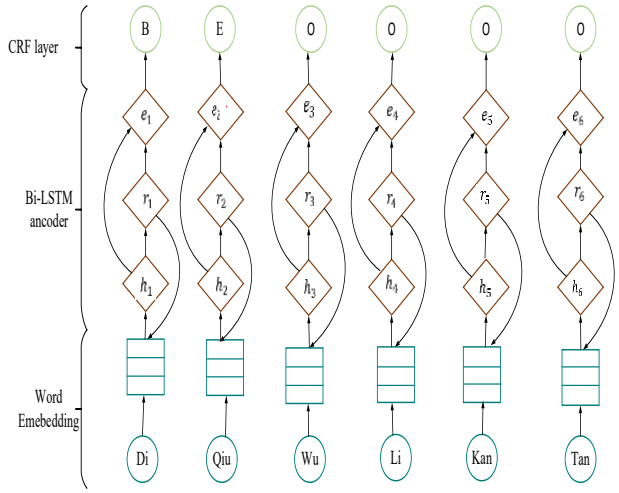

Fig. 4. BiLSTM-CRF architecture for context-aware entity recognition and sequence tagging in CTU-Tutor.

The BiLSTM-CRF architecture of the CTU-Tutor framework for recognising the correct entities and sequence tagging is shown in Fig. 4. It starts with the Word Embedding layer, in which every token in the instructional text is transformed into a dense representation of a vector that represents its semantic meaning. These embeddings are then fed into the BiLSTM Encoder, which processes the sequence in both forward and backward directions, thus identifying the past and future contextual dependencies within the text. Both directions are combined to give a complete representation of each token as the hidden states. The resulting contextual embeddings are then input into the Conditional Random Field (CRF) layer, which captures the relationship between the output labels to provide globally consistent sequence predictions. This combination allows the system to identify domain-specific entities like concepts, prerequisite skills, and learning outcomes with high precision. Using the contextual sensitivity of the BiLSTM and the structured prediction nature of the CRF, CTU-Tutor can extract semantically rich and pedagogically relevant units of knowledge out of unstructured instructional material.

LDA is used to add more semantic representation by topic modelling and building the knowledge graph [32]. LDA assumes that every document is a combination of latent topics and every topic is defined by a distribution over words. LDA is generated by the following process:

$$(w \mid \alpha, \beta) = \prod_{d=1}^{D} \int P(\theta_d|\alpha) \left(\prod_{n=1}^{N_d} \sum_{z_{dn}} P(z_{dn}|\theta_d)\ P(w_{dn}|z_{dn}, \beta) \right) d\theta_d \quad (10)$$

where, α and β are hyperparameters controlling topic distributions, θ_d represents the topic proportions for document d, and z_{dn} is the topic assignment for the n^{th} word in document d. Transformer-XL, used to understand deep sequences, BiLSTM-CRF, used to identify entities precisely, and LDA-driven knowledge graph construction are combined to provide CTU-Tutor with a complete representation of the educational content, between unstructured text and learner-centric knowledge delivery.

C. Personalized Content Generation

During this stage, the system produces adaptive learning content based on the profile and the knowledge level of the individual learner. The Transformer-XL model is fine-tuned with curriculum learning and further improved with human feedback alignment, which guarantees progressive knowledge provision between simple and complex concepts [33]. The learning process of the curriculum is as follows:

$$L_{total} = \sum_{i=1}^{n} w_i L_i \quad (11)$$

where, L_i represents the loss for the i^{th} difficulty level and w_i denotes its curriculum-based weighting factor that ensures gradual learning adaptation.

To achieve contextual grounding, user embeddings (E_u) derived from the profiling phase are fused with Retrieval-Augmented Generation (RAG) [34] outputs (E_r) to produce personalized responses:

$$E_c = \lambda E_u + (1 - \lambda) E_r \quad (12)$$

where, λ is the contextual balance coefficient controlling personalization versus retrieved knowledge influence. The final generated content Y_t is conditioned on the contextual embedding E_c:

$$Y_t = TransformerXL(E_c, History_{t-1}) \quad (13)$$

This integration enables the model to be coherent over long sequences and ensures that the generated content is relevant to the level of proficiency of the learner, already acquired topics, and the learning objectives.

e RAG component uses a dense semantic retriever based on Sentence-BERT to identify relevant passages from the educational corpus. The documents are segmented into overlapping passages of approximately 180 tokens with an overlap of 30 tokens and indexed using FAISS with inner-product search on normalized embeddings. For each learner–topic query, the retriever returns the top-k relevant passages, with $k = 5$ used as the default configuration. When retrieved passages contain conflicting evidence, passages with higher retrieval relevance and stronger agreement with the target concept are prioritized before conditioning the generator, while conflicting or low-confidence evidence is not treated as equally reliable. Retrieval quality was evaluated using Recall@k, while

grounding quality was assessed using concept coverage and evidence precision. To investigate the effect of retrieval depth, experiments were conducted using $k \in \{1, 3, 5, 10\}$. The balance coefficient controls the relative contribution of retrieved evidence and learner-personalization information during generation. Candidate values $\lambda \in \{, 0.2, 0.4, 0.5, 0.6, 0.8, 1.0\}$of were evaluated on the validation set, and the value providing the best overall balance between personalization, grounding, and generation quality was selected and fixed for the final test evaluation.

TABLE III. TEST CASE–BASED ILLUSTRATION OF PERSONALIZED CONTENT RECOMMENDATION AND GENERATION IN THE CTU-TUTOR FRAMEWORK

Cases	Input	Recommended course Topics	Lecture Notes	Questions &Answers
Case 1	Age: 12 Grade:7 Math Score: 70 Science Score: 80 Level: Intermediate	**Maths Topics:** Polygons, Rational Numbers, Probability, Graphical Representation, Angles and Triangles, Area and Perimeter **Science Topics:** Nutrition in Animals, Weather and Climate, Motion and Time, Electric Effects, Heat Energy, Light Reflection	**Nutrition in Animals:** Animals obtain food through ingestion, digestion, absorption, and assimilation. The process differs among herbivores, carnivores, and omnivores. Humans use organs like the stomach and intestines for digestion. This topic helps us understand biological processes and healthy nutrition.	Q: What is a food chain? Example? A: Energy transfer through eating. Example: Grass -> Rabbit -> Fox.
Case 2	Age: 15 Grade:9 Level: Beginner Math Score: 50 Science Score: 80	**Maths Topics:** Polynomials, Coordinate Geometry, Trigonometry, Quadratic Equations **Science Topics:** Gravitation, Atoms and Molecules, Diversity in Living Organisms, Natural Resources	**Gravitation:** Gravitation is the force of attraction between objects with mass. It governs the motion of planets and falling bodies on Earth. Understanding gravitation deepens knowledge of astronomy and physical laws of nature.	Q: What is the value of acceleration due to gravity on the surface of the Earth? A: $g = 9.8\ m/s^2$.

Table III demonstrates two test cases demonstrating the adaptive behaviour of the CTU-Tutor framework in the context of different learner profiles. The inputs of the learners, including Math score, Science score, grade level, and a proficiency category (Beginner, Intermediate, or Higher), are combined to create individual course topic suggestions, summarized lecture notes, and context-sensitive question-answer interactions in each case. Intermediate performers are assigned basic but conceptually challenging subjects like polygons, probability, motion, and heat. Conversely, students with lower scores are directed to concept reinforcement using basic geometry, trigonometry, life processes, and atoms and molecules. The lecture notes that are generated focus on the essential definitions, examples, and practical applicability, whereas the customized question-answer modules solidify the conceptual knowledge and self-evaluation. Overall, this table shows that CTU-Tutor is capable of dynamically matching the complexity, depth, and pedagogical focus of content to the individual learner's proficiency, which confirms its relevance in the generation of educational content.

D. XAI Layer

The XAI [35] Layer of the proposed personalized educational tutor system ensures that every decision made by the model is transparent, interpretable, and pedagogically explainable. Although deep learning models such as Transformer-XL and BERT-based embeddings provide unparalleled predictive power, their decision-making processes tend to be black-box, which is a problem in educational applications where explainability and trust are key factors. The XAI Layer fills this gap by combining SHAP (SHapley Additive exPlanations) to achieve global interpretability and LIME (Local Interpretable Model-agnostic Explanations) to achieve instance-level reasoning. Collectively, these techniques offer global and local information on the effects of user features on personalized recommendations and content generation that eventually allows transparent decision-making to educators and learners.

1) SHAP-based global feature attribution: The SHAP approach is based on cooperative game theory and gives each input feature a contribution score depending on its contribution to the output of the model [36]. For a model f(x), the SHAP value ϕ_i for a feature i represents its average marginal contribution across all possible feature subsets $S \subseteq F \setminus \{i\}$:

$$\emptyset_i = \sum_{S \subseteq F \setminus \{i\}} \frac{|S|!(|F|-|S|-1)!}{|F|!} [f(S \cup \{i\}) - f(S)] \quad (14)$$

Here, F represents the complete set of features, f(S) is the model prediction using the subset S, and ϕ_i quantifies the contribution of the feature i to the final prediction. To determine which features have the biggest impact on tailored topic recommendations, SHAP values are employed. By highlighting dominant attributes throughout the dataset, the aggregated SHAP plot offers global interpretability and helps educators comprehend important learning determinants. The SHAP analysis is shown in Fig. 5.

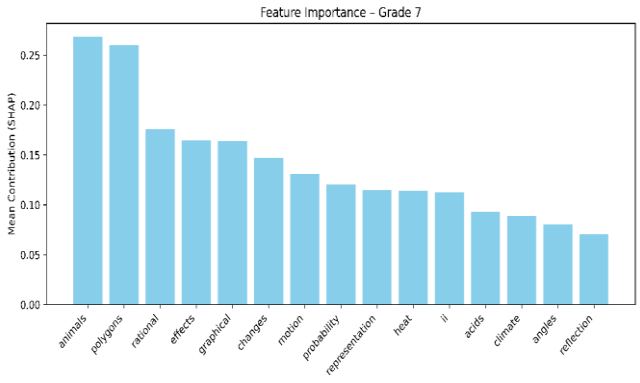

Fig. 5. Global SHAP feature importance plot illustrating the relative contribution of topic-related features to personalized content recommendations for Grade 7 learners.

Fig. 5 presents the SHAP-based feature importance analysis of Grade 7 learners across the world, which demonstrates the comparative role of various topic-based features in the individual recommendation model. It is noted that the highest contributions are made by animals and polygons, which indicates that the performance and interest of the learner in these subjects are the primary factors that influence the personalized content recommendation at this grade level. Rational numbers, effects, graphical concepts, and changes are features that have a moderate influence, as they reflect the supportive nature of the features in the formation of adaptive learning paths. Conversely, features such as acids, climate, angles, and reflection have relatively lower SHAP values, meaning that they have less influence on the recommendation results. Overall, this figure demonstrates that the CTU-Tutor model uses explainable AI to understand the most significant pedagogical motivators. This enables teachers to understand and trust the factors that influence individual decision-making in teaching decisions.

2) LIME-based local explanation: The LIME approach gives instance-level interpretability, which describes the way individual predictions are made on a given user profile [37]. It fits the complex model locally with an interpretable surrogate and is expressed as:

$$argmin_{g\epsilon G} L(f, g, \pi x) + \Omega(g) \quad (15)$$

where, f is the original complex model, g is a simple interpretable model (e.g., linear regression), L(f, g, π_x) is the loss function ensuring gapproximates fnear instance x, π_x is a locality weighting kernel, and Ω(g) penalizes model complexity. For every suggestion, LIME provides a human-readable justification, such as emphasizing that "Science marks above 85% increase the likelihood of recommending advanced Physics topics." This promotes user trust and helps educators design interventions by allowing transparent decision justification at the individual learner level. The process is shown in Fig. 6.

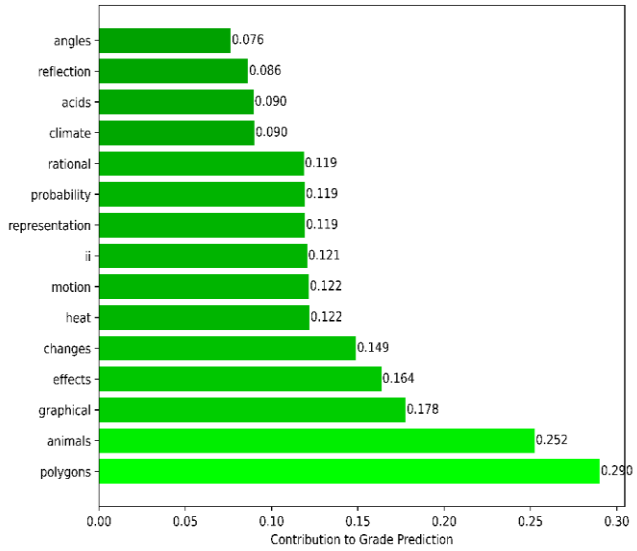

Fig. 6. LIME-based local feature contribution plot illustrating instance-level interpretability of topic influences on Grade 7 learner prediction.

Fig. 6 shows the contribution analysis of local features of LIME on a single Grade 7 learner, demonstrating the influence of some subject-related features on the model prediction at the instance level. The positive values indicate that the features increase the likelihood of the chosen recommendation or grade prediction. The strongest positive impact is produced by polygons and animals, which emphasizes that the high performance or interest of learners in the given topics is vital in the localized decision of the model. There are also features like graphical concepts, effects, and changes that have significant contributions, which implies that they are supportive of the prediction. Conversely, subjects such as angles, reflection, acids and climate lack a significant role, implying a relatively small role in the decision-making of the model by this specific learner. In general, this number shows that the CTU-Tutor framework utilizes LIME to explain the instances in a transparent and instance-specific way. This allows teachers and students to comprehend clearly why some personalized recommendations are produced.

IV. Results and Discussion

The performance analysis of the proposed CTU-Tutor model as compared to the current state-of-the-art personalized tutoring systems, such as ExPerT (Explainable Personalized Tutor) [23], REST-PG (Reinforcement-based Student Tutor with Personalization and Generation) [24], GSPT-CVAE (Goal-Specific Personalized Tutoring using Conditional Variational Autoencoder) [25], LONGLaMP (Long-form Language Model for Personalized Learning and Mentorship) [26] and Transformer_QA [27] are presented in the results and discussion section. CTU-Tutor was assessed on two different levels: intermediate classifications and text generation. The intermediate steps, including Transformer-XL sentence classification, BiLSTM-CRF concept/entity recognition, and K-Means-based topic recommendations, were evaluated using measures such as accuracy, precision, recall, F1-score, specificity, sensitivity, MCC, FNR and FPR. The generated output such as lecture notes, explanations, and question-answer pairs, was assessed separately using perplexity, BLEU, ROUGE-1/2/L and METEOR scores. Therefore, the classification measures assess the performance of the modules within the framework, whereas the generation measures evaluate the final output quality. The dataset consists of about 12,500 K-12 Mathematics and Science instructions in the form of openly available textbooks and curriculum guidelines for Grades 1-12. The test dataset consisted of 1,800 learner-topic pairs where each generated output was compared to the corresponding reference manually produced by humans.

To evaluate the proposed CTU-Tutor framework, a synthetic educational dataset was generated by integrating and refining information collected from multiple publicly available Kaggle datasets. Learner demographic and academic attributes, including age, Mathematics score and Science score, were obtained from the Student Academic Performance Dataset [https://www.kaggle.com/datasets/lorenzoscaturchio/student-academic-performance-dataset]. To better align the dataset with the proposed ITS, data extension and domain-specific attribute augmentation were performed. Two synthetic pedagogical attributes- grade (1-12) and level (difficulty level of the questions: basic, intermediate, and advanced) were

incorporated into the dataset. The age distribution was also expanded (age 6 – 18), to include K-12 age span. The recommendation of the topic was done on the basis of the K-12 curriculum, where topics were divided into groups according to the difficulty level of the concept. Mathematics reasoning problems with detailed step-by-step solutions were collected from the AIMO External Dataset [https://www.kaggle.com/datasets/alejopaullier/aimo-external-dataset] and MathInstruct Dataset: Hybrid Math Instruction[https://www.kaggle.com/datasets/thedevastator/mathinstruct-dataset-hybrid-math-instruction-tun], while Science question–answer pairs and explanatory learning materials were extracted from the ScienceQA dataset [https://www.kaggle.com/datasets/lephuocdat2/scienceqa] and AI2 ARC - Advanced Science Question [https://www.kaggle.com/datasets/thedevastator/advanced-science-question-dataset]. A synthetic dataset was constructed using information collected from the mentioned databases and conceptual definitions related to the specific topic. Subsequently, learner profiles were linked with appropriate Mathematics and Science instructional content based on proficiency levels to synthetically generate personalized learning instances comprising recommended topics, lecture notes, explanatory content, and question–answer pairs. The resulting integrated dataset was employed to train and evaluate the proposed CTU-Tutor framework for contextual learner modelling, adaptive content recommendation, long-form educational content generation, and explainable personalized tutoring.

Fig. 7(a) shows the accuracy performance of the proposed CTU-Tutor model compared to existing methods. The proposed model achieves the highest accuracy of 0.98, clearly outperforming baseline approaches. In contrast, ExPerT has an accuracy of 0.93, REST-PG 0.92, GSPT-CVAE 0.90, LONGLaMP 0.91, and Transformer_QA 0.94. These results demonstrate that the CTU-Tutor framework offers better personalization and consistency in the generated content. As a result, CTU-Tutor reduces both misclassification and personalization mismatch, leading to consistently higher prediction accuracy across diverse learner profiles.

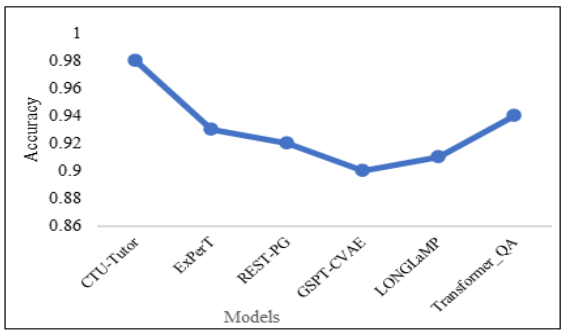

Fig. 7(b) shows the comparison of the performance of the F1-score of the proposed CTU-Tutor model and the existing methods. The highest F1-score of 0.98 is observed in the proposed model, indicating its high balance between precision and recall. Comparatively, ExPerT has an F1-score of 0.92, REST-PG has 0.88, GSPT-CVAE has 0.96, LONGLaMP has 0.87, and Transformer_QA has 0.93. These findings indicate that CTU-Tutor has always provided greater predictive reliability and accuracy in personalization, and it performs better than the existing models in terms of adaptation to learners. This high balance is made possible because proficiency-band-based learner clustering and long-range contextual modelling are integrated using Transformer-XL. CTU-Tutor reduces false positives and false negatives in personalized content prediction, and thus, enhances precision-recall trade-offs.

Fig. 7(c) shows the relative False Negative Rate (FNR) of the various models. The proposed CTU-Tutor has the lowest FNR of 0.013, indicating that it is highly capable of reducing the number of missed predictions relevant to the learner. ExPerT, conversely, reports an FNR of 0.056 REST-PG reports an FNR of 0.078, GSPT-CVAE reports an FNR of 0.092 and LONGLaMP reports an FNR of 0.089, and Transformer_QA reports an FNR of 0.055. These findings indicate that the CTU-Tutor framework significantly reduces false negatives, thereby enhancing reliability and ensuring that the key needs of learners are not overlooked. This decrease in FNR is primarily due to proficiency-conscious learner embeddings and long-context sentence modelling. CTU-Tutor allows the detection of learners' needs early and correctly, which is missed in short-context or generic personalization models.

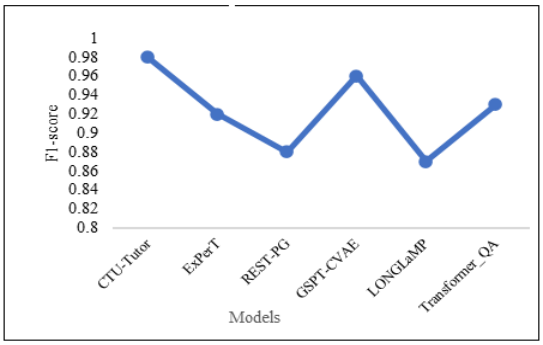

Fig. 7(d) shows the comparison of the False Positive Rate (FPR) of the proposed and existing models. The lowest FPR of 0.017 for the proposed CTU-Tutor indicates that it is capable of reducing the number of false positive predictions and thus enhancing reliability in content recommendation. Conversely, ExPerT has an FPR of 0.050, REST-PG has 0.063, GSPT-CVAE has the largest FPR of 0.096, LONGLaMP has 0.082, and Transformer_QA has 0.058. These findings validate the fact that the CTU-Tutor framework not only increases accuracy but also minimizes unnecessary false alarms, which guarantees accurate and context-based support to learners. The combination of the knowledge-graph-based content structuring and explainable feature attribution leads to this improvement. CTU-Tutor enables the model to filter out irrelevant or weakly supported suggestions and thus prevent over-prediction common in purely generative or retrieval-based systems.

Fig. 7(e) illustrates the comparison of the Matthews Correlation Coefficient (MCC) of the proposed and the existing models. The proposed CTU-Tutor has the highest MCC score of 0.97, which means that it is more predictive, reliable, and has a high balance of true positives, true negatives, false positives, and false negatives. Comparatively, ExPerT scores 0.92, REST-PG scores 0.94, GSPT-CVAE scores 0.91, LONGLaMP scores 0.89 and Transformer_QA scores 0.94. These findings affirm that the CTU-Tutor framework offers the best and most stable classification performance compared to the existing models. This high performance in MCC in CTU-Tutor collectively optimises learner profiling, long-context content comprehension and explainable decision refinement, which guarantees that error distribution is even across all classes, instead of focusing on a single performance indicator.

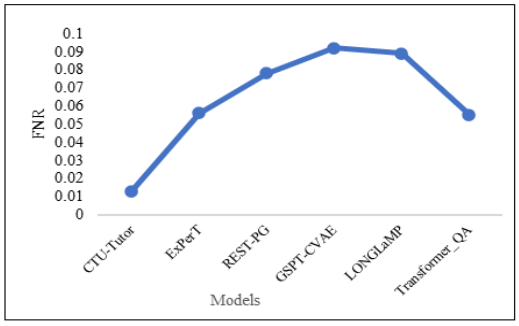

Fig. 7(f) shows the Negative Predictive Value (NPV) comparison of the proposed and existing models. The proposed CTU-Tutor has the highest NPV of 0.98, which implies that it properly determines the true negatives and reduces the false negatives. ExPerT, on the other hand, has an NPV of 0.91, REST-PG has 0.96, GSPT-CVAE has 0.91, LONGLaMP has 0.90 Transformer_QA has 0.94. These findings show that the CTU-Tutor framework is always better than the current models, which guarantees that the negative classes are predicted more reliably. These proficiency-conscious clustering and explainable filtering mechanisms in CTU-Tutor assist the model in effectively eliminating inappropriate or irrelevant content suggestions and enhance negative-class prediction accuracy.

Fig. 7. Performance comparison of the proposed and existing methods.

Fig. 7(g) compares the precision values of the proposed model with those of existing techniques, ExPerT, REST-PG, GSPT-CVAE, and LongLaMP. The proposed model achieves the highest accuracy at 0.98, followed by GSPT-CVAE at 0.96, ExPerT at 0.91, REST-PG at 0.90, LongLaMP at 0.88, and Transformer_QA at 0.93. This demonstrates that the CTU-Tutor model outperforms all existing models by providing better accuracy in detecting relevant instances with fewer false positives. This increased accuracy is achieved by incorporating knowledge-graph-based content validation and explainable feature attribution, which together discourage spurious suggestions, and only highly relevant matches between learners and content are maintained.

Fig. 7(h) illustrates the sensitivity comparison between the proposed model and existing techniques, including ExPerT, REST-PG, GSPT-CVAE, and LongLaMP. The proposed model achieves the highest sensitivity of 0.98, followed closely by GSPT-CVAE with 0.96, REST-PG with 0.90, ExPerT with 0.88, LONGLaMP with 0.85 and Transformer_QA with 0.94. This demonstrates that the CTU-Tutor approach effectively identifies true positive instances, showing enhanced responsiveness and detection capability compared to existing methods. This sensitivity is facilitated by long-range contextual modelling and curriculum-relevant content generation, which enables the system to find finer learner needs and learning cues that are frequently ignored by short-context or fixed personalization models.

Fig. 7(i) presents a comparison of specificity between the proposed model and current methods, including ExPerT, REST-PG, GSPT-CVAE, and LongLaMP. The highest specificity of the proposed model is 0.98, then GSPT-CVAE, 0.97, ExPerT, 0.91, REST-PG, 0.90, LONGLaMP, 0.88, and Transformer_QA, 0.94. This shows that the CTU-Tutor framework reduces false positives and has a better capacity to identify negative cases than other models. This higher specificity is enabled by proficiency-conscious learner modelling and explainable decision refinement, which enables the system to reject irrelevant or unsuitable content recommendations without lowering the accuracy of personalisation.

Fig. 8 shows the perplexity comparison of various models. The lowest perplexity of 11.0 was reached with the proposed model, which means that it has better prediction consistency and language understanding. The second-best performance is ExPerT with a perplexity of 12.5, then LongLaMP with 14.0, GSPT-CVAE with 15.7 and the highest perplexity of about 18.0 recorded by REST-PG and Transformer_QA with 13.1. The perplexity of the CTU-Tutor model is significantly lower, indicating that it is more capable of producing more coherent and contextually accurate outputs than current methods. This improvement is primarily attributed to the use of Transformer-XL with segment-level recurrence and curriculum-directed fine-tuning for generating long-form text stably and maintaining semantic continuity across long instructional sequences.

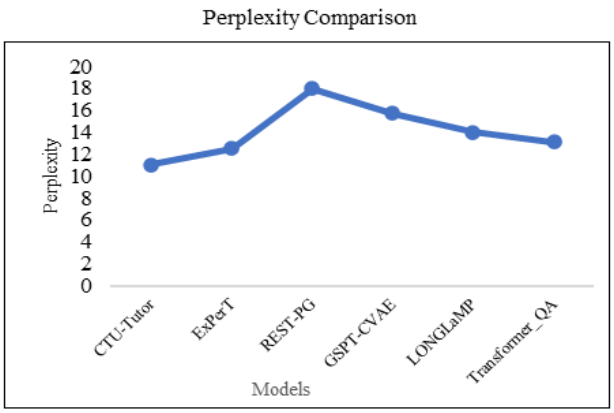

Fig. 8. Perplexity comparison of the proposed and existing methods.

Fig. 9 shows the ROUGE performance comparison of five models, which include Proposed, ExPeRT, REST-PG, GSPT-CVAE, and LongLaMP using ROUGE-1, ROUGE-2, and ROUGE-L measures. The Proposed model has the highest scores (0.98) in all three metrics, which indicates a high quality of summarization and a better fit to reference texts. ExPeRT comes right behind with a score of about 0.93-0.94, and REST-PG, GSPT-CVAE, and LongLaMP have slightly lower scores of 0.91-0.93. In general, the near-unity ROUGE values demonstrate that all models have a high level of text coherence and content relevance, and the CTU-Tutor model demonstrates the most effective linguistic overlap and contextual accuracy. This performance improvement is due to the combination of knowledge-graph-based content structuring and long-context

generation, which allows the model to maintain the important semantic units and discourse-level correspondence across the long-form instructional outputs.

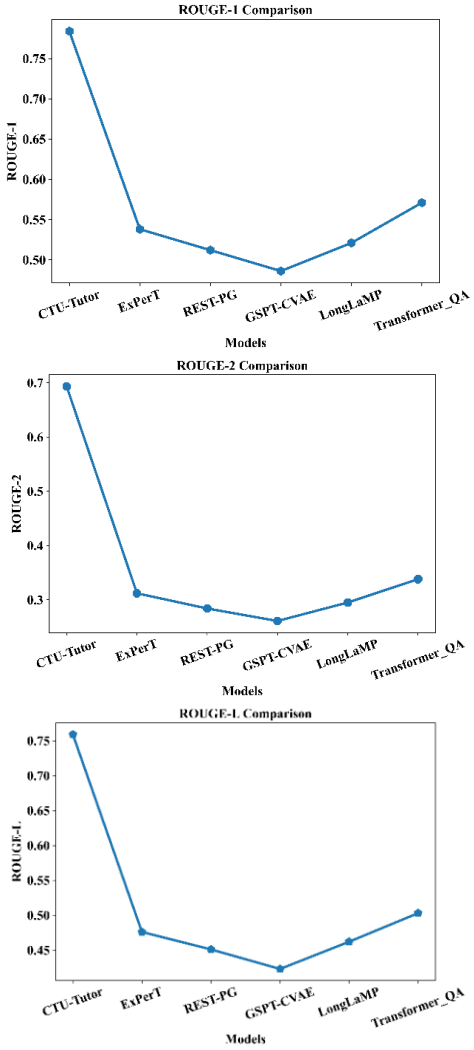

Fig. 9. ROUGE metrics comparison of the proposed and existing methods.

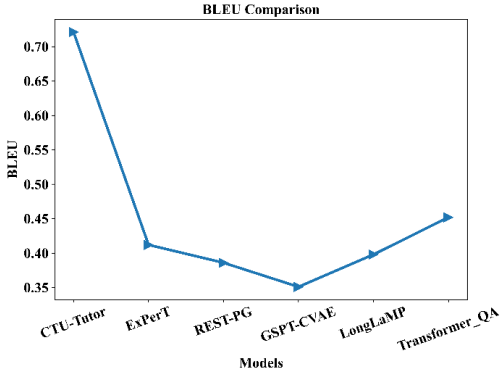

Fig. 10. BLEU comparison of the proposed and existing methods.

Fig. 10 shows the comparison of the BLEU score between the five models: Proposed, ExPeRT, REST-PG, LongLaMP, and GSPT-CVAE. CTU-Tutor achieved approximately 0.98 for BLEU, ROUGE-1, ROUGE-2, ROUGE-L, and METEOR. These unusually high scores are interpreted as measures of overlap with the human-authored references and should not be considered, in isolation, as evidence of overall linguistic or pedagogical quality. ExPeRT scores slightly lower at 0.93, then REST-PG at 0.92, and LongLaMP and GSPT-CVAE have a score of 0.91, and Transformer_QA has 0.94. The findings indicate that the CTU-Tutor model has the best language generation and consistency in translation among all of the other models tested. This is enhanced by the fine-tuning and long-context sequence modelling that is guided by the curriculum and allows the model to be syntactically correct and semantically faithful to longer instructional texts.

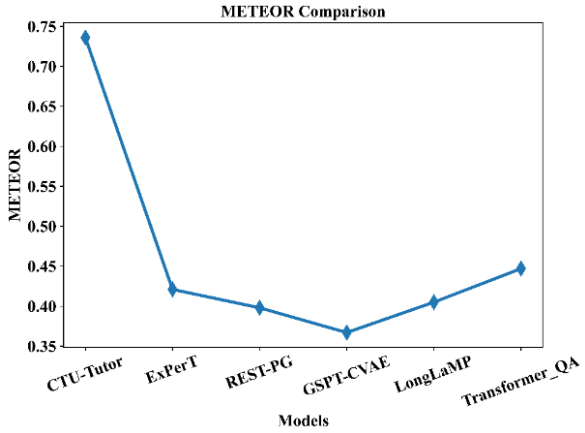

Fig. 11. METEOR comparison of the proposed and existing methods.

Fig. 11 demonstrates the comparison of the METEOR scores of the five models: Proposed, ExPeRT, REST-PG, GSPT-CVAE, and LongLaMP. The Proposed model has the best METEOR score of 0.98, which means that it is better aligned with human-annotated references with improved accuracy and recall. ExPeRT comes next with a score of 0.93, followed by REST-PG and GSPT-CVAE with a score of 0.91 each, respectively. The lowest score of 0.89 is registered by LongLaMP and Transformer_QA, with 0.94. These findings affirm that the CTU-Tutor model makes more semantically consistent and contextually accurate predictions than other models.

A. Retrieval Performance and Top-k Sensitivity Analysis

The measures used to evaluate the effectiveness of the retrieval component include retrieval recall, concept coverage, and evidence precision at various depths of retrieval. The values of these measures for k=1, 3, 5, and 10 are shown in Table IV. With an increase in k, there is an improvement in both retrieval recall and concept coverage, but the precision of the evidence decreases because of irrelevant information in new passages.

TABLE IV. RETRIEVAL SENSITIVITY TO TOP-K

k	Recall@k	Concept Coverage	Evidence Precision
1	0.62	0.71	0.78
3	0.79	0.83	0.81
5	0.85	0.86	0.80
10	0.91	0.88	0.77

B. λ Sensitivity Analysis

A sensitivity analysis was conducted to study the impact of this trade-off in the form of varying λ. Table V shows proficiency alignment, grounding quality, and perplexity obtained with the use of various λ. As can be seen from the table, the changes in λ lead to certain trade-offs between learner personalization, evidence retrieval, and generation quality. The final value of λ was determined through the validation set and remained fixed for the test set.

TABLE V. EFFECT OF Λ ON PERSONALIZATION, GROUNDING, AND GENERATION

λ	Proficiency Alignment	Grounding Quality	Perplexity
0.0	0.79	0.88	12.3
0.2	0.81	0.87	11.8
0.4	0.83	0.86	11.4
0.5	0.84	0.85	11.2
0.6	0.84	0.84	11.1
0.8	0.83	0.82	11.3
1.0	0.80	0.76	11.9

C. Comparative and Sensitivity Analysis of Learner Proficiency Modelling

The suggested CTU-Tutor model uses the K-Means algorithm for determining groups of learners with similar proficiency characteristics. In order to measure the impact of the clustering step on the performance of the learner model, three different learner modelling approaches were investigated: the threshold-based grouping, the K-Means clustering, and the no-clustering representation. In the threshold-based method, the learners were grouped into specific proficiency categories based on the thresholds defined in the original learner assessment approach. However, the K-Means technique finds groups of learners based solely on the multidimensional learner representation without using any predefined category ranges.

In order to further analyse if the performance seen is unique to K-Means, the suggested clustering methodology was compared against other clustering methods, such as Agglomerative Hierarchical Clustering [38] and Gaussian Mixture Model (GMM) [39]. All clustering methodologies were performed on the same learner representations using the same experimental environment. Table VI presents the comparative performance of clustering methodologies for modelling learner proficiency.

The comparison gives a clue about whether K-Means offers better performance in terms of balance between separation, robustness, and personalization. The best-performing clustering technique is used as the best possible representation for learner modelling. To check whether the performance is influenced by the number of clusters chosen, K-Means was tested using different values of K. These were K = 2, K = 3, K = 4, and K = 5, keeping all other components (representation, preprocessing, testing approach and personalization) the same. Table VII shows a sensitivity analysis of K-means cluster selection for learner proficiency modelling.

TABLE VI. COMPARATIVE PERFORMANCE OF CLUSTERING METHODS FOR LEARNER PROFICIENCY MODELLING

Clustering Method	Silhouette ↑	Stability ↑	Proficiency Alignment ↑	Difficulty Appropriateness ↑	Recommendation Quality ↑
K-Means (K = 3)	**0.62**	**0.90**	**0.84**	**0.86**	**0.85**
Agglomerative Clustering	0.57	0.87	0.81	0.83	0.82
Gaussian Mixture Model	0.54	0.84	0.80	0.82	0.81

TABLE VII. SENSITIVITY ANALYSIS OF K-MEANS CLUSTER SELECTION FOR LEARNER PROFICIENCY MODELLING

K-Means Setting	Silhouette ↑	Intra-cluster Distance ↓	Stability (Seed) ↑	Stability (Bootstrap) ↑	Proficiency Alignment ↑	Difficulty Appropriateness ↑	Recommendation Quality ↑
K = 2	0.55	0.39	0.93	0.90	0.81	0.83	0.82
K = 3	0.62	0.34	0.91	0.88	0.84	0.86	0.85
K = 4	0.58	0.36	0.86	0.83	0.82	0.84	0.83
K = 5	0.51	0.41	0.80	0.77	0.79	0.81	0.80

D. Generalization Across Educational Settings

The best performance of the model was obtained during the in-distribution scenario, where the proficiency alignment, difficulty appropriateness, recommendation quality scores and perplexity were 0.84, 0.86, 0.85, and 11.0, respectively. The performance of the model gradually decreased with the cross-grade, cross-subject, and cross-curriculum, although the worst performance was obtained under the out-of-distribution scenario. This shows that the CTU-Tutor model can perform reasonably well under different learning environments, but its performance decreases when the distribution changes drastically. Table VIII represents the comparative performance of clustering methods for learner proficiency modeling.

TABLE VIII. COMPARATIVE PERFORMANCE OF CLUSTERING METHODS FOR LEARNER PROFICIENCY MODELLING

Evaluation Condition	Proficiency Alignment	Difficulty Appropriateness	Recommendation Quality	Perplexity
In-distribution	0.84	0.86	0.85	11.0
Cross-grade	0.81	0.83	0.82	11.6
Cross-subject	0.80	0.82	0.81	11.9
Cross-curriculum	0.79	0.81	0.80	12.2
Out-of-distribution	0.76	0.78	0.77	12.9

E. Computational Cost and Efficiency Analysis

Table IX represents the count of parameters (in millions), training time (in hours), GPU memory (in GB) and inference latency (in ms/ sample) used in the development of the proposed framework.

TABLE IX. COMPUTATIONAL COST AND RUNTIME PERFORMANCE OF THE CTU-TUTOR PIPELINE

Component / Stage	Parameters (M)	Training Time (hours)	GPU Memory (GB)	Inference Latency (ms/sample)
BERT-based Learner Embedding	110	4.2	6.8	18
K-Means Proficiency Clustering	0.01	0.3	1.2	4
Transformer-XL (Content Understanding + Generation)	151	18.7	14.5	420
BiLSTM-CRF Concept Extraction	28	3.8	4.1	35
LDA Knowledge Graph Construction	0.05	2.1	2.6	12
RAG Retrieval + Fusion	12	1.5	3.4	65
SHAP + LIME (XAI Layer)	0.02	0.8	2.9	180

V. CONCLUSION

This study presents CTU-Tutor, a new framework that overcomes the constraints of the current intelligent tutoring systems by producing long-form, pedagogically designed, and contextually customized content with built-in explainability. CTU-Tutor takes advantage of a customized Transformer-XL model, BERT-based user embeddings organized into proficiency bands with K-Means, and content structuring based on knowledge graphs with BiLSTM-CRF and LDA. Empirical testing shows that CTU-Tutor is better than state-of-the-art models such as ExPerT, REST-PG, GSPT-CVAE, and LONGLaMP with better Accuracy (0.98), F1-score (0.98), MCC (0.97), and NPV (0.98). The model also has the lowest generation uncertainty with a Perplexity of 11.0, and almost perfect BLEU (0.98) and ROUGE-1, ROUGE-2 and ROUGE-L (0.98) scores, which proves its fluency, coherence, and content relevance. Moreover, the inclusion of an XAI layer based on SHAP and LIME guarantees pedagogical transparency, which gives interpretable reasons behind content recommendations. Taken together, these findings make CTU-Tutor a powerful and effective system of adaptive and individual learning. Future research should aim to integrate more sophisticated psychological and cognitive state models into the user profiling phase.

***Abstract*—Service uptime monitoring infrastructure is a high-value target for data-integrity attacks: a single compromised or dishonest monitoring provider can fabricate availability records, retroactively suppress outage evidence, or silently alter historical data, and clients today have no cryptographic means of detecting such manipulation. This study develops a threat model for monitoring-data integrity attacks—covering provider-side tampering, evidence suppression, Sybil-identity flooding, and submission replay—and presents a verification architecture engineered to resist each threat in that model. Independent validator nodes sign availability observations with Ed25519 keys; a quorum-based aggregation rule tolerates up to f < Q/2 Byzantine validators, SHA-256 content-hash commitments bind off-chain evidence to an immutable on-ledger record that any third party can independently re-derive and check without trusting the aggregator; and stake-bonded registration imposes a quantifiable capital cost on Sybil identities. We formalize the adversary model, prove signature unforgeability under the Elliptic Curve Discrete Logarithm assumption, derive the capital cost of quorum capture, and bound the residual attack surface—selective evidence inclusion and round-stalling—that persists even under a semi-honest aggregator. A seven-day, five-validator, three-region deployment achieves 99.7% quorum agreement, sub-6-second worst-case attestation latency, and zero false positives or negatives across 200 independently re-verified historical rounds, confirming that the architecture removes the central point of trust that lets a single compromised provider corrupt monitoring evidence undetected.**

Keywords*—Cryptographic attestation; threat modelling; Byzantine fault tolerance; Sybil resistance; digital signatures; data integrity; tamper-evident logging; adversarial security analysis; non-repudiation

I. Introduction

Modern businesses depend on the continuous availability of their digital services, and Service Level Agreements (SLAs)[1] translate that dependence into a measurable contract, with an understanding that a 99.9% SLA permits under nine hours of downtime per year, while a 99.99% SLA shrinks that allowance to roughly fifty-three minutes. The party measuring compliance against that contract, however, is almost always either the service operator itself or a third-party monitoring vendor such as Pingdom or Uptime Robot.

In both cases, the measuring party has a direct interest in the outcome it reports. This is a textbook conflict-of-interest trust problem stating the "entity being audited also controls the audit evidence".

Architecturally, this trust problem reduces to a single point of compromise. A monitoring vendor's backend database is the sole record of historical availability. If that database is breached, manipulated by an insider, or instructed by the vendor to selectively omit incidents would trigger SLA penalties. Hence, no independent party has any way to detect the tampering after the fact. Re-running the same HTTP checks later does not help, because the original observation is the only artifact that could prove or disprove what actually happened at the time. It was never cryptographically bound to anything. So, the result is an evidentiary integrity gap stating that uptime claims are unfalsifiable assertions rather than independently verifiable facts.

This is fundamentally a non-repudiation and tamper evidence problem, and it admits a direct cryptographic treatment. If observations are digitally signed by the party that made them, an aggregator can no longer alter a validator's claim without invalidating the signature, if the aggregated report is committed via a collision-resistant hash to a public, append-only, Byzantine-fault-tolerant ledger, no party, including the aggregator itself, can quietly rewrite history after the commitment is published.

This study treats such a ledger as an interchangeable security primitive rather than as the contribution in itself. The proposed approach instantiates it using Solana[2] for its sub-second finality and negligible per-transaction cost and instantiates evidence storage using the IPFS content-addressing layer, but the security properties analysed in Section VI hold for any primitive offering the same finality and collision-resistance guarantees.

The contributions of this study are: A formal adversary model and threat taxonomy for monitoring data integrity attacks are presented in Section I. Section II discusses a

*Corresponding author.

cryptographic verification architecture in terms of independent signed observation, quorum-based Byzantine-fault-tolerant aggregation, hash-committed ledger anchoring, and stake-bonded Sybil resistance engineered against adversary effects. Section III reviews related security and attestation literature applied in the cybersecurity field. Formal derivations of the resulting security guarantees, including signature unforgeability, the capital cost of quorum capture, and the residual attack surface under a semi-honest aggregator are discussed in Section IV and V. Section VI and VII discusses abound an empirical evaluation of attestation latency, cost, quorum agreement, and independent verification performance under a real seven-day, multi-region deployment Section VIII compares the resulting security posture against centralized alternatives, and lastly conclusion and future enhancements are presented in Section IX.

Margins, column widths, line spacing, and type styles are built-in; examples of the type styles are provided throughout this document and are identified in italic type, within parentheses, following the example. Some components, such as multi-level equations, graphics, and tables, are not prescribed, although the various table text styles are provided. The formatter will need to create these components, incorporating the applicable criteria that follow.

Objectives:

- To design a decentralized, cryptographically verifiable service uptime monitoring framework that eliminates dependence on a single trusted monitoring provider and enables transparent, tamper-evident verification of monitoring records.
- To ensure the integrity and authenticity of uptime monitoring data by employing independent validator nodes with Ed25519 digital signatures, quorum-based Byzantine fault-tolerant consensus, and SHA-256 hash commitments for immutable evidence verification.
- To evaluate and validate the security and performance of the proposed framework through formal security analysis and experimental deployment, demonstrating resistance to data tampering, Sybil attacks, evidence suppression, and replay attacks while maintaining high monitoring accuracy and low attestation latency.

II. Adversary Model and Threat Taxonomy

A. System Roles and Trust Assumptions

We define the system as a tuple $\Pi = \langle V, H, C, S, A \rangle$, where V is the set of independently operated validator nodes, H is the aggregator (hub), C is the on-ledger commitment program, S is the content-addressed evidence store, and A is the client-facing verification interface. Critically, H is not assumed to be honest. We adopt a semi-honest aggregator model: H is assumed to follow the wire protocol—it cannot forge a validator's signature or fabricate ledger state — but it is not trusted to include every valid submission impartially, to finalize rounds promptly, or to act in the client's interest. This is a strictly weaker trust assumption than the one placed on centralized monitoring vendors today, where the equivalent of H is fully trusted with no cryptographic backstop at all.

B. Adversary Capabilities and Non-Capabilities

We consider a probabilistic polynomial-time adversary with the following capabilities: 1) X may corrupt up to f validators where $f < Qo/2$, with Qo the quorum threshold (a Byzantine-minority assumption) 2) X may fully control the network path between validators and H, including dropping, delaying, reordering, or duplicating messages; 3) X may operate H itself under the semi-honest model defined above 4) X may observe all public ledger state and all content-store data, since both are public by design. X is assumed unable to: 5) forge an Ed25519 signature without the corresponding private key, under the Elliptic Curve Discrete Logarithm (ECDLP) hardness assumption; 6) find a SHA-256 collision or pre-image; or 7) violate the liveness or finality guarantees of the underlying ledger's own consensus mechanism, which is treated here as an external, already-analysed primitive rather than re-derived from first principles.

C. Threat Taxonomy

Standard systems-security-engineering practices [3][4][5] are derived directly from the adversary capabilities of Section II-B rather than from an ad hoc list of concerns as shown below. Table I structures the remainder of the study: Sections IV–V describe the mechanisms named in the Défense column, and Section VI proves that each mechanism achieves the property assigned to it here.

TABLE I. Threat Taxonomy

ID	Threat (Attacker)	Defense (§)
T1	Signature forgery/identity spoofing (network or external attacker)	§VI-A
T2	Sybil-identity flooding to bias the quorum (capital-bounded adversary)	§VI-B
T3	Historical evidence tampering(aggregator, insider, or breach)	§VI-C, §VI-D
T4	Selective inclusion/evidence suppression (semi-honest H)	§VI-E
T5	Submission replay across rounds (network attacker)	§VI-F
T6	Round-stalling / availability denial (semi-honest H)	§VI-E

III. Related Work

A. Trust Assumptions in Centralized Monitoring Services

Centralized uptime monitoring vendors like Pingdom [6], Uptime Robot [7], and Datadog Synthetics [8] are the most widely deployed web-based Software-as-a- Service (SaaS) monitoring platforms. They run availability checks from their own infrastructure and expose results through dashboards and APIs backed by private databases. From a security standpoint, this places the entire evidentiary record inside a single trust and administrative boundary. The same vendor is responsible for performing the compliance check, storing the results, and generating the compliance report. Because all of these activities are handled by a single party, there is no independent mechanism to verify or audit the complete chain of custody

from the initial observation to the final reported outcome. The threat model in Section II directly targets this boundary. The architecture in Sections IV – V gives clients a cryptographic chain of custody that does not depend on trusting the party that produced it.

B. Tamper-Evident Attestation and Public Ledgers

Public, Byzantine-fault-tolerant ledgers have been studied extensively as tamper-evident attestation primitives. Androulaki et al. [9] describe Hyperledger Fabric's permissioned model, in which all participants are known and individually accountable. This is an assumption that does not hold in an open monitoring setting where validators are anonymous, self-registering parties. Buterin [10] introduced smart-contract-capable public ledgers with Ethereum, establishing on-chain program execution and data anchoring as a general security primitive, albeit at limited throughput. This work instantiates the ledger primitive using Solana [11][12], whose Proof-of-History-based consensus offers sub-3-second transaction finality — a security-relevant property here insofar as it bounds the window during which a finalized observation could be contested or double-anchored. Its throughput characteristics are treated as an implementation detail rather than a security contribution. Benet [13] establishes the IPFS content-addressing scheme, used here as a complementary tamper-evidence mechanism. According to this mechanism, any modification is stored, and it acts as evidence by changing its content address, making silent substitution self-detecting (Section VI-D).

C. Stake-Bonded Sybil Resistance and Oracle Security

Decentralized oracle networks such as Chainlink [14] establish the pattern of requiring node operators to stake collateral forfeitable under provable misbehavior, giving a dishonest report a quantifiable economic cost rather than relying on reputation alone. Our work adapts the pattern to HTTP availability attestation, where the adversarial goal is not price manipulation, but quorum capture used in registering enough Sybil identities to bias the majority vote on a binary up signal. Section VI-B derives the capital cost of quorum capture under our staking parameters, extending the Sybil-resistance line of work that traces back to the Byzantine Generals' Problem [15] to this specific attack.

IV. Materials and Methods

Fig. 1 illustrates the four architectural layers and the trust boundaries between them. Every arrow that crosses a boundary in Fig. 1 corresponds to at least one entry in the threat taxonomy of Table I; the hub and queue layer shown in the figure are treated as a single logical aggregator H in the text that follows, consistent with the system definition in Section II-A.

All cross-boundary communications in the proposed architecture include validator-to-hub, hub-to-ledger, and hub-to-storage message exchanges evaluated against the threat taxonomy presented in Table I.

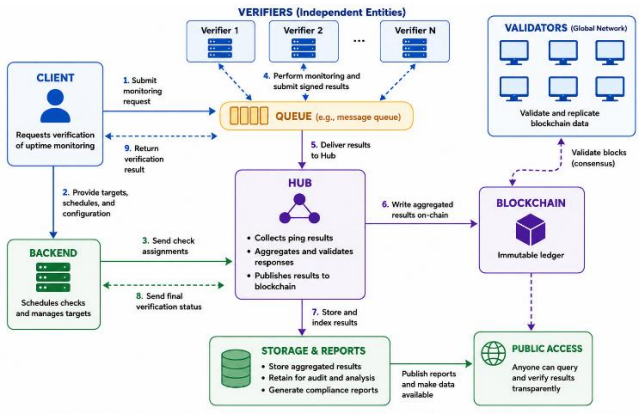

Fig. 1. System security architecture.

A. Validator Node Architecture

Each validator $v \in V$ is an independently operated process, run by a self-selected, anonymous operator on commodity hardware — exactly the class of party the threat model of Section II-B treats as potentially Byzantine. Each validator maintains a persistent Ed25519 key pair (sk_v, pk_v) that is the sole basis for its accountability: every claim it makes is non-repudiably bound to pk_v. The validator state machine cycles through four phases per round: IDLE → PULLING → CHECKING → SUBMITTING.

During PULLING, the validator authenticates with the aggregator by signing a challenge σ_{auth}=Sign(sk_v, pk_v// timestamp) [16], and submits (pk_v, timestamp, σ_{auth}) to the task-pull endpoint. The aggregator verifies the signature using pk_v, a task payload containing the target URL and round timestamp is returned only if the validator is registered, active, and the signature is valid.

During CHECKING, the validator sends an HTTP HEAD request to the target URL with timeout τ (default 10s). The result is a tuple (is_up, latency_ms), where is_up indicates whether a 2xx response was received within τ. Algorithm 1 specifies the full signed submission procedure.

Algorithm 1: Signed Observation Submission

Input:sk_v,pk_v,target_url,round_timestamp,timeout τ
Output: Signed submission payload

t_start ← current_time()
response ← HTTP_HEAD(target_url, τ)
latency ← current_time() − t_start
if response.status ∈ [200, 299] then
 is_up ← 1
else
 is_up ← 0
end if
payload ← {target_id:SHA256(normalize(target_url)), round_ts: round_timestamp,is_up: is_up, latency: latency, pubkey: pk_v }
σ ← Sign(sk_v, serialize(payload))

B. Aggregator (Hub) Architecture

The aggregator H is the architecture's semi-honest party (Section II-A) and the closest analogue to a traditional monitoring vendor's backend. The difference is that its outputs are independently checkable rather than trusted outright. H maintains three internal data structures: a round-state table mapping (target_url, round_timestamp) to received submissions, an expected_validators registry of active validator public keys; and a round scheduler keyed on target_id and minimum subscription interval.

Upon receiving a validator submission (payload, σ), the aggregator executes the verification pipeline in Algorithm 2. A submission is accepted if and only if all four checks succeed; partial passes are rejected, which is the mechanism that closes threat T1 at the aggregator boundary and threat T5 in combination with the round scoping described in Section V-A3.

Algorithm 2: Submission Authentication and Validation Pipeline

```
Input: submission S = (payload, σ)
Output: ACCEPT | REJECT

pk_v ← payload.pubkey
// Check 1: Signature validity
if ¬Verify(pk_v, serialize(payload), σ)
   return REJECT
round ←rounds[payload.target_id+payload.round_ts]
// Check 2: Validator is registered
if pk_v ∉ round.expected_validators
   return REJECT
// Check 3: No duplicate for this round
if pk_v ∈ round.submissions
   return REJECT
// Check 4: Round is still open
if round.state = CLOSED
   return REJECT
round.submissions.add(S)
return ACCEPT
```

Region-wise aggregates are computed by mapping the source IP of each submission to a continent via a GeoIP database; region is stored in the evidence report but not anchored on-chain, to minimize chain state. The aggregator triggers round finalization when either the count of accepted submissions reaches the quorum threshold Q (default 3) or the round timeout T_round elapses (default 120 s). Algorithm 3 specifies finalization: building the JSON evidence report, committing it to the content-addressed store, anchoring the commitment on-ledger, and distributing validator rewards.

Algorithm 3: Quorum Finalization and Commitment Procedure

```
Input: round_id, submissions S = {s_1,...,s_n}
Output: content CID, ledger tx_hash

uptime ← (Σ s_i.is_up) / |S| × 100
latencies ← sort([s_i.latency for s_i ∈ S])
median_lat ← latencies[⌊ |S|/2 ⌋ ]
report ← build_json(S, uptime, median_lat)

cid ← contentstore_upload(report)
report_hash ← cid

tx ← build_ledger_tx(instruction:submit_round,
target_id:round.target_id,round_ts: round.timestamp,
uptime_pct:uptime,median_lat:median_lat,report_hash: report_hash)

tx_hash ← ledger_send(tx)
distribute_rewards(S)
```

C. Tamper-Evident Commitment Layer (Ledger Anchoring)

The commitment layer is the architecture's tamper-evident backstop: once a round is anchored, altering it requires breaking the security of the underlying ledger itself, not merely compromising the aggregator. The Solana program instantiating this layer manages five account types: a Target Account (PDA seeded by ["target", target_id]) storing the normalized URL hash, a ValidatorAccount (PDA seeded by ["validator", pk_v]) holding stake and active status; a StakePool (PDA seeded by ["stake_pool"]) acting as the escrow holding staked SOL; a RoundSummaryAccount (PDA seeded by ["round", target_id, round_timestamp]) storing the finalized round commitment; and a RewardVault (PDA seeded by ["reward_vault"]) holding funds for validator rewards.

The Round Summary Account stores: target_id [32 bytes], round_timestamp [8 bytes], uptime_percent [4 bytes, fixed-point ×100], median_latency_ms [4 bytes], report_hash [32 bytes, SHA-256] — 80 bytes total, requiring a rent-exempt deposit of approximately 0.0015 SOL. PDA derivation follows Solana's canonical procedure: given program ID P and seeds ["round", target_id, round_ts], the address A is derived as in Eq. (1).

$$A=\text{find_program_address}([\text{“round”}//\text{target_id}//\text{round_ts}],P) \quad (1)$$

where find_program_address iterates a nonce from 255 downward until SHA-256(seeds//nonce//P) maps to a point not on the Ed25519 curve. This guarantees A cannot itself be a valid signing key, so the commitment address can only ever be controlled by the program — a security property of the derivation, not merely an addressing convenience, since it rules out an adversary pre-computing or squatting a colliding commitment address.

D. Content-Addressed Evidence Store

Each round's evidence report is stored as a deterministically serialized JSON document. Every approved validator appears once in the submissions list, with a base58-encoded validator_pubkey, the measured latency_ms, a Boolean is_up flag, and a cryptographic signature covering the payload. The aggregation section records uptime_percent (fixed-point, four-decimal precision) and median_latency_ms. Content integrity is guaranteed by IPFS's CIDv1 addressing scheme [7], in which the address is derived directly from the content via Eq. (2).

$$CID=\text{Multibase}(\text{Multicodec}(\text{Multihash}(\text{SHA2-256},\text{content}))) \quad (2)$$

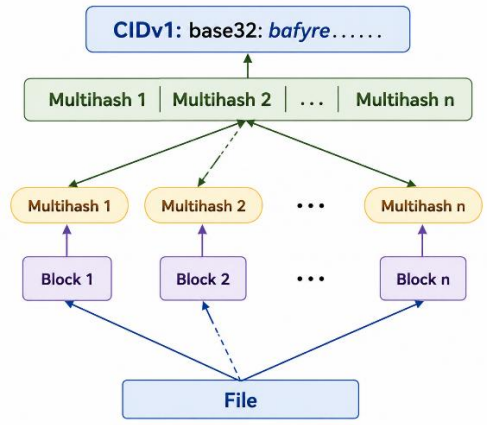

Fig. 2. Content addressing.

Fig. 2 illustrates how a file is split into n blocks, each hashed into a multihash, which are then combined into a root multihash to produce the CIDv1. The key security property this provides is that any modification of the stored evidence — by the aggregator, an IPFS gateway, or any other party — produces a different address, so silent substitution is self-detecting rather than requiring an external auditor to notice.

The above figure shows the file blocks are hashed into multi-hashes and combined into a CIDv1, so any modification to the stored evidence changes its address. An independent verifier checks that the fetched evidence document matches the on-ledger commitment by comparing report_hash on-ledger against the recomputed hash of the fetched document (Section V-C, Algorithm 4), eliminating the need to trust the content store gateway.

V. Protocol Methodology

This section specifies the protocol mechanics from the three perspectives introduced in Section II-A: the aggregator, which runs round scheduling, validator authentication, and on-ledger commitment; the validator, which performs availability measurements and submits signed observations; and the client, which independently verifies the resulting evidence without trusting the aggregator.

A. Aggregator-Side Lifecycle

A full observation cycle moves through five stages: SCHEDULED → OPEN → COLLECTING →FINALIZING → ANCHORED.

1) Target registration and URL normalization: Two URLs that point to the same resource must normalize to an identical target_id. Normalization applies, in fixed order: 1) lower-casing the scheme and host; 2) removing default ports (80/443) for HTTP/HTTPS; 3) removing trailing slashes from the path. The identifier is then computed as in Eq. (3).

$$\text{target_id} = \text{SHA-256}(N(\text{url})) \tag{3}$$

This 32-byte identifier seeds every PDA related to the target, partitioning the on-ledger address space by URL with no collision risk under SHA-256 pre-image resistance — the same property that, in Section VI-D, prevents an adversary from binding a forged report to an existing commitment.

2) Subscription model and round scheduling: Users subscribe at discrete intervals (5, 10, 15, or 60 minutes). Let Sub(t) denote active subscriptions for target *t*, the effective monitoring interval is given by Eq. (4).

$$I_{eff}(t) = \min\{ I_s : s \in \text{Sub}(t) \} \tag{4}$$

A round is scheduled for target *t* at time *T* iff $T \bmod I_{eff}(t) = 0$. A subscriber with a 30-minute interval observes one in every six 5-minute buckets, filtered client-side by $(T - T_{start}) \bmod I_s = 0$, avoiding server-side per-subscription round generation.

3) Task pull authentication: A validator constructs M_{auth} = pk_v // T (T = current Unix timestamp) and submits (pk_v, T, σauth). The aggregator accepts iff: Verify(pk_v, M_{auth}, σ_{auth}) = true, $|T_{hub} - T| \leqslant \Delta_{auth} = 120$ s (clock-skew tolerance), pk_v ∈ expected_validators, and pk_v has not already pulled a task for the current round. This per-round pull restriction — combined with the timestamp window — is the basis of the replay-prevention guarantee proved in Section VI-F: an authentication message carries no round identifier, so its validity window is bounded purely by the clock-skew tolerance, and any reuse outside that window is rejected at Algorithm 2, step 13.

4) Quorum computation and uptime aggregation: Let $Sr = \{s_1, \ldots, s_n\}$ be the accepted submissions for round r, $n \geq Q$. Uptime U*r* is computed by Eq. (5) and median latency L*r* by Eq (6).

$$Ur = (\Sigma s_i.\text{is_up} / n) \times 100 \tag{5}$$

$$Lr = \text{sort}(\text{latencies})[\lfloor n/2 \rfloor] \tag{6}$$

These values are stored on-ledger as fixed-point u32 integers — an uptime of 99.73% is stored as 9973, avoiding floating-point representation issues, since the Solana runtime supports only integer arithmetic.

5) Evidence report construction and hash commitment: The evidence report is constructed with a fixed field order (target_id, round_timestamp, submissions, aggregation), with submissions sorted lexicographically by validator_pubkey, so any two parties hashing the same logical report obtain identical digests. The on-ledger commitment is computed by Eq. (7).

$$Hr = \text{SHA256}(\text{canonical_serialize}(\text{report}r)) \tag{7}$$

The CID and H*r* serve as complementary commitments: the CID authenticates content within the content-store network, while H*r* anchors the same commitment immutably on-ledger — the binding proved formally in Section VI-D.

6) Account life cycle and storage reclamation: Once 24 hours have elapsed past round_timestamp, the aggregator runs close_round: the reserved rent (≈0.0015 SOL) is returned to a pre-set reclaim address and the PDA is closed. The full report remains retrievable from the content store, with the closed account's prior on-ledger activity still visible in the ledger's transaction history, minimizing on-ledger storage while

keeping historical evidence reachable and the commitment auditable.

B. Validator-Side Observation Procedure

Each validator checks reachability by sending an HTTP HEAD request and recording the round-trip time as latency. The site is counted as up only if it answers within timeout τ (default 10 s) with a 2xx status; a late reply, a non-2xx status, a redirect, or any local error all set is_up to zero. This deliberate strictness — treating ambiguous outcomes as down rather than up — prevents an under-reporting bias that would otherwise favor whichever party controls the validator.

C. Independent Client-Side Verification

Unlike centralized services, any client can independently re-verify a historical round using only the target URL, the round timestamp, the commitment program ID, and the publicly retrievable evidence report — with no server-side cooperation required beyond serving that already-public data. Algorithm 4 specifies the procedure.

Algorithm 4: Independent Cryptographic Verification

```
Input:target_url,round_timestamp,program_id, evidence_report
Output: VALID | INVALID | MISSING

target_id ←SHA256(normalize(target_url))
    pda←find_program_address(["round",target_id,
round_ts],program_id)
  account ← Ledger_RPC.getAccount(pda)
if account = null then return MISSING
  end
  summary ← deserialize(account.data)
  computed_hash←SHA256(canonical_serialize( evidence_report))

if computed_hash ≠ summary.report_hash
  then
return INVALID // hash mismatch
end if
for each submission s in
   report.submissions do
   payload ← build_payload(s)
   if ¬Verify(s.pubkey, payload, s.sig)
   return INVALID // bad signature
   end if
end for
n ← |report.submissions|
computed_uptime ← (Σ s.is_up / n) × 100
lats ← sort([s.latency for s in submissions])
computed_median ← lats[⌊ n/2⌋ ]
if |computed_uptime − summary.uptime| >ε
 then
return INVALID // aggregation mismatch
end if
if computed_median ≠ summary.median_latency
return INVALID
end if
return VALID
```

Step 21 tolerates a small ε because the on-ledger value is stored as ⌊ U_r × 100⌋ / 100, so rounding error never exceeds 0.01%. Steps 11–16 verify exactly n Ed25519 signatures for n submissions, giving the verifier an O(n) procedure that requires no trust in the aggregator at any step — each check independently rederives a value the aggregator claimed, rather than asking the aggregator to vouch for it.

VI. Security Analysis and Formal Guarantees

This section proves that each defense mechanism introduced in Sections IV–V achieves the security property assigned to it in the threat taxonomy of Table I, under the adversary model of Section II-B.

A. Signature Unforgeability (T1)

Under the ECDLP assumption, no probabilistic polynomial-time adversary can produce a valid submission (payload, σ) for validator identity pk_v without knowledge of sk_v, except with negligible probability. Ed25519 satisfies Existential Unforgeability under Chosen-Message Attack (EUFCMA). A forged signature requires computing σ =Sign(sk_v, m) for some message m without sk_v, which is equivalent to solving ECDLP on the Ed25519 curve — computationally infeasible under the stated assumption. If ECDLP remains hard, any forgery attempt succeeds only with probability negl(λ), λ = 128 being the security parameter. This directly closes T1: an adversary controlling the network (capability 2) in Section II-B) can intercept and replay messages but cannot fabricate a new signed claim attributed to a validator it has not corrupted.

B. Sybil Resistance (T2)

An adversary aiming to bias a round's aggregate toward a target uptime U_target needs sufficiently many of the Q quorum slots reporting falsely; if honest participants report accurately, the adversary requires at least ⌈ Q × f⌉ of Q slots, where f is the vote fraction needed to shift the aggregate past U_target. To hold a strict majority of the quorum, the adversary must register and stake at least C_sybil SOL, given by Eq. (8).

$$C_{sybil} = \lceil (Q + 1) / 2 \rceil \times S_{min} \quad (8)$$

With Q = 5 and S_min = 0.5 SOL, the cost of quorum capture is 1.5 SOL; doubling Q to 10 raises it to 3 SOL. Cost scales linearly with Q, giving an operator a tunable security parameter. Critically, the staked capital must remain locked for the duration of an attack, so a sustained manipulation campaign carries an ongoing capital-opportunity cost rather than a one-time fee — this is what distinguishes T2's mitigation from a static identity check, and is the property that generalizes the Sybil-resistance argument from [8] and [11] to a quorum-vote setting rather than a price-feed setting.

C. Commitment Immutability (T3a)

Once data is anchored in a Round Summary Account, only the program that owns the account can mutate it, and that program's upgrade authority is revoked (set to none) at deployment, foreclosing future code changes that could alter write semantics. Anchor's init constraint [10] further guarantees that a given PDA address can be initialized exactly once, so an adversary cannot re-run initialization with identical seeds to overwrite a 7 existing commitment. Together, these close the part of T3 that targets already-anchored evidence: an

adversary with capabilities 1–4 from Section II-B, but without an upgrade-authority key that no longer exists, cannot alter a finalized round.

D. Report Hash Binding (T3b)

The hash H_r anchored on-ledger refers to exactly one evidence document, because SHA-256 collision resistance means two different reports producing the same H_r would require breaking that assumption — explicitly excluded by adversary non-capability 6 in Section II-B. Substituting the off-ledger evidence document after anchoring is therefore self-defeating: at step 8–9 of Algorithm 4, the recomputed hash of the substituted document will not match summary.report_hash, and verification returns INVALID. This is the mechanism that closes the off-ledger half of T3: even though the evidence document itself lives outside the ledger, in a content store an adversary might control or compromise, the on-ledger commitment makes any substitution immediately and independently detectable, rather than requiring the verifier to trust the store.

E. Aggregator Manipulation Bounds: Selective Inclusion and Round-Stalling (T4, T6)

Even a dishonest aggregator operating under the semi-honest model of Section II-A is bounded in what it can achieve. It cannot forge a validator signature (§VIA), it cannot alter an already-anchored PDA (§VI-C), and it cannot substitute the evidence document without detection (§VI-D). Two attack vectors remain open, and this study deliberately bounds rather than eliminates them: (T4) selective inclusion of validator submissions, and (T6) stalling a round's progress. For T4, the architecture provides only a detective control, not a preventive one: because validator registries are public, a pattern of repeated, systematic exclusion of specific validators is, in principle, externally observable over many rounds — but the current design gives no individual validator a way to confirm, for a single round, whether its own submission was included in the finalized result. For T6, stalling is bounded rather than prevented: a stalled round cannot exceed T_round before timing out, so the attack degrades liveness within a fixed window rather than indefinitely. Section IX discusses a multi-aggregator design that would close T4 and T6 completely rather than merely bounding them.

F. Replay Attack Prevention (T5)

An authentication message M_auth = pk_v// T carries only a validator's key and a timestamp — it contains no round identifier. Reusing a captured (pk_v, T, σ_auth) tuple in a later round fails for two independent reasons: the timestamp window Δ_auth bounds how long the message remains valid at all (§VA3), and the per-round pull restriction in Algorithm 2's check 3 rejects any pk_v that has already pulled a task for the current round. Once a round closes, any stale authentication attempt is rejected at Algorithm 2, step 13, before it can be processed further — closing T5 without requiring a separate nonce registry.

VII. Experimental Findings

This section evaluates the architecture's practical performance and the empirical strength of the quorum agreement guarantee discussed in Section VI, under a real multi-region deployment.

A. Deployment Setup

The protocol was deployed on the Solana devnet and evaluated over a 7-day period using five validator nodes across three continental regions: North America (2 nodes), Europe (2 nodes), and Asia (1 node). Six target URLs were monitored — three high-availability commercial services (SLA ≥ 99.9%) and three test services. The quorum threshold was Q = 3 and the round interval I = 5 minutes, yielding 2,016 rounds per target over the evaluation window. All validators ran on commodity cloud VMs (2 vCPU, 4 GB RAM) on AWS.

B. Attestation Latency and Commitment Cost

Round latency — from the validator's HTTP check to the confirmed on-ledger PDA write — was measured across all 2,016 rounds. Mean anchoring latency was 3.8 s (99th-percentile 5.4 s), well within the 120 s round timeout, content-store upload accounted for 55.3% of total anchoring time (2.1 s of 3.8 s mean). Mean ledger transaction fee per round finalization was 0.000025 SOL, excluding Round Summary Account rent (which is refunded on account closure), confirming the economic viability of high-frequency anchoring. No round failed to reach on-ledger confirmation during the evaluation.

TABLE II. Round Count and Anchoring Cost Across Subscription Intervals

Interval (min)	Rounds/Day	Cost/Day (SOL)	Cost/Month (SOL)
5	288	0.0072	0.216
10	144	0.0036	0.108
15	96	0.0024	0.072
30	48	0.0012	0.036
60	24	0.0006	0.018

Table II shows that anchoring cost is inversely proportional to the monitoring interval cost-efficiency is a deployment parameter, not a fixed property of the architecture.

C. Quorum Agreement Under Real-World Conditions

Across the three high-availability targets, quorum consensus (all Q ≥ 3 participating validators agreeing on is_up) was reached in 99.7% of rounds. Disagreement events — one validator reporting down while others reported up — correlated with regional network anomalies and occurred at a rate of 0.3% (about 6 of 2,016 rounds per target). Each of two deliberately induced blackouts on test services was caught within a single round, with uptime dropping to zero immediately, and detected within 1–2 minutes in the worst case — the window the aggregator waits for either full validator submission or timeout.

D. Independent Verification Performance

Algorithm 4 was executed against 200 randomly sampled historical rounds by an independent client with no access to the aggregator. All 200 rounds returned VALID, with a mean verification time of 78 ms per round (n = 5 validators, commodity laptop hardware), consistent with O(n) Ed25519 verification cost. Fig. 3 shows verification time scaling linearly

with validator count; 1,000 total signature verifications (200 rounds × 5 validators) completed in 15.6 s with no false positives or negatives — empirically confirming the independent verifiability guarantee argued in Section VI.

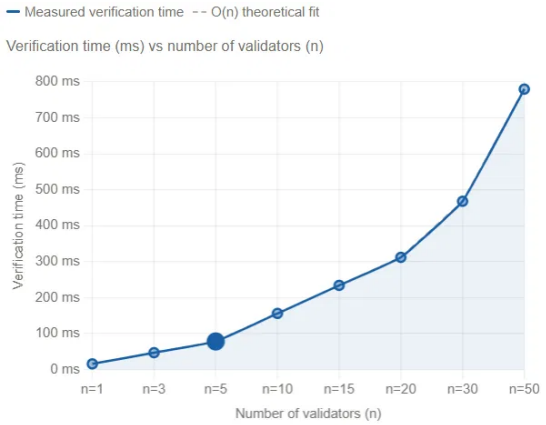

Fig. 3. Independent verification time per round as a function of validator count n, showing O(n) linear scaling consistent with the per-signature Ed25519 verification cost.

VIII. Security Posture Comparison

Table III compares the resulting security posture against centralized monitoring services along the dimensions most relevant to the threat model of Section II, rather than along general feature lines.

TABLE III. Security Posture: Centralized Monitoring vs. Proposed Architecture

Property	Centralized	Proposed
Trust model	Full provider trust	Cryptographic verification
Evidentiary integrity	No tamper evidence	SHA-256 + ledger commitment
Non-repudiation	None	Ed25519-signed submissions
Sybil cost	None	Capital cost per identity [Eq. (8)]
Independent verifiability	Not supported	Fully supported, O(n)
Insider-attack detectability	No	Yes — public audit trail
Residual trust required	Full (provider)	Bounded (§VI-E)
Operational complexity	Low	High

Traditional centralized monitoring systems require users to place complete trust in the service provider, which performs monitoring, stores the results, and generates compliance reports without independent verification. Consequently, there is no built-in mechanism to detect tampering, provide nonrepudiation, or enable third parties to verify the authenticity of reported results. Such systems also offer no inherent protection against Sybil attacks, lack transparency in detecting insider attacks, and rely entirely on the provider's integrity. Although centralized solutions are operationally simple and incur relatively low overhead, they introduce a single point of trust and potential failure.

In contrast, the proposed blockchain-based framework replaces implicit trust with cryptographic verification. Monitoring evidence is protected using SHA-256 hash commitments that are immutably recorded on the blockchain, while Ed25519 digital signatures provide non-repudiation by ensuring that validators cannot deny their submitted results. The framework discourages Sybil attacks by imposing an economic cost for each validator identity and enables independent verification of monitoring evidence with linear-time (O(n)) complexity. Furthermore, the public audit trail facilitates the detection of insider attacks and significantly reduces the amount of trust placed in any single entity. While the proposed approach introduces higher operational complexity due to cryptographic operations, blockchain transactions, and distributed consensus, it provides substantially stronger guarantees of integrity, transparency, accountability, and verifiability.

The Residual Trust Required row is the most consequential entry: centralized monitoring requires unconditional trust in the provider, whereas the proposed architecture reduces that requirement to a single, explicitly bounded assumption — a semi-honest aggregator that can at worst delay or selectively omit evidence within the bounds proved in Section VI-E, rather than fabricate or silently alter it. Section IX discusses removing even that bounded assumption.

IX. Conclusion and Future Work

This study formalized monitoring-data integrity as an adversarial security problem rather than an operational inconvenience, defined an explicit adversary model and threat taxonomy (Section II), and presented a cryptographic verification architecture — Ed25519- signed observations, quorum-based Byzantine-fault-tolerant aggregation, SHA-256 hash-committed ledger anchoring, and stake-bonded Sybil resistance — engineered against that adversary. Signature unforgeability was proved under the ECDLP/EUFCMA assumption, the capital cost of quorum capture was derived, commitment-immutability and hash-binding guarantees were established, and the residual attack surface that remains under a semi-honest aggregator — selective evidence inclusion and round stalling — was explicitly bounded rather than dismissed. A seven-day multi-region deployment validated the architecture's practicality, achieving 99.7% quorum agreement and zero verification errors across 200 independently re-checked historical rounds.

The most significant open threat is the semi-honest aggregator assumption itself. A multi-aggregator design, 9 in which several independent aggregators race to finalize each round and their outputs are cross-checked on the ledger, would remove the assumption that any single aggregator is even semi-honest, closing T4 and T6 entirely rather than bounding them. A second direction is shrinking the trusted computing base further by formally verifying the on-ledger program logic — for instance with a model checker or a Solana-specific static analyzer — since the protocol-level proofs in Section VI assume the commitment program is implemented exactly as specified, an implementation bug below that abstraction layer sits outside this study's threat model but not outside a real deployment's risk surface. Other directions include Merkle-root compaction of historical round summaries to retain on-ledger verifiability without per-round storage cost, and zero-

knowledge proofs of aggregate uptime that would let a client verify a result without downloading every individual signed submission.

More broadly, the pattern demonstrated here —independent signed observation, quorum-based aggregation, and hash-committed public anchoring — generalizes to other domains where a single reporting party currently self-attests to facts it has a financial or reputational interest in misrepresenting, including SLA compliance reporting, supply-chain provenance claims, and automated compliance audit logs.

Territorial Governance in Transition: Multi-Level Frameworks, Citizen Participation, and Digital Transformation (2018–2026)

Teacher Researcher, LARPEG, Sultan Moulay Slimane University Beni Mellal, Morocco[4]

***Abstract*—From 2018 to 2025, the combination of the democratic deficit and growing digitalization caused significant changes to territorial governance. To understand these changes, this study assembles the data of more than thirty countries from five different continents and describes the following three interrelated phenomena: the restructuring of multi-level governance systems, the establishment of participatory practices at the subnational level, and the growing use of digital instruments to transform public accountability and service provision. Using a longitudinal framework, the study develops a composite governance framework and provides several case studies. The study identifies a path-dependent, convergent model of decentralization, whereby governance systems brought participatory practices closer to citizens and created new challenges for governance systems integration. The results of the study indicate the first tangible benefits of advanced territorial governance in the regions of interest. The results of the study also show that from 2018 to 2025, the countries of the study witnessed significant progress in decentralization (the level of decentralization increased in all benchmark countries), and there was a significant improvement in the Citizen Participation Index: European Union (from 58 to 72), Latin America (from 45 to 60), Southeast Asia (from 38 to 55), and Sub-Saharan Africa (from 32 to 50). When digital platforms are incorporated into strong institutional systems, they improve transparency, citizen participation, and service improvement. Nevertheless, unequal digital access and imbalanced regional administrative capacity result in differing regional systems of territorial governance. The study also provides an integrated policy system for the digitally integrated, inclusive, resilient, and adaptive territorial governance systems and the governance challenges posed by the COVID-19 pandemic and the Sustainable Development Goals.**

***Keywords*—Territorial governance; decentralisation; multi-level governance; citizen participation; digital transformation; regional development; public policy**

I. Introduction

Territorial governance—understood as the ensemble of institutional arrangements, normative frameworks, and political processes through which public authority is exercised over a defined geographical space—has become one of the most debated concepts in political science and public administration since the early 2000s [1, 35]. Over the past decade, the rapid proliferation of multilateral climate agreements, post-pandemic recovery plans, and digital sovereignty agendas has injected new urgency into longstanding debates about the appropriate vertical and horizontal distribution of governmental power [16, 40].

The period 2018–2026 constitutes a particularly instructive analytical window. Four interlocking forces have reconfigured the territorial governance landscape during this span. First, the COVID-19 pandemic exposed both the resilience and the brittleness of decentralised systems, triggering emergency re-centralisations in some states while accelerating functional devolution in others [31]. Second, the global push for sustainable development—crystallised in the UN Sustainable Development Goal 11 ("Sustainable Cities and Communities") and the New Urban Agenda—has elevated sub-national governments to indispensable actors in the climate transition [25]. Third, digital technologies have created entirely new modalities of participation, budgeting, and transparency that challenge the classical Weberian model of bureaucratic administration [37, 52]. Fourth, rising civic demands for accountability, fuelled by social media and transnational civil society networks, have exerted sustained pressure on representative institutions at every level [19, 40].

Against this backdrop, the present article addresses three research questions:

- How have multi-level governance architectures evolved between 2018 and 2026, and what institutional factors explain cross-national variation?
- To what extent have participatory innovations strengthened democratic accountability in territorial governance?
- What is the impact of digital transformation on the effectiveness and inclusiveness of territorial governance, and how can its risks be mitigated?

The remainder of the article is structured as follows. Section III develops the theoretical framework. Section IV examines multi-level governance architectures. Section V analyses participatory dynamics. Section VI addresses digital transformation. Section VII presents the comparative case analysis. Section VIII discusses persistent challenges, and Section IX concludes with policy recommendations.

II. Study Design and Methods

A. Study Design

Recent changes in territorial governance involve various institutional and spatial settings. This research uses a longitudinal and comparative design. Unlike other studies, this

TABLE I. SUMMARY OF THE RESEARCH DESIGN

Methodological component	Description
Research design	Comparative longitudinal evidence synthesis combining qualitative and quantitative analyses.
Study period	2018–2025.
Geographical coverage	More than 30 countries across Europe, Africa, Asia, Latin America, and North America.
Research approach	Comparative analysis integrating longitudinal datasets, case studies, and institutional reports.
Main analytical dimensions	Multi-level governance; citizen participation; digital transformation.
Primary data sources	OECD, UN DESA, World Bank, European Commission, Open Government Partnership (OGP), V-Dem Project, and peer-reviewed literature.
Comparative indicators	Decentralisation Reform Index (DRI); Citizen Participation Index (CPI).
Purpose of the analysis	Identify comparative governance trends and develop an integrated policy framework for territorial governance.

Source: Author's synthesis based on the methodological framework adopted in this study.

research analysis looks at over thirty countries from five regions in the world, from 2018 to 2025. Through descriptive statistics, this design allows qualitative comparative analysis. In so doing, this design identifies governance trends, and incorporates institutional diversity, and the context-specific pathways. Constructed along three user-friendly pathways of the comparative literature and global policy assessments, the research design incorporates 1) the changing frameworks of multi-level governance systems, 2) the building of frameworks for participatory governance, and 3) the impact of technology on territorial governance. The pathways provide the substantive basis for the comparative evaluation, and the policy design that is part of the concluding section of the article. To enhance research design clarity and reproducibility, Table I captures key design features, research strategy, scope, data, dimensions of analysis, and how comparative indicators are created.

Table I highlights a design with multiple complementary evidence sources, which improves the analytical robustness of the comparison. Converging global governance trends, along with the recognition of contextual particularities within different countries and regions, is facilitated through the combination of international data sets, institutional reports, and comparative case studies. This pluralistic approach improves both the analytical robustness and the reproducibility of the research.

B. Selection of Countries and Comparison

The sample for the purpose of comparison was constructed using a focused sampling strategy incorporating three complementary frameworks. First, for countries to be included, significant reforms in territorial governance (decentralization, regionalization, and digital government reforms) had to be undertaken between 2018 and 2025. Second, countries from which international governance and institutional evaluation frameworks were available, were included. Third, the sample focused on countries from Europe, Africa, Asia, Latin America, and North America, thus allowing comparisons across different administrative systems and the varying levels of governance and institutional development. The final comparative corpus includes data from around thirty countries, while selected national case studies (e.g., France, Morocco, Kenya, Germany, Brazil, Indonesia, and Canada) are mentioned to show regional institutional trends without focusing on comprehensive analyses of particular countries.

C. Data Sources and Harmonisation

The analysis is based solely on secondary data from institutions and peer-reviewed articles with international recognition. Quantitative data were gathered from official records and publications of the OECD, United Nations Department of Economic and Social Affairs (UN DESA), World Bank, European Commission, Open Government Partnership (OGP), and Varieties of Democracy (V-Dem). These were supplemented by recent studies on decentralization, citizen participation, digital governance, and the governance of territories. Since there are many types of institutional data, a common framework for international comparison was used for data harmonization. Indicators were defined and documented for the same periods to achieve data consistency and comparable documentation for each country. The focus was on identifying significant trends and consistent institutional patterns in various governance structures, rather than determining the direction of causal links.

D. Construction of the Comparative Indicators

For the purpose of this exercise, two composite descriptive indicators, the Decentralization Reform Index (DRI) and the Citizen Participation Index (CPI), were created. These indicators are not formal international indicators. Rather, these indicators help synthesize the data reported by international organizations in comparative studies. The Decentralisation Reform Index provides a measure of progress on territorial governance reforms by using information on the delegation of administrative powers, fiscal decentralisation, regional self-governance, and mechanisms of institutional coordination. The Citizen Participation Index brings together evidence on various dimensions of participative governance, including participatory budgeting, deliberative/specialized forums, citizen assemblies, online participation tools, and supportive institutional mechanisms of civic engagement. To allow for longitudinal comparisons among various countries, the two indices were normalized, and for the purpose of this work, they were employed exclusively to illustrate the most relevant governance patterns in a general sense, without establishing any firm causal relations. Hence, the quantitative information in this section should be understood as a descriptive evidence in support of the comparative analysis, and not the results of any econometric exercise.

III. Theoretical Framework

A. Defining Territorial Governance

Territorial governance is a contested concept at the intersection of at least four disciplinary traditions: political science, urban planning, administrative science, and economic geography [6, 48]. . Although there are significant similarities between the governance of territories and related concepts such as governance at the regional level and the governance of urban areas and public administration, they cannot be equated. Regional governance is concerned with the coordination of policies and systems at the regional level, while urban governance is concerned with the governance of cities and their surrounding metropolitan areas. Public administration, on the other hand, is concerned with the execution of public policies through government and its bureaucracy. Territorial governance encompasses all of the areas described above, and combines them with the coordination of public, private, and civil actors at different spatial levels within a specific territory. Territorial governance is characterized, not by a given level of administration, but by the ability to organize collective action and integrate policies and reconcile the social, economic and environmental aspects and the different levels of government through a network of governance systems [21] [20]. For the purpose of this article, therefore, territorial governance is the multilevel coordination of shape (formal) governance mechanisms, integrating a variety of actors and policy spheres across a given territory. Following Hooghe and Marks (2019), we employ a broad institutional view and differentiate between Type I and Type II governance systems *Type I* governance allocates authority to a limited number of non-overlapping, general-purpose jurisdictions organised at a small number of levels. *Type II* governance involves task-specific jurisdictions at potentially many levels, with flexible membership and overlapping territorial scope.

This Type I/Type II distinction maps onto a fundamental tension in the literature between the efficiency-oriented logic of specialised functional governance and the democratic-legitimacy-oriented logic of comprehensive territorial units [17, 18]. Contemporary governance arrangements are typically hybrid: national states maintain Type I territorial hierarchies while deliberately creating Type II bodies for specific policy domains such as metropolitan transport, river-basin management, or innovation ecosystems [41].

B. Multi-Level Governance Theory

The concept of multi-level governance (MLG), originally developed to explain European integration [35], has been generalised into a comparative framework applicable to federal and unitary states alike. In its contemporary form, MLG acknowledges that governance processes are characterised by the simultaneous activation of supranational, national, regional, and local actors whose authority relations are neither strictly hierarchical nor purely networked [51][3].

Fig. 1 illustrates the standard multi-level architecture as applied to contemporary territorial governance, showing the vertical interplay between the supranational, national, regional, intermediate, and local tiers.

Additional to the conceptual distribution of power, multi-level governance employs certain institutional and political

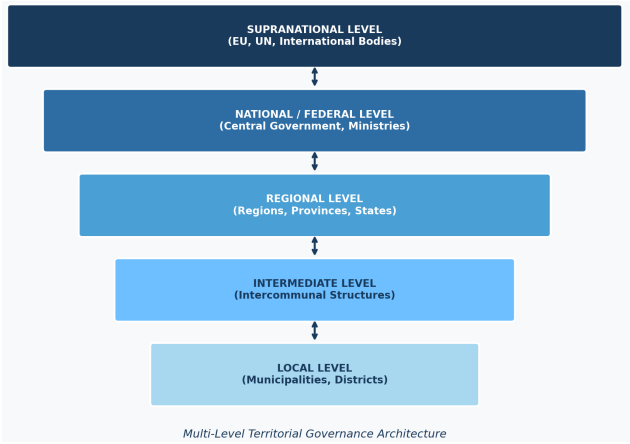

Fig. 1. Multi-level territorial governance architecture: Vertical distribution of authority from supranational to local tiers. Bidirectional arrows denote the simultaneous upward and downward flows of decision-making influence [35, 50].

mechanisms that determine how power is distributed between national and sub-national governments. These mechanisms consist of fiscal decentralisation, regulatory decentralisation, and mechanisms of accountability. Fiscal decentralisation enables regional and sub-regional governments to raise their own revenues, receive grants, and make decisions about public spending. Regulatory decentralisation allows sub-national governments various levels of legislative and administrative competence in different spheres such as planning, economic activities, transport, and the management of the environment. Accountability mechanisms such as legal control, financial audits, or the evaluation of performance, as well as citizen participation, ensure that devolved power is consistent to national policy and is transparent. To help elucidate the conceptual basis of multi-level governance, Table II brings together the fundamental building blocks of the various mechanisms that institute a redistribution of power from central to sub-national governments. These mechanisms comprise fiscal self-governance, regulatory powers, administrative decentralization, and systems of accountability. Collectively, these indicate the balance of governance power among the various levels [22] ,2019;[23].

Table II also shows that the redistribution of power in multi-level governance is far more complex than fiscal decentralization. The interrelation of financial resources, regulatory powers, administrative skills, and systems of accountability all work, collectively, to define the autonomy and the capacity of sub-national governments.

C. Theories of Participation and Legitimacy

Democratic legitimacy in territorial governance rests on two complementary pillars: *input legitimacy* (the responsiveness of processes to citizens' preferences) and *output legitimacy* (the effectiveness of policy outputs) [13, 52]. A third pillar—*throughput legitimacy*—has been proposed to capture the quality of the governance process itself: its accountability, transparency, inclusiveness, and openness to civil society [53].

The participatory turn in territorial governance, documented since the Porto Alegre participatory budgeting exper-

TABLE II. CONCEPTUAL DISTINCTION BETWEEN TERRITORIAL GOVERNANCE AND RELATED GOVERNANCE APPROACHES*

Concept	Primary focus	Main actors	Spatial scale	Key objective
Public administration	Policy implementation	Government agencies	Administrative units	Administrative efficiency
Urban governance	City management	Municipal authorities and urban stakeholders	City / Metropolitan area	Urban development and service delivery
Regional governance	Regional coordination	Regional governments	Region	Regional competitiveness and cohesion
Territorial governance	Multi-level coordination and collective action	Public, private and civil society actors	Multi-scalar territory	Integrated territorial development

iments of the 1990s, has accelerated dramatically with digital technologies. Fung [18] identifies a "participation ladder" from consultation to co-production to delegated authority, arguing that genuine empowerment requires not only formal mechanisms but also the organisational capacity of civil society to use them effectively.

IV. MULTI-LEVEL GOVERNANCE ARCHITECTURES (2018–2026)

A. Global Decentralisation Trends

The period under review has witnessed a paradoxical double movement in decentralisation. On the one hand, a range of countries—including Morocco, Kenya, Indonesia, and Peru—enacted significant devolution reforms transferring fiscal resources, regulatory authority, and service delivery mandates to sub-national governments [59]. On the other hand, emergency pandemic governance mechanisms, enacted between 2020 and 2021, temporarily re-centralised health, mobility, and economic policy in approximately 60% of OECD member states [42].

Fig. 2 charts the Decentralisation Reform Index for a sample of ten countries spanning five world regions, comparing 2018 and 2025 scores. The data reveal universal upward trends, with Morocco (+16 points), Kenya (+16 points), and Indonesia (+11 points) recording the most substantial gains, reflecting ambitious constitutional and legislative reform agendas.

Bringing decision-making closer to citizens is a common expectation with decentralisation. However, proximity - be it geographical or administrative - does not guarantee that poor governance will improve. In fact, the effectiveness of decentralised systems is determined by the institutional, financial, and administrative capacities of sub-national governments. Where local authorities have the resources, expertise and accountability, decentralisation can lead to greater policy engagement and service delivery. However, in the cases of weak, especially poor, institutional and fiscal systems, decentralisation will deepen local elite capture and create greater regional inequalities. This is especially the case when decentralisation occurs without financial resources or the means to fulfil the responsibilities, thereby creating asymmetrical governance in different regions (Gill, 2003; World Bank, 2022). For these reasons, when considering decentralisation, proximity should not be considered a goal. Instead, proximity is a condition that will only be successful when the quality of governance in the local regions is adequate and when there is good intergovernmental coordination.

B. Fiscal Decentralisation and Sub-National Finance

A central dimension of territorial governance reform concerns the fiscal architecture linking central government to sub-national entities. The 2020s have seen a gradual shift from grant-based to tax-sharing arrangements, increasing the own-revenue share of regional and local governments in approximately 38 countries [26, 44]. This trend is not uniform, however. Dollery et al. [15] document a persistent gap between de jure devolution—encoded in law—and de facto fiscal autonomy, which remains constrained by vertical fiscal imbalances, unfunded mandates, and weak local revenue administrations.

A notable institutional innovation in this domain is the development of *territorial contracts*: multi-year framework agreements between central governments and sub-national authorities specifying mutual obligations, performance targets, and co-financing arrangements. France's *contrats de plan État-région*, the German *Gemeindeordnung* reforms, and Morocco's *Contrats-programmes régionaux* all illustrate this trend toward negotiated inter-governmental relations [6, 49].

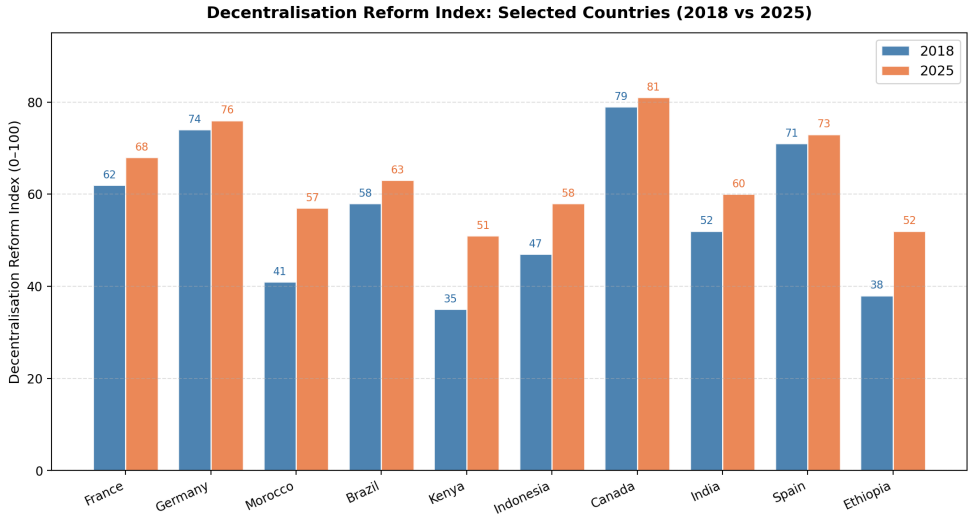

Fig. 2. Decentralisation Reform Index scores for selected countries, 2018 versus 2025 (composite index based on fiscal autonomy, regulatory authority, administrative capacity, and accountability indicators). Source: authors' compilation from Zweers et al. [61] and OECD [44].

TABLE IV. SELECTED METROPOLITAN GOVERNANCE REFORMS, 2018–2026

Case	Year	Key Reform Feature	Population (M)
Greater Paris	2018–21	Metropolis of Grand Paris consolidation; ITI funding	12.2
Casablanca-Settat	2020	Regional council empowerment; smart-city programme	7.1
Greater Nairobi	2019	Metropolitan area governance plan; SDG alignment	5.5
Bogotá Region	2021	Constitutional amendment; regional governance body	10.7
Jakarta MMA	2022	Capital relocation; new supra-metropolitan authority	34.5
Barcelona AMB	2019	Integrated transport & housing mandate	5.3
Lagos State	2023	Master Plan 2053; inter-local coordination councils	15.8
Buenos Aires RMBA	2020	Regional metropolitan committee reinstatement	14.8

Source: Authors, based on OECD [45], Habitat [25], and national sources.

C. Metropolitan Governance and Functional Regions

Perhaps the most significant architectural shift of the period is the growing recognition of functional urban regions as the appropriate spatial scale for strategic governance [41, 45] [14]. The metropolitan governance gap—the mismatch between the spatial extent of economic and social interdependencies and the boundaries of existing jurisdictions—has emerged as a structural challenge in rapidly urbanising societies [29].

The European Union's Integrated Territorial Investments (ITI) and Community-Led Local Development (CLLD) instruments, introduced in the 2014–2020 programming period and reinforced in the 2021–2027 cohesion policy framework, have encouraged the development of multi-jurisdiction governance platforms at the functional urban scale [16]. In the Global South, the proliferation of metropolitan development authorities—in Nairobi, Buenos Aires, Jakarta, and Casablanca—reflects a parallel functional logic [25].

Table IV summarises key features of selected metropolitan governance arrangements established or reformed between 2018 and 2026.

The world shows that territorial governance cannot simply rely on autonomous financing. Financial decentralization must have well defined clear regulatory competences combined with strong administrative capacities and embedded accountability frameworks. Where administrative and policy authority is not matched with revenue-raising powers, vertical fiscal misbalances are created limiting policy independence and increasing reliance on central government transfers. On the contrary, areas that combine regulatory powers with financial resources and accountability frameworks have better policy outputs and greater governance responsiveness to local development challenges, (OECD, 2022; World Bank, 2022).

V. CITIZEN PARTICIPATION AND DEMOCRATIC ACCOUNTABILITY

A. The Participatory Turn in Local Governance

Citizen participation in territorial governance has expanded significantly since 2018, driven by a combination of civic demand, policy innovation, and digital enablement [18, 38]. Participatory budgeting (PB)—the emblematic instrument of this trend—has spread to over 11,000 cities worldwide by 2025, compared with approximately 3,000 in 2016 . Yet the quality and depth of participation remain highly heterogeneous.

To help analyze the varying levels of effectiveness of different forms of citizen participation, Table V develops an analyti-

TABLE V. ANALYTICAL FRAMEWORK FOR EVALUATING CITIZEN PARTICIPATION MECHANISMS IN TERRITORIAL GOVERNANCE

Participation mechanism	Primary objective	Level of citizen influence	Key evaluation criteria	Expected policy impact	Contribution to institutional trust
Public consultation	Gather citizens' opinions before policy decisions	Low (consultative)	Transparency, inclusiveness, accessibility	Limited influence on final decisions; mainly improves information gathering	Low–Medium
Co-production	Joint design and delivery of public services	High (shared decision-making)	Inclusiveness, accountability, collaboration, responsiveness	Improved service quality, stronger policy ownership, and greater administrative responsiveness	High
Deliberative forums (Citizens' assemblies, panels)	Promote informed public deliberation and consensus-building	Medium–High	Representativeness, transparency, quality of deliberation, accountability	Better-informed policy recommendations and stronger democratic legitimacy	High
Participatory budgeting	Involve citizens in allocating public financial resources	High (direct influence on budget priorities)	Inclusiveness, transparency, accountability, influence on decisions	More responsive public spending and stronger local accountability	High
Digital engagement platforms	Facilitate continuous interaction between citizens and public authorities	Medium (depending on institutional design)	Accessibility, transparency, responsiveness, digital inclusion	Faster communication, broader participation, and enhanced policy feedback	Medium–High

Source: Author's synthesis based on the literature on participatory governance, deliberative democracy, digital government, and territorial governance.

cal framework that enables the comparison of key participatory mechanisms on the basis of aims, citizen influence, evaluation criteria, anticipated outcomes, and trust in institutions. This framework demonstrates the need to go beyond participatory initiatives to assess citizen participation. More specifically, it indicates that participation frameworks must include citizen influence, participation in the decision-making process, and the governance frameworks' sustainability.

Table III illustrates that participatory mechanisms can, and often do, lead to different governance outcomes as a result of different institutional designs. Public consultation is the most common participatory mechanism and the most popular participatory mechanism in policy-making, but it offers limited influence in policy outcomes. Co-production and participatory budgeting are participatory mechanisms that provide more citizen empowerment and influence through participation in the production of services and the allocation of budgeting resources. Participatory design and deliberation improve the legitimacy of democracy in policymaking and decision-making, while digital participation mechanisms expand participatory mechanisms. However, they can deepen and reproduce social inequalities if there is insufficient digital access and insufficient responsiveness and obligation on the part of institutions. In other words, the type of participatory mechanism does not guarantee the quality of the participatory process. Quality participatory mechanisms require inclusiveness, transparency, and accountability, as well as the provision of real influence in public participation and decision-making processes.

Studies of PB programmes in Africa, Latin America, and Europe consistently find that participation skews toward higher-educated, middle-income, and politically engaged populations, reproducing pre-existing inequalities in voice and representation [8][24].

Fig. 3 presents longitudinal data on our composite Citizen Participation Index (CPI) for four world regions from 2018 to 2025. European Union member states report the highest average CPI, benefiting from long-established participatory traditions and EU co-financing of civil society organisations. Sub-Saharan African countries show the strongest relative growth (+18 points), reflecting rapid institutionalisation of community-based governance in countries such as Rwanda, Ghana, and Kenya.

B. Deliberative Innovations: Citizens' Assemblies and Panels

Beyond traditional consultative mechanisms, the 2018–2026 period has seen a notable proliferation of *deliberative mini-publics*—randomly selected panels of citizens charged with formulating policy recommendations on complex territorial issues [55]. Ireland's Citizens' Assembly on biodiversity loss, France's Convention Citoyenne pour le Climat, and Scotland's Citizens' Assembly on post-COVID recovery all demonstrated that non-expert citizens, given adequate information and deliberative support, can produce sophisticated, actionable policy proposals [12].

At the sub-national level, citizens' panels on urban planning, transport, and housing have been piloted in cities including Bristol, Grenoble, Ghent, and Melbourne, typically operating as advisory bodies upstream of formal participatory procedures [55]. Evaluations of these experiences suggest that their impact on final decisions is variable and contingent on the political commitment of decision-makers to take recommendations seriously [7].

C. Gendered and Intersectional Participation

A growing body of research underscores the importance of explicitly addressing gendered and intersectional dimensions in participatory governance design [33]. Women's participation in formal local governance—as elected officials, administrators, and civil society representatives—has increased across all regions studied, with female local councillor shares rising

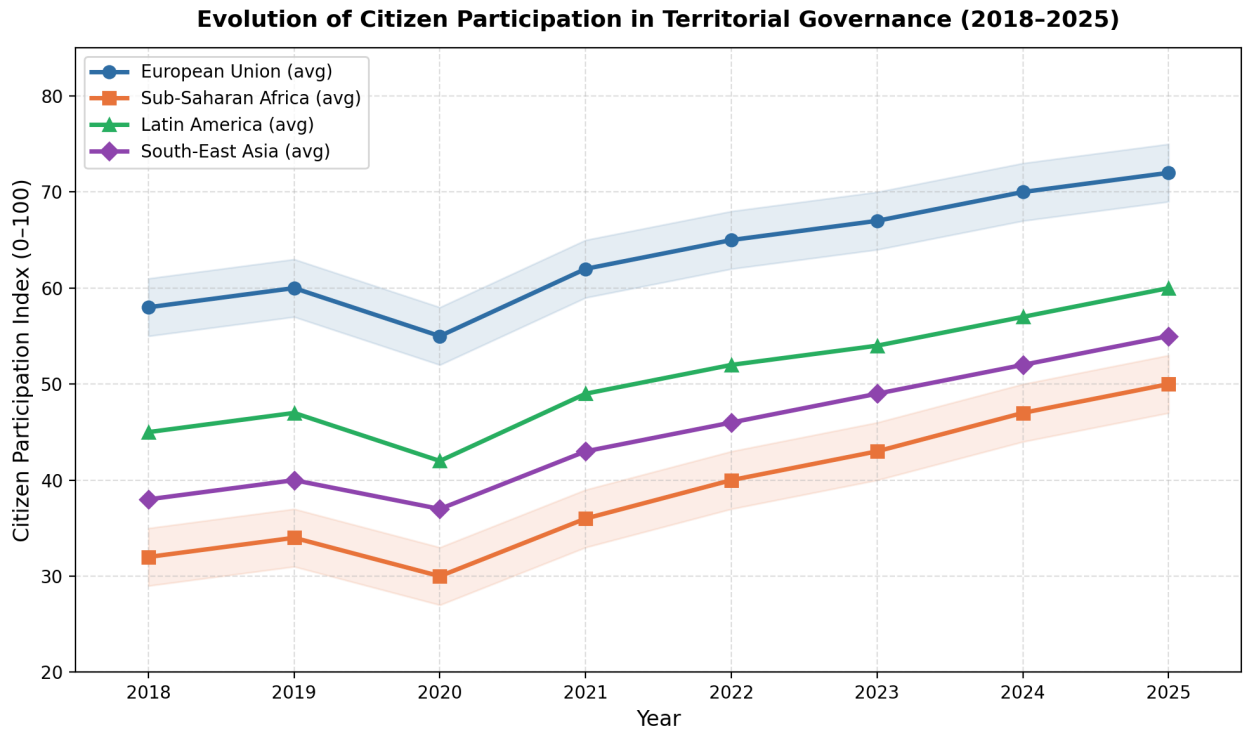

Fig. 3. Evolution of the Citizen Participation Index (CPI) by world region, 2018–2025. The CPI is a composite measure (0–100) aggregating seven sub-indicators including participatory budgeting coverage, public consultation frequency, civil society capacity, and digital civic engagement. Shaded bands represent ±1 standard error of the mean. Source: Authors' compilation from Sintomer et al. [54], IDB [26], and OECD [43].

from an average of 26% in 2018 to 34% in 2025 [27]. However, [33] [34] caution that numerical representation does not automatically translate into substantive voice, particularly when institutional cultures remain male-dominated.

VI. Digital Transformation of Territorial Governance

A. E-Government to Smart Territories

The trajectory from e-government to smart territorial governance represents a qualitative shift in the role of digital technologies: from automating existing administrative processes to fundamentally reconfiguring the relationship between public institutions and the territories they govern [36, 59]. The smart city paradigm—despite enduring critiques of its technocratic bias and corporate capture [30] [60]—has evolved toward a more citizen-centred, sustainability-oriented framing encapsulated in concepts such as the "15-minute city" and inclusive smart territories [37].

Fig. 4 presents a radar chart tracking the adoption of six digital governance tools across a sample of 45 territories from 2020 to a 2026 projection. E-participation platforms and open data portals show the highest adoption rates, reflecting relatively low implementation barriers, while blockchain-based governance applications—despite growing interest—remain nascent [51, 61].

It is critical to understand the difference between digital transformation and administrative digitalisation. Administrative digitalisation is the use of information technologies to

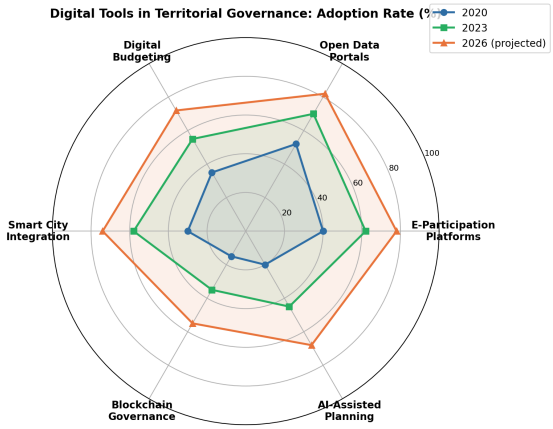

Fig. 4. Adoption rates (%) of six digital governance tools across 45 territories, 2020, 2023, and 2026 (projected). Data sources: OECD [47], IDB [26], UN DESA [57].

automate existing bureaucratic processes; this does not restructure governance and decision-making. In contrast, digital transformation is the change of processes, structures, and practices of government to facilitate and enhance the use of data for informed decisions, collaborative governance, integrated service delivery, and active digital engagement of the public. Digitalisation optimises administrative procedures. However, digital transformation reimagines governance and constructs public value through the innovation of systems functionalities and processes (Mergel et al. 2019; OECD, 2022; UN DESA,

TABLE VI. INSTITUTIONAL CAPACITY, DIGITAL TRANSFORMATION AND TERRITORIAL GOVERNANCE OUTCOMES

Institutional capacity dimension	High institutional capacity	Low institutional capacity	Expected territorial governance outcome
Legal and regulatory framework	Comprehensive digital governance legislation, clear legal mandates, and data protection regulations	Fragmented or outdated legal framework and regulatory uncertainty	Strong legal certainty and accountable digital governance versus inconsistent implementation
Administrative capacity	Skilled civil servants, strong digital competencies, and effective intergovernmental coordination	Limited technical expertise, weak coordination, and staff shortages	Efficient service delivery and policy implementation versus administrative bottlenecks
Fiscal and financial capacity	Sustainable ICT investment, diversified funding, and long-term digital strategies	Insufficient financial resources and dependence on central transfers	Continuous digital innovation versus fragmented digital projects
Digital infrastructure	High broadband coverage, interoperable platforms, and secure information systems	Limited connectivity, obsolete infrastructure, and fragmented digital systems	Inclusive digital public services versus unequal territorial access
Transparency and accountability	Open data policies, performance monitoring, and citizen oversight mechanisms	Weak transparency, limited monitoring, and low public accountability	Greater public trust and institutional legitimacy versus reduced civic confidence
Citizen digital inclusion	High digital literacy, accessible online services, and inclusive participation platforms	Digital divide, low digital skills, and unequal access to online services	Broad civic engagement versus exclusion of vulnerable populations
Overall governance trajectory	Transformative digital governance characterised by innovation, collaboration, and institutional resilience	Administrative digitalisation limited to process automation with persistent governance constraints	Territorial convergence versus two-speed territorial governance and widening regional disparities

Source: Author's synthesis based on the literature on digital government, institutional capacity, territorial governance, and multi-level governance.

2024). The term « institutional robustness » denotes the ability of public institutions to support digital governance through the integration of well-constructed statutes, administration, and funding, along with reliable, secure, and privacy-protecting information systems, accountability, and an adaptive learning culture. These elements create the conditions under which the use of digital technologies for governance can move beyond the automation of administrative processes. Without these, the use of the same digital tools will most likely lead to very different governance results (OECD, 2022; World Bank, 2022). To elucidate the circumstances under which digital transformation fosters active territorial governance, an analytical framework is provided in Table V, integrating institutional capacity, digital transformation, and governance results. The framework demonstrates that the combination of digital technologies and institutional maturity brings sustained public value. It also shows the role of varying institutional capacity in producing a two-speed territorial governance scenario in different regions.

Table VI illustrates that digital transformation is not a standalone technological phenomenon, but rather the convergence of digital innovation and the reform of governance-related institutions. Territorial regions that enjoy well-established legal systems and strong administrative, financial, and inclusive digital capacity are more likely to experience the transformational impact of governance. On the other hand, where institutional capacity is inadequate, digital offers a greater degree of administrative rationalization, but little improvement in the transparency, civic engagement, and quality of public services. These gaps result in a two-speed territorial governance phenomenon, which increasingly demonstrates the greater variety of institutional capacity compared to the availability of technologies. This article uses the term "two-speed territorial governance" to identify the results of these institutional asymmetries. In this context, we find that strong regions use digital transformation to promote transparency and citizen participation and improve public services. We find that less developed regions practice Administrative Digitalization. In this case, we find that less developed regions reinforce.

B. Open Data, Transparency, and Accountability

Open government data (OGD) initiatives have expanded considerably, with over 100 national and sub-national OGD portals now operational worldwide, and subnational portals growing faster than national ones since 2021 [47]. Jetzek [28] argues that the public value of open data in territorial governance is maximised when data ecosystems are designed around user needs, maintained with systematic quality controls, and linked to clear accountability mechanisms.

Participatory budgeting platforms that combine open fiscal data with interactive visualisation tools—such as those deployed in São Paulo, Warsaw, and Seoul—have been shown to significantly increase citizens' understanding of local budgetary constraints and improve the quality of participation [8, 54].

C. Algorithmic Decision-Making and Governance Risks

The growing use of algorithmic tools in territorial planning—from predictive policing to automated zoning recommendations and AI-assisted benefit allocation—raises urgent questions of accountability, explainability, and equity [30, 61]. identifies four systemic risks of algorithmic governance in territorial contexts: 1) the embedding of historical inequalities in training data; 2) the opacity of proprietary systems that frustrates democratic scrutiny; 3) the erosion of local contextual knowledge in favour of standardised data models; and 4) jurisdictional mismatches between the territorial scope of governance authority and the transnational infrastructure of digital platforms.

These concerns have prompted a wave of regulatory initiatives. The EU's Artificial Intelligence Act (2024), the African Union's Data Policy Framework (2022), and various sub-national AI ethics charters reflect a growing consensus that human oversight, explainability requirements, and non-discrimination audits are necessary conditions for legitimate algorithmic governance [2].

VII. Comparative Case Analysis

A. European Models: France and Germany

France and Germany represent contrasting yet instructive models of territorial governance reform during the study period. France's *loi NOTRe* (2015) had reduced the number of regions and transferred significant strategic planning competences to the new enlarged regions; the 2019–2026 period has seen consolidation of this architecture, punctuated by President Macron's uneven "Jacobin reflex" of re-centralisation during the COVID-19 emergency [49]. The Territoires d'industrie programme and the *Action Cœur de Ville* initiative illustrate an emerging neo-contractualist approach in which central government co-finances local projects in exchange for multi-year governance commitments [10].

Germany's federal system, by contrast, offered greater built-in resilience during the pandemic. *Länder* governments' capacity to adapt health-governance responses to local epidemiological conditions—within a nationally coordinated framework—has been cited as a comparative advantage [31] [32]. The *Gemeindefinanzreform* debate and the *Kommunalinvestitionsförderungsgesetz*

(Municipal Investment Promotion Act) reflect ongoing efforts to address structural fiscal disparities between affluent urban and lagging rural municipalities.

B. African Trajectories: Morocco and Kenya

Morocco's Advanced Regionalisation Reform, operationalised through the Organic Laws 111-14, 112-14, and 113-14 (2015), granted elected regional councils significant new competences in economic development, land planning, and social services. The 2021–2026 implementation period has seen variable performance across Morocco's twelve regions: Casablanca-Settat and Rabat-Salé-Kénitra have moved rapidly to establish integrated regional strategies, while more peripheral regions face capacity constraints [6] [4]. The national investment charter (2022) and the New Development Model (NDM) report reinforce the territorial dimension of economic governance by allocating dedicated envelopes for regional convergence [11].

Kenya's devolution architecture, established under the 2010 Constitution, has matured considerably since 2018. The 47 county governments now command approximately 20% of national revenue, with functioning own-revenue administrations and county-level integrated development plans [61]. Persistent challenges include horizontal equity in the distribution of equitable share transfers, boundary disputes, and the under-representation of marginalised groups in county assemblies [27].

C. Latin American Laboratory: Brazil and Colombia

Brazil's municipal governance landscape during 2018–2026 was characterised by a tension between the relatively robust constitutional architecture of municipal autonomy (established in 1988) and the fiscal austerity imposed by EC95 (the expenditure ceiling amendment), which constrained local investments in health, education, and infrastructure [56]. The election of Luiz Inácio Lula da Silva in 2022 has partially reversed this fiscal contraction through an expanded national investment programme with a strong territorial targeting component.

Colombia's territorial peace governance framework—centred on Programas de Desarrollo con Enfoque Territorial (PDET) in post-conflict regions—represents a globally significant experiment in integrating territorial governance with transitional justice objectives [26]. Evaluations note significant progress in community mobilisation but persistent implementation deficits linked to security conditions and institutional fragility in the most affected territories.

VIII. Persistent Challenges and Future Trajectories

A. Territorial Inequalities and Spatial Justice

Despite the progress documented across governance dimensions, territorial inequalities—both between and within countries—remain stubbornly persistent. The OECD's Regional Outlook 2022 reports that in most member countries, per capita GDP gaps between leading and lagging regions have not narrowed since 2018, and in some cases have widened [46]. Similar findings emerge from the World Bank's Spatial Inequality and Governance report [61], which identifies governance fragmentation and administrative capacity gaps as structural causes of territorial divergence in low- and middle-income countries.

Casellas [9] argues that the dominant efficiency-oriented discourse of metropolitan governance systematically undervalues the redistributive and solidarity dimensions of territorial governance, creating policy blind spots that exacerbate spatial injustice. A more politically conscious approach—one that explicitly addresses the territorial dimensions of class, race, and gender inequalities—is needed to achieve the SDG principle of "leaving no one behind" [58].

B. Climate Change and Territorial Resilience

Climate change is rapidly becoming the central structuring challenge of territorial governance. Berkes & Ross [5] and Habitat [25] document the growing mismatch between the slow-moving, jurisdiction-bounded logic of territorial governance and the transboundary, non-linear dynamics of climate risk. Coastal erosion, inland flooding, prolonged drought, and urban heat islands all require territorial governance responses that transcend existing jurisdictional boundaries and planning horizons.

The emergence of climate governance special-purpose bodies—coastal adaptation authorities, river-basin drought management committees, urban heat action councils—illustrates the Type II governance logic identified by Marks & Hooghe [35]: creating flexible, functionally specific governance arenas alongside, and in tension with, existing territorial hierarchies.

C. Trust, Legitimacy, and Democratic Resilience

A pervasive challenge for territorial governance across all studied contexts is the crisis of institutional trust. Global surveys consistently document declining public trust in government at all levels, with local and regional governments generally faring somewhat better than national institutions but

TABLE VII. COMPARISON BETWEEN EXISTING TERRITORIAL GOVERNANCE FRAMEWORKS AND THE PROPOSED INTEGRATED FRAMEWORK

Framework	Institutional architecture	Fiscal equity	Citizen participation	Responsible digital governance	Main contribution
OECD (2019)	✓	✓	Limited	Limited	Principles for decentralisation and multi-level governance
UN DESA (2021)	Limited	Limited	✓	✓	Digital government and citizen-centred public administration
World Bank (2022)	✓	✓	Limited	✓	Local governance capacity and service delivery
European Commission (2021)	✓	✓	✓	Limited	Territorial cohesion and multi-level governance
Proposed Framework (This study)	✓	✓	✓	✓	Integrated territorial governance combining institutional, fiscal, participatory and digital dimensions

Source: Author's synthesis based on OECD (2019), UN DESA (2021), European Commission (2021), and World Bank (2022).

still far from the levels of trust required for effective co-governance [39, 43]. Fung [18] argues that this trust deficit is both a symptom and a cause of democratic backsliding: as citizens withdraw from conventional participation channels, elites face reduced accountability, which further erodes trust in a self-reinforcing spiral.

IX. POLICY RECOMMENDATIONS AND CONCLUSIONS

A. An Integrated Framework for Inclusive Territorial Governance

Based on the evidence given for comparison in this study, an integrated policy framework for territorial governance has been developed. While many of the international organizations, as well as many of the scholars, have developed frameworks of governance in terms of the various facets of decentralization, fiscal governance, citizen engagement, and governance in terms of digital change, the majority of these frameworks are sector specific. The model of governance proposed in this study has the ambition of integrating the disparate yet complementary aspects of contemporary territorial governance in a model that addresses the institutional, fiscal, participatory, and digital aspects. The principal governance models outlined in the literature are featured in Table VII for a comparison with the model proposed in this study.

Drawing on the evidence reviewed in this article, we propose a four-pillar framework for inclusive, resilient territorial governance:

1) Institutional architecture: Align territorial governance boundaries with functional spatial interdependencies; promote flexible Type II governance for cross-boundary challenges while maintaining democratic Type I accountability structures.

2) Fiscal equity: Ensure that decentralisation transfers adequate fiscal resources alongside responsibilities; establish horizontal equalisation mechanisms to prevent the deepening of territorial inequalities.

3) Participatory depth: Move beyond consultative participation toward co-production and delegated authority in domains where communities have relevant knowledge and strong stakes; invest in the organisational capacity of civil society, particularly in marginalised territories.

4) Responsible digitalisation: Deploy digital tools as enablers of human-centred governance rather than as ends in themselves; establish algorithmic accountability frameworks, ensure universal digital access, and maintain non-digital participation pathways.

B. Conclusions

This article has charted the evolution of territorial governance over the period 2018–2026, a period of extraordinary disruption and innovation. The evidence converges on a qualified optimistic assessment: decentralisation is advancing, participatory repertoires are expanding, and digital tools are creating new opportunities for transparency and civic engagement. Yet the same period has revealed stubborn structural limitations: persistent territorial inequalities, governance fragmentation, capacity deficits, and the ever-present risk of democratic backsliding.

The COVID-19 pandemic and the accelerating climate emergency have, paradoxically, both tested and renewed the case for territorial governance: tested it by exposing the costs of coordination failures, and renewed it by demonstrating that local and regional governments possess irreplaceable knowledge, legitimacy, and agility in responding to complex territorial challenges.

The research presented here is subject to several limitations. The composite indices employed involve methodological choices that may not fully capture context-specific governance dynamics. The comparative case studies, while illustrative, cannot claim representativeness of the full diversity of global territorial governance arrangements. Future research should develop richer longitudinal datasets, particularly for the Global South, and engage more deeply with the lived experiences of governance actors and citizens.

The coming years will require territorial governance scholars and practitioners to engage more systematically with the intersections of governance, spatial justice, and climate resilience. The normative stakes could hardly be higher: the quality of territorial governance will, in large measure, determine whether humanity's urban majority inhabits flourishing communities or deepening spatial injustice.

***Abstract*—Intervention evaluation frequently relies on fixed analytical workflows that provide limited support for methodological adaptability, reproducibility, and systematic management of analytical variability. This study proposes a Feature Model-based configurable framework that represents data preparation, feature construction, statistical inference, robustness validation, and decision-support generation as interdependent analytical features. Mandatory, optional, alternative, and dependency-constrained decisions are modeled explicitly, enabling the systematic generation, validation, and diagnosis of reproducible analytical configurations. The framework was instantiated in a managerial capability development intervention involving micro-enterprises. Across the strategic, financial, and operational capability dimensions, the generated pipelines identified statistically significant improvements with Cohen's d values ranging from 0.48 to 0.65. The direction and inferential interpretation of the intervention effects remained stable across the admissible preprocessing, imputation, and testing configurations evaluated in the case study. Because the empirical assessment uses a single dataset from one application domain, the findings establish technical feasibility and within-case robustness rather than cross-domain generalizability. The study contributes a variability-aware analytical architecture and an open-source Python-based engine integrating Feature Model reasoning, configuration validation, and Parallel FastDiag-based conflict diagnosis, thereby supporting transparent, inspectable, and adaptable intervention-evaluation workflows.**

***Keywords*—Feature models; variability management; configurable systems; reproducible analytics; decision support systems; intervention evaluation**

I. Introduction

Intervention evaluation has become an essential activity in domains such as education, healthcare, organizational development, public policy, and sustainability management, where evidence-based decision making increasingly depends on the systematic analysis of complex and heterogeneous datasets [1]–[3]. As organizations generate larger volumes of information and rely more heavily on analytical evidence to support strategic and operational decisions, evaluation processes have evolved from isolated statistical procedures toward integrated computational environments that combine data preparation, analytical reasoning, validation, and decision support [4], [5].

Recent advances in data analytics, machine learning pipelines, and scientific workflow technologies have significantly improved the automation and reproducibility of analytical processes [6]–[9]. Modern analytical environments increasingly rely on structured pipelines capable of organizing data acquisition, preprocessing, feature engineering, statistical inference, visualization, and reporting into repeatable execution stages. Such approaches contribute to transparency, traceability, and reproducibility while reducing manual effort and facilitating the replication of empirical studies [10]–[12]. Nevertheless, many existing pipeline-based solutions remain centered on predefined analytical workflows and provide limited support for representing alternative methodological strategies or systematically managing dependencies among analytical decisions [13].

This limitation is particularly relevant in intervention evaluation scenarios. Analysts frequently face alternative decisions regarding data preprocessing strategies, missing-value treatment, feature construction procedures, statistical testing methods, robustness assessment techniques, and reporting mechanisms. These methodological choices can significantly influence analytical outcomes and subsequent recommendations for decision makers [14]–[16]. In practice, many of these decisions remain embedded within scripts, spreadsheets, or procedural artifacts rather than being represented explicitly as configurable elements. Consequently, analytical reproducibility, methodological traceability, and systematic comparison of alternative evaluation strategies become difficult to achieve [13], [17].

Research in configurable systems engineering provides promising mechanisms for addressing these challenges. Variability management has been extensively adopted in software-intensive systems to represent optional functionalities, alternative configurations, dependency constraints, and adaptation mechanisms [18]–[20]. Among the available variability-modeling approaches, Feature Models have emerged as one of the most widely used mechanisms for representing and reasoning about configuration spaces through mandatory, optional, alternative, and dependency-aware features [18], [20]–[22]. Their successful application has been reported in software product lines, adaptive systems, configurable services, testing environments, and machine learning ecosystems [23]–[26].

Feature Models provide not only a compact representation of configuration alternatives but also a formal basis for validating consistency constraints and automatically generating valid configurations. Recent studies have demonstrated their effectiveness for supporting automated reasoning, configuration validation, performance assessment, and variability-aware system design [24], [27], [28]. Furthermore, advances in automated analysis techniques have considerably expanded the practical applicability of Feature Models in complex decision-support scenarios

*Corresponding author.

[18], [20]. Despite these developments, their application within analytical evaluation environments remains limited.

Existing research primarily focuses on software product lines, configurable platforms, adaptive systems, testing strategies, and machine learning configuration problems [19], [23], [24]. Comparatively little attention has been devoted to representing methodological variability within intervention evaluation processes. As a result, alternative analytical strategies are rarely modeled explicitly, analytical dependencies are seldom validated automatically, and reproducible generation of alternative evaluation configurations remains largely unsupported.

To address this research gap, this study proposes a Feature Model-based configurable framework for reproducible intervention evaluation. The proposed approach conceptualizes evaluation as a configurable analytical system composed of interconnected components responsible for data preparation, feature construction, statistical inference, robustness validation, and decision-support generation. Analytical variability is represented explicitly through Feature Models, enabling systematic generation and validation of alternative evaluation configurations while preserving methodological consistency. The proposed architecture integrates principles from configurable systems engineering, variability management, and reproducible analytical pipelines into a unified evaluation framework [12], [18], [20], [23].

The framework is evaluated through a real intervention scenario focused on managerial capability development among micro-enterprises. Different analytical configurations are instantiated and executed under alternative methodological assumptions to examine reproducibility, robustness, and consistency within the selected case. The obtained results show that the proposed framework can generate valid analytical pipelines, support reproducible execution, and maintain stable conclusions across the analytical configurations considered. Cross-domain generalizability is not claimed from this single-case validation and requires independent replication in additional settings.

In addition, a Python-based analysis engine was developed to operationalize the proposed framework. The engine implements Feature Model reasoning services, analytical configuration validation, and conflict diagnosis through an integration with a Parallel FastDiag-based diagnosis mechanism [29], [30]. This implementation provides a reproducible software infrastructure that can be reused for variability- aware analytical evaluation scenarios.

The main contributions of this work are summarized as follows:

- A configurable analytical architecture that reformulates intervention evaluation as a variability-aware systems-engineering problem.
- A Feature Model-based mechanism for representing analytical variability, methodological dependencies, and valid evaluation configurations.
- An empirical validation demonstrating the applicability of the proposed framework for reproducible and robust intervention assessment.
- An open-source software prototype that provides reproducible infrastructure for Feature Model reasoning, configuration validation, and conflict diagnosis in variability-aware analytical environments.

The remainder of this study is organized as follows. Section II reviews the literature on reproducible analytics, configurable systems, and Feature Model-based variability management. Section III presents the proposed configurable evaluation framework, including its architecture, analytical pipeline, and variability representation mechanisms. Section IV describes the experimental validation and reports the empirical results obtained under different analytical configurations. Section V discusses the implications of the proposed approach for reproducibility, robustness, scalability, and decision-support systems. Finally, Section VI concludes the study and outlines future research directions.

II. Related Work

Research related to the proposed framework can be grouped into three main areas: reproducible analytics, configurable systems, and Feature Model-based variability management.

A. Reproducible Analytics and Analytical Pipelines

The increasing importance of evidence-based decision making has motivated the development of analytical environments capable of supporting transparent and reproducible workflows. Modern data pipelines organize activities such as preprocessing, feature engineering, statistical analysis, and reporting into structured and repeatable execution stages [6], [10], [12]. These approaches improve consistency and facilitate the replication of empirical studies while reducing manual intervention throughout the analytical process.

Recent research has also emphasized the importance of workflow automation and configurable analytical infrastructures. Hasan and Tausif [7] propose automated machine-learning pipelines for enhanced data analytics, while Pulivarthy et al. [11] discuss scalable data-pipeline architectures for real-time analytical environments. Similarly, emerging scientific workflow platforms increasingly support automated execution and reproducible experimentation across heterogeneous computational environments [8].

Despite these advances, most analytical pipelines remain implemented through predefined execution sequences. Alternative preprocessing strategies, statistical procedures, and validation mechanisms are typically embedded within scripts or implementation artifacts rather than being represented explicitly as configurable analytical decisions. Consequently, methodological variability remains difficult to manage systematically [13].

B. Configurable Systems and Variability Management

Variability management constitutes a central research topic in software engineering because it enables the systematic representation and control of alternative system configurations. Configurable systems have been successfully applied in software product lines, adaptive applications, testing environments, and configurable services [19], [31].

Several studies have demonstrated that variability-aware approaches improve maintainability, adaptability, and reuse by

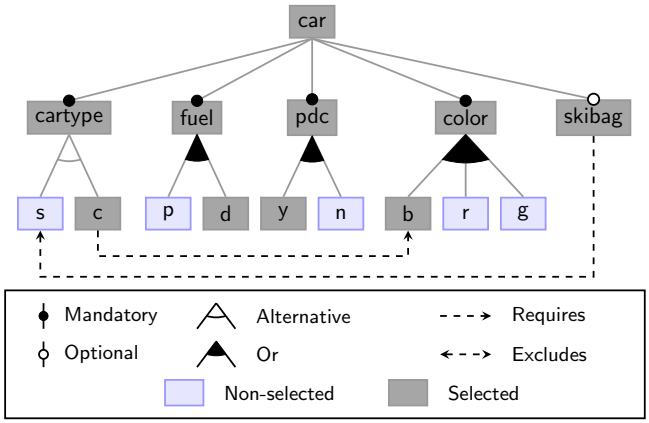

Fig. 1. Feature model illustrating mandatory, optional, alternative (XOR), OR-group, and dependency-based relationships in configurable systems. Reproduced from [32].

explicitly capturing configuration alternatives and dependency constraints [23], [25]. More recently, variability concepts have been extended beyond traditional software products toward machine-learning environments and configurable analytical platforms. For example, Tavares et al. [24] employ Feature Models to support machine-learning model selection, illustrating how variability management can facilitate systematic exploration of alternative analytical solutions.

Although configurable-system research provides mature mechanisms for representing alternatives and validating constraints, relatively few studies have explored their application within intervention evaluation processes. Most existing approaches focus on software configuration rather than methodological variability in analytical workflows.

C. Feature Models and Automated Analysis

Feature Models represent one of the most widely adopted formalisms for variability representation. They provide mechanisms for describing mandatory, optional, alternative, and dependency-related features within a configuration space [18], [20]. In addition to compact variability representation, Feature Models support automated reasoning tasks such as consistency verification, valid configuration generation, dependency analysis, and optimization [20], [27].

Fig. 1 illustrates a simplified Feature Model. The root feature represents the configurable system, while child features describe variability through mandatory, optional, alternative, and OR-group relations. Cross-tree constraints such as *requires* and *excludes* capture dependencies among features and support automated reasoning during configuration generation.

The importance of Feature Model analysis has been demonstrated in multiple application domains. Galindo et al. [18] review automated Feature Model analysis techniques, while Vidal-Silva et al. [21], [22] analyze product configuration mechanisms and automated reasoning approaches for variability-intensive systems. Recent work continues extending Feature Model applications toward adaptive systems, machine-learning configuration, and performance assessment [24], [28].

Despite the maturity of Feature Model research, their application to evaluation frameworks remains largely unexplored. Existing studies primarily address software products, configurable platforms, and engineering systems, leaving a gap regarding the representation and management of methodological variability in intervention evaluation environments.

D. Research Gap

The literature demonstrates substantial progress in reproducible analytics, configurable systems, and Feature Model-based variability management. However, these research streams remain largely isolated. Analytical evaluation frameworks typically provide reproducible execution but limited support for formal variability management, whereas configurable-system approaches focus on software products rather than analytical workflows.

Based on the reviewed literature, no integrated framework was identified that represents intervention evaluation as a configurable analytical system whose preprocessing strategies, analytical methods, robustness procedures, and decision-support mechanisms can be modeled, validated, and instantiated through Feature Models. This gap motivates the configurable evaluation framework proposed in this work.

III. Proposed Configurable Evaluation Framework

This section presents the proposed Feature Model-based configurable framework for reproducible intervention evaluation. The framework conceptualizes analytical evaluation as a configurable system whose components, methodological decisions, and validation mechanisms can be represented explicitly through variability models. Rather than relying on fixed analytical workflows, the proposed approach enables the systematic generation and validation of alternative analytical configurations while preserving methodological consistency and reproducibility.

The framework integrates concepts from configurable systems engineering, variability management, and reproducible analytics [18]–[20]. Analytical decisions are modeled as configurable features connected through dependency constraints, allowing valid evaluation pipelines to be generated automatically from a shared variability representation.

A. System Architecture

The proposed architecture is organized into five interconnected layers, as illustrated in Fig. 2. The first layer is responsible for data acquisition and integration from heterogeneous sources. The second layer performs preprocessing activities such as data cleaning, normalization, transformation, and missing-value handling. The third layer executes analytical procedures including feature construction, statistical analysis, and intervention assessment. The fourth layer performs robustness and validation activities, while the fifth layer generates decision-support outputs for analysts and stakeholders.

This layered architecture separates analytical concerns while allowing different methodological alternatives to be instantiated according to specific evaluation requirements. As a result, evaluation workflows can be adapted without modifying the underlying system structure.

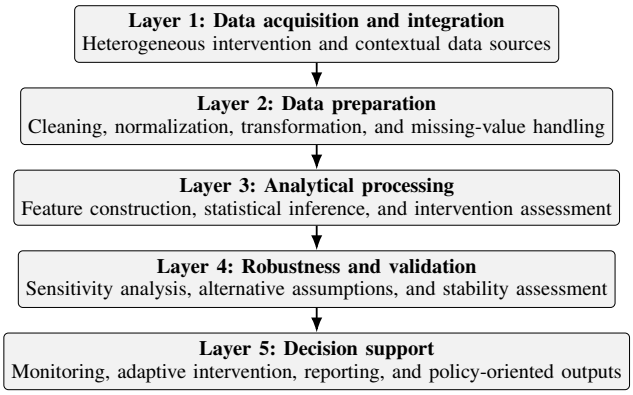

Fig. 2. Layered architecture of the proposed configurable evaluation framework.

B. Configurable Analytical Pipeline

The analytical process is represented as a configurable pipeline composed of sequential but variable stages. Each stage may contain multiple implementation alternatives that can be selected according to evaluation objectives, data characteristics, or methodological preferences.

The pipeline includes five principal activities:

- Data preparation.
- Feature construction.
- Statistical analysis.
- Robustness validation.
- Decision-support generation.

Data preparation includes activities such as cleaning, normalization, and treatment of missing values [14], [16]. Feature construction transforms raw variables into analytical representations suitable for evaluation tasks. Statistical analysis executes the selected analytical procedures, while robustness validation evaluates the stability of obtained results under alternative assumptions. Finally, decision-support generation produces interpretable outputs that facilitate evidence-based decision making.

Representing these activities as configurable elements allows multiple evaluation strategies to be instantiated while preserving analytical traceability and reproducibility.

C. Feature Model Representation

Variability within the evaluation process is represented through a Feature Model. Feature Models provide a compact mechanism for describing mandatory, optional, alternative, and dependency-related features within a configuration space [18], [20].

Fig. 3 illustrates the conceptual Feature Model adopted in this work. The root feature represents the configurable evaluation framework. From this root, variability is organized into four major groups corresponding to preprocessing, analytical methods, validation procedures, and reporting mechanisms.

TABLE I. Feature Relationships used in the Configurable Framework

Relationship	Description
Mandatory	Required in all configurations
Optional	Included when necessary
Alternative	Exactly one feature selected
Or-group	One or more features selected
Requires	Dependency constraint
Excludes	Mutual exclusion constraint

Mandatory features define components that must appear in every valid configuration, whereas optional features allow adaptation to specific evaluation requirements. Alternative groups represent mutually exclusive methodological choices, while cross-tree constraints ensure that incompatible analytical decisions cannot coexist within the same configuration.

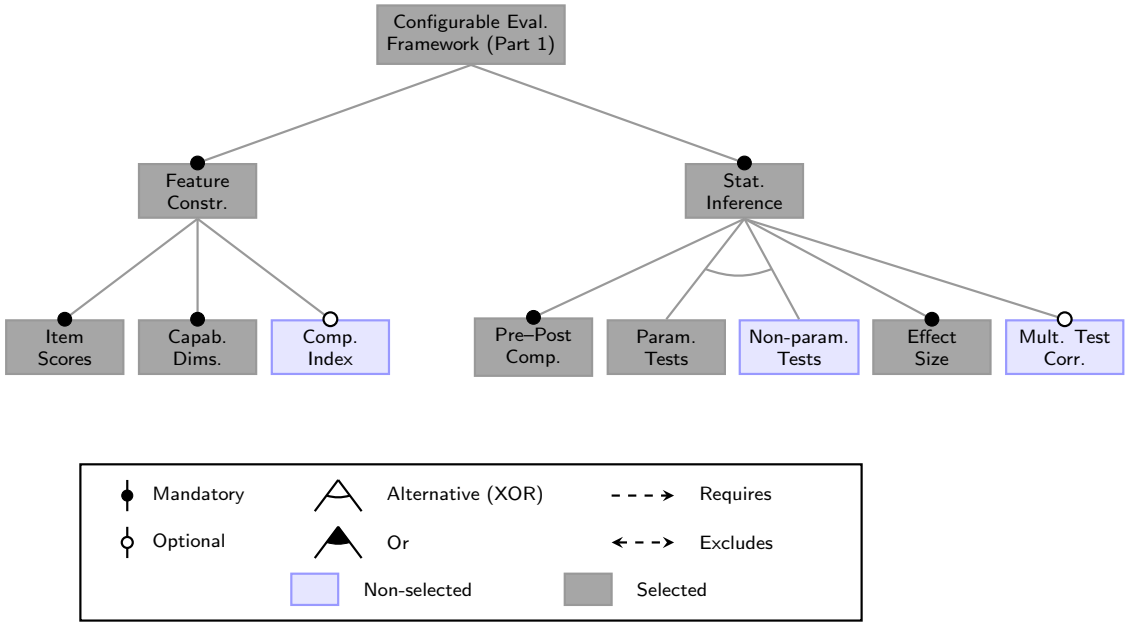
Table I summarizes the principal variability relationships used within the framework.

The resulting variability representation enables systematic exploration of valid analytical configurations while ensuring consistency among methodological decisions.

D. Configuration Reasoning

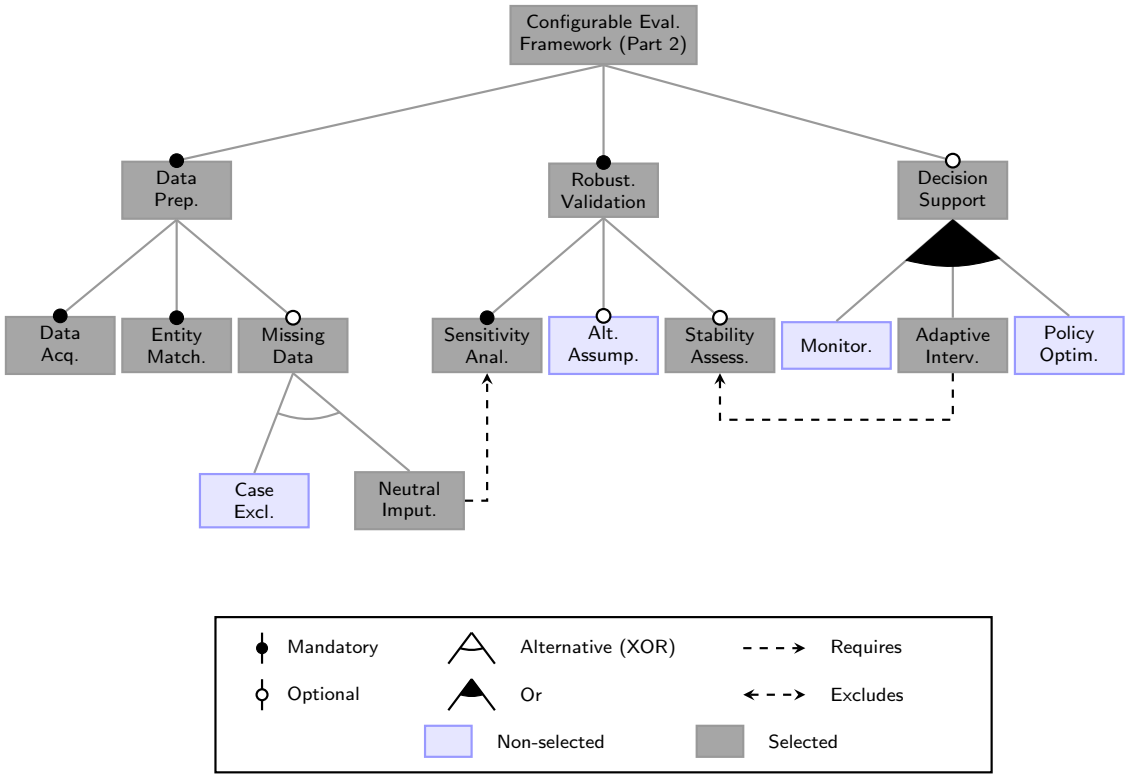
Once variability is represented through the Feature Model, automated reasoning mechanisms can be applied to validate configurations and generate admissible analytical pipelines [18], [20].

Configuration reasoning begins by selecting the desired analytical features. Dependency constraints are subsequently evaluated to verify consistency. Invalid configurations are automatically rejected, while valid configurations are transformed into executable analytical pipelines.



Algorithm 1 summarizes the configuration generation process.

Algorithm 1 Generation of Valid Analytical Configurations



1: Select candidate features
2: Validate mandatory features
3: Evaluate dependency constraints
4: Remove inconsistent selections
5: Generate valid configuration
6: Instantiate analytical pipeline
7: Execute evaluation workflow

The automated generation of valid configurations provides three important advantages. First, it guarantees methodological consistency through constraint validation. Second, it facilitates reproducibility by explicitly documenting analytical decisions. Third, it enables the systematic exploration of alternative evaluation strategies without requiring manual reimplementation of analytical workflows.

The resulting framework therefore combines variability-aware system design with reproducible analytical execution, providing a foundation for configurable intervention evaluation environments.

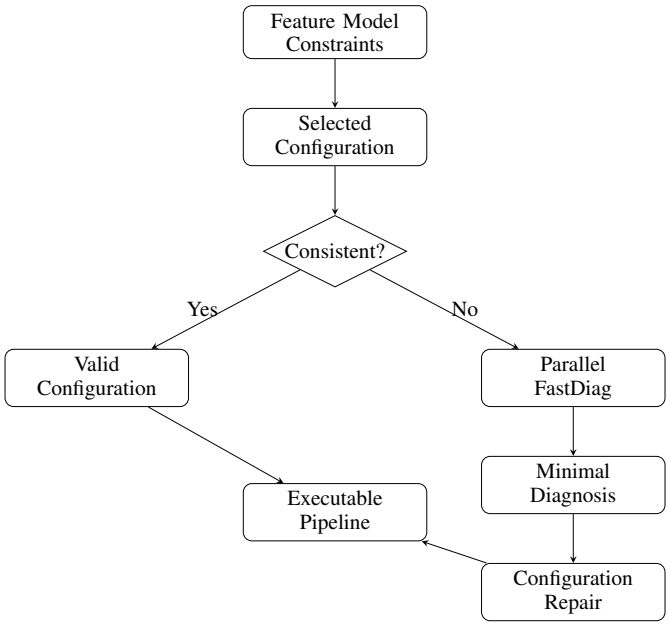

Fig. 5. Automated conflict-diagnosis workflow integrating feature model validation and parallel fastdiag-based configuration repair.

E. Automated Variability Analysis Engine

To operationalize the proposed configurable evaluation framework, an automated variability-analysis engine was developed. The engine combines Feature Model reasoning, constraint validation, configuration generation, and conflict diagnosis services within a unified software architecture. Inspired by the reasoning capabilities commonly available in Feature Model analysis frameworks [18], [20], the proposed solution implements equivalent services in Python and extends them with diagnosis mechanisms based on Parallel FastDiag.

The objective of the engine is to transform variability models into executable analytical pipelines while ensuring that all generated configurations satisfy the dependency constraints defined within the Feature Model. In addition, the engine supports automated diagnosis of inconsistent configurations, providing analysts with explanations and minimal corrective actions whenever constraint violations are detected.

1) Engine architecture: Fig. 4 presents the architecture of the proposed automated variability-analysis engine.

The architecture is organized into four principal components. The first component corresponds to the Feature Model repository, which stores the variability structure representing analytical decisions and their relationships. The second component implements reasoning services responsible for consistency verification, constraint validation, and generation of valid configurations. The third component incorporates a Parallel FastDiag-based diagnosis module capable of identifying minimal sets of conflicting analytical decisions whenever inconsistencies are detected. Finally, the fourth component transforms valid configurations into executable analytical pipelines that can be used during intervention evaluation.

This modular organization separates variability representation from execution logic, facilitating future extensions and incorporation of additional analytical services without modifying the underlying framework.

2) Reasoning services: The reasoning layer provides the core functionality required for automated analysis of analytical Feature Models. Its primary responsibility is to determine whether a selected set of analytical features constitutes a valid configuration according to the structural and dependency constraints defined in the variability model.

The implemented reasoning services include consistency verification, validation of mandatory and optional features, evaluation of alternative and OR-groups, dependency analysis, and generation of admissible configurations. These services are executed before pipeline instantiation to ensure that analytical workflows satisfy all methodological requirements.

Cross-tree constraints are evaluated automatically through logical reasoning procedures. *Requires* relationships guarantee that dependent analytical components are activated together, whereas *excludes* relationships prevent incompatible analytical procedures from appearing in the same configuration.

The resulting reasoning process produces a set of valid configurations that can be transformed into executable analytical workflows while preserving methodological consistency and reproducibility.

3) Parallel fastdiag-based conflict diagnosis: Although consistency verification determines whether a configuration satisfies all Feature Model constraints, it does not explain the causes of an inconsistency. To address this limitation, the proposed framework incorporates a Parallel FastDiag-based diagnosis mechanism capable of identifying minimal sets of conflicting analytical decisions.

Fig. 5 summarizes the diagnosis process executed when a selected analytical configuration violates one or more dependency constraints. The workflow combines automated validation, conflict detection, diagnosis generation, and configuration repair in order to restore consistency before pipeline execution.

As illustrated in Fig. 5, every analytical configuration is first validated against the constraints defined in the Feature Model. Consistent configurations are transformed directly into executable analytical pipelines. When a constraint violation is detected, the configuration is submitted to the Parallel FastDiag module, which computes a minimal diagnosis identifying the smallest set of analytical decisions responsible for the inconsistency.

The resulting diagnosis supports automated configuration repair by indicating which features should be removed, modified, or complemented to restore consistency. This capability improves transparency because invalid configurations are not merely rejected; instead, analysts receive actionable explanations and corrective recommendations that facilitate reproducible analytical evaluation.

4) Implementation availability: The automated variability-analysis engine was implemented in Python to support Feature Model reasoning, configuration validation, and conflict diagnosis. The current implementation extends an existing open-source Parallel FastDiag framework for model-based diagnosis [30] and incorporates additional services for analytical configuration management. The current prototype extends an existing Parallel FastDiag implementation and is publicly available through the following GitHub repository: https://github.com/cvidalmsu/A-Python-FD-implementation

The repository currently provides the diagnosis infrastructure used by the proposed framework and serves as the foundation for the integration of Feature Model reasoning, automated configuration generation, and analytical pipeline management.

To facilitate reproducibility and future extensions, the software prototype is publicly available through a GitHub repository*. The repository currently provides the diagnosis infrastructure used by the framework and serves as the foundation for integrating Feature Model reasoning, automated configuration generation, and analytical pipeline execution capabilities. The repository serves as a living research artifact that supports inspection of the diagnosis engine, replication of experimental procedures, and future extensions of the variability-analysis framework.

The implementation of the automated variability-analysis engine combines variability modeling, reasoning services, and diagnosis mechanisms within a unified Python-based software infrastructure. Table II summarizes the principal implementation characteristics of the current prototype. The architecture was designed to facilitate extensibility, allowing future integration of additional reasoning services, optimization algorithms, and analytical components while maintaining compatibility with the existing diagnosis framework.

As shown in Table II, the proposed prototype combines Feature Models, automated reasoning, configuration generation, and Parallel FastDiag-based diagnosis within a unified Python-based architecture. The reasoning layer supports consistency checking, dependency validation, and automated generation of admissible configurations, whereas the diagnosis engine identifies minimal sets of conflicting analytical decisions whenever constraint violations are detected. Valid configurations are subsequently transformed into executable analytical pipelines, enabling reproducible evaluation workflows. The implementation is publicly available through a GitHub repository, facilitating inspection, replication, and future extension of the framework by the research community.

TABLE II. IMPLEMENTATION CHARACTERISTICS OF THE AUTOMATED VARIABILITY-ANALYSIS ENGINE

Component	Implementation
Programming Language	Python 3
Variability Representation	Feature Models
Configuration Generation	Automated Feature Model-based generation
Constraint Validation	Logical reasoning
Reasoning Services	Consistency checking and dependency analysis
Conflict Diagnosis	Parallel FastDiag
Diagnosis Output	Minimal conflict sets
Pipeline Generation	Reproducible analytical pipelines
Execution Platform	Cross-platform
Repository	GitHub
Repository URL	https://github.com/cvidalmsu/A-Python-FD-implementation

IV. EXPERIMENTAL VALIDATION

The objective of the experimental validation is to assess the applicability of the proposed configurable evaluation framework in a real intervention scenario and to determine whether the generated analytical configurations preserve methodological consistency, reproducibility, and robustness. Following common validation strategies adopted in configurable analytical systems and reproducible computational workflows [6], [7], [12], the framework was instantiated using a real intervention dataset and evaluated under multiple valid analytical configurations.

The validation focuses on three complementary aspects:

- Generation of valid analytical configurations from the Feature Model.
- Execution of reproducible analytical pipelines under different methodological assumptions.
- Stability of intervention conclusions across alternative configurations.

A. Intervention Dataset

The empirical validation was conducted using a dataset obtained from a managerial capability development intervention involving micro-enterprises. The intervention followed a pre–post evaluation design in which participants were assessed before and after the training process.

The dataset contains variables associated with managerial capability development and organizational performance indicators. The evaluation framework processes these variables through configurable analytical pipelines that include data preparation, feature construction, statistical analysis, robustness validation, and reporting activities.

The selected dataset is particularly suitable for validation because it contains heterogeneous variables, multiple capability dimensions, and several analytical alternatives that can be represented through Feature Models. Similar intervention-oriented evaluation approaches have been widely adopted in education, healthcare, and organizational development research [1], [2].

Table III summarizes the principal characteristics of the dataset.

TABLE III. CHARACTERISTICS OF THE INTERVENTION DATASET

Characteristic	Description
Evaluation design	Pre–post intervention
Data type	Numerical and ordinal
Capability dimensions	Multiple managerial capabilities
Analytical variables	Performance indicators
Pipeline stages	Five configurable stages
Validation approach	Multiple configurations

B. Configuration Space Analysis

Analytical variability is represented through the Feature Model introduced in Section III. The model captures alternative preprocessing strategies, analytical procedures, robustness mechanisms, and reporting options.

During validation, configuration reasoning automatically evaluates dependency constraints and excludes inconsistent selections before pipeline execution. This guarantees that only valid analytical configurations are instantiated.

Examples of configurable decisions include:

- Data preprocessing alternatives.
- Missing-value treatment strategies.
- Statistical analysis procedures.
- Robustness assessment mechanisms.
- Reporting and visualization options.

Fig. 6 illustrates the reasoning process responsible for validating dependencies and generating admissible analytical configurations.

The explicit representation of variability enables systematic exploration of alternative analytical strategies while preserving consistency constraints defined within the Feature Model [18], [20].

C. Experimental Results

Multiple valid analytical configurations were generated automatically through the variability-analysis engine described in Section III-E. Each configuration satisfied all Feature Model constraints and was transformed into an executable analytical pipeline through the automated reasoning process.

The generated configurations differed in terms of data preprocessing procedures, statistical inference methods, and robustness validation mechanisms. Despite these methodological variations, all admissible configurations produced consistent intervention conclusions, indicating that the proposed framework preserves analytical reproducibility while supporting controlled variability. This result is particularly relevant because it demonstrates that alternative methodological choices can be explored without compromising the validity or interpretability of the evaluation outcomes.

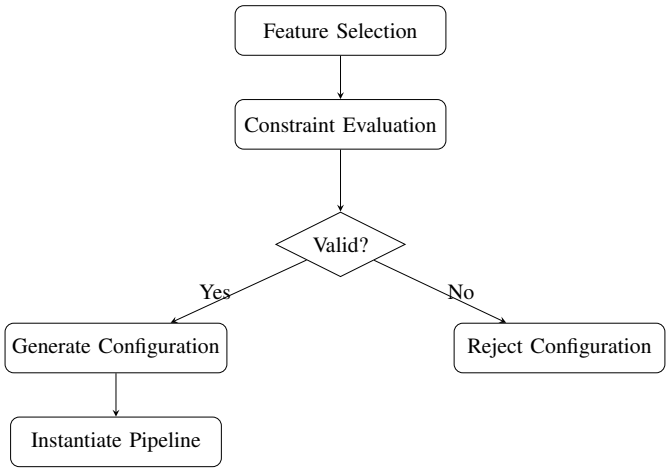

Fig. 6. Configuration reasoning process used to validate constraints and generate admissible analytical configurations.

TABLE IV. STATISTICAL INFERENCE RESULTS AND EFFECT SIZES ACROSS MANAGERIAL CAPABILITY DIMENSIONS

Dimension	$\Delta\mu$	p**-value**	**Cohen's** d
Strategic	0.17	< 0.01	0.65
Financial	0.14	< 0.01	0.52
Operational	0.12	< 0.05	0.48

Table IV summarizes the intervention outcomes obtained from the analytical pipelines generated automatically by the proposed framework. Improvements were observed across all evaluated capability dimensions, with statistically significant differences and moderate effect sizes. The consistency of these results across multiple valid configurations suggests that the framework can support reproducible and interpretable intervention assessments while enabling controlled methodological variability.

In addition to generating valid analytical workflows, the proposed framework incorporates automated diagnosis services through the Parallel FastDiag-based analysis module. Whenever an invalid analytical configuration is detected, the diagnosis engine identifies minimal sets of conflicting methodological decisions responsible for the observed inconsistency.

Table V presents representative diagnosis examples produced by the Parallel FastDiag module. For each invalid analytical configuration, the engine identifies a minimal corrective action capable of restoring consistency. These examples illustrate how the framework supports explainable conflict resolution in addition to conventional configuration validation.

These diagnosis examples were generated automatically

TABLE V. EXAMPLES OF ANALYTICAL CONFIGURATION DIAGNOSES

Invalid Configuration	Minimal Diagnosis
Parametric Tests + Non-parametric Tests	Remove one test
Neutral Imputation without Sensitivity Analysis	Add Sensitivity Analysis
Adaptive Intervention without Stability Assessment	Add Stability Assessment
Multiple Test Correction without Statistical Inference	Add Statistical Inference

by the Parallel FastDiag module integrated into the Python-based variability-analysis engine. For each invalid configuration, the diagnosis process identified a minimal set of conflicting analytical decisions whose correction was sufficient to restore consistency. This capability demonstrates that the framework supports not only configuration validation but also explainable conflict resolution.

The consistency of intervention outcomes across multiple analytical configurations, together with the successful identification of minimal diagnoses for invalid configurations, indicates that the proposed framework effectively combines reproducible analytics, automated reasoning, and conflict diagnosis within a unified evaluation environment. Furthermore, all analytical configurations contributing to the reported results were validated before execution, ensuring methodological consistency throughout the evaluation process.

D. Robustness Assessment

A robustness analysis was performed to determine whether analytical conclusions remained stable under alternative methodological assumptions. Different valid configurations were executed using distinct combinations of preprocessing procedures, analytical strategies, and validation mechanisms.

The resulting outputs exhibited a high degree of agreement across all evaluated configurations. No configuration generated contradictory conclusions regarding intervention effectiveness. This stability indicates that the framework is capable of preserving reproducibility while allowing analytical variability.

To make the qualitative labels reproducible, stability was assessed relative to the baseline pipeline. For configuration c and capability dimension j, let $d_{c,j}$ denote the corresponding effect size and define the maximum absolute effect-size deviation as:

$$D_c = \max_j |d_{c,j} - d_{0,j}|, \tag{1}$$

where, $d_{0,j}$ is the baseline effect size. Stability is classified as *High* when all effect directions and significance decisions are preserved and $D_c \leq 0.10$; as *Moderate* when all effect directions are preserved and $0.10 < D_c \leq 0.20$; and as *Low* when an effect direction reverses, a substantive inferential conclusion changes, or $D_c > 0.20$. These study-specific operational thresholds distinguish negligible, limited, and potentially consequential changes in standardized effect magnitude and should be reported together with the configuration-specific D_c values in the final experimental record. Table VI reports the classification obtained for each analytical configuration.

Furthermore, the explicit representation of methodological decisions provides full traceability of analytical choices, facilitating audit, replication, and comparison of evaluation processes. Such characteristics are particularly relevant in decision-support environments where transparency and reproducibility are essential requirements [12], [13].

Overall, the experimental validation demonstrates that the proposed framework successfully integrates variability management and reproducible analytics within a unified evaluation architecture. The obtained results confirm that Feature Model-based configuration can be used to generate valid analytical pipelines while maintaining consistent conclusions across heterogeneous methodological configurations.

V. DISCUSSION

The principal implication of the case study is not merely that several pipelines reproduced a similar intervention conclusion, but that the analytical design space itself became explicit and machine-checkable. Conventional reproducibility practices typically preserve code, data, and execution environments while leaving the rationale and admissibility of methodological alternatives implicit. By representing those alternatives as features and constraints, the proposed framework extends reproducibility from re-executing one fixed pipeline to inspecting and validating a family of methodologically coherent pipelines. This distinction is important in intervention evaluation because apparently minor choices concerning missing data, statistical tests, or robustness procedures can otherwise remain hidden inside scripts or analyst-specific routines.

The integration of conflict diagnosis adds a second interpretive contribution. A conventional validator can reject an inconsistent analytical configuration, but rejection alone provides limited support for correction or audit. Parallel FastDiag identifies minimal sets of selected decisions that must be reconsidered to restore consistency. In practical terms, this converts configuration failure into an explainable methodological event: analysts can determine whether a problem originates from mutually exclusive tests, an unmet sensitivity-analysis requirement, or a missing prerequisite for an adaptive intervention. Such explanations may improve governance and reviewability in settings where analytical decisions must be justified to researchers, managers, or external auditors.

The results also reveal an important boundary condition. Stability across the configurations evaluated in one dataset does not imply that every admissible configuration is statistically equivalent, nor does it establish that the same Feature Model will transfer unchanged to another domain. Feature selection and cross-tree constraints encode methodological knowledge; therefore, model quality depends on the completeness and correctness of that knowledge. As the configuration space grows, additional challenges may emerge concerning constraint maintenance, computational cost, and the risk of representing procedurally valid but substantively inappropriate combinations. Domain expert review remains necessary even when logical consistency is automated.

TABLE VI. ROBUSTNESS ANALYSIS ACROSS ANALYTICAL CONFIGURATIONS. STABILITY LABELS FOLLOW THE QUANTITATIVE THRESHOLDS DEFINED IN EQ. 1

Configuration	Significance preserved	Stability	Interpretation
Baseline Pipeline	Yes	High	Reference configuration ($D_c = 0$).
Case Exclusion	Yes	Moderate	Effect directions were preserved, but the reduced analytical sample produced a larger deviation from the baseline effect magnitudes.
Neutral Imputation	Yes	High	The conservative preprocessing alternative preserved effect directions, inferential decisions, and effect-size proximity to the baseline.
Non-parametric Testing	Yes	High	The distribution-free alternative preserved the substantive interpretation and remained within the high-stability effect-size threshold.

From an implementation perspective, separating variability representation from pipeline execution supports controlled extension. New preprocessing methods, inference procedures, or reporting mechanisms can be introduced by extending the Feature Model and the corresponding execution components rather than by rewriting a monolithic workflow. The public Python repository strengthens this contribution by exposing the diagnosis infrastructure for inspection and reuse. Nevertheless, the current repository should be interpreted as an evolving research artefact and integration foundation rather than as a mature, domain-independent evaluation platform.

The empirical scope must also be interpreted conservatively. Validation was conducted with a single managerial capability intervention involving micro-enterprises. Consequently, the evidence supports technical feasibility, configuration-level reproducibility, and within-case robustness, but not cross-domain generalizability. Transferability to healthcare, education, public administration, or industrial analytics requires new Feature Models, domain-specific constraints, and independent empirical replications. A stronger validation program should compare multiple datasets and domains, report the size and structure of each configuration space, measure reasoning and diagnosis time, and evaluate whether independent analysts can reproduce both the selected configurations and the resulting conclusions.

Overall, the framework provides a promising basis for treating methodological variability as a first-class analytical concern. Its main value lies in making analytical alternatives explicit, validating their dependencies before execution, and providing actionable diagnoses when configurations are inconsistent. These capabilities complement, rather than replace, established statistical validation and domain expertise.

VI. CONCLUSION

This study presented a Feature Model-based configurable framework for reproducible intervention evaluation. The proposed approach conceptualizes analytical evaluation as a configurable system in which preprocessing strategies, analytical procedures, robustness mechanisms, and reporting alternatives are represented explicitly through variability models. By integrating principles from configurable systems engineering and reproducible analytics, the framework enables the systematic generation and validation of alternative analytical configurations while preserving methodological consistency.

The single-case validation demonstrated that the framework is capable of generating valid analytical pipelines through automated configuration reasoning and constraint verification. Across the three managerial capability dimensions, Cohen's d values ranged from 0.48 to 0.65, and the substantive conclusions remained stable across the analytical configurations considered. Within this case, analytical variability was therefore managed without compromising the direction or interpretation of the reported intervention effects. These findings suggest that Feature Models provide an effective mechanism for formalizing methodological decisions, improving traceability, and supporting transparent evaluation processes.

From a broader perspective, the study contributes to bridging two traditionally independent research areas: variability management and analytical evaluation. While configurable systems research has largely focused on software products and adaptive applications, intervention evaluation has generally relied on static analytical workflows. The proposed framework demonstrates how variability-aware approaches can be extended to analytical environments, enabling flexible yet controlled evaluation processes capable of adapting to different methodological requirements.

The framework also offers practical benefits for organizations and researchers seeking reproducible and auditable analytical workflows. The explicit representation of analytical decisions facilitates replication, comparison of alternative strategies, and systematic exploration of methodological assumptions. Furthermore, the modular architecture supports future extensions involving new preprocessing procedures, analytical methods, validation mechanisms, and reporting components.

Several limitations should be acknowledged. The empirical validation was conducted using a single intervention scenario focused on managerial capability development, and additional studies are required to evaluate generalizability across domains such as healthcare, education, public administration, and industrial analytics. Furthermore, the current implementation concentrates on statistical evaluation workflows and does not yet

incorporate advanced artificial intelligence or machine-learning services as configurable analytical components.

Future research will focus on extending the proposed framework through the integration of predictive analytics, machine-learning pipelines, automated model selection, and large-language-model-based decision-support services. Additional developments will target the Python-based variability-analysis engine, incorporating advanced Feature Model reasoning services, optimization algorithms for configuration generation, and large-scale benchmarking capabilities. Future empirical studies involving larger datasets and more complex analytical environments will enable a deeper assessment of scalability, robustness, and practical applicability. The public repository will evolve into a comprehensive experimental platform supporting reproducible research, automated diagnosis, and variability-aware analytical systems.

***Abstract*—Large Language Models (LLMs) offer strong capabilities for Natural Language Processing, yet their inherent uncertainty often produces hallucinations, confident but incorrect statements, which is critical in domains requiring precise knowledge representation. Retrieval-Augmented Generation (RAG) reduces this risk through information retrieval, but standard pipelines still suffer from fragmented context and weak alignment between queries and legal provisions, limiting trustworthy knowledge extraction. This study proposes a Metadata-Aware RAG architecture to improve grounding in large legal corpora. It integrates: 1) Sub-chunking with Legal Metadata Inheritance, which transforms unstructured legal PDFs into granular, metadata-rich fragments; and 2) an Adaptive Filter Creator, a pipeline that extracts structured constraints and compiles optimized hybrid retrieval queries. These components enhance semantic alignment, reduce uncertainty-driven hallucinations, and strengthen neural information retrieval. Using a curated Peruvian labor law corpus and 150 manually validated question–answer pairs, the system was evaluated across three LLMs (Llama-3.1-8B, GPT-OSS-20B, Gemma-3-27B). The proposed architecture achieves double-digit improvements over a Naive RAG baseline across all four RAGAS metrics—Context Precision, Context Recall, Factual Correctness, and Faithfulness—with gains ranging from 13.10% to 28.15%; notably, Faithfulness surpasses 0.90 for Gemma-3-27B. Statistical analysis confirms significance ($t(11) = 15.49$, $p = 4.06 \times 10^{-9}$) with an extremely large effect size (Cohen's $d = 4.47$). Regression results show minimal influence of model size (slope < 0.005), indicating that retrieval design has a stronger influence than parameter count in the evaluated setting.**

***Keywords*—RAG; Retrieval-Augmented Generation; LLMs; legal question answering**

I. Introduction

Workers' limited knowledge of their own rights remains a persistent barrier to fair and dignified employment. Informational asymmetries between employers and employees can translate into inconsistent treatment and tangible harm to workers [1]. In many contexts, employees are unaware of basic protections (e.g., those in the Employment Act 1955), which in turn fuels dissatisfaction and workplace disputes [2]. Evidence further indicates that workers with stronger knowledge of employment law are more inclined to advocate for change: seeking higher wages, better regulation, and improved conditions, and that union members, who often have superior access to information, are especially likely to act on this knowledge [3], [4]. Better-informed employees also tend to display deeper organizational commitment, suggesting that knowledge dissemination is not only a matter of rights but also of organizational health [5]. Yet the landscape is dynamic and complex: frequent legal updates, incomplete information, and perceived withholding of information pose substantial obstacles to workers becoming fully informed [4]. These factors call for stronger strategies by employers and policymakers to democratize access to labor-rights information, including comprehensive resources that integrate legal and economic perspectives to help workers navigate compliance complexities across jurisdictions [6].

Conversational agents (chatbots) offer a promising channel for narrowing these gaps at scale. Their always-on availability provides continuous support, enabling workers to explore policies, procedures, and rights without waiting for human agents [7], [8], [9], [10]. At the same time, responsible deployments must retain a human-in-the-loop for configuration, training, and escalation of complex or out-of-scope queries [7], [11]. Personalization can further increase impact by tailoring explanations to an individual's role, context, or language preferences, while automation of repetitive informational tasks ensures consistent, timely guidance [12]. Effectiveness also hinges on usable interaction: clear language, intuitive navigation, and supportive interface cues reduce cognitive load and help users find what they need [13]. Interactive feedback loops improve clarity and answer quality over time, and trust must be cultivated through consistency and transparency so that workers consider the chatbot's outputs reliable [14], [15].

A core obstacle to trust, however, is the phenomenon of *hallucinations* in large language model (LLM) systems: confidently stated but incorrect, illogical, or fabricated assertions [16], [17], [18], [19]. Hallucinations often arise from insufficient or biased training data and from the predictive nature of generative models, which optimize for fluency rather than grounded factuality [19], [17]. The legal domain's complexity and variability exacerbate these risks: nuanced statutory language, exceptions, temporal validity, and jurisdictional de-

*Corresponding author.

pendencies challenge purely generative approaches [20]. The consequences are non-trivial. Misinformation on labor rights can produce adverse legal and social effects, undermining user safety and institutional legitimacy [16], [17], [21]. Robust verification and validation workflows, augmented with contextual indicators and embedded markers, help constrain generation and surface provenance, thereby reducing the likelihood and impact of hallucinations [16], [18], [21].

Retrieval-Augmented Generation (RAG) has emerged as a practical mitigation strategy by grounding model outputs in authoritative, up-to-date sources at inference time [22], [23], [24]. In the legal domain, RAG improves accuracy and relevance by integrating external knowledge directly into the generation loop, a critical property when answering complex questions that demand precise citations and scope conditions [25], [26], [27], [28]. Compared with static fine-tuning, RAG-enabled assistants can draw from evolving corpora (statutes, regulations, jurisprudence, administrative guidance), thereby improving currency and reducing drift [27], [28], [29]. Evaluating such systems also requires adapted frameworks and metrics sensitive to retrieval-grounded reasoning [30]. When properly engineered, RAG-based legal chatbots can deliver expert-like answers while curbing hallucinations by privileging reliable documents during response synthesis [28], [31], [32].

Beyond model and prompt design, the quality of a RAG system hinges on how the corpus is partitioned ("chunking") and queried. Chunks that are too coarse dilute topical focus; chunks that are too fine lose essential legal context and citation anchors. Retrieval quality further depends on whether index structures preserve jurisdictional and versioned metadata and whether query-time filters can faithfully express the question's scope. Consequently, improvements in both storage (how documents are chunked and represented in the vector database) and search (how queries are mapped to structured constraints) have first-order effects on context Recall, context Precision, answer Faithfulness, and factual Correctness.

These limitations reveal a gap in current legal RAG approaches: existing pipelines do not systematically exploit the hierarchical structure and legal metadata of source documents to jointly guide document representation and query-time retrieval. To address this gap, this study makes three main scientific and technical contributions. First, it introduces a metadata-aware legal document representation based on hierarchical sub-chunking with legal metadata inheritance, preserving clause-level context and provenance during document segmentation and vector indexing. Second, it proposes an Adaptive Filter Creator that extracts structured constraints from user queries and combines them with hybrid similarity-based retrieval, progressive filter relaxation, and cross-encoder reranking. Third, it provides an empirical evaluation of the proposed retrieval architecture against a Naive RAG baseline across three contemporary open-weight LLMs of different scales, using Context Precision, Context Recall, Factual Correctness, and Faithfulness, complemented by statistical analysis of the observed improvements. Together, these contributions provide a retrieval architecture designed to improve the factual grounding, contextual relevance, and reliability of legal question-answering systems.

The remainder of this study is organized as follows. Section II presents the related work and research background. Section III describes the proposed Metadata-Aware RAG architecture and its main components. Section IV presents the experimental methodology, dataset, evaluation metrics, and implementation details. Section V reports and analyzes the experimental results, followed by a discussion of their implications and limitations. Finally, Section VI presents the conclusions and directions for future work.

II. Background

A. Large Language Models

Large Language Models (LLMs) are neural sequence models trained to predict the next token in text. Given a tokenized sequence $x_{1:T}$ over a vocabulary $\mathcal{V}$, an LLM learns a conditional distribution:

$$p_\theta(x_t \mid x_{<t}) = \mathrm{softmax}\big(W\, h_t + b\big) \tag{1}$$

where, h_t is the hidden state at position t and W, b project to $|\mathcal{V}|$ logits. Training maximizes the likelihood of observed text (equivalently minimizes cross-entropy):

$$\mathcal{L}_{\mathrm{LM}}(\theta) = -\sum_{(x_{1:T}\sim\mathcal{D})}\sum_{t=1}^{T}\log p_\theta(x_t \mid x_{<t}) \tag{2}$$

$$\mathcal{L}_{\mathrm{LM}}(\theta) = H(p_{\text{data}}) + \mathrm{KL}\big(p_{\text{data}} \parallel p_\theta\big) \tag{3}$$

so the model approximates the data distribution p_{data} by minimizing $\mathrm{KL}(p_{\text{data}}\|p_\theta)$ in expectation over the training corpus $\mathcal{D}$.

B. Hallucinations

Despite strong fluency, LLMs can generate confident but incorrect content. In our legal/labor rights context, the principal drivers are:

1) Objective mismatch: The learning target is *likelihood under* p_{data}, not *truth*. Because the expectation in $\mathcal{L}_{\mathrm{LM}}$ is over real data, assigning probability mass to plausible-but-false strings outside p_{data} is not directly penalized. This favors fluent, distributional plausibility over verified factuality.

2) Noisy / incomplete corpora: Pretraining data may contain errors, outdated laws, or conflicting jurisdictions; the model internalizes such patterns.

3) Distribution shift: Legal facts are temporal (effective dates, amendments). Queries about post-cutoff changes require knowledge the model never saw; it may extrapolate incorrectly.

C. Embeddings

An embedding is a vector representation of a discrete object (token, sentence, document) that places semantically related items close together in a continuous space. Formally, an encoder/embedding model f_ϕ maps text x to a point in $\mathbb{R}^d$:

$$\mathbf{z} = f_\phi(x) \in \mathbb{R}^d. \tag{4}$$

Such that semantic similarity in language corresponds to geometric proximity in the vector space. Concretely, an embedding model implements a function $f_\phi : \mathcal{X} \to \mathbb{R}^d$ that produces a fixed-length representation $\mathbf{z} = f_\phi(x)$ for input x, typically normalized to $\|\mathbf{z}\|_2 = 1$ to enable cosine or inner-product similarity. Unlike autoregressive LLMs that *generate* sequences, embedding models *encode* inputs into vectors that can be indexed and searched efficiently.

D. Retrieval-Augmented Generation (RAG)

A fundamental limitation of large language models is their bounded context window: they can only process a finite number of tokens in a single pass. This constraint precludes the possibility of simply feeding all relevant documents into the prompt, especially when working with large or multi-document corpora. To address this, a Retrieval-Augmented Generation (RAG) pipeline augments an autoregressive language model with a simple dense-retrieval step. Documents are preprocessed into fixed-size *chunks* and embedded; at inference, the query is embedded, the top-k nearest chunks are fetched, concatenated with the query, and passed to the LLM to generate an answer.

Let $\mathcal{C} = \{d_i\}$ be chunked documents with embeddings $\mathbf{z}_i = f_\phi(d_i)$. For a query x with embedding $\mathbf{q} = f_\phi(x)$, retrieval is:

$$C_k(x) = \underset{d \in \mathcal{C}}{\arg\,\text{top-k}}\ s(x, d) \tag{5}$$

$$s(x, d) = \mathbf{q}^\top \mathbf{z}_d = \frac{\langle f_\phi(x), f_\phi(d) \rangle}{\|f_\phi(x)\|\,\|f_\phi(d)\|} \tag{6}$$

The generator conditions on the query and retrieved context C_k:

$$p_\theta(y \mid x, C_k) = \prod_t p_\theta\big(y_t \mid x, C_k, y_{<t}\big) \tag{7}$$

and the answer $\hat{y}$ is obtained by decoding (e.g., greedy or top-p sampling).

1) Typical design in practice: A naive RAG baseline typically chunks documents into fixed-length windows (e.g., N tokens) with small overlaps and minimal cleaning; indexes each chunk in a vector database by storing its embedding–identifier pair $(\mathbf{z}_d, \text{doc-id})$ and enabling approximate nearest-neighbor (ANN) search; performs retrieval via pure dense similarity; assembles the prompt by *stuffing*, i.e., concatenating the top-k chunks into a single context block; and decodes with standard LLM settings (e.g., fixed temperature) without explicit verification or abstention logic. The main pipeline is illustrated in Fig. 1.

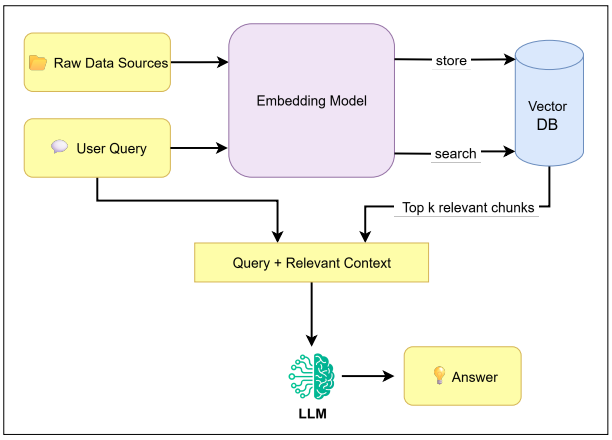

Fig. 1. Naive RAG.

However, this naive configuration introduces several well-known limitations. First, the use of fixed-size chunking with minimal preprocessing often leads to fragmented context, redundancy, or inclusion of irrelevant text, which degrades retrieval accuracy [33]. Second, relying solely on dense similarity for approximate nearest-neighbor (ANN) search increases the risk of retrieving semantically similar but contextually inappropriate passages [33]. Third, the practice of prompt "stuffing" by concatenating top-k chunks into a single context block frequently results in noisy or incoherent inputs to the LLM, especially when the retrieved passages overlap or conflict [33]. Moreover, decoding with fixed hyperparameters and without any verification or abstention mechanisms makes the system highly vulnerable to hallucinations and ungrounded responses [34]. Collectively, these limitations constrain the effectiveness and robustness of naive RAG pipelines, particularly in domain-specific or compliance-sensitive enterprise scenarios [34].

III. Proposed Metadata-Aware RAG Architecture

The proposed approach consists of a Retrieval-Augmented Generation architecture designed to address the limitations previously identified in conventional RAG pipelines, often referred to as naive RAG configurations. Fig. 3 shows the pipeline of our proposal. The approach is structured around two core components.

A. Sub-Chunking with Legal Metadata Inheritance

Our processing approach employs a multi-step method that transforms unstructured documents into enriched fragments, ready for indexing. The process is illustrated in Fig. 2, and comprises the following steps:

1) Document transformation: The process begins with unstructured documents. In an initial stage, these files are converted to an intermediate format, like Markdown (.md). Subsequently, a preprocessing phase is conducted to clean the text by removing headers, footers, and other irrelevant elements. This step is performed either algorithmically or manually, as required.

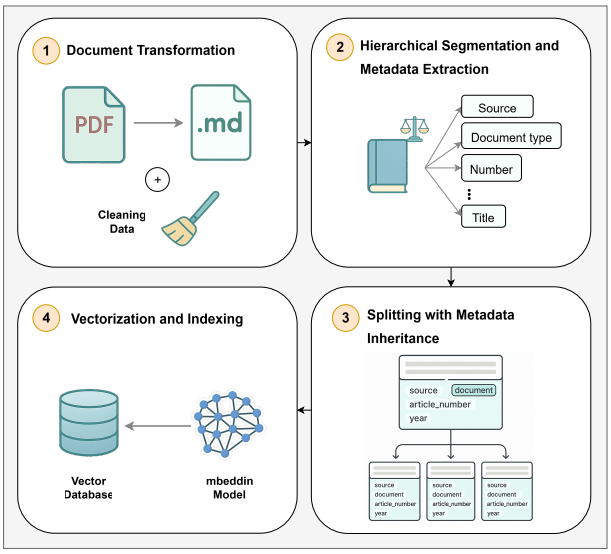

Fig. 2. Sub-chunking with legal metadata inheritance.

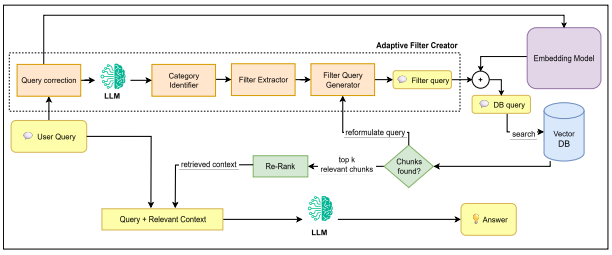

Fig. 3. Metadata-aware RAG (our proposal).

2) Hierarchical segmentation and metadata extraction: Next, a hierarchical splitting technique is applied to segment each document into coherent legal units. A key advantage of legal texts is that they are inherently structured and generally follow predictable patterns, which can be systematically exploited for segmentation. For example, a Compendium of Labor Regulations may include a heterogeneous set of instruments, such as supreme decrees, legislative decrees, ministerial resolutions, and laws, each identified by various attributes. This built-in regularity allows the segmentation process to align with the natural hierarchy of the documents rather than relying on arbitrary token-based splits.

This process not only divides the content but also extracts the metadata inherent to each section (e.g., the article number or the title of the law). The output is a semi-structured `JSON` document where the content and its metadata are formally linked.

3) Splitting with metadata inheritance: After the hierarchical segmentation and extraction of metadata, the resulting `JSON` documents are still relatively large. To facilitate effective semantic retrieval and to ensure that no relevant information is overlooked by the language model, these documents are further divided into smaller fragments.

Each fragment retains a full copy of the metadata from its parent document, ensuring that the structural context is preserved. This process allows the system to maintain precise references to the source of each fragment, which is critical for both accuracy and traceability in downstream tasks.

4) Vectorization and indexing: Finally, these enriched sub-fragments are processed through an embedding method to convert them into numerical vectors. These vectors are then indexed in a vector database, allowing fast and accurate semantic retrieval during queries.

B. Adaptive Filter Creator

This process involves a structured workflow of sequential stages designed to process the user query, optimally retrieve and organize information from the vector database, and extract the most relevant fragments. These fragments are then integrated into an enriched context, which forms the basis for generating the final response. Each step is illustrated in Fig. 4

Processing commences with the evaluation of the user's query.

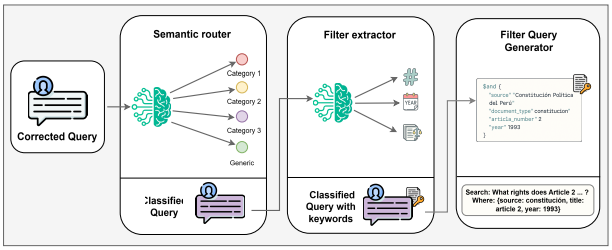

Fig. 4. Adaptive filter creator.

1) Query correction: The user's query is first corrected grammatically and cleaned. This step is important because it reduces ambiguities and ensures that subsequent retrieval and generation stages operate on a clear and well-structured input.

2) Semantic router: An LLM classifies the query intent into a set of predefined document categories, thereby narrowing the search to the most relevant data subset. If the LLM fails to assign a category with sufficient confidence, the system defaults to a comprehensive search across all documents to ensure information retrieval.

3) Filter extractor: The LLM analyzes the query to identify entities that correspond to explicitly mentioned metadata values (e.g., article number, year, document, etc.), which are then used to build the query for the database.

4) Filter query generator: This stage receives the outputs from the preceding modules to assemble the final optimized query. It follows a two-step strategy: first, metadata filtering is applied using the extracted entities (e.g., year, document source) to restrict the search space to a subset of documents that explicitly match those attributes; second, within this filtered subset, a semantic search is conducted with the user's embedded query vector to retrieve chunks that best align with the user's intent.

This component also includes a fallback mechanism: if a query is too restrictive and yields no results, filters are progressively removed to ensure that chunks are always retrieved.

The final output of this stage is an initial set of top-k relevant chunks from the vector database.

While the initial chunks are relevant, they are passed through a refinement stage to maximize precision. The top-k chunks are sent to a cross-encoder model, which performs a more thorough and computationally intensive analysis than the initial vector search. It directly compares the user's query against each chunk to calculate a highly precise relevance score. This process reorders the list, ensuring that the chunks with the highest semantic relevance are moved to the top.

Finally, the highest-scoring, re-ranked sub-chunks are concatenated to form a single, highly focused, and enriched context. This refined context is then supplied to the final generative LLM, along with the original user query, to synthesize the information and articulate a coherent final answer.

IV. Materials and Methods

A. Experimental Setup

The experiments were designed and executed on a local workstation equipped with an Intel(R) Core(TM) Ultra 9 285K Tetracosa-core (24 core) processor, 128 GB of RAM, and an NVIDIA GeForce RTX 5090 graphics processing unit (GPU) with 32 GB of VRAM for computational acceleration.

The software framework was implemented within a Python 3.10 environment. The LangChain library was employed for the orchestration of the RAG pipelines. Text embeddings were generated using the HuggingFace library, with the resulting vectors stored and managed in ChromaDB. The Ollama platform was utilized for local serving of language models, and quantitative evaluation was conducted using the Ragas framework.

B. Dataset

The corpus for this study was built to provide a representative knowledge base of the Peruvian legal framework, with a particular emphasis on labor law. The primary sources were the Political Constitution of Peru and three major legal compilations: the General Labor Compendium, the Private Labor Regime, and the Special Labor Regime. These compilations consist of a vast collection of legal instruments, including laws, supreme decrees, ministerial resolutions, and legislative decrees. Although they do not cover the entire body of Peruvian labor legislation, they represent a highly significant portion of it, with an aggregated volume exceeding 3,000 pages of legal text.

The corpus was processed using the proposed sub-chunking approach, resulting in more than 6,000 sub-chunks.

The metadata associated with each sub-chunk and indexed in the vector database included: *source* (e.g., "General Labor Compendium"), *document_type* (e.g., "decree"), *title* (e.g., "Legislative Decree No. 728"), *topic* (e.g., "labor_law"), *year* (e.g., 1991), and the original source link.

C. Models

For embedding, the *BAAI/bge-m3* model was employed, chosen for its strong multilingual coverage and proven effectiveness in semantic similarity tasks. In the reranking stage, the *jina-reranker-v2-base-multilingual* model was applied to reorder retrieved passages, thereby enhancing contextual precision and mitigating irrelevant matches. Finally, for the generation stage, three Large Language Models (LLMs) of varying scales and characteristics were empirically compared: *llama-3.1* (8b), *gemma-3* (27b), and *gpt-oss* (20b).

This comparative evaluation enabled us to assess trade-offs between open-source and proprietary models, as well as between efficiency and generation quality. Table I presents the main specifications of the evaluated LLMs.

TABLE I. Main Specifications of the Evaluated LLMs

Specifications	Llama-3.1-8B	Gemma-3-27B	GPT-OSS-20B
Parameters	8B	27B	21B
Size	4.9 GB	17 GB	13 GB
Max Context	128K tokens	128K tokens	128K tokens

D. Metrics

The evaluation of Retrieval-Augmented Generation (RAG) systems requires metrics that go beyond conventional text similarity or lexical overlap measures. Traditional metrics such as BLEU or ROUGE primarily assess surface-level similarity between generated and reference texts, which fails to capture the degree of factual grounding or the contextual relevance of retrieved evidence. To address these limitations, the Retrieval-Augmented Generation Assessment Suite (RAGAS) [35] was employed in this study as a specialized framework for evaluating the quality, factual consistency, and contextual reliability of RAG-based systems.

RAGAS introduces a unified set of metrics designed to measure how faithfully and effectively a model integrates retrieved knowledge into its responses. Specifically, four key metrics were used in this research, Faithfulness, Factual Correctness, Context Recall, and Context Precision, to compare the performance of the Naive RAG and the proposed Metadata-Aware RAG. Together, these metrics quantify both the trustworthiness of generated answers and the relevance of the retrieved evidence, offering a comprehensive evaluation of retrieval and generation quality.

1) Faithfulness: Faithfulness measures the degree to which the generated answer is grounded in the retrieved context. It quantifies the proportion of factual statements in the generated answer that are supported by the retrieved passages. If S denotes the set of factual statements extracted from the answer and S_c the subset verifiable within the retrieved context, then:

$$\text{Faithfulness} = \frac{|S_c|}{|S|} \tag{8}$$

A high value indicates that the model relies primarily on retrieved knowledge rather than hallucinated or unsupported content. In practice, this metric is estimated using an entailment model to automatically determine whether each factual claim in the answer is logically entailed by the retrieved passages.

2) Factual correctness: Factual Correctness evaluates the alignment between the generated answer (A_{gen}) and a ground-truth reference answer (A_{ref}). It measures the proportion of statements in A_{gen} that are semantically consistent with A_{ref}, regardless of whether they appear in the retrieved documents. Formally:

$$\text{Factual Correctness} = \frac{|S_{match}(A_{gen}, A_{ref})|}{|S(A_{gen})|} \tag{9}$$

where, S_{match} represents the subset of factual statements in A_{gen} that are semantically equivalent or entailed by A_{ref}. This metric is computed using a natural language inference (NLI) model to evaluate textual entailment between answer segments. It reflects the objective accuracy of generated outputs, which is particularly crucial in domains such as legal question-answering, where factual errors may alter the legal meaning of the response.

3) Context recall: Context Recall quantifies how effectively the retriever retrieves all relevant information required to answer a query. Let R denote the set of all relevant information units in the knowledge base, and R_{ret} the subset retrieved by the system. Then:

$$\text{Context Recall} = \frac{|R_{ret} \cap R|}{|R|} \tag{10}$$

High recall implies that the retriever captures most of the necessary evidence from the knowledge base, thereby minimizing omission errors. This metric is calculated by comparing the semantic similarity between the retrieved passages and the reference evidence set, using embedding-based cosine similarity with a predefined relevance threshold τ.

4) Context precision: Context Precision evaluates the proportion of retrieved information that is truly relevant to the question, penalizing the inclusion of irrelevant or noisy passages. Let R_{ret} represent all retrieved passages and R_{rel} the subset deemed relevant:

$$\text{Context Precision} = \frac{|R_{rel}|}{|R_{ret}|} \tag{11}$$

This metric provides insight into the selectivity of the retriever: higher precision values indicate fewer irrelevant documents and a cleaner, more focused context for the generator. In this work, relevance was determined by computing the cosine similarity between the query embedding and each retrieved passage embedding, labeling a passage as relevant if $\text{sim}(q, d) \geq \tau$.

5) Implementation details: All metrics were computed automatically using the open-source `ragas` Python library, which implements these definitions through a pipeline combining:

- Semantic entailment models (`deberta-large-mnli`) for faithfulness and factual correctness,
- Sentence-transformer embeddings (`all-MiniLM-L6-v2`) for computing context recall and precision,
- Automatic parsing of model outputs into atomic factual statements via dependency-based segmentation.

Each score was averaged across the full evaluation dataset, consisting of a balanced set of legal question–answer pairs. All metrics were normalized to the range $[0, 1]$, where higher values indicate better performance.

6) Interpretation: Collectively, these four metrics provide a multidimensional view of RAG performance. *Faithfulness* and *Factual Correctness* assess the quality of generation, while *Context Recall* and *Context Precision* evaluate retrieval quality. A robust RAG system should exhibit both high recall (completeness) and high precision (relevance), along with faithful and factually correct generations. In this study, these metrics serve as the foundation for comparing the Naive RAG and the proposed Metadata-Aware RAG across different model sizes and configurations.

E. Experiments

The experimental procedure was designed to systematically evaluate the performance of three LLMs, comparing the traditional Naive RAG configuration with the proposed Metadata-Aware RAG approach.

The evaluation used a curated set of 150 question-answer pairs derived from the Peruvian legal corpus. The dataset was created in two stages. First, a generative language model was used to generate candidate questions and answers from randomly selected chunks of the corpus. Second, the generated pairs were manually reviewed and validated by two legal experts: one specializing in law and belonging to the research team, and one external expert specializing in labor law. Only those pairs that met the validation criteria were retained.

A question-answer pair was retained only if: 1) the question was clear and unambiguous; 2) the answer could be found in a single identifiable passage of the corpus; and 3) the answer appeared verbatim in the source text. The questions were also distributed across the main labor regimes and constitutional rights to provide coverage of the main legal topics in the corpus.

Regarding difficulty, the questions were designed to evaluate the retrieval of specific legal information from the corpus rather than complex multi-hop legal reasoning. They require the system to identify relevant provisions and retrieve the corresponding information from the appropriate legal passage, including details such as legal requirements, applicable dates, conditions, and article references. The requirement that the answer be explicitly stated in the source text excludes questions that depend on combining information from multiple documents or performing extensive legal interpretation. This design allows the evaluation to focus on retrieval accuracy and factual grounding, while reducing the influence of the reasoning capabilities and hallucination tendencies of the generation model.

For both the Naive RAG baseline and the proposed Metadata-Aware RAG, retrieval depth was fixed at $k = 5$,

and generation was performed with a temperature of 0.1 to balance determinism and lexical variation. Both pipelines were evaluated under identical conditions, ensuring that the only difference between them lay in the retrieval architecture. Each was tested with three open-weight LLMs: Llama-3.1-8B, GPT-OSS-20B, and Gemma-3-27B. These models were selected based on three complementary considerations. First, they represent recent high-performing open-weight LLMs with different parameter scales, enabling the evaluation of the proposed retrieval architecture across increasing model capacities. Second, these model families have broad practical availability through major LLM inference services, supporting their relevance to contemporary real-world LLM applications. Third, the selected range allows the influence of model size on the proposed architecture to be assessed under controlled conditions. Finally, the 8B to 27B parameter range reflects the maximum capacity feasible for local inference, as the 27B model reaches the 32 GB VRAM physical limit of the RTX 5090 workstation utilized in this study.

The following objectives were considered in order to validate the proposed architecture:

- To evaluate the performance of Naive RAG and the proposed Metadata-Aware RAG using three language models of different sizes.
- To measure the improvement achieved by the proposed RAG over the Naive RAG across all evaluation metrics.
- To determine the influence of model size on the performance of the proposed RAG.
- To statistically validate the effectiveness of the proposed RAG compared to the Naive baseline.

F. Implementation Details

To ensure experimental reproducibility, the main hyperparameters, retrieval settings, and model configurations are specified as follows. The document chunking pipeline utilizes a primary structural split based on legal boundaries (e.g., full decrees, laws, or articles), followed by recursive sub-chunking with a maximum window of 250 tokens and a 30-token overlap to preserve boundary context. Semantic vector embeddings are generated using BAAI/bge-m3. During query execution, the Adaptive Filter Creator performs an initial hybrid vector search retrieving $k_{initial} = 20$ candidate passages. If metadata filters yield no results, progressive filter relaxation is applied. Candidates are then re-ranked using jina-reranker-v2-base-multilingual, with the top $k = 5$ passages selected for prompt synthesis. A cosine similarity threshold of $\tau = 0.65$ is enforced during context evaluation. All generative inference is performed with a temperature of $T = 0.1$ and top-$p = 0.9$ sampling.

The source code and implementation materials are publicly available at https://github.com/avjovet/Metadata-AwareRAG.

V. Results

A. Evaluation of Naive and the Oroposed RAG Across Different Language Models

The first experimental objective was to evaluate the performance of the *Naive RAG* and the *proposed Metadata-Aware RAG* pipelines using three large language models (LLMs) of different sizes: *Llama 3.1 8B*, *GPT-OSS 20B*, and *Gemma 3 27B*. Each model was assessed under identical retrieval and generation conditions to ensure comparability. The evaluation employed the four RAGAS metrics previously described: Context Precision, Context Recall, Factual Correctness, and Faithfulness, to capture both retrieval quality and generation trustworthiness.

TABLE II. Comparison of Naive RAG and Proposed Metadata-Aware RAG Across Three Language Models and Four RAGAS Metrics. Bold Values Indicate the Best Performance for Each Metric

RAG Pipeline	Metric	llama-3.1-8b	gpt-oss-20b	gemma-3-27b
Naive RAG	Context Precision	0.730	0.732	**0.734**
	Context Recall	0.710	**0.714**	**0.714**
	Factual Correctness	0.597	**0.620**	0.615
	Faithfulness	0.725	**0.762**	0.755
Our RAG	Context Precision	0.917	0.922	**0.929**
	Context Recall	0.905	0.912	**0.915**
	Factual Correctness	0.745	0.758	**0.772**
	Faithfulness	0.820	0.868	**0.913**

As observed in Table II, the proposed Metadata-Aware RAG consistently outperformed the Naive RAG across all evaluated metrics and models. The improvement is particularly pronounced in the *Faithfulness* and *Context Precision* dimensions, which measure the degree of grounding and relevance of retrieved evidence. For instance, when using *Gemma 3 27B*, faithfulness increased from 0.755 to 0.913, and context precision from 0.734 to 0.929, demonstrating a significant reduction in unsupported or noisy content generation.

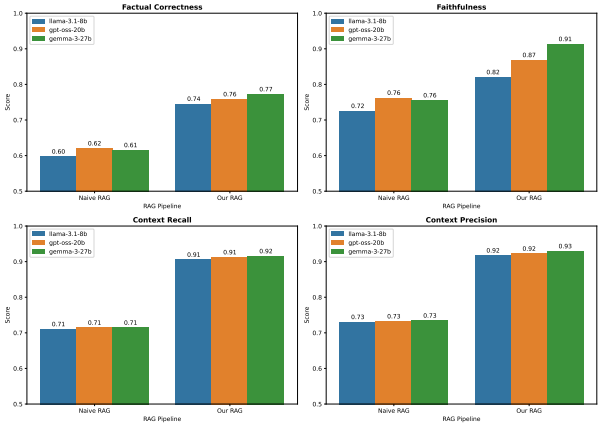

Fig. 5. Performance comparison of Naive RAG and proposed Metadata-Aware RAG across three language models and four RAGAS metrics. The proposed RAG shows consistent improvements across all models and evaluation dimensions.

Fig. 5 visually reinforces the numerical trends observed in Table II. The proposed RAG demonstrates clear and consistent gains in all four RAGAS metrics, with particularly strong effects in *Faithfulness* and *Context Precision*. The uniformity of the improvements across the three models indicates that the proposed retrieval enhancements generalize effectively across architectures of varying capacities.

Overall, these results confirm that the proposed RAG achieves a robust balance between retrieval coverage (high recall) and relevance (high precision) while improving factual

grounding and semantic accuracy. This experiment establishes a quantitative baseline for subsequent analyses, which further measure relative improvements, assess the influence of model size, and statistically validate the observed differences.

B. Improvement Achieved by the Proposed RAG Over the Naive RAG

The second objective of this study was to quantify the improvement achieved by the proposed Metadata-Aware RAG pipeline relative to the Naive RAG baseline across all evaluation metrics and language models. The aim of this analysis is to determine the magnitude of gains attributable to the introduction of metadata-guided retrieval and structured context filtering mechanisms.

As illustrated in Fig. 6, the proposed Metadata-Aware RAG exhibits consistent and substantial performance improvements across all metrics: *Factual Correctness*, *Faithfulness*, *Context Recall*, and *Context Precision*. The visual trends reveal that for each language model, the proposed RAG achieves higher scores, with particularly pronounced gains in *Context Recall* and *Context Precision*. These results confirm that metadata-aware retrieval contributes both to broader information coverage and to more relevant evidence selection, directly enhancing the generation phase by improving factual and contextual grounding.

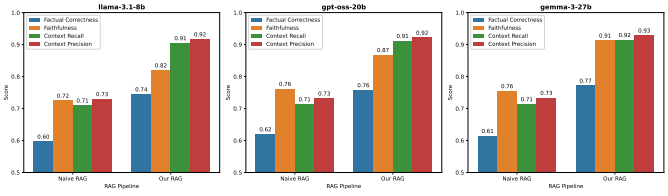

Fig. 6. Comparison of Naive RAG and proposed Metadata-Aware RAG across three language models and four RAGAS metrics. The proposed RAG consistently demonstrates higher scores, reflecting significant improvements in retrieval precision, contextual grounding, and factual reliability.

To complement the visual analysis, Table III reports the percentage improvement of the proposed RAG over the Naive RAG for each metric and model. The proposed RAG yields double-digit gains in every setting, with improvements ranging from 13.10% to 28.15%. The highest relative improvement was observed for *Context Recall* with *Gemma-3-27B* (28.15%), followed closely by *Context Precision* (26.57%) and *Factual Correctness* (25.53%) using the same model. These results confirm that larger models benefit even more strongly from metadata-aware retrieval, amplifying the improvements over the baseline pipeline.

The consistent improvement across all metrics and models provides strong evidence that the proposed RAG enhances the retrieval and generation process in a robust and scalable manner. The proportional increases in Context Precision and Context Recall confirm that metadata-guided retrieval reduces noise while increasing the availability of relevant information. The accompanying rise in Faithfulness and Factual Correctness demonstrates improved grounding and factual reliability, reinforcing the claim that retrieval quality directly influences answer trustworthiness.

TABLE III. PERFORMANCE IMPROVEMENT (%) OF THE PROPOSED METADATA-AWARE RAG OVER THE NAIVE RAG ACROSS METRICS AND MODELS

Metric	Model	Naive RAG	Our RAG	Improvement
Factual Correctness	llama-3.1-8b	0.597	**0.745**	24.79%
	gpt-oss-20b	0.620	**0.758**	22.26%
	gemma-3-27b	0.615	**0.772**	**25.53%**
Faithfulness	llama-3.1-8b	0.725	**0.820**	13.10%
	gpt-oss-20b	0.762	**0.868**	13.91%
	gemma-3-27b	0.755	**0.913**	**20.93%**
Context Recall	llama-3.1-8b	0.710	**0.905**	27.46%
	gpt-oss-20b	0.714	**0.912**	27.73%
	gemma-3-27b	0.714	**0.915**	**28.15%**
Context Precision	llama-3.1-8b	0.730	**0.917**	25.62%
	gpt-oss-20b	0.732	**0.922**	25.96%
	gemma-3-27b	0.734	**0.929**	**26.57%**

These results strongly support the conclusion that metadata-aware retrieval mechanisms significantly strengthen RAG pipelines, providing systematic benefits regardless of model size and suggesting that such strategies may be essential components of future trustworthy LLM-based information systems.

C. Influence of Model Size on the Performance of the proposed RAG

To assess whether larger language models yield additional benefits for the proposed Metadata-Aware RAG, we evaluated the evolution of each RAGAS metric across three model sizes: 8B, 20B, and 27B parameters. Fig. 7 visualizes the performance tendencies for both pipelines. The dashed lines correspond to the Naive RAG, while the solid lines show the behavior of the proposed RAG.

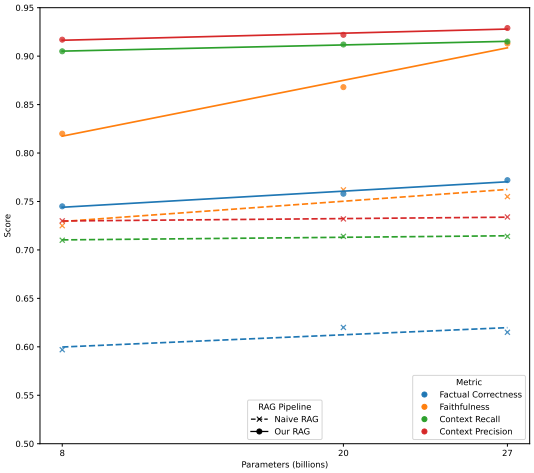

Fig. 7. Regression of model size (in billions of parameters) against performance scores across the four RAGAS metrics. Solid lines represent the proposed Metadata-Aware RAG, while dashed lines represent the Naive RAG.

The visual trends reveal two consistent patterns.

First, at every model size and for every metric, the proposed RAG scores are *always* higher than the Naive RAG scores. This performance gap remains stable across all parameter scales, confirming that the metadata-aware retrieval mechanism provides benefits that are independent of model capacity.

Second, the slopes of the regression lines are extremely small for most metrics, indicating that increases in parameter count, from 8B to 27B, lead to only marginal improvements. For *Context Precision*, *Context Recall*, and *Factual Correctness*, the curves grow slightly but remain nearly flat, suggesting that model size exerts minimal influence on these dimensions. In practical terms, each additional billion parameters yields only a very small increase in score, and the effect is nearly negligible.

TABLE IV. LINEAR REGRESSION BETWEEN MODEL SIZE (BILLIONS OF PARAMETERS) AND METRIC SCORES FOR NAIVE AND THE PROPOSED RAG. LARGER SLOPES INDICATE GREATER SENSITIVITY TO MODEL SCALING

Metric	RAG Pipeline	slope	intercept	r value	p value	std error
Context Precision	Naive RAG	0.00021	0.72823	**0.98865**	**0.09599**	**0.00003**
	Proposed RAG	**0.00061**	**0.91151**	0.96972	0.15706	0.00015
Context Recall	Naive RAG	0.00022	0.70856	0.93130	0.23734	0.00009
	Proposed RAG	**0.00053**	**0.90090**	**0.99710**	**0.04850***	**0.00004**
Factual Correctness	Naive RAG	0.00105	0.59137	0.83592	0.36987	0.00069
	Proposed RAG	**0.00138**	**0.73295**	**0.98522**	**0.10960**	**0.00024**
Faithfulness	Naive RAG	0.00174	0.71540	0.85156	0.35131	0.00107
	Proposed RAG	**0.00480**	**0.77904**	**0.99128**	**0.08414**	**0.00064**

To formalize these observations, Table IV reports the regression coefficients and statistical indicators. Across all metrics, the proposed RAG consistently exhibits slightly higher slopes than the Naive RAG, reflecting its better capacity to extract value from larger models. However, even these slopes remain small in absolute magnitude, again confirming that model size is not a decisive factor for performance gains.

The regression results confirm the visual findings: Model size has very limited influence on the performance of either RAG pipeline. The extremely small slopes indicate that the improvement per billion parameters is minimal and practically negligible for most metrics.

The only partial exception is Faithfulness in the proposed RAG, which shows the steepest slope (0.00480) and the strongest correlation ($r = 0.99128$). Although still small, this slope is meaningfully larger than those of the other metrics, suggesting that larger models are better at maintaining contextual grounding when combined with metadata-aware retrieval.

Overall, the results demonstrate that the proposed RAG consistently outperforms the Naive RAG across all models, regardless of size. Model size itself contributes little additional performance**, except for a modest gain in Faithfulness. The architecture of the retrieval pipeline matters far more than the parameter count, emphasizing the importance of metadata-aware design in RAG systems.

D. Effectiveness of the Proposed RAG Compared to the Naive Baseline

Before conducting the statistical validation, a qualitative visual analysis was performed to compare the overall behavior of both RAG pipelines. Fig. 8 illustrates the distribution of performance scores for the Naive RAG and the proposed RAG across all models and evaluation metrics.

The first panel aggregates all scores by pipeline, showing a clear upward shift in the distribution for the proposed RAG. The second and third panels further decompose the results by model and by pipeline, respectively, consistently revealing higher median values and reduced variability for the proposed approach. Together, these visual patterns suggest a systematic improvement in performance that motivates the subsequent statistical analyses.

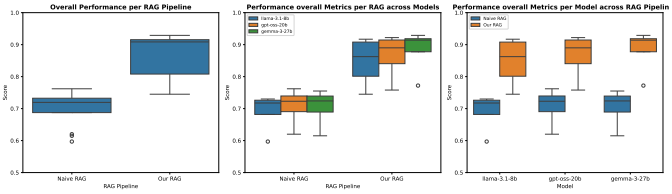

Fig. 8. Qualitative comparison of overall performance between the Naive RAG and the proposed RAG. Left: aggregated scores per pipeline. Center: performance across models. Right: performance per model across pipelines.

To statistically validate whether the proposed Retrieval-Augmented Generation (Our RAG) provides superior performance compared to the Naive RAG baseline, a series of inferential tests were conducted. These include 1) a normality assessment using the Shapiro–Wilk test, 2) a paired t-test for mean comparison, and 3) the computation of Cohen's d to quantify the magnitude of the effect.

1) Normality test: Prior to performing the parametric analysis, the assumption of normality was verified on the paired differences between the two systems. The Shapiro–Wilk test was selected due to its sensitivity in small samples ($n = 12$). The results are summarized in Table V.

TABLE V. SHAPIRO–WILK NORMALITY TEST ON PAIRED DIFFERENCES BETWEEN THE PROPOSED RAG AND NAIVE RAG

Statistic	p-value	Decision (at $\alpha = 0.05$)
0.869	0.064	Fail to reject normality

As the p-value exceeds 0.05 ($p = 0.064$), the null hypothesis of normality cannot be rejected, indicating that the paired differences are approximately normally distributed. Consequently, a paired t-test was deemed appropriate for subsequent analysis.

2) Paired t-Test: The paired t-test was applied to determine whether the mean performance of the proposed RAG was significantly higher than that of the Naive RAG across the 12 paired observations. The results are presented in Table VI.

TABLE VI. PAIRED t-TEST RESULTS COMPARING THE PROPOSED RAG AND NAIVE RAG

t-statistic	df	p-value (one-tailed)	Mean diff.	95% CI	Decision
15.49	11	4.06×10^{-9}	0.164	[0.141, 0.187]	Reject H_0

The test revealed a statistically significant improvement in performance for the proposed RAG system ($t(11) = 15.49$, $p < 0.001$). The mean difference in scores was 0.164, with a 95% confidence interval ranging from 0.141 to 0.187, confirming that the proposed approach consistently outperformed the baseline.

3) Cohen's Effect Size Analysis: To quantify the magnitude of this improvement, Cohen's d was computed based on the mean and standard deviation of the paired differences:

$$d = \frac{\bar{X}_{\text{diff}}}{s_{\text{diff}}} = \frac{0.164}{0.0367} = 4.47$$

This value ($d = 4.47$) corresponds to an *extremely large effect size*, indicating that the difference in performance is not only statistically significant but also practically meaningful. In practical terms, the proposed RAG consistently produced higher metric scores across all evaluation criteria.

The combination of a very low p-value ($< 10^{-8}$) and a large effect size ($d > 4$) provides strong evidence that the improvements achieved by the proposed RAG are not attributable to random variation. This confirms the effectiveness of the architectural modifications and the metadata-aware retrieval strategy integrated into the proposed RAG. These results validate the hypothesis that the proposed pipeline significantly enhances factuality, faithfulness, and contextual grounding compared to the Naive baseline.

VI. Discussion

The results obtained in this study provide evidence that the proposed Metadata-Aware RAG architecture substantially improves performance relative to the Naive RAG baseline under the evaluated legal question-answering setting. This controlled comparison demonstrates the benefit of incorporating hierarchical metadata-aware retrieval into a conventional RAG pipeline, while broader comparisons with alternative advanced RAG architectures remain an important direction for future evaluation.

A first point of discussion concerns the mechanisms underlying these gains. The substantial increases in Context Precision and Context Recall suggest that metadata-aware retrieval improves both the coverage and the relevance of retrieved evidence. By explicitly encoding jurisdictional markers, structural identifiers, and article-level metadata, the system reduces the incidence of semantically close but contextually irrelevant matches, while simultaneously enhancing the likelihood that all necessary fragments are retrieved. These retrieval gains translate directly into improvements in Factual Correctness and Faithfulness, confirming that more accurate and legally grounded evidence reduces opportunities for hallucinations during generation. The cross-encoder reranking module further reinforces this effect by prioritizing fragments with high semantic alignment to the query.

The regression analysis provides additional insight into the role of model size in the proposed architecture. Although larger models typically yield improved generation capabilities, the slopes of the regression lines across metrics were extremely small, revealing that parameter count only marginally influences performance. This finding underscores a central implication of our work: architectural improvements in retrieval are far more impactful than scaling model size for legal RAG. The only notable exception was Faithfulness, where larger models exhibited a modest but consistent advantage in grounding answers to retrieved evidence. Even in this case, however, the effect was minor relative to the improvements brought by metadata-aware retrieval.

Another relevant aspect concerns the practical significance of the proposed architecture for trustworthy legal assistants. The results suggest that investments in corpus engineering, including cleaning, hierarchical segmentation, metadata extraction, and structured retrieval, can provide substantial improvements in retrieval relevance, factual correctness, and grounding without requiring larger language models. In practical deployments, preserving legal metadata and provenance can also facilitate the identification and verification of the source provisions supporting an answer, which is particularly relevant in legal settings where traceability is essential. The results further suggest that improving the retrieval layer can be a more practical strategy than relying solely on model scaling, since the proposed architecture consistently improved performance across models of different sizes. These findings support the use of structured retrieval mechanisms, robust query filtering, and fine-grained provenance tracking when designing reliable legal information systems.

Several limitations should be acknowledged. The evaluation focuses on Peruvian labor law; however, the proposed retrieval mechanisms can be adapted to other legal domains by adjusting their domain-specific metadata and document structures. The dataset consists of synthetic questions with manual verification but does not include real-world user queries or adversarial prompts. Additionally, all evaluations were conducted offline; user studies and longitudinal deployment analyses were outside the scope of this work. Future research may extend the proposed architecture to multi-jurisdictional settings, incorporate temporal validity constraints, evaluate robustness to ambiguous or adversarial queries, and explore integration with active learning strategies for corpus refinement.

VII. Conclusions

This work introduced a Metadata-Aware Retrieval-Augmented Generation architecture designed to improve trustworthiness, factual consistency, and contextual grounding in legal question–answering systems. The proposed approach integrates hierarchical sub-chunking with legal metadata inheritance and an Adaptive Filter Creator capable of generating structured, metadata-guided retrieval queries. Evaluated across three language models of different scales, the system demonstrated substantial and consistent improvements over a Naive RAG baseline.

Across all RAGAS metrics (context precision, context recall, factual correctness, and faithfulness), the proposed RAG yielded double-digit gains for every model. These improvements were statistically significant, with a large effect size, confirming that metadata-aware retrieval and reranking materially enhance the quality of both retrieved evidence and generated answers. Importantly, the architecture consistently outperformed the baseline regardless of model size, indicating that retrieval design has a stronger impact on performance than increasing parameter count. Only Faithfulness showed a modest, incremental benefit from larger models.

The findings highlight the importance of corpus engineering, metadata extraction, and structured retrieval pipelines for deploying reliable, legally grounded conversational agents. By improving the relevance and coverage of retrieved fragments, the proposed method reduces hallucination risks and strengthens factual alignment, offering a practical and scalable strategy for legal information systems.

This study is limited by its focus on a single jurisdiction, an offline evaluation setting, and a curated dataset of synthetic questions. Future work should include ablation studies and benchmarking against enhanced and legal-domain RAG variants to further assess the individual contributions and state-of-the-art positioning of the proposed architecture.

In summary, the proposed Metadata-Aware RAG demonstrates that retrieval architecture, rather than model size, is the dominant factor in achieving accurate, faithful, and contextually grounded responses in legal RAG systems.

***Abstract*—Receipts are vital documents that validate transactions by capturing key details such as dates, items purchased, prices, and seller information. However, accurately documenting receipts is often compromised by issues like blurring, which can result from poor image quality, physical wear, or suboptimal scanning conditions. While the Processing Key Information Extraction from Documents Using Improved Graph Learning-Convolutional Networks (PICK) deep learning model is effective for structured information extraction, it struggles with processing blurred text, leading to inaccuracies in data retrieval. To overcome these challenges, this research introduces AlphaOCR, a web-based application that integrates the PICK model with advanced Optical Character Recognition (OCR) technology. The methodology integrates OCR-based line-item recognition with PICK-based structured-field extraction to extend the range of information recovered from receipts. The deep learning component was evaluated using mean Entity Precision (mEP), mean Entity Recall (mER), mean Entity F1-score (mEF), and mean Entity Accuracy (mEA), together with a paired t-test for the entity-level mEF results. PICK-2 increased the mEF from 83.32% to 83.88%, corresponding to a modest absolute gain of 0.56 percentage points. The complete AlphaOCR configuration combining PICK-2 with EasyOCR achieved an overall accuracy of 87.96% under the evaluation setting used in this study. Among the OCR models evaluated, EasyOCR achieved a Character Accuracy Rate (CAR) of 92.04% and provided the most suitable output characteristics for integration with PICK-2 within the tested configuration. The reported results should be interpreted within the experimental scope of this study rather than as a direct performance ranking against previously published systems that used different datasets, tasks, extracted fields, and evaluation metrics. AlphaOCR provides a practical integrated workflow for receipt information extraction, although broader claims regarding robustness, scalability, and generalisability require evaluation on larger and more diverse receipt collections. This research contributes to receipt information extraction primarily through the system-level integration of graph-based key information extraction, OCR-based item recognition, output fusion, and a web-based verification workflow. Future work should evaluate the system on larger and more diverse datasets and investigate enhanced semantic understanding and additional document types.**

I. Introduction

Artificial intelligence (AI) enables computer systems to perform tasks involving pattern recognition, data interpretation, prediction, and decision-making. Machine-learning models have been applied to security-related problems, including Internet of Things threat detection and interpretable risk analysis [1]. Predictive machine-learning methods have also supported environmental monitoring by modelling complex water-quality characteristics from observed data [2]. In the financial and socioeconomic domain, classification algorithms have been used to identify household overspending patterns among different income groups [3]. Unsupervised learning techniques, including clustering, have been applied to analyse and classify student academic performance [4]. Optimisation and data-fusion approaches have further supported scientific applications such as ligand-based virtual screening [5]. Deep-learning architectures have also demonstrated strong image-classification capability in medical applications, including the automated classification of malignant and benign skin lesions [6]. Together, these studies demonstrate the adaptability of AI, machine learning, and deep learning across structured-data, predictive, optimisation, and image-analysis tasks. This broad technical capability provides a foundation for their application to document-understanding problems, although receipt information extraction introduces additional challenges related to text recognition, document layout, and field relationships.

The rapid increase in digital transactions has led to a substantial growth in the volume of digital receipts generated across industries [7]. As organisations seek to digitise and streamline their operations, the accurate extraction and processing of information from these receipts has become crucial [8]. Optical Character Recognition (OCR) technologies have been widely adopted for this purpose. Yet, they face challenges in dealing with the diverse formats, fonts, and layouts inherent to receipts [9]. These challenges often result in inaccuracies in data extraction, which can undermine the efficiency and reliability of automated systems [10].

The practical impact of these limitations is also reflected in previous receipt-processing studies. Kumar et al. reported an accuracy of 83% for larger bill receipts, corresponding to a residual error proportion of approximately 17% under their experimental setting [14]. Odd and Theologou reported an

accuracy of 72.32% for price extraction, leaving approximately 27.68% of the evaluated price fields incorrectly extracted [19]. Although these values were obtained under different experimental conditions, they demonstrate that apparently strong document-level recognition performance may still leave a substantial proportion of business-relevant fields requiring manual verification or correction. Such residual errors can propagate into expense records, transaction summaries, and downstream reporting workflows. These documented field-level errors motivate the need for a receipt-processing architecture that does more than recognise individual characters. The system must also preserve the relationships among structured receipt fields, line-item descriptions, and their corresponding prices.

This research introduces AlphaOCR, an advanced system designed to address the limitations of existing OCR methods, particularly in receipt processing. The system leverages deep learning models, specifically the PICK (Processing Key Information Extraction) models, which are enhanced through hyperparameter tuning to improve performance [11]. The study compares two versions of the PICK model: PICK-1, the original model developed by Yu et al. (2020), and PICK-2, a modified version that incorporates improvements aimed at increasing accuracy and efficiency.

Despite progress in receipt understanding, three technical limitations remain insufficiently addressed in the reviewed approaches. First, the PICK configuration used in this study extracts a fixed set of structured entities but does not directly recover line-item product descriptions and their corresponding prices. Second, conventional OCR engines can recognise characters from the receipt body, but their outputs do not necessarily preserve phrase continuity or the structural association between a product description and its price. Third, independently generated structured-field and OCR outputs require an explicit fusion and verification mechanism before they can be used as a coherent transaction record.

The unresolved research gap is therefore not limited to blur sensitivity. It concerns how graph-based structured information extraction and OCR-based line-item recognition can be integrated without losing field relationships, while allowing uncertain or incorrect outputs to be reviewed before storage and reporting. AlphaOCR addresses this gap through a dual-branch architecture in which PICK-2 extracts predefined structured entities, an OCR component processes line-item content, and a web-based verification stage consolidates and corrects the combined output.

Accordingly, this study investigates whether a graph-based structured extractor can be extended with an OCR branch and a verification layer to recover both receipt-level entities and line-item information within a unified processing workflow.

The primary objectives of this research are to compare PICK-1 and PICK-2 using multiple entity-level evaluation metrics, to examine the performance of different OCR engines when integrated with PICK-2, to evaluate the resulting AlphaOCR receipt-processing configuration, and to assess the usability of its web-based application. Rather than claiming direct superiority over previously published systems, the study characterises the performance of the proposed components under a common internal evaluation setting.

The objectives of this study are as follows:

- To introduce AlphaOCR, an integrated receipt-processing architecture that combines graph-based key information extraction through PICK-2 with OCR-based product and price recognition.
- To compare PICK-1 and PICK-2 using mEP, mER, mEF, and mEA, and to evaluate TesseractOCR, KerasOCR, and EasyOCR under the same study-specific experimental setting.
- To implement the integrated model as a web-based application supporting receipt upload, output fusion, user verification, correction, analysis, and report generation.

This article is organised into key sections: Section II reviews recent literature on receipt processing and OCR advancements. Section III outlines the methodology used in this research, detailing the experimental setup and model configurations. Section IV offers an in-depth analysis of the experimental outcomes, including model performance and usability testing. Finally, Section V summarises the findings, discusses the research implications, and Section VI concludes the study and suggests potential directions for future work. To position this architecture within existing document-processing research, the next section compares OCR-centred, layout-aware, and graph-based information-extraction approaches.

II. Related Work

In 2019, Anh Le Duc, Dung Van Pham, and Tuan Anh Nguyen conducted a study on text detection and recognition in receipts. They used the Connectionist Text Proposal Network (CTPN) algorithm for detecting text, utilising Visual Geometry Group (VGG-16), Bidirectional Long Short-Term Memory (BiLSTM), and bounding box regression to detect horizontal text effectively. They employed the Attention-based Encoder-Decoder (AED) algorithm for text recognition, which used DenseNet and OCR for validation and was particularly effective at recognising mathematical expressions and handwritten Vietnamese characters [12]. The study utilised the SROIE2019 dataset, which was divided into training, testing, and validation sets. Three variations of the CTPN algorithm were tested: CTPN alone, CTPN with preprocessing, and CTPN with preprocessing and OCR validation. The best results were achieved with the CTPN combined with preprocessing and OCR validation, yielding F1, Precision, and Recall scores of 71.9%, 72.5%, and 71.3%, respectively. While the CTPN with preprocessing alone had a slightly higher Recall of 72.3%, the combined approach outperformed across other metrics. A key limitation was the exclusion of handwritten text detection and recognition, indicating a direction for future research [13].

In 2020, Vedant Kumar and his team conducted a study that used OCR technology to extract information from receipt and bill images, making them machine-readable [14]. The study applied four main methods: removing shadows and watermarks, segmenting long invoices, recognising and extracting text, and retrieving relevant information. They used OpenCV for image processing due to its effectiveness in handling image data and Tesseract OCR for text extraction because of its ability to detect text in various languages and produce outputs closely matching the input images. Although the specific dataset details were not provided, the researchers tested their approach

on 25 bill receipts, achieving high accuracy rates—97% for small bill receipts and 83% for larger ones. Peak Signal-to-Noise Ratio (PSNR) values ranged from 38.13 to 42.57 dB. While PSNR was less pivotal in this study, the main strength of their research was the ability to extract text even in the presence of watermarks and shadows. However, a limitation was that the method was best suited for images with printed text [14].

In 2019, Xiaohui Zhao, Endi Niu, Zhuo Wu, and Xiaoguang Wang developed an OCR system for extracting key information from receipts. The study introduced grid positional mapping for CNN algorithms, utilising two versions: Convolutional Universal Text Information Extractor (CUTIE-A), which merges features from various resolutions, and CUTIE-B, which uses atrous convolution and ASPP to improve context detection [16]. They tested the system using the SROIE2019 dataset, split 75:25 for training and testing. CUTIE-A achieved AP scores of 90.8% for taxi receipts, 77.7% for food and entertainment receipts, and 69.5% for hotel receipts, with softAP scores reaching up to 97.2%. CUTIE-B performed even better, outperforming models like CloudScan and BERT. However, the study had a limitation: it lacked preprocessing steps to connect text into meaningful entities during grid mapping, relying only on existing algorithms [17].

In 2020, Weiliang Liu and colleagues developed an end-to-end neural-network method for recognising taxi receipt information without relying on conventional image-processing and OCR pipelines. The method used an SSD model with a VGG-16 backbone to identify informative regions and a specialised CNN and GRU network for character recognition. The dataset contained 1,800 taxi receipt images, and the reported cross-validation accuracy was 94.36%. The evaluation was restricted to taxi receipts from a specific company in Beijing [15]. A related application-oriented taxi receipt text-recognition system was subsequently presented by Liu et al. [18].

In 2018, Joel Odd and Emil Theologou investigated the use of OCR in machine learning for classifying receipts and extracting specific data points. They converted physical receipt datasets to digital form and trained several machine learning algorithms, comparing the performance of four: LinearSVC, MLP, Na¨ıve Bayes, and DummyClassifier. The Google Drive REST API was selected for OCR, demonstrating better accuracy than the Azure Computer Vision API [19]. The study found that LinearSVC performed best, achieving 94.07% accuracy for receipt classification and 72.32% for extracting specific data points like prices. However, the overall accuracy was still not optimal, indicating a need for more advanced methods to improve results.

In a study by Peng Zhang et al., the TRIE model achieved the highest accuracy of 93.26% for information extraction from receipts, outperforming the GCN model's 92.60%. The dataset used included SROIE2019 and a combination of Chinese text receipts and resumes. The TRIE algorithm, which integrates FPN and ResNet-50, demonstrated superior performance in this context [20].

In 2020, Yu et al. introduced the deep learning model PICK, designed for extracting key information (KIE) from documents [21]. Evaluated using the SROIE2019 dataset, PICK outperformed baseline models, achieving an impressive mEF score of 96.1%. This model integrates convolutional visual features, graph learning, sequential encoding, and CRF-based structured prediction for key information extraction [21].

In 2019, Xiaojing Liu and colleagues introduced a model for extracting information using a combined textual and visual approach [22]. The study utilised the Value-Added Tax Invoices (VATI) and International Purchase Receipts (IPR) datasets, highlighting the benefits of incorporating visual elements into information extraction. Their Bidirectional Long Short-Term Memory (BiLSTM) + Conditional Random Fields (CRF) + Graph Convolutional Network (GCN) model outperformed baseline models, achieving an F1 score of 87.3% on VATI and 83.6% on IPR [22].

In 2020, Bodhisattwa Prasad Majumder and their team demonstrated that Representation Learning models significantly outperformed Bag of Words (BoW) and Multilayer Perceptron (MLP) models in extracting information from receipts and invoices, achieving an F1 score of 83.9% on the Invoices1 and Invoices2 datasets, and 83.3% on the SROIE2019 dataset [23]. In 2022, Cheng Jian Lin and colleagues proposed the YOLOv4-s model, which was compared to YOLOv3, YOLOv4, and YOLOv5 on printed and handwritten receipt datasets. Although it was tested on a specific dataset, YOLOv4-s achieved the highest accuracy of 99.39%, showcasing its strength in minimising downsampling during image processing [24].

Finally, Chang et al. (2004) present a real-time license plate recognition method that addresses challenges like varying plate sizes, orientations, and lighting conditions [25]. Their system utilises image processing techniques to locate and segment license plates from camera-captured images, enhancing key features through edge detection and morphological operations. After detecting the license plate, the system extracts characters using template matching or neural networks. The system was evaluated for accuracy and efficiency across different conditions, demonstrating its effectiveness in overcoming the typical challenges of license plate recognition systems.

The numerical results reported in previous studies should be interpreted with caution. For example, TRIE reported an accuracy of 93.26%, while YOLOv4-s reported an accuracy of 99.39% [20], [24]. However, these values were obtained using different datasets, task definitions, document categories, extracted fields, and evaluation procedures. Similarly, the mEF reported for the original PICK study and the overall accuracy reported for AlphaOCR represent different evaluation scopes. Consequently, these reported values do not constitute a direct head-to-head comparison and should not be used to rank the methods solely according to their numerical scores.

A broader review of deep-learning-based information extraction was provided by Yang et al. [21], who surveyed the evolution from earlier feature-engineering pipelines to more recent neural architectures for extracting structured information from documents.

Table I shows a transition from OCR-centred pipelines towards layout-aware and graph-based document-understanding models. OCR-centred approaches can recover text effectively but do not inherently preserve semantic relationships among receipt fields. In contrast, structured KIE models such as PICK and TRIE model visual and contextual relationships,

TABLE I. COMPARATIVE SYNTHESIS OF RECEIPT AND DOCUMENT INFORMATION-EXTRACTION APPROACHES

Study	Architecture	Dataset	Main Strength	Reported Limitation	Remaining Gap
Le et al. [12]	CTPN, VGG-16, BiLSTM, and attention-based recognition	SROIE2019	Combines text detection and recognition for receipt images	Handwritten content was not evaluated and the pipeline contains multiple processing stages	Limited support for unified structured-field and line-item extraction
Kumar et al. [14]	OpenCV preprocessing and Tesseract OCR	25 bill receipts	Handles shadows, watermarks, and printed-text degradation	Performance decreased for larger bills and the method focused on printed text	No explicit modelling of relationships among extracted fields
Zhao et al. [16]	CUTIE-A/B with grid-based convolutional document modelling	SROIE2019 and receipt categories	Represents text and spatial layout in a two-dimensional grid	Depends on grid mapping and lacks an explicit verification workflow	Limited integration of OCR outputs with user-correctable structured records
Liu et al. [15]	SSD with VGG-16 and CNN–GRU recognition	1,800 taxi receipts	High recognition accuracy within a specific receipt domain	Restricted to taxi receipts from a specific company	Limited cross-domain generalisation and field extensibility
Odd and Theologou [19]	OCR services with conventional machine-learning classifiers	Custom receipt collection	Demonstrates receipt classification and field extraction from OCR text	Price and date extraction remained substantially less accurate than receipt classification	OCR text was not integrated with graph-based document structure
TRIE [20]	FPN, ResNet-50, text recognition, and information extraction	SROIE2019, Chinese receipts, and resumes	End-to-end text reading and information extraction	Uses task- and dataset-specific evaluation settings	No user-assisted correction or application-level output fusion
PICK [11]	CNN, graph learning, BiLSTM, and CRF	SROIE2019	Models visual, spatial, and sequential relationships among document entities	The evaluated configuration extracts a predefined entity schema	Does not directly recover product–price line-item pairs in the present implementation
AlphaOCR	PICK-2, OCR, output fusion, and web-based verification	SROIE2019 and a controlled OCR evaluation	Combines structured fields, line-item recognition, and user verification in one workflow	OCR evaluation and usability assessment remain limited in scale	Requires broader external validation and more automated line-item association

but their output schemas and evaluation settings are task-specific. AlphaOCR was therefore designed to combine the complementary strengths of these approaches: graph-based structured-field extraction, OCR-based line-item recognition, and user-assisted output verification.

PICK was selected as the structural information extraction component of AlphaOCR not because it achieved the highest reported numerical result among all cited approaches, but because its architecture was specifically designed for key information extraction from visually rich documents. Its combination of convolutional feature extraction, graph-based relationship modelling, sequential encoding, and structured prediction enables it to represent spatial and contextual relationships among receipt fields.

The contribution of AlphaOCR is therefore positioned as a system-level integration rather than a claim of state-of-the-art extraction accuracy. PICK-2 extracts the predefined structured entities of company, address, date, and total, whereas the OCR component extends the output to product-level text and price information. The combined system further provides output fusion, user verification, correction, storage, and reporting within a web-based workflow. A direct comparison with TRIE, YOLOv4-s, or other external systems would require those models to be reimplemented and evaluated on the same data partition, extracted fields, preprocessing procedures, and evaluation metrics. The comparison identifies the need for an architecture that combines structured-field modelling, line-item OCR, output fusion, and user verification. The following section describes how these components were implemented in AlphaOCR.

III. METHODOLOGY

TThe AlphaOCR system was designed to support the extraction of structured fields and line-item information from receipts. Fig. 1 illustrates the development process, highlighting the integration of three primary components: the PICK deep learning model, the OCR model, and the web-based application. The methodology involves five phases: PICK model development, OCR extraction and PICK integration, output fusion, Post-Processing and Web Application Deployment, and AlphaOCR System Evaluation.

A. PICK Model development

The PICK component comprises three main modules: an encoder capable of interpreting the layout and text in the input image, a graph module that receives embeddings from the encoder to explore and extract hidden features in the receipt embeddings, and a decoder that identifies phrases with the highest probability values.

1) Encoder: The encoder in the PICK model uses Convolutional Neural Networks (CNNs) to extract hierarchical features from the receipt images. These features include spatial and visual patterns, such as text blocks, lines, and characters. The encoder transforms the raw image data into feature maps, a foundation for further analysis. The feature maps represent the various components of the receipt, allowing the model to capture the structure and layout of the document. This is crucial for identifying key regions containing important information, such as the receipt's header, body, and footer.

2) Graph module: After encoding, the extracted features are passed to the graph module, which employs Graph Learning-Convolutional Networks (GLCN) to model the relationships between different text regions. Each node corresponds to a text region in this graph representation, and edges represent the spatial and logical relationships between these regions. The graph module is essential for understanding the layout of the receipt and how different elements are interconnected. For example, it helps the model determine the

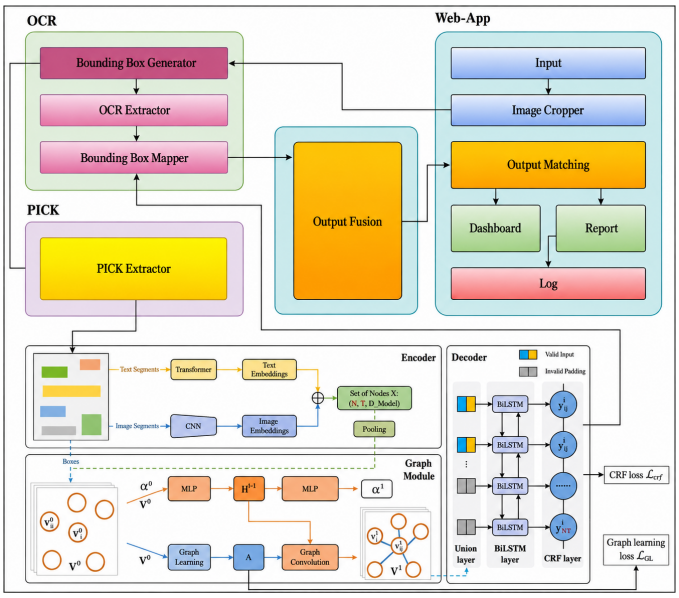

Fig. 1. AlphaOCR model development.

relationship between a product name and its corresponding price or between the company name and the total amount. By learning these relationships, the model can more accurately interpret the structure of the receipt and extract relevant information.

3) Decoder: The decoder stage of the PICK model integrates Bidirectional Long Short-Term Memory (BiLSTM) networks and Conditional Random Fields (CRF) to generate the final structured output. BiLSTM networks capture sequential dependencies between text regions, ensuring that the model accurately reflects the order and flow of information on the receipt. For instance, it helps ensure that product names are correctly associated with their prices and that dates are properly linked to their respective transactions. The CRF layer then takes these sequential outputs and applies structured prediction to make coherent and contextually accurate decisions about the content of the receipt. This structured prediction allows the model to extract key fields, such as the company name, address, date, and total amount, with high precision and consistency.

The development of AlphaOCR began with the construction, adaptation, and training of the PICK deep learning model. This model was trained on the publicly available SROIE2019 dataset, which consists of 973 purchase receipts from Malaysia. The SROIE2019 dataset comprises three key components: images, bounding boxes, and entities, all of which are essential for model training. The images, provided in *.jpg format, often include varying degrees of blurring, reflecting real-world challenges such as poor image quality. The bounding boxes, stored in *.csv format, contain coordinates that enclose the text within the image, and the entities, saved in *.json format, represent the crucial information the model must extract from the receipt. In this dataset, the bounding box files also store the text bounded by these coordinates, allowing the model to effectively learn how to recognise and extract key information despite potential blurring. These components are commonly referred to as img (image), box (bounding box),

B. OCR Extraction and PICK Integration

Once the models are trained, the AlphaOCR system integrates the outputs of the PICK and OCR models to produce a comprehensive extraction of receipt information:

1) OCR extraction: The OCR component consists of three main modules: a bounding box generator that creates boundary boxes around phrases on the receipt, an OCR extractor for extracting text from the receipt's body, and a bounding box mapper that maps the boundary boxes to the areas identified by the OCR model. The PICK deep learning model is specifically designed to extract four key pieces of information from a receipt: the issuing company, the company address, the date of issuance, and the total payment made. The OCR model extracts two additional important details, namely the product and price. Initially, the receipt is processed by the PICK deep learning model to extract the four main pieces of information.

Afterwards, the receipt is cropped and focused solely on the body section to extract information related to the product, quantity, and product price. This technique simplifies the complex post-processing of text by narrowing the focus to the body section, which is crucial since receipts are generally divided into three main sections: header, body, and footer.

2) PICK extraction: Simultaneously, the PICK extractor module processes the original receipt image to extract key information. During this process, the encoded feature maps generated by the CNNs are analysed by the graph module to understand the spatial layout of the receipt. The graph module identifies and models the relationships between different text regions, such as the connection between the header (e.g., company name) and the footer (e.g., total amount). The BiLSTM networks within the decoder then analyse the sequence of text regions to maintain logical consistency. At the same time, the CRF layer finalises the structured output, accurately extracting fields such as the company name, address, date, and total amount.

3) Bounding box mapping: The bounding box mapper module examines the extracted results, visually mapping the identified text areas on the receipt. This step ensures accurate identification and localisation of information.

C. Output Fusion

Following the extraction process, the Output Fusion module merges the data from the PICK and OCR models into a single, coherent output. This fusion process is essential for integrating the structured data extracted by the PICK model with the textual information extracted by the OCR model. The module aligns and combines the different data points to create a unified dataset that is both comprehensive and easy to interpret. The result is a complete and accurate representation of the receipt's content, ready for further processing or display.

D. Post-Processing and AlphaOCR Web Application Deployment

The post-processing phase is crucial in refining the fused output to ensure the extracted information is accurate and user-friendly. This final, polished data is presented to users through a web-based application, the primary interface for interacting with the processed information.

In the Output Matching and Feedback stage, the system presents the extracted data via the web application's output matching module. Users are encouraged to review and correct the extracted text, especially for crucial details such as the company name, address, date, amount paid, and product information. This feedback mechanism is essential for continuously improving the system's accuracy.

The refined data is then displayed on an Analysis Dashboard within the web application, allowing users to download the extracted information. The dashboard includes interactive features such as filtering, sorting, and exporting, allowing users to manipulate the data according to their needs.

In terms of Data Storage and Access, all extracted and refined information is consolidated and securely stored in a singular log file. This file is accessible to the administrator through the application's backend, ensuring the data is archived securely and available for future reference or analysis.

The AlphaOCR web application consists of seven main modules: the input module, which receives receipt images; the image cropper, which trims the body section of the receipt; the output fusion module, which integrates the extraction results from both OCR and PICK into a single output; the output matching module, which corrects and aligns the extracted text with its appropriate category (such as company name, company address, date, total amount paid, product, or product price); the dashboard, which displays an analysis of the extraction results; the report module, which allows users to download the processed information; and the log module, which stores cumulative extraction data accessible by the admin through the application's backend.

The AlphaOCR web-based application was developed using Python, leveraging key modules such as Streamlit, which is particularly effective in presenting a deep learning model as a user-friendly web application. Fig. 5 illustrates the design of the AlphaOCR User Guide interface, offering users clear instructions and guidance on using the application. Fig. 6 displays the design of the AlphaOCR Home interface, where users can upload receipt images and initiate the extraction process. Finally, Fig. 7 showcases the design of the AlphaOCR Extractor interface, where users can view, review, and interact with the extracted data.

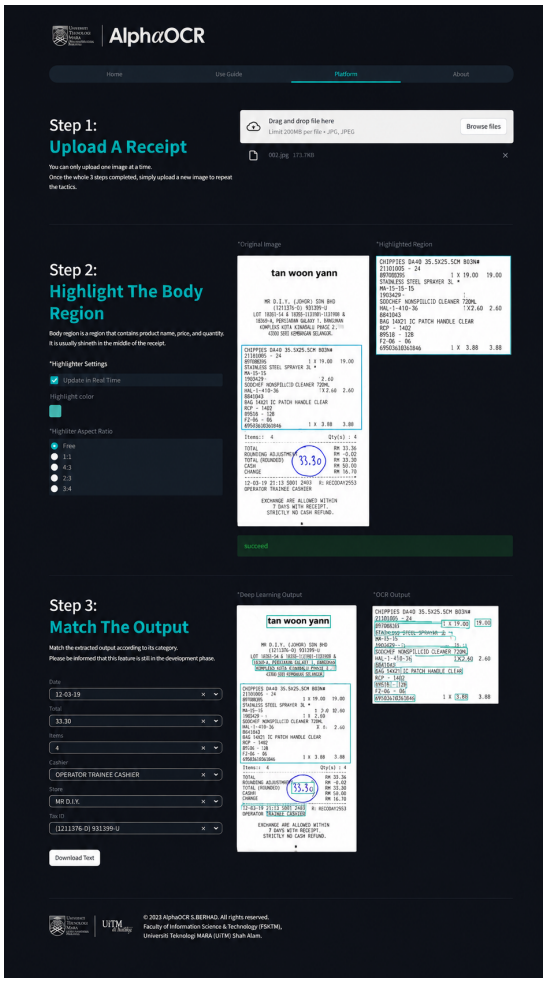

Fig. 7. Design of the AlphaOCR extractor interface.

E. AlphaOCR System Evaluation

The deep learning component of AlphaOCR was evaluated by comparing PICK-1 and PICK-2 using four entity-level metrics: mean Entity Precision (mEP), mean Entity Recall (mER), mean Entity F1-score (mEF), and mean Entity Accuracy (mEA). These metrics were examined across the extracted entities and during both the training and testing phases. In addition to the descriptive comparison, a paired t-test was applied to the paired entity-level mEF values to assess whether the observed difference between PICK-1 and PICK-2 was statistically significant. Because statistical significance does not by itself indicate the practical magnitude of an improvement, the absolute difference in mEF between the two models was also reported and interpreted together with the loss values and the consistency between training and testing performance.

The OCR comparison was conducted using 20 selected phrases from one standardised receipt image. The same phrases were processed using TesseractOCR, KerasOCR, and EasyOCR to provide a consistent within-image comparison. This controlled evaluation was intended to support OCR-engine selection for the AlphaOCR prototype rather than to serve as a general benchmark across diverse receipt collections.

TABLE II. EVALUATION PHASES AND MODELS

Component	Evaluation Phase	Model
Deep Learning Model	Evaluating the performance of two PICK models through multiple assessment metrics.	PICK-1, PICK-2
OCR Model	Controlled phrase-level comparison for OCR-engine selection.	TesseractOCR, KerasOCR, EasyOCR
Web-based Application	Conducting usability testing on the developed application.	AlphaOCR

In addition to the technical evaluations, a formative usability assessment was conducted to identify interface, navigation, and interaction issues in the AlphaOCR web application. The assessment involved 15 participants organised into three groups of five. The small-group evaluation was intended to support prototype refinement. It was not designed to provide a statistically representative estimate of usability or satisfaction for the broader population of intended users. The resulting evaluation design examined the structured extractor, the OCR engines, the integrated configurations, and the formative user interaction. The next section reports the corresponding experimental and usability results.

IV. RESULTS

The evaluation phase was crucial for assessing the effectiveness of the AlphaOCR system. This phase involved evaluating the performance of the PICK models, comparing different OCR models, and conducting usability testing for the web-based application, as summarised in Table II. Table II outlines the evaluation phase of a system consisting of three key components: a deep learning model, an OCR model, and a web-based application. During the evaluation of the deep learning model, the performance of two models, PICK-1 and PICK-2, was assessed using multiple metrics to determine their effectiveness in tasks such as entity recognition and information extraction. In the OCR model evaluation, The three OCR engines were compared using the controlled phrase-level evaluation protocol described in Section III-E. This phase focused on measuring the accuracy and efficiency of these models in text extraction. Lastly, the web-based application was subjected to usability testing to evaluate its interface, user experience, and overall functionality, with AlphaOCR being the specific application under review. This comprehensive evaluation process ensured that each system component was thoroughly tested for performance, accuracy, and user-friendliness.

A. Deep Learning Model PICK

The deep learning component of the AlphaOCR system was tested using two versions of the PICK model. The first version, PICK-1, is the original model developed by Yu et al., which served as the baseline for comparison. The second version, PICK-2, is a modified iteration of the original model, incorporating hyperparameter tuning designed to enhance performance.

As summarised in Table III, the two versions of the PICK model differ in backbone depth and activation function while sharing the same optimiser. PICK-1, which uses the ResNet-50 architecture, the Adam optimiser, and the ReLU activation function, served as the baseline model for performance comparison. PICK-2, the enhanced version, utilises the deeper ResNet-152 backbone, still employs the Adam optimiser, but incorporates the Leaky ReLU activation function with the aim of improving model performance. These variations in architecture and activation functions were intended to optimise the model's accuracy and effectiveness in the deep learning tasks of the AlphaOCR system.

TABLE III. PARAMETER SETTINGS FOR PICK-1 AND PICK-2

Model	ResNet	Optimizer	Activation Function
PICK-1	ResNet-50	Adam	ReLU
PICK-2	ResNet-152	Adam	Leaky ReLU

Fig. 8 shows a comparison of four key evaluation metrics, including mean Entity Precision (mEP), mean Entity Recall (mER), mean Entity F1-score (mEF) and mean Entity Accuracy (mEA) across different entities for the PICK-1 and PICK-2 models, divided into training and testing phases. The green colour scheme represents the PICK-1 model, with darker green indicating training results and a lighter green for testing results. Similarly, the orange scheme is used for the PICK-2 model, with darker orange for training and lighter orange for testing.

The observations from Fig. 8 reveal that PICK-1 generally exhibits higher precision during training, particularly in the "Date" entity. However, PICK-2 demonstrates more consistent precision during testing, notably in "Company" and "Total." Both models maintain stable values across entities when examining recall, with PICK-1 showing slightly higher recall during training. In the testing phase, PICK-2 matches or surpasses PICK-1 in recall for the "Date" and "Company" entities, indicating better generalisation. The F1-score trends align with precision and recall, where PICK-1 performs better during training, especially for "Date," but PICK-2 displays a more balanced F1-score during testing. Accuracy remains high for both models across all entities, with PICK-1 showing slightly better accuracy during training. However, PICK-2 demonstrates less variability between training and testing, suggesting it may generalise better in real-world scenarios. Fig. 9 compares GL Loss, CRF Loss, and Total Loss values between the PICK-1 and PICK-2 models across both training and testing phases. The colour scheme remains consistent, with green representing PICK-1 and orange representing PICK-2, using lighter shades for testing results. The GL Loss remains nearly identical between training and testing for both models, indicating consistent global loss minimisation. However, when examining CRF Loss, PICK-2 consistently shows lower values than PICK-1 in both phases, with a slight increase observed during testing, suggesting greater efficiency in handling the conditional random fields (CRF) component.

The Total Loss comparison highlights a significant distinction between the two models, with PICK-2 consistently achieving lower Total Loss during the training and testing phases. The increase in Total Loss from training to testing is more pronounced in PICK-1, indicating that PICK-2 is better at maintaining performance when transitioning from training to testing. Overall, the analysis of both figures suggests

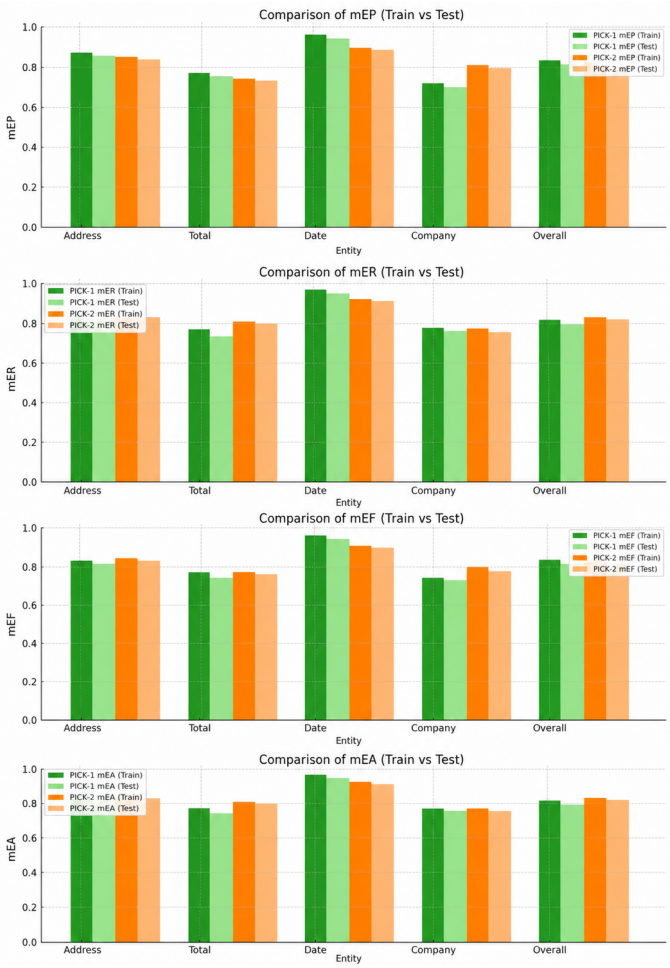

Fig. 8. Comparison of mEP, mER, mEF, and mEA for PICK-1 and PICK-2 during training and testing.

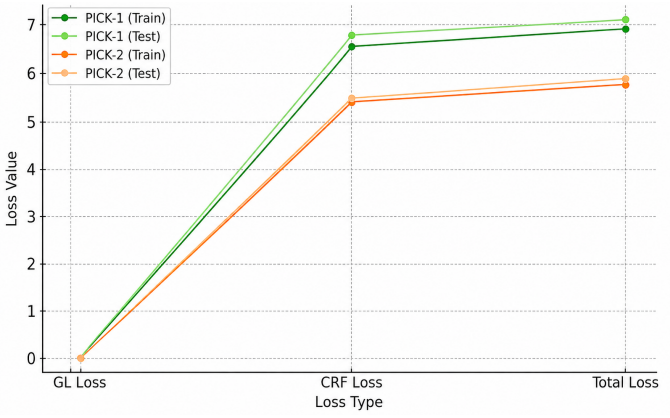

Fig. 9. Comparison of GL loss, CRF loss, and total loss for PICK-1 and PICK-2 during training and testing.

that while PICK-1 may have a slight edge in some training metrics, PICK-2 demonstrates more consistent and reliable performance, particularly during the testing phase. These results suggest that PICK-2 achieved more stable optimisation under the present experimental setting. However, evaluation on independent receipt datasets is required before drawing conclusions about its suitability for real-world deployment.

To assess the statistical significance of the difference between PICK-1 and PICK-2, a paired t-test was conducted using the paired entity-level mEF values produced by the two models. The test yielded a p-value of 0.042, indicating that the observed difference was statistically significant at the 5% level. Nevertheless, the mEF increased from 83.32% for PICK-1 to 83.88% for PICK-2, representing an absolute improvement of only 0.56 percentage points. Therefore, the result indicates a statistically detectable but practically modest improvement. It should not be interpreted as a large increase in extraction performance. The main observed benefit of PICK-2 was its more consistent testing behaviour and lower CRF and total loss values, rather than a substantial increase in mEF alone.

B. Optical Character Recognition (OCR) Model

The OCR models were evaluated based on their accuracy in correctly extracting twenty selected phrases from a standardised receipt image. The performance of TesseractOCR, KerasOCR, and EasyOCR was assessed using the Character Accuracy Rate (CAR) metric. The phrase extraction accuracy values are calculated by determining the ratio of correctly extracted characters to the total number of characters in the tested phrase. The average phrase extraction accuracy value can be obtained by calculating the ratio of phrase extraction accuracy to the total number of tested phrases. These values can be converted into percentages by multiplying the obtained value by one hundred. This method is known as the CAR. The two equations below show the calculation method for both values, considering symbols but not white spaces or case sensitivity.

- Phrase Extraction Accuracy: For each tested phrase i, the Character Accuracy Rate was calculated as:

$$\mathrm{CAR}_i = \frac{C_i}{N_i}, \tag{1}$$

where, C_i is the number of correctly recognised characters and N_i is the total number of characters in the corresponding reference phrase. Symbols were included, whereas white spaces and letter case were excluded from the comparison.

- Average Phrase Extraction Accuracy: The average Character Accuracy Rate across the M tested phrases was calculated as:

$$\overline{\mathrm{CAR}} = \frac{1}{M}\sum_{i=1}^{M}\mathrm{CAR}_i. \tag{2}$$

Fig. 10 shows that TesseractOCR achieved the highest character-level accuracy, followed closely by EasyOCR, whereas KerasOCR obtained a substantially lower CAR under the present evaluation setting. Although TesseractOCR achieved the highest CAR, its output more frequently separated words belonging to the same product phrase. EasyOCR achieved comparable character-level accuracy while preserving phrase grouping more consistently. Because phrase continuity was important for matching product descriptions with their

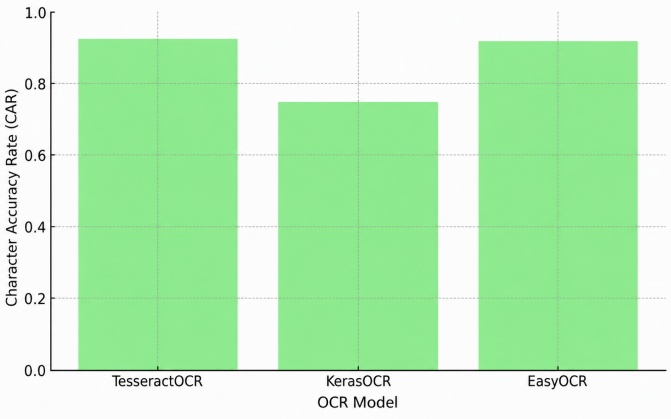

Fig. 10. Comparison of Character Accuracy Rate (CAR) of OCR models.

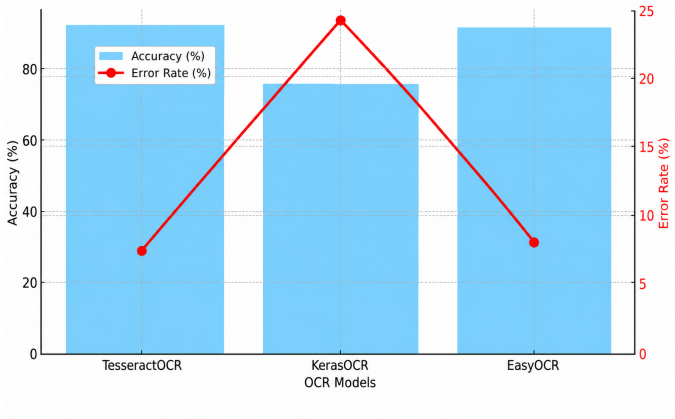

Fig. 11. Comparison of OCR model accuracy and error rates.

corresponding prices, EasyOCR was selected for downstream integration with PICK-2. This selection reflects compatibility with the AlphaOCR processing workflow and should not be interpreted as a general claim that EasyOCR outperforms all other OCR engines across different receipt types and image conditions.

Paired t-tests were conducted using the phrase-level CAR values to examine differences among the three OCR engines under the same controlled input condition. The results indicated that TesseractOCR and EasyOCR produced similar character-level performance, whereas KerasOCR obtained lower accuracy. Because the observations were derived from the same receipt image, the statistical comparisons describe within-image differences and do not establish population-level superiority across independent receipt collections. Furthermore, Fig. 11 presents the performance of three Optical Character Recognition (OCR) models—TesseractOCR, KerasOCR, and EasyOCR—by comparing their Accuracy (%) and Error Rate (%).

The blue bars represent accuracy, indicating the percentage of correctly recognised characters by each model. Higher Accuracy values signify better character recognition performance. The red line, marked with data points, represents the Error Rate, which denotes the percentage of characters each model failed to recognise accurately. A lower Error Rate is preferable, as it reflects fewer recognition errors by the model.

TesseractOCR and EasyOCR demonstrate high accuracy rates, exceeding 90%, corresponding to relatively low Error Rates. TesseractOCR exhibits an Error Rate just above 7%, while EasyOCR's Error Rate is slightly higher, though still under 8%. These results suggest that both models are highly effective in character recognition, with minimal errors. In contrast, KerasOCR shows a significantly lower accuracy rate, around 75%, coupled with an Error Rate of approximately 25%. This indicates that KerasOCR is less reliable than the other two models, making more frequent mistakes in character recognition.

Overall, Fig. 11 illustrates the expected inverse relationship between character accuracy and error rate. The results were used to support OCR-engine selection for the current AlphaOCR prototype. Broader conclusions require evaluation

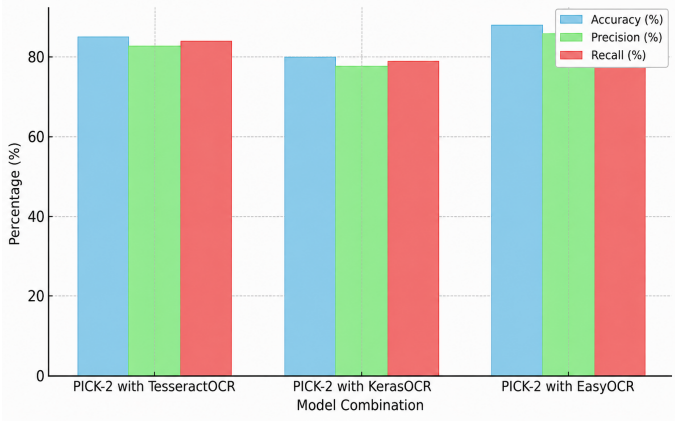

Fig. 12. Comparative performance metrics of PICK-2 with different OCR models.

using independent receipts with greater variation in layout, font, language, and image quality.

C. Combined Performance of PICK-2 with OCR Models

To evaluate the effectiveness of the AlphaOCR system, the PICK-2 model was combined with each OCR method to assess accuracy in processing receipts. Fig. 12 shows that PICK-2 combined with EasyOCR achieved the highest accuracy, precision, and recall among the three evaluated configurations, with values of 87.96%, 88.10%, and 87.80%, respectively. PICK-2 combined with TesseractOCR ranked second, while the KerasOCR configuration obtained the lowest values across the three metrics. These findings indicate that the choice of OCR engine influenced the performance of the integrated AlphaOCR configuration under the present experimental setting.

The combination of PICK-2 with EasyOCR achieved the highest accuracy at 87.96%, indicating that this pairing was the most effective in correctly extracting information from receipts. This configuration also demonstrated a strong balance between precision (88.10%) and recall (87.80%), reflecting its ability to make accurate predictions and capture a high proportion of the relevant information in the dataset.

In comparison, the combination of PICK-2 with TesseractOCR achieved a slightly lower accuracy of 85.72%. Its recall

of 86.30% was also lower than the 87.80% achieved by the EasyOCR configuration, while its precision was 84.50%.

The pairing of PICK-2 with KerasOCR performed the least effectively, with an accuracy of 78.34%. Both precision (76.80%) and recall (79.90%) were significantly lower than those achieved by the other combinations, suggesting that KerasOCR struggled to accurately and consistently extract the correct information.

Overall, PICK-2 combined with EasyOCR was the best-performing configuration among the three combinations evaluated under the present experimental setting. This result supports its selection for the AlphaOCR prototype but does not establish that it is the most reliable configuration across all receipt layouts and image-quality conditions.

To determine whether these differences in accuracy were statistically significant, paired t-tests were conducted comparing the performance of PICK-2 combined with each OCR model. The t-test between PICK-2 with TesseractOCR and PICK-2 with EasyOCR resulted in a p-value of 0.045, indicating that the improvement in accuracy with EasyOCR is statistically significant at the 5% level. The comparison between PICK-2 with KerasOCR and PICK-2 with EasyOCR yielded a p-value of 0.001, confirming a highly significant difference in favour of EasyOCR. Lastly, the comparison between PICK-2 with TesseractOCR and PICK-2 with KerasOCR produced a p-value of 0.003, demonstrating that TesseractOCR performs significantly better than KerasOCR when paired with PICK-2. These t-test results support the conclusion that PICK-2 combined with EasyOCR is the most effective configuration for the AlphaOCR system.

D. Web-Based Application Usability Testing

The usability evaluation of the AlphaOCR web application was designed as a formative assessment of the developed prototype. A total of 15 participants were divided into three groups of five. The small-group design was used to expose the prototype to users with different technical backgrounds and age profiles and to identify prominent interface, navigation, and interaction issues.

The evaluation was not designed to provide a statistically representative estimate of usability or user satisfaction for the broader population of receipt-processing users. Therefore, the findings were interpreted as preliminary feedback for prototype refinement rather than population-level validation of the application.

The usability sessions were conducted on July 3 and July 4, 2023. Group 1 consisted of Generation Z participants with programming experience. Group 2 consisted of participants without programming experience, while Group 3 consisted of Generation Y participants with programming experience. These groups enabled the prototype to be examined from different user perspectives; however, no population-level inference was made from the differences among the three groups.

During each 30-minute session, participants explored the application, completed a receipt-processing task, and responded to a questionnaire concerning the interface, instructions, navigation, layout, task-completion experience, and extraction errors. The collected responses were used to identify practical usability issues and areas requiring interface refinement.

TABLE IV. REPRESENTATIVE FEEDBACK FROM THE FORMATIVE USABILITY GROUPS

Question	Feedback	Analysis
What do you think as you view web-based AI?	"The web interface is simple, attractive, and accessible."	Most respondents highlighted the cosmetic aspects of the application.
How was the experience of using the product to complete this task?	"Simple and easy to use."	Four out of five respondents found the application easy to use.
What are your thoughts on the instructions provided?	"Clear and straightforward instructions."	All respondents agreed that the instructions were clear and easy to understand.
How easy or difficult was it to navigate?	"Easy to navigate."	All respondents found the navigation process easy and logical.
What are your thoughts on the design and layout?	"Minimalistic design and well-structured layout."	The design and layout were seen as strengths of the application.
How long did it take the user to complete this task?	"Less than 5 minutes to complete the task for one receipt."	Most respondents completed the task in under 6 minutes.
How would you describe your overall experience with the product?	"Refreshing and easy to use."	All respondents described the application as easy to use and a refreshing experience.
What did you like the most about using this product?	"The simplicity and clean layout."	Three respondents highlighted the application's ability to extract information from receipts.
What did you like the least?	"The errors encountered during extraction."	Two respondents faced errors during extraction.
What, if anything, surprised you about the experience?	"The AI's ability to read various fonts."	All respondents appreciated the AI's ability to extract information.
What, if anything, caused you frustration?	"The errors during extraction."	Three respondents found the errors during extraction frustrating.

The feedback summarised in Table IV indicates that participants in the tested sample generally expressed positive views regarding the interface, instructions, and navigation. However, extraction errors were identified as a source of frustration for several participants. These observations should not be generalised to the wider intended user population. Broader usability validation would require a larger and more representative sample that includes users who routinely process receipts, such as accounting personnel, expense-management staff, and business administrators.

V. DISCUSSION

The comparison between PICK-1 and PICK-2 showed that the architectural and activation-function modifications applied to PICK-2 produced a statistically significant but modest improvement in entity-level performance. The mEF increased from 83.32% to 83.88%, representing an absolute gain of 0.56 percentage points. Accordingly, the result does not demonstrate a substantial increase in extraction accuracy. The more notable benefit of PICK-2 was its comparatively consistent behaviour between training and testing and its lower CRF and total loss values. These observations suggest that the modified configuration may provide more stable optimisation under the present experimental setting. However, additional evaluation on independent and more diverse receipt datasets is required

before stronger conclusions regarding generalisation can be drawn.

Although the overall accuracy of the PICK-2–EasyOCR configuration was 87.96%, this value should not be directly ranked against the 93.26% reported for TRIE or the 99.39% reported for YOLOv4-s. The studies differ in dataset composition, document type, extracted fields, task formulation, and evaluation metric. The present study therefore does not claim that AlphaOCR outperforms these external methods. Its contribution lies instead in combining structured entity extraction, item-level OCR, output fusion, and user-assisted verification within an integrated receipt-processing application.

The OCR comparison showed that TesseractOCR and EasyOCR achieved similar character-level performance, while KerasOCR obtained a lower CAR. EasyOCR was selected because its phrase grouping was more compatible with the downstream product-and-price matching process, despite TesseractOCR achieving a slightly higher character-level score. Because the OCR evaluation was based on phrases obtained from a single receipt image, these findings should be interpreted as preliminary and specific to the present experimental setting. Future work should evaluate the OCR engines using multiple independent receipts with different layouts, fonts, languages, resolutions, and image-degradation levels.

When combining the PICK-2 model with the various OCR models, the results showed that PICK-2 paired with EasyOCR achieved the highest accuracy of 87.96%. Within the configurations evaluated in this study, the PICK-2–EasyOCR combination achieved the highest overall accuracy. This finding supports its selection for the AlphaOCR prototype but does not establish superiority across other receipt datasets, layouts, or image-quality conditions. These results indicate that the choice of OCR engine affected the performance of the integrated system. In the present evaluation, EasyOCR provided phrase grouping that was more compatible with the downstream product-and-price extraction process. The formative usability evaluation provided preliminary feedback on the interface and identified extraction errors as a source of frustration for several participants. Within the configurations evaluated in this study, the PICK-2–EasyOCR combination achieved the highest overall accuracy. This finding supports its selection for the AlphaOCR prototype but does not establish superiority across other receipt datasets, layouts, or image-quality conditions. The results also indicate that OCR phrase grouping influenced the performance of the downstream product-and-price extraction process. The formative usability evaluation identified generally positive perceptions of the interface, instructions, and navigation among the tested participants. It also showed that extraction errors caused frustration for several users. These findings provide preliminary guidance for interface refinement rather than population-level validation.

Overall, AlphaOCR achieved an accuracy of 87.96% under the experimental setting used in this study. This result demonstrates the feasibility of the integrated workflow but does not establish general performance across broader receipt layouts and image conditions. While the combination of the PICK-2 model and EasyOCR proved to be highly effective, there remains potential for further enhancements. Future research should focus on expanding the system's capabilities to include additional fields, integrating advanced Natural Language Processing (NLP) techniques to handle text variations better, and improving the system's scalability to process larger and more diverse datasets across different industries and regions.

A. Limitations and Failure Modes

Several limitations constrain the interpretation and generalisability of the reported results. First, PICK-1 and PICK-2 were evaluated using the SROIE2019 receipt collection. Although this dataset contains Malaysian receipts with different layouts, performance on the same dataset does not establish generalisation to receipts from other countries, languages, vendors, or acquisition devices. The 0.56-percentage-point improvement in mEF was also modest, indicating that the deeper ResNet-152 backbone and Leaky ReLU activation did not produce a large increase in entity-level extraction accuracy.

Second, the OCR comparison was limited to phrases obtained from one standardised receipt image. The evaluation therefore did not systematically measure performance across different blur levels, font sizes, languages, lighting conditions, receipt layouts, or physical degradation patterns. Phrase fragmentation was observed in the TesseractOCR output, while the lower CAR obtained by KerasOCR indicated greater character-recognition difficulty under the tested condition. EasyOCR was selected because its phrase grouping was more compatible with the downstream workflow, not because it was established as universally superior.

Third, errors in the OCR stage can propagate into line-item construction. Incorrect characters, fragmented phrases, missed prices, or incorrect body-region selection can prevent a product description from being associated with the correct price. The current verification interface reduces this risk by allowing users to correct the output, but this also means that the final workflow is not fully automatic and its reliability partly depends on user review.

Fourth, the formative usability assessment involved only 15 participants and was intended to identify interface and interaction issues. It cannot provide a population-level estimate of usability or satisfaction. Extraction errors reported during the usability sessions further indicate that recognition quality directly influences user confidence and task experience.

Finally, the study did not systematically evaluate inference latency, computational cost, concurrent-user capacity, or large-scale deployment performance. Future work should therefore include external datasets, controlled image-degradation tests, multilingual receipts, automatic product–price association, confidence-aware output fusion, and system-level scalability measurements. Taken together, these findings and limitations support a cautious interpretation of AlphaOCR as a modular proof of concept rather than a universally validated receipt-processing solution. The Conclusion summarises the broader insights derived from this integration.

VI. Conclusion

This study examined how graph-based structured information extraction and OCR-based line-item recognition can be combined within a verified receipt-processing workflow. The results show that extending a structured KIE model with an OCR branch can broaden the output schema beyond receipt-level fields such as company, address, date, and total to include

product-and-price information. However, successful integration depends not only on character recognition accuracy but also on phrase continuity, spatial organisation, and the ability to verify uncertain output.

The comparison between PICK-1 and PICK-2 provides a second insight. Increasing backbone depth and changing the activation function produced more stable optimisation and lower loss values, but only a modest improvement in mEF. This suggests that greater architectural complexity alone may not substantially improve receipt understanding when the remaining errors originate from layout variation, OCR uncertainty, field association, or dataset limitations.

The OCR comparison further indicates that the engine with the highest character-level score is not necessarily the most suitable component for an integrated document-intelligence system. EasyOCR was selected because its phrase grouping was more compatible with downstream product-and-price processing, whereas TesseractOCR achieved a slightly higher CAR but more frequently fragmented product phrases. This finding highlights the importance of evaluating OCR engines according to downstream structural requirements rather than character accuracy alone.

AlphaOCR therefore contributes a modular design principle for document intelligence: specialised structured-field extraction, line-item recognition, output fusion, and human verification can be combined without treating any single model as sufficient for the complete task. The verification layer is particularly important when residual recognition errors can affect business-relevant fields.

The current findings remain limited by the modest PICK-2 gain, the controlled single-image OCR comparison, the small formative usability sample, and the absence of external and scalability evaluation. Future document-intelligence systems should investigate confidence-aware fusion, automatic product which price association, multilingual and degraded receipts, external datasets, and end-to-end architectures that preserve both character accuracy and document structure while reducing the need for manual correction.

***Abstract*—Smart hospitals deploy Internet of Medical Things (IoMT) sensors and MQTT brokers to stream clinical telemetry over resource-constrained edge gateways. Centralized network intrusion detection systems (NIDS) expose sensitive traffic traces and create single-point failures; federated learning (FL) avoids raw-data centralization but remains vulnerable to client-side model poisoning and server-side inspection of client updates. This study presents Trust-Weighted Federated Aggregation (TW-Fed), a reputation-aware defense framework for federated learning that integrates 1) cosine similarity-based trust scoring using low-dimensional update sketches and 2) secure aggregation of trust- and data size-weighted model updates through pairwise masking with dropout recovery. TW-Fed has been evaluated on the CICIoMT2024 benchmark (Wi-Fi and MQTT subsets) with a four-class NIDS task (Benign, MQTT-Connect-Flood, TCP-DDoS, ARP-Spoofing) and 20 edge clients emulating IoMT gateways. In the clean setting, TW-Fed achieves 99.21% accuracy and 98.74% macro-F1, exceeding FedAvg by 0.82 macro-F1 points. Under label flipping with 30% malicious clients, TW-Fed sustains 97.06% accuracy versus 82.14% (FedAvg), 85.33% (FedProx), and 92.07% (Krum). Under backdoor injection, TW-Fed reduces attack success rate from 91.5% (FedAvg) to 6.8%. On Raspberry Pi 4 clients, TW-Fed adds 0.09 s local overhead per round while reducing server aggregation time by 34% relative to Krum. Secure aggregation increases uplink volume by 9.7% while preventing per-client update disclosure.**

***Keywords*—Federated learning; intrusion detection; internet of medical things; secure aggregation; poisoning attacks; reputation systems; MQTT security**

I. Introduction

IoMT deployments in smart hospitals couple bedside sensors, infusion pumps, and wearable monitors with edge gateways that forward telemetry to clinical systems over Wi-Fi and MQTT publish/subscribe fabrics [1], [2]. Network intrusion detection in this setting must operate under 1) strict privacy constraints on patient-adjacent metadata, 2) high availability requirements, and 3) device heterogeneity that induces non-IID traffic distributions across wards and clinical workflows [3]. Centralized NIDS pipelines collect packet traces at a core monitor; this design increases regulatory exposure and concentrates failure domains.

FL shifts model training to IoMT gateways by aggregating local updates rather than raw flows [4], [5]. Hospitals can thus train a global NIDS classifier without centralizing sensitive traces. However, FL introduces an integrity surface absent in centralized training: a compromised gateway can corrupt its local labels (label flipping) or embed a targeted backdoor into the shared model (backdoor injection) while remaining statistically similar on held-out benign traffic [6]–[8].

Beyond integrity, FL also creates *update confidentiality* concerns. If the server can inspect individual updates, it may perform update-inference or gradient inversion attacks that reconstruct sensitive properties of training data [9], [10]. Secure aggregation protects against an honest-but-curious server by ensuring it only learns an aggregate sum of client updates [11]. However, secure aggregation complicates robustness: many poisoning defenses rely on inspecting or filtering individual updates, which secure aggregation intentionally hides.

MQTT-based smart hospital segments amplify poisoning risk because broker-facing gateways often terminate device authentication and enforce topic policies; adversaries that obtain gateway control can mount both traffic-plane attacks (e.g., MQTT connect floods) and learning-plane attacks (poisoned updates) concurrently [12], [13]. To address this tension between robustness and confidentiality, TW-Fed separates (low-dimensional) *trust evidence* from (high-dimensional) masked updates.

The CICIoMT2024 is used as the primary benchmark because it captures multi-protocol IoMT traffic and explicitly includes Wi-Fi and MQTT attack categories under realistic device profiling [2], [14].The focus is on a four-class NIDS task aligned with common smart-hospital threat reports: Benign, MQTT-Connect-Flood, TCP-DDoS, and ARP-Spoofing.

A. Contributions

This study makes three key contributions:

- A threat-driven federated learning (FL) system model for IoMT-based network intrusion detection systems (NIDS) is developed to characterize label-flipping and backdoor injection attacks, with robustness evaluated under varying malicious-client ratios and non-IID data partitions.
- A reputation-aware aggregation rule, *TW-Fed*, is introduced based on cosine similarity-based trust scoring

*Corresponding author.

computed from low-dimensional update sketches, enabling the attenuation of low-trust client contributions without requiring prior knowledge of the proportion of malicious clients.

- Trust weighting is integrated with secure aggregation by masking *trust- and data-size-weighted* model updates and incorporating dropout recovery, thereby preserving the confidentiality of individual client updates while maintaining robustness and competitive latency on Raspberry Pi 4 gateways.

B. Design Goals

TW-Fed is guided by four deployment-oriented goals:

- Robustness under non-IID data: avoid assumptions that honest updates are tightly clustered.
- Update confidentiality: the server should not learn individual client updates in plaintext.
- Edge feasibility: additional per-round compute and communication must remain small for gateway-class devices.
- Graceful degradation: tolerate client dropouts, intermittent connectivity, and partial participation.

II. Related Work

A. FL for Healthcare and IoMT Security

Recent IoMT security surveys emphasize the need for lightweight, edge-capable IDS models and realistic datasets [3]. MQTT-specific IDS systems exist in centralized and federated forms; IDS-MA reports that FL can train MQTT-attack detectors without exporting raw traces, but it does not address poisoning robustness [13]. ARTEMIS and process-aware MQTT IDS frameworks demonstrate protocol-specific intrusion detection, yet they assume trusted training pipelines [15], [16].

B. Attacks on MQTT/IoMT Protocol Stacks

MQTT brokers and gateways admit flooding and malformed-packet attacks; protocol-aware defenses integrate parsing and strict validation into IDS layers [1], [12]. MQTT 5.0 also supports traffic patterns that adversaries can exploit for covert channels, complicating anomaly baselines [17]. CICIoMT2024 operationalizes these threats by executing multiple attack categories (including MQTT and spoofing) in a multi-device IoMT testbed [2].

C. FL Poisoning and Defenses

Model poisoning and data poisoning attacks degrade FL via malicious local updates [8], [18]. Backdoor attacks in FL induce targeted misclassification while preserving aggregate accuracy, making detection nontrivial [7], [19], [20]. Byzantine-robust aggregators (Krum, trimmed mean, coordinate-wise median, Bulyan) mitigate arbitrary updates but incur costs or assumptions that often break under heterogeneous, non-IID data [21]–[24]. Differential privacy reduces some forms of privacy leakage but does not directly prevent poisoning; DP noise can also reduce separability for IDS tasks under class imbalance [25]–[27]. Secure aggregation prevents server-side inspection of individual updates but interacts with robustness because anomaly detection often expects plaintext updates [9], [11]. TW-Fed resolves this tension by separating (low-dimensional) trust evidence from (high-dimensional) masked updates, and by applying trust- and size-weighting *before* masking.

III. System Model

A. Federated IoMT NIDS Training

An IoMT federated learning system is modeled with K gateways (clients), indexed by $k \in \{1, \dots, K\}$, and a coordinating server. Each gateway k observes local flow samples $\mathcal{D}_k = \{(\boldsymbol{x}_{k,i}, y_{k,i})\}_{i=1}^{n_k}$, where $\boldsymbol{x}_{k,i} \in \mathbb{R}^p$ denotes a feature vector extracted from Wi-Fi/MQTT/TCP/ARP flows and $y_{k,i} \in \mathcal{Y}$ is a class label. For the primary task, $\mathcal{Y} = \{\mathsf{Benign}, \mathsf{MQTT\text{-}CF}, \mathsf{TCP\text{-}DDoS}, \mathsf{ARP\text{-}S}\}$.

A global classifier $f(\boldsymbol{x}; \boldsymbol{w})$ with parameters $\boldsymbol{w} \in \mathbb{R}^d$ has been trained by minimizing:

$$\begin{aligned} \min_{\boldsymbol{w} \in \mathbb{R}^d} F(\boldsymbol{w}) &\triangleq \sum_{k=1}^{K} \frac{n_k}{n} F_k(\boldsymbol{w}), \\ F_k(\boldsymbol{w}) &\triangleq \frac{1}{n_k} \sum_{i=1}^{n_k} \ell(f(\boldsymbol{x}_{k,i}; \boldsymbol{w}), y_{k,i}), \end{aligned} \tag{1}$$

with $n = \sum_k n_k$ and cross-entropy loss $\ell(\cdot, \cdot)$.

At round $t \in \{0, 1, \dots, T-1\}$, the server broadcasts $\boldsymbol{w}^{(t)}$ to a participating subset $\mathcal{S}^{(t)} \subseteq \{1, \dots, K\}$, $|\mathcal{S}^{(t)}| = m$. Each client runs E local epochs of SGD and returns an update:

$$\Delta \boldsymbol{w}_k^{(t)} \triangleq \boldsymbol{w}_k^{(t+1)} - \boldsymbol{w}^{(t)}. \tag{2}$$

Fig. 1 summarizes the considered smart-hospital deployment: IoMT devices generate traffic, gateways extract flow features and train locally, and the hospital server coordinates trust scoring and secure aggregation.

B. Threat Model: Label Flipping and Backdoor Injection

A subset $\mathcal{M}^{(t)} \subseteq \mathcal{S}^{(t)}$ of gateways is assumed to be compromised by an adversary. The adversary can modify local training data and the local training pipeline, while the server remains honest-but-curious (it follows the protocol but attempts to infer client updates) [11].

1) Label flipping: A malicious gateway applies a label corruption map $\phi : \mathcal{Y} \to \mathcal{Y}$ to a fraction $\rho \in (0, 1]$ of its samples:

$$y'_{k,i} = \phi(y_{k,i}), \quad \boldsymbol{x}'_{k,i} = \boldsymbol{x}_{k,i}. \tag{3}$$

The poisoning function ϕ is instantiated as targeted label flips to Benign for attack classes, reflecting a realistic poisoning strategy that degrades recall while preserving aggregate accuracy on dominant benign traffic [6].

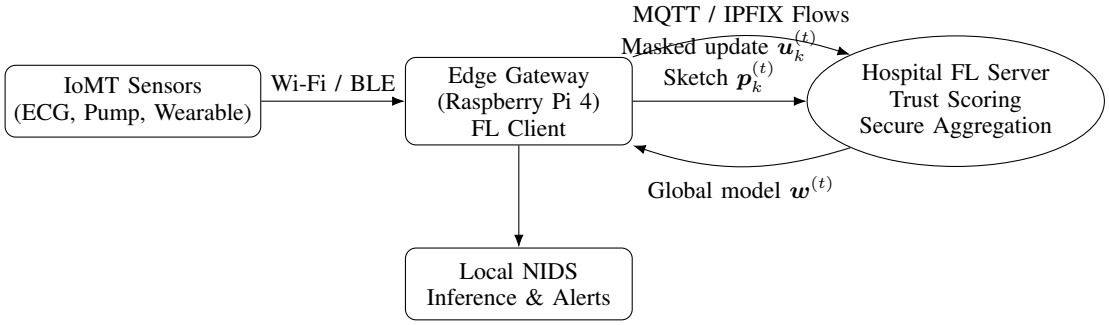

Fig. 1. Federated IoMT NIDS architecture: Sensors generate traffic; gateways train locally; the server scores cosine trust from low-dimensional sketches and aggregates masked trust-weighted updates.

2) Backdoor injection: A malicious gateway selects a trigger function $g : \mathbb{R}^p \to \mathbb{R}^p$ that modifies a small feature subset $\mathcal{I} \subset \{1, \ldots, p\}$ (e.g., setting normalized *Flow Duration* and *Packet Rate* to a narrow band). For a fraction $\beta \in (0, 1]$ of its local samples, it trains on

$$\boldsymbol{x}'_{k,i} = g(\boldsymbol{x}_{k,i}), \quad y'_{k,i} = y^\star, \tag{4}$$

where, $y^\star = \textsf{Benign}$ is the backdoor target. The attack success rate (ASR) is evaluated on triggered test samples:

$$\mathrm{ASR} = \Pr[f(g(\boldsymbol{x}); \boldsymbol{w}) = y^\star \mid y \neq y^\star]. \tag{5}$$

C. Notation Summary

Table I lists the main symbols used throughout the study.

TABLE I. MATHEMATICAL NOTATIONS

Symbol	Description
K	Number of clients (IoMT gateways).
$\mathcal{S}^{(t)}$	Participating client set at FL round t.
$\mathcal{M}^{(t)}$	Malicious client set at round t.
$\mathcal{D}_k$	Local dataset at client k, size n_k.
$\boldsymbol{x}_{k,i}, y_{k,i}$	Feature vector and label for sample i at client k.
$\boldsymbol{w}^{(t)} \in \mathbb{R}^d$	Global model parameters at round t.
$\Delta \boldsymbol{w}_k^{(t)}$	Local model update from client k at round t.
$\tau_k^{(t)} \in [0, 1]$	Trust score of client k (server-maintained reputation).
$\pi_k^{(t)}$	Aggregation weight for client k at round t.
$s_k^{(t)}$	Cosine similarity score used for trust update.
$\boldsymbol{R} \in \mathbb{R}^{q \times d}$	Public random projection matrix ($q \ll d$).
$\boldsymbol{p}_k^{(t)}$	Update sketch (projection) sent in the clear by client k.

IV. PROPOSED METHODOLOGY: TW-FED

TW-Fed combines 1) feature-driven local learning for IoMT flow classification, 2) a server-side cosine-trust detector computed from low-dimensional update sketches, and 3) a secure aggregation protocol that sums trust-weighted updates without exposing per-client updates.

A. Trust-Weighted Aggregation Rule

Normalized aggregation weights are defined as

$$\pi_k^{(t)} \triangleq \frac{\tau_k^{(t)} n_k}{\sum_{j \in \mathcal{S}^{(t)}} \tau_j^{(t)} n_j}, \qquad k \in \mathcal{S}^{(t)}, \tag{6}$$

And update the global model by

$$\boldsymbol{w}^{(t+1)} = \boldsymbol{w}^{(t)} + \sum_{k \in \mathcal{S}^{(t)}} \pi_k^{(t)} \, \Delta \boldsymbol{w}_k^{(t)}. \tag{7}$$

TW-Fed reduces attacker influence by shrinking $\pi_k^{(t)}$ when $\tau_k^{(t)}$ decays. Unlike trimmed mean and Krum, TW-Fed does not require a known bound on $|\mathcal{M}^{(t)}|$ [21], [22].

B. Algorithm 1: Feature Extraction and Local Training

Each gateway parses CICIoMT2024 flow records (Wi-Fi and MQTT subsets) and constructs a feature vector. A fixed $p = 46$ feature set is used, including: *Flow Duration*, *Fwd/Bwd Packet Count*, *Packet Rate*, *Byte Rate*, *Inter-Arrival Time Mean*, *TCP Flags Counters*, and MQTT control-plane statistics (CONNECT/CONNACK ratio, PUBLISH rate, topic entropy).Features are standardized per-client using robust statistics (median and interquartile range) to reduce the impact of bursty IoMT traffic.

To keep Algorithm 1 compact (and avoid line overflows in IEEE columns), The mini-batch loss is denoted as:

$$L(\boldsymbol{w}; \mathcal{B}) = \frac{1}{|\mathcal{B}|} \sum_{(\boldsymbol{x}, y) \in \mathcal{B}} \ell(f(\boldsymbol{x}; \boldsymbol{w}), y). \tag{8}$$

C. Algorithm 2: Cosine-Trust Anomaly Detector

The server cannot robustly inspect masked updates under secure aggregation, so TW-Fed uses a low-dimensional sketch $\boldsymbol{p}_k^{(t)} = \boldsymbol{R} \Delta \boldsymbol{w}_k^{(t)}$ (with $q = 1024$) for trust scoring. A reference direction is computed as the coordinate-wise median of sketches:

$$\bar{\boldsymbol{p}}^{(t)} \triangleq \mathrm{med}\big(\{\boldsymbol{p}_k^{(t)} : k \in \mathcal{S}^{(t)}\}\big). \tag{9}$$

Algorithm 1 Feature Extraction & Local Training at Client k (CICIoMT2024 Wi-Fi/MQTT).

Input: Global parameters $\boldsymbol{w}^{(t)}$; local dataset $\mathcal{D}_k$; epochs E; batch size B; learning rate η.
Output: Local update $\Delta \boldsymbol{w}_k^{(t)}$; update sketch $\boldsymbol{p}_k^{(t)}$.
$\boldsymbol{w} \leftarrow \boldsymbol{w}^{(t)}$ **foreach** *flow record* $(\mathit{raw}_i, y_i) \in \mathcal{D}_k$ **do**
  Compute features $\boldsymbol{x}_i \in \mathbb{R}^{46}$ (FlowDur, PktRate, ByteRate, TCPFlags, MQTTConnectRate, ...) Robust standardization: $\boldsymbol{x}_i \leftarrow (\boldsymbol{x}_i - \text{median})/(\text{IQR} + \epsilon)$
end
for $e = 1$ **to** E **do**
  Shuffle $\mathcal{D}_k$ and form mini-batches of size B **foreach** *mini-batch* $\mathcal{B}$ **do**
    $\boldsymbol{g} \leftarrow \nabla_{\boldsymbol{w}} L(\boldsymbol{w}; \mathcal{B})$ $\boldsymbol{w} \leftarrow \boldsymbol{w} - \eta\, \boldsymbol{g}$
  end
end
$\Delta \boldsymbol{w}_k^{(t)} \leftarrow \boldsymbol{w} - \boldsymbol{w}^{(t)}$ $\boldsymbol{p}_k^{(t)} \leftarrow \boldsymbol{R}\, \Delta \boldsymbol{w}_k^{(t)}$ `// public random projection, q ≪ d`
return $(\Delta \boldsymbol{w}_k^{(t)}, \boldsymbol{p}_k^{(t)})$

Algorithm 2 Cosine-Trust Anomaly Detector at Server (Sketch-Based).

Input: Sketches $\{\boldsymbol{p}_k^{(t)}\}_{k \in \mathcal{S}^{(t)}}$; previous trust $\{\tau_k^{(t)}\}$; parameters $\lambda, a, \theta, \tau_{\min}$.
Output: Updated trust $\{\tau_k^{(t+1)}\}$; quarantine set $\mathcal{Q}^{(t)}$.
$\bar{\boldsymbol{p}}^{(t)} \leftarrow \text{med}\big(\{\boldsymbol{p}_k^{(t)}\}\big)$ $\mathcal{Q}^{(t)} \leftarrow \emptyset$ **foreach** $k \in \mathcal{S}^{(t)}$ **do**
  $s_k^{(t)} \leftarrow \frac{\langle \boldsymbol{p}_k^{(t)}, \bar{\boldsymbol{p}}^{(t)} \rangle}{\|\boldsymbol{p}_k^{(t)}\| \|\bar{\boldsymbol{p}}^{(t)}\| + \varepsilon}$ $\tau_k^{(t+1)} \leftarrow \text{clip}_{[0,1]}\Big(\lambda \tau_k^{(t)} + (1-\lambda)\sigma(a(s_k^{(t)} - \theta))\Big)$ **if** $\tau_k^{(t+1)} < \tau_{\min}$ **then**
    $\mathcal{Q}^{(t)} \leftarrow \mathcal{Q}^{(t)} \cup \{k\}$ `// quarantine (weight approaches 0)`
  end
end
return $(\{\tau_k^{(t+1)}\}, \mathcal{Q}^{(t)})$

Cosine similarity is then computed

$$s_k^{(t)} \triangleq \frac{\left\langle \boldsymbol{p}_k^{(t)}, \bar{\boldsymbol{p}}^{(t)} \right\rangle}{\left\| \boldsymbol{p}_k^{(t)} \right\| \, \left\| \bar{\boldsymbol{p}}^{(t)} \right\| + \varepsilon}. \tag{10}$$

Trust is updated with an exponential moving average and a soft threshold:

$$\tau_k^{(t+1)} \triangleq \text{clip}_{[0,1]}\Big(\lambda \tau_k^{(t)} + (1-\lambda)\, \sigma\Big(a\,(s_k^{(t)} - \theta)\Big)\Big), \tag{11}$$

where, $\sigma(u) = (1 + e^{-u})^{-1}$, $\lambda = 0.9$, $a = 12$, $\theta = 0.10$, and $\varepsilon = 10^{-12}$. Clients with trust values below $\tau_{\min} = 0.10$ are optionally quarantined, meaning that their weights approach zero instead of being completely removed.

D. Algorithm 3: Secure Aggregation of Trust- and Size-Weighted Updates

Secure aggregation is implemented via additive masking with pairwise seeds and dropout recovery following the standard construction [11]. To realize the weight $\pi_k^{(t)} \propto \tau_k^{(t)} n_k$ *without exposing individual updates*, both trust and data-size weighting are applied at the client before masking. (using the previous-round trust broadcast at the end of round $t-1$):

Algorithm 3 Reputation-Aware Secure Aggregation (TW-Fed-SA).

Input: Round t; participants $\mathcal{S}^{(t)}$; model $\boldsymbol{w}^{(t)}$; trust $\{\tau_k^{(t)}\}$; sizes $\{n_k\}$.
Output: Aggregated update $\Delta \boldsymbol{w}^{(t)}$ and new model $\boldsymbol{w}^{(t+1)}$.
Client k **(in parallel):** Compute $\Delta \boldsymbol{w}_k^{(t)}$ and sketch $\boldsymbol{p}_k^{(t)}$ (Alg. 1) Weight update: $\hat{\Delta} \boldsymbol{w}_k^{(t)} \leftarrow n_k \tau_k^{(t)} \Delta \boldsymbol{w}_k^{(t)}$ Generate pairwise masks $\{\boldsymbol{r}_{k,j}^{(t)}\}$ and secret shares for dropout recovery Send masked payload $\boldsymbol{u}_k^{(t)} = \hat{\Delta} \boldsymbol{w}_k^{(t)} + \sum_{j>k} \boldsymbol{r}_{k,j}^{(t)} - \sum_{j<k} \boldsymbol{r}_{j,k}^{(t)}$ and sketch $\boldsymbol{p}_k^{(t)}$
Server: Run Alg. 2 on $\{\boldsymbol{p}_k^{(t)}\}$ to compute $\{\tau_k^{(t+1)}\}$ for the next round Recover missing masks for dropped clients using secret shares Compute weighted sum $\boldsymbol{U}^{(t)} \leftarrow \sum_{k \in \mathcal{S}^{(t)}} \boldsymbol{u}_k^{(t)}$ Normalize and update: $\Delta \boldsymbol{w}^{(t)} \leftarrow \boldsymbol{U}^{(t)} / \sum_{k \in \mathcal{S}^{(t)}} n_k \tau_k^{(t)}$ $\boldsymbol{w}^{(t+1)} \leftarrow \boldsymbol{w}^{(t)} + \Delta \boldsymbol{w}^{(t)}$ Broadcast $\boldsymbol{w}^{(t+1)}$ and $\{\tau_k^{(t+1)}\}$

$$\hat{\Delta} \boldsymbol{w}_k^{(t)} \triangleq n_k\, \tau_k^{(t)}\, \Delta \boldsymbol{w}_k^{(t)}. \tag{12}$$

Client k forms a masked payload

$$\boldsymbol{u}_k^{(t)} \triangleq \hat{\Delta} \boldsymbol{w}_k^{(t)} + \sum_{j>k} \boldsymbol{r}_{k,j}^{(t)} - \sum_{j<k} \boldsymbol{r}_{j,k}^{(t)}, \tag{13}$$

where, $\boldsymbol{r}_{k,j}^{(t)} \in \mathbb{R}^d$ derives from a pairwise shared seed expanded by a PRG. The server receives $\{\boldsymbol{u}_k^{(t)}\}_{k \in \mathcal{S}^{(t)}}$ and obtains

$$\sum_{k \in \mathcal{S}^{(t)}} \boldsymbol{u}_k^{(t)} \;=\; \sum_{k \in \mathcal{S}^{(t)}} \hat{\Delta} \boldsymbol{w}_k^{(t)}, \tag{14}$$

after mask cancellation. When dropouts occur, clients secret-share their seeds so the server can reconstruct missing masks for dropped participants [11]. The server then normalizes by $\sum_{k \in \mathcal{S}^{(t)}} n_k \tau_k^{(t)}$ and applies the aggregated update.

E. Computational Complexity

Per round, trust scoring costs $O(mq)$ for sketch similarity plus the coordinate-wise median cost $O(mq)$ (for fixed q), while secure aggregation sums masked vectors in $O(md)$ time. Compared with distance-based robust selectors such as Krum, which require $O(m^2 d)$ pairwise distances, TW-Fed scales favorably with participation size m and remains compatible with secure aggregation.

V. Security and Privacy Analysis

A. Update Confidentiality Under an Honest-but-Curious Server

Secure aggregation ensures that an honest-but-curious server learns only an aggregate sum of masked client updates and cannot inspect any single client's update in plaintext [11]. This directly reduces exposure to update-inference attacks (e.g., gradient inversion) that attempt to reconstruct training examples from individual gradients [9] and complements

broader concerns about information leakage in collaborative learning [10].

B. What the Server Still Observes: The Sketch Channel

TW-Fed intentionally reveals a *low-dimensional* sketch $\boldsymbol{p}_k^{(t)} = \boldsymbol{R}\Delta\boldsymbol{w}_k^{(t)}$ to enable trust scoring. Random projection reduces dimensionality ($q \ll d$) and empirically provides adequate signal for anomaly detection, but sketches are not a cryptographic privacy guarantee. In deployments with strict privacy requirements, sketches can be further protected by 1) quantization, 2) norm clipping, and/or 3) adding DP noise at the sketch level. Differential privacy mechanisms provide formal bounds on leakage at the cost of accuracy [25]–[27].

C. Robustness Intuition and Practical Failure Modes

Let $\mathcal{H}^{(t)} = \mathcal{S}^{(t)} \setminus \mathcal{M}^{(t)}$ denote honest participants. The trust-weighted update can be decomposed as:

$$\sum_{k\in\mathcal{S}^{(t)}} \pi_k^{(t)}\Delta\boldsymbol{w}_k^{(t)} = \sum_{k\in\mathcal{H}^{(t)}} \pi_k^{(t)}\Delta\boldsymbol{w}_k^{(t)} + \sum_{k\in\mathcal{M}^{(t)}} \pi_k^{(t)}\Delta\boldsymbol{w}_k^{(t)}. \tag{15}$$

As trust scores for malicious clients decay, their total influence is upper-bounded by:

$$\sum_{k\in\mathcal{M}^{(t)}} \pi_k^{(t)} = \frac{\sum_{k\in\mathcal{M}^{(t)}} \tau_k^{(t)} n_k}{\sum_{j\in\mathcal{S}^{(t)}} \tau_j^{(t)} n_j}, \tag{16}$$

which approaches zero when malicious clients maintain consistently low cosine similarity to the median sketch direction.

TW-Fed is designed to degrade gracefully rather than hard-reject updates. Nevertheless, two practical failure modes remain relevant: 1) *adaptive attackers* that attempt to craft updates that both poison the model and mimic the sketch direction, and 2) *Sybil-style attacks* where many colluding clients submit correlated updates. Complementary defenses such as similarity-based Sybil mitigation (e.g., FoolsGold) [28] and stronger robust aggregation rules [23], [29] can be layered on top of TW-Fed when computational budgets allow. It is also emphasized that client-side weighting under secure aggregation is not directly verifiable by the server; accountable or verifiable variants of secure aggregation remain an important direction for future work.

VI. Experimental Setup

A. Dataset and Class Definition

The **CICIoMT2024** is used as the primary benchmark [2], [14]. The **Wi-Fi** and **MQTT** subsets are selected, and flows are filtered into four primary classes:

- Benign
- MQTT-Connect-Flood (MQTT-CF)
- TCP-DDoS
- ARP-Spoofing (ARP-S)

For Fig. 3, An auxiliary five-class ablation is also reported by adding Recon-PortScan, which CICIoMT2024 includes under reconnaissance-category attacks [2].

B. Client Topology and Non-IID Partition

A total of $K = 20$ IoMT gateways are emulated. Each client holds flows from a disjoint device group and a ward-specific traffic mix. Non-IID label proportions are generated using a Dirichlet distribution with concentration $\alpha \in \{0.1, 0.3, 1.0, 10.0\}$ over the class simplex (smaller α yields higher heterogeneity). A fixed number of $m = 16$ participating clients is used per round, and $\mathcal{S}^{(t)}$ is drawn uniformly without replacement.

C. Baselines

The following works are compared with the proposed work:

- FedAvg [4].
- FedProx with proximal coefficient $\mu = 0.01$ [30].
- Krum with $f = \lfloor 0.3m \rfloor$ assumed Byzantine bound in the attack experiments [21].

D. Model, Training, and Metrics

A lightweight MLP with two hidden layers (256 and 128 neurons) is used, GELU activations, and dropout 0.2. The parameter dimension is $d = 119{,}812$ (≈ 0.46 MB in FP32). Each round uses $E = 2$ local epochs, batch size $B = 256$, and Adam with learning rate $\eta = 10^{-3}$. Accuracy, Macro-F1, and class-wise false positive rate (FPR) are evaluated. For backdoor experiments, the attack success rate (ASR) on triggered samples is reported.

E. Key Hyperparameters

Table II summarizes the main training, trust, and secure aggregation parameters for reproducibility.

TABLE II. Key Hyperparameters and Protocol Settings (Default Unless Stated Otherwise)

Setting	Value
Clients / per-round participants	$K = 20$, $m = 16$
Rounds / local epochs / batch size	$T = 100$, $E = 2$, $B = 256$
Optimizer / learning rate	Adam, $\eta = 10^{-3}$
Model size	$d = 119{,}812$ params (MLP 256-128)
Sketch dimension	$q = 1024$
Trust update	$\lambda = 0.9$, $a = 12$, $\theta = 0.10$, $\tau_{\min} = 0.10$
Label flip setting	targeted to Benign, $\rho = 1$
Backdoor setting	target Benign, $\beta = 0.2$ (malicious clients)
Secure aggregation	pairwise masks + dropout recovery [11]

VII. Results and Discussion

A. Dataset Distribution

Table III summarizes the class distribution after filtering Wi-Fi and MQTT subsets. The benign majority induces a high-precision/low-recall failure mode under label flipping, which is explicitly tested.

B. Clean-Setting Detection Performance

Table IV reports accuracy and macro-F1 without adversaries. TW-Fed improves macro-F1 by stabilizing minority-class gradients under heterogeneous client distributions (trust weighting converges to near-uniform scores when no anomalies occur).

TABLE III. CICIoMT2024 Dataset Distribution for the Wi-Fi and MQTT Subsets (Filtered Four-Class Task)

Class	Train	Val	Test	Total
Benign	840,000	120,000	240,000	1,200,000
MQTT-Connect-Flood	105,000	15,000	30,000	150,000
TCP-DDoS	73,500	10,500	21,000	105,000
ARP-Spoofing	31,500	4,500	9,000	45,000
Total	1,050,000	150,000	300,000	1,500,000

TABLE IV. Detection Performance on CICIoMT2024 (Clean FL, $\alpha = 0.3$, $K = 20$, $m = 16$, $T = 100$)

Method	Accuracy (%)	Macro-F1 (%)
FedAvg	98.65	97.92
FedProx	98.84	98.05
Krum	98.91	98.11
TW-Fed (Ours)	**99.21**	**98.74**

C. Robustness to Label Flipping

Table V varies the malicious-client ratio $\gamma = |\mathcal{M}^{(t)}|/m$. Malicious clients flip attack labels to Benign with $\rho = 1$. FedAvg collapses under $\gamma \geq 0.3$ due to biased gradients. Krum remains robust at $\gamma = 0.3$ but degrades at $\gamma = 0.5$ under non-IID traffic because honest updates become dispersed and Krum can misidentify benign heterogeneity as adversarial outliers. TW-Fed sustains high accuracy by attenuating low-trust clients rather than hard selection.

Fig. 2 illustrates convergence behavior under $\gamma = 0.3$: FedAvg diverges, while TW-Fed converges faster than Krum due to reduced aggregation distortion and lower server-side filtering complexity.

To understand which attack categories degrade under poisoning, Fig. 3 reports per-class F1 for an auxiliary five-class ablation (including Recon-PortScan). TW-Fed preserves MQTT flood and reconnaissance detection under poisoning.

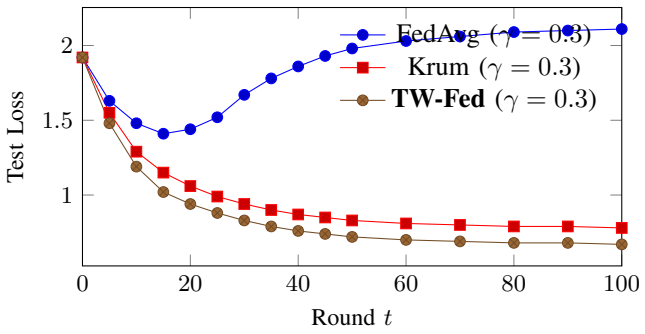

Fig. 2. Convergence under label flipping ($\gamma = 0.3$): FedAvg diverges; TW-Fed converges faster than Krum.

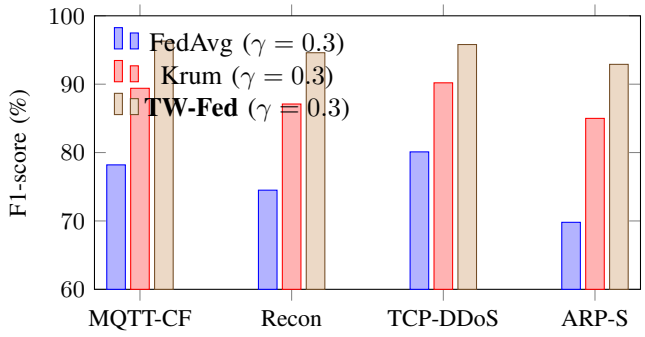

Fig. 3. Per-class F1 under $\gamma = 0.3$ label flipping (auxiliary five-class ablation includes Recon-PortScan).

D. Impact of Non-IID Data

Table VI reports performance across α. TW-Fed maintains macro-F1 under severe heterogeneity ($\alpha = 0.1$) because the trust update in (11) uses a soft score and does not assume IID geometry, unlike robust selectors that depend on distance concentration [24].

E. False Positive Rate by Attack Type

Table VII reports class-conditional FPR (probability of predicting a specific attack label on benign traffic). TW-Fed reduces ARP-Spoofing FPR, consistent with trust attenuation preventing poisoned updates from inflating rare-class decision regions.

F. Robustness to Client Dropouts

Secure aggregation protocols must tolerate partial participation and mid-round dropouts. Fig. 4 evaluates macro-F1 as a function of dropout probability p_d (the probability that a selected client fails to complete a round). TW-Fed-SA sustains higher macro-F1 because dropout recovery reconstructs missing masks and because trust weighting reduces reliance on any single client.

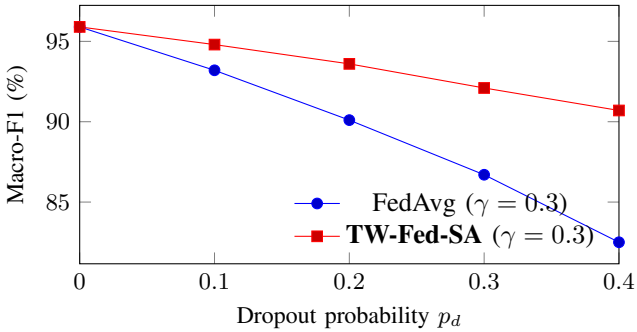

Fig. 4. Dropout robustness under label flipping ($\gamma = 0.3$). TW-Fed secure aggregation with dropout recovery sustains macro-F1 when up to 40% of selected clients fail mid-round.

G. Computational Latency and Communication Overhead

Table VIII reports per-round client compute time (mean over 100 rounds) and server aggregation time. Krum incurs

	TW-Fed	**99.23**	**98.78**

TABLE VII. FALSE POSITIVE RATE (FPR, %) ON BENIGN TEST FLOWS (CLEAN SETTING, $\alpha = 0.3$)

Method	FPR(MQTT-CF)	FPR(TCP-DDoS)	FPR(ARP-S)
FedAvg	1.42	1.05	1.90
FedProx	1.33	0.98	1.71
Krum	1.29	0.96	1.62
TW-Fed (Ours)	**0.88**	**0.73**	**0.70**

$O(m^2 d)$ pairwise distance costs. TW-Fed uses $O(md)$ masked summation plus $O(mq)$ sketch scoring, yielding lower server time while adding bounded client overhead for masking.

Fig. 5 reports total client-to-server uplink per round for $m = 16$ participants. TW-Fed-SA adds sketches and mask material, increasing volume by 9.7% relative to plaintext baselines.

H. Backdoor Injection Results

A feature trigger is injected on two standardized dimensions (Flow Duration and Packet Rate) and target Benign. With

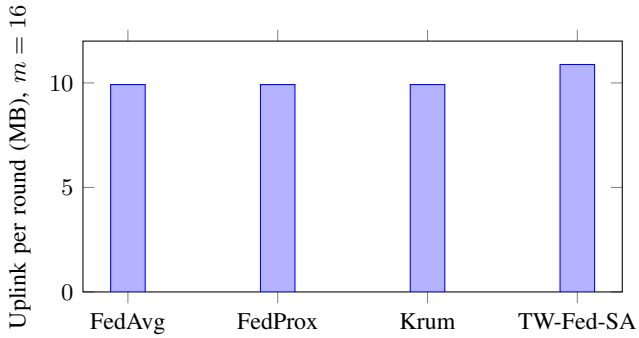

Fig. 5. Total client-to-server uplink per round for $m = 16$ participants. TW-Fed secure aggregation adds sketches and mask material, increasing volume by 9.7% relative to plaintext baselines.

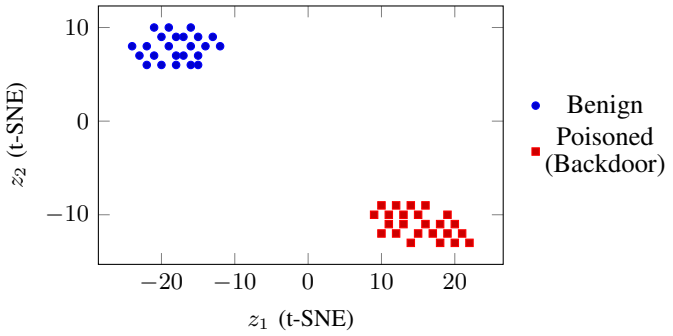

Fig. 6. Illustrative t-SNE embedding of penultimate-layer features of the global model. Backdoor-poisoned flows form a separable cluster; TW-Fed attenuates malicious influence, reducing ASR (Section VII-H).

$\gamma = 0.3$ malicious clients and $\beta = 0.2$ trigger fraction at malicious clients, FedAvg achieves ASR $= 91.5\%$ (attack persists after convergence). Krum reduces ASR to 21.3% but sacrifices macro-F1 by 4.9 points due to non-IID over-filtering. TW-Fed reduces ASR to 6.8% while maintaining macro-F1 $= 95.4\%$ on the four-class task. In the conducted runs, the trust trace shows that malicious clients typically converge to $\tau_k < 0.15$ within 12–18 rounds, after which their effective aggregation weight $\pi_k^{(t)}$ becomes negligible.

Fig. 6 provides an illustrative representation-space view (t-SNE on penultimate-layer embeddings) showing that backdoor-poisoned samples can form a separable cluster; TW-Fed reduces the persistence of this separation by attenuating malicious influence during training.

TABLE VIII. COMPUTATIONAL LATENCY (RASPBERRY PI 4 CLIENTS; $d = 119{,}812$; FP32; $m = 16$)

VIII. CONCLUSION

TW-Fed is presented as a reputation-aware secure aggregation protocol for IoMT intrusion detection in smart hospitals. TW-Fed computes cosine-based trust scores from update sketches and aggregates trust- and size-weighted masked updates with dropout recovery. On CICIoMT2024 (Wi-Fi and MQTT subsets), TW-Fed achieves 99.21% accuracy and 98.74% macro-F1 in the clean setting and maintains 97.06% accuracy under 30% malicious label flipping. Under backdoor injection, TW-Fed reduces ASR from 91.5% to 6.8% with bounded latency overhead on Raspberry Pi 4 gateways. As future work, a comprehensive study will be conducted by varying the sketch dimension (q) to assess its impact on trust-scoring fidelity and communication overhead.In addition, future work will evaluate TW-Fed using a broader range of classifier architectures, including CNN- and LSTM-based models, to determine whether its performance benefits remain consistent across different model types. Another important direction will be a more comprehensive security analysis under stronger adversarial settings, including malicious servers, server–client collusion, and compromised aggregation coordinators. Finally, future work will investigate the integration of verifiable trust evidence, such as protocol-compliant sketch commitments, together with accountable secure aggregation mechanisms that enable gateways to demonstrate the correctness of weighting and masking operations without exposing raw model updates.

***Abstract*—Simply calculating the readability score or the degree of lexical overlap for Arabic technical text simplification does not provide the full picture because an explanation that is shorter may still damage the technical meaning, weaken terminology consistency, or fail to reduce learner difficulty. This study introduces the Pedagogical Simplification Gain Index (PSGI Auto), which is automatic and interpretable, and is designed to measure the pedagogical gain brought about by simplification. Three elements are integrated into PSGI Auto: meaning preservation gain, terminology clarity gain, and concision gain. The technique was tested on Arabic simplification outputs sourced from five information technology areas, which provided a human reference score obtained from three independent expert raters. There is a strong and statistically significant correlation between PSGI Auto and human PSGI judgments, with a Pearson correlation of 0.779, Spearman correlation of 0.755, and 81.6% direction agreement. The results suggest that PSGI Auto can possibly be used as a practical and interpretable learner-oriented Arabic technical simplification tool that would help to identify whether simplification results in pedagogical improvement, not just a superficial change in the text. Since the validation is carried out on a relatively small dataset, the metric is to be interpreted as an initial one requiring further validation by comparison with well-established simplification metrics and larger-scale testing.**

***Keywords*—Arabic technical text simplification; automatic text simplification; pedagogical evaluation; PSGI Auto; human evaluation**

I. Introduction

In the field of educational technology, Automatic Text Simplification (ATS) plays an important role, as it aims to make learning more accessible to different groups of learners by reducing linguistic complexity while preserving semantic integrity [1], [2]. Although considerable progress has been made in the simplification of general-domain texts, adapting technical and scientific content for Arabic-speaking learners remains a major challenge [3], [4]. Arabic technical texts contain a high density of terminology, complex morphological structures, and frequent code-switching with English technical terms, which can make them difficult for non-expert readers to understand [5], [6]. In educational and technical contexts, the purpose of simplification is not merely to substitute words, but also to preserve technical meaning while improving clarity for learners; this concern has been emphasized particularly in biomedical and health-information simplification, where inaccurate simplification can reduce the usefulness of specialized content [7], [8].

Although Arabic simplification corpora are becoming increasingly available, such as the SAMER Corpus for fiction and emerging resources for technical domains, the evaluation of these systems still lacks metrics that genuinely reflect pedagogical utility [3], [9]. Traditional evaluation protocols generally rely on surface-level metrics or general semantic similarity scores that are unable to capture the complex trade-off between simplicity and technical accuracy [10], [11]. A simplified passage that appears easier on the surface may still distort the intended meaning; this risk motivates the use of meaning-preservation evaluation alongside readability or simplicity evaluation [1], [12], [13]. This gap highlights the need for evaluation frameworks that align with human expert judgments regarding meaning preservation and terminology clarity [1], [14].

To address this limitation, this research introduces the Pedagogical Simplification Gain Index (PSGI Auto), an interpretable automatic metric that aims to measure the pedagogical gain of Arabic technical text simplification. PSGI Auto differs from many existing evaluation metrics that score a single output independently; it employs a gain-oriented approach that assesses the glossary-guided output relative to a baseline output. This design is motivated by prior work on reference-less and language-independent simplification evaluation, but the explicit baseline-relative gain formulation is proposed in the present study [15], [16]. The metric consists of three primary dimensions: meaning preservation (ΔM), terminology clarity (ΔT), and concision (ΔC). These dimensions are motivated by prior work on interpretable simplification feedback and pedagogically suitable simplification, while the specific weighting scheme is a pedagogical assumption introduced in this study [17], [18]. We validate PSGI Auto by comparing the results of this lightweight formula against human expert ratings across five IT domains, thereby assessing its ability to approximate pedagogical judgment in a preliminary Arabic technical simplification scenario. Prior Arabic simplification and automated scoring studies motivate the broader methodological context, but the PSGI validation itself is conducted in the present study [19], [20]. Therefore, the contribution is presented as a compact and interpretable metric proposal, rather than as a definitive replacement for established automatic metrics or human evaluation.

II. Related Work

The evaluation of text simplification systems has usually been carried out through the combined use of readability formulas and reference-based metrics. Readability indices, such as the Flesch-Kincaid Grade Level (FKGL), typically estimate text difficulty through surface features such as sentence length and word-level properties [4], [11]. Although they are computationally efficient, these formulas have several limitations. Arabic

*Corresponding author.

readability research has shown that readability assessment requires language-sensitive modeling and that surface features alone are insufficient to capture the full difficulty of Arabic texts; these limitations are even more important when texts contain technical terminology [6], [21]. In the Arabic context, machine learning models for readability assessment have recently been studied, supported by contextual embeddings to better capture syntactic and semantic subtleties [22], [23]. However, these methods mainly estimate difficulty levels rather than assessing the pedagogical benefit achieved through the simplification process.

Reference-based metrics, such as BLEU and ROUGE, originate from machine translation and summarization tasks. They focus on the degree of n-gram overlap between system outputs and human references [24], [25]. However, n-gram overlap is poorly suited to simplification, since it penalizes valid paraphrases and structural changes that differ from the reference, regardless of simplification quality [16], [26]. In response to this limitation, the SARI metric was introduced specifically for simplification. It operates by assessing the addition, deletion, and retention of n-grams [10], [24]. Although SARI correlates better with human judgments of simplicity, it does not provide an explicit account of meaning preservation. This can lead to cases where texts receive high scores for being simpler while containing semantically distorted information [1], [25].

More recent metrics, such as AMAT, LENS, and BERTScore, rely on semantic representations to measure meaning relations through contextual embeddings [12], [27]. BERTScore performs token-level matching using contextual embeddings and is widely used as a semantic similarity metric that is less dependent on exact n-gram overlap than traditional lexical metrics [27], [28]. LENS further advances this direction by combining simplicity, fluency, and meaning preservation into a learned simplification metric [29]. Despite these advancements, general-purpose metrics do not directly evaluate whether domain-specific terminology is used or explained appropriately. This is important for technical simplification, where lexical choices and specialized concepts can strongly influence the usefulness of the output [7], [30]. Moreover, these metrics generally score each output independently rather than modeling the gain achieved over a specific baseline output, which is the baseline-relative perspective introduced in the present study [15], [16], [31].

In the Arabic context, attention has mainly been placed on developing specific corpora and models for simplification, including hybrid approaches that combine machine translation with transformer-based lexical models [5], [32]. Studies have also investigated how control tokens and sequence-to-sequence architectures can influence the degree of simplification [20], [33]. Nevertheless, the assessment of Arabic simplification and readability systems is still frequently connected to adapted evaluation practices or limited human evaluation, and existing work does not yet provide a dedicated automatic metric for Arabic technical pedagogical simplification that jointly captures meaning preservation, terminology clarity, and concision [3], [4]. Recent advances in meaning preservation metrics, such as MeaningBERT and JUDGEBERT, highlight the need for domain-specific semantic evaluation; however, such resources remain almost nonexistent in the Arabic technical education context [12], [13]. Therefore, metrics that jointly assess meaning preservation, terminology clarity, and concision within the same framework remain absent for Arabic technical texts.

III. Proposed Metric

This section of the study discusses the Pedagogical Simplification Gain Index (PSGI) used in this research. PSGI does not simply assess the readability level of a simplified text; rather, it estimates the *gain* produced by the simplification process relative to a baseline output. A good simplification should preserve the original technical meaning, clarify important terms, and reduce unnecessary textual burden. Therefore, the automatic PSGI is defined as a weighted sum of three gain components: meaning preservation gain, terminology clarity gain, and concision gain. The automatic PSGI formula is conceptualized as follows:

$$PSGI_{auto} = 0.50\Delta M + 0.30\Delta T + 0.20\Delta C \tag{1}$$

where, ΔM represents the increase in meaning preservation, ΔT represents the increase in terminology clarity, and ΔC represents the increase in concision between the baseline and simplified outputs. The weights reflect a predefined pedagogical assumption rather than values learned from the validation set: meaning preservation is treated as the most important condition for useful simplification, followed by terminology clarity and concision. This choice avoids fitting the metric directly to the human ratings used for validation, but it also means that the weights should be further examined through future sensitivity and ablation analyses.

For a specific source text i, the three gain components are calculated as follows:

$$\Delta M_i = M_{i,simplified} - M_{i,baseline}, \tag{2}$$
$$\Delta T_i = T_{i,simplified} - T_{i,baseline}, \tag{3}$$
$$\Delta C_i = C_{i,simplified} - C_{i,baseline}. \tag{4}$$

The meaning component M estimates lexical-semantic fidelity to an independently prepared Arabic reference representation of the source technical content. In the present version, M is computed as the cosine similarity between character-level TF-IDF vectors extracted from that reference and the generated output:

$$M_i = \cos\left(\mathrm{tfidf}(Source_i), \mathrm{tfidf}(O_i)\right), \tag{5}$$

In the above expression, $Source_i$ denotes the Arabic reference representation of source technical content, whereas O_i denotes the generated output for item i. Character-level TF-IDF was selected as a lightweight, reproducible baseline that is relatively tolerant of Arabic affixes, borrowed English terms, and inconsistent tokenization. It remains a surface-sensitive proxy, however; it cannot establish semantic equivalence between different valid paraphrases. Accordingly, the results validate the complete PSGI Auto formulation only in this initial setting, and future work should compare this component with Arabic or multilingual embedding-based similarity measures.

The terminology component T measures the proportion of expected glossary terms that are actually used in the output. For a given source text i, let G_i denote the glossary set containing the terms related to it. Terminology coverage is defined as:

$$T_i = \frac{|\{g \in G_i : g \in O_i\}|}{|G_i| + \epsilon}, \tag{6}$$

We set $\epsilon = 10^{-8}$. Each study item has at least one expected term; the constant is therefore only a numerical safeguard and does not affect the reported scores. The definition measures coverage, not contextual correctness, explanation quality, or pedagogical usefulness. It can reward unnecessary insertion and can miss valid paraphrases; the terminology component should consequently be interpreted as a glossary-alignment feature rather than an independent measure of terminology clarity. The conciseness component C is computed from the character-length reduction achieved relative to the Arabic reference representation.

$$C_i = \max\left(0, 1 - \frac{len(O_i)}{len(Source_i) + \epsilon}\right), \tag{7}$$

The length of the output in character count is denoted by $len(\cdot)$ after the preprocessing step. According to this formulation, shorter outputs receive higher values, but outputs that are longer than the source representation are not rewarded. The possibility that excessive shortening may damage meaning is the reason behind the small weight of concision in Eq. 1. The human reference score is computed based on five expert-rating dimensions. For each evaluated output, the Human Pedagogical Score (HPS) is defined as:

$$HPS = \frac{R + S + T + M + (6 - D)}{5} \tag{8}$$

Here, R signifies readability, S denotes simplicity, T stands for terminology clarity, M refers to meaning preservation, while D illustrates learner difficulty. Learner difficulty has a reverse scoring method, meaning that $(6 - D)$ is used for it, since greater difficulty implies lower pedagogical quality. The human PSGI is finally calculated as the discrepancy between the simplified and baseline HPS values.

$$PSGI_{human} = HPS_{simplified} - HPS_{baseline}. \tag{9}$$

If the PSGI value is positive, it suggests improvement relative to the paired baseline; it does not establish that the final output is objectively high quality. A value close to zero indicates minimal relative change, while a negative value indicates deterioration relative to that baseline.

IV. Methodology and Experimental Design

The study works with a controlled dataset of Arabic technical text simplification outputs that include five information technology domains: programming, databases, networks, cybersecurity, and cloud computing. Each source text has two corresponding generated outputs: a baseline output and a glossary-guided simplified output. Fig. 1 summarizes the paired computation and validation design. The objective is to examine whether the automatic PSGI score aligns with expert judgments of pedagogical simplification gain.

A. Generation Conditions

Two outputs under controlled generation conditions were produced for each source text. The baseline condition generated a simplified Arabic explanation without explicit glossary constraints. The glossary-guided condition generated a simplified Arabic explanation while encouraging the use or explanation of expected technical terms. Both outputs were paired by source text, which allows PSGI to be computed as a gain score rather than as an isolated output-quality score. Raters were not informed whether an output came from the baseline or glossary-guided condition, and outputs were presented using anonymized evaluation identifiers in randomized order. This blinding and randomization step is important because PSGI includes a terminology-coverage component and the glossary-guided condition may otherwise receive an artificial advantage. The blinding procedure reduces the risk that human scores are biased toward the glossary-guided condition, although it does not remove the need to test PSGI Auto against external automatic metrics that do not use the proposed weighting scheme.

B. Dataset

There are 100 outputs generated from 50 technical source texts in the dataset. Each source document comes with one baseline output and one glossary-guided simplified output. The dataset is distributed evenly over five technical domains, with 20 outputs assigned to each domain. The validation is carried out at the text level by pairing the baseline outputs with the corresponding simplified outputs that are generated from the same source text. Before the analysis was done, the dataset was examined for missing values, duplicated rows, duplicated text-mode pairs, and inconsistent metadata. No required values were missing, and no duplicated evaluation identifiers or invalid ratings were found. One paired item was excluded from the gain analysis because the baseline and simplified outputs were identical. Ultimately, the final PSGI Auto against PSGI Human validation involves 49 valid paired comparisons.

C. Human Evaluation

The evaluation of each output was carried out independently by three raters using five distinct criteria: readability, simplicity, terminology clarity, meaning preservation, and learner difficulty. The scoring for each of these five criteria was done on a scale of 1–5. Higher points stand for better quality for readability, simplicity, terminology clarity, and meaning preservation. For learner difficulty, a higher number of points indicates greater difficulty, and therefore learner difficulty is inverted. That is to say, learner difficulty is inverted in Eq. 8 when computing the Human Pedagogical Score. For every output, the mean scores from the three raters were obtained for each criterion. The human PSGI was then computed by subtracting the baseline HPS values from the simplified HPS values for the same text. This design views expert judgment as the human reference standard and assigns automatic PSGI computation to the ranking values. Inter-rater reliability was calculated on the 100 rated

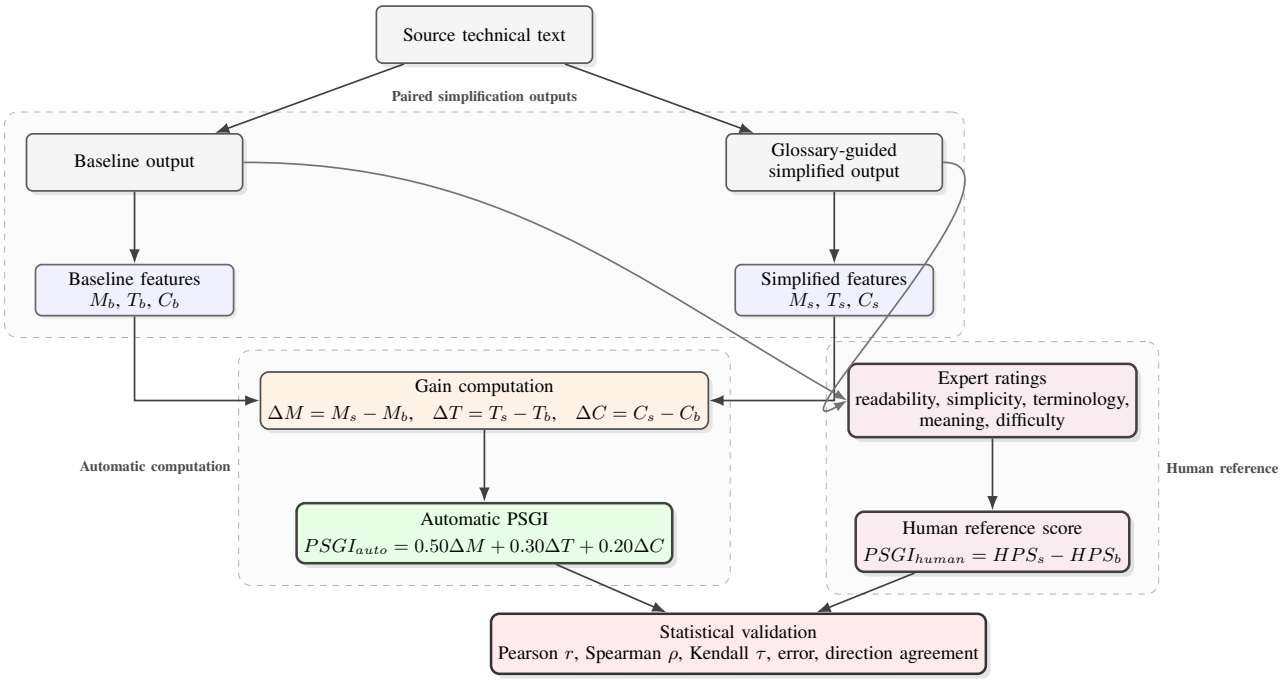

Fig. 1. PSGI Auto computation and validation workflow.

TABLE I. INTER-RATER RELIABILITY ACROSS THE THREE EXPERT RATERS. ICC(2,1) REPORTS SINGLE-RATER RELIABILITY, WHILE ICC(2,K) REPORTS RELIABILITY AFTER AVERAGING THE THREE RATERS

Rating dimension	ICC(2,1)	ICC(2,k)
Readability	0.604	0.821
Simplicity	0.599	0.818
Terminology clarity	0.582	0.807
Meaning preservation	0.648	0.847
Learner difficulty	0.547	0.783
Human Pedagogical Score	0.681	0.865

TABLE II. RELIABILITY OF RATER-LEVEL PAIRED HUMAN PSGI GAINS ACROSS 49 SOURCE-TEXT PAIRS

Statistic	Value
ICC(2,1)	0.714
ICC(2,k)	0.882

outputs before averaging the three raters. Table I displays both single-rater ICC and average-rater ICC values. We additionally computed ICC on rater-level paired HPS gains (Table II); the average-rater gain ICC(2,k) is 0.882. Thus, the averaged three-rater paired gain is a reasonably reliable reference for this pilot study, while learner difficulty remains the most subjective individual dimension.

D. Automatic PSGI Computation

The automatic PSGI computation involves only text-derived features and excludes the human ratings. Meaning preservation is estimated through similarity to the manual Arabic reference, terminology clarity through glossary-term coverage, and concision through the change in output length. These features are computed for both outputs of each paired source text, transformed into gain values, and combined using Eq. 1. To examine whether the weighted formula adds value beyond its individual components, the validation includes diagnostic component variants and reference-overlap baselines calculated on the same outputs. These comparisons test incremental alignment with the human PSGI reference; they do not establish broad superiority over all established simplification metrics.

E. Validation Procedure

The main validation compares $PSGI_{auto}$ with $PSGI_{human}$ across 49 valid paired items. Pearson correlation estimates linear association, while Spearman correlation and Kendall's tau estimate rank agreement. MAE and RMSE quantify prediction error after scale alignment. Direction agreement is reported because the sign of PSGI indicates relative improvement or deterioration. We additionally report bootstrap confidence intervals, leave-one-pair-out correlation ranges, and the reliability of rater-level paired gains. These robustness analyses are descriptive because the dataset is small.

V. RESULTS

In this part, the empirical validation of PSGI Auto against PSGI Human is presented. The analysis utilizes 49 valid paired comparisons after excluding one identical baseline–simplified pair.

A. Overall Validation

Table III and Fig. 2 summarize the association between automatic and human PSGI. The overall correlation is encouraging for this pilot sample, but it should not be interpreted as a stable population estimate. The rank correlations indicate that the association is not solely linear. Robustness results in

TABLE III. VALIDATION OF $PSGI_{auto}$ AGAINST $PSGI_{human}$

Metric	Value
Valid paired items	49
Pearson r	0.779
Pearson p	4.40e-11
Spearman ρ	0.755
Spearman p	3.79e-10
Kendall τ	0.562
Kendall p	1.27e-08
MAE	0.250
RMSE	0.295
R^2	0.525
Direction agreement	81.6%

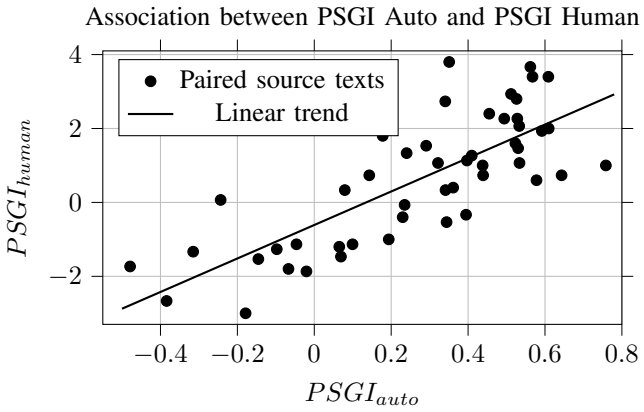

Fig. 2. Scatter plot generated from the 49 valid paired comparisons between PSGI Auto and raw human PSGI. The positive trend is consistent with the strong Pearson correlation reported in Table III.

TABLE IV. ROBUSTNESS CHECKS FOR THE OVERALL PEARSON CORRELATION

Check	Value
Observed Pearson r	0.779
Bootstrap 95% interval	[0.671, 0.860]
Leave-one-pair-out range	[0.758, 0.798]

Table IV show the extent to which the estimate changes under resampling and leave-one-pair-out analysis.

The automatic score achieves 81.6% direction agreement with the human score. Thus, for most pairs in this sample, PSGI Auto and the human reference agree about the direction of change relative to the baseline.

B. Human Rating Summary

In Table V, the averaged human ratings are given according to the generation condition. The outputs that are guided by the glossary obtain higher mean scores for readability, simplicity, terminology clarity, meaning preservation, and the overall HPS. Learner difficulty decreased from 3.26 to 2.61, which is positive because lower difficulty means that learners can more easily access the material.

C. Ablation and Weight Sensitivity

The ablation analysis examines the weighted PSGI formula against equal-weight and component-only variants. Table VI

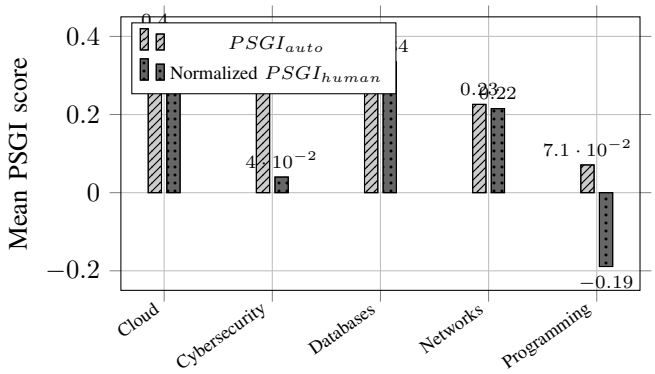

Fig. 3. Domain-level mean PSGI Auto and normalized PSGI Human scores. Positive values indicate pedagogical gain after simplification, while negative values indicate harmful simplification. Human PSGI is normalized by dividing the raw score by four for visual comparability with PSGI Auto.

shows that the proposed weighting has the highest correlations among these internal variants. The advantage over equal weights is small, so the weights should be considered pedagogically motivated and promising rather than optimized or definitive. Meaning gain is the strongest individual component; terminology and concision gains are positively correlated in this sample but are insufficient on their own to judge pedagogical quality.

D. Comparison with Reference-Overlap Baselines

Table VII compares PSGI Auto with reference-overlap baselines on the same 49 paired outputs. These metrics are included as transparent, reproducible diagnostic baselines. A complete comparison with SARI, BERTScore, and LENS is outside the present dataset and implementation: SARI requires an Arabic complex-source/reference configuration that is not available here, and Arabic-validated implementations of BERTScore and LENS should be selected and evaluated in a separate, preregistered benchmark. Accordingly, this table does not claim to settle comparative performance against those metrics.

PSGI Auto has higher correlation than the listed baselines in this sample. This result is consistent with the value of combining the three features, but it remains preliminary and does not demonstrate general superiority.

E. Domain-Level Results

Table VIII and Fig. 3 report descriptive domain-level results. Human PSGI is divided by four in the figure solely for scale comparability. Each domain contains only nine or ten pairs; consequently, the domain correlations have very wide uncertainty and are not interpreted as stable domain-specific findings.

F. Interpretation of the Main Finding

The principal finding is that the proposed formula correlates with human paired gain scores in this dataset. PSGI Auto is computed from text-derived features, whereas the reference is based on independently collected expert ratings. The ablation results suggest that combining meaning preservation, glossary alignment, and concision is more aligned with the human gain

TABLE V. HUMAN RATING SUMMARY BY GENERATION CONDITION. GAINS ARE COMPUTED AS GLOSSARY-GUIDED MINUS BASELINE ACROSS THE 49 VALID PAIRED COMPARISONS

Dimension	Baseline mean	Glossary-guided mean	Mean gain	Gain SD
Readability	3.50	4.05	0.55	1.59
Simplicity	3.31	3.80	0.49	1.75
Terminology clarity	2.83	3.80	0.97	1.80
Meaning preservation	2.90	3.44	0.54	1.98
Learner difficulty	3.26	2.61	-0.65	1.83
Human Pedagogical Score	3.06	3.70	0.64	1.73

TABLE VI. ABLATION AND WEIGHT-SENSITIVITY ANALYSIS AGAINST HUMAN PSGI ACROSS 49 VALID PAIRED COMPARISONS. DIRECTION AGREEMENT REPORTS WHETHER THE AUTOMATIC AND HUMAN GAIN SIGNS MATCH

Variant	Pearson r	p-value	Spearman ρ	Kendall τ	Direction agreement
PSGI current $(0.50/0.30/0.20)$	0.779	4.40e-11	0.755	0.562	81.6%

TABLE VII. CORRELATION OF PSGI AUTO AND REFERENCE-OVERLAP BASELINES WITH HUMAN PSGI ACROSS 49 PAIRED COMPARISONS. BASELINES ARE GLOSSARY-GUIDED MINUS BASELINE SCORES AGAINST THE MANUAL ARABIC REFERENCE

Metric	Pearson r
PSGI Auto	0.779
BLEU-1 gain	0.643
ROUGE-L-like gain	0.739
Character TF-IDF gain	0.657

TABLE VIII. DOMAIN-LEVEL COMPARISON BETWEEN PSGI AUTO AND PSGI HUMAN

Domain	n	Mean PSGI Auto	Mean PSGI Human	Pearson r
cloud	10	0.402	1.460	0.447
cybersecurity	10	0.300	0.160	0.790
databases	10	0.362	1.340	0.544
networks	10	0.226	0.860	0.885
programming	9	0.071	-0.756	0.866

reference than the evaluated individual components. This should be interpreted as initial evidence for the formulation under the tested generation conditions, not as proof that the metric is universally valid or that glossary-term occurrence itself causes pedagogical improvement.

VI. DISCUSSION

The validation results indicate that PSGI Auto may provide an initial approximation to expert judgments of relative pedagogical gain. Its baseline-relative design asks whether an intervention improves an output compared with its paired baseline. This is useful because a shorter text may still weaken technical meaning or terminology. It does not, however, imply that a positive PSGI score certifies the final output as high quality.

The weights were specified before validation from a pedagogical priority: preserving meaning is necessary, terminology alignment can support technical learning, and concision is beneficial only when it does not remove essential content. The small difference from equal weights means that this rationale should not be confused with empirical optimization. The terminology component is particularly constrained by coupling: the glossary-guided condition was encouraged to use the same glossary that PSGI Auto measures. Blinded, randomized human rating reduces rater bias but does not remove this metric–intervention coupling. Future validation should include outputs generated without glossary guidance and deliberate adversarial cases, including unnecessary term insertion, valid paraphrases, meaning deletion, and overly compressed text.

The domain results are descriptive only. With nine or ten pairs per domain, apparent differences can be driven by a few observations. PSGI Auto should therefore be treated as a practical screening signal for the studied setting, alongside human review, rather than as a replacement for human evaluation.

VII. THREATS TO VALIDITY

This study has several limitations. First, the validation dataset contains 49 valid paired comparisons after one identical pair was removed. The overall estimates are therefore preliminary, and the domain-level estimates are especially uncertain. Second, the weights were not learned from the human ratings, but the small difference from equal weights means that they require larger sensitivity analyses. Third, the benchmark includes reference-overlap and component baselines, not a complete SARI, BERTScore, or LENS comparison. Future work should use an Arabic complex-source/reference dataset and validated Arabic or multilingual implementations of these metrics on the same outputs. Fourth, the glossary used to guide one generation condition also informs the terminology-coverage feature. This coupling can inflate the apparent contribution of glossary coverage. Fifth, coverage alone cannot assess whether a term is correct, necessary, explained, or pedagogically helpful; valid paraphrases may be penalized. Sixth, character-level TF-IDF is a lightweight surface-sensitive proxy for meaning and cannot reliably recognize all semantically equivalent Arabic formulations. Seventh, the human reference uses paired HPS gains. We report gain-level reliability, but direct learner outcomes remain necessary to establish educational benefit.

Finally, the study does not include deliberately constructed failure cases or a full influence analysis beyond leave-one-pair-out checks. These should be included before deploying PSGI Auto as an operational evaluation metric.

VIII. Ethical and Reproducibility Considerations

The present article is an analysis of generated text outputs and expert evaluations. No student performance data, sensitive personal data, or intervention data were included in the study. The expert ratings were collected voluntarily and were subsequently analyzed using anonymized output identifiers. To ensure reproducibility, the study documents the generation conditions, PSGI formulation, rating procedure, and validation statistics. The anonymized generated outputs, rating files, derived PSGI tables, and calculation scripts can be made available upon reasonable request.

IX. Conclusion

This study introduces PSGI Auto, an interpretable metric for assessing relative pedagogical gain in Arabic technical text simplification. It combines meaning-preservation gain, glossary-alignment gain, and concision gain. On a small paired dataset, PSGI Auto correlates encouragingly with three-rater human PSGI gains. The evidence is preliminary: the dataset is small, terminology coverage is coupled to the glossary-guided intervention, the meaning feature is surface-sensitive, and the benchmark is incomplete. Future research should use larger and more diverse datasets, adversarial failure cases, independent terminology evaluation, stronger Arabic semantic models, direct learner outcomes, and a full comparison with established simplification metrics.

Sustainability-Centric Software Development: A Quantitative Framework for the SDLC

Madhura G K[1]*, Piyush Kumar Pareek[2]
Department of Computer Science and Engineering, Nitte Meenakshi Institute of Technology,
Nitte (Deemed to be University), Bengaluru, India[1]
Visvesvaraya Technological University, Belagavi, India[2]

***Abstract*—Although software systems increasingly shape energy consumption, economic output, and societal welfare, most development methods still prioritise schedule, cost, and functionality. This paper presents an approach to software development that prioritises sustainability by embedding environmental, economic, and social objectives into the SDLC from the very beginning. The framework represents sustainability as a set of quantifiable variables that are combined into a Global Sustainability Index (GSI). These metrics include operational energy and carbon footprint, total cost of ownership (TCO), maintainability index, defect density, and a normalised Social Impact Score (SIS). An empirical measurement architecture gathers runtime and process data for continuous improvement, while phase-level "sustainability budgets" direct trade-offs across requirements, design, implementation, testing, and operation. The framework is evaluated in a repeated-measures industrial study of six production software systems (758 KLOC in total, 58 engineers, six application domains), in which every system is observed over four counterbalanced release cycles governed respectively by the proposed framework and by three established approaches: GREENSOFT, GreenSDLC, and the Sustainability Quality Model (SQM). The proposed framework attains the highest GSI (0.86 $\pm$ 0.03), a statistically significant improvement of 10–19% over the competing frameworks (paired t-tests, all Holm-adjusted $p < 0.002$, Cohen's $d_z > 2.5$). Relative to current models, energy usage and carbon emissions are cut by 10–20%, and they are decreased by approximately 30% when compared to a no-framework baseline. Normalised maintainability and defect density both improve over a five-year timeframe, and total cost of ownership drops 4–9%. Consistently higher levels of social impact and stakeholder satisfaction are observed, particularly for user groups who are marginalised. Ninety-five percent confidence intervals and effect sizes are reported for every headline comparison, and the principal limitations of the framework are stated explicitly together with mitigation strategies. These results show that all three dimensions can be improved with explicit quantitative sustainability integration without a rise in long-term costs.**

Keywords*—Sustainability-centric framework; social impact score; total cost of ownership; global sustainability index; software development lifecycle

I. Introduction

Modern software systems' design and operation now prioritize sustainability [1]. Companies that rely heavily on software depend on complicated systems with social consequences and life-cycle costs that go well beyond the initial development phase [2]. Meanwhile, digital services now make up a sizable portion of the world's energy demand. Environmental, economic, and social impacts are often only considered implicitly or on an as-needed basis in traditional software engineering procedures, which prioritize functional correctness, performance, and delivery time [3]. Because of this, a lot of systems force businesses to employ outdated, inefficient designs, have fragile code bases, and provide unequal user experiences [4].

Various software frameworks that prioritize sustainability have been put forward to tackle these problems. Guidelines for environmentally effective operation and disposal are highlighted by GREENSOFT [5], which promotes sustainability throughout the software product, process, and deployment life cycle. Green SDLC models [6], [7], [10] incorporate sustainability checkpoints into traditional SDLC phases, encouraging teams to consider environmental impacts during requirements, design, and testing. Energy consumption, resource optimisation, and durability are the sustainability qualities that the Sustainability Quality Model (SQM) [8], [9] adds to software quality models. Although there have been significant advancements in these methods, they are still mostly checklist-based or qualitative, and they do not offer much quantitative help when it comes to comparing different design options, monitoring progress between releases, or weighing the pros and cons of environmental, economic, and social goals [11], [12].

Metrics that are strict but also practical are necessary for organizations [13]. It is important for teams to know how different decisions, like data placement, architectural style, or refactoring technique, impact operational energy, total cost of ownership, and stakeholder wellbeing [14]. In order to track sustainability in real time, rather than just at project completion, they must find a means to incorporate these data into preexisting DevOps processes [15], [16]. Sustainability is still in its aspirational stage without such quantitative integration, and it is easy to de-prioritize when time or money is limited [17].

In order to fill these gaps, this study presents a framework that is focused on sustainability. Sustainability is modeled in the framework as a multi-dimensional goal that includes social, economic, and environmental aspects. Energy consumption, carbon footprint, economic efficiency, accessibility rating, maintainability index, fault density, and stakeholder-group satisfaction are some of the measurable measures that are defined. A standardized and aggregated set of these indicators is the Global Sustainability Index (GSI), which gives a clear and understandable picture of how sustainable a system is as a whole. Incorporating these indicators into each SDLC stage

*Corresponding author.

is made possible by phase-level sustainability budgets and limitations. To validate these metrics, operational and process data are collected by an empirical measurement architecture.

A. Contributions of this Paper

The specific and novel contributions of this work are summarised below.

- A dimension-wise formalisation of software sustainability in which environmental, economic, and social objectives are expressed as normalised, commensurable metrics (Eq. 6–15), so that heterogeneous quantities such as kilowatt-hours, currency, and survey scores can be compared on a single scale.
- A Global Sustainability Index (GSI) that aggregates the three dimension scores through explicit, auditable weights (Eq. 16–17), replacing the qualitative or checklist-based judgements used by existing frameworks with a reproducible scalar indicator.
- A phase-level sustainability budgeting and compliance mechanism (Eq. 18–19) that distributes each dimension goal across lifecycle phases, so that sustainability is enforced continuously rather than audited only after deployment.
- An empirical measurement architecture that instruments source repositories, CI/CD pipelines, and runtime agents, closing the loop between the formal definitions and observed system behaviour (Eq. 20–21).
- A sustainability-driven optimisation loop in which design decisions, policy parameters, and dimension weights are updated from empirical feedback across releases (Eq. 24–27), making the framework compatible with agile and DevOps practice.
- A repeated-measures industrial evaluation across six production systems spanning six application domains, reported with standard deviations, 95% confidence intervals, paired significance tests, and effect sizes (Section III-H, Section III-I, and Section IV-B), together with a full specification of the experimental protocol to support independent replication.
- An explicit account of the framework's drawbacks, each paired with a concrete mitigation strategy and a corresponding direction for future work (Section IV-C).

Here is the breakdown of the remaining sections of the paper: In Section II, the relevant literature is reviewed. In Section III, the technique that has been suggested is laid out in great depth, together with the case study design and the statistical analysis procedure. Section IV delves into the analysis of the results, the statistical significance of the observed improvements, and the limitations of the approach. Lastly, Section V draws conclusions.

II. Related Works

Incorporating the three tenets of sustainability, Schulte, S. N., et al. [18] offers an evaluation framework for digital solutions, including digital twins, virtual reality, and worker assistance systems. Using the framework's organized template, one may find and evaluate the potential environmental, social, and economic impacts in a systematic manner. Key performance indicators (KPIs) and success criteria are the foundation of this procedure. Experts from both the business and academic sectors met in workshops to review the assessment system. During these sessions, attendees tested the framework's viability and efficacy by applying it to various digital solution use cases. As a useful decision-support tool, the results show that the created evaluation framework can give a thorough picture of the predicted effects of digital solutions. A comprehensive evaluation is guaranteed by the framework, which takes into account all three sustainability pillars. The framework's adaptability to many sectors and application domains is a result of its flexible and scalable architecture. It is a versatile tool for assessing digital solutions.

Enterprise systems, supply chains, Internet of Things (IoT) sensors, regulatory filings, social media, and other various datasets can be continuously aggregated according to Mayegun, K. O., et al. [19]. By analyzing these data streams using AI-powered platforms, valuable insights may be extracted, which improves the accuracy of ESG measurements, simplifies reporting, and reveals significant risks and opportunities. To greatly improve data integrity and shorten reporting latency, AI models may automate sustainability metric classification, find disclosure errors, and predict ESG trends. Additionally, AI enables companies to create coherent narratives that portray the generation of long-term value and the consequences on stakeholders by integrating sustainability data with financial key performance indicators. This allows for dynamic integrated reporting. The requirement for intelligent reporting systems is being heightened by new legal frameworks, such as the rules set out by the International Sustainability Standards Board (ISSB). This paper takes a look at how top companies are incorporating AI and Big Data into their sustainability accounting processes, talks about some of the problems with implementing it, like data governance and model transparency, and then shows how these technologies could mould the future of adaptive and responsible corporate reporting.

In order to improve the efficacy of the continuous integration environment, Benjamin, J., et al. [20] present four interrelated measures. The interconnectedness of these measures is supported by a hypothesis and a set of guidelines. Using a hybrid LSTM-GRU model, the authors validate the metric criteria and how they relate to effective builds. Data from CI builds is well-suited for time series analysis due to its sequential nature and temporal dependencies. In order to optimize software development workflows and make better decisions, it is helpful to use time series techniques to gain insights on the CI process dynamics. For this reason, the authors validate the DKMR and present a hybrid LSTM-GRU model to forecast the construction outcome. The study highlights the interdependence and positive impact on build outcomes of measures like LC (Long Commit), BT (Build Time), TSC (Time between Successive Commits), and BBFT (Build Breakage Fixing Time). A final method, the "Dynamic Build Success Optimization Algorithm," has been created using these interrelated critical indicators. As a whole, DevOps techniques benefit from this algorithm's ability to improve the

continuous integration environment's efficiency and dependability.

An early-stage approach for accurately estimating reliability qualities is proposed by Chatterjee, S. [21] using type-2 fuzzy logic (T2FL). The suggested method has built the suggested T2FL model's rule basis on top of human expertise. Another method that has been suggested for analyzing the effect of dependability attributes on software modules is stacked deep neural networks (SDNNs), which are based on neural networks. In order to produce stronger and more durable solutions, SDNN ensembles multiple architecture-based deep neural networks that were trained using the estimated dependability attributes to identify software modules. The proposed methodology has been validated by two simulation studies. When compared to existing baseline models, the suggested method outperforms them in terms of accuracy. Helping software developers create reliable software on time and within budget is the goal of the proposed strategy.
