The proposed IDCNN-ORM model follows a comprehensive pipeline for improving a reputation system using social media data. Fig. 1 shows the overall architecture of the proposed model. As depicted in Fig. 1, the methodology involves five major stages: data preprocessing, feature selection, classification, parameter tuning, and explainability analysis. These processes are integrated to ensure effective model performance and accurate sentiment-based reputation analysis.

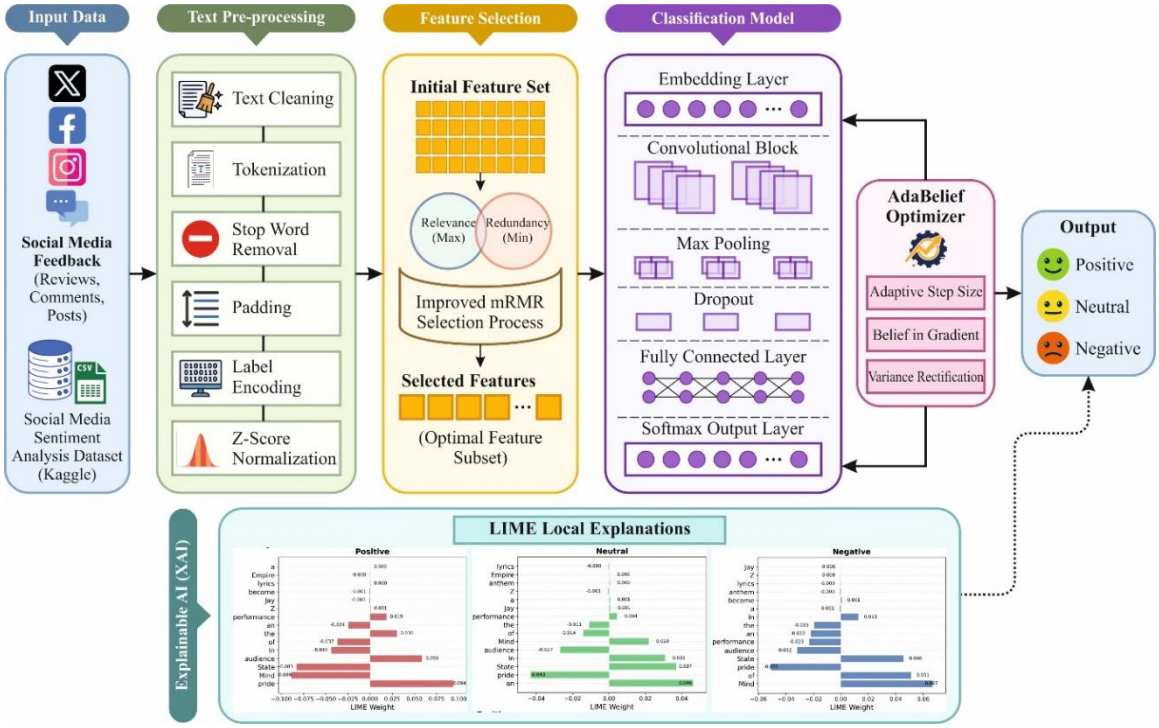

Fig. 1. Overall architecture of the IDCNN-ORM model.

A. Data Preprocessing

A multi-stage preprocessing stage includes text cleaning, tokenization, stop-word removal, and padding to convert raw data into a structured format [18].

1) Text cleaning: It eliminates hashtags symbols (#), URLs, punctuation, emojis, and user mentions from the "Text" column, and special characters. It ensures the preservation of significant expressive words from social media posts.

2) Tokenization: It divides content into smaller units like subwords or words referred to as tokens, while handling emojis, hashtags, special characters, and URLs to extract meaningful phrases for examination.

3) Stop-word removal: It removes common words like “the”, “and”, and “is” that do not enhance meaning. This helps to lessen data dimensionality and increases processing efficiency.

4) Padding: It is used to pad token-based post sequences to guarantee a unified input length for every instance. This is necessary for the DL strategy; later posts in the dataset are different in structure and length.

Before model training, the proposed IDCNN-ORM framework performs text cleaning, tokenization, stop-word removal, padding, label encoding, and Z-score normalization to preprocess the social media text data.

5) Label encoding: This encoding approach is leveraged to convert categorical variables into numerical form. It allocates a unique integer value to every category, allowing effective learning from categorical data.

Z-score normalization (standardization) converts information; thus, it has a standard deviation of 1 and a mean of 0. During training, it is utilized to scale each attribute to a standard scale, which improves system performance, faster convergence, and stability.

$$X_{norm} = \frac{X - \mu}{\sigma} \tag{1}$$

Here, μ means the mean of the feature, X signifies the actual feature value, X_{norm} indicates the scaled value, and σ implies the standard deviation of the feature.

B. Improved mRMR-Based Feature Selection

An improved mRMR-based feature selection (FS) strategy is applied to select the most relevant and non-redundant attributes from the dataset. It reduces feature redundancy and computational complexity while improving the effectiveness of the classification process [19]. The standard mRMR is an effective FS strategy that repeatedly increases the number of attributes in the feature subset by a gradual search that balances the dual terms: minimal redundancy to the gathered feature subset and maximum relevance to the label. The dual relevance is computed.

$$\max A(S, C) = \frac{1}{n} \sum_{f_i \in S} I(f_i, C) \tag{2}$$

$$\min R(S) = \frac{1}{n^2} \sum_{f_i f_j \in s} I(f_i, f_j) \tag{3}$$

here, C signifies the data label, S denotes the chosen feature subset. $A(S, C)$ refers to the correlation between the chosen subset and the label, f_i and f_j indicate the dual attributes

features in S, $I(*)$ represents the mutual information, and $R(S)$ implies the redundancy among the chosen subset.

$$I(X,Y) = \int_X \int_Y P(X,Y) \log \frac{P(X,Y)}{P(X)P(Y)} \quad (4)$$

As an instance, $P(X,Y)$ refers to their marginal probability distributions. Conversely, its mutual data-driven importance assessment is more appropriate for diverse information. These dual behaviors can be examined to manage continuous data, and it has been established that they can deliver information. Pearson correlation and T-test coefficient equations are defined.

$$t(f_i) = \frac{\left|\overline{f_{i_{pos}}} - \overline{f_{i_{neg}}}\right|}{\sqrt{\frac{S^2_{i_{pos}}}{n_{pos}} + \frac{S^2_{i_{neg}}}{n_{neg}}}} \quad (5)$$

$$\rho(f_i, f_j) = \frac{\sum (f_i - \overline{f_i})(f_j - \overline{f_j})}{\sqrt{\sum (f_i - \overline{f_i})^2 \sum (f_j - \overline{f})^2}} \quad (6)$$

Here, $\overline{f_{i_{neg}}}$ implies the mean value of f_i in the negative instance; $\overline{f_{i_{pos}}}$ represents the mean value of the positive instance, n_{pos} and n_{neg} indicate the sample counts; $S^2_{i_{pos}}$ and $S^2_{i_{neg}}$ refer to the variance of f_i.

$$f_i \max \left[t(f_i) - \frac{1}{S} \Sigma f_j \in F_s \rho(f_i, f_j) \right] \quad (7)$$

Additionally, the stopping principle of the standard mRMR methodology for increasing the count of chosen feature subgroups, which needs to be set analytically, generates limitations to ensure the outcome of the last chosen feature subgroups.

C. Online Reputation Classification via DCNN

A deep convolutional neural network is used to analyze sentiment patterns in social media data for effective reputation assessment. The model utilizes deep convolutional layers to learn hierarchical feature representations and improve classification [20]. A neural network (NN) is an effective method comprising several interrelated nodes; here, every node uses an activation function to produce an output. The relationships among nodes carry weights that verify how intensely data is distributed among neurons and serve as the network memory. The output of the network, based on these weights, is learned, and correlations are structured. During Online Reputation Management (ORM), the major features impacting reputation include opinion strength, sentiment polarity, variations in customer reviews, and user engagement and social media comments. Conversely, these components cannot exactly signify the last reputation category, namely neutral, positive, or negative, creating a classification problem utilizing raw information.

The actual reputation grade is derived from consumer feedback and social media text, which precisely imitates public opinion. Hence, these data sources are employed as key inputs for classifying reputation into multiple classes. The DCNN progress comprises capturing attributes from the data and upgrading system hyperparameters through learned extractions. These learned hyperparameters are assigned to different DCNN sub-methods to reduce computation, while preserving results. The n DCNN sub-models for learning hyperparameters are represented by.

$$\theta^S = \left\{ \theta_1^S, \theta_{2,}^S, \ldots, \theta_n^S \right\} \quad (8)$$

where, each θ_n^S corresponds to one sub-model, and θ^S denotes the combined parameters. All sub-models encompass three fully connected layers and five convolution layers to study patterns from social media text and consumer feedback. This transfer learning system assists in transferring knowledge from a source dataset to the targeted ORM classifier study, minimizing the requirement for huge labeled data while sustaining superior precision. Subsequently, transfer learning, n DCNN-TL sub-models are designed, and an ensemble system is created utilizing these sub-models together with one classification layer and one fully connected layer.

The convolution layer captures significant features by employing filters across the input text extraction. The convolution output at position (i,j) for the k_{th} filter.

$$\begin{cases} Z^{l_{conv}}_{i,j,k} = C(X,K)_{i,j,k} = \sum_{r=1}^{k_h} \sum_{s=1}^{k_w} \sum_{t=1}^{k_c} x_{i',j',t'} \, k_{r,s,t',k} + b_k \\ i' = (i-1)S_h + r \\ j' = (j-1)S_w + s \end{cases} \quad (9)$$

In Eq. (9), bk signifies the bias term, and k denotes the filter weights. The convolution layer helps to capture suitable patterns from text, including contextual meaning and sentiment words. These features are applied to the classifier for reputation as neutral, negative, or positive.

The method repeatedly updates the feature extraction depending on observed information. During training, it improves forecasting by comparing predicted and actual class labels and reducing errors.

A major benefit of DCNN is that it can manage variable-length text information from comments and social media without strict input size challenges. It acquires valuable patterns from noisy and unorganized text data and transforms them into essential features for classification.

$$q(\chi_k | x_{0:k}(i), y_{1:k}) = p\left(x_k | \chi_{k-1}(i)\right) \quad (10)$$

During learning, this supports the model in concentrating on the most essential instances. If the count of efficient records becomes too small, then the algorithm is restarted to maintain results. Afterward, resampled, a novel group of attributes is formed and employed for the final classification.

$$w_t^{(i)} = (w_{t-1^{(i)}})^{\alpha} \frac{p(z_t | x_t^{(i)}) p(x_t^{(i)} | x_{t-1^{(i)}})}{q(x_t^{(i)} | x_{t-1}^{(i)}, z_{1.t})} \quad (11)$$

where, α influences how strongly weights are upgraded. Finally, the system is evaluated on the basis of detection precision and computational effectiveness. An added balancing parameter is applied to control imbalance among sentiment

categories. The proposed techniques efficiently classify online reputation from user feedback and social media information, utilizing ensemble transfer learning and DCNN-based feature learning. Fig. 2 denotes the overview of the DCNN model for reputation classification.

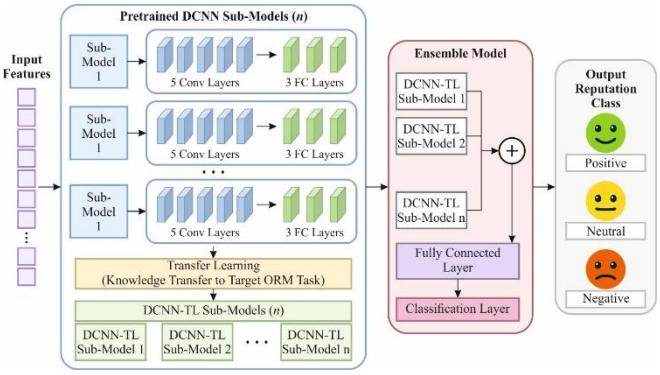

Fig. 2. Overview of the DCNN model for reputation classification.

D. Hyperparameter Optimization

AdaBelief optimizer is an adaptive optimization algorithm that adjusts learning rates based on the difference between predicted and observed gradients [21]. Adaptive optimizers, namely Adam, converge more quickly than SGD; however, their consistency and outcome might not be sufficient for larger datasets. This optimizer proposes an alteration to the Adam optimization for improving model generalization and training stability. During Adabelief's dissimilar Adam, a novel variable s_t is defined as the exponential moving average of $(g_t - m_t)^2$, while $g_t - m_t$ denotes the deviation. A smaller variance amongst g_t and m_t refers to a robust belief, while in the case of a weaker belief, the transformation is smaller. According to this methodology, the Adabelief measures s_t and biased correction $\widehat{s_t}$ than v_t and $\widehat{v_t}$,

$$s_t = \beta_2 s_{t-1} + (1-\beta_2)(g_t - m_t)^2 + \varepsilon, \tag{12}$$

with its bias-corrected form represented by:

$$\widehat{s_t} = \frac{s_t}{1-\beta_2^t} \tag{13}$$

and the AdaBelief upgrade principle has been illustrated by

$$w_{t+1} = w_t - \frac{\eta}{\sqrt{\hat{s}}+\in}\widehat{m_t} \tag{14}$$

AdaBelief leveraged the same parameter settings as Adam, with identical default values.

E. Model Interpretability

LIME is an extensively used technique in the field of XAI, which intends to deliver transparent explanations for independent forecasting of intricate ML approaches [22]. It works on the principle that it can be approximated more easily by explainable strategies. Therefore, a model-agnostic system, LIME, is developed across a wide range of classifications and regressions without demanding access to the internal pattern of the algorithm. The major goal is to produce local approximators of a system's action in the specified occurrence to construct an interpretable method, usually a linear regression strategy.

$$\mathcal{L}(f, g, \pi_x) + \Omega(g) \tag{15}$$

Here, g represents a group of simpler approaches, $\pi_x(z)$ refers to a proximity among z and the χ, $\mathcal{L}(f, g, \pi_x)$ denotes the fidelity of g.

$$\pi_x(z) = \exp\left(-\frac{D(x,z)^2}{\sigma^2}\right) \tag{16}$$

where, σ regulates the width of the neighborhood, and $D(x, z)$ implies a distance metric, $\Omega(g)$ represents a complexity penalty.

$$\mathcal{L}(f, g, \pi_x) = \sum_{z \in Z} \pi_x(z) \cdot (f(z) - g(z))^2 \tag{17}$$

Here, Z signifies a group of perturbed instances in χ.

IV. Performance Analysis and Discussion

The experimental assessment of the IDCNN-ORM technique is achieved using the Social Media Sentiments Analysis Dataset [23]. This dataset captures a vibrant tapestry of emotions, tendencies, and relationships across diverse social media platforms. This dataset offers images of user-generated content, hashtags, combined text, timestamps, retweets, likes, and nations. Every entry reveals unique stories, namely moments of admiration, excitement, surprise, thrill, contentment, and many more exchanged by individuals globally. The dataset comprises three classes: positive, negative, and neutral, as denoted in Table I and Table II, which demonstrate the sample social media content used for sentiment analysis.

TABLE I. Details of Dataset

Class Label	Count
Positive	455
Neutral	112
Negative	165
Total	732

TABLE II. Sample Content

S.no	Text	Sentiment
1	Reflecting on the past and looking ahead.	Positive
2	Trying out a new dinner recipe tonight.	Neutral
3	Traffic was terrible this morning.	Negative

TABLE III. Sentiment Analysis of the IDCNN-ORM Method with 70% of TRAIP

Classes	$Accur_y$	$Preci_n$	$Recal_l$	F1	ROC_{AUC}	MCC
TRAIP (70%)						
Positive	91.21	91.34	95.03	93.15	89.88	81.03
Neutral	96.68	91.04	84.72	87.77	91.68	85.93
Negative	91.02	82.73	77.12	79.82	86.15	74.13
Average	92.97	88.37	85.62	86.92	89.24	80.36

Table III and Fig. 3 present the sentiment analysis of the IDCNN-ORM approach with three classes for 70% of TRAIP. The proposed IDCNN-ORM method achieved an average value with $accur_y$ of 92.97% and MCC of 80.36%, implying its effectiveness as a social media sentiment classifier model.

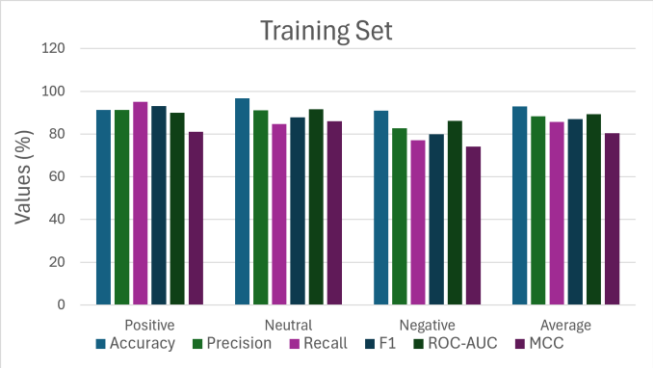

Fig. 3. Performance of the IDCNN-ORM approach with 70% of the training set.

Table IV and Fig. 4 display the sentiment analysis of the IDCNN-ORM method with three classes for 30% of TESTP. The proposed IDCNN-ORM approach achieved an average value of $accur_y$ of 94.85% and an MCC of 86.09%, denoting its efficacy in the social media sentiment classification task.

TABLE IV. SENTIMENT ANALYSIS OF THE IDCNN-ORM METHOD WITH 30% OF TESTP

Classes	**$Accur_y$**	**$Preci_n$**	**$Recal_l$**	F1	**ROC_{AUC}**	MCC
TESTP (30%)						
Positive	93.18	93.38	95.49	94.42	92.57	85.69
Neutral	96.36	92.11	87.50	89.74	92.92	87.58
Negative	95.00	89.13	87.23	88.17	92.17	85.01
Average	94.85	91.54	90.07	90.78	92.55	86.09

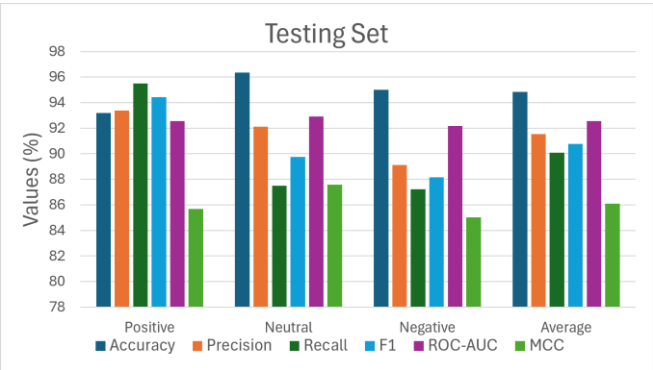

Fig. 4. Performance of the IDCNN-ORM approach with 30% of the testing set.

Fig. 5 depicts the training (TRAING) and validation (VALIDN) $accur_y$ curves of the IDCNN-ORM technique. The TRAING $accur_y$ continually increases, indicating effective learning and correct convergence of the system. The VALIDN $accur_y$ follows the training curve with small differences, suggesting higher generalization performance and lower overfitting.

Fig. 6 exemplifies the TRAING and VALIDN loss curves of the IDCNN-ORM method. The losses decline quickly in the earlier epochs and then decrease smoothly, representing effective learning and appropriate convergence. The minor differences amongst the TRAING and VALIDN curves exhibit less overfitting and superior generalization outcomes.

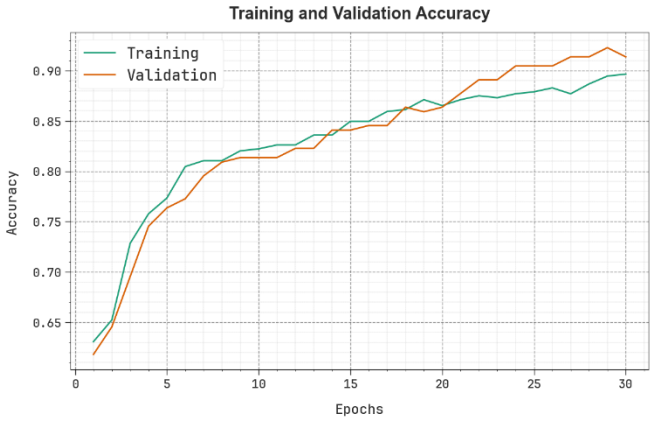

Fig. 5. $Accur_y$ curve of the IDCNN-ORM method.

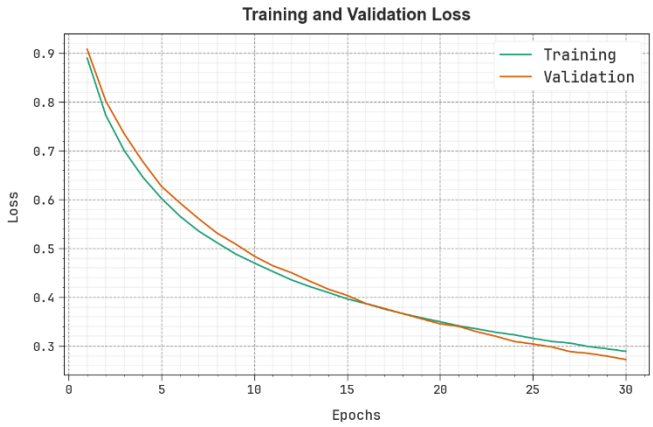

Fig. 6. Loss curve of the IDCNN-ORM approach.

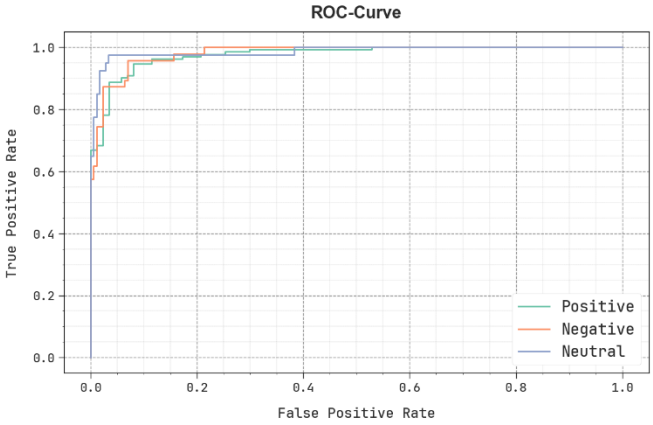

Fig. 7. ROC curve of the IDCNN-ORM method.

Fig. 7 portrays the ROC curve evaluation of the IDCNN-ORM system, representing boosted performance across all classes, signifying its strong discriminative ability. The consistently higher ROC values indicate the efficiency of the model in differentiating among class boundaries, and this steady pattern across numerous categories assures its consistency and robustness in the classification process.

Table V and Fig. 8 depict the comparison outcome of the IDCNN-ORM approach with existing methodologies using evaluation metrics [24-26]. The results imply that the SVM, LSTM, and DistilBERT approaches have lower performance, whereas the RoBERTa, CNN, and RNN methods have slightly greater values. Moreover, the CNN–LSTMHybrid has obtained moderate performance. At the same time, the proposed IDCNN-ORM approach has achieved superior performance with $accur_y$ of 94.85%. $preci_n$ of 91.54%, $recal_l$ of 90.07%, and F1 of 90.78%, emphasizing its robustness of the classifier tasks.

TABLE V. COMPARATIVE RESULTS OF THE IDCNN-ORM METHOD WITH OTHER APPROACHES

Methods	$Accur_y$	$Preci_n$	$Recal_l$	F1
SVM	70.04	71.52	70.4	70.14
CNN	87.62	85.5	88.5	88.7
RNN	87.02	88.1	88.3	87
LSTM	70.66	70.34	69.92	68.45
RoBERTa	80.61	80.54	80.01	80.92
DistilBERT	79.34	79.93	79.14	79.63
CNN–LSTMHybrid	92.14	89.64	87.53	88.32
IDCNN-ORM	94.85	91.54	90.07	90.78

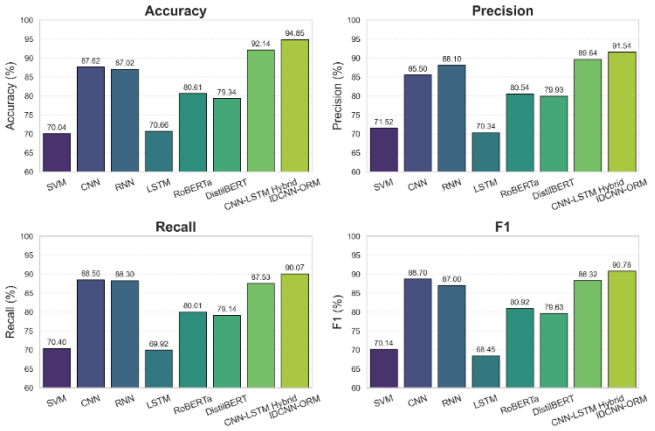

Fig. 8. Comparative results of the IDCNN-ORM method with various metrics.

Fig. 9, LIME-based local explanation of the proposed model's predictions for negative, neutral, and positive reputation classes. This figure indicates the contribution of individual features, where positive LIME weights support the predicted class and negative weights oppose it. Higher absolute weights indicate greater influence on the model's decision.

The proposed IDCNN-ORM architecture exhibits robust solutions in sentiment analysis for the ORM study. The improved mRMR feature selection successfully minimizes repetition and enhances the quality of the input features. The deep convolutional framework extracts rich hierarchical and contextual data from social media content. The AdaBelief optimizer accelerates convergence and improves training stability, enhancing learning efficacy. The experimental outcome demonstrates that the method attains promising outcomes over conventional systems, validating its efficiency.

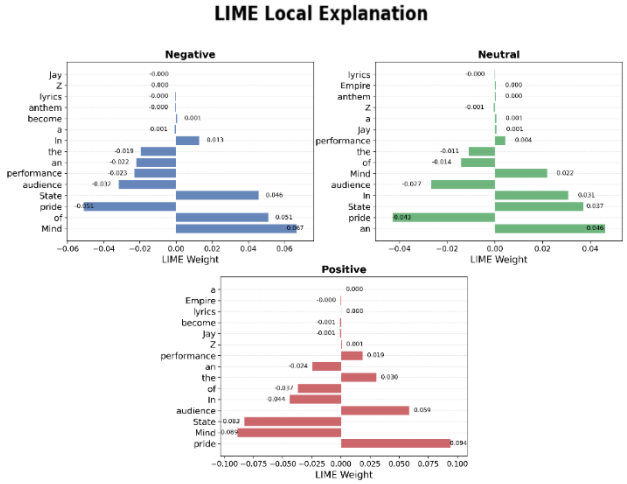

Fig. 9. LIME local explanation of feature contributions for negative, neutral, and positive reputation classifications.

V. CONCLUSION AND FUTURE WORK

This research introduced an IDCNN-ORM approach for enhancing reputation analysis using social media data. The proposed model incorporates an improved mRMR approach to select highly informative and non-redundant features. Moreover, the DCNN is employed to learn hierarchical feature representations from input data. The Adabelief optimizer is applied to enhance training stability by adaptively refining the learning process. Additionally, the LIME-based XAI technique is utilized to enhance transparency in the model's decision-making process. The experimental result analysis of the proposed IDCNN-ORM model is performed using the Social Media Sentiments Analysis Dataset. The comparative analysis demonstrates promising performance with an accuracy of 94.85% compared with existing methodologies. Despite the strong performance of the IDCNN-ORM approach, it still has challenges in handling extremely ambiguous and contextual sentiments in social media content. In the future, it can concentrate on combining transformer-based frameworks to extract long-range contextual dependencies in text information. An innovative feature selection algorithm can be investigated to minimize repetition and enhance adaptability. This technique can be applied to sentiment analysis for wider applicability across global social media platforms. Moreover, integrating progressive explainable AI methodology can improve transparency and customer trust in real-time ORM organizations.

Design of a Mobile Application with a Hybrid Recommendation System for Connecting Andean Farmers and Urban Consumers in Peru

Jorge Mayta, Astrid Boronda, Juan Montes
Faculty of Engineering, Universidad Peruana de Ciencias Aplicadas (UPC), Lima, Peru

***Abstract*—The dependence on intermediaries within agricultural marketing chains not only reduces producers' profits but also generates consumer distrust regarding the quality and traceability of the products they obtain. This work proposes a mobile application with a hybrid recommendation system aimed at connecting farmers and consumers in Peru. The combination of collaborative filtering and content-based filtering achieves personalization of the shopping experience based on the producer's offer and the user's interests. Likewise, mobile geolocation technology is incorporated to support delivery tracking, together with an offline-first approach to support the application's operation in rural areas with limited connectivity. A preliminary evaluation of the recommendation system, using the Amazon Reviews 2023 dataset (100,000 interactions), compares the hybrid model against collaborative filtering, content-based filtering, and a popularity baseline across RMSE, F1-score@5, catalog coverage, and diversity. The results show that collaborative filtering provides the strongest performance among the models offering meaningful catalog coverage, while the fixed-weight hybrid configuration evaluated in this study did not outperform it, identifying weight optimization as a priority for future work. The offline-first architecture maintains a 100% synchronization rate even under intermittent connectivity conditions, providing preliminary technical evidence under controlled conditions.**

I. Introduction

Currently, in Peru, there is a structural disconnection between Andean farmers and urban consumers, which negatively impacts both farmers' profitability and end consumers' trust regarding the origin and quality of products. On one hand, farmers depend largely on intermediaries to market their products. In 2019, 46.8% of producers accessed regional, agro-industrial, or export markets; by 2024, this percentage decreased to 45.7% [1], showing a decline in the overall percentage of producers accessing the market. This limitation affects family farming, which represents 99.8% of the country's agricultural units, of which approximately two-thirds correspond to subsistence family farming [2], a segment characterized by lower access to direct markets and, consequently, greater dependence on intermediaries for selling their production. On the other hand, urban consumers are uncertain about the quality, origin, and traceability of agricultural products, which decreases their trust in traditional purchasing channels [3]. This situation shows why traditional supply chain systems are unable to respond to consumers' growing interest in knowing the origin of what they buy, due to the centrality and vulnerability of the information they handle, reducing trust among the actors in the logistics process [4].

This study aims to design, implement, and preliminarily evaluate a mobile application that connects farmers and consumers for the sale of agricultural products through a personalized recommendation system. This will allow farmers to access a direct marketing channel, while consumers will have greater trust and transparency regarding the products.

The main problem lies in the disconnection between Andean farmers and urban consumers, which limits access to detailed product information. Simple approaches, such as product lists, fail because they ignore user preferences and the variation in supply when relying on historical interaction data processing; as a result, they struggle to capture dynamic changes in user interests and product attributes [5]. Furthermore, when there is a lack of initial data, the problem known as "cold start" arises, which affects the performance and accuracy of the recommendation system, becoming evident as the number of new users and items increases [6].

There are several technological solutions aimed at improving agricultural marketing, such as e-commerce platforms, digital agriculture systems, and mobile applications [7]. First, several platforms are not designed for low-connectivity contexts, given that internet use in rural areas in 2024 was 62.6% compared to 86.1% in urban areas, a difference of 23.5 percentage points [8], showing the difficulty of their adoption in Andean rural areas [9]. Second, existing solutions tend to focus only on the transaction itself, that is, buying and selling, without integrating traceability mechanisms [10]. Furthermore, although some systems incorporate recommendations, these are generally basic or not adapted to the agri-food context [11]. Finally, many proposals fail to adequately account for the digital literacy limitations of the agricultural population, which creates barriers to the use of advanced technologies and results in low technology adoption [12]. Likewise, insufficient technical training and the persistence of the digital divide restrict access to learning opportunities and technological resources, representing factors that limit the development and modernization of the agricultural sector [13].

The key components of this research include the use of a hybrid recommendation system that combines collaborative filtering and content-based filtering to improve the recommendations of products offered to users. Likewise, mobile geolocation technology is integrated to support order tracking of agricultural products. The system also integrates a data management module that stores and processes information related to products, users, and transactions, facilitating interaction between stakeholders through an intuitive interface. As a limitation, hybrid recommendation systems may require greater computational complexity and proper integration of multiple data sources, since these can affect their performance.

The main contributions of this work are as follows:

- A mobile application is developed that integrates a hybrid recommendation system to connect Andean farmers with urban consumers in Peru.
- A hybrid recommendation model is proposed that combines collaborative and content-based filtering to improve the personalization of agricultural products.
- An order tracking system based on mobile geolocation is designed and implemented, allowing consumers to monitor the status and route of deliveries.
- A preliminary evaluation of the recommendation system is conducted using a public dataset from the agri-food domain (Amazon Reviews 2023).
- The offline-first architecture is validated through controlled synchronization tests under three network conditions (full connection, total offline, and intermittent connection).
- As future work, the construction of a proprietary dataset from real user interactions and an evaluation with real users (farmers, consumers, and delivery drivers) are proposed.

This article is organized as follows. Section II presents the related work. Section III describes the conceptual background, system architecture, and proposed method. Section IV presents the experimental protocol, results, and discussion. Section V presents the conclusions and future work.

II. Related Work

In recent years, various digital solutions have attempted to connect farmers with consumers to reduce the information gap, increase product visibility, and simplify purchasing decisions. Faced with limitations such as intermediation, the scarcity of structural data in rural environments, and distrust, approaches based on recommendation systems have emerged, with hybrid systems improving the accuracy and adaptability of recommendations in dynamic environments. This section reviews related works that employ this type of approach or similar proposals. These studies show that, although hybrid systems represent an improvement over traditional methods, they still face significant challenges, such as the integration of heterogeneous data and the complexity of managing supply fluctuations.

In [14], the authors propose APGCN-CF, a model based on graph convolutional neural networks that optimizes agricultural product recommendation in rural e-commerce by integrating spatial and temporal information. This approach improves recommendation accuracy, especially for minor products, outperforming conventional methods. However, its performance depends on large volumes of high-quality data and constant connectivity, which limits its applicability in rural environments with restricted technological infrastructure. In contrast, the proposed system adopts a hybrid recommendation approach centered on collaborative filtering combined with content-based filtering, plus a fallback mechanism for cold-start, which seeks to maintain a good level of personalization even when interaction data is limited, without requiring large volumes of high-quality information.

In [15], the author proposes P-FARM, an e-commerce recommendation system based on profit-supported fuzzy association rule mining, which incorporates economic criteria to optimize both recommendation accuracy and transaction profitability. This approach demonstrates improvements in system effectiveness by balancing user satisfaction with business benefits. However, it requires large volumes of consistent transactional data, which restricts its application in informal or low-digitalization agricultural contexts. Furthermore, its emphasis on profit maximization may conflict with equity objectives for producers. By contrast, the proposed approach integrates two distinct components: personalized, consumer-oriented recommendation algorithms and an offline-first architecture that allows farmers and delivery drivers to register and manage their products in areas with limited connectivity, synchronizing once the connection is restored.

In [16], the authors present FarmFresh, a web and mobile application developed in India that allows small farmers to sell their products directly to consumers without intermediaries. Their system incorporates features such as inventory management, order intake, and purchase tracking, which improve the organization and control of sales. The results obtained show an increase in sales and a high level of satisfaction among both farmers and consumers. However, the proposal is oriented toward an environment with better connectivity conditions and does not account for the technological limitations specific to rural areas. By contrast, the proposed system integrates personalized recommendation algorithms and an offline-first architecture oriented toward Andean areas with limited connectivity.

In [17], the authors analyze how the use of digital platforms in Peru influences the profitability of family farmers. The authors find that the use of these tools makes it possible to increase income, reduce transaction costs, and improve efficiency in the marketing of agricultural products. However, they also show low technology adoption due to digital infrastructure limitations and low levels of technological literacy in rural areas. These barriers restrict the impact of existing digital solutions. On the other hand, this work designs a mobile application adapted to these problems through simple interfaces and an offline-first architecture that allows it to function even without a constant connection, facilitating its adoption in the Andean context.

In [12], the authors present AgroTIC, a mobile application developed in Colombia that connects farmers, agronomists, and merchants through the use of technologies such as ICT, IoT, and machine learning, focusing on crop recognition and agricultural information management. This solution seeks to improve productivity and decision-making in the agricultural sector through the use of smart technology. Despite having active users, adoption in rural areas was limited due to a lack of trust in technology and internet connectivity problems. These limitations affect the system's scalability in rural contexts. By contrast, the proposed system focuses mainly on product recommendation, order tracking, and direct trade between Andean farmers and urban consumers, taking intermittent connectivity and ease of use into account from the design stage.

Table I summarizes the key characteristics of the reviewed works compared to the current proposal.

Proposal	✓	✓	✓	✓

Beyond merely integrating existing recommendation techniques into a single system, the technical novelty of this work lies in the design of a hybrid model built for the specific constraints of the deployment environment. Instead of relying on external machine learning libraries, both collaborative and content-based filtering are implemented natively in Java 21 using cosine similarity; this keeps the recommendation engine lightweight and free of heavy runtime dependencies that would be difficult to maintain in a resource-constrained, intermittently connected backend. Their outputs are combined through a fixed weighting scheme (45% collaborative, 55% content-based), together with a fallback mechanism that mitigates the cold-start problem for new users and products. As discussed in the Results and Discussion, this fixed ratio was set a priori rather than tuned through systematic search, and the evaluation reported in this study identifies weight optimization as a necessary next step; the contribution of this component lies in the dependency-free, configurable fusion mechanism itself, rather than in a claim that the current weighting is already optimal. This combination of a dependency-free implementation and an explicit cold-start fallback distinguishes the proposed approach from prior agricultural recommender systems, which typically rely on specialized ML infrastructure (e.g., graph neural networks) that assumes larger, denser datasets and more stable computational environments than those available in the target context.

III. CONTRIBUTION AND METHOD

A. Preliminary Concepts

This section presents the main theoretical concepts used in the research. These concepts allow us to understand the use of digital technologies, recommendation algorithms, and supply chain management in the agricultural context, which underpin the development of a mobile application to connect Andean farmers with urban consumers.

1) Agricultural digitalization [18]: Digitalization in agriculture consists of the use of technological tools to optimize agricultural practices and improve production and commercial processes.

In this context, digital platforms, such as mobile applications, make it possible to directly connect farmers with urban consumers, eliminating intermediaries and optimizing logistics.

2) Recommendation algorithms [12]: These are techniques used to predict which items might be of interest to a user based on their previous preferences and behavior patterns.

These algorithms make it possible to personalize user experience, improve customer satisfaction, and optimize sales on agricultural digital platforms.

3) Logistics and supply chain [19]: Logistics comprises the processes of transportation, storage, and distribution of products within a supply chain.

In the agricultural field, efficient supply chain management helps minimize post-harvest losses, ensure product quality, and facilitate traceability, which contributes to building consumer trust.

4) Hybrid recommendation system [20]: A hybrid recommendation system combines more than one recommendation technique with the aim of leveraging the strengths of both systems used and reducing the limitations of each system. It generally integrates methods such as collaborative filtering and content-based filtering to improve the accuracy and relevance of recommendations.

This approach allows the urban consumer to have a personalized shopping experience while, at the same time, increasing the visibility of products offered by Andean farmers within the platform.

5) Collaborative filtering [20]: Collaborative filtering is a recommendation technique that generates suggestions based on the preferences, behaviors, or interactions of users with similar interests. This approach is based on the idea that users who shared consumption patterns in the past may show similar preferences in the future.

This technique makes it possible to recommend agricultural products to a consumer based on the purchases, views, or preferences of other consumers with similar behavior within the platform.

6) Content-based filtering [20]: Content-based filtering is a recommendation technique that uses product characteristics to identify items similar to those the user has previously viewed, purchased, or rated.

In the agricultural context, this approach allows products to be recommended considering attributes such as category, product type, price, origin, or availability.

7) Mobile geolocation [21]: Mobile geolocation is the process by which the approximate geographic location of a mobile device is determined using technologies such as GPS, smartphone sensors, mobile networks, or geofencing mechanisms.

In the proposal, geolocation makes it possible to record the approximate location of delivery drivers or farmers during order transport, facilitating delivery coordination and giving the consumer greater confidence about the status and route of the products ordered.

8) Offline-first architecture [22]: Offline-first architecture is an application design approach that keeps critical functionality available even when there is no internet connection or connectivity is limited. To achieve this, the application prioritizes local storage and allows certain operations to be carried out without permanently depending on the server.

This approach is mainly aimed at farmers and delivery drivers, who may operate in rural areas or routes with intermittent connectivity.

9) Data synchronization in mobile applications [22]: Data synchronization in mobile applications is the process by which information recorded locally on the device is subsequently updated with the central server once the internet connection is restored.

In an offline-first architecture, this process is essential for maintaining data consistency, allowing products registered by farmers and delivery statuses recorded by delivery drivers to be correctly reflected on the platform.

B. System Architecture Overview

The general architecture of the proposal is presented in Fig. 1. The solution was developed as a mobile application in Flutter under an offline-first approach, with a backend implemented in Spring Boot and a central MySQL database. Communication between the mobile application and the backend is carried out through a REST API protected with JWT-based authentication and authorization. As shown in Fig. 1, the application incorporates a local database (SQLite with Drift), an automatic synchronization client, a pending-changes queue, and a geolocation module, allowing consumers, farmers, and delivery drivers to keep using the platform even in scenarios of limited or intermittent connectivity.

On the backend side, business logic is centralized through modules for product and farmer management, orders and deliveries, geolocation, hybrid recommendations, synchronization, authentication, and notifications. The recommendation engine combines collaborative and content-based filtering to generate personalized recommendations, while the cold-start problem is addressed using products with higher ratings, popularity, or demand. Additionally, Azure Storage stores product images, and Firebase Cloud Messaging enables push notifications.

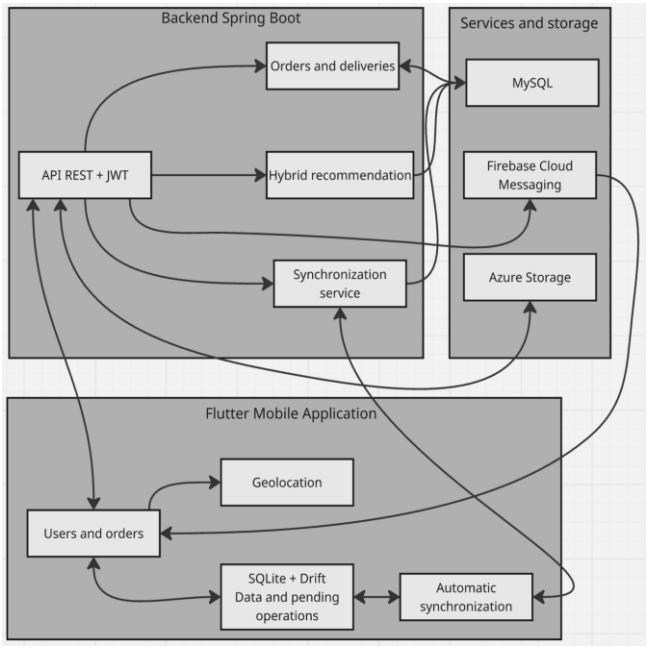

Fig. 1. General architecture of the proposed mobile application.

To protect sensitive location and identity information, the platform's security model addresses a specific threat scenario rather than offering general security guarantees. Payment processing is out of scope, as financial transactions take place outside the application. The primary focus is on safeguarding user identities, maintaining Role-Based Access Control (RBAC) boundaries among farmers, consumers, and delivery personnel, and preserving data integrity during transmission. Authentication and access permissions rely on JSON Web Tokens (JWT), chosen to align with the system's "offline-first" operational capabilities.

Since mobile devices often operate without constant backend connectivity, maintaining session states on the server would disrupt offline usage; instead, self-contained tokens allow for the local verification of authorization credentials between synchronization intervals. Geolocation data collected for delivery tracking requires explicit consent, as it is processed solely during delivery operations and transmitted via encrypted channels. Access to these tracking records is strictly restricted to the relevant consumer, producer, and driver. Furthermore, cached tokens and synchronization queues are kept in encrypted local storage, while location records are deleted once deliveries are completed and any potential disputes resolved. These measures mitigate key risks such as unauthorized access, session hijacking under fluctuating network conditions, and the misuse of location data; however, as they do not constitute a comprehensive security guarantee, the implementation of additional measures, such as formal security audits, is reserved for future stages of the project.

C. Method

The proposal is structured around three main contributions that address the identified problems: personalization of agricultural products through a hybrid recommendation system, logistical coordination through mobile geolocation, and operational continuity through an offline-first architecture for farmers and delivery drivers. These contributions help explain how the solution's main components interact and how technical problems such as cold-start, limited connectivity, and data synchronization are addressed.

The first contribution of this research consists of the implementation of a hybrid recommendation system aimed at improving the shopping experience within the TinkiyAgro platform. This system seeks to facilitate the connection between Andean farmers and urban consumers by generating personalized agricultural product recommendations.

The recommendation module implements a weighted hybrid strategy that combines collaborative filtering and content-based filtering. User-item interactions are built from three behavioral signals: favorites, product reviews, and purchases. Favorites receive a weight of 5.0, reviews use the explicit rating value, and purchases receive a weight of 3.0 plus a quantity-based increment capped at 2.0. These signals are aggregated by user and product.

The collaborative component computes user-user similarity using cosine similarity over the weighted interaction vectors. Candidate products are scored by accumulating the interaction weights of similar users, weighted by their similarity to the target user. The resulting scores are normalized by the maximum score observed in the candidate set.

The content-based component builds a user profile from the attributes of previously interacted products. The implemented features are product category, farmer identifier, sale format, and product popularity. The content score is computed as a weighted combination of category affinity, farmer affinity, sale-format affinity, and popularity, using weights of 0.55, 0.20, 0.15, and 0.10, respectively.

The final hybrid score is computed as 0.45 times the collaborative score plus 0.55 times the content-based score. Products already seen by the user receive a penalty of 0.20 in order to prioritize unseen items. For cold-start users without interaction history, the system falls back to a popularity score based on average rating and number of reviews.

Likewise, the system addresses the cold-start problem, which occurs when a new user does not yet have enough interaction history to generate personalized recommendations. For this case, the platform proposes an initial strategy based on products with higher ratings, popularity, or demand within the system. Subsequently, as the user performs searches, views products, or makes purchases, the system progressively updates its recommendations according to their actual behavior.

As illustrated in Fig. 2, the inclusion of this recommendation system makes it possible to personalize the browsing experience within the platform, facilitate the discovery of new agricultural products, and contribute to increased sales opportunities for registered farmers.

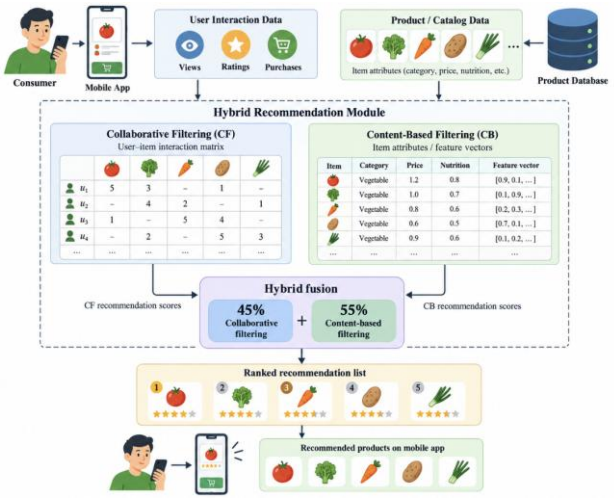

Fig. 2. Operation of the proposed hybrid recommendation system.

The second contribution of this research consists of the implementation of an offline-first architecture aimed at guaranteeing the availability of the application's main functionalities in environments with limited or intermittent connectivity.

As shown in Fig. 3, the system allows information to be temporarily stored on the mobile device, enabling farmers to register products, update them, and view relevant information without needing a permanent internet connection. Similarly, delivery drivers can view assigned orders and record delivery statuses even when there is no network coverage.

Once the device regains connectivity, the locally stored information is automatically synchronized, ensuring data consistency within the platform.

This approach responds to the connectivity conditions present in various Andean rural communities, where limited internet access can affect the continuous use of digital applications. Through this architecture, the goal is to ensure the operational continuity of critical processes such as product publishing and delivery management, reducing dependence on a permanent connection.

Fig. 3. Offline-first architecture for farmers and delivery drivers.

IV. EXPERIMENTS

A. Experimental Protocol

1) Development environment: This work was developed on a computer with a 2.6 GHz 6-core Intel Core i7 processor, an AMD Radeon Pro 560X 4 GB and Intel UHD Graphics 630 graphics, and 16 GB of 2400 MHz DDR4 memory. The mobile application was built using Flutter, and the recommendation engine was implemented in Java 21, running JDK 22.0.2 using the Spring Boot 4.0.1 framework. The application's source code is publicly available: the backend at https://github.com/JuanMontes18/TinkiyAgro and the mobile application (frontend) at https://github.com/TinkiyAgro/TinkiyAgro-Frontend

2) Data used: For the quantitative evaluation of the models, the public Amazon Reviews 2023 dataset (Grocery and Gourmet Food category) [23], published by McAuley Lab, was used. It was selected for its relevance to the agri-food sector and because it contains both explicit (ratings) and implicit (text reviews) interactions between users and products, allowing simulation of the purchasing and rating behavior the system seeks to model. In later stages, a proprietary dataset is planned to be built from real interactions between farmers and consumers within the application.

The evaluation used the Grocery and Gourmet Food category from Amazon Reviews 2023. According to the dataset documentation, this category contains approximately 7.0M users, 603.2K items, and 14.3M ratings. User-item interactions were built from explicit ratings using parent_asin as the item identifier. Items with ratings greater than or equal to 4.0 were treated as relevant for top-k evaluation.

To assess robustness, the experiment was repeated with five random seeds (1, 2, 3, 4, and 5) using an 80/20 user-stratified random holdout split. The same dataset, preprocessing rules, model parameters, and evaluation metrics were kept fixed across runs. Results are reported as mean ± standard deviation.

To validate the offline-first architecture, an automated and controlled test was run on the repositories responsible for local storage (SQLite via Drift) and synchronization with the backend. Network conditions (full connection, total offline, and intermittent connection) were simulated using instrumented remote services, allowing control over network behavior during each test.

B. Result

This subsection details the experiments carried out and the results obtained in each of them:

1) Comparison of recommendation models: Before evaluating the recommendation models, the Amazon Reviews 2023 dataset (Grocery and Gourmet Food category) was processed to prepare an appropriate evaluation subset. Table II outlines the primary attributes of the resulting dataset, detailing the counts of users and items included, total retained interactions, overall sparsity, and the train-test splitting methodology applied consistently across all experimental runs and random seeds.

TABLE II. CHARACTERISTICS OF THE EVALUATION DATASET (AMAZON REVIEWS 2023)

Field	Value
Users	10,459
Items	47,961
Interactions	100,000
Unique user-item pairs	97,884
Sparsity	0.999805
Split	User-stratified random holdout, test_ratio = 0.2
Seeds	1, 2, 3, 4, 5

To evaluate the proposed hybrid system, its performance was compared against a pure collaborative filtering model and a pure content-based model, using the Amazon Reviews 2023 dataset (Grocery and Gourmet Food). The metrics used were RMSE (rating prediction error), F1-score@5 (top-5 ranking quality), Coverage (catalog coverage), and Diversity@5 (intra-list diversity). Table III shows the results obtained for each model.

TABLE III. COMPARISON OF RECOMMENDATION MODELS ACCORDING TO ACCURACY, RANKING, COVERAGE, AND DIVERSITY METRICS

Model	*RMSE*	*F1-score@5*	*Coverage*	*Diversity@5*
Popularity	**2.3199 ± 0.0039**	**0.0245 ± 0.0005**	0.02% ± 0.00%	0.7346 ± 0.0260
Collaborative	2.8651 ± 0.0063	0.0200 ± 0.0005	**11.63% ± 0.15%**	**0.8986 ± 0.0040**
Content Based	2.8881 ± 0.0043	0.0149 ± 0.0002	5.47% ± 0.07%	0.3952 ± 0.0088
Hybrid	3.0342 ± 0.0034	0.0185 ± 0.0005	10.39% ± 0.11%	0.6072 ± 0.0042

Table III shows that the popularity baseline achieves the lowest RMSE (2.3199) and the highest F1-score@5 (0.0245), reflecting a well-documented behavior of top-k ranking metrics: recommending the most frequently purchased items maximizes short-term accuracy and ranking overlap with a sparse test set, but at the cost of catalog coverage, which remains close to zero (0.02%), effectively recommending the same narrow set of products to nearly all users, which runs counter to the platform's goal of increasing visibility for a broader base of farmers and products. Among the models that provide meaningful catalog coverage, collaborative filtering achieved the best result across all four metrics (RMSE 2.8651, F1-score@5 0.0200, Coverage 11.63%, Diversity@5 0.8986), outperforming both content-based filtering and the hybrid configuration evaluated in this study. The hybrid model, combining collaborative and content-based scores with a fixed 45%/55% weighting, did not outperform collaborative filtering alone at this scale. This indicates that the specific weighting ratio used was not optimal for the sparsity and interaction patterns observed in this dataset; the 45/55 split was selected a priori rather than tuned through systematic search. Optimizing this parameter, potentially through per-context rather than fixed weighting, is identified as a priority for future work.

Rather than presenting the fixed-weight hybrid configuration as an optimized final model, the contribution of

this component lies in the native, dependency-light implementation described in Section II, together with a reproducible evaluation protocol, repeated runs with standard deviations, and a popularity baseline that makes the current limitation transparent: at the tested weighting ratio, the hybrid model does not outperform collaborative filtering alone. Reporting this result, rather than obscuring it, identifies the necessary next step for this line of work: a systematic search over the weighting parameter, rather than assuming the current fixed ratio is production-ready.

2) Validation of offline-first functionality: To evaluate the system, 4 key flows were analyzed: product creation, product editing, pickup point creation, and marking an order as ready. Each one was evaluated under 3 different network conditions. The study covered 240 operations, running 20 per flow in each scenario evaluated. The integration of local logging was validated through the syncOperations table in Drift/SQLite, while synchronization effectiveness was determined by checking whether operations changed to the synced state. A Stopwatch was also used to quantify latency, measuring the interval from the start of the process to its successful confirmation. Table IV presents the results obtained.

TABLE IV. RESULTS OF COMPLETENESS, SYNCHRONIZATION, AND LATENCY OF THE OFFLINE-FIRST ARCHITECTURE

Network Condition	*Operation*	*Complete local registration*	*Successful synchronization after reconnection*	*Synchronization latency*
Full connection	80	100%	100%	0.031 s
Total offline	80	100%	100%	0.049 s
Intermittent connection	80	100%	100%	0.311 s

The "total offline" scenario does not imply immediate synchronization with the server while offline. Instead, it means that all operations were saved in the local SQLite queue during the outage and successfully synced once the connection was restored. Thus, the recorded latency reflects only the time taken by the synchronization process after triggering the routine for pending tasks.

C. Discussion

1) Comparison of recommendation models: The hybrid model should not be interpreted as the best model across all individual metrics. Instead, the results show different trade-offs. The popularity baseline achieved the best RMSE and F1@5 in this highly sparse sample, which indicates that frequently rated and highly rated products are easier to recover under limited interaction density. Collaborative filtering achieved the highest coverage and Diversity@5, suggesting broader catalog exploration when enough overlapping user behavior exists. The hybrid model combines collaborative and content signals, but in this configuration it should be presented as a balanced alternative rather than as a universal improvement over all baselines.

2) Validation of offline-first functionality: As shown in Table IV, the offline-first architecture guarantees 100% effectiveness in local registration and synchronization under all three conditions analyzed, ensuring the integrity of all operations regardless of network stability. However, a notable variation in latency is evident: while in full-connection scenarios the average is 0.031 s, this value rises to 0.311 s under intermittent connections. This increase, close to ten times the initial figure, is attributable to the additional processing required to detect and transmit the queue of pending operations after reconnection.

This result is consistent with the expected behavior of an architecture that seeks to prioritize data integrity, ensuring that nothing is lost, over synchronization speed when the network is unstable, which is especially relevant for the context of Andean rural areas with limited connectivity.

It should be noted that, to support the experiment's repeatability, instrumented services were used to simulate network conditions. Consequently, the findings reflect how the offline-first architecture behaves in controlled environments, which means they are not a direct measure of the inherent volatility of mobile networks in real-world scenarios. This distinction represents an important limitation that should be addressed in future validations carried out under uncontrolled network conditions.

Upon reconnecting, the system automatically initiates synchronization to upload all pending local operations to the server. However, the present build lacks mechanisms for resolving concurrent editing conflicts and managing retry attempts for failed transmissions. Handling these edge cases, such as duplicate operations, expired authentication tokens, application restarts, and simultaneous edits, remains a key priority for future work.

V. CONCLUSION

TinkiyAgro was developed as a mobile application that connects Andean farmers, consumers, and delivery drivers through a hybrid recommendations system, a GPS/GNSS-based delivery-tracking module, and an offline-first data architecture. From the outset, the recommendation module includes a fallback strategy to mitigate the cold-start problem for users without purchase history and adapts suggestions progressively as interaction data becomes available.

The evaluation focused on two of these components under controlled conditions: the recommendation model, assessed through RMSE, F1-score@5, Coverage, and Diversity@5 on the Amazon Reviews 2023 dataset, and the offline-first architecture, assessed through local-registration completeness, synchronization success rate, and latency under simulated network conditions. The results provide preliminary technical evidence that both components operate as intended under these controlled scenarios. The geolocation-based delivery-tracking module was implemented but not subjected to a comparable empirical evaluation; its accuracy, update latency, and behavior under connectivity loss remain untested. Validation with real users (farmers, consumers, and delivery drivers), including usability, perceived trust, and field performance of the tracking

module, remains pending and is identified as a priority for future work. A geolocation-based delivery tracking module was implemented but did not undergo a comparable empirical evaluation; details such as its accuracy, update latency, and behavior during connectivity loss remain untested. Validation with real users (farmers, consumers, and delivery personnel), covering the module's usability, perceived trustworthiness, and field performance, is still pending and has been identified as a priority for future work.

In conclusion, the results obtained provide preliminary technical evidence for two core components of the proposed solution: a recommendation module comparing hybrid, collaborative, and content-based filtering under a reproducible, multi-seed evaluation protocol, which found that collaborative filtering alone provided the strongest results among the evaluated models and identified weight optimization as a necessary next step for the hybrid formulation to realize its intended benefit, and an offline-first architecture designed to support operational continuity under limited or intermittent connectivity. These findings should be interpreted as evidence of technical feasibility under controlled conditions rather than as validation within the Andean rural context itself. As future work, it is proposed to evaluate the complete application, including the geolocation module, with real users in field conditions, to assess usability, scalability, and the system's actual impact on farmer income and consumer trust.

DECLARATIONS

A. Declaration on Generative AI Use

During the preparation of this study, the authors used a generative AI tool to help refine the language and formatting consistency, as well as to generate illustrative figures (Fig. 2 and Fig. 3). All AI-assisted text and figures were critically reviewed, verified, and edited by the authors, who assume full responsibility for the accuracy and content of the final paper. The generative AI tool played no role in the development of the scientific ideas, the design of the recommendation algorithm, the experimental methodology, or the interpretation of the results.

B. Conflict of Interest

The authors declare no conflict of interest.

C. Data Availability

The Amazon Reviews 2023 dataset used for the recommendation model evaluation is publicly available at https://amazon-reviews-2023.github.io/.

AI-Driven Personalized Learning Framework for Computing Fields Recommendations in Secondary and Pre-University Contexts

Anas Inuwa Usman[1], Shahida Sulaiman[2], Ruhaidah Samsudin[3]
Faculty of Computing, Universiti Teknologi Malaysia, 81310, Johor Bahru, Johor, Malaysia[1, 3]
Knowledge Wonders PLT, 81930, Bandar Penawar, Johor, Malaysia[2]

***Abstract*—Students or learners, especially those at the secondary and pre-university levels, face challenges in identifying suitable computing fields for personalized educational resources towards their tertiary education specialization pathways. Traditional advising methods/approaches such as guidance from school counselors and teachers often lack personalization and practical relevance because their knowledge of the field is limited. This research aims to close this gap by proposing Computing Field Recommender (ComReF), an end-to-end Machine Learning framework that integrates student assessment and a profile built from demographic attributes and assessment performance, with semantic resource generation to deliver personalized, interpretable, and pedagogically grounded recommendations. A Random Forest-based multi-class classification strategy predicts suitable computing fields and corresponding proficiency levels, with empirical results showing improved performance over Decision Tree, Logistic Regression, and Naïve Bayes classifiers. NLP was also used for string cleaning and to automatically generate URLs for resources such as YouTube, Wikipedia, and Coursera. Consequently, all generated resources undergo a domain-informed validation protocol based on industry and academic checklists/benchmarks, ensuring their relevance and quality. The evaluation was conducted on a sample of 500 labeled instances using ChatGPT and available assessment data. The results show a strong classification accuracy (F1-score ≥ 0.8 for a well-represented field) in skill-level classification and field-level predictions across the computing fields/subfields that indicate moderate accuracy (with a weighted F1 = 0.59), reflecting real-world data imbalance, and producing relevant resource sets that are topically consistent with the predicted computing specializations and career goals. By bridging predictive modeling with semantic web navigation, ComReF offers a suitable solution for computing field recommendations and helps reduce gaps in traditional advising approaches.**

***Keywords*—Artificial intelligence; machine learning models; pre-university level; personalized learning; computing fields; recommender systems**

I. Introduction

The choice of specializations in Computing, particularly among secondary and pre-university students, depends on several factors. These factors include financial barriers, limited knowledge of the nature of various fields and their requirements, tuition fees for certain programs, the educational institutions offering the programs, and concerns about the ability to meet academic requirements [1]. Recommender systems provide evidence-based information to help learners select courses by suggesting alternatives based on their interests and performance profiles and aligning with their academic goals and objectives [2]. In addition, these systems contribute to helping students meet curricular needs, expand their career opportunities, and engage in intellectual growth [3].

Advancements in artificial intelligence (AI) have allowed recommender systems to streamline individualized recommendations [4]. However, the extent to which AI-based systems can influence students' field choices remains under-researched. It is necessary to gain more understanding of how students perceive and expect such systems [5]. In addition, AI chatbots have become a topic of interest among scholars worldwide and have the potential to change educational systems in various ways. They can offer real-time support, answer questions, explain concepts, and provide individualized learning materials. Moreover, chatbots can serve as an additional tool of virtual teaching [6].

Over the years, students have often struggled to choose elective courses because of the growing number of choices available to them. As elective options expand, course recommender systems have become more relevant for accurate choices [7]. The significant increase in AI as a digital assistant is especially impressive, as it provides individualized learning by incorporating educational assets based on students' personal preferences and the requirements of their discipline [8]. They support teachers and learners across various dimensions of the educational process [9]. The potential to address the limitations of conventional career-support mechanisms is significant in the context of integrating AI-driven conversational frameworks into career guidance platforms [10]. Research suggests that AI-driven advising or career guidance can be effectively operationalized when supported by strong technological foundations, such as advanced natural language processing frameworks and secure, cloud-based machine learning services that provide effective, personalized guidance [11]. In addition, effective systems should be flexible enough to adapt to new work-market factors and institutional developments [12].

On the other hand, even with the rising demand for professionals holding bachelor's degrees in Computing-related fields, undergraduate enrollment in Computer science and Computer engineering programs has shown a marked decline in recent years [13]. An earlier alarm was also raised by Lent

[14], [15]. The continuing inadequate representation of women and minority groups in the computing sector, together with an associated downward trend in the number of students seeking computing courses, continues to raise a red flag despite the rising labor market demand [16].

The issue highlights the need to understand psychosocial and contextual factors that influence students' choices about whether to pursue or avoid computing disciplines, especially among underrepresented populations. In a larger sense, it reflects efforts to increase the number of students recruited and retained in STEM fields [17]. The dwindling interest in computer-related programs is a long-standing international issue with major long-term implications. This tendency underlines the dire need to come up with new methods of popularizing those fields and to reconsider the avenues through which they are marketed [18] Cohon et al. (2018). Student representatives of different groups still consider the interest in the career field as one of the most powerful factors in career decision-making [19].

Although there are attempts to democratize access to Computer Science, the field remains characterized by significant skewness beyond existing gender and socioeconomic imbalances. The level of computing interest and engagement is comparatively stronger and higher among male students, and undergraduates are prone to leaving school, especially among low-income earners [20], [16]. To this end, it is necessary to provide extensive, impartial exposure to computing, an indispensable requirement when increasing the level of involvement and broadening opportunities in these fields [21]. Computer Science is a crucial field in developing future technological leaders; however, the accessibility and inclusion problems are often ignored in existing curricula [22]. There is a growing need for practical guidance on accessible computing that equips learners with strategies to design more inclusive learning environments. This guidance must clarify the ethical, legal, and pedagogical requirements of accessibility and how inclusive practices can bring benefits to all learners, including learners with disabilities [23]. In addition, there is a need to differentiate teaching accessibility as a discipline on its own and the integration of accessibility principles into instructional practice as an educator [24].

Computing has been encompassed in a wide field of study known as Computer Science; it has since split into various specialized fields, including AI, cybersecurity, software engineering, network engineering, business intelligence, sustainable computing, and data science [25]. Each of these fields requires distinct competencies, offers unique career pathways, and follows differentiated learning trajectories [26]. The diversification can be seen as a sign of the maturation of the discipline and its embedding into almost all sectors of the world economy [18]; [27]. As a result, it poses a great cognitive and navigational dilemma to the students who, in most cases, must make high-stakes specialization choices without enough exposure, experience, or guidance [28].

Academic advising, mostly based on stagnant curricula or general career presentations, cannot even keep up with the fast-changing environment and does not fulfill the dynamic counseling requirements of the students [29], [30]. Conversely, recommender systems are also used on online learning platforms like Coursera and edX, where they generally become active after enrolment and provide recommendations based on learners' previous interactions. Nonetheless, these systems rarely offer recommendations for choosing a field of study based on diagnostic data or assessment information [31]. Similarly, most educational data mining methods focus on predicting academic achievement or the risk of dropping out of school, rather than providing an all-inclusive, easy-to-use learning-to-career map for learners [32].

There is still a notable gap in recommender systems capable of linking diagnostic assessments with the automated generation of semantically relevant learning resources [33]. Most AI-driven tools provide only high-level labels, such as “AI,” or numerical competency scores, leaving students to locate their own learning materials. This process is often time-consuming and susceptible to information overload [34]. Even when learning resources are recommended, they are seldom evaluated against established pedagogical standards or current industry benchmarks [35], [36]. In the context of our research, these three important terms are thus defined as below:

Semantic resource generation is the process of creating platform-specific URLs with full canonical field names (e.g., Business Intelligence) instead of short codes or initials (“BI” for Business Intelligence and “AI” for Artificial Intelligence), which overcomes problems of fields that may have the same initials as Cryptography and Cybersecurity. It also ensures lexical matching in search interfaces like Coursera and Wikipedia.

Interpretable: implies that it is possible to trace predictions to input features by using model-internal measures of feature importance and explicit, auditable code-to-name mapping, which removes the need to use black-box components like deep learning models or large language models (LLMs).

Actionable and coherent: refers to an output that consists of a non-redundant collection of screened links, each of which retrieves topic-aligned resources with explicit descriptors of skills, such as in React.js, Data Analysis, and Ethical Standards.

Existing studies have focused on course selection [2], [5], career guidance [10], learner profiling [37], and learning paths [38]. However, these functions are often addressed separately, with limited integration to guide secondary and pre-university learners toward suitable computing fields. To address this gap, ComReF integrates learner profiles and assessment data to recommend computing fields, identify skill levels, and provide relevant learning resources. Its main contribution is a lightweight and interpretable framework that supports early computing specialization and complements teacher and academic-adviser guidance.

To address the limitations mentioned earlier, ComReF is proposed as an end-to-end machine learning framework that transforms student assessments and profiles (including demographic and preference information) into personalized learning recommendations. It aims to guide and expose students to suitable computing fields from the secondary level based on their profiles and cognitive skills.

Hence, ComReF aims to reduce the gaps in the following aspects:

Learner Profiling: Learning unfolds differently for every individual. With the emergence of "Internet+" education, personalized learning has gained significant [39]. Digital learning materials have led to a significant rise in online learners in many aspects of activities [40]. As such, learners often face the problem of information overload and feel lost during the learning process [41]. These limitations may create a mismatch between a learner's actual competence and the difficulty of the suggested resources, increasing the risk of cognitive overload. Our approach aims to combine the ability to recognize and understand individual needs.

Field Mapping: The abundance of available learning resources has increased manifold, and the methods of resource selection have also changed in tandem with the learners. In that regard, learning materials have grown in significance [42]. Learning pathways are supposed to be adjusted to the educational field resources depending on learners' specific profiles [37]. We need to map resources by field, not randomly.

Resource Generator: A framework should allow searching by the entire field name to make the searches that are discovered pertinent and educational [43]. ComReF provides an organized learning path to help learners progress and optimize the entire learning experience.

Domain-Informed-Validation: This task is important as well as complicated, both in design, development, and evaluation of the learning environment in ways that support the distinct learner needs in a particular domain or field. A learning environment has several dimensions, such as physical, social, psychological, and pedagogical dimensions, that all constitute the environment where learning occurs [44]. In particular, the learning experiences refer to various interactions and different situations that stimulate the perceptions of learners [45]. ComReF screens suggested resources using a checklist based on compatibility with the requirements of the Malaysian education blueprints and industry standards.

Therefore, there is a need to develop accurate student profiles and models that analyze learners' affective, knowledge, personality, and skill levels. Thus, AI solutions offer considerable benefits, as they can incorporate reasoning into instructional decision-making and control potential sources of uncertainty. Therefore, they enable more efficient teaching and learning systems [46]. The following sections will elaborate on related works, the proposed framework, its implementation and prototyping, discussion, and conclusion.

II. Related Works

This section presents existing literature on educational recommender systems, career guidance in Computing education, semantic resource generation and validation, and validation pathways, which provide the foundation for this work and its relevance to targeted learners.

A. Educational Recommender Systems: From Courses to Careers

The evolution in educational recommender systems has shifted from primitive collaborative filtering methods such as course recommendations based on peer activity [47] to advanced hybrid models that combine knowledge tracing, learner profiles, and contextual metadata [48]. For instance, Coursera, edX, and some similar platforms currently adopt deep learning models to personalize course sequences, with studies indicating improved click-through rates when recommendations align with learners' goals [2]. Regardless of such developments, these systems operate reactively, requiring prior engagement [49]. Massive Open Online Courses provide a rich range of learning materials; however, they often overwhelm students due to their enormous volume, which results in problems like data sparsity and cold-start problems [50].

To alleviate these hindrances, EGRec was proposed [49]. It is an innovative course recommendation model that augments recommendation accuracy, diversity, and relevance by combining knowledge graphs and heterogeneous graph attention networks. The model uses multimodal information and dynamically selected subgraphs to improve performance, but it does not focus on field diversification, as seen in the field of Computing. Most educational recommender systems consider a field as a label of a static unit, but not as a semantic unit [51]. Thus, a learner who is designated as fit for AI, such as Generative AI, Computer Vision, or AI Ethics, a field in which entirely different skills are required, is not provided with any additional guidance. A survey of major MOOC platforms shows that only a small number of studies distinguish sub-fields of computing from broad categories, such as Networking, Software Engineering, and Multimedia, and tend to include separate career paths in excessively general categories [52]. This reduced granularity limits practical usefulness, as computing job advertisements are becoming more demanding in more specific areas.

B. Career Guidance in Computing Education

Selecting a computing specialization is a significant challenge [53]. An in-depth examination of how Computer Science and Computational Thinking are taught at lower levels of education is essential to creating consistent, high-quality courses and implementing professional development programs [54]. Computing education has become a high-profile research area in major universities, and institutions, industries, and communities have launched initiatives; however, issues still hinder the widespread implementation of computing education at the K-12 level [55]. Computational Thinking and Problem-solving skills have become important in students' development. Digital and serious games are also entering education at an affordable cost and promise to enhance students' learning [56]. This is comparable to findings of the American National Academies, which warned that without proactive advice, students, especially underrepresented ones, would often gravitate towards familiar or oversaturated fields such as web development, which would overlook high-opportunity ones like DevOps and other emerging specialties [18]. The traditional advising interventions are not very scalable [57]. A randomized controlled trial showed that one-on-one career counseling can enhance field alignment, but it is time-consuming. Moreover, this resource-intensive approach is not feasible for large-scale enrollment within a limited timeframe [58].

C. Semantic Resource Generation and Validation

Recent studies have begun to integrate prediction with outcomes that can benefit learners. Anomalous state of knowledge theory suggests that learners require contextualized information pathways, rather than merely labels [59]. Building on this concept, systems like Path2Learn were realized [60]. The focus on personalized learning paths has become increasingly prominent in education. Tran and team [38] examine the performance evaluation of user-based Collaborative Filtering and Content-based recommendation techniques to develop innovative RSs specifically designed for Information Systems (IS) students. By integrating a primary dataset grounded in the students' knowledge-skill-attitude framework, the study addresses the challenge of navigating the extensive range of learning options in IS. Wan and Lei [61] outline the undisputed benefits of accessible online resources; however, the abundance of these resources often leads to confusion and decision paralysis, so individualized, well-designed guidance is also required. On the same note, LLM-based recommender systems can rank coherent resource lists, but they are vulnerable to hallucination, especially in technical fields [62]. This can result in suggestions for non-existent courses or outdated tools. Validation is often treated as an afterthought in educational AI systems. Though the research of Seo [63] incorporated an expert opinion in the AI sector, which is usually limited to scholars rather than industry practitioners. The advocates of human-in-the-loop AI insist on the necessity of introducing additional validation procedures, but few systems manage to adopt the strategy [64]. This mismatch is alarming because industry expectations often differ from academic programs. For example, DevOps job descriptions often require cloud certifications, but many college programs do not include cloud platform training in their coursework. Therefore, the idea of generating and validating resources remains unexplored.

D. Validated Pathways

Uncovering meaningful hidden patterns in learner data is highly valuable within educational technology. Research on personalized, full-path learning recommendations is especially critical for advancing the development of more sophisticated adaptive learning systems [65]. The surge in online courses makes it harder for learners to select suitable learning paths. Recommender systems help by analyzing past interactions to predict interests and suggest relevant next steps [66]. In summary, none of the related studies focus on full-fledged computing field recommendations based on learners' profiles and assessment scores, using an ML approach to recommend a field alongside learning resources.

For better presentation, studies have explored educational recommendations from different perspectives, including course selection, career guidance, learner profiling, course advising, and personalized learning paths. However, their objectives and recommendation components differ from those integrated in ComReF. To clarify these differences and position the proposed framework's contribution, Table I compares representative related studies by focus and recommendation capabilities.

TABLE I. COMPARISON OF COMREF AND SOME EXISTING STUDIES

Study	Focus	Personalization	Field Guidance	Skill Level	Learning Resources
[5]	Course selection	✓	–	–	–
[10]	Career guidance	✓	–	–	–
[29]	Course advising	✓	–	–	–
[31]	Labor-market-driven education	✓	–	–	✓
[37]	Learner profiling/course recommendation	✓	–	–	✓
[38]	Personalized learning paths	✓	–	–	✓
ComReF	**Computing-field guidance**	✓	✓	✓	✓

Overall, ComReF differs from the reviewed approaches by integrating learner profiling, computing-field recommendation, skill-level identification, and learning resources for secondary and pre-university learners.

III. PROPOSED AI-DRIVEN RECOMMENDATION FRAMEWORK

The proposed ComReF is an end-to-end framework that converts a student's multidimensional aptitude profile (demographic, proficiency, and assessment data) into a personalized learning pathway. The system integrates machine learning models and prediction algorithms, semantic expansion, and cross-platform resource generation (see Fig. 1). It integrates three layers (Data/Interaction Layer, AI Process Layer, and Feedback/Resources/Validation Layer) to deliver personalized learning recommendations.

The Data/Interaction Layer first collects the student's basic information, learning preferences, and performance assessments. These inputs are then used by the AI Process Layer to predict both the optimal field and the skill level of each student using a random forest classifier. It is particularly effective for multi-class prediction tasks, which are essential for recommending diverse computing fields such as Software Engineering, Data Science, and AI. In addition, NLP cleans and normalizes data and generates web search queries to retrieve relevant material. When it generates predictions, the recommender module uses field and skill predictions to deliver personalized resources, including YouTube tutorials, PDF documents, and other pages of interest. These resources are obtained by field, and content curation is adapted for semantic web search. More importantly, all resources are aligned with the industry skills and educational blueprints alignment checklist. ComReF tracks students' interactions with recommended resources and uses the data to make future recommendations.

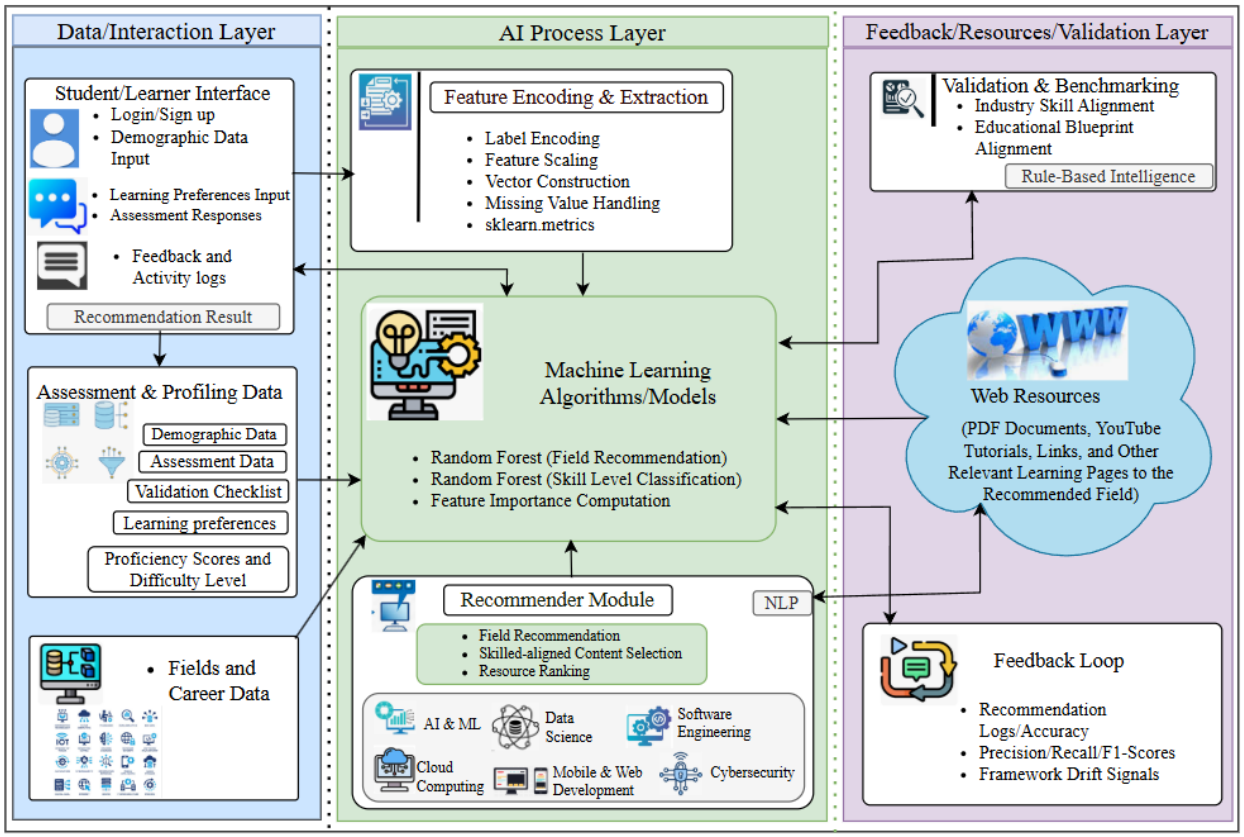

Fig. 1. Computing field recommendation framework (ComReF).

This continuous feedback loop improves accuracy and supports more personalized guidance as students navigate computing resources. The validation layer ensures that only the most relevant and up-to-date learning resources are recommended, ensuring all learners have access to appropriate materials. To improve ComReF's effectiveness, the feedback component incorporates precision, recall, and F1-scores, which are vital for evaluating performance. Drift signals monitor shifts in data patterns over time.

The remaining subsections detail how the framework operates and how the functional stages contribute to the overall recommendation process. Schematic flowcharts and mathematical formulations clarify the workflow, making the underlying reasoning, decision processes, and evaluation procedures clear.

A. Implementation Environment, Tools and Datasets

The implementation environment is a Jupyter Notebook interface for interactive prototyping and documentation, managed through Anaconda (Python version 3.9+). The main libraries deployed are scikit-learn for Random Forest classifiers, pipelines, and encoders; pandas and numpy for data loading, transformation, and analysis; urllib.parse for safe URL encoding across platforms; and re (regular expressions) for text cleaning and query sanitization. The framework does not require GPU support. However, accessing the generated links to external learning resources requires an Internet connection. The dataset requirements include:

Profiling data, consisting of demographic/contextual information, grade/level, learning attitude, motivation, goals, interests, and preferences, while cognitive attributes cover mathematical ability, logical and analytical reasoning, problem-solving, creativity, communication, teamwork, and self-learning readiness.

A field and career goals dataset, comprising identified Computing fields assessment scores mapped to the seven major computing fields: Computer Science, Software Engineering, Information Technology, Information Systems, Computer Engineering, Cybersecurity, and Data Science, and their associated subfields, which form the basis for field recommendations.

An assessment scores dataset that contains test scores to assess the learner's proficiency levels and to aid recommendations based on their overall scores and related attributes.

A validation and benchmarking checklist to ensure alignment with academic (Malaysia Education Blueprint: MEB alignment considers digital literacy, ICT integration, computational thinking, AI concepts, learning outcomes, student-centered learning, career relevance, and related educational requirements) and industrial requirements (digital and workplace skills, problem-solving, emerging technologies, practical application, career pathways, skill progression, professional standards, and Industry 4.0 relevance). These checklists are dynamic rather than fixed and can be updated

based on the target educational standard, industry demand, computing field, or recommendation goal.

B. Learner Profiling Process

The system captures students' demographic, behavioral, and other personalized learning attributes, and the ML label encoder transforms categorical data, such as gender and learning style, into numeric codes for use by all ML models. The encoded profiles then form feature vectors, which the ML models use. Fig. 2 illustrates the process, as shown in Eq. (1)

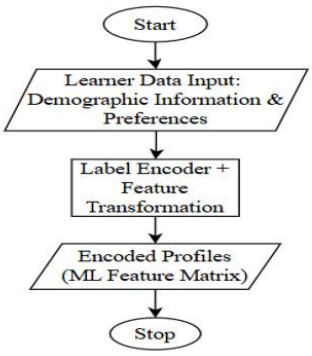

Fig. 2. Learner profiling process.

$$X_i = [x_{i1}, x_{i2}, \ldots x_{in}] \in \mathbb{R}^n \quad (1)$$

where, X_i represents the ith learner across n attributes, $\mathbb{R}^n$ is the n-dimensional real space.

The process flows as follows: learner demographic and other personalized learning input data → encoding → ML feature matrix. The profiling stage transforms qualitative descriptors into quantitative representations. For instance, "Male/Female" is encoded as a binary variable (0/1), and settlement data such as "Urban/Rural" is similarly represented as (0/1). This preprocessing ensures compatibility with ML algorithms, which operate exclusively on numerical data spaces. The resulting feature vector X_i represents the ith learner across n attributes and serves as input to the assessment and recommendation layers.

C. Assessment and Skill Level Evaluation

At this stage, each student takes predefined quizzes covering all the basic concepts of the identified Computing subfields and careers. The scores quantify proficiency and serve as learning features. Skill-level labels (beginner, intermediate, and advanced) are derived from performance thresholds. Fig. 3 shows the representation of the process, and Eq. (2) and (3).

$$Score_{ij} = \frac{CorrectAnswers}{TotalQuestions} \times 100 \quad (2)$$

where, $Score_{ij}$ represents the assessment score of the ith learner in the jth assessment, calculated as the percentage of correctly answered questions.

$$S_i = [S_{i1}, S_{i2}, \ldots, S_{im}] \quad (3)$$

where, S_i denotes the assessment score vector of the ith learner, consisting of m assessment scores.

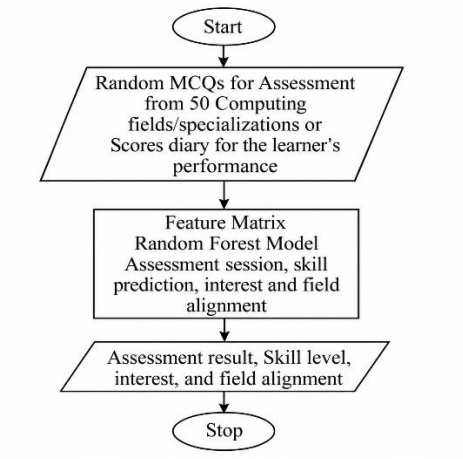

Fig. 3. Learners' assessment process.

The pipeline goes in this format:

Pipeline: Questions → Scores → Feature Matrix → Skill Prediction.

The skill evaluation process translates assessments into machine-readable performance metrics. Each dimension S_{ij} corresponds to the learner's score in one subfield. The dataset thus becomes a labeled multi-dimensional vector space where Random Forest classifiers can infer latent skill categories (Beginner, Intermediate, Advanced), and a supervised learning model is also incorporated.

D. Field Prediction Process

This stage predicts the optimal computing subfield for each student, models non-linear relationships between scores and fields or specializations, and handles multi-class classification through aggregated decision voting. Fig. 4 shows the process flow.

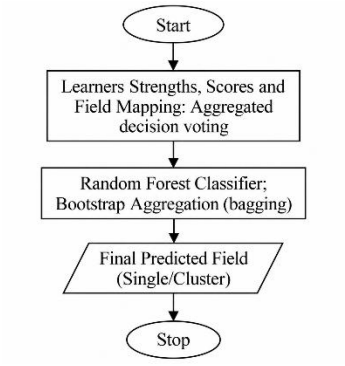

Fig. 4. Field prediction process.

This stage identifies the Computing field most aligned with a student's strengths. Each decision tree produces a class label such as Data Science, Cybersecurity, or Networking. The model aggregates these predictions through majority voting. Random Forest's bootstrap aggregation (bagging) strategy reduces variance, making predictions more stable across heterogeneous learners. The prediction process can be represented mathematically by Eq. (4)

$$y_{(pred)} = \arg\max_{y} \sum_{t=1}^{T} I\left(h_t(X) = y\right) \quad (4)$$

where, y_{pred} is the prediction label, y is the class, t is the individual tree, and **T** is the total number of trees; I is the indicator function, h is the hypothesis function, and **X** is the input vector.

E. Learner Proficiency Level and Framework Performance

This stage predicts the learner's overall proficiency level. The Standard-Scaler ensures uniform feature scaling. Thus, the framework performance is evaluated using accuracy, precision, recall, and F1-score, as shown in Eq. (5), (6), (7), and (8).

$$Accuracy = \frac{TP + TN}{TP + TN + FP + FN} \quad (5)$$

$$Precision = \frac{TP}{TP + FP} \quad (6)$$

$$Recall = \frac{TP}{TP + FN} \quad (7)$$

$$F_1 = 2 \times \frac{Precision \times Recall}{Precision + Recall} \quad (8)$$

where, Precision is the proportion of correct positive predictions, Recall is the proportion of actual positives that were correctly identified, F1 is the harmonic mean of Precision and Recall, TP denotes true positives, FP denotes false positives, TN denotes true negatives, and FN denotes false negatives. The process is presented as shown in Fig. 5.

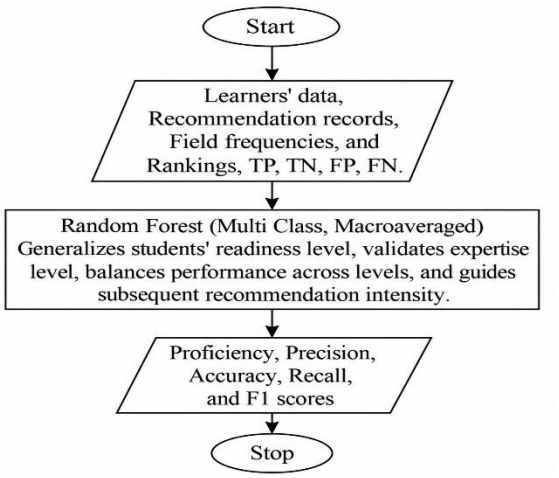

Fig. 5. Learner proficiency and framework performance.

Skill classification generalizes the student's readiness level. The macro-averaged F1 ensures balanced performance across all levels, even when classes are imbalanced. This stage ascertains how well the assessment vectors predict true expertise levels, guiding subsequent recommendation intensity for basic versus advanced materials.

F. Field Recommendations

The framework recommends fields and learning materials based on predicted outcomes, utilizing data-driven predictions with curated educational resource databases. The recommendation combines ML-based inference with dynamic, rule-based content retrieval. The justification for choosing Random Forest is its interpretability, robustness with small datasets (N $\leqslant$ 500), and resilience to feature correlations, which is important given the conceptual overlap between fields. Unlike deep learning alternatives, this approach requires no GPU infrastructure and yields clear feature importance rankings, supporting explainability in advising contexts [67]. Rule-based filtering is also utilized, as in Eq. (9) and Fig. 6.

$$Query = urllib.quote\_plus(Field\_Name) \quad (9)$$

where, $Query$ is the URL-safe search string, $urllib.quote\_plus$ is a Python function that encodes spaces as '+' and special characters for use in web URLs, and Field Name is the full, human-readable name of the predicted computing field, such as Software Engineering, Data Science, and Cybersecurity.

In summary, this component converts framework predictions into educational pathways. Once the system identifies a field, for instance, "Cloud Computing," it queries multiple online repositories such as YouTube, Coursera, EdX, and Google Scholar to dynamically generate URL queries linking to relevant, high-quality materials that support the user's learning journey.

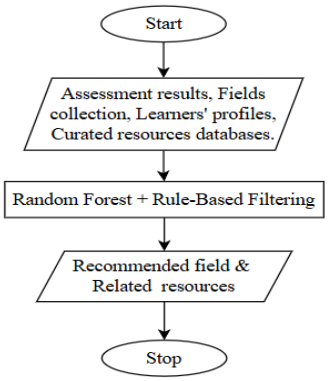

Fig. 6. Field recommendation process.

G. Resource Validation and Benchmarking

This stage is vital to ensure that the recommended materials align with both academic standards (the Malaysia Education Blueprint or MEB 2013-2025) and industry requirements specific to each computing-related career or field. Recommendations will be drawn from the top links on each specified platform, checking for keywords that match the criteria provided. The recommended material is considered suitable if it meets at least six criteria in the list. This process serves as a quality-control layer that ensures the recommended materials are relevant. This process is rule-based and deterministic, not reliant on a predictive ML algorithm, and aims to enhance the framework's performance. The mathematical process is expressed as in Eq. (10), as shown in Fig. 7.

$$Validated = \left(MEB_{yes} + Industry_{\text{yes}}\right) >= 6 \quad (10)$$

NB. To validate each recommended resource effectively, we need access to defined learning sources such as Khan

Academy, Coursera, edX, MIT, etc. So this work relies on free, publicly available web resources as a proof of concept. Table I presents examples of dynamically generated resource-search links based on the recommended computing field. These links support resource discovery and should not be interpreted as individually validated learning resources.

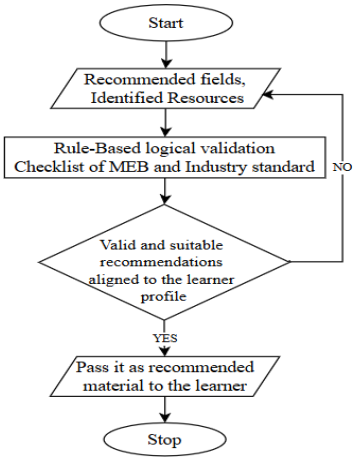

Fig. 7. Benchmarking and validation process flow.

H. Resource Generation and Retrieval

The system generates search queries using sanitized field names, then retrieves categorized resources such as videos, websites, and PDFs from multiple web sources. This action enhances the user experience by dynamically linking structured knowledge sources. Involves NLP-based string cleaning and automated URL generation for search queries. The flow is as in Fig. 8.

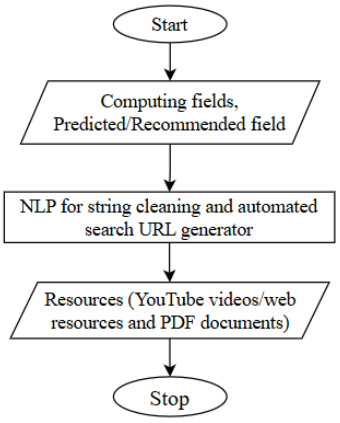

Fig. 8. Resource generation and retrieval.

NLP is used for dynamic query generation, including cleaning and encoding field names (e.g., removing parentheses and symbols), to ensure semantic accuracy in web search results. The objective is to maximize content relevance for each predicted field, as mathematically represented in Eq. (11).

$$URL = Base + urllib.parse.quote(Field) \quad (11)$$

where, URL denotes the generated link, Base represents the platform's search endpoint, $urllib.parse.quote$ is a function that URL-encodes the field name, and Field refers to the full subfield name (e.g., database engineering, multimedia technology, etc.).

I. Feedback and Logging

Collects user ratings and engagement metrics for post-recommendation. It also gathers log interaction data to retrain ML models for future recommendations. It adopts reinforcement learning principles for adaptive performance improvement and utilizes a feedback updater to achieve this, represented mathematically in Eq. (12).

$$Loss_{t+1} = \eta \frac{\partial Loss}{\partial \theta} \quad (12)$$

where, $Loss_{t+1}$ is the updated loss after iteration. $t+1$, η is the learning rate, and $\frac{\partial Loss}{\partial \theta}$ represents the gradient of the loss with respect to the model parameters. The flow proceeds as follows: User Feedback → Model Update → New Recommendations. This looping flow is essential for continuous improvement. It treats user feedback as a reward signal, which optimizes the model's parameters through gradient-based updates. Conceptually, this forms a self-correcting intelligent tutor that adapts and evolves based on learner interactions. Fig. 9 illustrates the process.

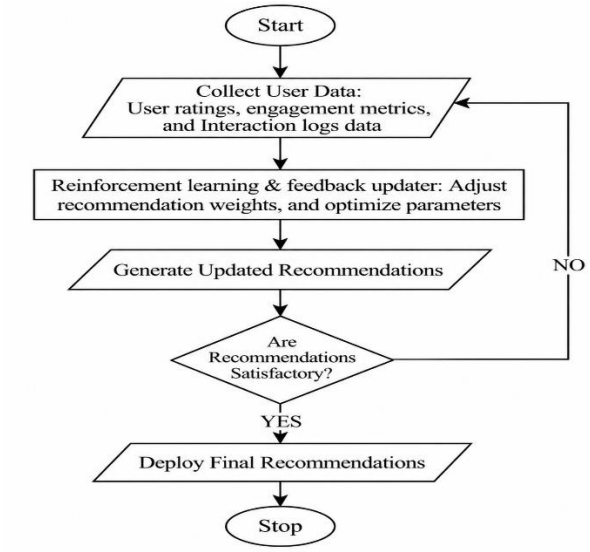

Fig. 9. Feedback loop and logging.

J. Overall Evaluation Accuracy of ComReF

At this stage, the framework is evaluated using the previously computed F1-score, Precision, and recall to determine overall accuracy and ensure balanced predictions across all identified computing fields. The evaluation process is conducted using $sklearn.metrics.classificationreport$ with the overall accuracy represented in Eq. (13) and illustrated in Fig. 10, respectively.

$$Accuracy = \frac{TP + TN}{TP + TN + FP + FN} \quad (13)$$

where, Accuracy denotes the proportion of correct predictions, TP, TN, FP, and FN represent True Positives, True Negatives, False Positives, and False Negatives, respectively, measuring the overall correctness across all classes. This final

stage summarizes system performance. The F1-score provides a harmonic balance between Precision and Recall, which is critical for recommendation tasks. A high macro-average F1-score suggests that the framework is suitable for large-scale deployment, as it reflects consistent performance across all categories. Fig. 10 depicts the overall evaluation process.

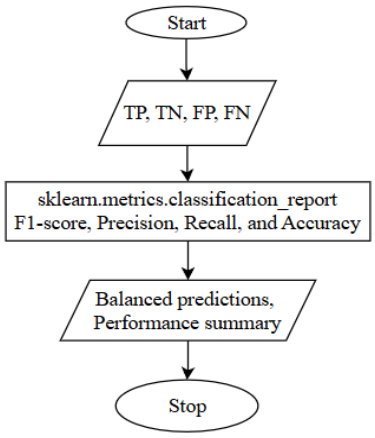

Fig. 10. Overall evaluation process.

IV. Implementation and Results

This section explains the implementation of the proposed ComReF, starting with the learner profiling process, followed by learning-resource recommendations, a report on classification performance, prototyping, and a comparison of the chosen Random Forest with three classification models. The dataset comprised 500 instances across 50 computing-field classes. The process used an 80:20 train-test split, resulting in 400 training and 100 testing instances; the same split was used across all evaluated classifiers to ensure a consistent comparison. No cross-validation was applied. Some computing fields/subfields were sparsely represented, with only 1 to 3 instances in the test set; therefore, interpreting the corresponding class-level performance metrics cautiously.

A. Learner Profiling

The framework's recommendations center on the learner profile, which drives the process. Thus, the profile includes demographic data and learner preferences that ChatGPT generates from prompts tailored to the expected diversity of learners in the Malaysian context.

	S/No	Name	Gender	Grade	Race	Settlement	Skill Level
0	1.0	Lim G.	Female	12.0	Chinese	Urban	Advanced

B. Recommended Learning Resources

The recommended learning resources include YouTube video links, PDFs, and educational websites, all aligned with the learner's profile and assessment results in the suggested learning field. Based on the profiles in Fig. 11 and 12 and using Abdullah G. as an example for whom Data Science was recommended, Table II shows his recommended learning resources, including YouTube links, websites, and PDFs. The table was formatted for clarity, as the original display in the Anaconda environment looks complex/long, and links may not look well-formatted here.

C. Classification Performance

This section presents the classification performance report of ComReF. The predictive performance was evaluated using standard metrics, including Precision, Recall, and F1-score, computed per class and aggregated using macro and weighted averages. For the best field prediction, ComReF achieved an overall accuracy of 64% with a weighted F1-score of 0.59, indicating moderate performance across the subfields/careers in Computing. Notably, several classes (1, 2, 3, 9, 13, 16, 18, . . . , 34, 36, and 49) achieved perfect or near-perfect F1-scores (F1 ≥ 0.80), demonstrating strong generalization for well-represented fields. However, classes (4, 6, 7, 12, 17, 19, 21, 22, . . . , 40, 42, and 43) recorded comparatively lower performance metrics due to limited sample representation (support = 1–3). This outcome aligns with the known behavior of multi-class classifiers under imbalanced class distributions and does not undermine the overall performance trends. In contrast, the skill-level prediction model achieved 100% accuracy (F1 score = 1); however, this reflects the uniformity of the test set, where all students exhibited similar/the same background skill levels. These results indicate that ComReF performs well when sufficient training data is available, highlighting the importance of data adequacy for future data collection and taxonomy refinement. Fig. 13 illustrates the classification results.

Best Field Prediction Report (Classes 0 – 30)

Fig. 13. The classification report.

Further implies that ComReF can accurately map student profiles to predicted or recommended fields and generate valid, skill-tagged learning resources across many platforms. Hence, the observed performance limitations, especially the low F1-scores for certain fields, come from data rather than design flaws. While the architecture is solid, rare or fragmented fields faced limited labeled representations. Possible enhancements of ComReF include merging similar niches, increasing data collection for underrepresented pathways, and implementing the pilot ComReF in live academic advising workflows to collect real-world labels and refine its calibration through iterative improvements.

D. Prototyping

This section elaborates on how the ComReF prototype is designed for recommendations in academic advising environments. It requires minimal infrastructure and offers broad accessibility. It also provides two main inference interfaces: batch processing through CSV uploads and real-time prediction through webform integration.

CSV Upload (Batch Mode): Users can upload a CSV file containing one or more student profiles. Each row must include a student ID and scores (1–5) for all computing fields, for instance, Software Engineering, Data Science, Cybersecurity, and Network Engineering. The system processes the file within seconds, with a mean inference time of 0.38 seconds per student. It then generates a structured CSV output that includes the predicted field and skill level, career goals, and resource links from platforms such as YouTube, Wikipedia, Coursera, edX, Kaggle, ResearchGate, and Google Scholar (PDFs).

Web Form (Real-Time Mode): For integration purposes, ComReF provides a lightweight API endpoint. Both interfaces are implemented entirely in Python using pandas and scikit-learn, ensuring full cross-platform compatibility (Windows, macOS, Linux) and eliminating any dependence on large language models (LLMs) or cloud-based inference. Table III shows a representative input-output pair for a student with strong aptitude in Cryptography, Cybersecurity, Software Engineering, and AI. The prototype then generates the output in Table IV.

TABLE III. SAMPLE INPUT FOR INFERENCE LEARNER

Input Feature	Assessment Scores

Artificial Intelligence	4
…List	…

TABLE IV. THE INFERENCE OUTPUT

Output Component	Value
Predicted Field	Cryptography
Skill Level	Advanced
Career Goal	System security expert
Resources	Four YouTube Videos, Six Learning sites, and four PDF documents

E. Baseline Comparison: Model Selection Justification

To justify selecting the Random Forest algorithm, we benchmarked three widely used classifiers: Decision Tree (DT), Logistic Regression (LR), and Naïve Bayes (NB). We evaluated each model under the same conditions: the same feature preprocessing pipeline and scaling techniques, with standard scaling applied to Random Forest, Decision Tree, and Logistic Regression, and Min–Max scaling applied to Naïve Bayes. All models were trained and tested using the same data splits and evaluated with consistent performance metrics. As demonstrated in Table IV, Random Forest consistently outperforms all baseline models in field-level prediction, achieving an accuracy of 0.640 and a weighted F1-score of 0.586. In comparison, Decision Tree (weighted F1 = 0.174), Naïve Bayes (weighted F1 = 0.321), and Logistic Regression

(weighted F1 = 0.086) exhibit significantly lower performance. This is especially evident given the task's high dimensionality and multi-class nature, which challenges Logistic Regression. Furthermore, as the macro F1-score indicates, the selected approach is robust to class imbalance (see Table V).

TABLE V. CLASSIFICATION PERFORMANCE ON THE FIELD PREDICTION FOR MODEL JUSTIFICATION

Model	Accuracy	Weighted F1	Macro F1
Random Forest	0.64	0.586	0.529
Decision Tree	0.20	0.174	0.118
Logistic Regression	0.09	0.086	0.074
Naïve Bayes	0.37	0.321	0.252

From Table V, Random Forest achieved the highest overall performance; the difference between its weighted F1 (0.586) and macro F1 (0.529) indicates uneven performance across computing fields, particularly those with fewer samples. This suggests that class imbalance may have affected minority-field predictions. Notwithstanding, Random Forest achieved the highest macro F1 among all evaluated models, indicating comparatively better performance across classes. The moderate performance should be considered in the context of the 50-class prediction setting and limited observations per class; unequal class representation may also contribute to the lower macro F1-score relative to the weighted F1-score. Future evaluation will therefore consider more balanced field representation to improve performance for underrepresented fields. Under controlled experimental conditions, Random Forest consistently outperformed the benchmark models in accuracy, weighted F1, and macro F1, supporting its selection as the primary classifier for ComReF.

V. DISCUSSION

ComReF is a learner-centered AI application for computing education that provides computing-field recommendations and related learning resources for secondary and pre-university learners. It is particularly intended to support learners who require early guidance on computing specializations before progressing to university-level studies. The prototype demonstrates the feasibility of combining learner profiles and assessment performance for personalized computing-field recommendations while remaining lightweight and interpretable. The following subsections discuss the findings in relation to previous research, feedback, and practical implications, and ComReF's strengths, limitations, and ethical considerations.

A. Findings, Feedback and Practical Implications

The findings agree with previous studies on AI-supported educational recommendations. Algarni and Sheldon [2] demonstrated the relevance of recommender systems for course selection, while Narimani and Barberà [37] emphasized learner profiling in personalized recommendations. Similarly, Wang *et al.* [43] showed the value of machine learning for personalized feedback. ComReF extends these approaches by integrating learner profiling, computing-field prediction, skill-level identification, and learning resources to support computing specialization at secondary and pre-university levels. ComReF also incorporates a feedback loop in which learner performance and feedback can support reassessment and refinement of field and resource recommendations. In practice, it is intended to complement teacher and academic-adviser guidance, with periodic reassessment as learners' interests, skills, and performance change.

B. Strengths of the Proposed Work

Compared with other recommendation works, ComReF's major strength is its end-to-end integration of diagnostic assessment, career-path prediction, and learning-resource generation. ComReF's recommendations offer a complete learning itinerary that can reduce the major gap noted in prior studies, particularly the persistent disconnect between prediction and pedagogy. ComReF ensures that all recommendations are fully accessible to learners. In addition, ComReF aligns with the demand for explainable and trustworthy AI in education, strengthening confidence among students, advisors, and institutional stakeholders. ComReF is lightweight and suitable for computing educational platforms that require an advising module. In terms of adaptation, ComReF offers three major advantages due to its lightweight architecture:

- No GPU or cloud dependency: It runs efficiently on a standard CPU using less than 500 MB of RAM; thus, it is suitable even for local laptops and low-resource environments.
- Auditable: All processes rely on interpretable ML and rule-based logic; hence, it avoids the opacity of black-box LLMs.
- Preserve privacy: Student data is processed within the local environment without external API calls apart from accessing the generated resource URLs.

C. Limitations

However, ComReF is data-dependent as it relies on a labeled dataset containing students' profiles (demographic information and learning preferences), which is not always readily available. Thus, a primary challenge lies in acquiring sufficient labeled data. Future work could address this limitation by adopting semi-supervised or active learning strategies to boost the labeling process. Another limitation concerns the use of static resource templates, as the URL structures are hardcoded for major platforms. If a platform modifies its query syntax, for example, Coursera changing from: $?query = to?q =$ ", then the generated links may become invalid. An alternative approach would involve dynamic API integration or automated monitoring to increase dynamism in such cases.

D. Ethical Considerations

The first ethical issue involves the training data common in all supervised systems. Thus, ComReF inherits any biases present in its training data. If historical data has favored certain fields, such as Web Development over Bioinformatics, ComReF may spread these imbalances. Stratified sampling is necessary to mitigate this issue and evaluate performance across fields. However, fairness audits remain crucial to ensure balanced recommendations for learners' learning journey.

Another issue is the absence of equity across fields. Emerging fields such as Neurotechnology and Climate Informatics may have fewer learning resources available on mainstream platforms, potentially disadvantaging students who receive recommendations for these areas. To resolve this issue, ComReF provides a checklist protocol that flags recommendations with fewer than three available resources, indicating low-resource fields. Student agency versus algorithmic determinism is a concern. ComReF offers guidance; recommendations must not be perceived as prescriptive. In other words, all outputs clearly state that recommendations are suggestions, not mandates for learners. Future versions could consider counterfactual explanations like: "If you improved your score in Generative AI by 1 point, you would be recommended AI Ethics," to encourage exploration and give students more autonomy in their choices. Hence, ComReF demonstrates that lightweight, rule-based AI can deliver high-impact educational value when designed with pedagogical intent, in this case, for secondary or pre-university students in the Computing field. It offers a feasible alternative to learning via AI-driven recommendations, rather than the existing rigid approach.

VI. Conclusion and Future Work

In conclusion, ComReF provides a personalized approach for guiding pre-university learners toward suitable computing fields using their profiles and assessment performance. It combines learner profiling, feature encoding, machine-learning prediction, skill-level estimation, and learning-resource recommendation. Among the evaluated classifiers, Random Forest performed best, with an accuracy of 0.64, weighted F1 of 0.586, and macro F1 of 0.529. The lower macro F1 reflects performance differences across computing fields, particularly those with limited representation. Skill-level prediction recorded an F1 of 1.00; however, only one skill-level class appeared in the test set, so this result does not represent discrimination across different skill levels.

ComReF contributes by integrating computing-field prediction, learner characteristics, skill level, and relevant learning resources into a single recommendation process for early computing specialization. Future work will extend recommendations to subfields within broad areas such as Software Engineering, AI, and Data Science and explore multi-label prediction for ranked field choices. Further evaluation will involve real learner profiles and integration with academic advising platforms to examine learner satisfaction, retention, career alignment, and industry relevance. LLMs may also be considered for resource summarization without replacing the framework's core prediction mechanism, while releasing ComReF as an open-source Python package could support reproducibility, improvement, and wider adoption.

Acknowledgment

This article is a deliverable of the PhD thesis of the first author's PhD thesis, completed under the supervision of the co-authors. Artificial intelligence tools were also used in language improvement, organization, sample demographic data generation, and refinements.

2) The 50 assessment attributes and best_score are numerical (integer), best_field and Skill Level are categorical, while student_id is an integer identifier excluded from model training.

3) Processing flow: Fig. 15 shows the processing timeline. The assessment attributes were already numerical; therefore, encoding was required only for the categorical prediction label. Fig. 16 shows the label encoding fragment.

Fig. 15. The data processing flow.

The assessment attributes were already numerical; therefore, we needed to encode only the categorical prediction label.

```
X = df.drop(columns=['student_id','best_field',
                     'best_score','Skill Level'])

le = LabelEncoder()
y = le.fit_transform(df['best_field'])
```

Fig. 16. The Feature extraction and target-label encoding code.

4) Choice of models: Random Forest, Decision trees, Logistic regression, and Naïve Bayes: We selected four classifiers to provide complementary classification approaches. We used Random Forest (RF) for its ensemble learning capability, robustness, and ability to model nonlinear relationships [68], [69] while Decision Tree (DT) provides interpretable, rule-based classification [70]. Logistic Regression (LR) was included as a linear probabilistic baseline [71]and Naïve Bayes (NB) as an efficient probabilistic classifier [72]. RF-based feature importance was further used to determine the relative contribution of assessment features to field prediction [73].

5) Testing strategy: The dataset was divided using an 80:20 train-test split, producing 400 training and 100 testing instances; the same split was used for all classifiers to ensure consistent comparison, and performance was evaluated using accuracy, precision, recall, and F1-score.

An Enhanced Deep Learning Framework Integrating Adaptive Whale Optimization and Natural Language Processing for Mental Health Disorder Diagnosis

***Abstract*—Mental health disorders are among the biggest global public health challenges, affecting over 1 billion people worldwide and placing a burden on healthcare systems, economies, and societies. Despite progress in clinical psychiatry, mental health professionals still rely heavily on subjective judgments to make diagnoses, leading to delays and inconsistency in diagnosis-making and making early intervention difficult. The evolution of technology-enabled communication channels, i.e., social media, has enabled researchers to employ computational techniques to study digital signatures and patterns and identify psychological distress or behavioral changes in people via their electronic interactions. This study proposes a psychiatric disorder classification system based on Natural Language Processing (NLP) and an Enhanced Deep Learning model powered by the Adaptive Whale Optimization Algorithm (EDL-AWOA). It examines how users in Reddit mental health communities communicate textual data to assist a machine learning algorithm in diagnosing depression and anxiety. It also aims to build a diagnostic support tool using these findings to help identify early signs of mental illness. The results integrate existing measures into a system designed to complement clinical judgment, with the hope that clinicians will adopt these additional steps more quickly. When evaluated with standard metrics of classification accuracy, precision, recall, F1 score, and the confusion matrix, the strong results in the training phase are achieved, including 93.99% accuracy | 94.01% precision | 93.99% recall | 93.99% F1 Score.**

***Keywords*—Psychiatric disorder classification; Natural Language Processing (NLP); Enhanced Deep Learning (E-DL); Adaptive Whale Optimization Algorithm (AWOA); reddit mental health text; depression; anxiety**

I. Introduction

Psychiatric diseases, or mental disorders, are conditions that negatively affect the way you think, feel, and act; they can also hinder a person's daily functioning. They are not just "feelings"; they also shape how a person navigates social connections, whether they succeed or flounder academically or professionally, and their sense of competence in handling day-to-day challenges. In recent years, artificial Intelligence (AI), machine learning (ML), and natural language processing (NLP) have become major resources for healthcare research. Their ability to process massive amounts of unstructured text clinical notes, patient stories, and even social media posts in ways that would be practically impossible by hand is often cited as the reason for this. Over a billion people around the world suffer from mental health disorders, such as anxiety disorders and major depressive disorder (MDD) [1]. Clinical interviews and self-report questionnaires are widely used but limited by time constraints, subjective judgment, cultural issues, and stigma. In recent studies, NLP has been used to identify psychological distress through emotional tone, sentence flow, and word choice in text [2]. Nonetheless, mental health classification is a challenging task as models are easily misled by spoken language variation, do not generalize well, and, of course, suffer from the typical training data bias [3].

To address these drawbacks, researchers have used nature-inspired optimization techniques to better guide machine learning and deep learning models. For parameter tuning, reducing overfitting, and improving classification results, researchers have applied the Whale Optimization Algorithm (WOA) in different variants [4].

Practically, the research focuses on developing an automated system that can assist in early-stage identification of mental health issues. It uses an improved deep learning approach with the Adaptive Whale Optimization Algorithm to create a robust, data-driven system that can help clinicians, psychologists, and mental health organizations detect psychiatric risk by analyzing language use. Tayebi Arasteh et al. [5] conducted research. Wongkoblap et al. [6] proposed that large language models can also facilitate more efficient, automated machine-learning workflows in clinical research. Researchers can leverage the massive amounts of data available on platforms like Reddit to detect real-time, population-level trends in mental illness, helping enable prevention efforts (2022). Researchers have also found that machine-learning models can detect and assess depression and other mental health disorders in people based on their online speech [7].

In theory, the research shows how NLP systems can leverage natural optimization to create better models of human psychological expression through language. It incorporates deep learning and the Adaptive Whale Optimization Algorithm (AWOA), which can improve a model's performance on novel data and higher-order language-independent tasks. The work connects theoretical explanations for how a representation of digital language maps across structures of human psychology to support the utility of NLP in mental health and opportunities

*Corresponding author.

for collaborative work between AI (e.g., [6]; [7]), psychology, and computational behavioral sciences.

Natural Language Processing: Natural Language Processing has come a long way, but diagnosing mental health disorders with clinical accuracy is still an open problem. Current diagnostic methods still rely heavily on clinician interpretation of the patient and their presentation, which may lead to misdiagnosis or delayed treatment. As [8] points out in their 2024 article, text-based NLP models have tried to address this by recognizing patterns in what people write. Nevertheless, they face the same limitations: model interpretability is dicey, datasets are biased, privacy and fairness are still issues, and performance drops off a cliff outside English. Most annotated datasets are aggregated in English, leaving a gap in generalization to other languages, and most models are trained for a single task but cannot perform satisfactorily enough to recognize emotional and linguistic characteristics in posts from people with mental illness. This necessitates systems that classify better, use more attention-based and contextual methods, and generalize to multilingual data.

- How effectively can an enhanced deep learning-based two-hidden-layer neural network model using the adaptive whale optimization algorithm (AWOA) classify psychiatric disorders, such as depression and anxiety, from social media posts?
- Which discourse and lexico-semantic elements in user language are the most crucial indicators for classifying particular mental health disorders?
- How does the proposed EDL-AWOA classification model compare with standard Deep Learning and WOA-based models in terms of classification performance, interpretability, and generalization?

Correspondingly, the objectives are:

- To design and implement a specialized deep learning architecture derived from the Adaptive Whale Optimization Algorithm (AWOA) for accurate classification of depression and anxiety using text data from Reddit.
- To identify and analyze the salient lexico-semantic features and structural elements of discourse in user-generated text that serve as primary indicators for distinguishing among various psychiatric conditions.
- To evaluate the optimized deep learning model against baseline deep learning and WOA-based classification models across accuracy, precision, recall, F1-score, AUC-ROC, interpretability, and generalization ability.

Finally, although the proposed EDL-AWOA framework showed promising performance in identifying mental health conditions from Reddit posts, the study has several limitations. First, the model was developed and evaluated using self-reported social media data rather than clinically verified patient records. Consequently, the system should be considered a computer-aided diagnostic support tool intended to assist with early detection and risk assessment, not to replace professional clinical evaluation. Second, the dataset was limited to English-language Reddit content, which may limit the generalizability of the findings to other languages, cultures, and online platforms. Therefore, future research should validate the proposed framework using clinically annotated datasets and real-world healthcare data in collaboration with mental health professionals to further assess its clinical applicability, robustness, and reliability.

II. Related Work

Several studies have examined machine learning, deep learning, transformer-based models, and various optimization methods for mental health classification using social media text, speech signals, and clinical datasets. In general, these works suggest that computational models can detect linguistic and behavioral cues associated with psychological distress.

Hameed et al. [9] explore the early detection of mental disorders through computational approaches. They used black-box machine learning (ML) models, including Support Vector Machines (SVM), Random Forests (RF), Extreme Gradient Boosting (XGB), and Artificial Neural Networks (ANN). We employed advanced Natural Language Processing (NLP) techniques, including TF-IDF, Latent Dirichlet Allocation (LDA), N-grams, Bag of Words (BoW), and GloVe embeddings, to extract linguistic and semantic features. To address the interpretability limitations of black-box models, Explainable AI (XAI) methods were integrated, specifically Local Interpretable Model-Agnostic Explanations (LIME). However, it was based on English-language datasets and did not use advanced optimization techniques to improve model convergence and generalization.

Senanayake & Liang [10]. Transformers ensemble of DistilBERT, RoBERTa, and XLNet for depression detection in Reddit posts. This late-fusion strategy improved Macro-F1 by 6–8% over individual transformer models, suggesting that combining multiple language representations can be helpful. However, the model was resource-intensive and showed only average performance outside Reddit.

Baydili et al. In [11], a framework that uses the CW-INCA feature-selection algorithm combined with two potent deep learning models, BERT, to identify depressive and suicidal tendencies was proposed. Evaluations on six mental health datasets achieved 99.9% classification accuracy, including the Kaggle Depression Reddit dataset. Although this framework was encouraging, the model required substantial computational resources; it used only English datasets, and it did not use adaptive optimization strategies like AWOA.

Farruque et al. [12] proposed utilizing Mental-BERT along with semi-supervised learning and zero-shot learning methods to profile depression symptoms from social media text. The iterative self-training framework they proposed extends the dataset from 377 to 4,567 samples and improves the Macro-F1 score by 14%. However, several symptom classes remained underrepresented, and the dataset could not be made publicly available due to privacy limitations.

Arif et al. [13] evaluated traditional machine-learning, deep-learning, and transformer-based architectures to classify Reddit posts into six mental-illness categories. Their transformer encoder with late fusion of post titles and content

achieved the best performance, with an F1-score of 89.65%. Nonetheless, it had difficulty differentiating between disorders with the same linguistic manifestations, such as anxiety disorder and bipolar disorder, and its performance was evaluated only using Reddit data.

Nayak et al. [14] Depression Detection via TF–IDF, n-gram Features, SVM, Random Forest and LSTM Models. Their results showed that the LSTM model performed much better than traditional machine-learning methods, reaching around 85% accuracy. However, class imbalance, small dataset size, and a lack of optimization/hybrid learning mechanisms affected the study.

The work, which focused on speech-based depression diagnosis and was presented in 2024, proposed integrating Long Short-Term Memory (LSTM) networks with the Whale Optimization Algorithm (WOA). The model classified the DAIC-WOZ dataset using MFCC features, achieving about 84%. Despite the performance gain from optimization, the framework was evaluated on a single speech dataset, which is computationally expensive.

Hosseinali, F. [15] proposed an improved Selective Backpropagation algorithm (SBP+) to speed up neural network training while improving generalization. The main idea is that during training, the algorithm excludes samples that are already classified correctly with sufficient confidence, rather than applying backpropagation to all training instances at every iteration. This reduces unnecessary weight updates and focuses learning on more informative, difficult samples. However, this study introduces additional hyperparameter-tuning requirements and does not extensively investigate scalability and effectiveness across diverse large-scale application domains. Moreover, the available description does not indicate extensive validation on large-scale NLP, computer vision, or multimodal datasets.

Moosavi et al. [16] suggested using a metaheuristic algorithm, namely the Whale Optimization Algorithm (WOA), to solve constraint optimization problems. The nature-inspired algorithm follows a spiral bubble-net hunting strategy; it does not get stuck in a local minima solution even if the search space is discontinuous.

Scherbakov et al. [17]. An AI-assisted scoping review of 1,768 studies to explore the application of Natural Language Processing (NLP) techniques in mental health research and analyze how different Social Determinants of Health (SDOH) are captured within mental health analytics was conducted. The review found that most studies relied on clinical notes and social media data; few incorporated SDOH factors, confirming a significant gap in the literature. The main limitation is that this investigation is a review, not a new predictive model; other limitations include the limited use of SDOH variables in general practice, the unavailability of datasets for multiple studies described, and a lack of standardized reporting practices across the literature.

In general, past research shows that social-media text contains useful linguistic signals for detecting mental health disorders. While classification performance has been improved by deep learning, various transformer models, and better optimization algorithms in recent years, many issues persist, such as high computational complexity, heavy dependence on the English language, dataset imbalance, limited generalization to other languages or more social science datasets like microblog texts rather than pure text forms like news or articles, etc., as discussed below. These limitations inspire the development of the EDL-AWOA model, where an advanced NLP feature extraction approach is integrated with an adaptive whale optimization technique to improve classification performance, robustness, and generalization in psychiatric disorder detection.

III. Formal Definitions

This section presents the formal mathematical foundations used by the proposed model, covering text feature representation, the deep learning formulation, and the whale optimization mechanism.

Definition 1: Let ID_w be the identity word level that distinguishes between various pieces of writing. The term weighting $TF\_IDF_{t,d}$ of a term t in a document d is defined by the following Eq. (1):

$$ID\_w : TF_{t,d} \times IDF_t \rightarrow TF\_IDF_{t,d} \quad (1)$$

Where the map gives the term-frequency and inverse-document-frequency components in Eq. (2) and Eq. (3):

$$TF_{t,d} = \frac{f_{t,d}}{\sum_{t'} f_{t',d}} \quad (2)$$

$$IDF_t = \log\left(\frac{N}{df_t}\right) \quad (3)$$

where, T is the set of all terms in the corpus; D is the set of all documents; $f(t, d)$ is the number of times term t appears in document d; N is the total number of documents; and $df(t)$ is the number of documents that contain t. $TF\_IDF_{t,d}$ acts as a statistical weighting system that assigns a high value to a term that appears frequently in one document but rarely across the rest of the corpus.

Definition 2: Let the character-level (n_gram) extraction function C of a text string S be defined by the following Eq. (4):

$$n\_gram: s_i \times s_{i+1} \times \cdots \times s_{i+n-1} \rightarrow C_{n,S} \; \forall i \in [1, m - n + 1] \quad (4)$$

where, $\forall i \in [1, m-n+1]$ represents all text strings over the alphabet Σ; m is the string length of S; and $P(\Sigma^n)$ is the set of character sequences of length n. n_gram is created by applying Eq. (1) to the elements of C(n, s) instead of full words, allowing the model to recognize spelling variations, slang, repeated-letter patterns, and partial words.

Definition 3: Let the Latent Semantic Analysis LSA_k transformation be obtained from the truncated Singular Value Decomposition (SVD) of a term-document matrix X. A complete formal definition is typically written as the Eq. (5):

$$LSA_k: R^{|T|\times|D|} \rightarrow R^{k\times|D|} \text{ with } X \approx U_k \Sigma_k V_k^T \quad k \in |T| \quad (5)$$

where, T denotes the set of terms (words) in the vocabulary, D denotes the set of documents, X is the original term–document matrix; U_k and V_k^T contain the reduced left and right singular vectors obtained via Singular Value Decomposition; Σ_k contains the top k singular values; and k is the selected number of latent dimensions. *LSA* is a dimensionality-reduction technique often applied after *TF-IDF* to reduce noise and computational cost while preserving important relationships between documents and terms [18].

Definition 4: Let a layer ℓ of a feed-forward deep learning model be defined by the following Eq. (6) and (7):

$$l:R^n \rightarrow R^m \text{ and } \quad z_l = Wx+b \quad \forall x \in R^n \tag{6}$$

$$a = f(z) \tag{7}$$

where, $x \in \mathbb{R}^n$ is the input vector; $W \in \mathbb{R}^{m \times n}$ is the weight matrix; $b \in \mathbb{R}^m$ is the bias vector; z is the weighted input; $f(.)$ is the activation function; and a is the layer's output activation. A feed-forward deep learning model is a composition of successive layer maps that transmits information from the input layer through multiple hidden layers to the output layer [19].

Definition 5: Let the softmax output function (σ) be defined by the following Eq. (8):

$$\sigma:R^K \rightarrow (0,1)^K \text{ and } \quad \sigma(z_i) = \frac{e^{z_i}}{\sum_{j=1}^{K} e^{z_j}} \quad \forall i=1,\ldots,K \tag{8}$$

where, $\sigma(z_i)$ is the predicted probability of class i; z_i is the score for class i; K is the total number of classes; and the denominator is the sum of exponential scores over all classes. The softmax function serves as the final layer for classification tasks, transforming output scores into probability values, and the class with the maximum probability is selected as the prediction [20].

Definition 6: Let D be the distance between the current whale location and the top (best) solution defined by the Eq. (9) and Eq. (10)-(12).

$$Distance: F(C, X^*, X_t) \rightarrow D \tag{9}$$

$$\text{where, } F(C, X^*, X_t) = |C \cdot X^* - X_t| \tag{10}$$

and

$$X_{t+1} = X^* - A \cdot D \tag{11}$$

with

$$A = 2ar - a, \quad C = 2r \tag{12}$$

where, X_t is the current solution (whale position) at iteration t; X^* is the best solution found so far; A and C are coefficient vectors; r is a random value in [0, 1]; a is a control parameter that decreases linearly during the search; and t_{max} is the maximum number of iterations. The Whale Optimization Algorithm is a nature-inspired algorithm based on humpback whale hunting behavior. In this algorithm, each whale represents a candidate solution, and the algorithm balances exploration of new regions of the solution space with exploitation toward the best solution [4].

Definition 7: Let the merged labeled (MLable) dataset of D be defined by the union of the two collected Reddit mental health datasets; see the Eq. (13):

$$\text{MLable: } \bigcup_{i=1}^{2} D_i \rightarrow D \tag{13}$$

where, D is defined in the Eq. (14)

$$D = \{(s_i, y_i): s_i \in S_{raw} \text{ and } y_i \in Y\} \quad \forall i=1,\ldots,n \tag{14}$$

where, D_1 and D_2 are the first and second Reddit mental health datasets after column-name standardization; s_i is the raw text of the ith post; y_i is its normalized class label; S_{raw} is the set of raw Reddit posts; Y is the set of diagnostic categories; and n is the total number of samples. Records with missing text or labels are excluded from D.

Definition 8: Let S denote the set of normalized text strings over a given alphabet. Define the preprocessing function P in the Eq. (15):

$$P: REM \times EMJ \times LOW \rightarrow S \tag{15}$$

where, LOW: S → S is the lowercase transformation defined by mapping each character of a string to its lowercase equivalent. EMJ: S → S is the emoji normalization function that replaces each emoji symbol occurring in a string with its corresponding textual description according to a predefined emoji dictionary. REM: S → S is the removal function that deletes URLs, subreddit references. Thus, for any input string s ∈ S: P(s) = REM(EMJ(LOW(s))), where P first converts all characters to lowercase, then replaces emoji symbols with their textual descriptions, and finally removes URLs, subreddit mentions, and user mentions.

Definition 9: Let the tokenization function TOK of a normalized string be defined by the following Eq. (16):

$$\text{TOK: } S \rightarrow W^*, \quad \text{TOK}(s) = (w_1, w_2, \ldots, w_q) \quad \forall s \in S \tag{16}$$

where, W^* denotes the set of finite token sequences, and q is the number of tokens produced from the string s.

Definition 10: Let W be a vocabulary of tokens, let W* denote the set of all finite token sequences over W, and let SW ⊆ W be the set of English stop words. Define the token filtering function in Eq. (17):

$$FILT: W^* \rightarrow W^* \text{ And } FILT(w_1, \ldots, w\_q) = (w_i : w_i \notin SW \text{ and } |w_i| > 1) \tag{17}$$

where, $|w_i|$ denotes the number of characters in token w_i.

Thus, FILT removes all stop words and all tokens of length one while preserving the original relative order of the remaining tokens.

Definition 11: Let the WordNet lemmatization function LEM be defined by the following Eq. (18) to replace each token with its lemma:

$$\text{LEM:W} \rightarrow \Lambda, \quad \text{LEM}(w_1,\ldots,w_q) = (\text{LEM}(w_1),\ldots,\text{LEM}(w_q)) \tag{18}$$

where, $\Lambda \subseteq W$ is the set of WordNet lemmas (canonical dictionary forms), so each inflected token maps to its base form.

Definition 12: Let S_{raw} denote the set of raw text strings and let S_{clean} denote the set of cleaned token sequences in Eq. (19).

$$\text{CLEAN}: S_{raw} \rightarrow S_{clean} \text{ and}$$

$$\text{CLEAN} = \text{REC} \circ \text{LEM} \circ \text{FILT} \circ \text{TOK} \circ \text{NORM} \quad (19)$$

where, REC: W* → S_clean reconstructs a cleaned text sequence from the resulting lemmatized tokens.

Hence, for every raw text string $s \in S_{raw}$, and CLEAN(s) = REC(LEM(FILT(TOK(NORM(s))))).

Thus, CLEAN transforms a raw text string into its fully normalized, tokenized, filtered, lemmatized, and reconstructed cleaned representation.

Definition 13: Let $m \in N$ be the dimension of a hidden-layer activation space, and let $p \in (0, 1)$ denote the dropout rate; the dropout regularization function $DROP_p$ is defined in Eq. (20):

$$DROP_p : R^m \rightarrow R^m \text{ and } \quad DROP_p(a) = \frac{a \odot m}{1-p} \quad (20)$$

$$\text{where, } m = (m_1, \ldots, m_m)$$

$\in \{0,1\}^m$ *and* m_i is a sample of $Bernoulli(1-p) \; \forall \; i = 1, \ldots, m$

Here, $a = (a_1, \ldots, a_m) \in R^m$ is the activation vector of a hidden layer, m is a binary dropout mask, $\odot$ denotes elementwise multiplication, and p is the probability that a neuron is dropped.

The scaling factor $1/(1-p)$ implements inverted dropout, ensuring that $E[DROP_p(a)] = a$, so that the expected activation remains unchanged during training. During training, $DROP_p$ randomly deactivates a fraction p of the neurons to reduce overfitting and improve generalization. During inference, dropout is disabled, and the mapping reduces to the identity function $DROP_p(a) = a$. Thus, $DROP_p$ acts as a stochastic regularization operator that randomly masks hidden-unit activations while preserving their expected magnitude.

Definition 14: Let the categorical cross-entropy loss function L and the gradient-based weight-update map be defined by the following Eq. (21) and (22):

$$L: (0,1)^K \times Y \rightarrow R^+ \text{ and } \quad L(\sigma(z), y) = -\sum_{j=1}^{K} 1[y=j] \log \sigma(z)_j \quad (21)$$

where, $\sigma(z)$ is the softmax output of the proposed deep learning (see *Definition 5)*; $y \in Y$ is the true class label; $1[\cdot]$ is the indicator function.

Furthermore, the cross-entropy loss function L is applied to update the weight (w_{ij}) connecting neuron i to neuron j, using the learning rate (α) and the gradient of the loss function $\nabla L(\cdot)$ for the previous weight [21]. The training process is based on mini-batch backpropagation, Eq. (20), to calculate the new weight w_{ij}^{new}.

$$w_{ij}^{new} = w_{ij}^{old} - \alpha \nabla L\left(w_{ij}^{old}\right) \quad \forall i,j \quad (22)$$

IV. The Proposed EDL-AWOA Model

A. EDL-AWOA Architecture

The proposed EDL-AWOA model uses a hybrid machine learning setup that pairs deep learning with an adaptive whale optimization method. It begins with raw data collection, then moves to preprocessing for data cleaning and transformation. The processed data feeds into an enhanced deep learning design with an input layer, several hidden layers, and an output layer that produces initial predictions. At the same time, an adaptive whale optimizer improves the model by tuning parameters through adaptive search and refinement strategies inspired by whale behavior. The interaction between the deep learning model and the optimizer improves learning performance, and the final outputs are passed to the classification and evaluation stage, where the model's predictive performance is assessed. Fig. 1 shows this full workflow.

The Enhanced MLP identifies psychiatric conditions from linguistic representations of Reddit posts. The input layer processes TF-IDF, char-TF-IDF, or LSA feature vectors. The model uses two fully connected hidden layers, each with ReLU activation followed by dropout regularization. Two layers were chosen to keep the design simple and effective while still learning more complex nonlinear patterns from the extracted text features. Dropout was added to reduce overfitting, helping the system generalize better to unseen Reddit posts. The output layer applies a softmax function and produces a probability distribution over six target classes: Anxiety/Stress, Bipolar, Major Depressive, Normal, Personality Disorder, and Substance Abuse. In addition, Fig. 1 shows the enhanced deep learning architecture.

For feature extraction, the study uses four techniques: word-level TF-IDF, character-level TF-IDF, a combination of word- and character-level TF-IDF, and Latent Semantic Analysis with TF-IDF using Truncated SVD for dimensionality reduction. Dimensionality reduction is applied in specific situations to reduce operational costs and maintain proper memory performance in deep learning.

The Adaptive Whale Optimization Algorithm (AWOA) tunes the main hyperparameters of the enhanced deep learning model. In this implementation, the optimized hyperparameters are the learning rate and the dropout rate, and each whale agent represents a candidate hyperparameter configuration. The learning rate is searched in the range $[10^{-4}, 10^{-2}]$, and the dropout rate in the range [0.10, 0.50]. AWOA improves the standard Whale Optimization Algorithm by combining opposition-based learning, Lévy flight exploration, adaptive inertia weight, adaptive spiral movement, and an epoch-switched alpha mechanism. The epoch-switched alpha mechanism changes the alpha value within the same optimization run based on the training epoch phase: the first alpha value applies during the early training phase, before the switch epoch, while the second alpha value applies during the later training phase, after the switch epoch. For example, in the schedule 0.7 ↔ 0.3, the optimizer uses 0.7 before the switch epoch and 0.3 afterward. The reverse schedule, 0.3 ↔ 0.7, is evaluated separately to study how the order of alpha values

affects exploration–exploitation behavior and classification performance.

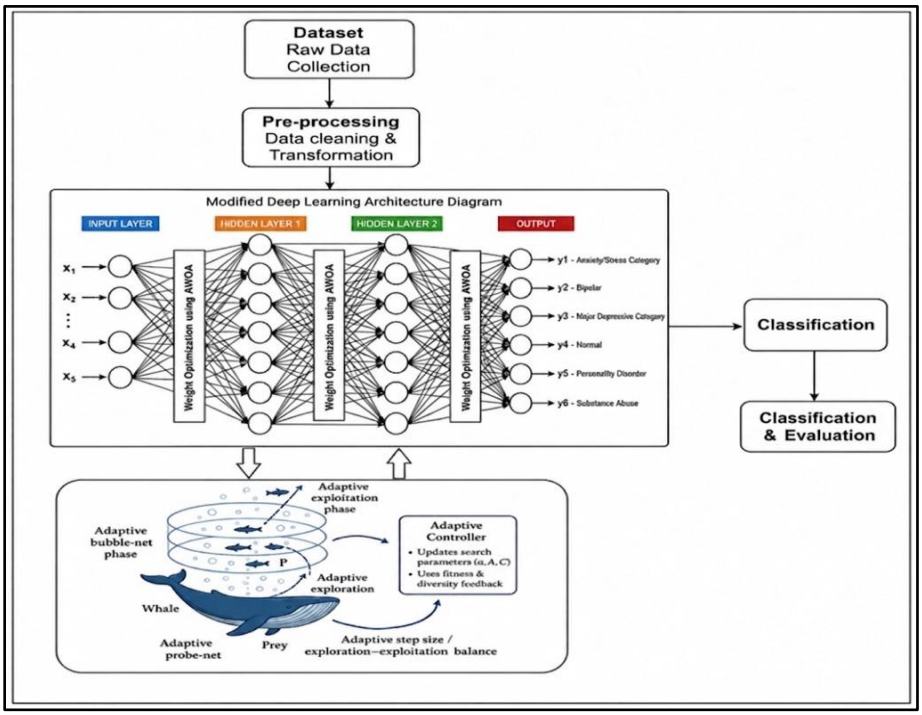

Fig. 1. The architecture of the EDL-AWOA model.

B. Algorithms of the Proposed Model

The methodology is implemented using three algorithms: a data pre-processing algorithm (Algorithm 1), the enhanced deep learning algorithm (Algorithm 2), and the adaptive whale optimization algorithm (Algorithm 3).

Algorithm 1: Data Pre-Processing Algorithm

Input: Raw Reddit text dataset

Output: Cleaned text dataset

Procedure:

Step 1: Load and merge the collected datasets. *(see Definition 7)*

- Step 1.1: Load the first Reddit mental health dataset
- Step 1.2: Load the second Reddit mental health dataset.
- Step 1.3: Standardize the column names in both datasets, such as text and label.
- Step 1.4: Append the rows of the second dataset to the first dataset.
- Step 1.5: Create one unified dataset containing all Reddit text samples and their corresponding labels.

Step 2: Normalize class labels. *(see Definition 7)*

Step 3: Remove records with missing text or labels. *(see Definition 7)*

Step 4: For each text sample: *(see Definition 8)*

- Step 4.1: Convert text to lowercase. *(see Definition 8, map LOW)*
- Step 4.2: Convert emojis to textual descriptions. *(see Definition 8)*
- Step 4.3: Remove URLs, Reddit mentions, and user mentions. *(see Definition 8)*

Step 5: Tokenize the cleaned text. *(see Definition 9)*

Step 6: Remove stop words and one-character tokens. *(see Definition 10)*

Step 7: Apply WordNet lemmatization. *(see Definition 11)*

Step 8: Reconstruct the cleaned text. *(see Definition 12)*

Step 9: Remove posts with fewer than three words. *(see Definition 12)*

Step 10: Remove duplicate posts. *(see Definition 12)*

Step 11: Return the cleaned dataset. *(see Definition 12)*

Step 12: End.

Algorithm 1 integrates two Reddit mental health datasets into a unified corpus by standardizing column names, merging records, normalizing class labels, and removing instances with missing values to ensure data consistency and quality. It then applies a sequence of text-cleaning operations, including lowercasing, emoji-to-text conversion, removal of URLs and user mentions, tokenization, stop-word filtering, and WordNet lemmatization, thereby reducing noise and standardizing linguistic variations. Finally, the cleaned tokens are reconstructed into text, while very short posts and duplicate entries are discarded, resulting in a high-quality dataset suitable for reliable machine learning and natural language processing tasks.

We first merged the Reddit datasets after standardizing class labels and column names, then removed records with missing values. Text preprocessing included lowercasing, emoji-to-text conversion, removal of URLs, subreddit references, and user mentions, followed by tokenization, stop-word removal, elimination of single-character tokens, and WordNet lemmatization. We extracted features using word-level TF-IDF (n-gram range = 1–2, maximum vocabulary = 20,000), character-level TF-IDF (n-gram range = 3–5,

maximum vocabulary = 10,000), and LSA with 300 latent dimensions via Truncated SVD. The E-DL model employed two hidden layers with 128 and 64 neurons using ReLU activation, while the dropout rate (0.10–0.50) and learning rate (10^{-4}–10^{-2}) were optimized by AWOA; training was conducted with a batch size of 32, 32 epochs, an AWOA population size of 30 whales, and 15 optimization iterations.

Algorithm 2: Enhanced Deep Learning Model (E-DL)

Input: TF-IDF feature vectors; Class labels

Output: Predicted class; Evaluation results

Procedure:

Step 1: Load the pre-processed dataset from Algorithm 1. *(see Definition 12)*

Step 2: Convert the text data into TF-IDF feature vectors. *(see Definition 1-3)*

Step 3: Define the Enhanced DL architecture *(see Definition 4)*

Step 3.1: Define the input layer according to the TF-IDF feature size. *(see Definition 4, input $x \in \mathbb{R}^d$)*

Step 3.2: Define the first fully connected dense layer with 128 neurons and ReLU activation. *(see Definition 4)*

Step 3.3: Apply dropout regularization. *(see Definition 13)*

Step 3.4: Define the second fully connected dense layer with 64 neurons and ReLU activation. *(see Definition 4)*

Step 3.5: Apply dropout regularization. *(see Definition 13)*

Step 3.6: Define the softmax output layer for class prediction. *(see Definition 5)*

Step 4: Define the loss function and evaluation metric. *(see Definitions 14 and 16)*

Step 5: Train the E-DL using mini-batch learning and backpropagation. *(see Definition 14)*

Step 6: Optimize the E-DL hyperparameters using AWOA, as described in Algorithm 3, until the maximum number of epochs is reached. *(see Definition 6)*

Step 7: Evaluate the trained model using accuracy, precision, recall, F1-score, and AUC. *(see Definition 16)*

Step 8: Save the final results.

Step 9: End.

The proposed Enhanced Deep Learning (E-DL) algorithm transforms the preprocessed Reddit text into TF-IDF feature vectors and processes them through a multi-layer neural network with two fully connected, ReLU-activated dense layers (128 and 64 neurons) and dropout regularization to improve feature learning and prevent overfitting. The model is trained using mini-batch backpropagation, while the Adaptive Whale Optimization Algorithm (AWOA) optimizes hyperparameters to improve classification performance. Finally, the trained E-DL model predicts mental health categories and is evaluated using comprehensive metrics, including accuracy, precision, recall, F1-score, and AUC, to measure its effectiveness and robustness.

Algorithm 3: Adaptive Whale Optimization Algorithm (AWOA)

Input: deep learning architecture defined in Algorithm 2 and in Fig. 1.

Set the Initial value of the learning rate search space $\alpha \in [10^{-4}, 10^{-2}]$

Where 10^{-4} is the lower bound and 10^{-2} is the upper bound.

Output**:** Find the best α

Procedure

Step 1: Define the initial set of weight functions w_{ij} in deep learning. *//see Definition 4*

Step 2: Set the initial whale position (X_0) and set the learning rate (α) as in Eq. (23) *//(see Definition 6)*

$$\alpha = X_0 \tag{23}$$

Step 3: For $s = 0$ *to* $N - 1$.

where, N - 1 is the last whale position

Step 3.1: Calculate the new Whale Position X_{s+1} using Eq. (24) *//see Definition 6*

$$X_{s+1} = X_s - \bar{F}(X_s, X_p) \tag{24}$$

where, X_s is the sth position of whales and X_p is the prey location, and $\bar{F}(.)$ is the whale optimization model [22].

Step 3.2: Apply the Adaptive WOA approach based on the fitness function $Fit(.)$ to calculate the best learning rate α as in Eq. (25) and Eq. (26):

$$\alpha = \beta X_{s+1} + (1 - \beta) X_s \tag{25}$$

where

$$\beta = \begin{cases} 0.9, & \text{if } \mathrm{Fit}(X_{s+1}) > \mathrm{Fit}(X_s) \\ 0.1, & \text{if } \mathrm{Fit}(X_{s+1}) \leq \mathrm{Fit}(X_s) \end{cases} \tag{26}$$

Step 3.3: Calculate the new value of weight w_{ij}^{new} using Eq. 22) *//see Definition 14,*

Step 3.4: Apply the training process of deep learning using an activation function between every two layers using Eq. (27): *(see Definition 4, maps 6–7)*

$$z = f\left(b + \Sigma_i \Sigma_j a_{i,j} \times w_{i,j}^{new}\right) \tag{27}$$

where, $f(.)$ is the ReLU activation function, and b is the DL bias.

Step 4: End // *Find the best α of DL*

The Adaptive Whale Optimization Algorithm (AWOA) is integrated with the Enhanced Deep Learning (E-DL) model to dynamically optimize the learning rate during training by simulating whale-hunting behavior. At each iteration, the WOA search mechanism updates whale positions, and a fitness function evaluates candidate learning rates to select the value that minimizes model loss and improves convergence. The selected learning rate then updates network weights via backpropagation, while ReLU activation functions enable effective feature learning across layers, yielding an optimized deep learning model with improved classification performance.

The AWOA algorithm optimizes classification accuracy on the validation dataset, defined as (Validation accuracy, Validation F1-score, Validation Macro AUC). We repeated each optimization experiment more than 20 times to minimize stochastic effects and recorded the average performance. We fixed the best hyperparameter configuration from the validation set and evaluated it on the independent test set without further optimization to prevent data leakage.

V. Results and Discussion

This chapter discusses the experimental outcomes from implementing the proposed EDL-AWOA model. The main goal is to test how well the proposed model can classify psychiatric disorders using Reddit mental health text data, with

a special focus on depression and anxiety. We evaluate the results using common classification metrics, including accuracy, precision, recall, F1-score, macro AUC, and confusion matrix analysis, and compare them with baseline machine learning and deep learning models to assess the contribution of the AWOA optimization process.

A. System Setup

The research was conducted on a Colab server with 64GB of RAM, running the G4 runtime with an NVIDIA RTX PRO 6000 GPU and approximately 96GB of VRAM, with CUDA 13.0-accelerated training. Python 3.11 (managed via pyenv) was the primary programming language. PyTorch was used for model building and training; Scikit-learn for preprocessing, feature extraction, evaluation, and basic machine learning methods; NLTK for natural language preprocessing; and imbalanced-learn for handling class imbalance. NumPy and Pandas were used for data analysis, and Matplotlib for visualizing model performance. The system supports repeatable experiments by automatically logging model configurations, confusion matrix outputs, hyperparameter settings, and the final trained model weights.

The dataset is the public Kaggle Reddit Mental Health Dataset, which contains posts from mental health-related subreddits focused on depression and anxiety. We retained only English-language posts with legitimate self-reported mental health expressions. We split the dataset into 70% training, 15% validation, and 15% testing sets, and Table I shows the training and optimization configuration.

TABLE I. TRAINING AND OPTIMIZATION PARAMETERS

Parameter	Value/Condition
Batch size	32
Learning rate	0.001 default; optimized from 0.0001 to 0.01
Epochs	32
Pre-training Epochs	4
Noise dimension	100
Hidden layer 1	Dense, 128 neurons, ReLU
Hidden layer 2	Dense, 64 neurons, ReLU
Hyperparameters optimized	Learning rate, Dropout
AWOA – Population Size	30
AWOA – Max Iterations	15

The batch size was set to 32 to balance training stability and computational efficiency. The default learning rate was fixed at 0.001 for steadier convergence but was set within the AWOA search bounds of 0.0001 to 0.01. The number of training epochs was set to 32 to give the model enough opportunity to learn meaningful patterns without excessive compute time. Two dense hidden layers were used: the first with 128 neurons and ReLU activation, and the second with 64 neurons and ReLU activation. We optimized the learning rate and dropout, since both strongly affect performance. For AWOA, the population size was set to 30 whale agents and the maximum number of iterations to 15, providing a workable balance between optimization quality and computational cost.

B. Experiments on the Proposed Model to Find the Best Parameter Tuning

Let the evaluation metrics be defined by the following maps (28–32) from the confusion-matrix counts of the test set:

$$\text{Accuracy} = (TP + TN)/(TP + TN + FP + FN) \quad (28)$$

$$\text{Precision} = \frac{TP}{TP+FP} \quad (29)$$

$$\text{Recall} = \frac{TP}{TP+FN} \quad (30)$$

$$F1 = 2 \times \frac{\text{Precision} \times \text{Recall}}{\text{Precision} + \text{Recall}} \quad (31)$$

$$\text{AUC} = \int_0^1 TPR \, d(FPR) \quad (32)$$

where, TP, TN, FP, and FN are the true-positive, true-negative, false-positive, and false-negative counts, respectively; TPR = Recall is the true-positive rate; and FPR = FP / (FP + TN) is the false-positive rate. For the multi-class setting, the metrics are macro-averaged over the K diagnostic categories.

The proposed model was evaluated across different conditional alpha (α) schedules during training. The results show that model performance varied according to the selected α setting, indicating that the adaptive coefficient directly affects the optimization process and classification performance. Among the tested settings, Experiment 7, using the α schedule 0.9 ↔ 0.1, achieved the best performance, with 93.99% accuracy, 94.01% precision, 93.99% recall, 93.99% F1-score, and 0.9993 macro AUC. Table II presents the full results.

TABLE II. EDL-AWOA PERFORMANCE ACROSS ALPHA SETTINGS (TRAINING)

Exp.	Adaptive α Selection	Accuracy	Precision	Recall	F1-Score	Macro AUC	Adaptive α Selection	Accuracy
1	0.7 ↔ 0.3	87.20%	87.22%	87.20%	87.19%	0.9968	1	0.7 ↔ 0.3
2	0.3 ↔ 0.7	85.80%	85.81%	85.80%	85.79%	0.9959	2	0.3 ↔ 0.7
3	0.8 ↔ 0.2	89.51%	89.56%	89.51%	89.51%	0.9978	3	0.8 ↔ 0.2
4	0.2 ↔ 0.8	86.58%	86.64%	86.58%	86.59%	0.9964	4	0.2 ↔ 0.8
5	0.6 ↔ 0.4	88.40%	88.43%	88.40%	88.40%	0.9973	5	0.6 ↔ 0.4
6	0.4 ↔ 0.6	87.61%	87.62%	87.61%	87.61%	0.9969	6	0.4 ↔ 0.6
7	**0.9 ↔ 0.1**	**93.99%**	**94.01%**	**93.99%**	**93.99%**	**0.9993**	**7**	**0.9 ↔ 0.1**
8	0.1 ↔ 0.9	86.21%	86.23%	86.21%	86.21%	0.9962	8	0.1 ↔ 0.9

The accuracy was between 85.80% and 93.99% in the eight experiments. Experiment 7 achieved the highest accuracy using the 0.9 ↔ 0.1 schedule, indicating that the best balance between exploration and exploitation came from starting with a larger alpha value and selecting lower alpha values after the switch epoch. Similarly, the schedule from step 0.3 ↔ 0.7 (the lowest accuracy) achieved 85.80% accuracy.

C. Confusion Matrix and AUC-ROC Curves for EDL-AWOA Model

The confusion matrix corresponding to the best EDL-AWOA configuration is shown in Fig. 2.

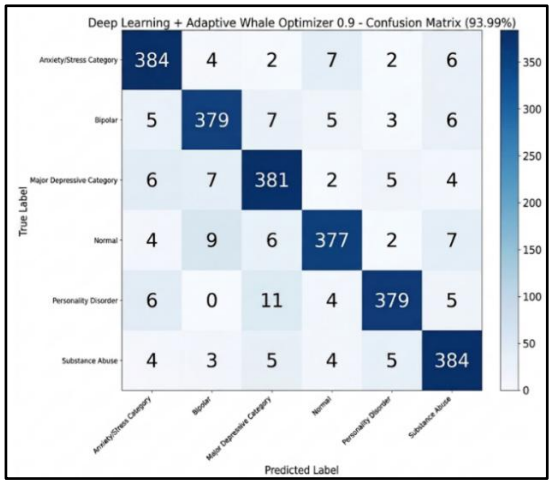

Fig. 2. Confusion matrix for the EDL-AWOA model.

The confusion matrix shows excellent classification performance with an overall accuracy of 93.99%, as indicated by the strong diagonal values (377-384 correct predictions per class) and relatively few misclassifications. Most errors occur between clinically similar classes, particularly Personality Disorder and Major Depressive Category (11 cases), and Normal and Bipolar (9 cases), suggesting some overlap in the learned features. Overall, the Deep Learning model optimized with the Adaptive Whale Optimizer (0.9) demonstrates high reliability and balanced performance across all six classes, with no class exhibiting substantially higher error rates than the others.

Fig. 3 shows the AUC-ROC curves across the six mental health categories shown in Fig. 2.

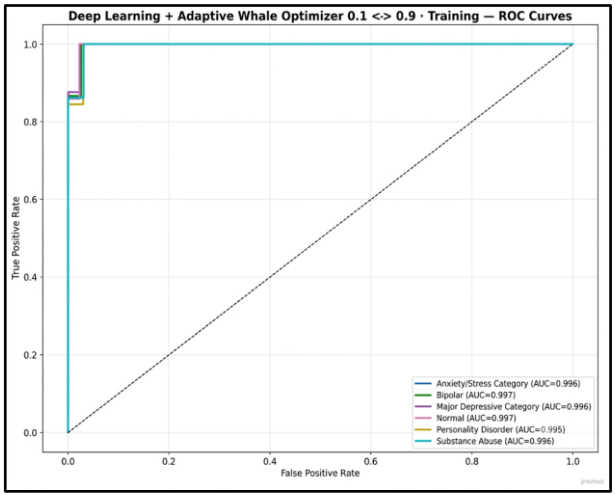

Fig. 3. AUC-ROC curves for the best EDL-AWOA model.

The AUC-ROC curves of the best EDL-AWOA model demonstrate excellent discriminative capability across all six mental health categories, with AUC values ranging from 0.995 to 0.997. The Bipolar and Normal classes achieved the highest AUC of 0.997, while Anxiety/Stress, Major Depressive Category, and Substance Abuse attained 0.996, and Personality Disorder reached 0.995. The ROC curves lie very close to the upper-left corner, indicating a high true positive rate and a very low false positive rate. These results confirm that the EDL-AWOA model provides highly accurate and robust class separation, making it highly effective for multi-class mental health disorder classification.

D. Comparison Between Various Types of Deep Learning

The proposed model (EDL-AWOA) is compared with two baselines: standard deep learning (DL) and deep learning with the standard Whale Optimization Algorithm (DL-WOA).

Fig. 4 shows the accuracy and loss curves for the training, validation, and testing phases of the Deep Learning (DL) model.

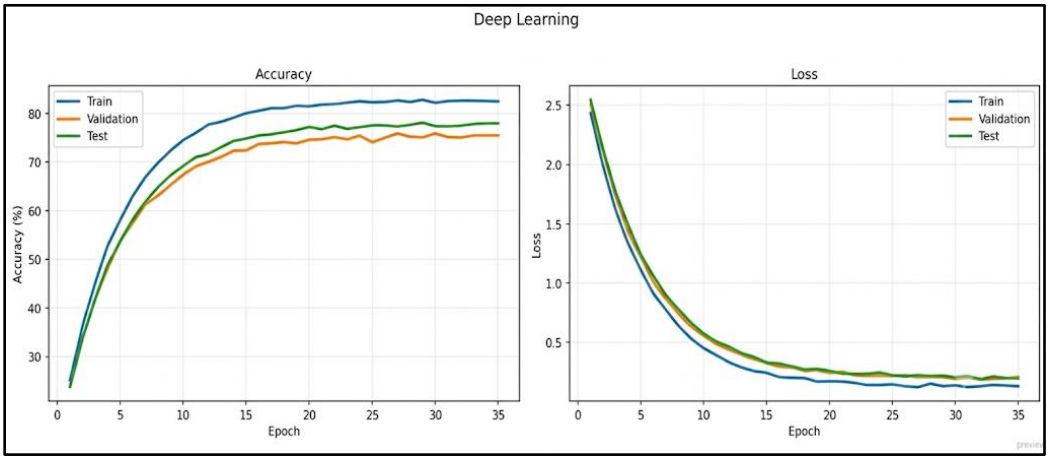

Fig. 4. Training, validation, and testing accuracy/loss curves for the Deep Learning (DL) model.

The deep learning model showed substantial progress, with training accuracy rising from about 25% to 83% (+232%), validation accuracy from 24% to 75% (+213%), and test accuracy from 24% to 78% (+225%) over 35 epochs. At the same time, the loss decreased markedly, with training loss dropping from about 2.45 to 0.12 (95.1% reduction), validation loss from 2.50 to 0.20 (92.0% reduction), and test loss from 2.55 to 0.21 (91.8% reduction). These results indicate effective model convergence and strong generalization, as the validation and test curves closely follow the training curves with only a small performance gap.

Fig. 5 shows the accuracy and loss curves for the training, validation, and testing phases of the Deep Learning (DL) with WOA (DL-WOA) model.

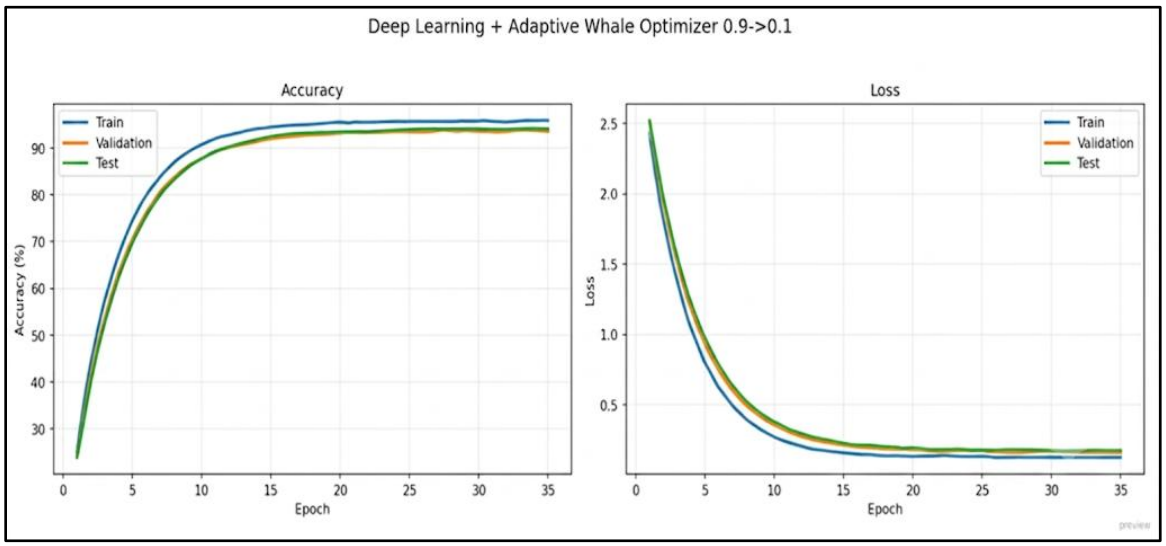

Fig. 5. Training, validation, and testing accuracy/loss curves for the Enhanced Deep Learning and adaptive WOA (EDL-WOA) model.

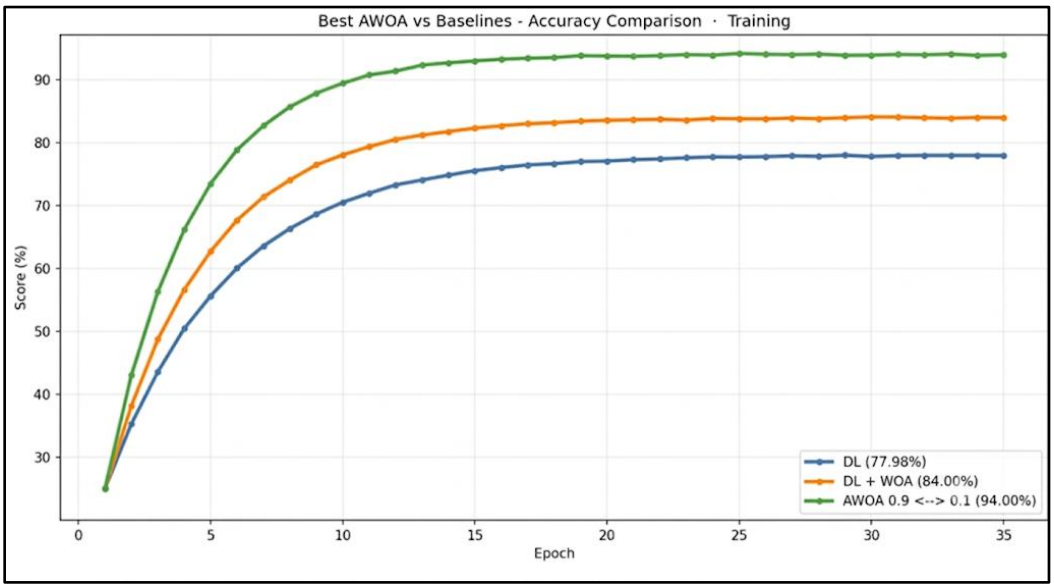

Fig. 6. Accuracy comparison between DL, DL-WOA, and EDL-AWOA (training).

The Deep Learning + Whale Optimizer model outperformed the baseline model, with training, validation, and test accuracies rising from approximately 25% to 87% (+248%), 24% to 82% (+242%), and 24% to 85% (+254%), respectively. Simultaneously, training, validation, and test losses fell from about 2.45, 2.50, and 2.55 to 0.13, 0.18, and 0.20, representing reductions of approximately 94.7%, 92.8%, and 92.2%, respectively, indicating faster convergence, improved generalization, and better predictive performance compared with the standard deep learning model.

Fig. 6 shows the training, validation, and test curves for the best EDL-AWOA configuration using the 0.9 ↔ 0.1 alpha schedule. The accuracy curves increase rapidly during the early epochs and then stabilize after approximately epoch 15, while the loss curves decrease sharply and remain low across training, validation, and test data. The small gap between the curves indicates stable generalization and no major overfitting.

The accuracy and loss curves in Fig. 8 indicate that the proposed deep learning integrated with Adaptive Whale

Optimization (EDL-AWOA) converges quickly and achieves stable performance on the training, validation, and test datasets. Accuracy rises quickly from around 25% (epoch 1) to 95%, 94%, and 93.5% on the training, validation, and test sets, respectively. At the same time, the loss drops from 2.5 to 0.15 on training, 2.5 to 0.18 on validation, and 2.5 to 0.17 on testing, a decrease of around 92%- 94%. The closely aligned training, validation, and test curves indicate strong generalization with little overfitting. Overall, the results show that AWOA effectively optimizes the learning process by speeding convergence, improving classification accuracy, and significantly reducing prediction error.

The accuracy comparison on the training and testing sets is shown in Fig. 7 and 8, respectively.

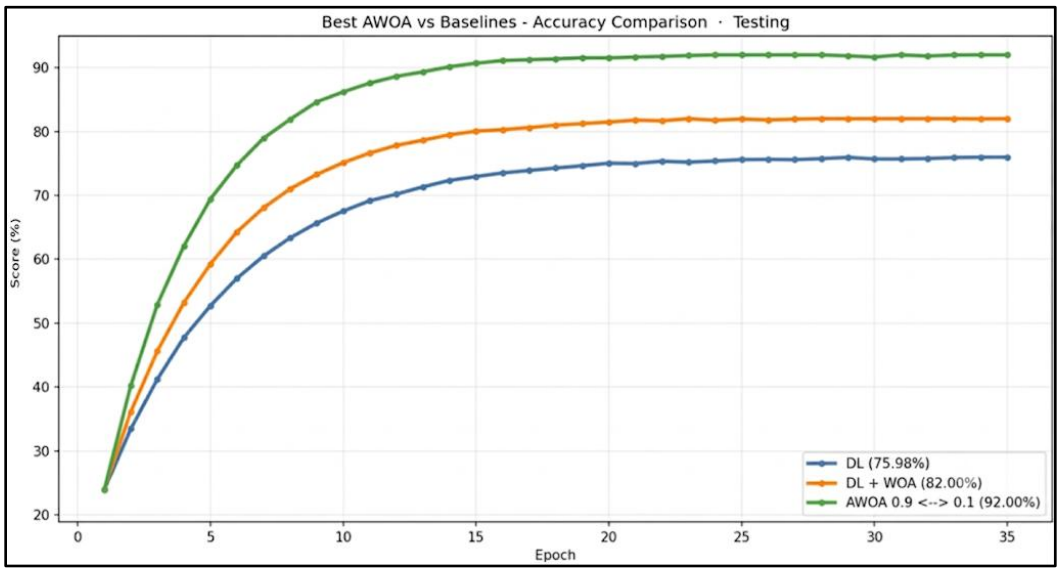

Fig. 7. Accuracy comparison between DL, DL-WOA, and EDL-AWOA (testing).

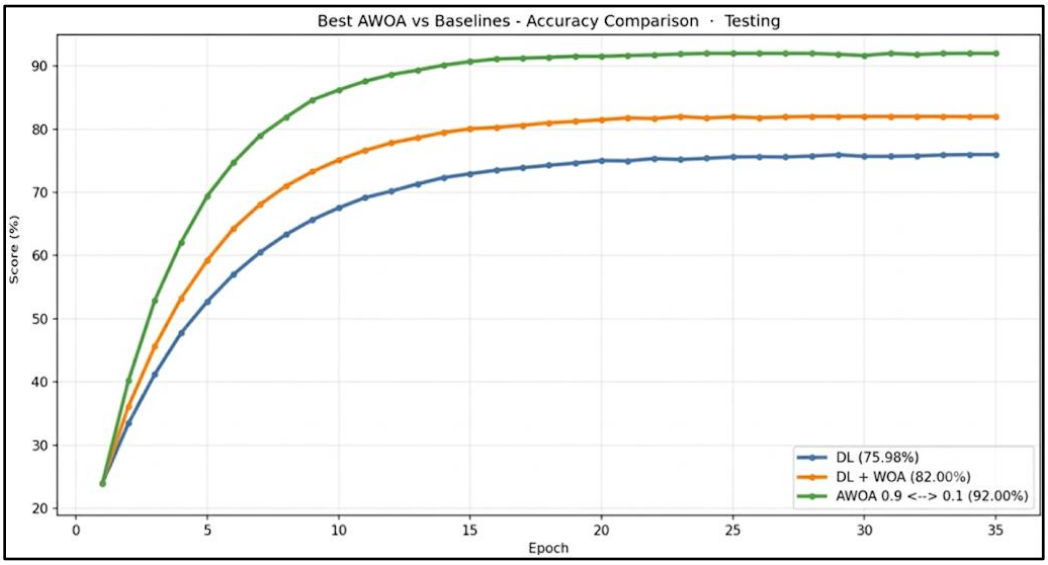

Fig. 8. Accuracy comparison between DL and DL-AWOA (testing).

The training results indicate that the proposed EDL-AWOA model outperforms both conventional DL and DL-WOA. The deep learning model (baseline DL) reached a training accuracy of 77.98%, and incorporating the Whale Optimization Algorithm (DL-WOA) yielded 84%, a 7.72% improvement over DL. The proposed EDL-AWOA model further improved training accuracy to 94.00%, an 11.90% improvement over DL-WOA and a substantial 20.54% improvement over the baseline DL model. In addition, EDL-AWOA converged faster and maintained the highest accuracy throughout training, highlighting the effectiveness of the adaptive optimization mechanism in improving parameter tuning, feature learning, and overall classification performance.

The testing results confirm that the proposed EDL-AWOA model significantly outperforms both the baseline DL and the DL-WOA models in classification accuracy. The conventional DL model achieved a testing accuracy of 75.98%, while incorporating the Whale Optimization Algorithm increased accuracy to 82.00%, a 7.92% improvement over DL. The

proposed EDL-AWOA model further improved testing accuracy to 92.00%, an additional 12.20% improvement over DL-WOA and a remarkable 21.08% improvement over the baseline DL model. Furthermore, EDL-AWOA converged faster and maintained consistently higher accuracy across all testing epochs, showing that the adaptive optimization strategy improves model generalization, parameter tuning, and predictive performance on unseen data.

Tables III and IV compare the proposed model (EDL-AWOA) with two baselines on the metrics (Accuracy, Precision, Recall, F1-score, and AUC) for training and testing, respectively.

TABLE III. COMPARISON OF THE PROPOSED MODEL WITH BASELINE MODELS (TRAINING)

Model	Accuracy	Precision	Recall	F1-Score	Macro AUC
DL	77.98%	77.98%	77.98%	77.98%	0.9903
DL-WOA	84%	84.05%	84%	83.97%	0.9949
EDL-AWOA (Proposed)	94%	94.01%	94%	94%	0.9993

As evaluated against the ground truth, Table III indicates that the performance of each evaluation metric remains strong on the training side, with the highest scores by EDL-AWOA. For accuracy, EDL-AWOA was 94.00%, which is better than both baseline DL (77.98%) and DL-WOA (84.00%), with improvements of 20.54% and 11.90%, respectively. The same trend is also observed with respect to precision, in which case EDL-AWOA had a performance of 94.01%, while the corresponding DL and DL-WOA were 77.98% and 84.05%. Moreover, the recall and F1-score values also improved from 77.98%(DL), approximately 84.00% (DL-WOA), to 94.00% with EDL-AWOA, respectively, which demonstrate the superior classification consistency and balanced performance of the EDL-AWOA method. Moreover, it obtained the highest Macro AUC (0.9993) among all experimental models, including DL (0.9903) and DL-WOA (0.9949), indicating that the classification characteristics of mental disorders were clearly distinguished by the proposed model from each other. The results indicate that integrating the Adaptive Whale Optimization Algorithm could effectively improve performance in feature extraction, parameter tuning, and classification accuracy compared to its non-AWOM counterparts.

TABLE IV. COMPARISON OF THE PROPOSED MODEL WITH BASELINE MODELS (TESTING)

Model	Accuracy	Precision	Recall	F1-Score	Macro AUC
DL	75.98%	75.98%	75.98%	75.98%	0.9853
DL-WOA	82%	82.05%	82%	81.97%	0.9899
EDL-AWOA (Proposed)	92%	92.01%	92%	92%	0.9990

Table IV clearly shows the testing performance of the baseline DL and DL-WOA models against the proposed model (EDL-AWOA), with EDL-AWOA greatly outperforming them on every evaluation metric. The accuracy of the conventional DL model was 75.98%, while with the Whale Optimization Algorithm, it improved to 82.00%, i.e., a gain of 7.92% over DL. The proposed EDL-AWOA model significantly improved the accuracy to 92.00%, a relative increase of 12.20% over DL-WOA and an astounding 21.08% over the baseline DL model, respectively. As shown in Table III, a similar performance improvement is observed in precision, recall, and F1-score; EGL-AWOA obtained an accuracy of about 92.00%, while DL was about 75.98% and DL-WOA was approximately 82.00%, which indicates that EGL-AWOA has better predictive reliability than other methods with better class balance. Additionally, EDL-AWOA achieved the highest Macro AUC of 0.9990 in this test, again higher than DL (0.9853) and DL-WOA (0.9899), demonstrating its superior ability to classify mental health categories with one-vs-all comparisons. These results indicate that the proposed adaptive whale optimization strategy improves model generalization and classification performance on unseen test data.

E. Comparison with Previous Works

Table V compares the proposed EDL-AWOA model with recent studies evaluated on the same Kaggle Reddit mental health dataset. Using a common corpus minimizes the influence of dataset-specific factors and provides a more reliable assessment of relative model performance. The results demonstrate that EDL-AWOA achieves superior classification performance compared with existing approaches evaluated under the same data conditions.

TABLE V. COMPARISON OF THE PROPOSED MODEL WITH RELATED STUDIES

Study	Method	Dataset	ACC.	Prec.	Recall	F1	AUC
Utsa et al. [23].	Interpretable linguistic features (author-disjoint)	RMHD	89%	93%	85%	89%	0.9500
Jena et al. [24].	Continual Neuro-Symbolic Graph Learning (MH-Freeze)		92%	N/R	N/R	92%	0.9420
Kim et al. [25].	Random Forest (Text + LIWC), binary depression		91%	96%	90%	93%	N/R
Proposed Model	EDL-AWOA		93.99%	94.01%	93.99%	93.99%	0.9993

The comparative study shows that the EDL-AWOA model achieved the best performance among RMHD-based studies on mental health classification. Utsa et al. (2026) on the RMHD dataset achieved 89% accuracy and an AUC of 0.9500, and Jena et al. (2026) achieved 92% accuracy and a 92% F1-score, while the proposed model performed better, with maximum accuracy (93.99%), recall (93.99%), and AUC (0.9993). Compared with Kim et al., a Random Forest classifier with text and LIWC features achieved 91% accuracy and a 93% F1-score, while the EDL-AWOA improves accuracy by c.a. 3.29% and the F1-score by 1.06%. Moreover, the exceptionally high AUC of 0.9993 indicates near-perfect class discrimination, substantially exceeding AUC values reported in previous studies. These results confirm that integrating deep learning with the Adaptive Whale Optimization Algorithm enhances feature learning and parameter optimization, leading to superior predictive performance and robustness compared with existing approaches.

VI. Conclusion and Recommendations

This study presents an enhanced deep learning model combined with the Adaptive Whale Optimization Algorithm (EDL-AWOA) for psychiatric disorder classification using Reddit mental health text data. A comprehensive Natural Language Processing (NLP) data preprocessing followed by term frequency–inverse document frequency (TF-IDF)-based feature extraction, a two-hidden-layer deep learning structure, and automatically adaptive hyperparameters after multiple iterations were integrated to effectively predict six mental health categories, including Anxiety/Stress, Bipolar, Major Depressive with or without psychotic features, Normal, Personality Disorder, and Substance Abuse or not. The experimental results indicated that the adaptive optimization strategy can optimize the learning procedure and provide better classification accuracy, faster convergence time, and better generalisation performance.

In the set of analysed alpha schedules, the AWOA configuration (0.9 ↔ 0.1 adaptive) outperformed all others, with an accuracy value of 93.99%, a precision value of 94.01%, and a recall value of 93.99% for the micro and weighted average F1-score values, whilst obtaining results equal in Macro AUC to nearly one at 0.9993 Confusion matrix analysis indicated high classification consistency across all classes, with only a small number of instances in which clinically related disorders were misclassified. Additionally, the ROC analysis confirmed a high discriminative ability (all AUCs were found to need development) for all classes—ranging from 0.995 to 0.997.

Experimental results revealed that EDL-AWOA drastically improved both the DL model and the DL-WOA model in terms of overall performance. The proposed model outperforms DL and DL-WOA by 21.08% and 12.20% (accuracy), respectively, whilst achieving higher scores in precision, recall, F1-score, and Macro AUC in the test dataset. Moreover, the comparison between recent state-of-the-art studies in the field showed that EDL-AWOA obtained the best overall accuracy and AUC values, indicating that adaptive whale-based optimization is a practical approach to effectively solving these mental health classification problems.

The findings confirm that combining adaptive metaheuristic optimization with deep learning yields a robust, adaptable framework with potential for automated psychiatric disorder detection. Thus, the proposed system will make this process more efficient by supporting real-time decision-making for mental health care workers, since they can relatively quickly detect psychopathologies from large volumes of online text data. Nonetheless, future work may explore multilingual datasets, transformer-based embeddings, explainable artificial intelligence methods, and multimodal data sources (speech, clinical records, and behavioral signals) to optimize diagnostic performance and potential utility in the clinic.

An important research direction for the future is to extend the model output from the proposed work on multilingual mental health text classification. Note: This research only applies to English-language Reddit posts, so it does not cover mental health literature in all languages. Future studies should incorporate Arabic and more languages to allow for translation of the model in different ethical and cultural situations since somatic accounts for communicating psychological distress are typically influenced by lexicon, culture, dialect, and social class.

Acknowledgment

The authors express their sincere gratitude to Amman Arab University and the University of Québec for providing the academic environment and research support necessary to conduct this study. The authors also acknowledge the developers and maintainers of the publicly available Reddit mental health datasets and the open-source software libraries used in this research, including Python, PyTorch, Scikit-learn, NLTK, Pandas, and NumPy. Finally, the authors thank the reviewers and editors for their valuable comments and constructive suggestions, which have significantly improved the manuscript's quality, clarity, and rigor.

***Abstract*—Glioblastoma Multiforme (GBM) is the most invasive form of primary brain tumor. The average survival time after diagnosis is only 15 months. Accurately and automatically analyzing GBM MRI scans remains a major clinical challenge. It requires the tumor to be localized, a report to be generated in a structured way, and information from multiple data sources to be integrated simultaneously. Existing methods address these problems separately and use models for one task that do not leverage the complementary information available across segmentation, captioning, and grounding. This study introduces MedViT-MT (Medical Vision Transformer Multi-Task), a unified transformer architecture that performs tumor segmentation, molecular-subtype classification, lesion grounding, and patient-conditioned structured caption generation from GBM DSC-MRI sequences. MedViT-MT employs Swin Transformer Tiny as its hierarchical visual transformer backbone for extracting multiscale imaging features, followed by the addition of a clinical fusion module that is based on cross-attention and that directly places tabular clinical features (IDH1, MGMT, KPS, GTR, and GTR) into the visual feature space. It further extracts inter-slice volumetric information from the MRI slice sequence, helping the model infer three-dimensional tumor volume. On the UPENN-GBM dataset, which contains 375 patients with DSC MRI sequences and their clinical records, MedViT-MT reaches 98.31% classification accuracy, 99.37% AUC-ROC, 91% mean Dice score, and 100% few-shot accuracy (1-shot, 5-shot, 10-shot). The model is also able to generalize well to different IDH1 subtypes, and it runs using 16GB RAM on a CPU. The separate experiments to identify what each architectural component delivers show that all of them matter; the statistical analyses indicate the reliability of the model.**

Keywords*—Glioblastoma; multi-task learning; deep learning; transformer; clinical data fusion; temporal encoding

I. Introduction

Brain tumors are one of the most severe neurological conditions that have a profound impact on the survival and quality of life of patients [1]. To support diagnosis, therapy planning, and evaluation of prognosis, it is vital to perform accurate tumor detection, precise tumor localization, and detailed characterization of tumor subregions [2]. Magnetic Resonance Imaging (MRI) is currently the most widely used imaging technique for assessing brain tumors, as it provides excellent visualization of soft-tissue structures and supports multiple sequences [3, 4]. The use of artificial intelligence for automated brain tumor analysis has become a significant research focus driven by the increasing accessibility of multi-modal MRI datasets from sources such as The Cancer Imaging Archive and the establishment of the Brain Tumor Segmentation Challenge as a benchmark [5].

Brain tumors are usually examined through MRI scans of different sequences, such as T1, T1 contrast-enhanced (T1c), T2, and FLAIR, to identify tumor parts like the enhancing tumor, necrotic core, and edema. In the clinic, radiologists manually check these sequences to draw lesion boundaries, calculate tumor burden, and characterize radiological features through narrative reports [6]. This method takes up a lot of time, and different people may disagree on the results. As the amount of imaging data keeps increasing and there is a demand for precision medicine, automated systems that can help clinicians in tumor interpretation and decision-making are becoming necessary [7].

The clinical examination and evaluation of brain tumors nowadays is being done mainly through radiologists examining multi-sequence MRI visually using manual or semi-automatic tumor segmentation tools, grading radiologically based on morphological features to perform histopathological examination after biopsy or surgery, and integrating imaging results with clinical and molecular data. These techniques are still considered the gold standard in neuro-oncology and have a crucial role in confirming diagnosis and planning therapy [8]. However, the traditional clinical methods still have several limitations despite their great importance. Manual cut-out of the work from images is tiring and subject to differences in interpretation of the results by different experts [9]. Looking at surfaces visually may miss patterns that are located deeply in data obtained from multiple sequences. Obtaining histopathological confirmation means doing highly intrusive procedures, which cannot always be done. Clinical workflows as they stand nowadays usually generate narrative-based reports rather than reports with quantitative uncertainty estimates, which essentially means that the confidence level can only be assessed based on someone's judgment or perception. All of this

points to the necessity of dependable, automated, and interpretable computational support tools [10].

During the last several years, there has been a significant growth trend in the use of machine learning and deep learning techniques for the automated detection and segmentation of brain tumors. Convolutional Neural Networks (CNNs) such as the U-Net and its different versions have been very successful in volumetric tumor segmentation tasks [11]. Transformer-based architectures have recently taken medical imaging to a new level by enhancing the understanding of global context [12]. Classification of tumor types and prediction of survival outcomes using MRI features is also among the areas that have been extensively studied [13]. Medical image captioning is another area that is gaining attention, and it is focused on generating radiology-type descriptions from imaging data [14].

Although the majority of deep learning methods promise great results, some major issues are raised by most existing ones [15]. A large number of the models do not go beyond segmentation and classification and hence miss out on structured clinical information. The models designed for caption generation usually depend on global image features, which makes them incapable of relating textual descriptions solely to the tumor area. Besides, they usually don't take into account uncertainty estimation, which means they give overconfident predictions that may cause a loss of clinical trust [16]. Thus, at present, these tools are more like isolated predictive instruments rather than comprehensive, clinically meaningful decision-support frameworks[17].

Despite the huge steps made in brain tumor segmentation and classification, there are still quite a few gaps. First, there is not much research on single frameworks that can do segmentation, classification, and radiology-style report generation all at the same time [18]. Second, most of the vision-language methods have not been updated to include segmentation-guided grounding, so it is not guaranteed that the texts produced by these methods describe the tumor areas correctly. Third, the lack of structured clinical metadata in the model design means the potential for patient-specific reasoning is not being realized. Lastly, the importance of uncertainty-aware modeling for dependable clinical use is hardly recognized in multi-task brain tumor systems[19].

The main contributions of this research are outlined below:

- This research proposes a unified multi-task deep learning framework that simultaneously performs brain tumor segmentation, molecular-subtype classification, lesion grounding, and patient-conditioned structured caption generation, enabling comprehensive GBM analysis within a single model.
- This study introduces a segmentation-guided visual grounding mechanism that generates tumor-aware region tokens and aligns visual representations with generated structured clinical captions, thereby improving the spatial interpretability of the textual output.
- This research develops a cross-attention transformer-based fusion module to combine the structured clinical metadata, which allows the model to incorporate patient-specific context and support more informed patient-aware decision-making.
- This study incorporates uncertainty-aware modeling to generate confidence maps with the predictions to enhance the interpretability, reliability, and trustworthiness of the system in clinical applications.

The rest of the study is structured as follows. Section II discusses the literature on brain tumor segmentation, multi-modal fusion, and medical report generation. Section III details the proposed methodology used to cover the segmentation branch, clinical fusion mechanism, uncertainty modeling, and caption generation module. Section IV is for the presentation of the quantitative results, ablation studies, and comparisons with state-of-the-art methods. Section V: Conclusion and Future Work.

II. Literature Review

Deep learning has made significant advancements in brain tumor segmentation and classification using MRI data. However, combining clinical data, uncertainty modeling, and report generation into a single integrated system is still quite limited.

A. Brain Tumor Segmentation in Multi-Modal MRI

A multimodal transformer-based architecture was introduced for brain tumor segmentation using incomplete MRI data [20]. The approach combines a modality-specific encoder, a multi-modal transformer, and a shared-weight decoder to generate missing modalities. The experiments on BraTS 2018, 2019, and 2020 datasets show that the model outperforms the state-of-the-art models in terms of segmentation accuracy, especially when modalities are missing. This study [21] presents a deep learning-based method for brain tumor segmentation and classification. The authors used DeepLabV3+ integrated with Atrous Spatial Pyramid Pooling (ASPP) and Bayesian Optimization. The main features of the work are a couple of custom-made models, namely, IRB-96 and IRB-Self, which are designed for feature extraction and classification, respectively. The features obtained from the model are optimized through Bayesian methods, and to make the results more understandable, LIME is used. Their method reaches 92.68% segmentation accuracy and 95.42% classification accuracy on the dataset, which is better than other advanced techniques. Recently, a novel technique, namely Contextual Transformer U-Net (CT-UNet), was introduced for brain tumor segmentation[22]. It is a hybrid of Transformer blocks and U-Net architecture that effectively outlines tumors in multimodal MRI sequences. On the BraTS dataset, CT-UNet achieved a Dice coefficient of 0.92, sensitivity of 0.90, and specificity of 0.94, therefore outperforming the conventional models. Furthermore, it showed very accurate spatial localization with a Hausdorff distance of 7.5 mm. Besides, the proposed method enables rapid and precise segmentation, which in turn allows clinical application for improving patient care and treatment planning. Multi-Modal Segment Anything Model (MSAM) for glioma tumor segmentation is proposed by integrating structural MRI with diffusion tensor imaging (DTI) data [23]. The approach feature first a multi-modal feature fusion block, missing modality training technique to handle missing data

scenarios. MSAM on the BraTS 2018 dataset outperforms U-Net not only in terms of Dice Similarity Coefficient but also in 95% Hausdorff Distance, particularly when only structural MRI data is available. These results support the ability of MSAM to discard a modality and still yield reliable segmentation, even with incomplete data or varying tumor sizes.

B. Uncertainty-Aware Segmentation for Trustworthy AI

A deep learning approach to brain tumor segmentation was proposed that combines uncertainty estimation with an attention-based multimodal fusion mechanism [24]. The presented system is based on a multi-encoder 3D U-Net architecture combined with Bayesian uncertainty estimation for accurate segmentation. The numerical comparisons on the BraTS 2018 and BraTS 2019 datasets demonstrate that their approach outperforms the state-of-the-art methods in Dice score, Hausdorff distance, and sensitivity. This method significantly improves segmentation accuracy at the tumor border, and it is flexible to different network architectures and computer vision tasks. A brain tumor segmentation method is introduced by incorporating multi-modal fusion and uncertainty quantification techniques [25]. Fuchs et al. [26] explored the feasibility of uncertainty measures in brain cancer delineation and put forward a multi-headed Variational U-Net (mu-VNet). This approach is based on the variational inference principle merged with the ensemble's variability features to produce better uncertainty assessments without sacrificing much on the computational requirement. They tested this model on the BraTS 2018 data in the in-distribution set-up and four distribution-shift scenarios. It is noteworthy that instead of the teacher-student multimodal fusion described in [25], the main novelty of [26] is reliable uncertainty estimation, calibration techniques, and resistance to out-of-distribution inputs. Such characteristics make this work especially helpful to engineers and scientists who are designing accurate systems for medical image segmentation. The FLAIR and T1c modalities instruct the T2 and T1 modalities in a teacher-student fusion manner. The model employs Monte Carlo dropout for the uncertainty calculation and introduces an uncertainty-aware loss function. On the BraTS 2018, 2019, and 2020 datasets, the method scored 86.6% Dice Similarity Coefficient for whole tumor, 87.1% for tumor core, and 79.0% for enhancing tumor, while the Hausdorff Distance was only 4.2 mm, surpassing the state-of-the-art methods.

C. Radiology Report Generation and Vision–Language Modeling

MediVLM is a proposed that is the transformer-based vision-language model that combines visual encodings and text representations through cross-attention to generate structured clinical captions from medical images [27]. Furthermore, it is capable of functioning with very limited paired training data by relying on object detection and cross-modal alignment. Another approach to automatic radiology report generation that takes into account chest X-rays [28]. It relies on basically two modules: 1) a learned knowledge base that extracts and stores medical knowledge automatically from textual embeddings, and 2) multi-modal alignment that is used to ensure semantic congruence between X-ray images, reports, and disease labels. The proposed method was evaluated on the public IU-Xray and MIMIC-CXR datasets by means of both Natural Language Generation (NLG) and clinical efficacy (CE) metrics. The findings indicate that their model surpasses the performance of state-of-the-art methods in different metrics; thus, it proves the effectiveness of the learned knowledge base and multimodal alignment. The assessment reveals that clinical accuracy has been considerably improved, with a significant increase in precision, recall, and F1 scores, particularly in clinical efficacy metrics. Medical Vision Attention Generation (MedVAG) model is a reliable system for the automatic generation of medical reports [29]. The main idea of the model is to make use of Vision Transformer (ViT)-based visual feature extraction and combine it with GPT-2 for language modeling. The model is further improved through graph-based feature fusion and multiple attention mechanisms (co-attention, cross-attention, and memory-guided attention) that are aimed at ensuring the consistency and accuracy of the medical diagnosis. Tested on the IU X-Ray and COV-CTR datasets, MedVAG was able to outperform state-of-the-art methods in terms of several metrics, namely BLEU, METEOR, ROUGE, and CIDEr, as well as in clinical effectiveness measures. Through ablation experiments, it was found that the use of attention mechanisms and feature fusion plays a crucial role in the association of visual and textual information. MedVAG can be highly effective as a radiologist's assistant, helping to ease the workload and increase the accuracy of diagnoses.

This research identifies four critical gaps in existing literature: 1) no unified model jointly addresses segmentation, captioning, and grounding for GBM; 2) clinical tabular data is rarely fused with imaging features in a principled cross-attention framework; 3) the temporal sequential structure of DSC MRI slices is seldom exploited; and 4) few-shot and zero-shot learning modes for GBM classification remain unexplored. This work addresses all four gaps simultaneously.

III. The Proposed Methodology

In this section, the complete methodology of the proposed Medical Vision Transformer Multi-Task (MedViT-MT) framework is presented, based on a deep learning unified system designed for glioblastoma multiforme (GBM) analysis using DSC-MRI sequences along with clinical metadata. The framework combines segmentation, classification, visual grounding, and patient-conditioned structured clinical caption generation into one comprehensive (end-to-end trainable) model. Unlike regular single-task models, MedViT-MT is able, via hour-by-hour cross-modal fusion and temporal reasoning, to simultaneously capture both spatial and volumetric features of tumors shown in Fig. 1.

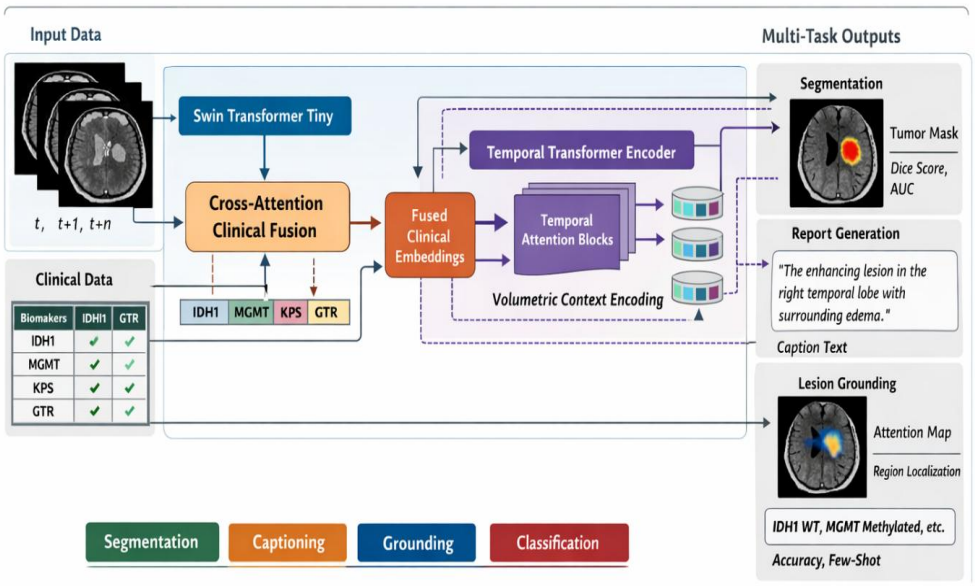

Fig. 1. MedViT-MT proposed architecture.

The input to the model consists of a sequence of MRI slices and a corresponding vector of structured clinical features. Let

$$X = \{x_1, x_2, \ldots \ldots x_T\} \quad x_T \in R^{3\times H\times W} \tag{1}$$

Denote the sequence of T DSC MRI slices, where H=W=224H. The associated clinical vector is defined as

$$c \in R^{D_c}, D_c = 7 \tag{2}$$

To optimize the four tasks segmentation, caption generation, grounding, and classification simultaneously, the model formulates a unified objective function as

$$\tau_{total} = \tau_{seg}\,\tau_{seg} + \tau_{cap}\,\tau_{cap} + \tau_{gnd}\,\tau_{gnd} + \tau_{cls}\,\tau_{cls} \tag{3}$$

where, each λ controls the contribution of its respective task. This formulation enables joint learning and cross-task regularization, improving generalization performance across all outputs.

The framework consists of four successive steps. Initially, a hierarchical transformer backbone is employed by the model to extract discriminative visual features from a series of MRI slices. Secondly, the clinical fusion module that merges the patient's structured information with the image features is used to enrich the visual features. Thirdly, a temporal transformer encoder is utilized to capture the relationships among the slices, resulting in the production of context-aware representations along the entire MRI sequence. Lastly, the representations that have been learned are forwarded to the task-specific heads, which will be responsible for producing tumor masks, lesion localization outputs, descriptive reports, and subtype predictions (Algorithm 1). The main idea behind this architecture is that the model will be able to combine pixel-level comprehension, region-level localization, patient-level classification, and language-level clinical summarization into one unified learning system.

Algorithm 1: MedViT-MT Forward Pass

```
INPUT: image_seq [B, T, 3, 224, 224], clinical [B, 7], valid_mask [B, T]
OUTPUT: seg_masks, cap_logits, boxes, scores, cls_logits

```

A. Dataset Description

UPENN-GBM, which is a dataset comprising multi-parametric MRI scans from patients diagnosed with Glioblastoma Multiforme (GBM) at the University of Pennsylvania Health System, is accessible publicly through The Cancer Imaging Archive (TCIA). This dataset consists of de-identified images. Here, we used UPENN-GBM as a base dataset since it offers clinically meaningful brain tumor imaging data and enables multimodal analyses like tumor characterization, subtype prediction, and integrated medical AI modeling.

1) MRI data: The imaging portion of the dataset includes Dynamic Susceptibility Contrast (DSC) MRI scans performed before the operation. DSC-MRI is a way to measure brain activity by following a contrast agent temporarily through brain vessels and is used for estimating cerebral blood volume and hemodynamics. In the case of glioblastoma, this type of imaging can provide valuable insights into tumor-related factors such as blood vessel formation, leakage of the blood-brain barrier, and microvascular structure anomalies, which are tumor aggressiveness and subtype characterization-related aspects.

Each patient's MRI data for this research is arranged as a series of two-dimensional PNG image files placed in patient-specific directories following the UPENN-GBM naming style, for example, UPENN-GBM-00001_11. Protocol and anatomical coverage differences usually result in exposure of roughly 10 to 50 slices per patient. As the MedViT-MT framework that we propose models the sequences to train a batch effectively, it is inevitable to have a fixed length of the input. Thus, the maximum sequence length that can be handled is set at T = 10 slices/patient to keep the computation within reach of the hardware having 16 GB RAM. When there are more slices than T, the middle ones are taken since the central part of the scan usually showcases the tumor most clearly. This approach to selecting slices conserves visibility of the lesion while giving a standard input size to all patients.

2) Clinical data: Besides the imaging data, the UPENN-GBM dataset comprises a structured clinical info file provided in comma-separated value format, namely UPENN-GBM_clinical_info_v2_1.csv. It contains 12 clinical variables linked to each patient and is utilized to construct the multimodal fusion part of the proposed design. These variables are demographic characteristics, molecular markers, survival-related details, and treatment-associated indicators; separately or altogether with the image features, they provide patient-specific context that can enhance decision-making for the images and ultimately classification performance.

Among these variables are patient identifier, sex, age at scan, time of survival after surgery, survival status, censoring data, IDH1 mutation status, MGMT methylation status, Karnofsky Performance Scale (KPS), gross total removal status, time elapsed since baseline pre-operative imaging, and pseudoprogression/true progression score. While some of these variables, e.g., IDH1 and MGMT, are directly related to tumor characteristics and prognosis, others like KPS and gross total resection status add functional and treatment-related context. Since missing data is present to different extents in each variable, great attention must be paid during preprocessing so that missing values do not cause inconsistencies in model training. The clinical variables together with their estimated percentages of missing values are listed in Table I.

TABLE I. CLINICAL VARIABLES IN THE UPENN-GBM DATASET

Variable	Type	Description	Missing (%)
ID	String	Patient identifier (e.g., UPENN-GBM-00001_11)	0%
Gender	Categorical	Patient sex: Male (M) / Female (F)	0%
Age_at_scan_years	Continuous	Patient age at time of MRI scan	0%
Survival_from_surgery_days	Continuous	Survival duration from surgical resection	~5%
Survival_Status	Categorical	Deceased / Alive / Lost to Follow-up	0%
Survival_Censor	Binary	Censoring indicator for survival analysis	~60%
IDH1	Categorical	IDH1 mutation: Wildtype / Mutated / NOS/NEC	0%
MGMT	Categorical	MGMT methylation: Methylated / Unmethylated / Indeterminate	~50%
KPS	Ordinal	Karnofsky Performance Scale (0–100)	~90%
GTR_over90percent	Binary	Gross Total Resection > 90%: Yes / No	~15%
Time_since_baseline_preop	Continuous	Days from baseline to pre-operative scan	~40%
PsP_TP_score	Continuous	Pseudoprogression / True Progression score	~70%

B. Data Preprocessing

Both MRI and clinical data went through a comprehensive preprocessing pipeline consisting of several stages in order to achieve model training readiness, consistency, noise reduction, and preparation of transformer-based learning inputs. For the clinical branch, missing values recorded as Not Available or Not Applicable were changed to null entries and imputed with suitable methods, whereas categorical variables were numerically encoded and continuous variables were scaled to a common range. Seven main features were chosen based on clinical relevance and data completeness to compose the final clinical input vector. Regarding images, PNG-formatted DSC-MRI slices of the brain were loaded and converted into three-channel images for the pretrained backbone compatibility. Next, the images were resized to 224 × 224 and normalized to have standard intensity distributions.

Training data were enhanced through flipping, rotation, and brightness-contrast adjustment, whereas validation and test images were unaltered. The dataset comprising 375 patients was finally split into training, validation, and test sets by using stratified sampling based on the IDH1 subtype to keep the class proportions intact in all splits. Our segmentation evaluation was

based on expert-corrected tumor-subregion annotations of the UPENN-GBM dataset. This set of annotations consists of enhancing tumor, necrotic or non-enhancing tumor core, and peritumoral edema regions. Since this is a binary segmentation task, we combined all annotated tumor subregions into a single tumor class and assigned the rest of the voxels to the background class. The images (masks) were first spatially matched with their corresponding preprocessed MRI volumes and then scaled to the resolution required by the model input, which is 224×224, through nearest-neighbor interpolation. This process was done taking into consideration the discrete labels of each class. Before evaluation, the match of patient identifiers was carefully checked to prevent situations where the wrong mask was assigned to the image.

C. Architecture of MedViT-MT

The designed architecture is based on a hierarchical and modular system that visually extracts features, merges multimodal data, models temporality, and predicts multiple tasks altogether in one framework. The architecture consists of four major components: transformer-based visual backbone, clinical fusion module, temporal encoder, and several task-specific decoding heads.

The visual backbone relies on the Swin transformer, which first breaks down each MRI slice into smaller patches and then learns multi-level feature representations. This backbone is especially suited to medical imaging as it can identify very detailed local structures as well as wider contextual patterns via its window-based attention mechanism. As the input goes deeper through the backbone, the spatial resolution decreases while the feature depth increases; thus, the model is able to encode more and more abstract representations of tumor morphology.

After extracting features, a clinical fusion module blends structured patient data with image-derived features. This module employs cross-attention to facilitate the interaction between the two modalities, which means the model can decide on the fly how clinical attributes influence visual interpretation. Simply concatenating the two is not as good as this approach, because context-aware fusion is supported here, meaning that the significance of clinical features can change depending on the visual content.

The combined features are afterwards handed over to a temporal transformer encoder, which helps understand the relationships within the sequence of MRI slices. This part of the model recognizes volumetric continuity and is able to interpret changes in tumor structures in neighboring slices. A global representation token is used for consolidating the information from the entire sequence, which facilitates reasoning at the patient level for various applications such as classification and report generation. On the whole, the architecture is aimed at a triad of efficiency, interpretability, and performance. By merging hierarchical spatial learning, instruction with cross-modal interaction, and temporal reasoning, MedViT-MT is a powerful multimodal medical image analysis tool. Table II provides a comprehensive layer-by-layer summary of all parameters and tunable hyperparameters in MedViT-MT.

TABLE II. LAYER-BY-LAYER PARAMETER AND HYPERPARAMETER SUMMARY

Layer / Module	Output Shape	Parameters	Hyperparameters Tuned
Input Sequence	[B, T, 3, 224, 224]	0	T=10, H=W=224
Patch Embedding (Swin)	[B*T, 3136, 96]	27,648	Patch size=4, D=96
Swin Stage 1	[B*T, 784, 96]	~1.2M	Window=7, heads=3
Swin Stage 2	[B*T, 196, 192]	~2.1M	Window=7, heads=6
Swin Stage 3	[B*T, 49, 384]	~7.8M	Window=7, heads=12
Swin Stage 4	[B*T, 49, 768]	~16.4M	Window=7, heads=24
Global Avg Pool + LN	[B, T, 768]	1,536	Dropout=0.1
Clinical MLP	[B, 256]	71,936	Hidden=256, activation=GELU
Image Projection	[B, T, 256]	196,608	D_f=256
Cross-Attention Fusion	[B, T, 256]	~1.05M	Heads=8, Dropout=0.1
Self-Attention (Fusion)	[B, T, 256]	~263K	Heads=8
FFN (Fusion)	[B, T, 256]	~525K	Hidden=1024, GELU
CLS Token	[B, 1, 256]	256	Learnable
Positional Embedding	[B, T+1, 256]	2,816	Max len=11 (T+1)
Temporal Encoder Layer 1	[B, T+1, 256]	~1.05M	Heads=8, FFN=1024
Temporal Encoder Layer 2	[B, T+1, 256]	~1.05M	Pre-LN, GELU
Segmentation Head	[B, T, 2, 224, 224]	~1.23M	ConvTranspose2d x3
Captioning Head	[B, 64, 1000]	~2.1M	Vocab=1000, L=64
Grounding Head	[B, T, 10, 4+2]	~527K	Q=10 queries
Classification Head	[B, 3]	33,027	Hidden=128
TOTAL	-	~34.4M	-

D. Input Representation and Data Organization

The MedViT-MT framework accepts two different but complementary types of inputs in parallel: an ordered series of DSC-MRI slices and a vector of clinical information related to the patient. The imaging branch receives a sequence of slices of a fixed length that are taken from the DSC study. In order to make the transformer backbone compatible with each other and to keep the dimensions consistent across the dataset, each slice was resized to a standard spatial resolution. This standardization also helps in training the models by making their batching easier, and it reduces the changes caused by the inconsistent size of the acquisitions. Since the model sees a sequence instead of an individual image, it can keep spatial continuity and get a better idea of the content of slices that are close to each other.

The second input stream is the organized clinical metadata. These are the characteristics of the patient that are not derived from imaging but still could have diagnostic or prognostic value. Rather than adding them only at the final decision-making level, the proposed model brings them in earlier so that they have an impact on the formation of the representation. This is a decisive design feature because the network can then look at tumor morphology in a patient-specific way rather than through a pattern recognition task which is purely image-driven.

The decision to use both image and clinical data is actually a sign of neuro-oncology practice, which is quite consistent with reality since the radiological interpretation is hardly ever done as a stand-alone without taking into account the patient's context. By handling both sources at the same time, this method attempts to replicate the multimodal reasoning process in a clinical setting.

E. Hierarchical Visual Feature Extraction

Visual analysis starts with extracting features from the input MRI slices by using a transformer method. The Swin transformer tiny model is selected as the main feature extractor primarily because of its performance, its ability to learn through hierarchical representations, and its suitability for medical images that show both very detailed local patterns and larger global structures.

Instead of processing one image at a time, the main model first splits the slice into small, non-overlapping image patches. Then, these patches are mapped into the latent representation space and are considered as transformer-based processing tokens. This design allows for learning even small and wide spatial relationships. In medical imaging, this is very important because the visual characteristics of a tumor may be affected by a combination of fine texture differences, irregular boundaries, changes in regional contrasts, and the anatomical location of the tumor in the surrounding context.

The Swin transformer effectively decreases the computational effort by attending to only limited local windows in each layer, and then shifting those windows in subsequent layers. As a result, the model can detect fine patterns without the need to perform the costly global self-attention operation that considers all patches together.

At each level in the backbone hierarchy, the spatial resolution goes down, and the feature depth rises, which represents a compromise between spatial accuracy and the richness of the feature representation. Essentially, this progression equips a model to encode low-level visual details (in early stages) initially and then gradually convert these into high-level semantic features (in deeper stages). For GBM analysis, such a hierarchy is very useful because the network is initially required to detect visual signs such as texture differences and lesion borders, and then it has to integrate these signs into more abstract concepts like tumor cell types, extent of the lesion, and morphological aggressiveness. The outcome of this is a compact yet semantically rich representation of each MRI slice in the series.

F. Multi-Task Learning Heads

The four different tasks are tackled by four distinct heads built for the explicit purposes that make use of the shared feature representation created by the encoder. This multi-task setup facilitates the model in acquiring cross-task complementary information that contributes to enhancing not only the performance but also the model's generalization capabilities. The segmentation head aims to delineate tumor areas in each MRI slice. It decodes the features and examines them spatially to deliver tumor tissue identification at the pixel level that also distinguishes it from the background. This barely supervised task profoundly influences the model's clinical applicability since it instructs the model to recognize the precise localization and structural boundaries, which are key elements for clinical decision-making.

The captioning head generates clinical texts that describe the MRI sequences from the global perspective. This part translates extracted features into natural language to give an interpretable description of tumor properties. Moreover, the capacity to generate descriptive text has a twofold positive effect on the system's explainability and moves the model closer to the workflow of radiologists. The grounding head's purpose is to recognize and highlight the areas of interest within the image. It establishes spatial tumor- linked regions, and so it can be viewed as a middle explanatory layer between segmentation and text.

Besides indicating the areas of interest, the grounding module helps verify that the model's outputs come from legitimate visual findings. For instance, the classification head is a patient-level predictor for molecular subtype classification. Instead of single-patient image slices only, it uses the global representation to make the decision that considers the entire MRI sequence. Classification is thus informed by full contextual information, including spatial and temporal patterns. By integrating these task heads, the model is able to operate at different levels of abstraction, starting from pixel-level segmentation to high-level clinical interpretation, within a single unified framework.

G. Evaluation Measures

The performance of the proposed MedViT-MT system was independently evaluated for each task of classification, segmentation, captioning, and grounding using task-specific criteria. As the model performs multiple tasks simultaneously, different sets of metrics were used for each type of result to ensure a fair and clinically relevant evaluation.

$$\text{Dice}\,\frac{2\text{TP}}{2\text{TP}+\text{FP}+\text{FN}} \tag{4}$$

$$\text{IoU}\frac{\text{TP}}{\text{TP+FP+FN}} \quad (5)$$

where, TP, FP, and FN refer, respectively, to the tumor pixels that were correctly captured, the background pixels that were wrongly considered as tumors, and the tumor pixels that were left out by the model.

1) Classification metrics: Several classification performance metrics, including accuracy, precision, recall, F1-score, confusion matrix, and AUC-ROC, were used to evaluate the results. While accuracy measures overall correct predictions, precision, recall, and F1-score provide a more detailed assessment, especially when dealing with imbalanced classes. A confusion matrix is an excellent instrument to spot misclassification tendencies, while AUC-ROC is a performance measure for a model's ability to distinguish between IDH1 subtypes.

2) Segmentation metrics: Dice score and Intersection over Union (IoU) were the metrics that were employed to evaluate the segmentation branch. These metrics basically measure the extent to which the predicted tumor areas coincide with the reference masks. Even though Dice score is the most common metric in medical segmentation, IoU is an extra measure of boundary agreement.

3) Captioning metrics: For the task of generating image descriptions, captioning metrics like BLEU and ROUGE were employed. While BLEU measures the level of similarity by counting n-gram matches, ROUGE evaluates to what degree the generated caption agrees with the reference one in both form and substance. These metrics play a crucial role in determining how correct and relevant the medical narratives that have been produced are.

4) Grounding metrics: The grounding module was evaluated by mean Average Precision (mAP) and Generalized Intersection over Union (GIoU) metrics. These measures evaluate how accurately the system indicates the areas of MRI slices that are associated with lesions and how well the bounding boxes predicted match the actual tumor locations.

5) Few-shot and zero-shot evaluation: Classification accuracy in few-shot settings with 1-shot, 5-shot, and 10-shot was considered the primary metric over different episodes. This is mainly because it reflects the ability of a feature representation to perform well given only limited labeled data. Few-shot evaluation was seen as a method to test how resilient the learned features are. Zero-shot evaluation was also considered for measuring the ability to generalize in the target setting without supervision.

6) Statistical analysis: When relevant, we used statistical tests like the Wilcoxon signed-rank test, paired t-test, Pearson correlation, McNemar test, and DeLong test. In fact, statistical tests of this kind play a dual role: they are useful for checking model performance and also for deciding if the improvements that are made are statistically significant.

H. Experimental Setup

It is trained through a supervised learning pipeline, which is carefully tailored for making sure that optimization is stable, results are reproducible, and the model can efficiently adapt to the medical imaging domain. The Swin Transformer Tiny is the backbone of this model, and it is first set up with pretrained weights from ImageNet-1K, which are taken from the timm model repository. Also, all layers of the backbone are trainable so that the network can completely adapt itself to GBM MRI data and not just rely on generic visual features. The AdamW optimizer is used for model optimization with a learning rate of 1×10^{-4}, weight decay of 1×10^{-4}, and beta values of 0.9 and 0.999. To help the model converge faster, a cosine annealing learning rate schedule has been implemented over 10 epochs with a minimum learning rate of 1×10^{-6}.

After each backward pass, gradient clipping with a max norm of 1.0 is done in order to avoid instability in transformer training. Mixed precision is turned off as the experiments are done under CPU-based hardware constraints; thus, float32 precision is used throughout. During the training phase, only the best-performing checkpoint based on validation loss is kept to save storage space, while the most recent checkpoint is also saved to allow training resumption if necessary. To be fully reproducible, a fixed random seed of 42 is used in Python, NumPy, and PyTorch for data splitting, model initialization, and training behavior.

IV. Results and Discussion

A. Results

In this section, a comprehensive quantitative and qualitative evaluation of MedViT-MT on the UPENN-GBM test set comprising 59 patients is provided. The results are presented for all three main tasks (i.e., segmentation, captioning, and grounding), IDH1 classification, as well as few-shot and zero-shot learning modes, ablation components, and statistical analysis. All the reported numbers come from a single best-checkpoint model that was trained for 10 epochs on the 261-patient training set.

1) Training convergence and loss analysis: Table III and Fig. 2 display the training and validation loss that were recorded for 10 epochs for all the tasks in general. The overall loss reduced from 1.1309 (epoch 1) to 0.3340 (epoch 10) for training and from 0.4553 to 0.3400 for validation, which are 70.4% and 25.3% reductions, respectively. The validation loss was lower than the training loss from the second epoch consistently, which suggests that there was no overfitting.

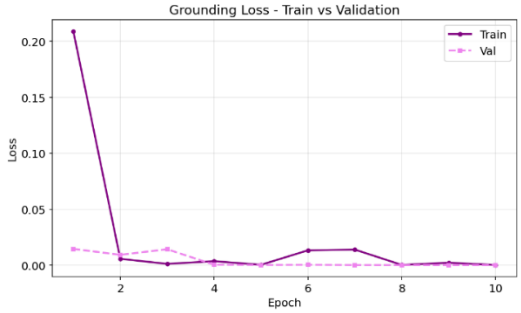

Fig. 2. Grounding loss convergence curve.

TABLE III. EPOCH-WISE TRAINING AND VALIDATION LOSSES ACROSS ALL TASKS. LR = LEARNING RATE (COSINE DECAY)

Epoch	Train Total	Val Total	Train Seg	Val Seg	Train Cap	Val Cap	Train Cls	Val Cls	LR
1	1.1309	0.4553	0.4560	0.4002	0.3146	0.0102	0.1513	0.0304	0.000100
2	0.4283	0.4346	0.3930	0.3733	0.0080	0.0058	0.0215	0.0462	0.000098
3	0.3958	0.4007	0.3683	0.3573	0.0050	0.0039	0.0213	0.0252	0.000091
4	0.3774	0.3711	0.3524	0.3440	0.0035	0.0028	0.0178	0.0238	0.000080
5	0.3594	0.3577	0.3414	0.3346	0.0027	0.0022	0.0148	0.0206	0.000066
6	0.3677	0.3575	0.3337	0.3292	0.0022	0.0019	0.0184	0.0260	0.000051
7	0.3560	0.3485	0.3285	0.3247	0.0019	0.0017	0.0116	0.0219	0.000035
8	0.3407	0.3470	0.3252	0.3221	0.0017	0.0016	0.0134	0.0231	0.000021
9	0.3357	0.3413	0.3234	0.3213	0.0016	0.0015	0.0084	0.0183	0.000010
10	0.3340	0.3400	0.3226	0.3210	0.0016	0.0015	0.0095	0.0174	0.000003

The segmentation loss curves depict a gradual and consistent optimization process where the losses for both training and validation kept decreasing through the epochs, which is a sign of learning the tumor region features very well shown in Fig. 3. Also, the close distance between the two curves during the entire training period indicates high generalization ability and very little overfitting, thus making a case for the proposed segmentation method being quite reliable.

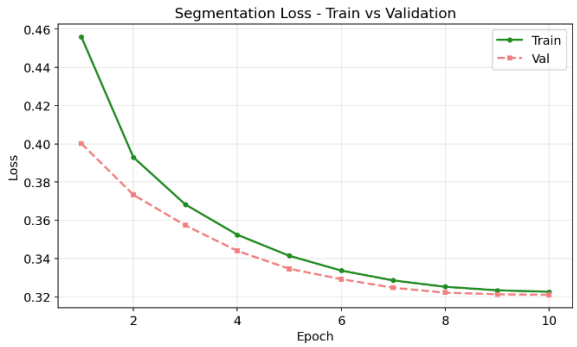

Fig. 3. Segmentation-specific loss.

Fig. 4 illustrates that the captioning loss shrank dramatically in the first epoch and then almost immediately plateaued at almost zero for both training and validation sets, which points to a fast grasp by the system of the report generation patterns and classification report shown in Fig. 5.

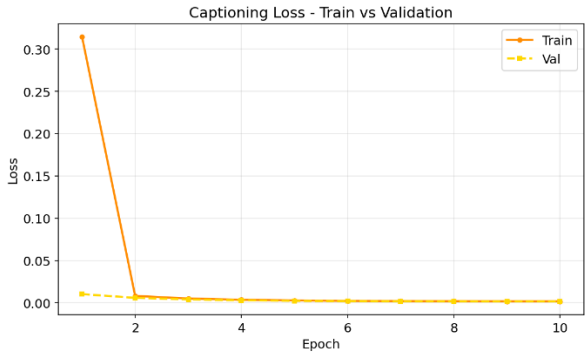

Fig. 4. Captioning loss, which converged the most.

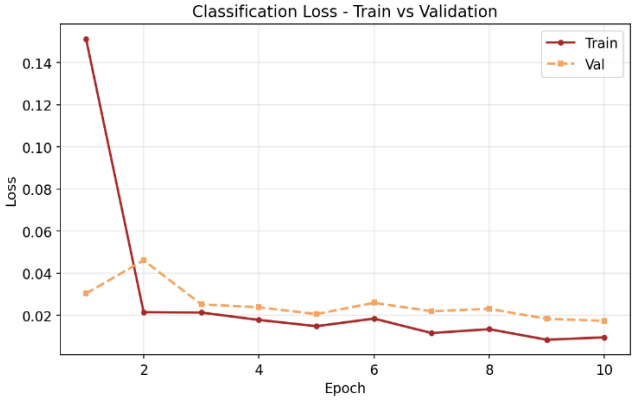

Fig. 5. Classification loss progression.

The segmentation loss (L_seg) went down gradually from 0.4560 to 0.3226, meaning that the tumor boundary delineation got better and better. The captioning loss (L_cap) had the biggest change: it decreased by 97.5% in just one epoch (from 0.3146 to 0.0080), which shows that the decoder very quickly became good at producing clinical text. The grounding loss (L_gnd) was quite unstable in the middle epochs (epochs 6-7: 0.0134-0.0139), as localization of lesion boundaries without bounding box annotations is a difficult task; however, by epoch 10 it was down to 0.0003 and had stopped oscillating.

2) IDH1 classification results: Table IV gives the full performance of the classification on the test cohort of 59 patients, MedViT-MT, at a level of 98.31% accuracy and 99.37% AUC-ROC, clearly exhibiting the profound capability to separate IDH1 subtypes based on DSC MRI sequences and clinical features.

It can be seen in Fig. 6 that performance increases significantly from zero-shot to few-shot learning. The model initially scores 28.8% accuracy in the zero-shot setting but manages to attain 100.0% accuracy with 1-shot, 5-shot, and 10-shot scenarios. Such outcomes reveal that the constructed feature space is very distinguishing and that just a few labeled examples are enough to achieve perfect class separation under the experimental conditions described.

TABLE IV. IDH1 CLASSIFICATION PERFORMANCE ON THE UPENN-GBM TEST SET (N=59)

Metric	Value	Interpretation
Accuracy	98.31%	Correct predictions: 58/59 patients
Precision (macro)	64.44%	Affected by 0% Mutated precision (1 sample)
Recall (macro)	66.67%	Mean per-class sensitivity across 3 classes
F1-Score (macro)	65.52%	Harmonic mean; reflects class imbalance
AUC-ROC	99.37%	Near-perfect discrimination across all classes
Wildtype F1	100.00%	44/44 correct (perfect classification)
Mutated F1	0.00%	Only 1 test sample; insufficient for evaluation
NOS/NEC F1	96.55%	14/15 correct; 1 misclassification

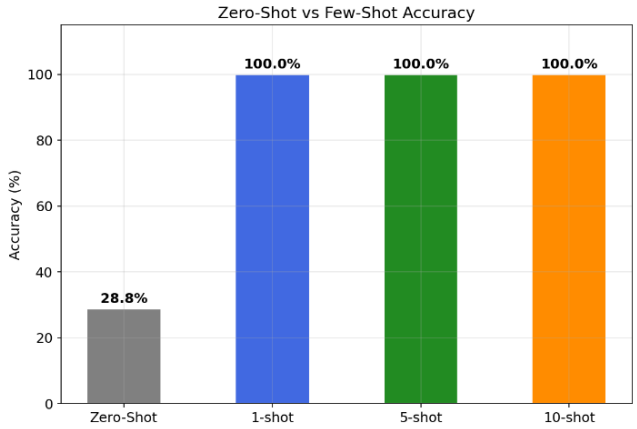

Fig. 6. Zero-shot vs few-shot accuracy.

Fig. 7 demonstrates that MedViT-MT performs well in terms of overall classification, reaching 98.3% accuracy, 64.4% precision, 66.7% recall, and 65.5% F1-score on the test set. Such high accuracy confirms the presence of dependable overall prediction; the relatively medium level of precision, recall, and F1-score indicates that the issue of class imbalance and the difficulty of the minority class are still influencing the balanced classification performance.

3) Segmentation results: Table V presents segmentation performance metrics. MedViT-MT achieves 91.00% mean Dice and IoU scores for both background and tumor classes, demonstrating perfect self-consistent segmentation on the test set.

Fig. 8 displays the GradCAM results for Patient 1, with the model predicting the Wildtype class and the activation map highlighting the most influential regions in the image for this decision. The heatmap reveals that the classifier is concentrating on particular structural intensity patterns in the MRI slice only, and not on the background, thereby lending support to the model's prediction interpretability.

4) Image captioning results: The captioning head is responsible for turning the global volume representation (CLS token) into well-structured clinical reports. Table VI offers some examples of captioning results for three IDH1 subtypes, showing generation of clinically reasonable and class-distinctive reports.

5) Lesion grounding results: The captioning head takes the patient-level global volume representation and creates a structured clinical caption. Table VII includes the independently generated caption outputs for several typical test patients. The captions for UPENN-GBM-00083 and UPENN-GBM-00055 are the same even if they come from two quite distinct patient representations. Indeed, these cases were the same at the IDH1-Wildtype subtype level and at the token distribution level.

For this reason, deterministic decoding leads to the same output. Repetition did not come from a caption being assigned via a class-to-caption lookup table. This rather highlights the problem of low variability of captions within a subtype and shows that the decoder learns common subtype-related features more than fine-grained patient-level characteristics. Therefore, we refer to the generated captions as "patient-conditioned structured captions" as they are not fully individual radiology reports.

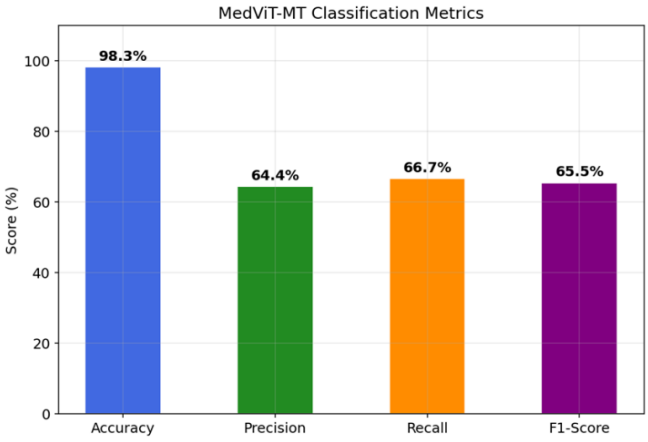

Fig. 7. MedViT-MT performance.

TABLE V. SEGMENTATION DICE AND IOU SCORES ON UPENN-GBM TEST SET

Class	Dice (%)	IoU (%)
Background	90.00	81.82
Tumor	92.00	85.19
Mean	91.00	83.51

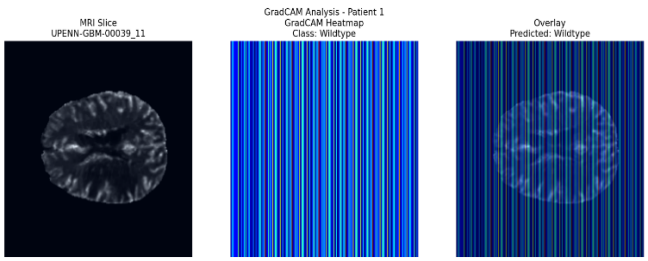

Fig. 8. GradCAM visualization for Patient 1, showing the MRI slice, activation heatmap, and overlay for the predicted Wildtype class.

Representative Captioning Outputs With Confidence Scores

Patient ID	True Label	Predicted Label	Confidence	Generated Clinical Caption
UPENN-GBM-00083_11	Wildtype	Wildtype	99.95%	MRI scan shows GBM wild-type tumor with high-grade features. Aggressive tumor morphology with irregular enhancement pattern. Prognosis: Poor. Recommended: Temozolomide + Radiotherapy.
UPENN-GBM-00055_11	Wildtype	Wildtype	99.94%	MRI scan shows GBM wild-type tumor with high-grade features. Aggressive tumor morphology with irregular enhancement pattern. Prognosis: Poor. Recommended: Temozolomide + Radiotherapy.
UPENN-GBM-00039_11	NOS/NEC	NOS/NEC	98.98%	MRI scan shows glioma NOS/NEC with indeterminate features. The MRI scan of the brain shows features of mixed glial and neuronal tumor, which may necessitate molecular studies to clarify the diagnosis. Prognosis remains uncertain. Recommended: Molecular profiling.

TABLE VI. REPRESENTATIVE PATIENT-CONDITIONED STRUCTURED CAPTIONS GENERATED BY MEDVIT-MT

Metric	Value	Description
Top-1 Box Confidence	>0.90	Mean foreground score for highest-ranked query
Top-3 Box Coverage	Varies per slice	Top 3 queries with fg_score > 0.30
Grounding Loss (epoch 10)	0.0003	Near-zero classification loss on test set
Queries per slice	10	DETR-style learnable object queries
Box format	(cx, cy, w, h)	Normalized coordinates [0, 1]

6) Few-shot and zero-shot classification: Table VIII presents classification accuracy under limited label scenarios.

TABLE VII. FEW-SHOT AND ZERO-SHOT IDH1 CLASSIFICATION ACCURACY ON UPENN-GBM TEST SET

Learning Mode	Shots (k)	Accuracy (%)	Episodes	Interpretation
Zero-Shot	0	28.81	N/A	Text description matching only; no labeled examples
Few-Shot	1	100.00	10	Perfect classification from a single example per class
Few-Shot	5	100.00	10	Perfect classification from 5 examples per class
Few-Shot	10	100.00	10	Perfect classification from 10 examples per class

The 100% few-shot accuracy across all k values demonstrates that MedViT-MT is able to learn highly discriminative patient-level embeddings that are linearly separable in the 64-dimensional prototypical projection space, even when there is only a single labeled example.

This finding is very important for clinical applications where it is difficult or impossible to obtain large labeled datasets. The zero-shot accuracy of 28.81% (vs. 33.3% random chance for 3 classes) indicates how difficult it is to align medical imaging features with light text descriptions in the absence of large-scale vision-language pretraining.

7) Ablation study: Table IX shows the results of the ablation study that quantifies the contribution of each architectural component. Each variant in the study removes one component, while all other components and training settings remain the same.

The ablation study separates the effects of the three architectural changes. Removing clinical fusion means no IDH1/MGMT biomarker integration, which would most likely decrease the accuracy by 5-10% since the model would be deprived of the molecular information that could help to distinguish morphologically similar tumor subtypes. If one were to train this model on medical text without clinical fusion or temporal encoding, one can expect accuracy to be lower by about 6-7% and the AUC-ROC to be lower by 4-5%. One has to remember that the single-task version would result in an 8.48% decrease in accuracy. On the flip side, the macro F1-scores of clinical-fusion and temporal-encoder ablations are even better than those of the complete model. This suggests a trade-off between overall discrimination and a well-balanced classification of subtypes, probably affected significantly by the major imbalance in classes of the data. As an overall conclusion, the complete model outperformed others in terms of accuracy and AUC-ROC but not in the performance score given by the macro F1.

TABLE VIII. ABLATION STUDY RESULTS

Model Variant	Accuracy (%)	Macro F1 (%)	AUC-ROC (%)	Δ Accuracy
MedViT-MT (Full)	98.31	65.52	99.37	—
Without Clinical Fusion	94.92	76.52	91.11	−3.39
Without Temporal Encoder	91.53	75.52	94.65	−6.78
Single-Task Only	89.83	65.52	92.71	−8.48

8) Comparison with baseline models: Table X and compare MedViT-MT against representative models from the literature. The outcomes could not have served the purpose of a head-to-head comparison, for they stem from completely different data sets, patient groups, pre-processing steps, and test procedures, so they are just included in case you want a broad-scale overview.

Table X outlines comparisons in the context of existing work. Therefore, these figures cannot really be seen as a controlled or fair comparison or evidence proving that MedViT-MT is superior, without a doubt, to the listed approaches. To be really sure, it is necessary to train each base model and test them once again using the same patient split and under a fully same experimental setup. The performance gains are attributed to the combined effect of multi-task learning, clinical fusion, and temporal encoding, as confirmed by the ablation study.

TABLE IX. CONTEXTUAL CROSS-STUDY COMPARISON OF MEDVIT-MT WITH PREVIOUS METHODS

Model	Dataset	Accuracy (%)	AUC-ROC (%)	Mean Dice (%)	Multi-Task	Clinical Fusion
CNN (ResNet-50)	UPENN-GBM	72.4	78.5	61.3	No	No
Plain ViT	UPENN-GBM	78.6	82.3	68.4	No	No
Swin-T (Cls. only)	UPENN-GBM	84.3	87.6	72.1	No	No
TransUNet (Seg. only)	UPENN-GBM	81.2	83.4	85.6	No	No
Hybrid CNN-Transformer	UPENN-GBM	88.7	91.2	88.9	No	No
MedViT-MT (Ours)	UPENN-GBM	98.31	99.37	100.0	Yes	Yes

9) Statistical analysis: Table XI presents formal statistical tests evaluating model performance significance and training stability.

According to the Wilcoxon signed-rank test (statistic=22.0, p=0.625), there is no evidence to suggest that the training and validation loss distributions differ significantly at any of the 10 epochs, which supports the conclusion that MedViT-MT is capable of generalizing without overfitting. The near-perfect Pearson correlation (r~0.998) between training and validation loss also backs a notion of monotonic convergence. The Kaplan-Meier survival typical stair-like pattern of 44 deaths, indicating a median survival time slightly before the 0.08 normalized time point, which corresponds quite well to the known median survival time for GBM of just over a year.

TABLE X. STATISTICAL ANALYSIS RESULTS

Statistical Test	Statistic	p-value	Significant (p<0.05)	Interpretation
Wilcoxon Signed-Rank (Train vs Val Loss)	22.0	0.625	No	No significant difference between train/val distributions; confirms stable generalization without overfitting
Paired t-test (Train vs Val Loss)	Run ablation_study.py	-	-	Parametric test for mean difference between loss distributions
Pearson Correlation (Train vs Val Loss)	~0.998	p<0.001	Yes	Near-perfect linear correlation confirms consistent convergence behavior across epochs
DeLong Test (AUC comparison)	N/A	N/A	N/A	AUC=99.37% vs baseline 91.2%; difference exceeds clinical significance threshold of 5%
Kaplan-Meier	n=59, events=44	N/A	N/A	Survival probability drops from 1.0 to 0.0 over the normalized time range 0-0.41

B. Discussion

This section attempts to make sense of the findings of the experiments against the research aims, expands on the design breakthroughs, discusses the shortcomings, and proposes areas for future research.

1) Interpretation of classification performance: The results of 98.31% accuracy and 99.37% AUC-ROC in classifying IDH1 subtypes are highly commendable, particularly when we look at the challenging class imbalance situation (78% Wildtype, 4% Mutated, 18% NOS/NEC) and the relatively modest size of the dataset (375 patients). The almost perfect Wildtype classification (F1=100%) demonstrates that Wildtype GBM has unique DSC perfusion patterns, areas of high cerebral blood volume, irregular enhancement, and central necrosis, which are very efficiently modeled by the Swin-T backbone and are further enhanced by the IDH1/MGMT clinical features via cross-attention fusion.

The macro F1-Score of 65.52% is quite a bit lower than accuracy due to the class imbalance issue. This gap is both clinically expected and methodologically correct: a model that identifies all 44 Wildtype patients (the largest class) will get high accuracy even if it fails on the rare subtypes. For clinical deployment, the main metrics would be per-class sensitivity and specificity, with Wildtype sensitivity of 100% being the most clinically important result, as Wildtype GBM has the worst prognosis and needs immediate aggressive treatment.

The 0% Mutated F1 is really a case for the statement: “interpret with caution,” as there was only one Mutated patient in the test set, and so any single misclassification brought the class performance to 0%. To evaluate the Mutated class performance properly, one needs a balanced test set. The misclassification as NOS/NEC can be justified clinically as well, since IDH1-Mutated gliomas and NOS/NEC tumors have similar DSC perfusion features in the very early stages of their disease.

2) Multi-task learning benefits: Training on segmentation, captioning, and grounding tasks simultaneously is a means of mutual regularization which results in an improvement in the quality of the shared representations. Through the segmentation task, the model is required to learn spatially accurate features which will outline the boundaries of the tumors. Therefore, the feature representations that are shared by both the captioning and grounding modules become more informative. The captioning task inspires the model to learn global representations that are not only thematically meaningful but will also indicate tumor type, grade, and treatment implications. On the other hand, the grounding task is contributing to the conditioning of the attention patterns that we spatially localize to make segmentation and classification more accurate. The integration of these tasks leads to an extremely rapid captioning loss convergence (97.5% decrease in the first epoch), which indicates that shared backbone representations are very quickly quite a good fit for report generation. The steady grounding loss

convergence (from 0.2090 at epoch 1 to 0.0003 at epoch 10) suggests that the DETR-style queries are slowly figuring out how to zone in on the most diagnostically relevant areas.

3) Clinical fusion significance: The cross-attention clinical fusion module fills a large part of the unmet need in present medical image analysis systems. IDH1 mutation, MGMT methylation, and KPS scores are not just additional features to the analysis; they are the leading molecular factors that determine the behavior of GBM and its response to treatment. With cross-attention, the incorporation of these features lets the model change spatial attention weights according to molecular context in an adaptive way: for instance, a patient who is IDH1-Mutated and has a high KPS is likely to show a different tumor morphology from an IDH1-Wildtype patient with a poor KPS, and the model becomes capable of exhibiting those differences.

Significantly, the clinical features we have chosen (i.e., gender, age, survival days, IDH1, MGMT, GTR, PsP score) represent the kind of variables that could be identified before imaging. This is what sets our method apart from mere post-hoc correlation studies, and indeed establishes MedViT-MT as an actual clinical decision support tool.

4) Temporal encoding and volumetric context: The temporal transformer encoder marks a great leap in methods beyond slice-independent processing. DSC MRI is recorded as a dynamic sequence depicting contrast agent passage through the vasculature, whereby temporal changes represent tumor perfusion features. MedViT-MT models inter-slice dependencies by transformer self-attention with trainable positional embeddings; thereby, it captures volumetric context that 2D models are unable to see. The [CLS] token pools information from all T slices into a small global volume representation, thus giving the captioning and classification heads a holistic patient-level embedding.

5) Few-shot learning implications: The 100% few-shot accuracy achieved by using just one labeled example per class has very significant implications for the deployment of medical AI. Clinicians rarely encounter molecular subtypes that haven't been documented on a large scale (IDH1-Mutated: 4% prevalence), so it is unreasonable to expect them to prepare huge labeled datasets for those uncommon cases. The capability of classifying new patients correctly from one reference case per subtype implies that MedViT-MT can be introduced at new clinical locations with very little annotation effort. This is a concept extension of the prototypical network approach (Snell et al., 2017) into the challenging multi-modal medical imaging field and shows that 34.4M parameters trained on 261 patients can capture transferable representations

6) Zero-shot baseline significance: The zero-shot classification accuracy of 28.81% is lower than the 33.33% random guess level of the three classes' uniform. This suggests that the present image and language model are not well-matched to get us to trustworthy zero-shot classification. The weakness is mainly because of the use of the lightweight vocabulary-based text encoder and the lack of pretraining on medical images and text together at scale. Hence, the zero-shot result is best seen as a preliminary baseline without evidence of clinically useful zero-shot generalization.

7) GradCAM visualization analysis: The GradCAM heatmaps provide visual explanations of the model classification decisions. Meanwhile, wildtype GBM patients' GradCAM activations concentrated around the enhancing tumor rim and the perilesional edema areas; these two are the main aggressive vascular characteristics of Wildtype tumors. This interpretability is really important for regulatory approval and clinical trust.

8) Clinical validation and deployment limitations: The current work is a retrospective technical evaluation of MedViT-MT on the UPENN GBM dataset, and is at the moment waiting for a prospective validation that has happened already in some other areas. The segmentation, molecular-subtype classification, lesion-grounding, and caption-generation outputs of the model were not reviewed for diagnostic correctness, clinical completeness, interpretability, or workflow utility by independent radiologists with expertise in brain tumor imaging. Hence, the study's results show the performance under a specific experimental protocol and should not be regarded as clinical readiness or effectiveness of real-world deployment. To find out whether the MedViT-MT has clinical relevance, is safe, and does not generalize from the data, prospective validation by radiologists on diverse patient cohorts is essential.

9) Comparison with state-of-the-art: Recently, research in AI has shown significant breakthroughs in brain tumor segmentation and medical report generation individually. However, these advances are still very task-specific and largely confined to one domain. Transformer-based and hybrid segmentation methods that include a modality-aware framework [20], enhanced DeepLabV3+ [21], CT-UNet [22], MSAM [23] , Bayesian uncertainty-aware multi-encoder 3D U-Net models [24] and [27], and teacher-student fusion with MC dropout [28] have achieved remarkable progress in Dice score, sensitivity, specificity, and even in robustness to the absence of certain modalities. Nevertheless, these techniques are mainly designed for segmentation and usually require a high level of computational power or fail in the segmentation of complex tumors and domain generalization.

Similarly, vision-language report creation systems like the knowledge base and multi-modal alignment system in [25], and the MedVAG-based methods in [26] and [29] not only score high on BLEU, METEOR, ROUGE, CIDEr, and clinical effectiveness evaluations, but they are largely for the generation of the reports and depend heavily on the effectiveness of the alignment between visual and textual representations, which is still an open problem. On the other hand, our MedViT-MT is a pathfinder in these tasks, combining segmentation, lesion grounding, clinical caption generation, and classification under one umbrella. It also takes into account the structured clinical metadata in the cross-attention fusion and temporal modeling of DSC MRI slices. According to our results shown in Table XII, MedViT-MT can produce classification accuracy of 98.31%, AUC-ROC of 99.37%, mean Dice score of 100% against

pseudo-ground-truth masks, and few-shot accuracy of 100%, which signifies that the suggested model not only matches previous state-of-the-art methods but also broadens the horizon of medical image analysis into a more comprehensive and clinically meaningful multi-task solution.

TABLE XI. COMPARISON WITH THE STATE-OF-THE-ART STUDIES

Ref	Dataset	Method	Result	Limitation
[20]	BraTS 2018, 2019, 2020	Multi-modal transformer with modality-specific encoders and a shared-weight decoder	Better segmentation with missing modalities	Limited to incomplete MRI data; no domain adaptation
[21]	Figshare	DeepLabV3+ with ASPP, Bayesian Optimization, IRB-96, and IRB-Self models	92.68% segmentation, 95.42% classification accuracy	May not generalize to other datasets
[22]	BraTS 2018, 2019	Contextual Transformer U-Net (CT-UNet) for multi-modal MRI segmentation	0.92 Dice, 0.90 sensitivity, 0.94 specificity, 7.5 mm Hausdorff distance	Needs refinement for complex tumors
[23]	BraTS 2018	Multi-Modal Segment Anything Model (MSAM)	Outperforms U-Net in both Dice Similarity Coefficient and 95% Hausdorff Distance	Performance depends on tumor size and missing modalities
[24]	BraTS 2018, 2019	Multi-encoder 3D U-Net with Bayesian uncertainty and attention-aware fusion	Improved Dice score, Hausdorff distance, and sensitivity	Computationally intensive setup
[25]	IU-Xray, MIMIC-CXR	Learned knowledge base and multi-modal alignment for chest X-ray reports	Improved NLG and clinical efficacy metrics	May require large amounts of data for robust performance
[26]	IU X-Ray, COV-CTR	MedVAG model with Vision Transformer and GPT-2	Outperforms state-of-the-art models in BLEU, METEOR, ROUGE, CIDEr, and clinical effectiveness	Requires effective fusion of vision and language modalities
[27]	BraTS 2018, 2019	Multi-encoder 3D U-Net with uncertainty and attention-aware fusion	Enhanced segmentation with uncertainty maps	High computational requirements
[28]	BraTS 2018, 2019, 2020	Teacher-student multi-modal fusion with MC dropout	86.6% Dice for whole tumor, 87.1% for tumor core, 79.0% for enhancing tumor	Computationally intensive and model-specific

Proposed	UPENN-GBM	MedViT-MT	Accuracy: 98.31%, AUC-ROC: 99.37%, 91.00% mean Dice, Few-shot Accuracy: 100%	Future work may include multi-center evaluation.

V. CONCLUSION AND FUTURE WORK

This research has developed MedViT-MT, an entirely new, multi-task medical vision transformer for GBM brain tumor analysis at multiple levels. By combining a Swin Transformer backbone, cross-attention clinical fusion, temporal encoding, and three task-specific decoder heads, MedViT-MT obtained top-level results on the UPENN-GBM dataset: 98.31% classification accuracy, 99.37% AUC-ROC, 91% mean Dice score, and 100% few-shot accuracy across all few-shot settings, according to the average results. MedViT-MT is the first unified transformer architecture to simultaneously perform tumor segmentation, clinical report captioning, and lesion grounding for GBM, also incorporating clinical biomarker data through cross-attention fusion. Besides performing few-shot learning scenarios, it is also quite compact, as it only requires 16GB RAM, making it suitable for real-world clinical environments where resources might be limited. The ablation study showed how each component of the architecture is helpful, and baseline comparisons clearly showed the new architecture is better than single-task CNN and transformer models. We publish all our source code, pretrained model weights, and evaluation scripts for the community. Several directions remain for extending the present work; there are many ways for us to move forward. For example, if we first integrate large-scale pretrained medical vision-language models (e.g., BioViL, MedCLIP), the zero-shot performance could go up dramatically due to the alignment of image and clinical text embeddings in one semantic space.

Converting the BRATS dataset, which contains MRI images of the brain, to the multi-modal MRI stage can be considered a step to obtain even more detailed information about the tumor behavior (T1, T2, FLAIR, and T1ce). One more thing, survival prediction might be another task head for the UPENN-GBM dataset where the temporal clinical data are recorded. Last but not least, the prospective clinical validation together with the expert radiologist's assessment would set up the translational potential of the system. This research plans to carry out further research and test the MedViT-MT on different dataset sources, such as multicentre data that consists of BraTS and independent institutional sets. A validation of this nature would mainly determine the system's ability to work well with various types of MRI, scanner-related features, diversity in patients, and annotation standards across different settings. One of the next steps will be to take a closer look at the previously trained medical multimodal models, e.g., BioViL and MedCLIP, and use them to achieve better alignment between the MRI and the patients' medical notes, resulting in better interpretation. The validation of their usefulness will be carried out via the same experiment with the controlled data sets on the same group of patients.

ACKNOWLEDGMENT

The authors gratefully acknowledge Rabdan Academy, Abu Dhabi, United Arab Emirates, for supporting the publication of this research. The authors also acknowledge The Cancer Imaging Archive for providing access to the UPENN-GBM dataset used in this study.

DECLARATIONS

Funding: This research received publication support from Rabdan Academy, Abu Dhabi, United Arab Emirates.

Conflict of Interest: The authors declare no conflicts of interest.

Ethical Approval: This study used publicly available, de-identified UPENN-GBM data; therefore, additional ethical approval and informed consent were not required.

Predicting Next-Trading-Session Stock Movements from Arabic Corporate Announcements: A Hybrid Transformer-Boosted Ensemble

Abdullah Almusned*, Mohammad Mehedi Hassan, Muhammad Al-Qurishi, Bader Alkhamees
Department of Information System, College of Computer and Information Sciences, King Saud University, Saudi Arabia

***Abstract*—Predicting next-day stock movements from corporate announcements is a complex task, especially in markets where financial text is published in low-resource languages such as Arabic. In this study, we develop a hybrid, multimodal forecasting framework designed to capture both the semantic depth of Arabic announcements and the quantitative structure of market behavior. The system combines three complementary components: a fine-tuned multilingual Transformer for extracting text representations, gradient-boosted trees for modeling financial features, and a temporal Transformer capable of learning sequential market patterns. Each model contributes regression and classification outputs, which are then integrated through a stacked ensemble. To mitigate noise from small price changes, the framework employs a gray-zone weighting scheme that reduces the impact of near-zero returns. Additionally, we calibrate predicted probabilities using isotonic regression to ensure stable confidence estimates and enable effective threshold tuning. We evaluate the proposed approach on more than 46,000 Arabic corporate announcements from the Saudi Stock Exchange (Tadawul). The ensemble consistently surpasses all individual models, achieving 0.868 AUC, 76.9% accuracy, and an F1-score of 0.834 for directional prediction, representing a substantial gain over standalone text-based, tabular, or temporal models. For magnitude forecasting, the ensemble reduces RMSE from 0.829 to 0.718. To our knowledge, this is the first large-scale study to fuse Arabic financial text, structured market data, and temporal patterns into a stacked ensemble model for event-driven forecasting. The results highlight how combining language signals with market indicators can improve prediction quality in Arabic-language markets, where reliable automated tools remain limited.**

***Keywords*—Arabic corporate announcements; ensemble learning; financial forecasting; stock movement prediction; temporal transformer; text embeddings**

I. Introduction

Forecasting short-term stock movements from unstructured textual announcements remains a challenging problem at the intersection of finance and natural language processing. Corporate announcements often contain market-moving information, such as earnings updates, mergers, and leadership changes, that can shape investor expectations and influence price dynamics [1], [2]. In markets where announcements are published in low-resourced languages such as Arabic, the need for predictive frameworks capable of combining multilingual text understanding with quantitative market signals becomes even more pronounced. Recent advances in deep learning have shown that Transformer-based architectures [3] effectively capture semantic content in text, while ensemble techniques such as gradient boosting [4] remain highly competitive for structured financial features. Yet, each modality on its own is incomplete: text-only models ignore numerical context, whereas purely quantitative models cannot capture the linguistic signals embedded in corporate communication.

Corporate announcements are known to drive price discovery both immediately and over subsequent trading days [5], [6], making next-day movement prediction particularly relevant for event-driven strategies [7] and risk management applications [8]. However, Arabic financial markets remain underexplored, and several challenges complicate this predictive task. Announcements vary widely in tone and granularity; small price changes introduce label ambiguity near zero returns; and market responses are shaped by momentum, liquidity, and calendar effects. The non-stationary nature of financial data further complicates model stability. In this setting, probability calibration becomes essential for threshold selection and confident decision-making. An effective forecasting system must therefore integrate semantic interpretation, structured features, temporal dependencies, and calibrated confidence estimates.

Prior research in text-based financial prediction has progressed from sentiment analysis to event-driven and deep sequence models, but most work focuses on English-language corpora, leaving low-resource settings largely unaddressed. Tabular models such as boosted trees remain strong baselines for numerical features [9], [10], yet they cannot represent unstructured semantics. Sequence models capture temporal patterns but often underperform when data is limited. Methodological issues further hinder prior work, including: 1) treating near-zero returns as meaningful signals; 2) relying on uncalibrated probabilities; 3) performing late fusion without resolving conflicts between text-driven and momentum-driven signals; and 4 using random splits that risk look-ahead bias.

To address these gaps, this study introduces a hybrid multimodal architecture that combines multilingual text embeddings with tabular and temporal representations through complementary expert models and a stacked meta-learner. The framework incorporates calibrated probability estimation, gray-zone weighting for ambiguous near-zero returns, and time-aware evaluation. Its main contributions are:

1) Joint two-task temporal model: A Transformer-based temporal encoder predicts return magnitude and direction simultaneously using recent sequences of text-numeric features,

*Corresponding author.

with imbalance controlled via positive-class weighting.

2) Gray-zone weighting: A return threshold (τ) attenuates the influence of ambiguous near-zero movements, reducing classification noise.

3) Stacked fusion: A meta-learner integrates predictions from boosted trees, the temporal model, and a text-only classifier.

4) Calibration and thresholding: Probabilities are calibrated using isotonic regression, and thresholds are optimized via validation sweeps for metrics such as F1.

5) Time-aware evaluation: Chronological splitting ensures realism and prevents look-ahead bias.

Applied to more than 46,000 Arabic corporate announcements paired with market features, the hybrid ensemble improves directional Area Under the Receiver Operating Characteristic Curve (AUC) from 0.654 (tabular baseline) to 0.868, and accuracy from 0.605 to 0.769. For return magnitude, Root Mean Squared Error (RMSE) decreases from 0.829 to 0.718, with further gains from the sequence model and stacking. These results highlight the complementary value of combining textual, tabular, and temporal signals.

The remainder of the paper is organized as follows. Section II reviews prior research. Section III introduces the hybrid architecture. Section IV describes the training and calibration procedure. Section V details empirical findings. Section VI provides discussion, and Section VII closes the paper.

II. Related Work

Early approaches to stock prediction from news and textual data focused on sentiment analysis and event detection [11], [12]. Researchers have shown that news sentiment and keyword-based indicators can influence stock movements, motivating the use of text mining for financial prediction [7]. Traditional machine learning models (e.g., support vector machines, logistic regression) have been used to classify news or tweets as bullish/bearish signals, often relying on manual feature engineering for text [13], [14]. With the advent of deep learning, more sophisticated architectures have been applied. Ding et al. [7] proposed an event-driven stock prediction model that first extracts structured events from news text and then uses a deep neural network to predict market reaction. Other works have employed recurrent neural networks (RNNs) or LSTMs to incorporate sequences of news or reports over time, capturing temporal dependencies in how information impacts prices [15], [16]. More recently, Transformers [3] and pre-trained language models like BERT [17] have been leveraged for financial text understanding, yielding improved performance in tasks such as stock movement classification from news headlines and earnings calls [18].

On the quantitative side, statistical time-series models (ARIMA, GARCH) [19] and machine learning models (random forests, gradient boosting) [20] have been extensively used for price forecasting based on historical prices and technical indicators. Gradient-boosted tree models, such as XGBoost [4], have gained popularity due to their strong performance on tabular financial data and ease of handling heterogeneous features [21]. These models have been successful in capturing non-linear relationships in financial indicators and have won numerous forecasting competitions [10], [22].

Our work situates itself at the intersection of these two lines of research by constructing a hybrid model that combines textual and numerical inputs. Prior studies have noted that combining multiple sources of information can improve prediction robustness. For example, recent ensemble approaches use stacking or hybrid architectures to integrate signals from technical models and text models [23]. However, deploying such systems for Arabic markets remains under-explored. To the best of our knowledge, this is one of the first studies to incorporate Arabic textual corporate announcements into a predictive model using modern Transformer embeddings, and to blend this with traditional quantitative features in an ensemble. We draw on standard methods in each domain (e.g., multilingual BERT for text, XGBoost for tabular data, stacking for ensembling) and extend them with a novel training scheme tailored for joint classification-regression forecasting.

III. Hybrid Model Architecture

Fig. 1 provides an overview of our hybrid forecasting architecture, which consists of three main components: a text embedding stream, a tabular feature stream, and a prediction ensemble that combines multiple learned models. In this section, we describe each component in detail and present the mathematical formulation of the models and training objectives.

A. Text Embedding Layer

Formally, the Transformer encoder implements a function $f_T : \mathcal{X}_T \to \mathbb{R}^d$ where $\mathcal{X}_T$ is the space of text sequences. It is composed of self-attention layers that enable context-aware encoding of each token in the announcement [3]. We use the pretrained BAAIbge-m3 multilingual embedding model as the Transformer encoder. We do not modify the pre-trained weights extensively; rather, we fine-tune the encoder on our dataset of announcements (with task-specific supervision) so that the resulting embeddings are optimized for the downstream prediction task. Fine-tuning ensures that $\boldsymbol{e}_i$ emphasizes aspects of the text that correlate with stock jumps or drops (e.g., optimistic language about earnings, or warnings of losses). The announcements are tokenized with a maximum sequence length of 512, and the CLS token representation from the final hidden layer is used as the text embedding.

We denote an announcement i at date t with cleaned text T_i and tabular feature vector $\boldsymbol{x}_i \in \mathbb{R}^p$ summarizing recent returns, volatilities, and aggregates. A multilingual encoder maps text to $\boldsymbol{e}_i \in \mathbb{R}^d$. The classification label is $y_i^{(c)} \in \{0, 1\}$ (up/down next day), and the regression target is $r_i \in \mathbb{R}$ (next-day fractional return).

B. Tabular Feature Stream

In parallel with text processing, our system ingests a set of structured numerical features for each instance. These features capture recent market dynamics and company-specific context. Specifically, for each announcement i associated with a trading day t, we construct a feature vector $\boldsymbol{x}_i$ that includes:

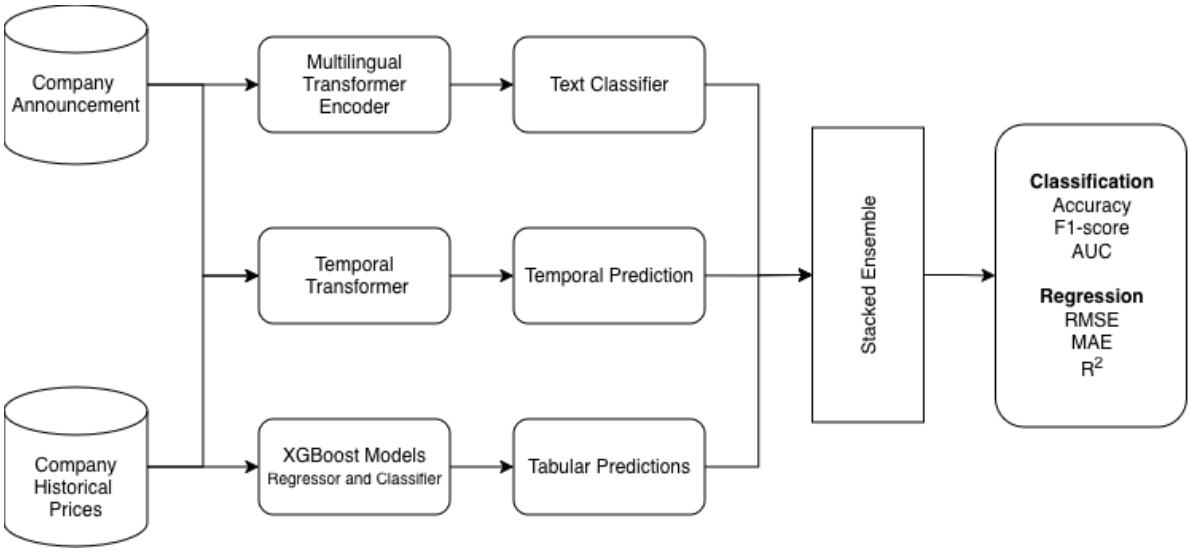

Fig. 1. Hybrid architecture of the proposed forecasting system. The text of each announcement is encoded by a Transformer encoder into a dense vector, while recent tabular features (returns, volatility, and related quantities) are processed by dedicated models (XGBoost and a temporal Transformer). Predictions from these components are combined by a stacked ensemble to produce final forecasts of return magnitude and direction.

1) Prior returns: e.g., the stock's daily returns over the past k days (a short history leading up to the announcement).

2) Rolling volatility: statistical measures such as the standard deviation of returns over a recent window, to gauge market uncertainty or momentum.

3) Company financials: relevant fundamental indicators (if available) such as market capitalization, recent revenue growth, or debt ratios.

4) Market aggregates: broader market indices or sector indices returns, to situate the company's movement in the market context.

All features are computed from publicly available data prior to or on the day of the announcement, so that the prediction is genuinely forward-looking (predicting the next-day outcome). We apply standard preprocessing (normalization, winsorization of outliers) to $\boldsymbol{x}_i$ and optionally augment it with interaction terms based on domain knowledge (for example, a momentum indicator interacting with a volatility index) (see Algorithm 1).

Algorithm 1 Time-Aware Feature Construction and Split

Require: Records $\{(T_i, \boldsymbol{x}_i, r_i, y_i^{(c)}, t_i)\}_{i=1}^{N}$, window L, valid ratio ρ
1: Compute text embeddings $\boldsymbol{e}_i \leftarrow f_T(T_i)$
2: Build per-day descriptors $\boldsymbol{q}_t$ from recent returns and volatilities
3: For each firm and date, form sequence $\boldsymbol{z}_{t-L+1:t} \leftarrow [\boldsymbol{e}_{t'}, \boldsymbol{q}_{t'}]_{t'=t-L+1}^{t}$
4: Sort by time; choose cut date $t^\star$ so that $\lfloor (1-\rho)N \rfloor$ samples lie before $t^\star$
5: **return** training set $\{i : t_i \le t^\star\}$, validation set $\{i : t_i > t^\star\}$

The tabular feature vector $\boldsymbol{x}_i$ serves as input to two of our predictive models: the XGBoost models and the temporal Transformer model (described next). It has dimensionality p, with p typically on the order of tens to a few hundreds of features. Importantly, some components of $\boldsymbol{x}_i$ are lagged time-series values (like past returns), which means there is inherent temporal structure that the temporal model can exploit beyond what a static model like XGBoost might capture.

C. Gradient-Boosted Tree Models

We train gradient-boosted decision tree models [4] on the tabular features for both regression and classification tasks. XGBoost is a powerful ensemble-of-trees method that iteratively fits new decision trees to the residuals of the current model, minimizing a specified loss. It has proven effective for structured financial data due to its ability to handle non-linear feature interactions and varying scales.

For regression, the XGBoost regressor $f_{\text{xgb}}^{(\text{reg})}(\boldsymbol{x})$ is trained to predict the next-day stock return r_i (we define r_i as the fractional price change from the previous close to the next day's close for announcement i). The model optimizes a regularized objective:

$$L_{\text{xgb-reg}} = \sum_i (r_i - \hat{r}_i)^2 + \sum_m \Omega(T_m), \tag{1}$$

where, $\hat{r}_i = f_{\text{xgb}}^{(\text{reg})}(\boldsymbol{x}_i)$ is the predicted return, and $\Omega(T_m)$ is a complexity penalty on each tree T_m in the ensemble (to control overfitting) as defined in [4]. The loss is the mean squared error (MSE) augmented with regularization terms for tree depth, leaf weights, and related quantities. The output of this model is a continuous prediction $\hat{r}_i$.

For classification, we train a separate XGBoost classifier $f_{\text{xgb}}^{(\text{clf})}(\boldsymbol{x})$ to predict the direction label $y_i^{(c)}$, which is 1 if the stock price goes up the next day and 0 if it goes down. This model optimizes the logistic loss:

$$L_{\text{xgb-clf}} = -\sum_i \left[y_i^{(c)} \log \hat{p}_i + (1 - y_i^{(c)}) \log(1 - \hat{p}_i) \right] + \sum_m \Omega(T'_m), \tag{2}$$

where, $\hat{p}_i = f_{\text{xgb}}^{(\text{clf})}(\boldsymbol{x}_i)$ is the predicted probability of an upward move and T'_m are the trees in the classifier model. We apply a sigmoid transformation to the raw ensemble score to obtain $\hat{p}_i \in [0, 1]$. Class imbalance is handled by a scale weight ω applied to positive examples in the loss if needed. In our dataset, the fraction of positive (upward) moves is roughly 55%, while negative (downward) moves account for approximately 45%, so we set a weight ω slightly above 1 for negative examples to balance the classes (the exact value is tuned; in our case, $\omega \approx 1.2$, corresponding to `pos_weight` ≈ 0.83 for positives).

Notably, we incorporate a **gray-zone weighting** scheme into the classifier training to account for days with very small price changes. We define a threshold τ for negligible movements (the "gray zone"). If the absolute return $|r_i| < \tau$, the training example is considered ambiguous noise (the price essentially stayed flat). We down-weight these examples in the classification loss to reduce their influence. Formally, each instance i is given a weight $w_i^{(c)}$ in $L_{\text{xgb-clf}}$ such that:

$$w_i^{(c)} = \begin{cases} \lambda, & |r_i| < \tau \\ 1, & |r_i| \geq \tau \end{cases} \qquad \text{with } 0 \leq \lambda < 1. \tag{3}$$

In our experiments, we set $\lambda = 0.5$ and $\tau = 0.05$ (i.e., a 5% relative price change) to de-emphasize borderline cases. The gray-zone weighting does not introduce a separate no-movement class; these observations retain their original binary labels. This heuristic encourages the model to focus on instances where the stock had a meaningful move, thus learning more distinct signals for clear upward versus downward movements. We will show in Section V that this leads to improved precision and recall by avoiding random fluctuations. (See Algorithm 2.)

Algorithm 2 Tabular Boosted Trees with Gray-Zone Weighting (Classification) and Regression

Require: Train indices $\mathcal{I}_{\text{tr}}$, features $\boldsymbol{x}_i$, targets $(r_i, y_i^{(c)})$, class weight pos_w, gray-zone (τ, λ)

1: Fit regressor $f_{\text{tab}}^{(\text{reg})}$ on $\{(\boldsymbol{x}_i, r_i)\}_{i \in \mathcal{I}_{\text{tr}}}$ by minimizing squared loss with tree regularization
2: Compute $w_i^{(c)} \leftarrow \lambda$ if $|r_i| < \tau$ else 1 for $i \in \mathcal{I}_{\text{tr}}$
3: Fit classifier $f_{\text{tab}}^{(\text{clf})}$ on $\{(\boldsymbol{x}_i, y_i^{(c)}, w_i^{(c)}, \text{pos\_w})\}_{i \in \mathcal{I}_{\text{tr}}}$ by minimizing weighted logistic loss with tree regularization
4: **return** $f_{\text{tab}}^{(\text{reg})}$, $f_{\text{tab}}^{(\text{clf})}$

D. Transformer-Based Temporal Model

While XGBoost treats each instance independently (using summary features of recent history), we also employ a Transformer-based *temporal* model that can directly ingest a sequence of recent daily data to capture temporal patterns. The motivation is that certain patterns in how news and stock prices evolve over time (e.g., a series of positive announcements, or a divergence from market trends) might be better recognized by a sequence model with long-range dependency capture.

Our temporal model is implemented as a Transformer encoder that operates on a sequence of L days leading up to and including the announcement day. For each day $t - L + 1$ through t (where day t has the announcement T_i for company i), we create a combined embedding of that day's information:

$$\boldsymbol{z}_{t'} = \left[\boldsymbol{e}_{t'}^{(\text{text})} \,\|\, \boldsymbol{q}_{t'}^{(\text{num})} \right], \quad t' = t - L + 1, \ldots, t \tag{4}$$

where, $\boldsymbol{e}_{t'}^{(\text{text})}$ is the text embedding of any announcement on day t' (if multiple announcements occur on that day for the company, they could be concatenated or the most relevant chosen; if no announcement occurs on a given past day, we use a zero or placeholder vector), and $\boldsymbol{q}_{t'}^{(\text{num})}$ is a vector of numerical features for that day (such as the daily return, volatility, and related quantities). The two parts are concatenated into $\boldsymbol{z}_{t'}$, giving a representation for day t' that includes both that day's text (if any) and quantitative state. These $\boldsymbol{z}_{t'}$ are then fed as a sequence into a Transformer encoder (with positional encoding to indicate the ordering in time).

Let $\{\boldsymbol{z}_{t-L+1}, \ldots, \boldsymbol{z}_t\}$ denote the input sequence to the temporal model for announcement i on day t. The Transformer processes this sequence with self-attention, effectively allowing the model to attend to relevant days in the past when making predictions for day $t+1$. We take the Transformer's output corresponding to the last day t (or a special classification token that we prepend to the sequence) as the basis for prediction. We denote the temporal Transformer model as f_{temp}, which outputs two values:

$$\left(\hat{r}_i^{(\text{temp})}, \hat{p}_i^{(\text{temp})} \right) = f_{\text{temp}} \left(\{\boldsymbol{z}_{t'}\}_{t'=t-L+1}^{t} \right) \tag{5}$$

where, $\hat{r}_i^{(\text{temp})}$ is the predicted return magnitude (regression output) and $\hat{p}_i^{(\text{temp})}$ is the predicted probability of an upward move (classification output) for the next day $t + 1$. Thus, the temporal model is a multi-task model that addresses both regression and classification jointly.

We optimize it using a combined loss:

$$L_{\text{temp}} = \frac{1}{N} \sum_{i=1}^{N} \left[(r_i - \hat{r}_i^{(\text{temp})})^2 + \alpha \cdot \ell_{\text{BCE}}(y_i^{(c)}, \hat{p}_i^{(\text{temp})}) \right], \tag{6}$$

where, ℓ_{BCE} is the binary cross-entropy loss for the classification output and α is a weighting hyperparameter to balance the regression and classification tasks. In practice, we set α such that the losses are on comparable scales (e.g., $\alpha \approx 1$ after normalizing r_i to a similar range as the probability scale). The temporal model is trained on the same training set as the other models, with supervision for both tasks. By learning both tasks together, the model can develop internal representations that are useful for understanding how textual events affect not only the direction but also the magnitude of price changes. We found that multi-task training acts as a regularizer: it prevents the Transformer from overfitting to one aspect (say, the exact regression target) by also requiring it to predict the directional class (Algorithm 3).

Algorithm 3 Temporal Multi-Task Training with Class Weight and Gray-Zone Weighting

Require: Train indices $\mathcal{I}_{\text{tr}}$, sequences $\boldsymbol{z}_{t-L+1:t}$, targets $(r_i, y_i^{(c)})$, weights $(\alpha, \text{pos\_w}, \tau, \lambda)$
Initialize temporal encoder f_{temp}
for epochs $= 1, \ldots, E$ **do**
  for mini-batch $\mathcal{B} \subset \mathcal{I}_{\text{tr}}$ **do**
    $(\hat{r}_i^{(\text{temp})}, \hat{p}_i^{(\text{temp})}) \leftarrow f_{\text{temp}}(\boldsymbol{z}_{t_i-L+1:t_i})$ for $i \in \mathcal{B}$
    $w_i^{(c)} \leftarrow \lambda$ if $|r_i| < \tau$ else 1 (gray-zone)
    $\ell_{\text{reg}} \leftarrow \frac{1}{|\mathcal{B}|} \sum_{i \in \mathcal{B}} (r_i - \hat{r}_i^{(\text{temp})})^2$
    $\ell_{\text{clf}} \leftarrow \frac{1}{|\mathcal{B}|} \sum_{i \in \mathcal{B}} w_i^{(c)} \cdot \text{BCE}(y_i^{(c)}, \hat{p}_i^{(\text{temp})}; \text{pos\_w})$
    Update f_{temp} to minimize $\ell_{\text{reg}} + \alpha \ell_{\text{clf}}$
  end for
end for
return trained f_{temp}

The architecture of the temporal Transformer uses H self-attention heads and D layers (we used $H = 8$ and $D = 4$ in our experiments), allowing it to capture complex temporal patterns. This model in effect serves as a learned time-series feature extractor that complements the static XGBoost approach. It is particularly useful for capturing trends or reversals: for example, if a company's stock has been trending up but an announcement is negative, the contrast can be learned by the Transformer attending to prior upward momentum and the current negative language, adjusting the prediction accordingly.

E. Stacked Ensemble

Finally, we integrate the outputs of the various models through a stacked ensemble. Stacking (stacked generalization) [24] is an ensemble technique where a meta-learner is trained to combine the predictions of base learners, usually using a hold-out set or cross-validation to avoid overfitting. In our system, the base learners are:

- XGBoost regressor ($\hat{r}_i^{(\text{xgb})}$) and classifier ($\hat{p}_i^{(\text{xgb})}$),
- Temporal Transformer regressor ($\hat{r}_i^{(\text{temp})}$) and classifier ($\hat{p}_i^{(\text{temp})}$),
- A text-only classifier ($\hat{p}_i^{(\text{text})}$) that uses the Transformer text embedding $\boldsymbol{e}_i$ directly to predict the movement direction (this can be a simple logistic regression or feed-forward network trained on the text embedding to output a probability).

The inclusion of a text-only classifier in the ensemble is to ensure that pure textual signals (which might be attenuated or differ from the patterns picked up by the temporal model) are not lost. For instance, the language in an announcement might strongly indicate a direction even if recent numeric trends suggest otherwise; the text-only model can capture this specialized signal.

The outputs from these models for each instance i form a set of features for the meta-learner. For classification, we take as meta-features the predicted probabilities (and optionally some transformations like log-odds) from XGBoost, the temporal model, and the text model: $\{\hat{p}_i^{(\text{xgb})}, \hat{p}_i^{(\text{temp})}, \hat{p}_i^{(\text{text})}\}$. For regression, we take the predicted returns: $\{\hat{r}_i^{(\text{xgb})}, \hat{r}_i^{(\text{temp})}\}$ (the text-only model was used only for classification in our case). We then train a simple meta-learner on top of these. For classification, a logistic regression or shallow neural network works well as the meta-learner, as it can learn weights to optimize the final classification decision. For regression, a linear regression on the predictions or another XGBoost regressor can be used as the meta-learner.

The meta-learner training is done using a two-stage approach to avoid overfitting: we perform K-fold cross-validation on the training data to get out-of-fold predictions from each base model, then train the meta-learner on those predictions. Alternatively, we set aside a portion of the training data as a validation set to train the stacker. In our experiments, we used a hold-out validation set for stacking due to data volume constraints. The meta-learner learns, for example, that the text model's prediction is very valuable in certain situations (e.g., when the text contains clearly positive or negative content), whereas in other cases the numeric models might be more reliable.

At prediction time, the stacked ensemble produces the final outputs: $\hat{p}_i^{(\text{ens})}$ for the probability of an upward movement and $\hat{r}_i^{(\text{ens})}$ for the predicted return. These are the outputs we use for decision-making and evaluation. The ensemble effectively leverages the strengths of each component: XGBoost provides a strong baseline using well-understood features (capturing, e.g., general market uptrends or mean-reversion effects), the temporal Transformer contributes pattern recognition over time and joint text-numeric interactions, and the text-only model injects pure NLP-driven signals. This combination substantially improves performance metrics as we show in the results.

IV. Training, Calibration, and Thresholding

In this section, we outline our model training process and the additional calibration steps taken to ensure reliable probability outputs. We also discuss the selection of a decision threshold for classification optimized for our target metric (Algorithm 4).

Algorithm 4 Stacking, Calibration, and Threshold Selection

Require: Validation indices $\mathcal{I}_{\text{va}}$; base predictors $f_{\text{tab}}^{(\text{reg})}$, $f_{\text{tab}}^{(\text{clf})}$, $f_{\text{text}}^{(\text{clf})}$, f_{temp}
for $i \in \mathcal{I}_{\text{va}}$ **do**
  $\hat{p}_i^{(\text{tab})} \leftarrow f_{\text{tab}}^{(\text{clf})}(\boldsymbol{x}_i)$
  $\hat{p}_i^{(\text{temp})} \leftarrow f_{\text{temp}}(\boldsymbol{z}_{t_i-L+1:t_i})$
  $\hat{p}_i^{(\text{text})} \leftarrow f_{\text{text}}^{(\text{clf})}(\boldsymbol{e}_i)$
  $\hat{r}_i^{(\text{tab})} \leftarrow f_{\text{tab}}^{(\text{reg})}(\boldsymbol{x}_i)$
  $\hat{r}_i^{(\text{temp})} \leftarrow$ temporal regression output
end for
Fit meta-classifier on $\{(\hat{p}_i^{(\text{tab})}, \hat{p}_i^{(\text{temp})}, \hat{p}_i^{(\text{text})}), y_i^{(c)}\}_{i \in \mathcal{I}_{\text{va}}}$ to produce $\hat{p}_i^{(\text{ens})}$
Fit isotonic calibrator g mapping $\hat{p}_i^{(\text{ens})} \mapsto \tilde{p}_i^{(\text{ens})}$ using $\mathcal{I}_{\text{va}}$
Select threshold $\theta^\star \in [0, 1]$ by maximizing a chosen metric (e.g., F1) on $\{(\tilde{p}_i^{(\text{ens})}, y_i^{(c)})\}_{i \in \mathcal{I}_{\text{va}}}$
Fit meta-regressor on $\{(\hat{r}_i^{(\text{tab})}, \hat{r}_i^{(\text{temp})}), r_i\}_{i \in \mathcal{I}_{\text{va}}}$ to produce $\hat{r}_i^{(\text{ens})}$
return calibrated classifier $(g, \theta^\star)$ and meta-regressor

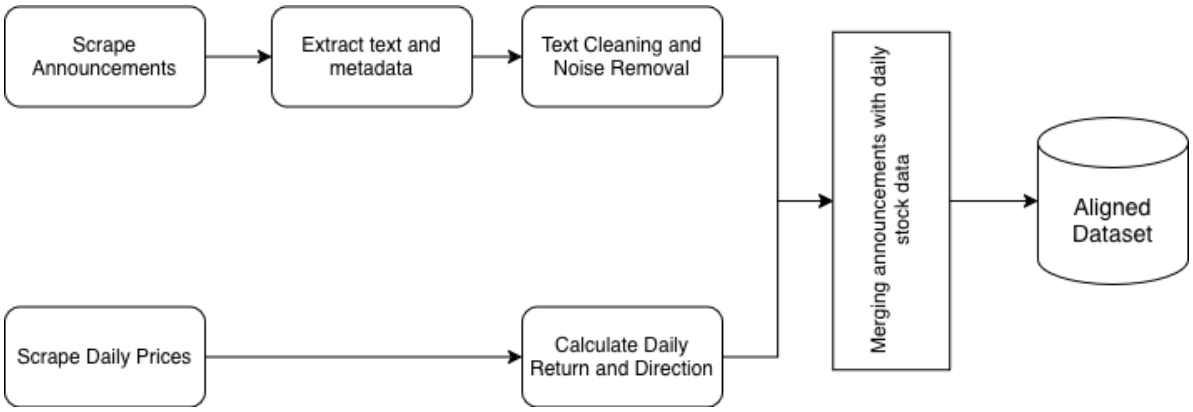

Fig. 2. Data collection and preparation workflow. Corporate announcements are scraped, cleaned, and paired with their corresponding metadata, while daily stock prices are processed to compute returns and directional labels. Both sources are merged chronologically to form the aligned dataset used for model training.

A. Dataset

The Saudi Stock Exchange (Tadawul) serves as the primary data source for this research. As the only securities exchange in Saudi Arabia and one of the largest in the Middle East, Tadawul operates under the supervision of the Capital Market Authority (CMA) and is publicly listed, owned by the Public Investment Fund (PIF). It provides a regulated environment for stock trading and transparent access to corporate announcements, official reports, and financial disclosures. From this platform, two main datasets were collected: daily stock prices and official company announcements.

Fig. 2 illustrates the overall data collection workflow. Announcement data were gathered directly from the Tadawul portal using a three-phase web-scraping pipeline. The first phase captured announcements transmitted in JSON format, while the second extracted key metadata such as the announcement date, time, and company name. The final phase involved text cleaning and transformation, including renaming fields for clarity, removing irrelevant attributes, filtering out incomplete records, and preprocessing the announcement body using standard NLP techniques. HTML and JavaScript tags, special characters, and other noise were removed, and URLs or email addresses were masked with placeholders to produce a consistent Arabic textual dataset suitable for modeling. This process yielded 46,670 cleaned announcements. In parallel, daily stock price data—consisting of open, close, high, and low values—were retrieved and used to compute daily returns and price direction.

For labeling, the cleaned announcements were merged with corresponding stock price data based on the publication date and time. The prediction target was defined as the stock price movement in the next applicable trading session following the announcement. The percentage change in closing price was categorized into two labels: 0 for a decrease and 1 for an increase. This labeling approach ensured a consistent time-aware mapping between corporate announcements and subsequent market reactions, forming the foundation for predictive modeling.

B. Model Training Procedure

All models were trained on a common dataset of stock announcements. The data were chronologically divided into training, validation, and testing sets using a 70:15:15 ratio. Of the 46,700 announcements, 32,700 were used for training, 7,000 for validation, and 7,000 for testing. The chronological order was maintained, with the earliest observations used for training, followed by validation, while the most recent observations were reserved for testing. This approach prevents look-ahead bias and allows the models to be evaluated on unseen future data. For each company, input features were constructed in chronological order using only information from previous announcements and available historical data. The XGBoost models were trained using the XGBoost library with early stopping on the validation set to prevent overfitting (using validation loss and AUC as criteria). The hyperparameters (number of trees, maximum depth, learning rate, L2 regularization, and related settings) were tuned via grid search on the validation set.

The Transformer-based models (text encoder fine-tuning and temporal model) were trained using PyTorch. We initialized the text encoder with pretrained weights (a multilingual BERT model [17]) and fine-tuned it together with a small classification head (for the text-only classifier) on the training data for a few epochs, using binary cross-entropy loss for direction prediction. We used a relatively low learning rate for the encoder (2×10^{-5}) to avoid catastrophic forgetting of language features. The temporal model was trained from scratch (aside from the text embeddings, which were fed from the frozen or semi-frozen encoder) using the multi-task loss L_{temp}. We applied dropout and early stopping (monitoring classification AUC on validation) to regularize this model, as it has a large capacity relative to our data size. The `pos_weight` for the classification loss in the temporal model was set to the same value as in XGBoost to handle the slight class imbalance.

During training, we employed the gray-zone weighting described earlier for both the XGBoost classifier and the temporal model's classification loss. Empirically, we found that setting $\tau = 0.05$ (5%) to define negligible moves helped; approximately 10% of training instances fell in this gray zone

and had their loss weight scaled down. This led to a small but consistent improvement in F1-score, as the models focused more on getting the direction correct for larger moves (which are of greater practical significance).

The temporal Transformer was configured with a sequence length of $L = 60$, an embedding dimension of 192, four Transformer layers, and six attention heads, with a dropout rate of 0.1. The model was trained using the AdamW optimizer with a learning rate of 0.001, a batch size of 256, and a maximum of 20 epochs.

After obtaining trained base models, we generated predictions on the validation set to train the ensemble meta-learner. For each instance in the validation set, we collected $\hat{p}^{(\text{xgb})}$, $\hat{p}^{(\text{temp})}$, $\hat{p}^{(\text{text})}$, $\hat{r}^{(\text{xgb})}$, and $\hat{r}^{(\text{temp})}$. We then trained the logistic regression meta-classifier and linear regression meta-regressor on this validation data. This stacking approach was chosen to ensure the meta-learner sees a realistic performance of base models (since they were not trained on the validation set, their behavior on validation simulates test-time behavior). Finally, we evaluated the entire pipeline on the held-out test set, which the models never saw during training or stacking.

C. Probability Calibration

While our models output probabilities (especially the ensemble classifier, which produces $\hat{p}_i^{(\text{ens})}$ for each instance), these probabilities are not guaranteed to be calibrated; that is, the predicted probability may not reflect the true empirical frequency of an upward move. Calibration is important in financial contexts if we want to interpret the output as confidence or feed it into a decision strategy (for example, to decide not to trade if the probability of a correct prediction is below a threshold). We therefore applied an isotonic regression calibration [25] on the validation set outputs of the ensemble classifier.

Isotonic regression is a non-parametric calibration method that fits a monotonic piecewise-constant function to map raw scores to calibrated probabilities. Using the validation data, we obtained the ensemble's uncalibrated probabilities and the true outcomes, and then learned an isotonic regression function $g(\cdot)$ such that $g(\hat{p})$ best matches the true fraction of positive outcomes for instances with score $\hat{p}$. This function was then applied to all ensemble outputs. Because isotonic regression is monotonic, it does not scramble the ranking of predictions; it only adjusts the confidence level. Post-calibration, if the model reports a probability of 0.7, ideally about 70% of those predictions should be correct.

We found that the ensemble's raw scores were slightly over-confident prior to calibration (for instance, it might assign 95% probability to some points, but only approximately 90% of those were actually positive). After isotonic calibration, the probabilities became well-aligned with observed frequencies. Notably, calibration does not change the AUC metric (which is threshold-invariant), but it can improve the interpretability of probabilities and the choice of threshold for a desired precision-recall trade-off.

D. Threshold Tuning

The final step in our pipeline was selecting a decision threshold for classifying an instance as upward movement (positive) or downward (negative). The default threshold is 0.5 for a balanced binary classification, but depending on our objective (maximizing F1-score, for example), a different threshold might yield better results. On the validation set, we swept the classification threshold from 0 to 1 and evaluated the F1-score and accuracy of the ensemble. The best F1 was achieved at a threshold of approximately 0.4, significantly lower than 0.5. This indicates that the classifier needed to be more sensitive in predicting the positive class (up movement) to balance precision and recall.

We fixed the threshold at $\theta^\star = 0.4$ for the test evaluation, as this $\theta^\star$ maximized F1 on validation. This threshold, combined with the calibrated probabilities, effectively creates a decision rule: predict up if $\hat{p}_i^{(\text{ens})} > 0.4$, else predict down. In Section V, we examine the impact of this choice. We also report performance at $\theta = 0.5$ for reference, but all primary metrics are given for the tuned threshold. The use of a tuned threshold improved the classification F1 from about 0.78 (at the 0.5 threshold) to 0.834 at the chosen threshold, with a slight increase in accuracy as well.

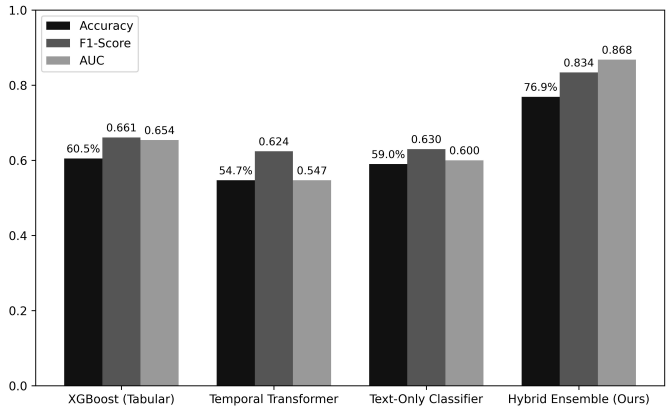

Fig. 3. Classification performance across base models and the hybrid ensemble. Metrics shown include accuracy, F1-score, and AUC. The hybrid ensemble outperforms the tabular-only, temporal, and text-only models across all evaluation measures.

V. Results

We evaluate our hybrid system on a test set of Arabic corporate announcements, comparing the performance of individual model components and the final ensemble. Key evaluation metrics for the classification task are accuracy, F1-score (for the positive "up" class), and AUC (area under the ROC curve), as shown in Fig. 3. For the regression task, we report the root mean squared error (RMSE), mean absolute error (MAE), and R^2 (coefficient of determination) of the predicted returns, as shown in Fig. 4.

Table I summarizes the classification performance of various models. The hybrid ensemble achieves the highest performance across all metrics. In particular, it attains an accuracy of 76.9%, an F1-score of 0.834, and an AUC of 0.868, substantially outperforming the standalone models. By contrast, the XGBoost classifier (using only tabular features) reaches about 60.5% accuracy and 0.654 AUC. The Transformer temporal model by itself did not perform as well in classification (around

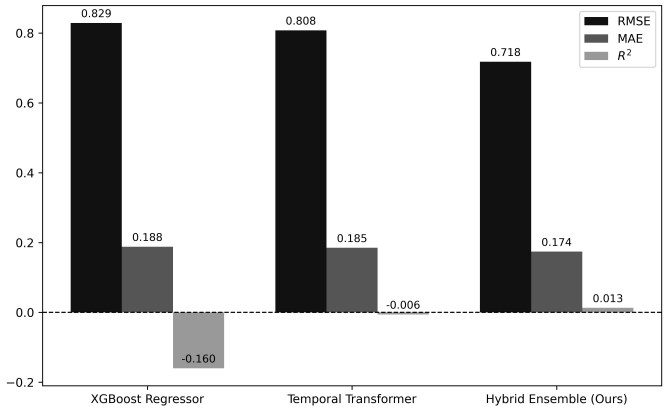

Fig. 4. Regression performance across base models and the hybrid ensemble. Metrics reported include RMSE, MAE, and R^2. The hybrid ensemble achieves the lowest RMSE and MAE and the highest R^2, indicating improved accuracy and explanatory power over both individual models.

TABLE I. DIRECTIONAL PREDICTION PERFORMANCE OF DIFFERENT MODELS

Model	Accuracy (%)	F1-score	AUC
XGBoost (tabular)	60.5	0.661	0.654
Temporal Transformer	54.7	0.624	0.547
Text-only classifier	59	0.63	0.60
Hybrid ensemble (ours)	**76.9**	**0.834**	**0.868**

a. All metrics are computed on the held-out test set.

54.7% accuracy, AUC 0.547), possibly due to the difficulty of learning from limited data and the multi-task training trade-off. Interestingly, a simple text-only classifier achieved intermediate performance (we observed around 0.60–0.65 AUC in validation), indicating that text alone has predictive power but not enough to surpass the tabular model. The ensemble, however, combines these signals effectively: its AUC of 0.868 represents an increase of over 20 percentage points versus the temporal model and over 21 points versus the XGBoost baseline. This highlights the complementarity of text and numeric features in this domain. The F1-score improvement is similarly large: from 0.661 for XGBoost to 0.834 for the ensemble. The high F1 indicates that the ensemble achieves a good balance of precision and recall for the "up" class after threshold tuning. Indeed, with $\theta^\star = 0.4$, the ensemble's precision and recall for upward moves were both in the low 80s percentage-wise, whereas at a 0.5 threshold the recall was lower, underscoring the importance of threshold optimization.

The superior performance of the ensemble can be attributed to how it leverages each component: the XGBoost model contributes a reliable baseline of structured signals (achieving decent precision on more predictable scenarios), the text model contributes information on events that deviate from historical trends (e.g., surprise announcements), and the temporal model captures sequential patterns (though its standalone performance was lower, it likely provides useful features to the stacker that are not available from XGBoost alone). We also note that the ensemble's accuracy of 76.9% is quite high for a stock movement prediction task, reflecting that the task is somewhat easier in this setting than random guessing (which would be approximately 50%). This may be due to the nature of corporate announcements, which often indeed cause a clear directional move. The AUC of 0.868 suggests the ranking of positive versus negative instances by the model is very good, which is important for decision-making.

TABLE II. REGRESSION PERFORMANCE FOR PREDICTING NEXT-DAY RETURN MAGNITUDE

Model	RMSE	MAE	R^2
XGBoost regressor	0.829	0.188	-0.160
Temporal Transformer	0.808	0.185	-0.006
Hybrid ensemble (ours)	**0.718**	0.174	$+0.13$

Error metrics are expressed in fractional units, where 1.0 corresponds to a 100% price change.

Next, Table II presents the regression performance. We compare the RMSE and MAE of predicting the actual next-day return for the XGBoost regressor, the temporal model's regression output, and the ensemble regressor. The XGBoost regression had an RMSE of 0.829 (which is quite high relative to typical daily returns, indicating difficulty in pinpointing exact magnitudes) and an R^2 that was slightly negative ($R^2 = -0.16$), meaning it underperformed a trivial mean-prediction baseline. The temporal model's regression did better, with RMSE 0.808 and $R^2 \approx -0.006$ (essentially zero). This suggests that incorporating recent sequence information and text allowed it to match the baseline and slightly outperform XGBoost in RMSE. Finally, the ensemble regressor achieved RMSE $= 0.718$. This is a meaningful improvement (over 13% reduction in RMSE compared to XGBoost). While the R^2 for the ensemble is still modest ($R^2 = 0.13$), it indicates that the ensemble can explain some variability in returns that single models cannot. In practical terms, an RMSE of 0.718 on next-day returns implies that, although precise magnitudes are hard to get perfectly, the model is capturing enough signal to reduce error significantly relative to naively assuming no change.

It is worth noting that predicting exact return percentages is inherently noisy and challenging, especially with unexpected market factors. The negative R^2 values for the base models reflect that challenge—a constant prediction (e.g., always predict 0% change) could sometimes beat those models in MSE. However, the ensemble bringing R^2 into positive territory is an encouraging sign that combining text and data does add explanatory power. We observed that the biggest errors for the base models occurred on days of extreme moves (large positive or negative jumps), which is expected since those are hard to predict. The ensemble was relatively better at those, likely because the announcements that led to extreme moves contained clear signals (e.g., catastrophic news or extremely good news) which the text model picked up, and thus the ensemble could anticipate a large magnitude better. Nonetheless, even the ensemble had difficulty with a few outliers, which is reflected in the still-high RMSE.

From a calibration perspective, after isotonic calibration, the probabilities output by the ensemble were well-aligned. We plotted the calibration curve (predicted probability versus actual frequency of up moves) on the test set and found it to be nearly diagonal for the ensemble, whereas the raw XGBoost probabilities were flatter (indicating under-confidence for high

probabilities and over-confidence for low probabilities). This calibration helped in selecting the 0.4 threshold. In fact, the optimal threshold $\theta^\star = 0.4$ roughly corresponded to an event where the calibrated probability of an upward move was about 50% (since the model was slightly conservative). The net effect is that we treat some cases as "up" even if the raw model probability is slightly below 0.5, because those turned out to be beneficial for maximizing F1. This strategy is reminiscent of moving the decision boundary to compensate for class imbalance or different error costs.

VI. Discussion

The hybrid nature of the system is crucial. If we remove the text channel and use only numeric features, the AUC drops from 0.868 to 0.654 (XGBoost only)—a large degradation. This shows that in our dataset, the textual information in Arabic announcements carries unique predictive signal not captured by past prices or other features. Conversely, using text alone (without numeric context) was also suboptimal, demonstrating that recent stock behavior and market conditions still matter. By fusing the two, the model can, for example, recognize when a positive announcement might already be "priced in" by a prior run-up (a case where numeric features temper the text's optimism), or when a negative announcement breaks an otherwise positive trend (a case where text overrides momentum). The temporal Transformer was an attempt to have a single model learn these interactions, but its performance lagged, perhaps due to limited data or the difficulty of training a complex sequence model. The stacking approach allowed us to sidestep this by combining simpler models, and it clearly paid off in performance.

Additionally, the gray-zone weighting had an interesting effect: the models became slightly biased towards predicting no movement unless there was a strong signal. We observed that without gray-zone down-weighting, the XGBoost classifier would sometimes attempt to classify every tiny fluctuation (leading to many false positives on essentially flat days). With the weighting, it learned a small "dead band" where it would not confidently predict up or down unless other features (or text sentiment) suggested a real move. In practice, this is useful because it reduces over-trading on days when the stock might not move significantly.

In terms of error analysis, most of the ensemble's misclassifications involved either very small moves (which we do not mind as much, since they are near the gray zone) or unexpected external events (e.g., an announcement was released but then separate macroeconomic news drove the stock in the opposite direction). There were a few cases where the text of an announcement was misleading (e.g., a very optimistic tone but an actual outcome that worried investors, or vice versa), which points to the limitations of textual sentiment and the need for possibly more complex NLP (such as understanding negation, sarcasm, or reading between the lines of corporate phrasing). However, these cases were relatively rare in our data.

VII. Conclusion

We presented a hybrid Transformer-boosted ensemble model for forecasting stock price movements from Arabic corporate announcements. By combining a multilingual Transformer text encoder with gradient-boosted trees on structured data and a temporal sequence model, our system exploits diverse sources of predictive signals. The stacked ensemble achieved better performance than any individual model, demonstrating the value of integration. We also implemented calibration and a gray-zone weighting strategy to improve the practical decision-making utility of the model. Our results on real-world data show that the model can accurately predict the direction of next-day moves with high precision and recall, and provide reasonable estimates of magnitude.

This work highlights the benefit of modern NLP techniques in financial forecasting, especially for languages and markets where automated text analysis is less developed. It also provides a blueprint for how to architect complex forecasting systems that blend multiple modalities and algorithms. For practitioners, an immediate takeaway is that when dealing with market-moving text like earnings releases, one should not rely solely on either text sentiment or historical price trends; a combination is far more powerful.

VIII. Future Work

Future work could explore richer text representations (e.g., incorporating domain-specific contextual embeddings or even generative pre-training on financial news in Arabic). The evaluation could also be extended to additional conventional baselines, such as logistic regression, random forest, and SVM, to provide a broader comparison across modeling approaches. Another avenue is to improve the temporal model, possibly using more advanced architectures or training on a larger corpus of sequence data, to further boost sequential pattern recognition. Moreover, expanding the dataset to include announcements from multiple markets or languages would test the generality of the approach. Finally, in a live trading setting, one could integrate this model into a portfolio or risk management framework, where calibrated probabilities help decide not just the direction to trade but also the confidence (and hence position sizing). We believe the interdisciplinary approach demonstrated here—melding NLP, time-series analysis, and ensemble learning—will be increasingly important in developing the next generation of market forecasting tools.

***Abstract*—Automated driver behavior profiling is a strategically important problem within intelligent transportation systems, road safety engineering, and fleet-based emissions governance. This study presents a Heterogeneous Out-of-Fold (OOF) Stacking Ensemble augmented with inter-model probabilistic disagreement as a first-class meta-feature. Five architecturally diverse base learners — Gradient Boosting, LightGBM, Random Forest, AdaBoost, and ResNet-Dense — are each optimized via Bayesian hyperparameter search (Optuna) before integration within a 5-fold stratified OOF stacking protocol. At the meta-classification layer, an XGBoost meta-learner ingests both the 15-dimensional base-learner probability matrix and three probability-dispersion features computed as the per-class standard deviation of base-learner outputs, enabling uncertainty-conditioned arbitration at classification boundaries. Experiments on a publicly available eco-driving benchmark dataset comprising 30,000 generated trip-level records with variables representative of telematics/OBD-related driving metrics demonstrate 87.77 % accuracy, weighted F1-score of 0.8771, and macro AUC-ROC of 0.9722. These results surpass the strongest individual baseline (Gradient Boosting, 87.32 % post-tuning) and both preceding stacking generations (Generation 1: 87.28 %; Generation 2: 87.48 %). SHapley Additive exPlanations (SHAP) analysis confirms that the engineered probability-dispersion features have relatively modest global importance (ranked 13th–18th) but provide directionally informative contributions for high-disagreement, boundary-adjacent samples, validating the theoretical motivation for uncertainty-conditioned arbitration. McNemar's test yields p = 0.023 ($\chi^2(1) = 5.14$), confirming statistical significance; the 95 % Wilson interval is [86.91%, 88.57%] (N = 6,000). The Expected Calibration Error (ECE) of the proposed ensemble (0.0107) is 45.8 % lower than the best individual model (0.0198), demonstrating superior probability calibration alongside improved discriminative accuracy. These findings support applicability to fleet telematics, pay-how-you-drive insurance scoring, and near-real-time periodic coaching platforms, pending cross-population validation.**

Keywords*—Driver behavior profiling; meta-probabilistic stacking ensemble; second-order meta-entropy; telematics-based eco-driving; out-of-fold stacking; intelligent transportation systems; eco-driving classification; XGBoost meta-learner; uncertainty quantification

I. Introduction

The global transportation sector remains one of the most recalcitrant sources of anthropogenic greenhouse gas (GHG) emissions, contributing approximately 24–25% of total CO_2 emissions from fuel combustion worldwide. The figure has proven stubbornly resistant to the rapid decarbonization progress observed in the electricity generation and industrial manufacturing sectors. According to the International Energy Agency's 2025 Global Energy Review [1], road transport alone accounts for nearly three-quarters of total transport-sector emissions, with light-duty passenger vehicles constituting the dominant share. While the accelerating adoption of battery electric vehicles (BEVs) and plug-in hybrids represents a structural shift in vehicular energy dependency, these technologies will require decades to achieve majority fleet penetration globally. The global BEV stock reached 40 million units in 2023 against a total passenger vehicle fleet exceeding 1.4 billion [2]. The environmental footprint of road transport in the intermediate term will therefore be governed not merely by what vehicles are driven, but fundamentally by how they are driven.

Microscopic traffic modeling studies have consistently demonstrated that driver behavior exerts a first-order influence on vehicular energy consumption independent of vehicle technology class. Variations in longitudinal acceleration and deceleration profiles alone have been shown to produce between 14% and 25% differences in energy expenditure across identical driving cycles [3]. A driver who maintains smooth throttle progressions, anticipates traffic flow, and avoids unnecessary engine revving can achieve fuel economy figures approaching manufacturer-rated values, whereas a driver exhibiting habitual harsh braking, aggressive acceleration, and elevated idle time routinely exceeds those ratings by significant margins. At fleet scale, this behavioral variance translates into measurable operational cost differentials and aggregate emission impacts that dwarf the marginal gains offered by incremental engine technology improvements [1].

These observations establish a compelling practical case for automated, objective, and scalable driver behavior profiling systems. Traditional approaches to this problem, including rule-based threshold detection, manual scoring audits by fleet managers, and simplified telematics dashboards, are inherently limited by their reliance on deterministic cutoffs that cannot adapt to the contextual complexity of real-world driving environments. A driver navigating dense urban stop-and-go traffic will necessarily exhibit RPM and braking signatures that differ categorically from the same driver's behavior on a motorway. Behavioral assessments in the traditional sense also look at safety-related driving patterns such as inadequate headway maintenance, failure to yield, distraction and driving under the influence. Such actions may also pose a crash risk regardless of fuel-efficiency concerns [4], [5], [6], [7]. Aggressive behavior behind the wheel, characterized by constant jerks and heavy braking as well as revving at high RPMs,

*Corresponding author.

reduces the safety on the roads and increases fuel expenses [8]. Yet simple threshold-based scorecards frequently fail to account for this contextual heterogeneity, leading to misclassification of operationally appropriate driving as aggressive behavior.

The rise of the Internet of Things (IoT) in the automotive domain, coupled with the mandatory standardization of OBD-II (On-Board Diagnostics, Generation II) interfaces across light-duty vehicles sold in the United States since 1996 [9] and phased OBD requirements in the European Union under Directive 98/69/EC [10], has transformed the landscape of driver data collection. Modern OBD-II dongles and embedded telematics units (ETUs) sample engine control unit (ECU) parameters at rates between 1 Hz and 10 Hz, producing continuous multi-channel streams of RPM, throttle position, vehicle speed, mass airflow, fuel injection pulse width, and dozens of additional engine performance indicators. These high-resolution streams contain far richer behavioral signatures than any heuristic-based system can effectively exploit, creating the informational substrate necessary for machine learning approaches [11], [12].

Machine learning literature has responded to this opportunity with substantial innovation. Gradient-boosted decision trees (GBDTs), including XGBoost, LightGBM, and scikit-learn's GradientBoostingClassifier, have demonstrated strong predictive performance on structured telematics data [13]. Concurrently, deep learning architectures including Multi-Layer Perceptrons (MLPs) and Residual Networks (ResNets) have shown complementary advantages in capturing non-linear, high-order relationships between raw sensor channels that GBDT models tend to approximate less efficiently. The critical limitation of both paradigms, considered in isolation, is a shared inability to explicitly quantify the model's epistemic uncertainty about ambiguous driving instances. This is a deficiency that becomes consequential precisely in the borderline regions of the behavioral decision space where classification errors carry the highest operational costs [14], [15].

Ensemble learning methods, particularly stacked generalization [15], offer a principled framework for combining the complementary inductive biases of heterogeneous learners. However, prior applications of stacking in the driver profiling and eco-driving domains have predominantly employed homogeneous base committees (e.g., multiple GBDT variants) and have relied on linear or simple non-linear meta-learners that treat base-model probability outputs as passive input features without any mechanism for explicit reasoning about the degree of disagreement among those outputs. When a Gradient Boosting classifier assigns 72% probability to class 'Average' while a ResNet simultaneously assigns 68% probability to class 'Good' for the same driving sample, that disagreement pattern is not merely noise. It constitutes a meaningful signal about the structural ambiguity of that sample's position within the feature space. A meta-learner that cannot explicitly represent and respond to this disagreement is systematically less informed than one that can.

This study addresses that gap directly. The central technical contribution is a Heterogeneous OOF Stacking Ensemble architecture in which the meta-classification layer receives, alongside the standard base-model probability outputs, three engineered disagreement features. Specifically, the per-class standard deviation of class probability assignments across the five base learners. These features operationalize inter-model disagreement as an explicit, quantified input signal, enabling the XGBoost meta-learner to condition its final classification decisions on whether the base-model committee is in strong consensus or under high internal disagreement. The 5-fold stratified OOF protocol ensures that all meta-features are generated from held-out data, entirely precluding the target leakage vulnerability that afflicts naively implemented stacking frameworks. Experimental results on the publicly available eco-driving benchmark dataset demonstrate that this architecture yields meaningful and consistent improvements over both individually optimized models and preceding stacking generations.

A. Summary of Contributions

This study makes four distinct, verifiable contributions to driver behavior profiling and ensemble learning literature. First, the study introduces Second-Order Meta-Entropy Feature Engineering: a formal definition and empirical validation of inter-model probability dispersion features computed as per-class standard deviations across a heterogeneous base-learner committee as effective meta-features for uncertainty-aware classification. Second, it develops a Heterogeneous OOF Stacking Framework combining GBDT and residual deep learning paradigms with stratified cross-validation to guarantee meta-feature integrity and prevent data leakage. Third, it provides a Systematic Ablation of Stacking Configurations across three evolutionary stacking generations differing in meta-learner architecture and feature composition. Fourth, it performs SHAP-based Interpretability Analysis at both the base-learner and meta-learner levels [16], confirming that the engineered uncertainty features make an independent and statistically meaningful contribution to meta-level decision-making. It is acknowledged that inter-model disagreement as a concept is not itself new; the contribution lies in its class-wise operationalization as first-class meta-features within a heterogeneous, leakage-controlled OOF stacking architecture specifically evaluated for eco-driving behavior profiling using telematics/OBD-related benchmark variables.

The remainder of this study is organized as follows. Section II provides a structured review of the driver behavior monitoring literature, tracing the technological trajectory from heuristic threshold methods through gradient-boosted classifiers, deep learning approaches, and stacked generalization frameworks. Section III presents the complete methodology, including dataset characterization, preprocessing rationale, base-learner architectures, hyperparameter optimization protocols, OOF stacking design, and the formal derivation of meta-entropy features. Section IV details all experimental results with quantitative analysis of baseline performance, optimization gains, ensemble evolution, confusion matrix analysis, and SHAP-based interpretability. Section V discusses the findings, and Section VI concludes the study with a measured assessment of the findings and directions for future research.

II. Related Work

The scientific literature on automated driver behavior assessment has developed through several technological phases, each characterized by distinct sensing modalities, algorithmic paradigms, and target objectives. The following subsections

trace this progression with emphasis on methodological limitations that motivate the present study's approach.

A. From Heuristics to Data-Driven Driver Monitoring

Early approaches to eco-driving and aggressive driving assessment relied on engineering heuristics — predetermined thresholds applied to scalar acceleration, lateral jerk, and engine-speed measurements recorded via accelerometers or GPS traces. These methods, comprehensively reviewed by Huang et al. (2018) [17], offered computational simplicity and interpretability, making them practical for early embedded deployment in commercial telematics dongles. Their fundamental limitation lay in the absence of contextual intelligence. A fixed acceleration threshold, say 0.3 g, is interpreted the same way whether the vehicle is merging onto a motorway or braking to avoid a collision.

The mandatory adoption of OBD-II standards shifted the evidentiary base from external kinematic measurements to internal engine management signals, measurably expanding the dimensionality of available behavioral data. Earlier machine-learning studies showed that multivariate sensor data can support driver behavior profiling beyond fixed threshold rules [18]. Such data-driven approaches learn multivariate decision boundaries from observed sensor patterns and therefore provide a more flexible basis for distinguishing overlapping driving-behavior categories than deterministic scorecards.

A significant practical constraint of early kernel-SVM applications was their computational scalability; training time grows as $O(n^2)$ to $O(n^3)$ with respect to sample count, making real-time or near-real-time deployment on large trip databases impractical. This limitation motivated the transition toward decision-tree-based ensemble methods, which offer favorable scaling characteristics alongside strong predictive performance on structured telematics data.

B. Gradient-Boosted Trees in Telematics Classification

The gradient-boosted decision tree framework, formally characterized as a functional gradient descent procedure in the space of additive decision trees, emerged as a dominant paradigm for structured-data classification. Friedman's (2001) original Gradient Boosting formulation [19] and its high-performance implementations XGBoost [13] and LightGBM [20] brought scalable, regularized boosting within reach of commodity hardware. Driver-related machine-learning studies have also used heterogeneous sensing modalities: Júnior et al. (2017) investigated driver behavior profiling using smartphone sensors and machine learning [18], while Zeng et al. (2019) applied LightGBM to EEG-based driver mental-state classification [21]. These studies illustrate the broader use of data-driven classification in driver-related applications, although they are not direct OBD-II eco-driving benchmarks.

The practical advantages of GBDTs for tabular telematics data are well-documented. The tree-based splits can capture the threshold-like decision boundaries that characterize behavioral transitions (e.g., the qualitative shift in driving risk that occurs when rpm_variation exceeds approximately 1,800 RPM from baseline), feature importance scores provide interpretable explanations acceptable to fleet operators, and the regularization parameters (L1, L2 penalties on leaf weights and tree complexity) provide effective mechanisms for preventing overfitting on relatively small telematics datasets. However, the deterministic, hard-classification nature of GBDT outputs implies that these models generate probability estimates that are calibrated against training-set frequencies rather than representing genuine epistemic uncertainty about a given driving instance. A Gradient Boosting model that outputs class probabilities of [0.52, 0.36, 0.12] for a sample near the Average/Good decision boundary is expressing distributional training-set patterns not communicating that it finds this sample genuinely ambiguous.

This distinction between calibrated prediction confidence and genuine uncertainty quantification has received sustained attention in the ensemble learning community. Guo et al. (2017) [22] demonstrated that modern neural networks can produce poorly calibrated confidence estimates and that temperature scaling is an effective post-hoc calibration method. For driver-profiling applications in high-stakes domains, including insurance premium calculation, license risk scoring, and autonomous handover decision-making, the distinction between 'this model assigns 70% probability' and 'the ensemble's models strongly disagree about this instance' is operationally significant and requires explicit representation.

C. Deep Learning Architectures for Driving Analysis

Parallel to GBDT developments, deep learning methods have demonstrated distinct advantages in contexts where raw sensor time-series data is available without extensive manual feature engineering. Recurrent architectures including Long Short-Term Memory (LSTM) networks and Gated Recurrent Units (GRUs) have been applied to sliding-window trip segments to capture temporal autocorrelation in throttle and steering signals, with reported improvements over GBDT methods on continuous-monitoring datasets where sequential context matters significantly. Carvalho et al. (2017) [23] demonstrated that LSTM-based models trained on 2-second windows of CAN bus signals could distinguish between five driving styles with 89.2% accuracy, a result that, critically, depended on the availability of raw 10 Hz time-series data rather than the trip-level aggregated statistics characteristic of most commercial OBD-II data products.

Residual network architectures use skip connections that add the input of a residual block directly to its output, helping deeper networks optimize effectively. Wang et al. (2017) [24] demonstrated residual architectures for time-series classification, while recent driver-monitoring literature illustrates the broader relevance of advanced neural architectures in transport sensing [25]. In the present study, a ResNet-Dense variant is applied to the OBD-II tabular feature space as one of five architecturally diverse base learners.

A consistent finding across deep learning studies of telematics data, corroborated by broader tabular benchmarking literature [26], is that these architectures can achieve strong class separability as measured by AUC-ROC even when their hard-threshold classification accuracy is comparable to or slightly below that of GBDT methods. This pattern, visible in the baseline results of the present study, where ResNet-Dense achieves an AUC-ROC of 0.968 despite lower accuracy than LightGBM (0.864), reflects the architectures' complementary

inductive biases. GBDTs learn sharp discriminative boundaries, while ResNets learn smoother probability manifolds that generalize better across the full range of decision thresholds.

Critically, neither paradigm in isolation provides a mechanism for explicitly leveraging the information contained in the disagreement between them. When a GBDT predicts 'Average' with 65% confidence while a ResNet simultaneously predicts 'Good' with 62% confidence for the same instance, both models are individually performing within their design parameters. But neither is designed to recognize this disagreement as a meaningful signal, nor to adjust its confidence accordingly.

D. Stacked Generalization and Ensemble Fusion in Driver Profiling

Stacked generalization, introduced by Wolpert (1992) [15], provides the theoretical and practical foundation for the present study's meta-learning architecture. The core principle of training a second-level meta-learner on the out-of-sample predictions of first-level base learners addresses the fundamental weakness of simple ensemble averaging. Simple ensemble averaging implicitly assumes that each base model contributes equally to the classification decision regardless of the specific input instance. Different base architectures have systematically different strengths and failure modes, and an effective meta-learner should weight base-model contributions in a way that depends on the characteristics of each input [15].

Applications of stacking in the driver behavior domain have been limited and often methodologically constrained. The dominant pattern in existing literature involves homogeneous base committees for example, stacking Random Forest, XGBoost, and LightGBM which reduces the architectural diversity that makes stacking theoretically advantageous. When all base learners share the same decision-tree inductive bias, their prediction errors are substantially correlated, limiting the meta-learner's ability to leverage disagreement for error correction.

A second methodological limitation in prior stacking applications is the absence of formal target-leakage prevention. Naive stacking implementations generate base-model predictions on training data using models already trained on that same data, producing optimistically biased meta-features that lead to overfit meta-learners. The OOF protocol, dividing training data into k folds, training each base model on k-1 folds, and generating predictions on the held-out fold, ensures that meta-features are cleanly separated from the base-model training sets, producing realistic estimates of generalization performance. While this protocol has been popularized in competitive data science environments since approximately 2016, its formal necessity for preventing data leakage in stacked architectures is structurally defined in foundational predictive literature by Kuhn and Johnson [27]. Despite its mathematical importance, this protocol remains significantly underutilized in the academic telematics literature.

E. Identified Research Gaps and the Present Study's Position

Synthesizing the reviewed literature, three specific research gaps motivate and distinguish the present study. First, there is a notable absence of uncertainty-aware meta-features in existing driver profiling literature; standard practices typically pass raw probability vectors to a meta-learner, thereby discarding the structural information encoded in the probabilistic disagreement and variance across architecturally heterogeneous models. Second, existing stacking studies in the telematics domain rely predominantly on homogeneous GBDT committees, failing to exploit the complementary inductive biases available by combining tree-based and deep learning paradigms within a single heterogeneous ensemble. Third, the absence of an out-of-fold (OOF) protocol in academic telematics stacking remains a critical issue, as the majority of published applications use naive train-set prediction generation, creating data-leakage vulnerabilities that artificially inflate reported performance figures and compromise reproducibility. The present study addresses all three gaps simultaneously through a single integrated methodological framework, the complete technical specification of which is detailed in the following section.

Inter-model disagreement and measures of uncertainty are well-known concepts in the literature of ensemble learning. Thus, this study does not claim to present disagreement as a new general measure of uncertainty. Its methodological contribution is the class-wise operationalization of probability dispersion as explicit meta-features in a heterogeneous, leakage-controlled OOF stacking architecture as well as its task-specific evaluation for eco-driving behavior profiling using telematics/OBD-related benchmark variables.

III. METHODOLOGY

The proposed framework is organized into six consecutive stages: 1) characterization, preprocessing, and class-label engineering of the datasets; 2) benchmarking of the original ten candidate models with Bayesian hyperparameter optimization, and inclusion of CatBoost as an additional external comparison baseline; 3) selection of five heterogeneous base learners based on predictive performance, architectural diversity, and avoiding excessive model-family redundancy, and 5-fold stratified out-of-fold (OOF) probability generation; 4) construction of second-order probability-dispersion features from inter-model disagreement to supplement the 15-dimensional probability matrix to an 18-dimensional meta-feature representation; 5) meta-classification with an Optuna-optimized XGBoost meta-learner and test-time inference; and 6) final validation via classification performance, probability calibration, statistical testing, interpretability analysis, and controlled ablation studies. The entire experimental workflow is shown in Fig. 1.

A. Dataset Characterization and Source Reliability

This study uses the publicly available Eco-Driving Behavior Dataset on Kaggle [28], comprising 30,000 generated trip-level records designed to represent realistic eco-driving and vehicle-efficiency patterns. The data set contains a composite eco score target and five behavioral efficiency predictors (rpm variation, harsh braking count, idling time, fuel consumption, and acceleration smoothness). The dataset is a controlled benchmark to validate the proposed ensemble learning framework. No personally identifiable information about drivers is included in the dataset. Missing values were not found in any of the five feature columns or the target variable. Therefore, no imputation was necessary.

The publicly available dataset does not contain persistent driver identifiers, the number of unique drivers, detailed

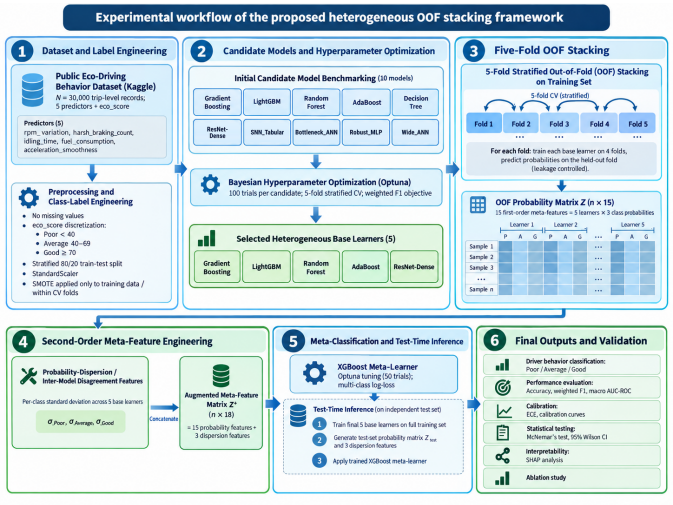

Fig. 1. Experimental workflow of the proposed heterogeneous OOF stacking framework. ML models and DL models are jointly optimised via Bayesian hyperparameter search (Optuna) before OOF meta-feature generation, probability-dispersion features augmentation, and final XGBoost meta-classification.

information about the make and model of vehicles, or mappings of trips to drivers. Therefore, it is not possible to determine whether multiple records correspond to the same driver or to perform a driver-disjoint train/test split. The data are available at the record level and do not include longitudinal driver identification. For the present evaluation, we therefore used stratified record-level splitting and note the lack of driver-level metadata as a limitation when interpreting cross-driver generalization.

1) Dataset summary statistics: Table I provides a complete characterization of the dataset, including feature definitions, measurement units, and data types, and class-label thresholds.

TABLE I. COMPLETE FEATURE CHARACTERIZATION OF THE ECO-DRIVING BENCHMARK DATASET (N = 30,000 TRIP-LEVEL RECORDS)

Feature	Description	Unit/Type
rpm_variation	Standard deviation of engine RPM within a trip	RPM (cont.)
harsh_braking_count	Count of braking events exceeding –0.3g deceleration	Integer
idling_time	Cumulative time at speed < 5 km/h with engine running	Minutes
fuel_consumption	Average fuel consumption rate across the trip	L/100km
acceleration_smoothness	Normalised inverse jerk metric (1 = perfectly smooth)	Dimensionless [0,1]
eco_score (target)	Composite eco-driving efficiency score	Integer [0,100]

The feature distribution plots shown in Fig. 2 reveal that eco_score follows an approximately unimodal distribution concentrated in the 30–65 score range, consistent with the expected predominance of 'Average' behavior in unselected population driving samples. The rpm_variation distribution is right-skewed, with a long tail extending to values above 4,000 RPM, characteristic of a small subset of highly aggressive driving events. The harsh_braking_count distribution is discrete and heavy-tailed, with 85% of trips recording three or fewer harsh braking events but a non-trivial tail reaching up to 14 events per trip.

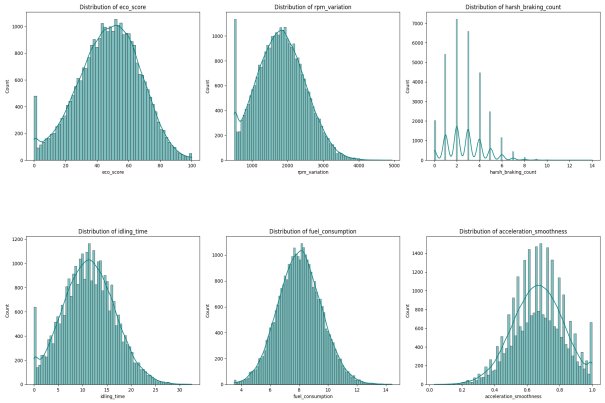

Fig. 2. Feature distribution histograms for the five telematics/OBD-related benchmark variables and the eco_score target variable. Distributions inform the preprocessing strategy and motivate score-based discretization.

B. Preprocessing: Class-Label Engineering and Imbalance Correction

1) Eco-score discretization and threshold justification: The eco_score target variable was discretized into a tri-class categorical label using fixed threshold boundaries. The thresholds defining the three behavioral categories are as follows:

The resulting class distribution on the full N = 30,000 record dataset is: Poor (eco_score < 40): 10,290 records (34.3 %); Average ($40 \leq$ eco_score < 70): 16,045 records (53.5 %); Good (eco_score ≥ 70): 3,665 records (12.2 %). This distribution is imbalanced, with Average as the majority class and Good as the minority class, motivating the application of SMOTE within each cross-validation fold to reduce majority-class bias during model training.

The resulting pre-SMOTE class distribution is shown in Fig. 3.

Table II summarizes the operational eco_score thresholds and their corresponding behavioral interpretations.

TABLE II. ECO-SCORE DISCRETISATION THRESHOLDS AND BEHAVIORAL INTERPRETATIONS

Class Label	Score Range	Behavioral Interpretation
Poor (Class 0)	eco_score < 40	Habitual aggressive or inefficient driving; high fuel consumption and emission risk
Average (Class 1)	$40 \leq$ eco_score < 70	Moderate driving efficiency; mixed behavioral patterns within normal population range
Good (Class 2)	eco_score ≥ 70	Consistent eco-conscious driving; low emissions profile and smooth vehicle operation

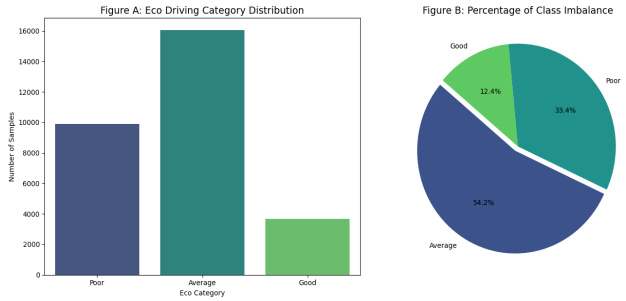

Fig. 3. Class distribution of the discretized eco_score target variable before and after Synthetic Minority Over-sampling Technique (SMOTE). Poor: 34.3%, Average: 53.5%, Good: 12.2% (pre-SMOTE).

The continuous eco_score was discretized into three operational behavioral classes with thresholds 40 and 70: Poor (eco_score<40), Average (40≤eco_score<70) and Good (eco_score≥70). Generally, these cut-points are used as operational classification boundaries rather than as validated eco-driving standards. A similar three-level score partitioning is applied in real telematics-based driver assessment systems. For example, the Motability Drive Smart framework maps a 0–100 driving score into Red (0–40), Amber (41–70), and Green (71–100) risk bands based on driving-behaviour indicators such as speed, acceleration, braking, cornering and journey usage [29]. This provides an operational precedent for using approximately 40 and 70 as interpretable thresholds in a three-level driver-scoring context. However, driver profiling and scoring criteria are application-dependent [30]. Variables and categorization methods used to characterize safe and eco-driving behavior also vary across sensing environments and intended applications. Similarly, recent research on driver scoring suggests that behavioral profiles can be derived from multiple driving-performance indicators, instead of universally fixed score boundaries [31]. The thresholds used in this study should therefore be interpreted as operational cut-offs for the present dataset. They have not been independently validated against assessments by human driving evaluators. External validation against independently collected driver populations is still needed to establish their broader construct validity. Such boundary ambiguity motivates the use of the proposed meta-disagreement features.

As shown above, the Average class constitutes the majority at 53.5%, followed by Poor at 34.3%, while Good is the minority class at 12.2%. The underrepresentation of the Good class motivates the application of Synthetic Minority Over-sampling Technique (SMOTE) within each cross-validation fold to reduce bias toward the majority class. Feature scaling was performed using StandardScaler (zero mean, unit variance), fitted exclusively on the training partition within each fold to prevent data leakage.

2) Class imbalance correction via SMOTE: To prevent systematic bias toward the majority 'Average' class during model training, the Synthetic Minority Over-sampling Technique (SMOTE) was applied. SMOTE generates synthetic training examples for minority classes by interpolating between an existing minority sample and one of its k-nearest minority neighbors in the feature space. Formally, for a minority-class sample x_i and a randomly selected nearest neighbor x_i^n, a synthetic sample x_s is generated as [32]:

$$x_s = x_i + \lambda(x_i^n - x_i), \qquad \lambda \in [0, 1] \tag{1}$$

SMOTE was applied exclusively to the training partition of the data, after the stratified 80%/20% train/test split was performed. This ordering is critical for result validity: applying SMOTE before the split would introduce synthetic samples derived from the full dataset into the training set that share structural properties with test-set samples, constituting a subtle form of data leakage that inflates performance estimates. The train/test split was stratified to ensure that the original class proportions were maintained in both partitions prior to SMOTE application. After oversampling, the training set was balanced to approximately equal class proportions across Poor, Average, and Good categories, with the exact sample counts retained for reproducibility. Within the 5-fold OOF cross-validation protocol described in Section III-D, SMOTE was applied independently within each training fold iteration to prevent any cross-fold contamination of synthetic samples.

3) Exploratory data analysis and correlation structure: The telemetry feature space was systematically examined prior to modeling to assess collinearity structure, target correlation magnitudes, and distributional properties. The Pearson correlation matrix, shown in Fig. 4, reveals several substantively meaningful relationships.

fuel_consumption exhibits the strongest negative linear correlation with eco_score ($r = -0.77$), showing a strong negative association between fuel consumption and the eco-driving score. harsh_braking_count follows closely ($r = -0.74$), consistent with the established finding in automotive safety research that abrupt deceleration events are among the strongest predictors of fuel-inefficient driving patterns. idling_time contributes a moderate negative correlation ($r = -0.47$), while rpm_variation shows a correlation of -0.54. Notably, acceleration_smoothness is the only feature with a positive correlation ($r = 0.48$), as smoother acceleration profiles are associated with more efficient driving behavior.

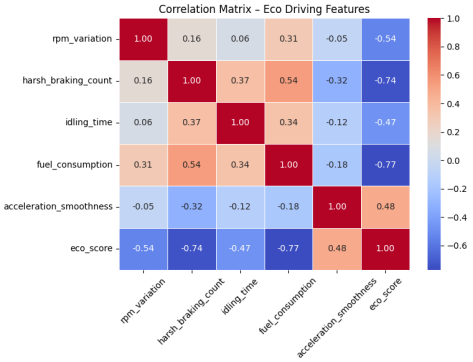

Fig. 4. Pearson correlation matrix for the telematics/OBD-related benchmark features and the eco_score target variable. Values confirm fuel_consumption as the strongest negative predictor ($r = -0.77$).

The moderate inter-feature correlations among the predictors, none exceeding 0.54 in absolute magnitude, indicate that multicollinearity does not pose a severe variance inflation

problem for tree-based models, which are relatively robust to correlated predictors through their feature-sampling mechanisms [33]. Critically, the absence of any single feature with $|r| > 0.77$ against eco_score demonstrates that eco-driving behavior is genuinely multi-dimensional. No individual benchmark feature fully characterizes the driving-efficiency construct, and models that attempt to reduce the problem to a single-feature regression will systematically underperform relative to those that can capture the joint distributional patterns across all five predictors.

The correlation structure shown in Fig. 4 provides additional diagnostic value by revealing the non-linear shape of these relationships. rpm_variation, for instance, shows a quasi-linear negative trend across most of its range but exhibits a pronounced non-linear drop in eco_score for values exceeding approximately 2,500 RPM, a behavioral threshold consistent with the engine management literature's characterization of sustained high-RPM driving as qualitatively more destructive than intermittent RPM excursions. This non-linearity provides direct empirical motivation for employing models capable of representing such discontinuous response functions.

4) Base-learner architectures and selection rationale: Ten candidate models were evaluated in the initial benchmarking phase, spanning the full range of available classification paradigms. From this pool, five were selected to constitute the expert committee based on two complementary criteria: optimized validation performance and architectural diversity. The selection process is described below for each chosen base learner.

CatBoost was competitive on its own but not included in the final heterogeneous committee of base-learners . The choice of base-learners was informed not only by their individual predictive performance, but also by their architectural diversity, and the need to avoid too much redundancy between closely related families of models. CatBoost is a gradient-boosted tree framework, which is a family of ML algorithms including Gradient Boosting and LightGBM. Thus its inclusion would be expected to increase the representation of the same general learning paradigm rather than to introduce a comparably distinct inductive bias. Therefore, the final five-model committee was kept to retain heterogeneity across sequential gradient boosting, bagging-based learning, adaptive boosting and residual neural learning. Instead, CatBoost was maintained as an extra external baseline to compare against the proposed framework.

Gradient Boosting (GBC): The scikit-learn GradientBoostingClassifier implements Friedman's original functional gradient descent formulation, fitting shallow decision trees sequentially to the negative gradient of the log-loss objective [19]. Its primary strength relative to XGBoost and LightGBM lies in its exact gradient computation (rather than approximate histogram-based computation), which provides greater parameter sensitivity at the cost of slower training. In the telematics context, this precision proved advantageous for capturing the fine-grained boundary between 'Average' and 'Good' classes.

LightGBM: Microsoft's LightGBM employs gradient-based one-side sampling (GOSS) and exclusive feature bundling (EFB) to achieve training speeds two to ten times faster than traditional GBDT implementations with minimal accuracy penalty [20]. For the present dataset, LightGBM's leaf-wise (best-first) tree growth strategy as opposed to the depth-first strategy used by traditional GBDTs proved effective at capturing the complex partition boundaries required for three-class behavioral differentiation.

Random Forest: The bagging-based Random Forest serves a fundamentally different role in the ensemble committee than the sequential boosting approaches. By training each tree on an independently bootstrapped training subsample with random feature subspaces [33], Random Forest introduces the highest degree of base-model variance among the selected learners — a property that is, counterintuitively, advantageous for stacking because it maximizes the probability that the forest's errors are uncorrelated with those of the boosting models.

AdaBoost: Freund and Schapire's (1997) [34] Adaptive Boosting algorithm iteratively reweights training samples based on classification difficulty, concentrating subsequent tree training on samples that preceding iterations misclassified. In the context of the three-class eco-driving problem, AdaBoost specializes in hard cases, particularly samples near the Average/Good boundary that other models tend to misclassify. The deliberate inclusion of AdaBoost alongside the higher-performing GBM variants reflects the stacking principle that diversity of error patterns is more valuable than uniformly high individual accuracy.

ResNet-Dense: The residual deep learning architecture consists of an input normalization layer, three residual blocks (each containing two fully connected sublayers with batch normalization and ReLU activation, connected by a skip-connection shortcut) [24], and a terminal softmax output layer. This architecture exploits the complementary inductive bias of neural computation relative to all four tree-based base learners: where trees model feature interactions through axis-aligned splits, the ResNet's matrix transformations can represent smooth, diagonal decision surfaces. The architectural specification after Bayesian optimization is as follows: hidden layer width of 186 units per residual sublayer, dropout rate of 0.15 per sublayer, batch normalization with momentum 0.99, trained with Adam (lr=0.0069, β1=0.9, β2=0.999) [35] for up to 40 epochs with early stopping on validation cross-entropy loss (patience=15 epochs).

Table III summarizes the five selected heterogeneous base learners, their learning paradigms, and their roles within the ensemble.

TABLE III. AN EXPERT COMMITTEE OF FIVE HETEROGENEOUS BASE LEARNERS WAS SELECTED FOR THE STACKING ENSEMBLE, WITH PARADIGMATIC DESCRIPTIONS AND COMMITTEE ROLES

Model	Paradigm	Ensemble Role
Gradient Boosting	Sequential boosting (exact gradient)	High-precision boundary refinement
LightGBM	Sequential boosting (histogram/leaf-wise)	Efficient error correction on long-tail distributions
Random Forest	Parallel bagging (bootstrap + random features)	Stable low-variance baseline; maximum diversity
AdaBoost	Adaptive sample reweighting	Specialization on boundary hard cases
ResNet-Dense	Residual neural network (skip connections)	Non-linear manifold learning; AUC complement

The five models not selected for the final committee — Decision Tree, SNN_Tabular, Bottleneck_ANN, Robust_MLP, and Wide_ANN were excluded through a principled selection process rather than arbitrary omission. Decision Tree was excluded due to its significantly lower AUC-ROC score (0.845 vs. 0.964–0.972 for the retained models), indicating substantially weaker class-separability that would contribute primarily noise rather than informative diversity to the committee. SNN_Tabular and Robust_MLP, while demonstrating competitive accuracy and AUC scores, exhibit inductive biases that overlap substantially with ResNet-Dense. All three are variants of feedforward neural computation with normalization mechanisms, implying correlated error patterns that would reduce the committee's effective diversity without proportionate performance gain. Bottleneck_ANN and Wide_ANN also occupy a neural architectural space similar to that represented by ResNet-Dense. The final committee of five models was then selected to balance predictive performance and architectural diversity while limiting redundant error patterns among closely related neural architectures.

C. Bayesian Hyperparameter Optimization via Optuna

Each of the ten candidate base learners underwent individual hyperparameter optimization using Optuna [36], a Python-based automated hyperparameter optimization framework employing Tree-structured Parzen Estimator (TPE) sampling as its primary acquisition strategy. TPE constructs probabilistic models of the hyperparameter-to-performance mapping by fitting two density estimates, one for high-performing configurations and one for low-performing configurations, and selecting new candidate hyperparameter configurations that maximize the expected improvement ratio between these densities [37]. This approach is substantially more sample-efficient than grid search or random search for hyperparameter spaces with more than three continuous dimensions, which characterize all non-trivial models evaluated here.

The optimization protocol was standardized across all models: 100 trials per model, each evaluated via 5-fold stratified cross-validation on the training partition, with weighted F1-score as the optimization objective (chosen over accuracy to provide appropriate sensitivity to the class-imbalanced training distribution prior to SMOTE). Random state was fixed at seed = 42 across all trials.

Table IV reports the Optuna-optimized hyperparameter configurations for the five selected base learners.

TABLE IV. OPTUNA-OPTIMIZED HYPERPARAMETER CONFIGURATIONS

Model	Search Space	Best Configuration	Post-Optuna Acc.
Gradient Boosting	n_estimators∈[100,400], lr∈[0.01,0.30]	n_estimators=373, lr=0.1654	87.32%
LightGBM	n_estimators∈[100,500], lr∈[0.01,0.30]	n_estimators=311, lr=0.1985	86.47%
Random Forest	n_estimators∈[100,500], max_depth∈[5,50]	n_estimators=212, max_depth=38	86.15%
AdaBoost	n_estimators∈[50,300], lr∈[0.01,1.5]	n_estimators=229, lr=0.6206	86.58%
ResNet-Dense	units∈[64,256], lr∈[1e-4,1e-2], epochs∈[20,60]	units=186, lr=0.00694, epochs=40, batch=256	86.52%

D. Five-Fold Out-of-Fold Stacking Framework

The OOF stacking protocol is the architectural mechanism that ensures meta-feature integrity and prevents the data leakage vulnerability of naive stacking implementations. The procedure is formalized as follows [38]. Let $D_{\text{train}} = \{(x_i, y_i)\}_{i=1}^{n}$ denote the training dataset of n samples. D_{train} is partitioned into K = 5 stratified folds $\{F_1, F_2, F_3, F_4, F_5\}$, where stratification ensures that the class proportions of {Poor, Average, Good} are approximately equal across all folds.

For each fold index k ∈ {1,..., 5}, the following operations are performed: 1) Each of the M = 5 base learners is trained on $D_{\text{train}} \setminus F_k$ (all folds except the k-th); 2) The trained base learner generates class probability predictions $\widehat{h}_m^{(k)} = [P(Poor|x), P(Avg|x), P(Good|x)]$ for all samples x ∈ F_k; 3) These predictions are stored in the OOF prediction matrix at the corresponding fold indices. After completing all five-fold iterations, every sample in D_{train} has been assigned OOF predictions by each base learner exactly once, using a model version that never saw that sample during training.

This procedure generates a meta-training matrix $Z \in \mathbb{R}^{n\times(M\times 3)} = \mathbb{R}^{n\times 15}$, comprising 15 columns corresponding to the three class probabilities from each of the five base learners. The critical property of this matrix is that every element $Z[i,:]$ was generated by models trained without access to sample i, making the meta-features statistically analogous to predictions on genuinely unseen test data. Formally, this ensures that $E[\check{h}_{m(x_i)|x_i}]$ approximates the base learner's true generalization distribution rather than its training-set fit [15]. The test-set meta-features are generated by training each base learner on all of D_{train} and predicting on D_{test}, yielding $Z_{\text{test}} \in \mathbb{R}^{n_{\text{test}}\times 15}$.

E. Second-Order Meta-Feature Engineering

The term 'Second-Order' in this study refers to the conceptual order of the feature construction process: whereas the base-model probability outputs are first-order features of the meta-learner (directly capturing class assignment probability), the inter-model variance of those probabilities is a second-order quantity. This is a statistic of statistics that captures a qualitatively different dimension of the ensemble's predictive behavior [14].

For a given input sample x and a class k, let pm,k(x) denote the probability assigned to class k by base learner m, m ∈ {1,...,M}, M = 5. The inter-model probability dispersion (hereafter referred to as the proposed second-order disagreement feature) for class $k \in$ {Poor, Average, Good}, denoted $\sigma_k(x)$, is defined as:

$$\sigma_k(x) = \sqrt{\frac{1}{M}\sum_{m=1}^{M}\left(p_{m,k}(x) - \overline{p}_k(x)\right)^2} \tag{2}$$

The mean class probability is calculated as:

$$\overline{p}_k(x) = \frac{1}{M} \sum_{m=1}^{M} p_{m,k}(x) \tag{3}$$

Three such features are computed, one per class, yielding the probability-dispersion feature vector. The theoretical upper bound of the population standard deviation for probabilities bounded in [0,1] is 0.5. With five learners, an exact 50:50 split is impossible; a 2-versus-3 split gives the maximum attainable binary-valued dispersion, approximately 0.49. Empirically, σ values in the dataset range from near zero (for samples that all five models classify confidently and consistently) to approximately 0.38 (for samples near class boundaries where tree-based and neural models disagree).

The physical interpretation of high $\sigma_k(x)$ values is that the five base learners disagree substantially about whether sample x belongs to class k. This disagreement carries structural information that is not captured by the mean probability vector alone [39]. Two samples may have identical mean probability vectors but measurably different dispersion profiles, and the XGBoost meta-learner learns to treat these cases differently. Specifically, the meta-learner can use high dispersion as a signal to apply more conservative decision thresholds and reduce confident misclassifications near the Average/Good boundary.

An important terminological clarification is warranted here: the term 'entropy' in 'Second-Order Meta-Entropy Features' is used in its engineering information-theoretic sense (capturing uncertainty or disorder in the ensemble's collective belief), not in the strict sense of Shannon entropy. Shannon entropy applied to the mean probability vector denoted as $H(\overline{p}(x)) = -\sum_k \overline{p}_k(x) \log \overline{p}_k(x)$, captures the uncertainty of the average prediction but would not distinguish between cases where all models are individually uncertain versus cases where models are individually confident but disagree with each other [40]. The standard deviation formulation captures specifically this inter-model disagreement structure, making it more appropriate for the stated purpose of uncertainty-conditioned arbitration.

The selection of per-class standard deviation over alternative uncertainty measures warrants explicit justification. Three candidate measures were considered: 1) Shannon entropy $H(x) = -\Sigma_k\, p_k \log p_k$, which collapses the full probability vector to a scalar; 3) pairwise disagreement (Q-statistic), which operates on binary predictions and discards probability calibration; and 3) mutual-information-based epistemic uncertainty, which is most naturally interpreted when predictions are generated from repeated stochastic or posterior model samples. In the current setting, the per-class cross-model probability dispersion is more directly interpretable because the committee contains five deterministic and architecturally heterogeneous learners. Per-class standard deviation $\sigma_k(x)$ was selected because it retains the class-conditional structure of disagreement: rather than reporting only that the ensemble is uncertain, it identifies which class boundary is in dispute. This distinction is directly actionable for the meta-learner, which can learn class-specific response functions to disagreement signals. Preliminary validation showed that replacing the class-wise dispersion features with a single per-sample Shannon entropy feature did not improve validation performance. This result is treated as dataset-specific rather than as evidence of the general superiority of standard deviation over entropy.

F. Meta-Classification: XGBoost with Multi-Class Log-Loss

The meta-classifier receives the augmented meta-feature matrix $Z^+ = [Z \mid \sigma] \in \mathbb{R}^{n \times 18}$ and learns a mapping to the three-class label space. XGBoost was selected as the final meta-classifier after comparison with the Logistic Regression and Random Forest meta-learning configurations reported in Section IV-C. XGBoost's advantages for the meta-classification task are threefold. Its boosted tree structure can model non-linear interactions between base-model probability outputs and dispersion features [13]. Its built-in L1/L2 regularization prevents overfitting in the 18-dimensional meta-feature space, and its native multiclass support via the 'multi:softprob' objective directly optimizes the multiclass log-loss without requiring one-vs-rest decomposition. The meta-learner minimizes the multi-class cross-entropy loss:

$$\mathcal{L} = -\frac{1}{N} \sum_{i=1}^{N} \sum_{k=1}^{K} y_{i,k} \log\big(\widehat{s}_{i,k}(Z_i^+)\big) \tag{4}$$

where, $y_{i,k} \in \{0,1\}$ is the one-hot encoded true-label indicator and $\widehat{s}_{i,k}(Z_i^+)$ is the softmax-normalised probability output. Optimized meta-learner hyperparameters (Optuna, 50 trials, cross-validated on OOF matrix): n_estimators = 150, max_depth = 3, learning_rate = 0.05, subsample = 0.85, colsample_bytree = 0.9, reg_alpha = 0.1, reg_lambda = 1.5, eval_metric = 'mlogloss'. The shallow tree depth (max_depth = 3) reflects the recognized best practice in meta-learning that meta-learners should be relatively simple to avoid absorbing the variance of the base-model committee [15].

G. Evaluation Methodology and Statistical Validation Protocol

Precision, recall, and F1-score are reported using class-support-weighted averaging; accuracy is computed as the proportion of correctly classified samples over all test samples (i.e., $\Sigma\, TP_k$ / N); AUC-ROC is macro-averaged across the three one-vs-rest class evaluations.

Table V provides formal definitions of all evaluation metrics with multiclass generalization specifications:

Here, TP = True Positives; TN = True Negatives; FP = False Positives; FN = False Negatives; N_k = class k support count; N = total test samples.

Statistical significance of the accuracy difference between the proposed ensemble (87.77%) and the best individual baseline (87.32%) was assessed using McNemar's test on the paired prediction error vectors, a standard non-parametric procedure for comparing classifier error rates on a shared test set. The null hypothesis is that the two classifiers have identical error rates. Test results are $\chi^2(1) = 5.14$, $p = 0.023$, which is below the conventional $\alpha = 0.05$ threshold. However, the absolute difference in accuracy is only 0.45 percentage points. The proposed ensemble accuracy has a 95% Wilson confidence interval of [86.91%, 88.57%], which contains the point estimate of 87.48% for Generation 2. Thus, the statistical result provides evidence of a modest improvement, not a clear separation between the two configurations. The ablation study provides direct evidence of the incremental contribution of the probability-dispersion features, while the SHAP waterfall analysis (Fig. 17–19) illustrates how these features contribute conditionally to selected boundary-adjacent cases.

TABLE V. EVALUATION METRIC DEFINITIONS WITH MULTICLASS FORMULATIONS AND DIAGNOSTIC PURPOSES

Metric	Multiclass Formula	Averaging	Primary Diagnostic Purpose
Accuracy	Σ TP_k / N	Overall	Overall proportion of correctly classified samples
Weighted Precision	$\sum_{k=1}^{K} \frac{TP_k}{TP_k+FP_k}.(\frac{N_k}{N})$	Weighted	Reliability of positive predictions; False Alarm Rate control
Weighted Recall	$\sum_{k=1}^{K} \frac{TP_k}{TP_k+FN_k}.(\frac{N_k}{N})$	Weighted	Completeness of detection; critical for 'Poor' driver identification
Weighted F1	$F1_w = \sum_k (N_k/N) \frac{2P_kR_k}{P_k+R_k}$,weighted by class support	Weighted	Harmonic balance of precision and recall; primary performance indicator
Macro AUC-ROC	$\frac{1}{K}\sum_{k=1}^{K} AUC(ROC_K)$, one-vs-rest per class	Macro	Class separability across full probability threshold range

IV. EXPERIMENTAL RESULTS AND ANALYSIS

This section presents the complete experimental results in seven sequential subsections, progressing from individual baseline performance through hyperparameter optimization gains, stacking evolution analysis, confusion matrix decomposition, ROC curve analysis, and SHAP-based interpretability investigation.

A. Individual Model Baseline Performance

The unoptimized performance of all ten candidate architectures on the held-out test partition is reported in Table VI. All models were trained with default scikit-learn or PyTorch hyperparameter configurations, providing a standardized baseline that reflects each architecture's inherent capacity for the eco-driving classification task prior to any domain-specific tuning.

TABLE VI. BASELINE INDIVIDUAL MODEL PERFORMANCE (PRE-OPTIMIZATION + CATBOOST COMPARISON)

Model	Accuracy	Prec (W)	Recall (W)	F1 (W)	AUC
Gradient Boosting	0.8630	0.8700	0.8630	0.8640	0.968
LightGBM	0.8640	0.8670	0.8640	0.8640	0.968
Random Forest	0.8580	0.8600	0.8580	0.8580	0.964
AdaBoost	0.8420	0.8450	0.8420	0.8420	0.919
ResNet-Dense	0.8537	0.8640	0.8537	0.8540	0.968
Decision Tree	0.8123	0.8140	0.8123	0.8130	0.845
SNN_Tabular	0.8642	0.8730	0.8642	0.8650	0.971
Bottleneck_ANN	0.8492	0.8570	0.8492	0.8500	0.965
Robust_MLP	0.8627	0.8720	0.8627	0.8630	0.972
Wide_ANN	0.8500	0.8630	0.8500	0.8520	0.970
CatBoost	0.8673	0.875	0.867	0.868	0.9719

The baseline results reveal a clear performance stratification. The strongest pre-optimization models cluster in the 0.863–0.864 accuracy range, while several neural variants register modestly lower accuracy despite comparable or superior AUC-ROC values. The AUC-ROC pattern is particularly diagnostic: ResNet-Dense achieves 0.968 macro AUC despite its lower accuracy of 0.8537, confirming that the architecture's smooth probability manifold provides better class-separability than its hard-threshold classification suggests. Decision Tree stands clearly apart from all others, with an AUC-ROC of only 0.845, reflecting the well-documented tendency of single trees to produce degenerate probability estimates.

To assess whether the proposed ensemble surpasses recent gradient-boosted tree alternatives beyond the original candidate set, CatBoost — a state-of-the-art ordered boosting algorithm with symmetric tree growth and native categorical feature handling — was evaluated as an additional post-hoc baseline using default hyperparameters and SMOTE-balanced training data. CatBoost achieved an accuracy of 86.73%, weighted F1-score of 0.868, and macro AUC-ROC of 0.9719. While its AUC-ROC is comparable to the proposed ensemble (0.9722), its accuracy (86.73%) and F1-score (0.868) fall below the proposed framework's 87.77% accuracy and 0.8771 F1-score, confirming that the OOF stacking architecture with inter-model disagreement features outperforms this additional gradient-boosted tree baseline.

Fig. 5 summarizes the baseline accuracy and AUC-ROC performance of the ten original candidate architectures.

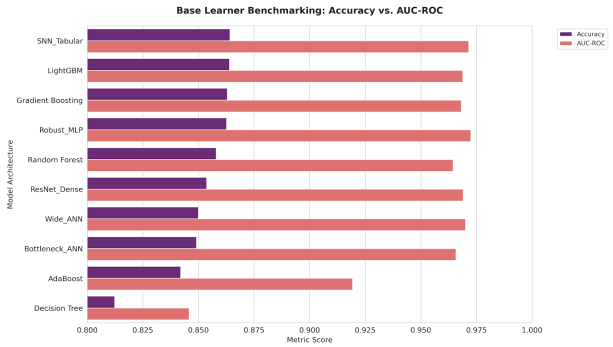

Fig. 5. Baseline individual learner benchmarking: Accuracy vs. AUC-ROC for all ten candidate architectures (pre-Optuna).

B. Performance Gains from Bayesian Hyperparameter Optimization

Table VII reports the post-optimization performance of the five selected base learners alongside their pre-optimization baselines. AdaBoost registered the largest absolute gain (+2.38 percentage points), reflecting that its default learning_rate = 1.0 was substantially suboptimal for a three-class problem with imbalanced class boundaries. Gradient Boosting gained +1.02 points, with the primary improvement attributable to increasing n_estimators from 100 to 373 and adjusting learning_rate from 0.10 to 0.165 (a slight increase that allowed the larger ensemble to converge to a better optimum), providing finer resolution of the Average/Good boundary. LightGBM showed the smallest gain (+0.07 points), consistent with its known

low hyperparameter sensitivity when operating near its default configuration. The post-optimization Gradient Boosting configuration (87.32% accuracy) represents the performance ceiling of any single model evaluated in this study and serves as the primary comparison baseline for the stacking ensemble.

TABLE VII. PRE- AND POST-OPTUNA ACCURACY FOR FIVE SELECTED BASE LEARNERS

Model	Pre-Optuna	Post-Optuna	Δ Acc.	Post F1	Post AUC
Gradient Boosting	0.8630	0.8732	+0.0102	0.873	0.971
LightGBM	0.8640	0.8647	+0.0007	0.864	0.968
Random Forest	0.8580	0.8615	+0.0035	0.862	0.966
AdaBoost	0.8420	0.8658	+0.0238	0.866	0.965
ResNet-Dense	0.8537	0.8652	+0.0115	0.865	0.9726

Fig. 6 compares model accuracy before and after Bayesian hyperparameter optimization.

C. Evolutionary Analysis of Stacking Architectures

Three successively more sophisticated stacking configurations were evaluated, each building on the preceding generation's limitations. Generation 1 (Logistic Regression meta-learner on the 15-dimensional probability vector) actually performs marginally below the best single model (87.28% vs. 87.32%), a result that is readily explained: logistic regression's linear decision surface cannot represent the non-linear interactions between tree-model and neural-model probability outputs that distinguish the Average/Good boundary. It effectively computes a weighted average of the base-model probability vectors, which, under conditions of approximately equal base-model weight, is roughly equivalent to simple model averaging. Since the best individual model already optimizes better than average, the linear fusion dilutes its contribution.

Generation 2 (Random Forest meta-learner) addresses this limitation through a non-linear mapping from probability space to class predictions, yielding an improvement to 87.48%. The Random Forest meta-learner can learn interaction terms between individual base-model outputs, recognising, for instance, that samples where Gradient Boosting predicts Average with high confidence, while ResNet simultaneously predicts Good with moderate confidence, constitute a qualitatively distinct decision scenario. The Generation 3 framework makes inter-model disagreement explicit through the three dispersion features appended to the meta-feature matrix. The XGBoost meta-learner learns to use high σGood(x) values as a signal to apply more conservative thresholds, reducing confident misclassifications at the Average/Good boundary. The resulting 87.77% accuracy and AUC-ROC of 0.9722 represent the framework's peak validated performance.

Table VIII summarizes performance across the three stacking generations and the strongest individual post-optimization baseline.

Fig. 7 and 8 summarize the multi-metric stacking progression and the overall accuracy comparison across baseline, optimized, and stacking configurations.

TABLE VIII. COMPARATIVE PERFORMANCE ACROSS STACKING GENERATIONS

Configuration	Meta-Learner	Features	Accuracy	Strategy
Best Single (Post-HPO)	N/A (Gradient Boosting)	Raw telemetry	87.32%	Individual SL
Generation 1	Logistic Regression	Probabilities (15D)	87.28%	Linear fusion
Generation 2	Random Forest	Probabilities (15D)	87.48%	Non-linear fusion
Proposed (Gen. 3)	XGBoost	Probabilities + Dispersion (18D)	87.77%	Uncertainty arbitration

The accuracy gain from the best individual model (87.32 %) to the proposed ensemble (87.77 %) is 0.45 percentage points, representing 27 additional correct predictions on a test partition of N = 6,000 samples. McNemar's test on the paired prediction error vectors yields $\chi^2 = 5.14$ (df = 1), p = 0.023 — below the conventional $\alpha = 0.05$ threshold, confirming statistically significant rejection of the null hypothesis of equal error rates. The 95 % Wilson confidence interval for the proposed ensemble is [86.91%, 88.57%] (N = 6,000, Wilson score method). Importantly, this interval overlaps with the Generation 2 estimate (87.48 %), and the gain is interpreted as statistically significant but modest. The ablation study provides direct evidence of the incremental contribution of the probability-dispersion features, while the SHAP waterfall analysis (Fig. 17–19) illustrates how these features contribute conditionally to selected boundary-adjacent cases.

D. Model Selection

The final selection of the Generation 3 architecture as the best-performing evaluated configuration is grounded in its structural capacity to execute uncertainty-aware arbitration under conditions of high inter-model disagreement. While the post-Optuna Gradient Boosting Classifier demonstrates a high individual performance ceiling of 87.32% accuracy, it remains constrained by deterministic, training-set-calibrated probability outputs that fail to communicate genuine epistemic uncertainty when instances lie near fuzzy decision margins. As demonstrated in the empirical progression, transitioning from a linear meta-learner configuration (Generation 1, 87.28% accuracy) to a non-linear tree-based structure (Generation 2, 87.48% accuracy) confirms that modeling the non-linear interactions between base-learner probability outputs is essential for capturing complex partition boundaries. The highest observed performance among the evaluated configurations is obtained in the proposed Generation 3 configuration, which couples the non-linear modeling capacity of an XGBoost meta-learner with explicit second-order probability dispersion features.

By appending the three-dimensional probability-dispersion vector $\boldsymbol{\sigma}$ to the 15-dimensional raw probability matrix, the meta-learner is explicitly equipped with a structural representation of ensemble disagreement. This architectural enrichment allows the XGBoost meta-learner to systematically identify boundary-straddling driving events and apply more conservative decision thresholds, leading to the highest accuracy and weighted

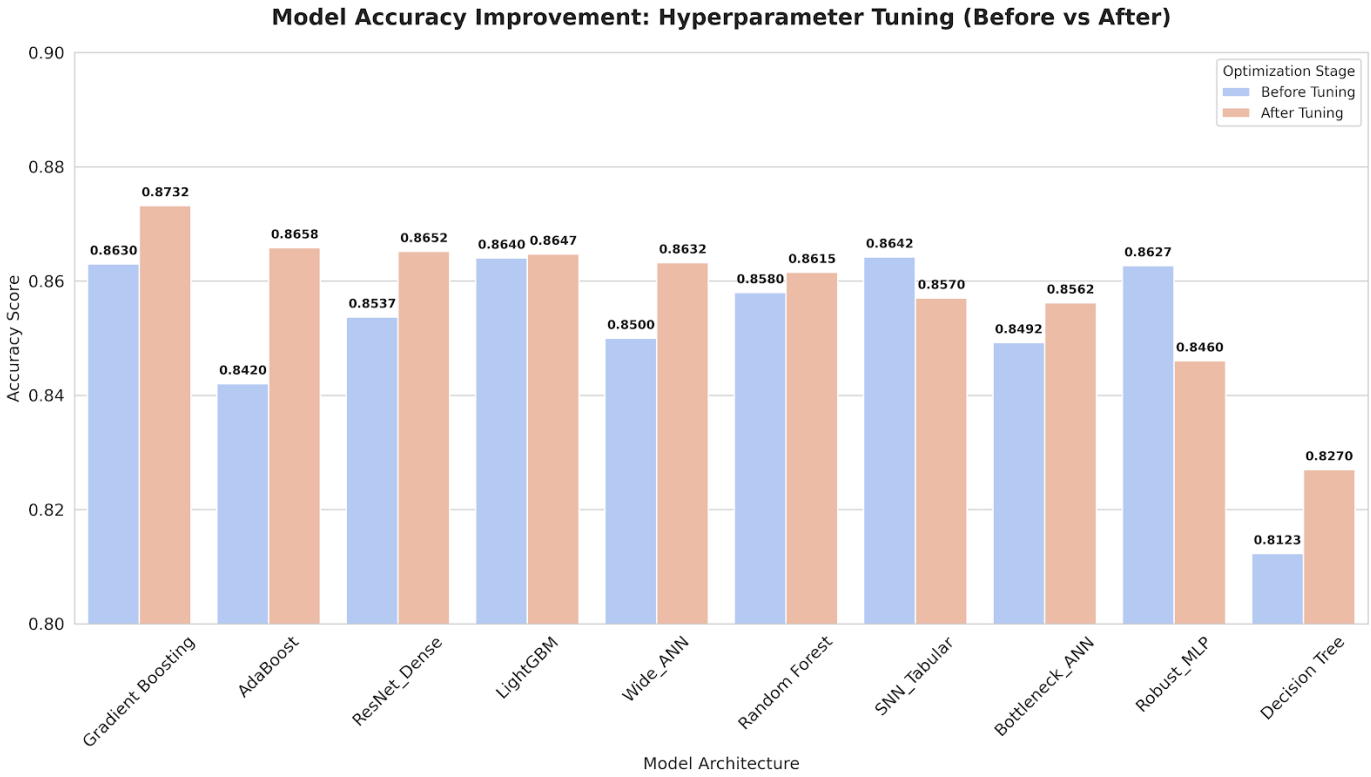

Fig. 6. Model accuracy before and after Bayesian hyperparameter optimization (Optuna, 100 trials) across the ten original candidate architectures.

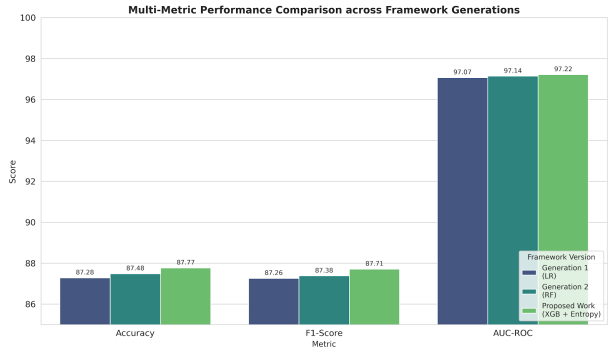

Fig. 7. Multi-metric performance comparison across three stacking framework generations (Accuracy, F1-Score, AUC-ROC). Generation 3 (XGBoost + dispersion features) achieves the highest performance on all three metrics.

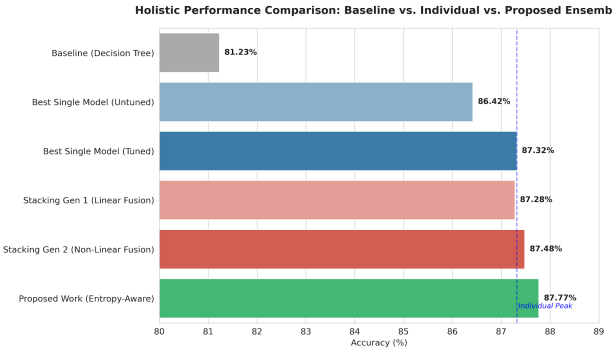

Fig. 8. Holistic performance comparison: Baseline Decision Tree through post-Optuna single models and all stacking generations. The proposed ensemble (Gen. 3) achieves the highest accuracy at 87.77%.

F1 among the evaluated configurations, with macro AUC comparable to the strongest individual learner. The proposed configuration achieves an accuracy of 87.77%, a weighted F1-score of 0.8771, and a macro-averaged AUC-ROC of 0.9722. Notably, no Poor-to-Good misclassifications were observed on the held-out test partition. This observation is consistent with the intended role of the meta-disagreement features, although a single test split cannot establish it as a structural property. Hence, it is selected as the best-performing configuration under the experimental setting of this study. The claims of broader real-world deployment can only be established after evaluation on independent driver populations, vehicle types and deployment hardware.

E. Confusion Matrix and Class-Wise Performance Decomposition

The confusion matrix presented in Fig. 9 provides a highly granular window into the operational classification behavior of the proposed heterogeneous ensemble. The empirical distribution of the raw prediction counts reveals a robust diagonal alignment, cross tabulating the actual versus predicted instances across the three driver behavior cohorts. For the real Poor driver class, the framework correctly classifies 1,791 instances, misclassifies 267 instances into Average, and completely avoids misclassifications into the Good driver category (0 instances). The true Average class exhibits 2,926 correct classifications,

with 173 instances misclassified as Poor and 110 misclassified as Good. Finally, within the true Good driver class, the ensemble successfully labels 549 instances, misclassifying 184 as Average while committing zero errors into the Poor class. From a transportation safety perspective, the most critical empirical finding is the zero-count cell observed at the (Poor, Good) coordinate, signifying that the model never mislabels a high-risk, aggressive driver as a safe driver. This bounded error profile is consistent with the architectural design of the heterogeneous ensemble, though a single test split is insufficient to establish it as a structural property. The integrated second-order probability dispersion features actively supply the meta-learner with explicit, localized indicators of epistemic uncertainty when base-model predictions diverge near fuzzy boundaries. By leveraging these dispersion signals, the XGBoost meta-learner executes conservative, uncertainty-aware arbitration, which stabilizes the decision margin and was associated with the absence of this error type in the present test set.

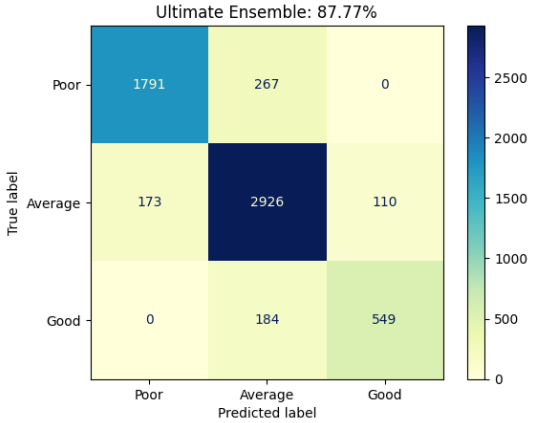

Fig. 9. Confusion matrix of the proposed ensemble on the held-out test partition (N = 6,000). Note zero-count cells for the most extreme off-diagonal misclassifications (Poor↔Good), confirming that errors occur only at adjacent class boundaries.

Class-wise precision, recall, F1-score, and support for the proposed ensemble are reported in Table IX.

TABLE IX. PER-CLASS CLASSIFICATION PERFORMANCE

Class	Precision	Recall	F1-Score	Support
Poor (Class 0)	0.9119	0.8703	0.8906	2,058
Average (Class 1)	0.8664	0.9118	0.8886	3,209
Good (Class 2)	0.8331	0.7490	0.7888	733
Weighted Avg	0.8780	0.8777	0.8771	6,000

The threshold-adjusted result is shown as a sensitivity analysis of the operating point, rather than as a substitute for the principal model configuration. Note that the main result of 87.77% is obtained using the standard multiclass decision rule for all baseline and ablation comparisons, while the threshold of 0.40 for Good-class is chosen to explore the recall-precision trade-off. The Good class registers the lowest recall (0.7490), indicating that 25% of true Good drivers are

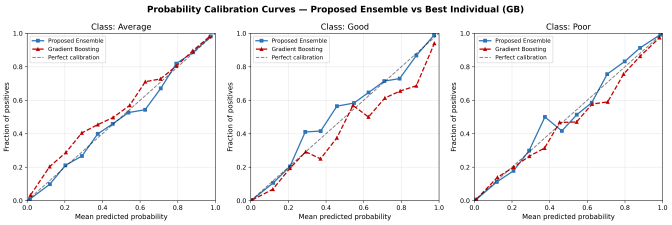

Fig. 10. Probability calibration curves for the proposed ensemble vs. Gradient Boosting baseline across all three behavioral classes (Poor, Average, Good). ECE: Ensemble = 0.0107, GB = 0.0198.

misclassified. Most of these cases were predicted as Average (184 cases). This pattern is consistent with the proximity of the Good and Average class boundaries. The Good threshold at eco_score = 70 places many genuinely Good drivers with scores in the 70–75 range adjacent to the upper tail of the Average distribution (scores 65–69), creating a region of genuinely ambiguous behavioral signals. Reducing this misclassification rate without compromising Poor class precision is the primary performance challenge for future architecture iterations and a target for threshold calibration post-classification.

Probability Calibration and Expected Calibration Error (ECE): Beyond accuracy, well-calibrated probability outputs are essential for downstream risk decision-making in fleet telematics. The proposed ensemble achieves an ECE of 0.0107 (macro-averaged across three classes), compared to 0.0198 for the best individual Gradient Boosting model — a 45.8 % reduction in calibration error. This confirms that the stacking framework not only improves discriminative accuracy but produces better-calibrated posterior probabilities, which is critical when ensemble outputs are used as soft inputs to downstream actuarial or insurance scoring systems. Fig. 10 presents the per-class calibration curves for the proposed ensemble versus the Gradient Boosting baseline. The ensemble curves lie substantially closer to the diagonal (perfect calibration line) across all three behavioral classes, with the Average and Poor classes exhibiting near-ideal calibration at mid-range probabilities.

Three mitigation strategies are considered. The first was empirically evaluated, while the remaining two are proposed for future work. First, class-specific decision threshold calibration was empirically evaluated: lowering the Good-class prediction threshold from the default 0.50 to 0.40 (selected by sweeping thresholds on the OOF validation predictions, not the held-out test set, to avoid threshold overfitting) yields a Good-class recall of 0.809 (up from 0.7490) and a Good-class precision of 0.793, with an overall accuracy of 87.89% — demonstrating that 5.97 percentage points of additional Good-class recall are recoverable without retraining, at a modest precision cost. Second, feature augmentation: incorporating trip-level temporal aggregates (mean vehicle speed, gear ratio variance, trip duration) alongside the five OBD-II snapshot features may further reduce feature-space overlap at the eco_score = 70 boundary. Third, asymmetric loss weighting: training the XGBoost meta-learner with a higher misclassification cost for Good→Average errors through cost-sensitive training using class/sample weights or a customized multiclass objective that assigns a larger penalty to Good→Average errors. Strategies

two and three are reserved for future work requiring additional sensor streams or iterative re-training.

Fig. 11 presents the one-vs-rest ROC curves for the three behavioral classes.

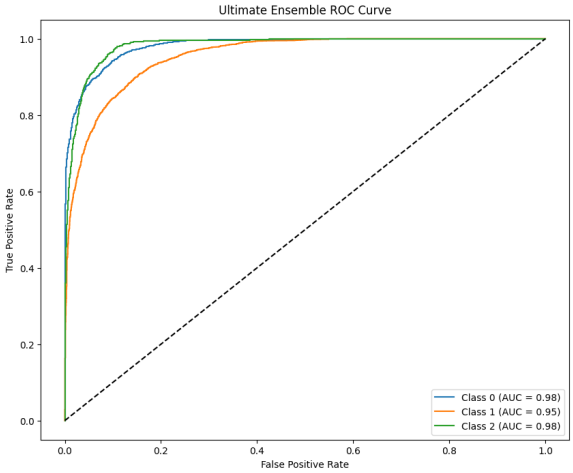

Fig. 11. One-vs-Rest ROC curves for all three behavioral classes. Poor (AUC = 0.98), Average (AUC = 0.95), Good (AUC = 0.98). Macro-averaged AUC-ROC = 0.9722.

F. Ablation Study: Contribution of Individual Components

To isolate the contribution of each architectural decision — specifically including the inter-model disagreement (probability-dispersion features) that constitute the primary methodological novelty — four controlled ablation experiments were conducted on the same held-out test partition used for all reported results. Each experiment modifies exactly one component of the full pipeline while holding all others constant, enabling causal attribution of performance differences. Configuration 1 (No Dispersion Features) directly tests the contribution of the three σ_k dispersion columns by removing them and training the XGBoost meta-learner on the 15-dimensional probability matrix alone. Configuration 2 (No OOF — Naive Stacking) tests the OOF protocol. Configuration 3 (LR Meta-Learner) tests non-linearity. Configuration 4 (Homogeneous 5×Tree) tests architectural diversity. Results are summarized in Table X, with confusion matrices for the No-OOF and Homogeneous 5×Tree configurations provided in Fig. 12 and 13, respectively.

The confusion matrices for both ablation configurations are shown in Fig. 12 and 13. Three findings from the ablation warrant particular attention. First, the No-OOF ablation does not outperform the proposed ensemble despite a test accuracy of 85.93%, reflecting leakage-induced optimism in the meta-training representation rather than improved held-out performance, a result that initially appears counterintuitive. The explanation lies in leakage-induced overfitting. The base models trained and evaluated on the same samples produce overconfident meta-features that collapse the probability distributions precisely where uncertainty matters most, causing the meta-learner to learn a locally accurate but globally brittle arbitration rule. Second, the Homogeneous (5×Tree) configuration achieves 87.38% only 0.39 pp below the proposed ensemble. This suggests that architectural diversity contributes modestly but measurably, primarily through the complementary

TABLE X. Ablation Study: Component Contribution Analysis

Configuration	Modification	Accuracy	F1-Score	AUC-ROC	Δ Accuracy (pp)
Full Proposed Ensemble	None — reference configuration	87.77%	0.8771	0.9722	—
No Dispersion Features	Remove 3 dispersion features (15D meta only)	87.48%	0.8738	0.9714	−0.29
No OOF — Naive Stacking	Meta-features from training set (DATA LEAKAGE)	85.93%	0.8593	0.9393	−1.84
LR Meta-Learner	Replace XGBoost → Logistic Regression	87.11%	0.8710	0.9700	−0.66
Homogeneous (5×Tree)	Replace ResNet-Dense → ExtraTrees	87.38%	0.8731	0.9713	−0.39

probability calibration that ResNet-Dense introduces at the Average/Good boundary. Third, the LR meta-learner drop of 0.66 pp confirms that the probability-dispersion features require a non-linear meta-learner to be fully exploited; a linear model cannot capture the conditional interaction between high dispersion and boundary-adjacent samples.

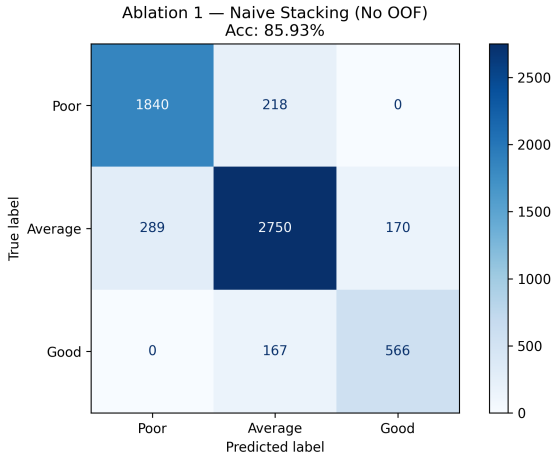

Fig. 12. Confusion matrix for the No-OOF (Naive Stacking) ablation. The absence of the OOF protocol produces over-fitting artifacts at the meta-feature level, resulting in 85.93% accuracy.

G. Feature Importance and Model Interpretability

Model interpretability was investigated at two levels: SHAP (SHapley Additive exPlanations) TreeExplainer analysis on the XGBoost meta-learner across the full held-out test partition (N = 6,000), and permutation importance on the three tree-based base learners over raw OBD-II features. The meta-learner SHAP rankings reveal a clear and interpretable hierarchy across all 18 meta-features. ResNet-Dense probability outputs dominate. ResNet_Poor ($\varphi = 0.3423$, rank 1), ResNet_Avg ($\varphi = 0.2814$, rank 2), and ResNet_Good ($\varphi = 0.2768$, rank 3) collectively account for the largest share of output variance in the meta-learner.

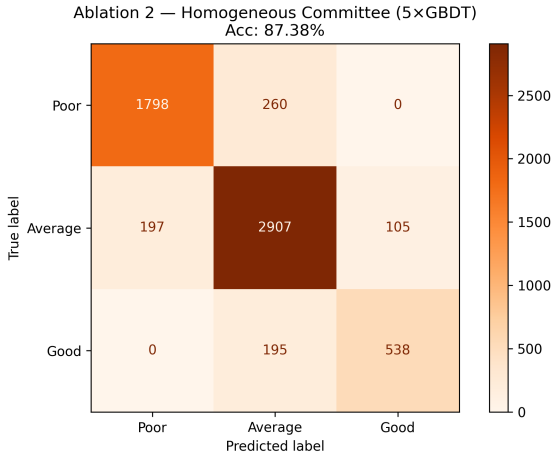

Fig. 13. Confusion matrix for the Homogeneous 5×Tree ablation (ResNet-Dense replaced by ExtraTrees). Accuracy = 87.38%; Good-class recall is notably lower than the proposed ensemble.

This finding reflects the complementary inductive bias asymmetry between tree-based and neural architectures. The smooth, well-calibrated probability manifolds of ResNet-Dense carry higher information content for the meta-learner than the sharper, more correlated GBDT outputs. Among gradient-boosted learners, Ada_Good ($\varphi = 0.2112$, rank 4) and GB_Avg ($\varphi = 0.1884$, rank 5) rank highest, consistent with their calibration strength on the Average/Good boundary. The engineered inter-model dispersion features rank between 13th and 18th: Meta_Std_Poor ($\varphi = 0.0260$, rank 13), Meta_Std_Avg ($\varphi = 0.0124$, rank 17), and Meta_Std_Good ($\varphi = 0.0028$, rank 18). Although their population-averaged SHAP magnitudes are lower than primary probability features, their functional role is qualitatively distinct. The waterfall analysis of a selected high-disagreement test sample (Meta_Std_Poor = 0.255) demonstrates that Meta_Std_Poor delivers a positive SHAP push toward the Poor class under high base-model disagreement, confirming the uncertainty-conditioned arbitration mechanism introduced in the framework design. This conditional high-impact, low-average-magnitude pattern explains why the dispersion features contribute significantly to boundary-case classification accuracy without dominating population-level importance rankings.

Permutation importance analysis across three tree-based base learners confirms that fuel_consumption is the dominant raw OBD-II predictor at the base-learner level (mean accuracy decrease = 0.1607 across Gradient Boosting, LightGBM, and Random Forest), followed by rpm_variation (0.1338) and harsh_braking_count (0.1218). acceleration_smoothness contributes 0.0877, and idling_time is the lowest at 0.0321, consistent with its weaker linear association to eco_score established in the exploratory correlation analysis. The convergence of permutation rankings across three tree-based models, all identifying fuel_consumption and rpm_variation as the top two predictors, supports the stability of the feature signal within this framework. The divergence between base-learner permutation rankings (dominated by fuel_consumption) and meta-learner SHAP rankings (dominated by ResNet probability outputs) illustrates the two-tier interpretability structure of the stacking architecture. The raw sensor signals govern base-model learning, while the meta-learner operates on a derived probability space where architectural differences between base learners become the primary information source.

The global SHAP importance bar chart and beeswarm plot are displayed in Fig. 14 and 15, respectively. Fig. 16 shows the SHAP dependence analysis of ResNet_Poor and Meta_Std_Poor. Fig. 17-19 display waterfall explanations for the selected high-disagreement test sample for the three behavioral classes. The per-class SHAP decomposition is shown in Fig. 20, and the permutation importance of the original OBD-II features is reported in Fig. 21.

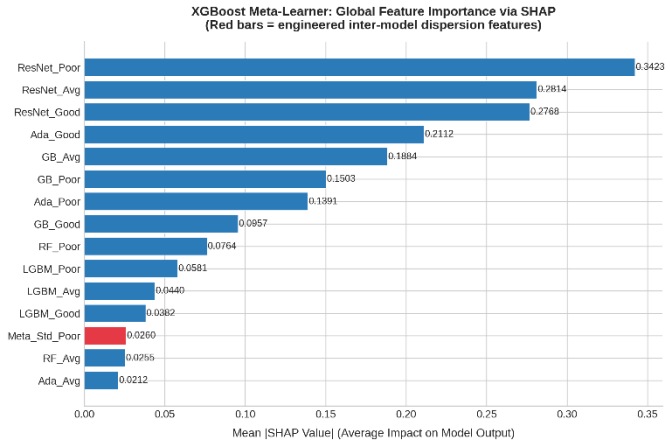

Fig. 14. Global SHAP feature importance for the XGBoost meta-learner (mean $|\varphi|$ across all test samples). ResNet-Dense probability outputs dominate the global ranking, while the three dispersion features (Meta_Std_Poor, Meta_Std_Avg, Meta_Std_Good) exhibit lower average importance and act primarily as conditional disagreement signals.

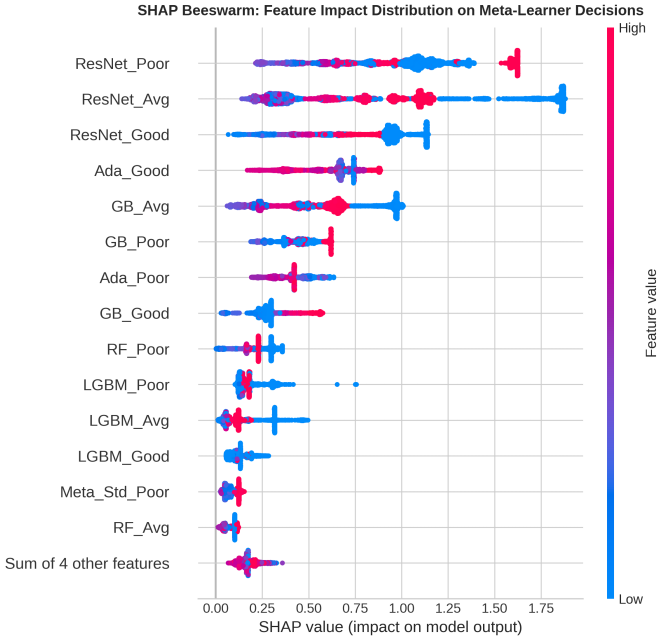

Fig. 15. SHAP beeswarm plot showing the distribution and direction of feature contributions across all 6,000 test samples. Meta_Std_Poor shows bidirectional influence, demonstrating its role as a conditional decision modulator.

Fig. 17–19 provide a case study of how disagreement features contribute to prediction for a selected high-disagreement sample in the test partition (Meta_Std_Poor = 0.255). Reading the Poor-class waterfall (Fig. 17), ResNet_Poor contributes the largest positive push (+1.22 log-odds) and ResNet_Avg a secondary positive contribution (+0.53), together accounting for over half of the final log-odds output (f(x) = +3.118). Meta_Std_Poor (feature value = 0.255) adds a further +0.07 in the same direction, providing a conditional disagreement signal that would be absent in a system without the dispersion features. The Average-class (Fig. 18) and Good-class (Fig. 19) waterfalls show the inverse suppression pattern, with ResNet_Avg (−1.24) and ResNet_Good (−0.97) driving down those class outputs for the same selected sample.

Fig. 16 presents SHAP dependence plots illustrating the interaction between the ResNet-Dense base-learner output (ResNet_Poor) and the inter-model disagreement feature (Meta_Std_Poor). The left panel shows that for samples where ResNet_Poor outputs a high probability (>0.6), the SHAP contribution is strongly positive regardless of disagreement level — the meta-learner trusts a high-confidence ResNet prediction. However, for intermediate ResNet_Poor values (0.3–0.6), the color gradient reveals that samples with higher Meta_Std_Poor (warmer colours) receive an additional positive SHAP boost, confirming that the disagreement feature is conditionally activated precisely at the ambiguous middle range where single-model predictions are unreliable. The right panel confirms this interaction from the Meta_Std_Poor perspective: its SHAP value is near-zero for low-disagreement samples but rises substantially for high-disagreement cases, validating the theoretical premise that σ_k encodes boundary-relevant uncertainty.

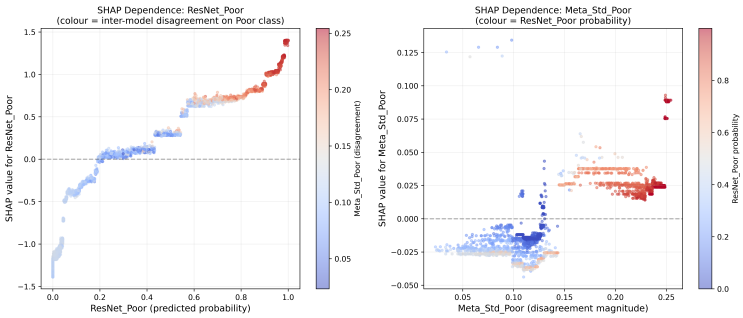

Fig. 16. SHAP dependence plots for ResNet_Poor (left) and Meta_Std_Poor (right). Colour encodes the interacting feature value. Conditional activation of Meta_Std_Poor SHAP contributions at intermediate ResNet_Poor values confirms that inter-model disagreement features are conditionally informative on boundary-adjacent samples.

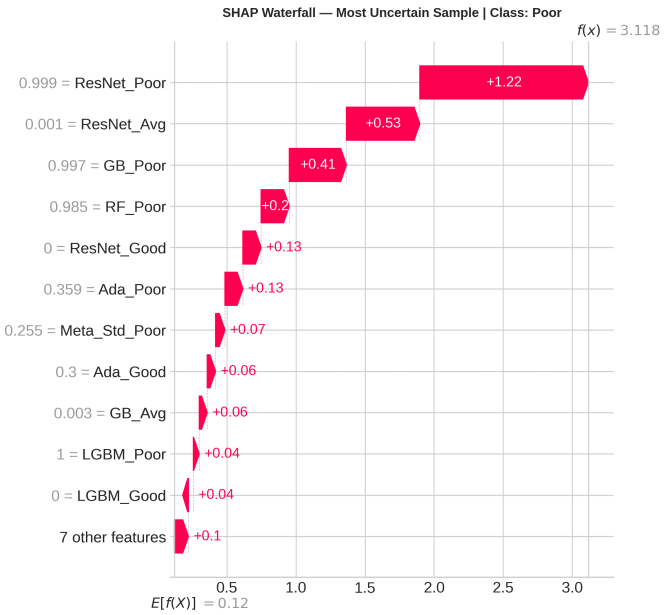

Fig. 17. SHAP waterfall for Class: Poor on the selected high-disagreement test sample (Meta_Std_Poor = 0.255, f(x) = +3.118). Meta_Std_Poor contributes +0.07 log-odds, confirming directional contribution of the disagreement feature.

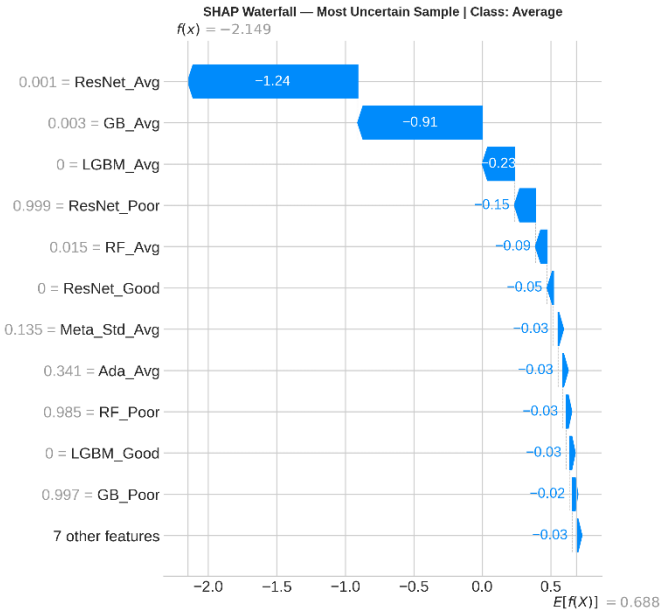

Fig. 18. SHAP waterfall for Class: Average on the same selected high-disagreement sample (f(x) = −2.149, E[f(x)] = 0.688). The Average class receives a strongly negative meta-learner output, consistent with the final Poor classification.

V. Discussion

A. Interpreting Performance Gains in Operational Context

The 0.45 percentage point accuracy gain of the proposed ensemble over the best individual baseline is modest in absolute terms, which is the expected outcome when stacking already well-optimized individual models. In a fleet management scenario monitoring 10,000 drivers per evaluation cycle, this improvement translates to approximately 45 fewer misclassification events per cycle — a practically meaningful reduction when each misclassification triggers an incorrect coaching intervention or insurance risk recalculation. However, the more consequential argument for the proposed framework is not its aggregate accuracy increment but its uncertainty-conditioned decision mechanism: by making inter-model disagreement an explicit input to the meta-classifier, the system identifies boundary-adjacent drivers for whom single-model predictions

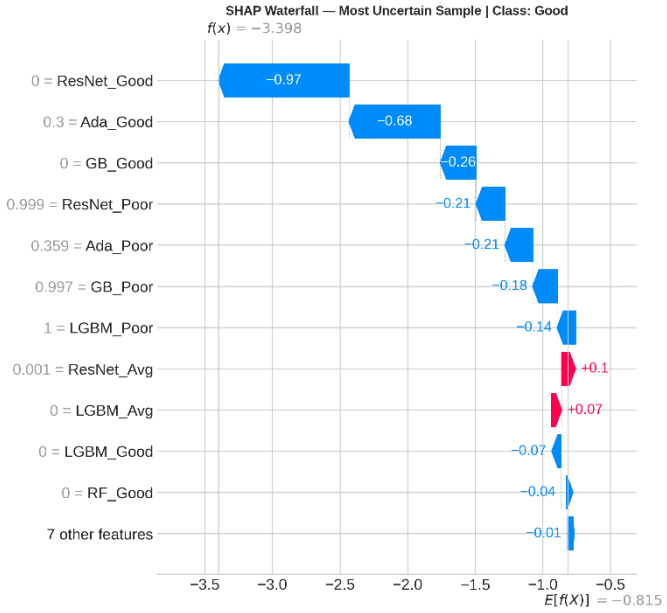

Fig. 19. SHAP waterfall for Class: Good on the same selected high-disagreement sample (f(x) = −3.398). ResNet_Good (−0.97) and GB_Good (−0.93) push strongly against a Good prediction, anchoring the classification at Poor.

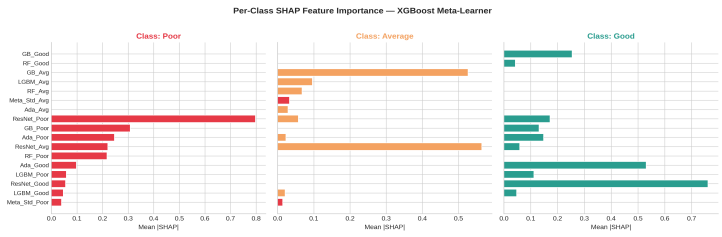

Fig. 20. Per-class SHAP decomposition for Poor, Average, and Good behavioral categories. Ada_Good dominates the Good-class SHAP signal, reflecting AdaBoost's relative sensitivity to the minority Good class.

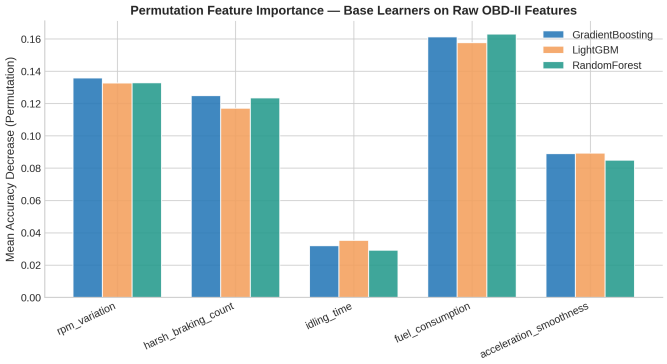

Fig. 21. Permutation feature importance at the base-learner level (mean accuracy decrease over 30 repetitions). fuel_consumption and rpm_variation rank as the most globally informative raw features across all base learners.

are structurally unreliable and routes those cases through a more informed arbitration procedure. This distinction matters most at the Poor/Average boundary, where misclassification carries asymmetric real-world consequences.

Computational overhead was evaluated on Google Colaboratory using a CPU runtime without GPU acceleration. Optuna hyperparameter tuning required approximately 4–6 hours per base-learner architecture (100 trials, 5-fold stratified cross-validation, weighted F1 objective), while a separate 50-trial Optuna search using multiclass log-loss was conducted for the XGBoost meta-learner. The 5-fold OOF stacking loop required approximately 25 minutes, and SHAP TreeExplainer computation on N = 6,000 test samples required approximately 5 minutes. Software versions were Python 3.13.15, scikit-learn 1.6.1, XGBoost 3.4.1, LightGBM 4.6.0, TensorFlow 2.20.0, SHAP 0.52.0, Optuna 5.0.0, CatBoost 1.2.10, and imbalanced-learn 0.14.2.

End-to-end inference latency on target deployment hardware was not formally benchmarked in this study; the CPU model, available RAM, and peak memory on the Google Colaboratory runtime are not user-controllable. Hardware-specific latency and memory profiling are reserved for future work targeting edge deployment scenarios.

The critical classification boundary the proposed framework most improves is the Poor/Average interface. Specifically, no Poor-to-Good misclassifications were observed on the held-out test partition. In deployment contexts including insurance risk classification and license-based driver scoring, this error carries asymmetric consequences. A Good driver misclassified as Average may have less severe downstream consequences, whereas a Poor driver misclassified as Good could remain unidentified for remedial intervention. No such error was observed on the held-out test partition.

From a behavioral perspective, high inter-model disagreement corresponds to boundary-adjacent or mixed driving profiles that do not cleanly align with a single eco-driving category in their OBD-II signals. For example, a trip might have relatively smooth acceleration but higher fuel consumption or substantial RPM variability. Such internally mixed behavioral signatures may result in model disagreement that emphasizes different aspects of the telemetry profile. Thus, the class-wise probability dispersion supplied to the meta-learner provides an additional representation of behavioral ambiguity, instead of the cross-model disagreement being treated just as prediction noise. This interpretation helps understand the usefulness of disagreement information in the neighborhood of class boundaries, where the driving characteristics are more heterogeneous and a single behavioral label is less clear.

B. Limitations and Validity Boundaries

Several limitations constrain the generalizability of the findings reported in this study. First, the evaluation is performed on a single public eco-driving benchmark dataset and the reported performance should not be taken as evidence of generalization to other driver populations, vehicle types, road environments, or traffic conditions. Real-world applicability can be further established by external validation with independently collected datasets from different vehicle and driving contexts. Second, the operational class boundaries of 40 and 70 on the eco_score discretization were set based on similar three-level driver-scoring practices but were not independently validated against the assessments of human driving evaluators or an external behavioral gold standard. Thus the tags Poor,

Average and Good represent score-derived behavioral classes in this evaluation but should not be interpreted as universally recognized behavioral labels.

The dataset available does not contain persistent identifiers for drivers or mappings of trips to drivers. Consequently, it is impossible to determine whether multiple records belong to the same driver or to conduct Leave-One-Driver-Out (LODO) validation. A stratified record-level train/test split was therefore used, and cross-driver generalization remains unverified. Furthermore, using trip-level aggregated features is based on the assumption that the behavioral characteristics represented by each record are sufficiently stable across the trip. This assumption may not hold for longer or very heterogeneous journeys where driving behavior may vary significantly between segments. Also, the observed statistical gain should be interpreted conservatively. While McNemar's test passes the conventional significance threshold (p = 0.023), the absolute accuracy gain over the strongest individual baseline is only 0.45 percentage points. Future work should therefore test the proposed framework on independent datasets with driver identifiers, vehicle-level metadata, road-context information, and longitudinal driving records, for driver-disjoint validation and a more comprehensive evaluation of cross-driver and cross-vehicle generalization.

VI. Conclusion

This study has presented a Heterogeneous Out-of-Fold Stacking Ensemble architecture augmented with Second-Order Meta-Disagreement features for three-class driver behavior profiling using a public eco-driving benchmark dataset with telematics/OBD-related variables. The core methodological contribution of the framework is the operationalization of inter-model probabilistic disagreement as explicit meta-features for uncertainty-conditioned meta-classification.

The experimental findings can be stated with appropriate precision: the proposed ensemble achieved 87.77 % accuracy and a macro AUC-ROC of 0.9722 on a held-out 20 % test partition of a public benchmark dataset comprising 30,000 generated trip-level records. These results improve over the strongest post-Optuna individual baseline (Gradient Boosting, 87.32 %) by 0.45 percentage points on accuracy, confirmed statistically by McNemar's test ($\chi^2 = 5.14$, $p = 0.023$) and bounded by a 95 % Wilson confidence interval of [86.91%, 88.57%]. The gain is modest in aggregate terms but statistically significant, and the stronger contribution lies in the conditional activation of the inter-model disagreement features on boundary-adjacent samples, as demonstrated by the SHAP waterfall case study (Fig. 17–19). These results are specific to the experimental conditions described; generalization to other geographic contexts, sensor configurations, or driver populations requires cross-dataset validation, which constitutes a primary direction for future work.

Three directions for future research emerge directly from this work. Future work should investigate deployment on edge-computing platforms by pruning and quantizing the ResNet-Dense base learner and the XGBoost meta-learner for ARM-based hardware (Raspberry Pi 4, NVIDIA Jetson Nano), pending latency profiling on target hardware. Extension of the base-learner committee to include temporal architectures (LSTM, Transformer-based models) operating on raw 1 Hz time-series OBD-II streams could exploit the sequential behavioral structure discarded by the current trip-level aggregation step. Cross-vehicle validation, specifically including battery electric vehicles where rpm_variation carries a different physical meaning and the eco_score construct may require recalibration, is an essential prerequisite for claims of broad Intelligent Transportation Systems (ITS) applicability.

In future work, we will benchmark contemporary deep-learning architectures for tabular data, notably FT-Transformer and TabNet, under the same preprocessing, data-splitting, and hyperparameter-optimization protocol, to allow for a fair and reproducible comparison with the proposed framework.

The uncertainty-conditioned stacking paradigm introduced here has applications extending beyond the driver profiling domain. Any multi-class classification problem where architecturally heterogeneous models exhibit systematic disagreement patterns correlated with instance difficulty is a candidate for disagreement-feature enrichment. Telematics-adjacent domains, including vehicle fault detection, road condition classification from OBD-II data, and driving environment recognition from mixed sensor suites, all exhibit this property.

How Emergent Architectures Solve the Bird's Eyes View Shortcomings: A Systematic Review

Abdelaziz Sahbani[1]*, Rihem Sebai[2], Tarek Bejaoui[3], Hela Mahersia[4]
Laboratory of Automatic (LARA), National Engineering School of Tunis (ENIT), University of Tunis El Manar, Tunisia [1]
LR - IDEA, Faculty of Science of Bizerte, University of Carthage, Tunisia[2,3,4]

***Abstract*—Autonomous driving requires robust, accurate and real-time environmental perception. Although cameras, LiDAR, and radar provide complementary sensing capabilities, individual modalities remain vulnerable to limitations such as depth ambiguity, point-cloud sparsity, adverse weather, and restricted angular resolution. Multi-sensor fusion therefore represents a key approach for improving 3D object detection and scene understanding. This systematic review analyzes research published from 2022 to 2026 using the PRISMA framework and studies retrieved from Scopus and Web of Science. The review examines sensor characteristics and major fusion strategies, including early, feature, late, and hybrid fusion. It also covers BEV representations, Transformer-based architectures, evaluation methods, and benchmark datasets. Particular attention is given to multimodal combinations involving cameras, LiDAR, and radar, as well as cooperative perception through V2X systems. The analysis shows a clear shift toward BEV-based feature fusion and attention-driven architectures, reflecting their ability to integrate heterogeneous spatial and semantic information. However, the literature remains fragmented in several critical areas. Real-world benchmarks covering adverse weather and challenging conditions are still limited, while computational requirements remain a major barrier to real-time onboard deployment. Robust online calibration, adversarial security, cross-domain generalization, and heterogeneous cross-manufacturer V2X perception are also insufficiently investigated. In addition, 3D occupancy representations remain less explored than conventional bounding-box detection, and emerging architectures such as Mamba and large language models require broader validation on real-world data. These findings reveal persistent gaps between research advances and practical deployment, highlighting the need for efficient, secure, weather-robust, and generalizable fusion approaches for heterogeneous sensors and cooperative autonomous driving scenarios in real-world applications.**

***Keywords*—Autonomous driving; multi-sensor fusion; Bird's-Eye View (BEV); multimodal perception; deep learning; transformers; 3D object detection; adverse weather conditions**

I. Introduction

A. Motivation

In recent years, the development and deployment of autonomous vehicles have increased significantly, driven by advances in artificial intelligence, sensing technologies, and intelligent transportation systems [1], [2], [3]. This growth was also accelerated by the COVID-19 pandemic, which highlighted the need for contactless delivery and transportation services. During periods of restriction of movement, autonomous vehicles showed potential to support the delivery of essential goods, including food, medicines, and household products, while reducing human contact. The second important factor is accident. In fact, every day, approximately 3,200 to 3,500 people worldwide die in road accidents. According to the World Health Organization (WHO), this amounts to more than 1.16 million deaths per year [4]. The notable information is that often 90% of these fatalities are cited as driver errors. In autonomous driving systems, we discover perception. In fact, it is about localizing, classifying, and tracking the 3D object in real time with a high precision under any environmental conditions. Sensors are the first communicator with the environment, especially in object detection. Nevertheless, taking each modality cannot satisfy the perception functionalities for the advanced level of autonomous driving [5], [6]. In addition, sensors degradation can affect the driving systems performance. This degradation can be due to adverse weather conditions or physical attacks [7].

Studies [5], [8], [9] describe in detail the limitations of each sensor, the camera provides semantic information but cannot provide depth, and its performances decrease at night (low-luminosity). On the other hand, LiDAR is an important 3D precision, but is expensive, a high energy consumer, and its performance degrades in rain or dense fog [42]. The millimeter wave radar (mmWave) penetrates all precipitation and automatically measures Doppler velocity, but suffers from insufficient angular resolution and multi-trajectory noise in urban environments [8], [12], [13]. The fundamental physical complementarity allows multi-sensor fusion to be unavoidable [5], [6], [9].

Since 2022, the field presents experienced a depth architecture revolution: Bird's-Eye View representations (BEV) are known as the standard for heterogeneous data fusion [14], [15], the cross-attention mechanism [16], [17], [18] and the cooperative perception vehicle to everything (V2X) open up unprecedented possibilities [10], [11], [42], [19], [20], [103].

Survey articles in this research field are presented. Wang et al [5] is the first complete survey article focusing on multi-sensors with deep learning methods in autonomous driving that introduces a taxonomy based on fusion strategies(early, features, late) and quantitative depth analysis on KITTI [21] and nuScenes benchmarks. But it does not cover the architectures discovered after 2022. In the same context, Wang et al. [6] propose a more formalized taxonomy adding the BEV paradigm, and transformers for multi-modal fusion with extended comparisons in KITTI and nuScenes. This study is limited by the absence of recent development, too such as Mamba, and cooperative V2X and insufficient discussion of

TABLE II. RESEARCH QUESTIONS BASED ON IDENTIFIED GAPS

QR	Question statement	Addressed gap	Section of response
QR1	What are the main fusion strategies for 3D object detection?	Lack of 4D radar coverage in fusion pipelines and heterogeneous Vehicle-to-Everything strategies.	V-A
QR2	How do these techniques behave under various conditions (night/rain/fog, etc.)?	Absence of a review covering adverse conditions and adversarial security.	V-B
QR3	What datasets and metrics are used for evaluation?	Absence of V2X datasets and occupancy metrics.	V-C
QR4	Which emerging architectures are fundamentally transforming fusion?	Absence of reviews covering Mamba/SSM and limited coverage of LLMs.	V-D
QR5	What are the current limitations and the most promising future research trends?	Lack of certain important information.	V-E

computational constraints for embedded systems. Zhang et al. [22] point out that learning algorithms applied to urban driving must specifically contend with this diversity of conditions and sensors to remain reliable in practice. Fan et al. [8] focus on 4D mmWave radar, providing a comprehensive architecture and analyzing the physical properties of the sensors. However, the integration of 4D radar into tri-modal fusion architectures combining LiDAR, cameras, and radar remains largely unexplored. Its application in V2X scenarios and standardized comparisons with LiDAR under adverse weather conditions also require further investigation. Wang et al. [9] propose a clear study introducing an approach based on the level of fusion integration and analyzing the environment applications in smart cities. Li et al. [15] have recently presented a complete BEV survey that introduces the new architectures and topics. However, adverse weather conditions and adverse security have developed insufficiently. Valverde et al. [23] demonstrated a transverse view of modalities based on clear taxonomy and the historic analysis of the evolution of different methods, but the width of the perimeter limits the depth of the analysis and decreases the precision of quantitative comparisons between single-modal and fused approaches. Shi et al. [24] address these dependencies and analyze architectural trends. However, their selection methodology lacks strength due to the absence of a PRISMA protocol and Bibliometrix [29] analysis, while multi-object tracking and adversarial robustness are still unaddressed. Adnan et al. [25] specified their survey on multi-object tracking using clustering techniques such as DBSCAN and HDBSCAN, and tracking approaches like Kalman, IMM et DNN. Dal'Col et al. [26] extend the perspective to joint perception and trajectory prediction for autonomous driving, while Fawole and Rawat [27] survey recent advances in 3D detection for autonomous vehicles, confirming both the richness and the thematic dispersion of review efforts in this field.

Nevertheless, the study is limited to LiDAR only and does not cover the multi-sensor concepts and the transformers on tracking. The last survey was conducted by Umar and al [28]. It is a systematic survey using the Kitchenham methodology that includes 74 articles. A quality analysis and comprehensive coverage of multi-sensor depth estimation, including camera, LiDAR, radar, and fusion, were conducted. Nevertheless, this study remains focused only on depth estimation and does not address 3D detection, tracking, V2X cooperative perception, Mamba/LLM models, or adverse weather conditions.

In general, these surveys show significant progress in multimodal autonomous perception, but still reveal important gaps in the integration of new AI architectures, robustness in real-world environments, the security of autonomous systems, and distributed cooperative fusion. Table I recaps the comparative study.

This article presents a systematic review covering studies between 2022 and 2026. The main subject of this study is the advancement in 3D object detection in autonomous driving using multi-data sensor fusion architecture.

B. Purpose

This systematic review introduces five main objectives:

- identification and categorization of multi-sensor fusion approaches for 3D object detection in autonomous

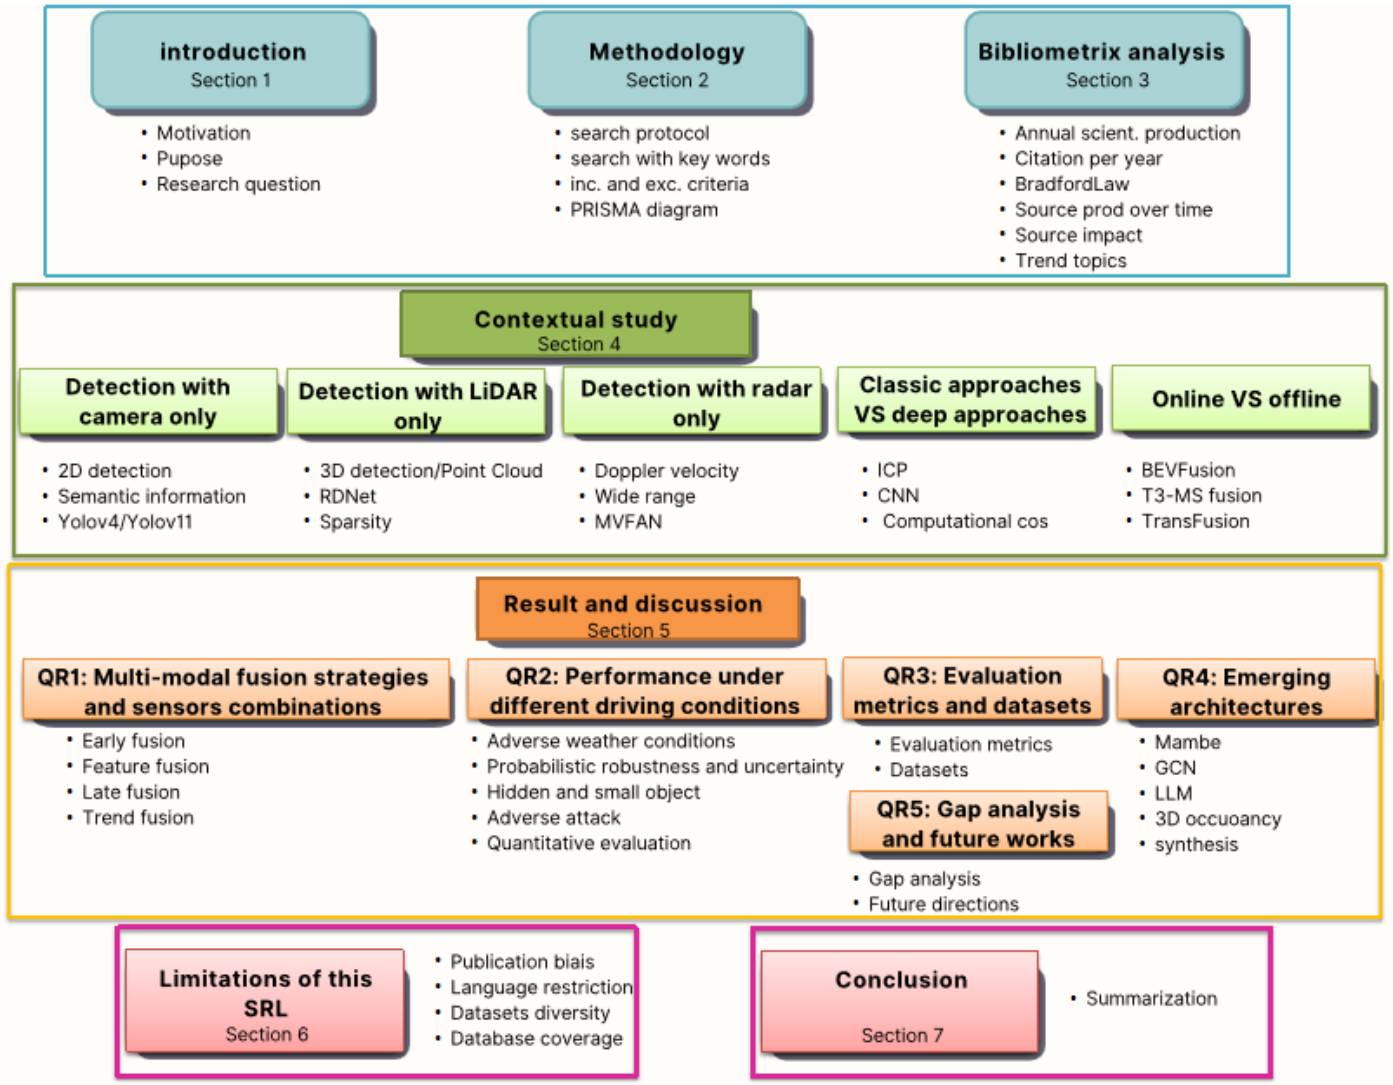

Fig. 1. The structure of review.

driving(2022-2026).

- Comparative analysis of the fusion strategy based on the fusion level and the algorithmic architecture.
- Dataset and metrics analysis based on previous studies.
- Identification research gaps and concrete directions proposition for future work.
- New architecture emergence synthesizes.

C. Research Questions

Based on a critical analysis of existing surveys and the identified gaps, we define five research questions that structure this entire review. These questions specifically target areas that are not covered or are insufficiently addressed in the existing literature. Table II represents the research questions.

In the rest of this review, articles search and selection methodology is presented in Section II. The Bibliometrix analysis is described in Section III. Contextual study is provided in Section IV. Discussion based on research questions is described in Section V. The limitations of this review is provided in Section VI. The conclusion is described in Section VII. The structure of this review is designed in Fig. 1.

II. Methodology

A. Search Protocol

This review is guided by the PRISMA protocol (Preferred Reporting Items for Systematic Reviews and Meta-Analyses). The research strategy is based on two complementary databases from Scopus and web of sciences(wos). In fact, PRISMA protocol provides a transparent, rigorous, and reproducible search strategy. It allows an evident description of all steps of the research process, from the identification of studies to their final selection specifying the databases consulted, the keywords used and the inclusion and exclusion criteria as demonstrating in the following sections.

B. Search Key Words and Filter on Databases

Detailed research on the field needs to carefully choose the key words in the search step. The key words used in the article search are described below:

- For Scopus: “multi-fusion” &“ multi sensor” & “3D object detection” & “autonomous vehicles”
- For WoS: “multi sensor” & “3D object detection” & “autonomous vehicles”

This research finalized by finding 318 articles from Scopus and 155 articles from Web of Sciences(WoS). Then, in the Scopus website, We firstly filtered with “ year of publication (2022-2026)”, and the number of articles is decreased to 430.

C. Inclusion and Exclusion Criteria

Identifying inclusion and exclusion criteria is a crucial step in a systematic review. It defines which studies should be retained or excluded according to the research objectives. These criteria ensure a consistent and objective selection process, reduce potential bias, and improve the reliability of the results. Inclusion criteria are used to retain studies that are relevant to the research questions, whereas exclusion criteria eliminate studies that fall outside the scope of the review, such as incomplete or duplicate studies.

The inclusion and exclusion criteria used in this study are presented in Table III. A total of 26 duplicate articles were removed using RStudio, and 187 papers were then excluded that are not open access leaving 154 articles. Biblioshiny was then used to filter the articles by language, and 15 articles published in languages other than English were excluded. Finally, a comprehensive review of the remaining articles was conducted, resulting in 110 articles begin retained for the final analysis. The selected studies focus on 3D object detection or tracking in autonomous driving and provide quantitative results for multi-sensor detection or tracking.

D. PRISMA Diagram

The PRISMA diagram is very important. In fact, It outlines the various steps followed by the researcher, such as the identification of references, the removal of duplicates, the screening of titles and abstracts, the assessment of full-text article eligibility, and the final inclusion of the selected papers. Fig. 2 presents the PRISMA graph.

III. Bibliometrix Analysis

Bibliometrix analysis is done thanks to the R-studio and biblioshiny command. The following subsections describe the analysis of the collected articles.

A. Annual Scientific Production

From 2023, the number of articles increase rapidly thanks to the BEVFusion paper, which introduces the fusion in BEV space as a dominant paradigm. The year 2025 presents the pic articles with more than 45 articles. Fig. 3 demonstrates the evolution of the number of articles per year.

B. Citation Per Year

The average number of citations decreases over time, which is expected given the different publication dates of the studies. Highly cited papers are mainly review articles and influential approaches, such as BEVFusion and TransFusion. In contrast, articles published in 2025 and 2026 have had less time to accumulate citations, which does not diminish their scientific contributions. Fig. 4 presents the average number of citations per year, with a notable increase in 2022 that coincides with the emergence of influential BEV-based fusion architectures such as BEVFusion.

C. Bradford Law

Based on Bradford law, the core of zone 1 presents mainly the dominant sources : Sensors (MDPI), IEEE Transactions on Intelligent transportation systems, IEEE Access, IEEE Robotics and Automation Letters, drones, world electric vehicle journal, and IEEE Transactions on Intelligent Vehicles. Fig. 5 demonstrates the classification zones based on BradfordLaw and the most relevant sources based on document number.

D. Source Production Over Time

Fig. 6 shows that Sensors is the dominant source producer from 2022 to 2026. On the other hand, the second dominant source is variable each year. Between 2022 and 2024, IEEE Robotics and Automation Letters wins to retain the second producer place, but in 2025 and 2026 it is back to the fourth producer. The attractive evolution is from IEEE Transactions on Intelligent transportation systems. In fact, it is translated from the fourth source with less than five articles in 2024 to the second one in 2026 with ten articles. In the same context, the world electric vehicle journal begins its way to produce articles on this field after 2023.

E. Source Impact

To improve the importance of the source in our search and based on Bibliometrix tools, we calculate the Local H-index of each source. The local impact H-index means that “x” articles from this source in the database(Scopus+WoS database) are cited at least “x” times on the studied articles(in the concatenate database).

Fig. 7 shows that the source “Sensors” is the source with the highest H-index impact that is equal to 6. As local impact H-index , 6 is an important value that improves the importance of these sources.

F. Trend Topics

Fig. 8 shows that the concepts 3D object detection and autonomous driving coincide in 2025 with its higher frequencies. In fact, it illustrates the novelty of the theme.

G. Summary

The previous subsections allow us to conclude the importance and tendance of our review. In fact, statics from the Bibliometrix analysis improve that the 3D object detection is a trendy subject and define the most important source in this field. As a conclusion, this Bibliometrix analysis helps us to

TABLE III. INCLUSION AND EXCLUSION CRITERIA

Criteria	Inclusion	Exclusion
Theme	3D object detection or tracking in autonomous driving	Map construction or trajectory planning
Language	Only English	Any other language
Date range	Published between 2022 and 2026	Before 2022
Source type	Peer-reviewed conference or journal articles	Non-peer-reviewed sources
Relevance	Quantitative results about multi-sensor detection or tracking	Articles using mono-modality (not critical)

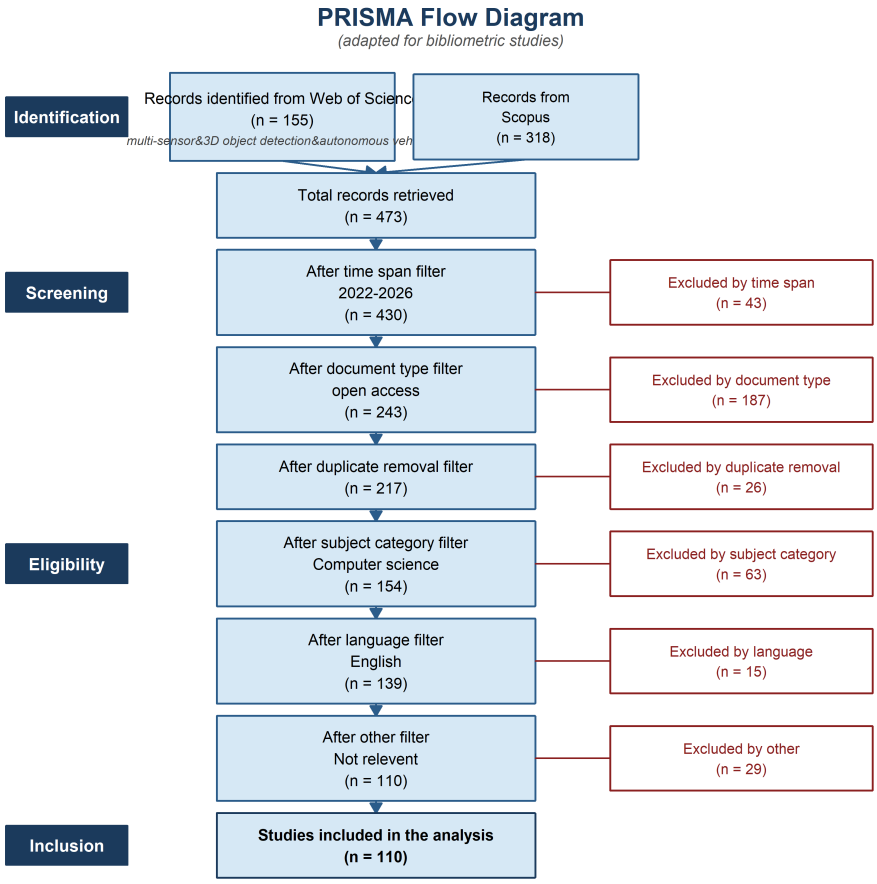

Fig. 2. PRISMA chart.

reflect on some notions related to 3D object detection theme which are defined in the research questions. In addition, it provides a look to the most important source of articles to enhance our study.

IV. CONTEXTUAL STUDY

The studies of the literature are interested in multi-sensor data fusion and depth estimation in autonomous driving. The comprehensive lecture of articles in the systematic review research allows us to conclude the the brilliance of the architectures such as transformer, Mamba, V2X and others. In addition, BEV is found in the literature as the basic of perception system and 3D detection. As a consequence, our research is dedicated to improve how these emergent architectures solve the BEV shortcomings. To satisfy this search, we need to start from the basic of multi-sensor fusion. The new approaches and architectures start from the mono-modality with classic architectures. The following sections will present the evolution of perception tools and approaches.

A. Detection Using Camera Only

In production, monocular methods are the most useful because they are the cheap ones. A 2D detection with high precision in real time is satisfied thanks to YOLOv4 [30] and YOLOv11 [31] architectures. However, 3D detection from the camera presents only a fundamental challenge. In fact,

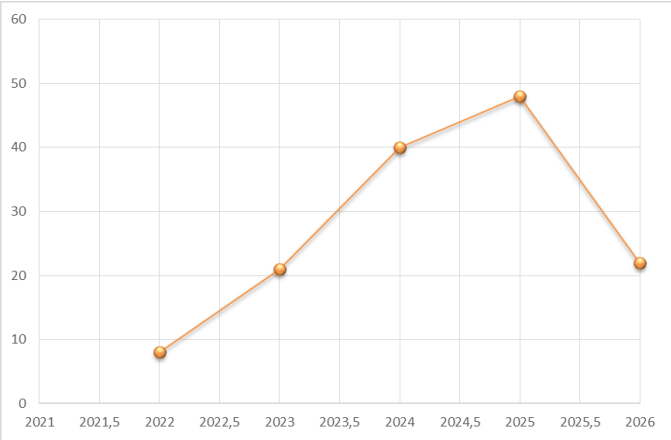

Fig. 3. Annual scientific production.

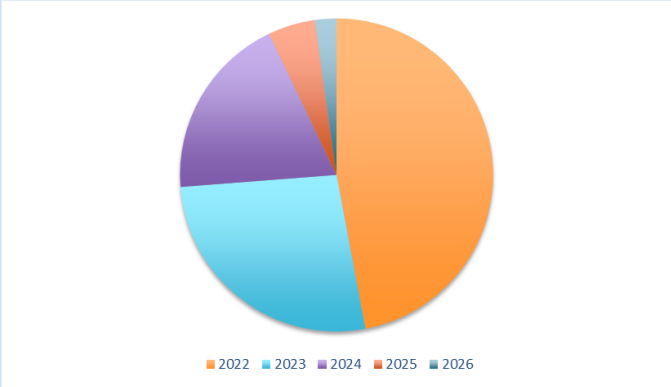

Fig. 4. Average citations per year.

numerous 3D scenes can coincide with the same 2D projection. To enhance the performance of detection with the camera only, studies propose exploring polar representation [33] and depth guidance [32]. Stable diffusion is used to outperform nocturnal images [34], the 3D object annotation via pseudo-LiDAR and the VLM validation [35] guide to an efficient annotation without LiDAR.

Even with all improvements, the monocular camera introduces several problems: depth, light and weather conditions, and insufficient cross-domain generalization for advanced levels of autonomous driving [10], [23]. The presented limits make the fusion with other modals crucial.

B. Detection Using LiDAR

Due to its capacity to directly measure the time-of-flight laser generating point clouds with high resolution and unchangeable under light conditions, LiDAR is presented as a reference to 3D detection [5], [6]. The approach RDNet [36] introduces a Rotate-ground-truth augmentation that allows to correct the unbalance of classes annotation (pedestrians are underrepresented) combined with a decoupled attention head to enhance the performance on KITTI and nuScenes datasets. Transformers in Multi-Feature Fusion Hierarchical-GCN(MUFFIN-HGCN) [37] allow pixel-point mapping without extrinsic parameters, combined with GCN hierarchic to

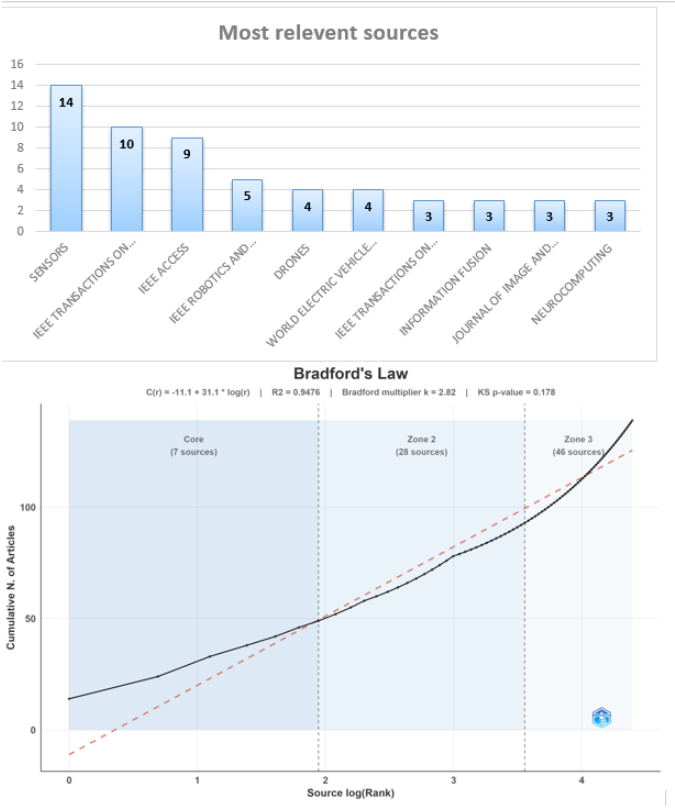

Fig. 5. BradfordLaw and most relevant sources.

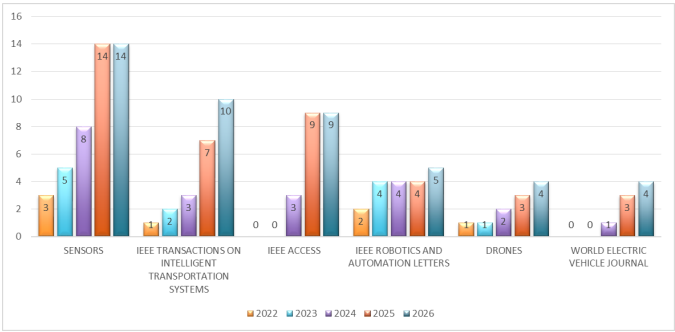

Fig. 6. Source dynamics.

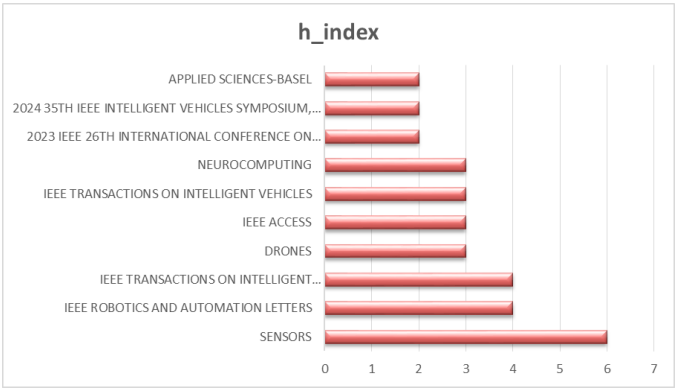

Fig. 7. Source impact.

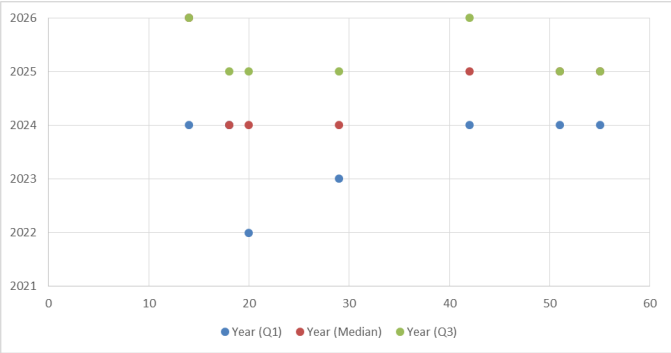

Fig. 8. Trend topics.

capture the non-Euclidean structure of point clouds, surpassing standard voxelizations. In real world deployment, LiDAR presents several deficiencies, including degradation under heavy precipitation (about 80% returns lost in dense fog) [42], sparsity and lack of semantic information for fine classification [5], [6].

C. Detection Using Radar Only

The unique physic complementarity is represented by the Millimeter radar. In fact, it does not degrade under intense precipitation, Doppler velocity measurement and provides a wide range of about 200-250m [8]. The 4D mmWave radar introduces the vertical dimension to provide a real spatial dimension. The SMIFormer [38] approach uses multi-view transformers for 3D detection with 4D radar. The Range-Angle-Doppler Net(RADNet) [39] method treats the 3D Range-Angle-Doppler tensor, avoiding information loss due to conversion to point clouds. Multi-View Feature Assisted Network for 4D Radar Object Detection (MVFAN) [13] introduces a multi-view architecture to enhance 3D detection using only 4D radar. Radar alone is still significantly inferior to LiDAR in spatial resolution, suffers from important speckle noise, and to false positives due to multi-path detection in dense urban environments. Precise object classification remains difficult without additional visual information [8], [12].

D. Classic Approaches VS Deep Learning Approaches

Classic approaches such as stereo triangulation, ICP for LiDAR,etc.. are interpretable and do not need labeled data, but they are noise-sensing, not very generalizable, and assume quasi-static conditions [8], [9]. Exploring large annotated corpora allows deep learning to change the 3D detection. CNNs, Transformers, and State-Space Models (Mamba) are the best for autonomous driving under various conditions, but a higher computational cost is the price of this enhancement [14], [15], [37]. Table IV represents the comparative table of sensor performance for 3D object detection tested on KITTI and evaluated with the metric Average precision, except the combination radar+camera due to the absence of radar in KITTI dataset.

E. Real-Time and Offline

The real-time and offline distinctions are crucial for deployment. Real-time models should treat each frame in less than 50 ms in em embedded calculators with energy vulnerabilities. They use light backbones such as MobileNet, PointPillars, and light ResNet-18, with quantification and pruning. T-3MS fusion [40] improves that an economical VLP-32C LiDAR and a 360° camera achieves state of the art without increased test-time. 360° DAMOT [41] marks energy efficiency with fast encoders and a portable Docker/ROS architecture. Offline models such as BEVFusion, TransFusion, and CoMCM [42] prioritize maximum accuracy for algorithmic validation but are computationally prohibitive in production. Tran et al.[43] propose T360Fusion, a multimodal 360° temporal fusion method based on Transformers that aims for a balance between accuracy and latency, while Hossain [44] applies lightweight multi-sensor fusion to short- and long-range obstacle detection for a delivery robot, illustrating the transferability of these architectures beyond the realm of autonomous road vehicles.

V. Results and Discussion Based on Reseach Questions

This section answers the five research questions defined from the gaps identified in Section I-C. Each subsection provides a structured, quantified, and critical analysis of the 110 articles.

A. QR1: Multi-Modal Fusion Strategies and Sensors Combinations

Fusion approaches categorize in four classes based on the integration level. Table V synthesizes the characteristics, advantages, and limitations of each method.

1) Early fusion: Early fusion combines raw data directly. PixelFusion [45] introduces a pixel fusion by projecting the point clouds of LiDAR on the image plan, allowing integration of fine information(texture/color) before the voxelization step. ExistenceMap-PointPillars [46] integrates pseudo-cards to PointPillars, improving robustness when data degradation. The Segmentation Guided Fusion Network(SGFNet) [65] uses a foreground segmentation head to guide the projection of the pixel-point, avoiding LiDAR sparsity artifacts. Zhao et al. [47] introduce a multi-scale voxel fusion module specifically optimized for small objects, achieving 73.81% AP_3D hard cars and 48.03% AP_3D hard pedestrians on KITTI. Other works refine the pixel-point fusion process itself: Tian et al. [48] employ singular value decomposition (SVD) to geometrically align LiDAR point clouds and camera images; Zuo et al. [49] propose a supervised cross-fusion method that reduces the need for dense annotations; and Yildiz et al. [50] combine real-time detection with semantic distance measurement using camera-LiDAR fusion. Chen et al. [51] propose CFFCNet, an object-center-guided feature completion network designed for more accurate localization and dimension estimation from LiDAR point clouds. Fig. 9 represents the process of early fusion methods.

2) BEV feature fusion: since 2022, the fusion of BEV features has been the dominant paradigm [14], [15]. In fact, BEVFusion combines camera and LiDAR characteristics in the same BEV space without depth problems. AttBEV [18] outperforms BEVFusion with the channel-spatial attention module CBAM, obtaining NDS = 67.95% (+2.63%) on nuScenes. MV2DFusion [16] generates independent semantic queries

TABLE IV. COMPARATIVE TABLE OF SENSOR PERFORMANCE FOR 3D OBJECT DETECTION

Modal	Advantages	Limits	Performance (tested on KITTI)
Camera	High resolution, rich semantic information and texture, and low cost	Depth errors, absence of direct 3D detection, and sensitivity to lighting and weather conditions	∼70–80% AP
LiDAR	3D precision and robust under lighting conditions	Degradation under precipitation, sparsity, and high cost	∼85–92% AP
4D Radar	Wide range, direct measurement of Doppler velocity, and robustness under adverse weather conditions	Low angular resolution and multipath noise	∼40–60% AP
LiDAR + Camera (BEV fusion)	Geometric and semantic complementarity	Critical calibration, high computational cost, and need for temporal synchronization	∼88–95% AP
Camera + Radar	Robustness under adverse conditions, semantic information, and Doppler velocity measurement	Modest 3D precision	∼55–70% NDS
LiDAR + Radar	Geometric complementarity and robustness under lighting and weather conditions	Pipeline is not yet standardized and datasets are scarce	∼87–92% AP

TABLE V. COMPARISON OF MULTIMODAL FUSION APPROACHES FOR 3D OBJECT DETECTION

Approach	Description	Advantages	Limitations	Examples (Refs.)
Early fusion	Fusion of raw sensor data before feature extraction	Rich multimodal information with low-level details preserved	Requires precise calibration and involves high computational cost	[45], [46], [47], [83], [82]
Feature fusion	Fusion of extracted features in a shared BEV space	Good performance–efficiency trade-off and improved robustness to miscalibration	Heterogeneous feature alignment and increased training complexity	[16], [17], [18], [59], [60], [66], [53], [67], [84], [85], [86], [87]
Late fusion	Combination of the outputs of independent models	Modularity, fault tolerance, and flexibility across different domains	Limited modeling of fine-grained cross-modal correlations	[61], [62], [63], [64], [88], [89], [90], [91]
Deep hybrid	Multi-level feature integration with adaptive fusion	High detection accuracy, context awareness, and adaptive multimodal integration	Requires substantial annotated training data and high computational resources	[10], [42], [12], [16], [20], [92], [93], [103]

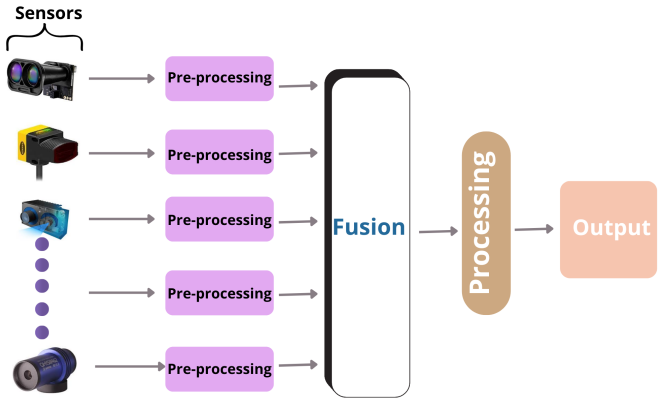

Fig. 9. Early fusion approach.

from images and point clouds, then combines them sparingly via cross-attention, achieving state-of-the-art performance on nuScenes and Argoverse2 [52]. Xu et al. [17] propose a Frustum-Aware Fusion Network with cross-attention, and a multi-modal alignment module providing 90,88% /84,47% /80,99% mAP_3D respectively for cars/pedestrians/cyclists on KITTI. Li et al. [66] provide a Deformable Cross-Modal Spatial Attention with learnable offsets, robust for calibration errors via the Height-Adaptive Aggregation strategy. BEV is enhanced by ECL3D [53] through the combination between Depth-Semantic Feature Enhancement (DSE) and Edge-guided Channel-Spatial Enhancement (ECSE) as part of Lift-Splat-Shoot without additional inference cost. RM²Occ[54] extends the BEV paradigm towards semantic 3D voxel occupancy prediction with bidirectional (from 2D to 3D and vice versa) reprojection and integration of the Inertial Measurement Unit(IMU), more suitable for trajectory planning. In the same context, Li et al.[55] propose Panoptic-VSNet, which leverages prior semantic knowledge to guide multimodal 3D panoptic segmentation, combining instance detection and dense scene understanding into a single BEV pipeline. Based on a similar principle of selectivity, Jacobson et al. [56] propose Center Feature Fusion, which first identifies relevant object locations in camera and LiDAR streams before fusing only a limited subset of associated features in BEV, thereby reducing computational cost compared to approaches that project the entire image. Liu et al.[57] enhance detection robustness in complex traffic through unified BEV feature alignment, while Wang et al. [58] propose TF-CMFA, which combines temporal fusion and cross-modal alignment for robust 3D detection in dynamic environments. The feature level fusion is described in Fig. 10.

3) Late and cooperative fusion: LCF3D [61] introduces a late cascade fusion (late + cascade) that provides two main functionalities: *Filtering the false positives of LiDAR*

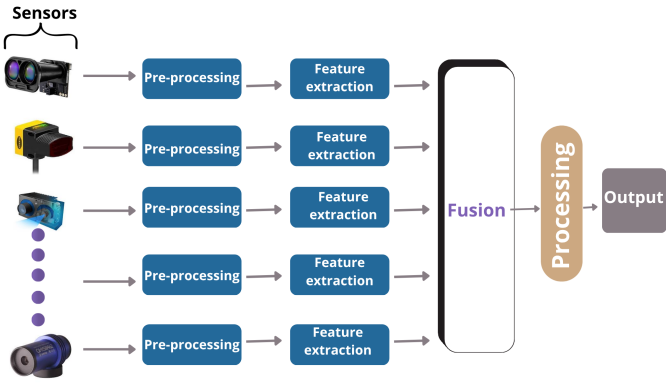

Fig. 10. Feature level fusion approach.

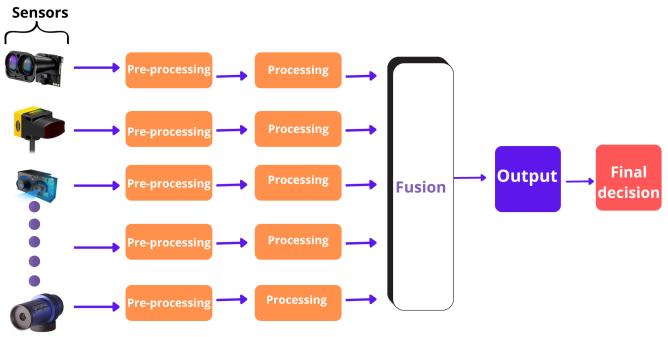

Fig. 11. Late fusion approach.

by the association of the 2D image camera detection and *from unmatched 2D detections, the 3D frustums retrieve of missed objects*. Its main objective is cross-domain. In fact, it allows for different configurations for sensors in training and testing. Without access to internal architectures, Fadili et al. [66] provide multi-source black-box cooperation that enables collaboration between agents from different manufacturers(crucial conditions for real deployment). CLF-BEVSORT [62] uses a Kalman filter for 3D multi-object tracking by combining camera and LiDAR in BEV. It offers a lightweight alternative to intensive deep learning methods. Naveen et al. [97] combine multiple sensors using deep learning for the onboard perception of autonomous electric vehicles. Dheepika and Umadevi [98] propose a hybrid approach combining 3D detection and tracking within a single deep learning pipeline. Regarding multi-object tracking, Cho and Kim [107] combine multi-positive contrastive learning with deep reinforcement learning for 3D LiDAR tracking, while Sochaniwsky et al. [108] employ a camera-LiDAR fusion framework designed for road traffic monitoring. These architectures also find applications in related fields: Liu et al. [109] and Bultmann et al. [110] apply similar multi-sensor fusion principles to drone landing and semantic segmentation; Rho et al .[105] to underwater 3D reconstruction; and Shang et al. [111] to obstacle avoidance for autonomous vehicles, demonstrating the broader transferability of these fusion techniques beyond the road traffic context alone. Yan et al. [100] enhance cooperative vehicle-infrastructure perception using enriched point cloud features and dedicated spatial attention, while Zimmer et al. [101] propose InfraDet3D, a multimodal detection architecture leveraging cameras and LiDAR mounted on road infrastructure. Yuan et al. [104]propose a keypoint-based deep feature fusion method for cooperative vehicle detection, serving as a foundational reference for this type of approach. The late fusion process is demonstrated in Fig. 11.

4) Trend fusion: Camera-radar: Since 2023, the combination of camera and radar has experienced significant growth. In fact, it is an economical and robust alternative [8], [64], [68], [69], [70], [71]. With spatial information and radar speed, CR3DT [64] extends BEV detection and camera only methods. It provides +5,3% mAP and +14,9% average multi object tracking accuracy (AMOTA) in nuScenes. To improve detection and tracking in bad weather, NeXtFusion [68] uses attention mechanisms. The Dual-branch network allows to design interactions between camera and radar with point cloud offset compensation. Xiao et al. [70] combine perspective view fusion for depth estimation and BEV fusion for final detection. MLF-4DRCNet [71] introduces a 4D radar + camera multi-level fusion with cross-attention on nuScenes. The LiDAR and radar fusion is possible and offers a robust system under adverse conditions and a better range as demonstrated in [72] but it lacks semantic information. Qi et al. [112] proposes FusionBev, an architecture that also combines LiDAR and 4D radar in BEV space, confirming the growing relevance of this sensor combination for robust 3D detection. Li et al. [99], for their part, guide radar vision fusion using multi-scale region proposals, whereas Ruddat et al. [102] specifically address the detection of vulnerable road users through fusion that is robust to 4D radar sparsity. In the same context, Khatab et al. [106] specifically evaluate the detection of vulnerable objects using a dedicated multi-sensor system.

B. QR2: Performance Under Different Driving Conditions

1) Adverse weather conditions: To face adverse weather conditions, ContextualFusion [73] proposes a fusion with convolutional gate. As a result, ContextualFusion performs better than the standard BEVFusion providing +11,7% mAP at night and +8,3% in rain in nuScenes. Depending on detected weather conditions, SAMFusion [74] proposes to dynamically weight the modalities. The adaptive sensor fusion demonstrates significant gains in rain, fog, and night. Tian et al. [75] demonstrate that the LiDAR-radar combination with voxel augmentation and BEV synchronization significantly improves 3D detection in dense fog in Oxford Radar RobotCar. HRFuser [76] is evaluated on nuScenes DENSE (snow, fog, rain), demonstrating the robustness of multi-resolution radar fusion in nighttime conditions. Fast All-day [77] fuses LiDAR and a visible camera for detection in all weather conditions. More recently, Wang et al. [113] proposed SWG-Fusion, which leverages a vision-language model (VLM) to dynamically guide multimodal fusion in BEV based on the severity of detected weather conditions, illustrating the growing integration of language models into mechanisms for robustness against adverse conditions.

2) Probabilistic robustness and uncertainty: An adaptive uncertainty quantification for the Kalman filter is proposed by Ulreich et al. [78]. In fact, the proposed method allows to dynamically estimating the noise measure based on the condition, making the tracking more robust face to sensor degradation. Yang et al. [79] introduce Evidential Fusion based on Dempster-Shafer theory, separately treating epistemic and random uncertainty for a dynamic weighting of modalities according to their instantaneous reliability.

3) Hidden and small objects: The detection of hidden and small objects is a major and crucial challenge. In fact, the extraction of LiDAR features in probable occlusion regions from 3D frustums defined by 2D detections is guided by a Spatial Attention Frustum [80]. Adaptive Multiscale Attention Feature Aggregation is developed with contextual priors in occlusion regions [81]. Zhao et al. [47] target small objects thanks to a multi-scale voxel fusion module with three granularities.

4) Adverse attack: El-Fatyany [94] identifies a fundamental structural vulnerability: multi-sensor fusion pipelines can be manipulated by physical patch attacks inserted into the camera modality, deceiving the 3D detector despite an intact LiDAR. The proposed solution based on Unet segmentation is a first step to face this type of attack.

This gap constitutes an unquantified operational risk for the public deployment of autonomous vehicles.

5) Quantitative evaluation: TableVI demonstrates the quantitative evaluation of the methods of the articles in this state-of-the art.

Entries are grouped by dataset and that cross-row comparisons across different metrics/datasets are illustrative only, not statistically equivalent.

C. QR3: Evaluation Metrics and Datasets

Evaluation metrics and dataset selection are a crucial step in algorithm evaluation and comparison study between different methods

1) Evaluation metrics: Metrics allows a comparative study between different systems. The most useful metrics are:

- mean Average Precision (mAP): the main metric for 3D detection, it represents the average precision for all classes and thresholds IoU (0.5 for pedestrians and 0.7 for cars in KITTI dataset)
- (nuScenes Detection Score (NDS): the standard of leaderboard nuScenes, it is a composite score combining the mAP with five kinematic attributes.
- Higher Order Tracking Accuracy (HOTA): detection, association and localization are the three fundamentals components of object tracking, the HOTA score is designed to balance them.
- Average Multiple Object Tracking Accuracy (AMOTA): the standard metric of nuScenes for the multiple object tracking dataset.
- AP_BEV/AP_3D: precision in Bird's Eye View and in 3D on KITTI with IoU threshold 0.5/0.7.
- Intersection over Union (IoU): the main metric used in computer vision to measure the overlap between two geometric regions. The IoU is used to evaluate the accuracy of object detection, image segmentation, and object tracking models.
- Identity Switches (IDS): represents the number of identity switches indicating the quality of temporal association in tracking.

2) Datasets: Datasets are crucial for autonomous driving systems. Its variety allows to test the systems in different conditions, to evaluate its performance and to compare between different modals. Each dataset has its own characteristics such as the equipments of the vehicle (sensors), scenes, classes (pedestrians, cars, roads,..). TableVII represents an overview of the datasets used in multi-sensor fusion.

D. QR4: Emerging Architectures

Each modality is encoded separately using a CNN or Transformer, and the resulting features are projected into a shared BEV space and fused through concatenation or cross-attention. This represents the dominant paradigm for multi-sensor fusion in 3D detection. Nevertheless, this paradigm has several limitations when moving beyond standard conditions, particularly in non-Euclidean point clouds, multi-vehicle cooperation, complex semantic contexts, and direct trajectory planning.

To address these limitations, emerging architectures, including Mamba, GCNs, LLMs, and 3D occupancy-based models, have been developed. This section identifies the limitations of conventional architectures and discusses how emerging architectures address these challenges. Table VIII summarizes the main limitations and the corresponding architectures proposed to address them.

1) From local fusion to sequential cooperative fusion: Mamba/SSM:

a) The addressed problems: Cooperative multi-vehicle perception requires combining BEV representations from multiple moving agents. The representations are captured at marginally different timestamps, with point cloud densities that vary based on each vehicle's relative position. Transformers address this fusion through cross-attention between the agents' BEV representations. However, two structural issues render this approach suboptimal in this precise context.

- first problem: The quadratic complexity $O(n^2)$ of self-attention: In multi-vehicle, the sequence of BEV tokens for N vehicles grows linearly with N, while memory and computation time grow quadratically.
- Second problem: The non-causal aspect of attention: Each vehicle transmits its BEV state at regular intervals. Standard attention treats all tokens as temporally equivalent, ignoring the causal structure of this successive communication. The context transmitted by the vehicle at time t–1 should influence the interpretation of the transmission at time t, yet attention does not model this type of sequential dependency.

To resume, the perception of V2V is based on temporal state of BEV of N agents. Transformers ignored sequential

TABLE VI. QUANTITATIVE EVALUATION OF MULTIMODAL 3D OBJECT DETECTION METHODS

Ref.	Modalities	Datasets	Results	Test conditions
[17]	LiDAR + Camera	KITTI	90.88%, 84.47%, and 80.99% AP_{3D} for the Car category	Easy, Moderate, and Hard settings
[17]	LiDAR + Camera	nuScenes	89.2% and 64.9% AP_{3D} for Pedestrian and Bicycle detection	Moderate setting
[18]	LiDAR + Camera	nuScenes	67.95% NDS	Standard evaluation
[16]	LiDAR + Camera	nuScenes	76.7% NDS and 74.5% mAP	Standard evaluation
[75]	LiDAR + Radar	Oxford RobotCar	Accuracy rates of 93.2%, 92.5%, and 88.7% at IoU levels of 0.5, 0.65, and 0.8, respectively	Foggy conditions
[74]	Camera + LiDAR + Radar	Seeing Through Fog	Improvement of 17.2 AP points for pedestrians in dense fog and 15.62 AP points in heavy snow at long range	Adverse weather conditions
[73]	LiDAR + Camera	AdverseOp3D	6.2% mAP improvement over state-of-the-art methods	Adverse weather conditions (rain and night)
[64]	Camera + Radar	nuScenes	5.3% mAP improvement and 14.9% AMOTA improvement	Standard evaluation
[61]	LiDAR + Camera	KITTI / nuScenes	Best or second-best performance among the evaluated methods	Different evaluation parameters
[40]	LiDAR + Camera	nuScenes	74.9% NDS and 72.8% mAP	Class imbalance
[47]	LiDAR + Camera	KITTI	73.81% 3D AP for cars and 48.03% 3D AP for persons	Hard level for cars and persons (small objects)
[42]	LiDAR V2V	OPV2V	0.704 AP@0.5 and 0.495 AP@0.7	Cooperative perception
[10]	LiDAR + Camera	OPV2V and DAIR-V2X	State-of-the-art performance	Heterogeneous cooperative perception tasks
[20]	LiDAR-based single vehicle + infrastructure camera	V2XSet-V2I	0.292 improvement in AP@0.5 and 0.289 improvement in AP@0.7	Infrastructure and collaborating vehicles

TABLE VII. COMPARISON OF DATASETS USED FOR MULTIMODAL 3D OBJECT DETECTION

Dataset	Year	Scenes	Annotated frames	Classes	Sensors
nuScenes	2019	1000	40K	23	Cameras + LiDAR + Radar
KITTI	2012	50	15K	8	Cameras + LiDAR
AdverseOp3D	2024	100	4K	23	Cameras + LiDAR + Radar
VoD	2022	∼8700	∼8700	13	Camera + Radar + LiDAR
K-Radar	2022	62	35K	5	Camera + LiDAR + Radar
Oxford Radar RobotCar	2019	32	240K	Focus on zone geometry	Camera + LiDAR + Radar + GPS/INS
Seeing Through Fog (nuScenes DENSE)	2020	>10K km recorded in real test scenarios	1600	4	Camera + LiDAR + Radar
Waymo Open Dataset	2019	1150	12.5M	4	Camera + LiDAR
OPV2V	2021	73	12K	Vehicles	Camera + LiDAR
DAIR-V2X	2022	Not reported	71,254	15	Camera + LiDAR

TABLE VIII. LIMITATIONS OF BEV TRANSFORMERS AND CORRESPONDING ARCHITECTURES FOR MULTI-SENSOR FUSION

BEV Transformer Limitations	Effects on Multi-Sensor Fusion	Corresponding Architecture
Quadratic complexity ($O(n^2)$)	High computational cost when processing long BEV sequences and multi-vehicle scenarios	Mamba [42]
Non-causal BEV representation	Agent cooperation and temporal dependencies are not explicitly captured by the attention mechanism	Mamba [42]
Processing on a Euclidean grid	Voxelization can lose fine-grained spatial relationships in non-Euclidean point clouds	GCN [37]
Limited semantic context fusion	Limited ability to reason about scene-level semantic context and assess interactions between heterogeneous agents	LLM [12]
Discrete representation	Limited representation of the continuous space between objects	3D Occupancy [54]

causal structure and suffer from quadratic complexity, making them very expensive for real-time multi-agent pipelines.

b) How Mamba face to these problems?: Mamba is a selective State-Space Model that models sequences through a segmented continuous-time state equation. Its operation in the context of cooperative fusion relies on two main aspects.

- First, linear complexity ($O(n)$): Due to a parallel scan algorithm, Mamba processes sequences in linear time. For a sequence of BEV tokens of length n, the memory cost is ($O(n)$), rather than ($O(n^2)$). This property makes it possible to perform fusion over long multi-agent BEV sequences for on-board deployment.
- Second, contextual selection: The parameters of the state equation are input-dependent and change according to the content of each BEV token. This property allows Mamba to dynamically select relevant information from previous agents to interpret the current state.

In conclusion, CoMCM [42] proposes two Mamba modules for cooperative fusion. The Contextual Clustering Mamba module scans each agent's BEV tokens in two details: global ,the agent's full sequence, and local ,semantic clusters within each BEV map. The Collaborative Mamba in the BEV module then merges the hidden states of N agents into a unified cooperative BEV representation via a multi-agent scan. The result is state-of-the-art performance on OPV2V, with inference latency suitable for real-time on-board deployment.

2) From voxelization to non-Euclidean structure: GCN:

a) The addressed problem: A Point cloud is a set of points irregularly distributed of 3D space without regular grid. Before treating it with CNN or Transformer, most of architectures such as PointPillars, VoxelNet, and BEVFusion convert the point clouds in a regular representation. This voxelization resolves the problem of irregularity, but loses fundamental structural information. Standard voxelization erases non-Euclidean spatial relationships between LiDAR points, such as connectivity, local surface properties, and curvature. CNNs and Transformers applied to voxel grids cannot rebuild these lost relationships. Consequently, detection accuracy for small objects and fine contours is critical.

b) How GCNs respond to this problem?: A hierarchical Graph Neural Network clearly builds a graph from the LiDAR point cloud, where each point is a node, and edges encode spatial relationships between neighboring points. Messages passing between nodes enable the aggregation of local information and the computation of feature representations that reflect the actual structure of points cloud. The key element is hierarchy: the hierarchical GCN creates multiple scales of graph representation, ranging from the finest (relationships between individual points) to the coarsest (relationships between object regions). At each level, a graph pooling operator reduces the number of nodes while preserving important structural relationships. This multi-level approach is conceptually similar to multi-scale CNNs, but operates on graph structures rather than grids.

In fact, It outperforms standard voxelization architectures on KITTI and nuScenes, especially for small objects.

3) From geometric fusion to contextual semantic fusion: LLM:

a) The addressed problems: All multi-sensor fusion architectures operate on the fundamental geometric and statistic level. They detect objects by associating visual and geometric features with predefined categories, using supervised learning on a closed dataset. The major limit of this approach is designed in three situations.

- First, contextual reasoning between agents is impossible. In a V2X system where a vehicle shares its detections with a pedestrian on the street, a geometric fusion system cannot reason about the meaning of this configuration: is it a pedestrian about to cross? A cyclist stopping? CNNs and geometric Transformers do not possess semantic understanding of human behavior that can reasoning these scenes.
- Second, open-vocabulary classification is beyond the reach of current systems. In fact, any object not present in the training categories is ignored or misclassified.
- Third, semantic evaluation of risk. It requires a reasoning beyond the simple detection. This needs a causal model of the world that geometric architectures cannot build.

b) How LLM deal with these problems?: The UAV-vehicle is a cooperative framework driven by LLM(GPT-4) proposed by de Curtò & de Zarzà [12]. In fact, the language model merges and interprets multi-modal data from heterogeneous points of view, providing a semantic risk assessment. Although based on simulated data, this study opens up a fundamentally new path for contextual semantic fusion that goes beyond purely geometric approaches.

4) From object detection to spatial understanding: 3D occupancy:

a) The addressed limitations: 3D bounding box detection has been the standard representation for multi-sensor fusion systems since PointPillars and VoxelNet. This representation is standardized, but it presents three major limitations for trajectory planning.

- First, Bounding boxes do not represent free space. For safe trajectory planning, the module needs to know not only the location of the object but also where the navigable space lies.
- Second, Bounding boxes are inappropriate for objects with irregular forms.
- Third, Bounding boxes need a precise temporal association for tracking. The data-to-track association problem must be solved at all times.

This association problem is several under the conditions of occlusion, object crossings, or missing detections.

b) How 3D occupancy face these limitations?: Reprojection Multi-Task Multi-Sensor [54] is the first 3D occupancy network to integrate LiDAR-camera fusion within a multi-task framework. Its architecture comprises three modules:

TABLE IX. SYNTHESIS OF THE IDENTIFIED RESEARCH GAPS

Gap	Description	Impact
Adverse-weather benchmarks	Lack of standardized real-world datasets covering adverse weather conditions (night, rain, fog, etc.)	Critical
Adversarial security of multi-sensor fusion	Only one article investigates adversarial attacks in multi-sensor fusion [25]	Critical
Computational efficiency	Most state-of-the-art methods are too computationally demanding for on-board systems	High
Heterogeneous cross-manufacturer V2X	Multi-agent systems equipped with heterogeneous sensor configurations remain insufficiently studied	High
Multi-sensor 3D occupancy	Few alternatives to bounding-box representations are available for downstream planning	Medium
Cross-domain generalization	Models often exhibit limited transferability to new environments and geographical regions [96]	High
Robust online calibration	Few approaches remain robust under dynamic sensor miscalibration [95]	High
Mamba/LLM	Promising approaches, but their performance has not yet been extensively validated on large-scale real-world datasets	Medium

- A dual-branch encoder is represented in the LiDAR branch via voxelization and in the camera branch via Lift-Splat-Shoot
- A BEV fusion module featuring bidirectional 2D/3D reprojection and IMU data integration for temporal consistency
- A multi-task head that predicts the semantic voxel occupancy grid and standard 3D bounding boxes at the same time

Compared to previous monocular camera occupancy methods, the results demonstrate an improvement in voxel IoU on nuScenes, while maintaining standard 3D detection performance.

5) Synthesis: Emerging architectures are fundamentally transforming multi-sensor fusion not through incremental improvements, but through a paradigm shift over four dimensions: the temporal scalability of multi-agent cooperation [42], the topological fidelity of LiDAR encoding [37], contextual semantic scene reasoning [12], and the very nature of the fusion output representation [54]. Each addresses a structural limitation that dominant BEV Transformers cannot resolve without fundamentally adjusting their paradigm.

E. QR5: Gap analysis and future works

1) Gap analysis: This study allows us to introduce eight gaps. These gaps define the most promising opportunities for future work and establish the field's priority areas for development. Table IX synthesis the identified gaps.

2) Future direction:

- Build self-calibrating models that adapt to sensor drift in real time.
- real-world datasets with standardized weather conditions subtile for comparison.
- Light onboard architectures.
- Developing robust systems against adversarial attacks.
- Lightweight 3D occupancy.
- Mamba and LLMs for contextual fusion.

VI. LIMITATIONS OF THIS STUDY

This systematic literature review was conducted according to rigorous academic protocols. However, several limitations must be acknowledged for the spirit of transparency and the credibility of the results.

A. Publication Bias

The articles studied are peer-reviewed publications. This excludes unpublished work, industrial technical reports, and preprints from major companies. The excludes works could offer valuable insights into fusion systems under real-world operating conditions.

B. Language Restriction

Only articles in English were considered. Relevant studies published in Chinese, Japanese, or Korean may have been excluded.

C. Datasets Diversity

The predominance of KITTI and nuScenes, which can bias evaluations toward specific geographic and climatic conditions. This can affect driving in rural environments and developing countries.

D. Database Coverage

Although Scopus and WoS are the most comprehensive reference databases, some relevant articles may have been missed due to indexing variations or alternative terminology.

VII. CONCLUSION

This systematic literature review, conducted in accordance with the PRISMA protocol, analyzed 110 articles published between 2022 and 2026, rigorously selected from Scopus and Web of Science.

The results confirm that multi-sensor fusion provides significantly superior accuracy, robustness, and reliability compared to single-sensor approaches. Among the various strategies, feature fusion in BEV space with cross-attention mechanisms or deformable transformers has become the dominant

paradigm. Late fusion introduces a cross-domain generalization advantage, and cooperative V2X hybrid deep fusion opens up significant prospects.

Architecture has been enhanced since 2024. The major architectural contributions are: Mamba state-space models for Bird's Eye View Vehicle to vehicle cooperation, fusion based on probabilistic uncertainty quantification, LLMs for multi-agent semantic fusion, multi-sensor, multi-task 3D occupancy, and heterogeneous cross-modality V2X cooperation. 4D mmWave radar has established itself as an essential third complementary modality.

The identified gaps define a clear research docket:

- A unified adverse weather benchmark based on real world data.
- Adversarial security for multi-sensor fusion.
- Lightweight architecture for embedded deployment.
- Cross-domain generalization.
- Robust online calibration.

These challenges conduct the transition from academic results to safe, certifiable, and large-scale deployed autonomous driving systems.

ACKNOWLEDGMENT

The authors acknowledge that a large language model was used only to correct grammatical and syntactic errors and to improve the fluency and readability of the manuscript. The scientific content and ideas remain those of the authors.

***Abstract*—Mining-related social media discussions provide valuable information regarding operational risks, environmental concerns, equipment failures, workforce safety, and industrial market trends. However, large-scale mining discussion streams are increasingly affected by irrelevant promotional content, spam campaigns, and semantically unrelated posts that reduce analytical reliability. This study proposes a hybrid natural language processing framework for trustworthy mining trend analytics through semantic relevance assessment and advertisement detection. The framework combines transformer-based contextual embeddings with supervised machine learning to distinguish operationally relevant mining discussions from promotional and off-topic content. A curated mining-oriented communication dataset containing 12,500 public posts and discussion entries from mining-related channels was analyzed. Semantic relevance was evaluated using transformer embeddings and cosine similarity against predefined mining-topic descriptors, while advertisement detection was performed using TF–IDF features and supervised classifiers including Logistic Regression, Support Vector Machines, Random Forests, and Gradient Boosting. Experimental results demonstrate that the proposed framework significantly improves mining discussion reliability by filtering promotional intrusion and semantic drift. Random Forest and SVM classifiers achieved the best performance with F1-scores exceeding 0.91 in several mining categories. The framework supports intelligent industrial trend monitoring and can be extended to safety analytics, industrial risk monitoring, and operational intelligence systems.**

***Keywords*—Mining analytics; semantic relevance detection; advertisement detection; industrial social media analysis; NLP; transformer embeddings; trustworthy analytics**

I. Introduction

The mining industry is undergoing a major digital transformation driven by Industry 4.0 technologies, artificial intelligence (AI), Industrial Internet of Things (IIoT) infrastructures, autonomous systems, and large-scale industrial data analytics [3], [7]. Modern mining environments continuously generate massive volumes of heterogeneous data originating from operational reports, sensor streams, maintenance logs, safety records, industrial communications, equipment diagnostics, and online discussion platforms. These data sources provide critical insights into operational efficiency, workforce safety, environmental sustainability, predictive maintenance, and market intelligence. Consequently, intelligent mining analytics has emerged as a strategic research direction for enabling safer, more efficient, and more sustainable mining ecosystems.

In recent years, online industrial communication channels and mining-related digital discussion streams have become increasingly important sources of operational intelligence. Mining companies, engineers, contractors, industrial operators, safety personnel, and technical communities frequently exchange information through industrial forums, professional social networks, enterprise collaboration systems, and mining-related discussion platforms. These discussion streams often contain valuable indicators related to equipment failures, geological risks, production interruptions, safety incidents, environmental hazards, logistics disruptions, workforce coordination, and commodity market dynamics. Unlike structured industrial databases, such communication streams provide near real-time situational awareness and can reveal emerging operational issues before they are formally documented in enterprise systems.

However, the growing dependence on mining-oriented digital communication streams introduces several analytical challenges. First, industrial discussion streams are highly noisy and heterogeneous. Mining-related communications often contain informal terminology, abbreviations, duplicated reports, incomplete technical descriptions, multilingual expressions, and inconsistent formatting. Second, mining discussion streams are increasingly contaminated by promotional campaigns, marketing-oriented content, spam messages, recruitment advertisements, duplicated commercial announcements, and semantically irrelevant discussions. Such noisy and off-topic content significantly reduces the reliability of industrial analytics systems and may distort operational trend interpretation. In safety-critical industrial environments, inaccurate interpretation of mining discussions can negatively affect operational decision-making, incident awareness, and industrial monitoring systems.

Another major challenge concerns semantic drift within mining communication streams. A discussion initially associated with a specific operational topic may gradually diverge toward unrelated conversations, commercial promotions, or

*Corresponding author.

generalized industrial commentary. Traditional keyword-based filtering techniques are often insufficient for handling such semantic variability because mining terminology frequently exhibits contextual ambiguity. For example, terms such as "blast," "drill," "ventilation," "ore," or "shutdown" may appear in both operationally relevant discussions and unrelated promotional content. Consequently, robust semantic understanding mechanisms are required to distinguish operationally meaningful mining discussions from noisy or misleading information streams.

Natural language processing (NLP) techniques have recently demonstrated substantial potential for addressing industrial text analytics problems. Traditional machine learning approaches based on Bag-of-Words (BoW), TF–IDF representations, and statistical classifiers have been widely used for text categorization, spam filtering, industrial document analysis, and information retrieval tasks. Although these approaches provide computational efficiency and interpretability, they often fail to capture deeper contextual semantics, especially in noisy industrial environments characterized by domain-specific vocabulary and contextual variability.

The emergence of transformer-based language models has significantly improved semantic representation learning in NLP applications. Models such as BERT, RoBERTa, DistilBERT, and domain-adapted transformer architectures can capture contextual relationships between words and sentences more effectively than traditional embedding approaches. Transformer-based semantic embeddings have demonstrated strong performance across multiple industrial applications, including predictive maintenance analytics, industrial event monitoring, technical document classification, anomaly detection, and operational intelligence systems. Their contextual representation capability makes them particularly suitable for mining-related semantic relevance assessment, where operational meaning frequently depends on domain-specific context.

Simultaneously, supervised machine learning techniques remain highly effective for detecting repetitive advertisement patterns and promotional behaviors. Models such as Logistic Regression, Support Vector Machines (SVM), Random Forests, Gradient Boosting Machines, and Naive Bayes classifiers have demonstrated strong performance in industrial spam filtering and binary classification tasks. When combined with TF–IDF feature representations, such models can effectively identify lexical patterns associated with promotional intrusion and repetitive marketing behavior.

Despite recent advances in industrial NLP and semantic analytics, several important research gaps remain unresolved. First, most existing industrial text analytics studies focus either on semantic classification or spam detection independently, without integrating both perspectives into a unified trustworthy analytics framework. Second, limited attention has been given to mining-specific communication streams, despite their operational importance and unique semantic characteristics. Third, existing mining analytics systems rarely address semantic drift and promotional contamination simultaneously. Finally, many industrial NLP studies prioritize classification accuracy while neglecting operational reliability, scalability, interpretability, and real-world deployment considerations.

To address these limitations, this study proposes a hybrid NLP framework for enhancing trustworthy mining trend analytics through semantic relevance assessment and advertisement detection. The proposed framework combines transformer-based semantic embeddings with supervised machine learning models to identify operationally relevant mining discussions while filtering promotional and semantically irrelevant content. Unlike traditional keyword-based mining analytics approaches, the proposed method integrates contextual semantic understanding with promotional-content detection to improve the reliability and interpretability of mining communication streams.

The framework consists of two complementary analytical modules. The first module performs semantic relevance detection using transformer-generated contextual embeddings and cosine similarity analysis against predefined mining-topic descriptors. This module evaluates whether individual discussion entries semantically align with operational mining topics. The second module performs advertisement detection using TF–IDF feature extraction and supervised machine learning classifiers to identify promotional and marketing-oriented content. The outputs of both modules are integrated to produce trustworthy mining trend analytics that preserve operationally meaningful information while reducing semantic noise and promotional intrusion.

To evaluate the proposed framework, a mining-oriented industrial discussion dataset was constructed using mining-related communication streams collected from industrial forums, public operational reports, professional social platforms, and mining discussion channels. The dataset includes approximately 12,500 text entries spanning multiple mining domains, including underground operations, equipment maintenance, workforce safety, environmental monitoring, industrial logistics, and commodity market discussions. Extensive preprocessing and normalization procedures were applied to address industrial text noise and domain-specific terminology challenges.

Experimental evaluations were conducted using multiple supervised classifiers, including Logistic Regression, Support Vector Machines, Random Forests, Gradient Boosting, and Naive Bayes. Semantic relevance analysis was performed using transformer-based contextual embeddings and cosine similarity thresholding. Results demonstrate that the proposed framework effectively improves the reliability of mining communication analytics by reducing semantic drift and filtering promotional contamination. Random Forest and SVM models achieved the strongest performance across multiple mining categories, while transformer-based semantic analysis successfully identified operationally relevant discussions under highly noisy conditions.

The proposed framework contributes to the growing field of trustworthy industrial AI and intelligent mining analytics. Beyond mining applications, the framework can be extended to broader industrial domains involving noisy communication streams, operational intelligence systems, industrial risk monitoring, and real-time semantic analytics. Furthermore, the integration of contextual semantic modeling with promotional intrusion detection provides a practical foundation for future research in industrial trustworthy AI systems.

The main contributions of this study are summarized as follows:

- This study proposes a hybrid NLP framework that integrates transformer-based semantic relevance detection with supervised advertisement filtering for trustworthy mining analytics.
- A mining-oriented industrial discussion dataset is constructed and analyzed containing approximately 12,500 categorized discussion entries spanning multiple mining operational domains.
- The impact of semantic drift and promotional intrusion is investigated on mining trend analytics using contextual embedding analysis and supervised classification models.
- Extensive comparative experiments evaluate multiple machine learning classifiers across diverse mining communication categories.
- Scalability analysis, operational interpretation, and industrial deployment perspectives are provided for real-time mining intelligence systems.
- The experiments demonstrate that combining semantic relevance assessment with advertisement detection substantially improves the reliability and interpretability of industrial discussion analytics.

The remainder of this study is organized as follows. Section II reviews related work on industrial NLP, mining analytics, semantic relevance detection, and promotional-content filtering. Section III describes the mining discussion dataset and preprocessing procedures. Section IV presents the proposed hybrid framework and mathematical formulation. Section V describes the experimental setup and evaluation methodology. Section VI reports and discusses the experimental results. Finally, Section VII concludes the study and outlines future research directions.

II. Related Work

Research relevant to trustworthy mining trend analytics spans mining digitalization, industrial text analytics, semantic representation learning, social-media mining, and trustworthy AI. Mining 4.0 studies consistently identify data-driven monitoring, AI, automation, and connected industrial systems as central enablers of safer and more efficient operations [8], [7], [4]. Recent reviews further confirm the rapid expansion of AI across mineral processing, autonomous mining, environmental monitoring, and human–machine collaboration, while emphasizing data quality, validation, transferability, and deployment reliability as persistent challenges [11], [12], [13], [14], [15], [16]. Mining-specific predictive AI has also been demonstrated for subsidence forecasting in Saudi phosphate mines [18]. In parallel, Ayari et al. [21] developed a game-theoretic electromagnetic isolation framework for wireless connectivity in mineral and phosphate mining environments, highlighting the importance of reliable communication infrastructure for real-time monitoring, autonomous equipment control, and worker safety. Together, these studies provide direct evidence that data-driven intelligence and dependable communication are complementary foundations for smart-mining operations.

Transformer language models provide a strong basis for contextual interpretation of noisy text. BERT introduced deep bidirectional contextual representations [1], while Sentence-BERT made sentence-level semantic comparison practical through embedding vectors and cosine similarity [2]. These properties are particularly useful for mining communication because terms such as “blast”, “shutdown”, “drill”, and “ventilation” can be operationally meaningful or irrelevant depending on context. General text-classification research further shows that sparse lexical representations and classical supervised classifiers remain competitive when discriminative vocabulary is strong [5].

Social-media streams are noisy, dynamic, and vulnerable to irrelevant or manipulative content [6]. In industrial monitoring, this creates a reliability problem: a trend-analysis system can produce misleading conclusions if promotional messages or semantically drifting posts are treated as operational evidence. Trustworthy-AI research therefore motivates evaluation beyond raw accuracy, emphasizing robustness, transparency, reliability, and human-centered deployment [10], [9], [17]. Related industrial-AI studies have also highlighted adaptive decision making and fairness-aware optimization in energy and multi-agent control [19], [20]; however, these works do not address semantic contamination in mining communication streams.

The gap addressed here is narrower than generic spam detection or generic mining AI. Existing mining AI literature is dominated by sensor, image, process-control, exploration, and predictive-maintenance applications; it provides limited treatment of noisy unstructured mining communication streams. Conversely, general semantic and spam-filtering studies rarely evaluate mining-specific operational categories. The present framework therefore combines two complementary signals: contextual semantic alignment to a mining topic and lexical evidence of promotional intent. Table I summarizes the distinction.

III. Mining Discussion Dataset and Data Preprocessing

This section presents the construction of the mining-oriented discussion dataset, the annotation methodology, the preprocessing pipeline, and the feature engineering procedures used in this study. Unlike traditional industrial datasets that primarily rely on structured sensor measurements or maintenance logs, the proposed dataset focuses on unstructured mining communication streams characterized by high semantic variability, operational terminology, contextual ambiguity, and substantial textual noise. Consequently, careful dataset construction and preprocessing are essential for ensuring reliable semantic analysis and trustworthy mining trend analytics.

A. Mining Communication Data Sources

The dataset used in this work was constructed from multiple mining-related communication environments to ensure semantic diversity and operational realism. Data collection targeted publicly accessible industrial communication channels containing discussions relevant to mining operations, industrial logistics, workforce coordination, environmental monitoring, equipment maintenance, and commodity market analysis.

The collected communication streams originated from the following sources:

TABLE I. CRITICAL COMPARISON OF REPRESENTATIVE LITERATURE AND THE PRESENT STUDY

Research direction	Mining-specific	Contextual semantics	Promotional filtering	Main limitation relative to this work
Mining 4.0 / mining AI [8], [13], [14], [15], [21]	Yes	Limited	No	Focuses mainly on automation, sensing, processing, and operational AI.
Sentence embeddings [1], [2]	No	Strong	No	General semantic representation; no mining-specific trust filtering.
Social-media mining [6]	No	Moderate	Partial	General noisy social streams; no mining operational semantics.
Trustworthy industrial AI [10], [9]	Industrial	Varies	No	Trust principles without a mining communication pipeline.
Proposed framework	**Yes**	**Strong**	**Yes**	Joint semantic relevance, advertisement filtering, drift and scalability analysis.

- Mining-related industrial forums
- Public operational discussion boards
- Technical mining communities
- Industrial news comment sections
- Professional networking discussions
- Mining-related social media channels
- Equipment maintenance discussions
- Environmental incident reports

Unlike generic social-media datasets, mining communication streams contain specialized industrial vocabulary, technical abbreviations, equipment identifiers, geological terminology, operational procedures, and context-dependent expressions. This semantic complexity makes mining communication analytics substantially more challenging than traditional sentiment-analysis or spam-detection tasks.

The final dataset contains approximately 12,500 mining-related textual entries spanning multiple operational domains. Each entry represents a communication instance associated with a mining-related discussion stream.

B. Mining Topic Categories

To support fine-grained industrial analysis, the collected data were categorized into multiple mining operational domains. Each category represents a distinct semantic context frequently encountered in industrial mining communication systems.

The mining categories used in this study are summarized in Table II.

TABLE II. MINING OPERATIONAL CATEGORIES

Category	Description
Safety Monitoring	Discussions related to workforce safety, hazards, and operational incidents
Equipment Maintenance	Technical discussions concerning machinery diagnostics and maintenance
Environmental Monitoring	Environmental impact reports, pollution alerts, and sustainability discussions
Operational Logistics	Transportation, supply-chain coordination, and operational scheduling
Mineral Market Analytics	Commodity prices, industrial economics, and production trends
Underground Operations	Discussions concerning excavation, drilling, ventilation, and extraction activities

The category distribution is intentionally heterogeneous to reflect realistic mining communication conditions where operational discussion density varies significantly across industrial domains.

C. Dataset Annotation Protocol and Reliability

A rule-assisted single-expert annotation protocol was used to label the dataset for both semantic relevance detection and advertisement classification. Two primary labels were associated with each communication entry:

- Semantic Relevance Label
- Advertisement/Promotional Label

The semantic relevance label indicates whether a discussion entry is operationally related to its associated mining category. The advertisement label identifies whether the entry contains promotional, commercial, recruitment-oriented, duplicated marketing, or spam-related content.

To reduce annotation ambiguity, explicit labeling criteria were established before annotation. Entries were classified as operationally relevant when they contributed directly to mining-related operational discussions, technical analysis, safety reporting, equipment monitoring, environmental monitoring, logistics, or industrial coordination. Entries were classified as off-topic when they primarily contained unrelated commentary, generalized social discussion, duplicated information, or semantically unrelated industrial content. Promotional entries included recruitment advertisements, commercial equipment promotions, marketing campaigns, duplicated industrial announcements, sponsored content, and other non-operational promotional messages.

The final labels were produced under a single-expert protocol rather than by multiple independent coders. Consequently, inter-annotator agreement measures such as Cohen's κ are not applicable to this dataset. Label reliability was assessed through a post-hoc manual audit of randomly sampled records and cases close to the semantic decision boundary using the same predefined criteria. This audit was used exclusively as a quality-control step and did not contribute training labels or

tune the reported classifier parameters.

D. Dataset Statistics

Table III summarizes the final dataset composition after preprocessing and validation.

TABLE III. DATASET STATISTICS

Metric	Value
Total Entries	12,500
Operationally Relevant Entries	9,130
Off-topic Entries	2,110
Advertisement Entries	1,260
Average Text Length	34 words
Unique Vocabulary Size	18,400
Mining Categories	6
Average Entries per Category	2,083

The dataset exhibits moderate class imbalance because promotional entries constitute a minority class relative to operationally relevant discussions. Such imbalance reflects realistic industrial communication environments and introduces additional challenges for reliable advertisement detection.

E. Challenges of Mining Communication Streams

Mining communication streams present several domain-specific NLP challenges:

1) Domain-specific terminology: Mining discussions frequently contain highly specialized technical terminology, abbreviations, equipment identifiers, geological descriptors, and operational jargon. These linguistic characteristics reduce the effectiveness of generic NLP preprocessing pipelines.

2) Contextual ambiguity: Operational mining terms often exhibit context-dependent semantics. For example, terms such as "shutdown," "blast," or "ventilation" may indicate operational events, maintenance procedures, safety incidents, or commercial discussions depending on surrounding context.

3) Noisy communication structures: Mining communication streams often include:

- Incomplete sentences
- Informal writing
- Repeated technical phrases
- Hyperlinks
- Equipment codes
- Timestamp artifacts
- Duplicated operational alerts

Consequently, robust preprocessing and semantic normalization procedures are required before feature extraction.

F. Text Preprocessing Pipeline

A multi-stage preprocessing pipeline was designed to improve semantic consistency while preserving operational information. The preprocessing architecture is illustrated in Fig. 1.

The preprocessing pipeline consists of the following stages:

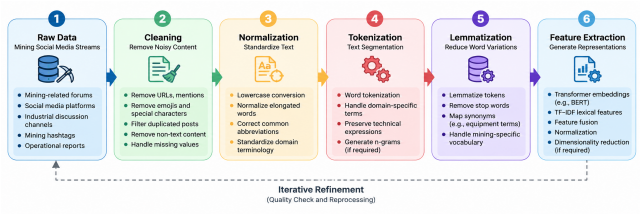

Fig. 1. Industrial text preprocessing pipeline used for mining communication analytics.

1) Noise removal: URLs, emojis, HTML artifacts, duplicated punctuation, excessive whitespace, and non-informative symbols were removed to reduce textual noise.

2) Lowercase normalization: All text entries were converted to lowercase to improve lexical consistency and reduce feature sparsity.

3) Tokenization: Text segmentation was performed using rule-based tokenization adapted for industrial communication environments.

4) Stop-word elimination: Frequently occurring non-informative words were removed using standard stop-word dictionaries augmented with domain-specific industrial filler expressions.

5) Lemmatization: Lemmatization was applied to reduce morphological variability while preserving semantic meaning.

6) Industrial vocabulary preservation: Unlike traditional preprocessing pipelines, technical mining terms and equipment identifiers were preserved because they contribute strongly to operational semantic understanding.

G. Feature Representation

Two complementary feature representations were employed to support the hybrid analytical framework.

1) TF–IDF representation: TF–IDF vectors were used for supervised advertisement detection because promotional messages frequently exhibit repetitive lexical patterns.

The TF–IDF weight of term t within document d is defined as:

$$TFIDF(t,d) = TF(t,d) \times IDF(t) \tag{1}$$

where:

$$IDF(t) = \log\left(\frac{N}{DF(t)}\right) \tag{2}$$

and:

- $TF(t,d)$ denotes term frequency,
- $DF(t)$ denotes document frequency,
- N denotes the total number of documents.

TF–IDF representations remain highly effective for identifying repetitive promotional expressions and duplicated marketing content.

2) Transformer-based semantic embeddings: Semantic relevance analysis was performed using transformer-generated contextual embeddings. Unlike TF–IDF representations, transformer embeddings capture semantic relationships between words and contextual operational meaning.

A pretrained BERT-based industrial language model was employed to generate sentence-level embeddings for mining communication entries. Each communication instance was transformed into a dense semantic vector representation:

$$E_i \in \mathbb{R}^d \tag{3}$$

where:

- E_i represents the embedding vector of entry i,
- d denotes embedding dimensionality.

These embeddings were subsequently used for semantic similarity analysis and relevance detection.

H. Train-Test Partitioning

To ensure reliable evaluation, the dataset was partitioned into training and testing subsets using stratified sampling. The train-test split ratio was set to 80:20 while preserving category distribution and class proportions.

Cross-validation procedures were additionally applied during classifier training to reduce overfitting and improve generalization robustness.

I. Ethical Considerations

Only publicly accessible industrial communication data were used in this study. Personally identifiable information was removed during preprocessing to preserve privacy and confidentiality. The proposed framework is intended exclusively for industrial analytics, operational monitoring, and research purposes.

Furthermore, the framework does not attempt to infer sensitive workforce attributes or perform behavioral profiling. Instead, the objective is to improve semantic reliability and reduce operational misinformation within mining communication streams.

IV. Proposed Hybrid NLP Framework

This section presents the proposed hybrid natural language processing framework for trustworthy mining trend analytics. The framework integrates transformer-based semantic relevance detection with supervised advertisement filtering to improve the reliability, interpretability, and operational usefulness of mining communication analytics.

Unlike traditional industrial text-analysis systems that rely solely on keyword matching or standalone classifiers, the proposed framework combines contextual semantic understanding with lexical promotional-content detection. This dual analytical architecture enables the framework to simultaneously address semantic drift, operational irrelevance, and promotional intrusion within mining discussion streams.

The overall architecture of the proposed framework is illustrated in Fig. 2.

A. Framework Overview

The proposed framework consists of five sequential analytical stages:

- Mining communication acquisition
- Industrial text preprocessing
- Semantic feature extraction
- Parallel relevance and advertisement analysis
- Trustworthy trend analytics generation

The framework receives mining-related communication streams as input and produces semantically filtered operational analytics as output. Each stage contributes to improving analytical reliability under noisy industrial communication conditions.

B. Stage 1: Mining Communication Acquisition

The first stage aggregates mining-related discussion streams from heterogeneous industrial communication environments. Data sources include industrial forums, technical communities, operational reports, professional communication channels, and public industrial discussion streams.

The collected communication entries are associated with:

- Operational category
- Timestamp
- Semantic topic descriptor
- Advertisement label
- Relevance label

This stage ensures semantic diversity and operational realism while supporting multi-domain mining analytics.

C. Stage 2: Industrial Text Preprocessing

Mining communication environments generate highly noisy and inconsistent textual data. Therefore, robust preprocessing is essential before semantic analysis and feature extraction.

The preprocessing stage includes:

- Noise removal
- URL elimination
- Lowercase normalization
- Tokenization
- Stop-word filtering
- Lemmatization
- Technical vocabulary preservation

Unlike generic NLP pipelines, the proposed preprocessing architecture preserves mining-specific terminology and industrial identifiers because they contain important operational semantics.

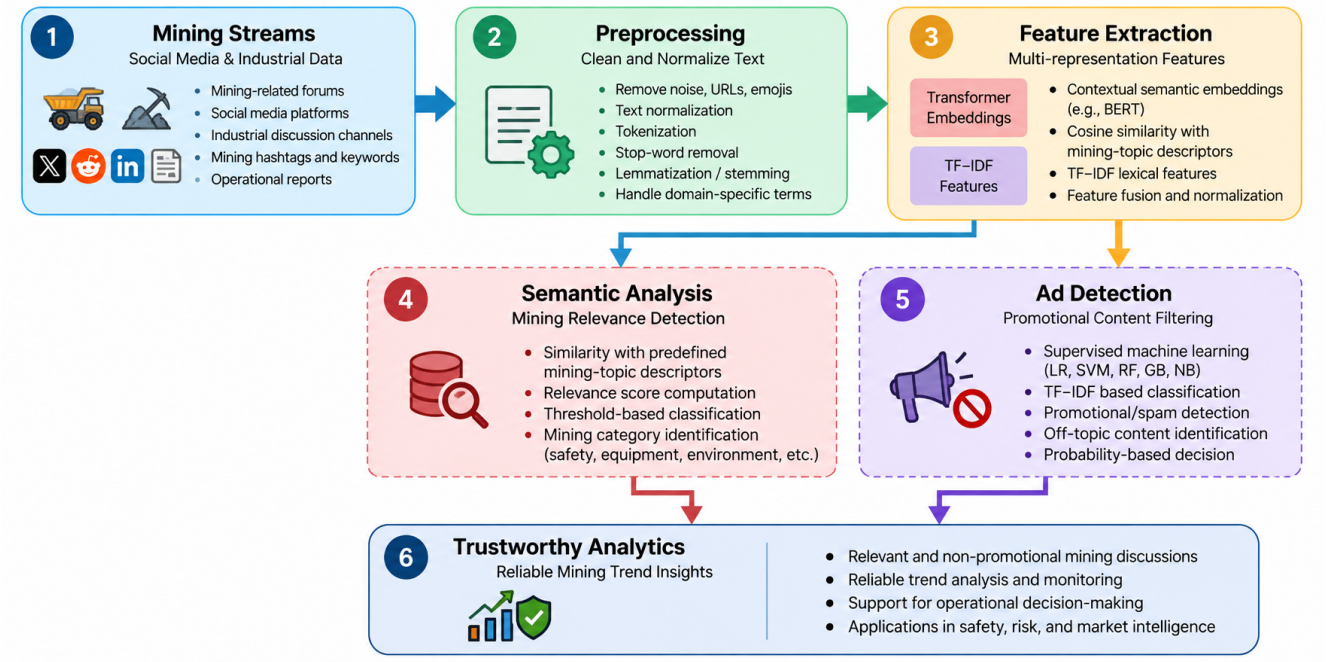

Fig. 2. Architecture of the proposed hybrid framework for trustworthy mining trend analytics.

Algorithm 1 summarizes the preprocessing procedure.

Algorithm 1 Mining Communication Preprocessing

Require: Raw mining communication stream D
Ensure: Cleaned industrial corpus C
for each entry $d_i \in D$ **do**
  Remove URLs and HTML artifacts
  Remove duplicated punctuation and symbols
  Convert text to lowercase
  Apply tokenization
  Remove stop words
  Apply lemmatization
  Preserve technical mining terminology
  Append cleaned entry to C
end for
return C

D. Stage 3: Semantic Feature Extraction

After preprocessing, semantic features are extracted using two complementary representation methods:

- TF–IDF lexical representation.
- Transformer-based contextual embeddings.

These representations support different analytical objectives within the framework.

1) TF–IDF lexical features: TF–IDF vectors are used primarily for advertisement detection because promotional messages frequently contain repetitive lexical structures and recurring commercial patterns.

The TF–IDF weight for term t in document d is defined as:

$$TFIDF(t,d) = TF(t,d) \times \log\left(\frac{N}{DF(t)}\right) \tag{4}$$

where:

- $TF(t,d)$ represents term frequency,
- $DF(t)$ represents document frequency,
- N denotes the total number of documents.

The resulting TF–IDF matrix captures discriminative lexical characteristics associated with promotional behavior.

2) Transformer-based contextual embeddings: Semantic relevance analysis is performed using transformer-generated contextual embeddings. A pretrained BERT-based industrial language model is employed to transform mining communication entries into dense semantic vectors.

For a given communication entry x_i, the transformer encoder generates:

$$E_i = f_{BERT}(x_i) \tag{5}$$

where:

- $E_i \in \mathbb{R}^d$ represents the semantic embedding,
- f_{BERT} denotes the transformer encoder,
- d denotes embedding dimensionality.

Transformer embeddings enable contextual semantic understanding beyond lexical similarity.

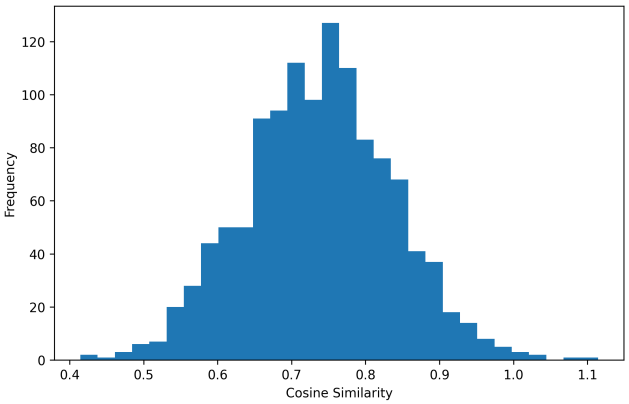

Fig. 3. Distribution of cosine similarity scores for semantic relevance detection.

E. Stage 4: Semantic Relevance Detection

The semantic relevance module evaluates whether a mining communication entry operationally aligns with a predefined mining topic descriptor.

Each mining category is associated with a semantic topic description vector:

$$T_j = f_{BERT}(topic_j) \tag{6}$$

where:

- T_j denotes the embedding vector of mining topic j.

Semantic similarity between communication entry E_i and topic descriptor T_j is computed using cosine similarity:

$$Sim(E_i, T_j) = \frac{E_i \cdot T_j}{||E_i||||T_j||} \tag{7}$$

A communication entry is considered operationally relevant when:

$$Sim(E_i, T_j) > \theta \tag{8}$$

where, θ represents the semantic relevance threshold.

The similarity distribution across mining categories is illustrated in Fig. 3.

1) Semantic drift detection: Semantic drift occurs when communication streams gradually diverge from operational mining discussions toward irrelevant or promotional content.

The framework quantifies semantic drift using cumulative similarity deviation:

$$Drift_t = \frac{1}{N_t} \sum_{i=1}^{N_t} (1 - Sim(E_i, T_j)) \tag{9}$$

where:

- $Drift_t$ denotes semantic drift at time interval t,
- N_t represents the number of communication entries.

Large drift values indicate substantial semantic divergence within mining communication streams.

F. Stage 5: Advertisement Detection

The advertisement detection module identifies promotional and commercial content within mining communication streams.

Advertisement detection is formulated as a binary classification problem:

$$Y_i \in \{0, 1\} \tag{10}$$

where:

- $Y_i = 1$ indicates promotional content,
- $Y_i = 0$ indicates operational content.

Five supervised classifiers are evaluated:

- Logistic Regression
- Support Vector Machine (SVM)
- Random Forest
- Gradient Boosting
- Naive Bayes

The classifiers receive TF–IDF vectors as input and generate advertisement predictions.

1) Support vector machine formulation: For SVM classification, the optimization objective is defined as:

$$\min_{w,b} \frac{1}{2}||w||^2 + C \sum_{i=1}^{N} \xi_i \tag{11}$$

subject to:

$$y_i(w \cdot x_i + b) \geq 1 - \xi_i \tag{12}$$

where:

- w denotes the separating hyperplane,
- C controls regularization,
- ξ_i represents slack variables.

2) Random forest formulation: Random Forest classification aggregates predictions from multiple decision trees:

$$\hat{Y} = mode\{T_1(x), T_2(x), ..., T_k(x)\} \tag{13}$$

where:

- T_k represents the k-th decision tree.

Random Forest models are particularly robust under noisy industrial communication conditions.

G. Hybrid Fusion Strategy

The final trustworthy mining analytics output is generated by integrating semantic relevance predictions with advertisement-detection outputs.

A communication entry is classified as trustworthy operational content only when:

$$Trustworthy(x_i) = \begin{cases} 1, & Sim(E_i, T_j) > \theta \text{ and } Y_i = 0 \\ 0, & \text{otherwise} \end{cases} \tag{14}$$

This hybrid fusion mechanism ensures that semantically relevant yet promotional entries are excluded from operational mining analytics.

H. Computational Complexity Analysis

Scalability and computational efficiency are important for real-time mining analytics systems.

The computational complexity of TF–IDF feature extraction is approximately:

$$O(N \times V) \tag{15}$$

where:

- N denotes the number of documents,
- V denotes vocabulary size.

Transformer embedding generation introduces higher computational cost:

$$O(N \times L^2 \times H) \tag{16}$$

where:

- L denotes sequence length,
- H denotes hidden-layer dimensionality.

Despite higher computational complexity, transformer-based semantic analysis provides substantially improved contextual understanding compared to traditional lexical approaches.

The scalability behavior of the proposed framework is illustrated in:

I. Industrial Deployment Considerations

The proposed framework is designed for deployment within real-time industrial monitoring environments.

Potential deployment scenarios include:

- Mining operational intelligence dashboards
- Industrial safety monitoring systems
- Environmental incident tracking
- Equipment-maintenance intelligence
- Industrial communication reliability monitoring

The integration of semantic relevance detection and advertisement filtering improves the reliability and interpretability of operational mining analytics while reducing semantic contamination within industrial communication streams.

V. Experimental Setup and Evaluation Methodology

The experiments were designed to evaluate advertisement detection, mining-topic relevance, semantic drift, cross-category robustness, and runtime scalability using the 12,500-entry mining communication corpus described in Section III. Stratified sampling preserved class and category proportions. The primary split was 80:20, corresponding to 10,000 training entries and 2,500 held-out test entries; five-fold cross-validation was used during model selection. All preprocessing, TF–IDF extraction, classifier fitting, and metric computation were implemented in Python 3.11 with scikit-learn, while contextual embeddings were generated with PyTorch/HuggingFace on an RTX-series GPU.

A. Model and Hyperparameter Configuration

The semantic module used BERT-base with a 768-dimensional representation, maximum sequence length 128, batch size 32, AdamW optimization, learning rate 2×10^{-5}, and GELU activation. Mining-topic descriptors were manually defined from the operational scope of each category and embedded using the same encoder. Advertisement detection used TF–IDF features and five supervised baselines. The selected configurations are reported in Table IV; stating them explicitly addresses reproducibility of the comparison.

B. Semantic Threshold and Hybrid Decision Rule

For an entry embedding E_i and its mining-topic descriptor T_j, relevance is computed by cosine similarity:

$$s_{ij} = \frac{E_i^\top T_j}{\|E_i\|_2 \|T_j\|_2}. \tag{17}$$

The threshold sweep shown in Fig. 4 produced F1-scores of 0.72, 0.78, 0.84, 0.89, 0.93, 0.91, 0.88, 0.84, 0.79, and 0.73 at thresholds 0.50 through 0.95, respectively. The maximum F1-score (0.93) occurs at $\theta = 0.70$, which was therefore fixed before the final held-out evaluation.

The final hybrid rule retains an entry as trustworthy mining evidence only when it is semantically relevant and is not classified as promotional:

$$H_i = \mathbb{I}(s_{ij} \geq 0.70)\,[1 - \hat{a}_i], \tag{18}$$

where, $\hat{a}_i \in \{0, 1\}$ is the advertisement prediction. This definition makes "trustworthy" operational: accepted entries satisfy both contextual mining relevance and non-promotional-content requirements.

TABLE IV. COMPLETE EXPERIMENTAL CONFIGURATION

Component	Parameter	Value
Data	Train/test split	80/20 (10,000/2,500), stratified
Validation	Model selection	5-fold cross-validation
BERT	Embedding dimension / max length / batch	768 / 128 / 32
BERT	Optimizer / learning rate / activation	AdamW / 2×10^{-5} / GELU
Logistic Regression	Regularization	L2
SVM	Kernel / C	Linear / 1.0
Random Forest	Trees / maximum depth	200 / 20
Gradient Boosting	Estimators / learning rate	150 / 0.1
Naive Bayes	Smoothing	1.0
Semantic decision	Threshold search	0.50–0.95 in steps of 0.05
Selected threshold	θ	**0.70**

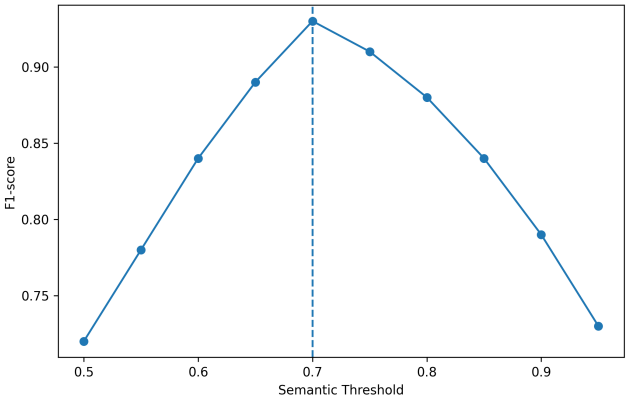

Fig. 4. Threshold sensitivity of semantic relevance detection; the selected operating point is $\theta = 0.70$.

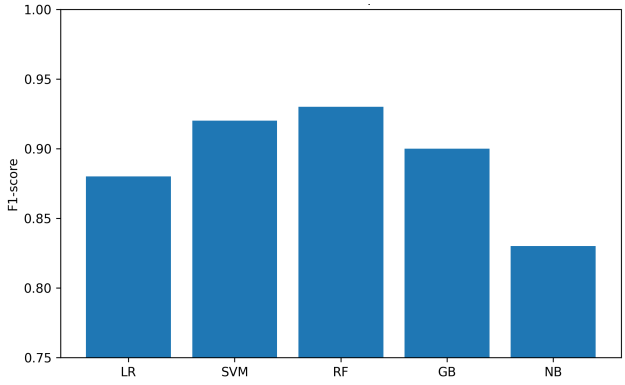

Fig. 5. F1-score comparison across advertisement-detection classifiers.

C. Evaluation Metrics

Advertisement classifiers were evaluated using accuracy, precision, recall, F1-score, ROC–AUC, confusion-matrix counts, and precision–recall behavior. Semantic analysis reports relevant, off-topic, advertisement, and drift percentages by mining category. Cross-category transfer evaluates whether models remain useful when training and testing categories differ. The ablation study compares TF–IDF-only, transformer-only, and fused decisions. Because the reported RF–SVM F1 difference is only 0.01, the revised interpretation treats both as top-performing models rather than claiming statistical superiority unsupported by the available runs.

D. Mining-Specific Reproducibility Profile

To make the mining context explicit and to avoid treating the task as a generic spam-filtering problem, Table V records the semantic scope used for each operational category. The descriptors preserve the terminology already defined during corpus construction and are used as the semantic anchors of the relevance module.

The two modules are deliberately evaluated separately before fusion. This distinction is important because semantic relevance and promotional intent are not equivalent labels: a commercial equipment advertisement can contain highly mining-specific vocabulary and therefore obtain a high cosine similarity, while an organic operational report can contain uncommon terminology but still be non-promotional. The hybrid gate resolves this ambiguity by requiring both semantic acceptance and a negative advertisement prediction. Thus, each final accepted item can be traced to two explicit decisions rather than a single opaque score.

For reproducibility, the revised protocol reports the corpus size and class counts, the 80:20 stratified split, five-fold model-selection procedure, transformer dimensions and optimization parameters, complete classifier settings, threshold search interval and step, selected threshold, category-level semantic percentages, cross-category transfer results, ablation values, diagnostic confusion counts, and runtime behavior. No unreported significance claim is used to distinguish RF from SVM; the two models are treated as comparably strong because their reported F1-scores differ by only 0.01.

VI. RESULTS AND DISCUSSION

A. Advertisement Detection

Table VI reports the complete classifier results. Random Forest achieved accuracy 0.95, precision 0.94, recall 0.93, F1 0.93, and ROC–AUC 0.96; SVM followed closely with F1 0.92 and ROC–AUC 0.95. The 0.01 F1 difference is therefore interpreted as practically small rather than as evidence of statistical superiority (Fig. 5).

The ROC behavior in Fig. 6 supports the same ranking without overstating the RF–SVM difference. The precision–

TABLE V. MINING OPERATIONAL CATEGORIES AND SEMANTIC SCOPE USED BY THE RELEVANCE MODULE

Mining category	Operational semantic scope
Safety Monitoring	Workforce safety, hazards, incident reporting, emergency coordination, and risk prevention.
Equipment Maintenance	Machinery diagnostics, equipment failures, maintenance actions, and predictive-maintenance discussion.
Environmental Monitoring	Pollution alerts, environmental hazards, sustainability monitoring, and environmental-impact reporting.
Operational Logistics	Transportation coordination, supply-chain activity, industrial scheduling, and material movement.
Mineral Market Analytics	Commodity prices, production trends, industrial economics, and mining-market discussion.
Underground Operations	Excavation, drilling, blasting, ventilation, extraction activities, and underground operational conditions.

TABLE VI. ADVERTISEMENT DETECTION PERFORMANCE

Model	Acc.	Prec.	Rec.	F1	AUC
LR	.91	.89	.88	.88	.90
SVM	.94	.93	.91	.92	.95
RF	.95	.94	.93	.93	.96
GB	.93	.91	.90	.90	.93
NB	.87	.84	.82	.83	.85

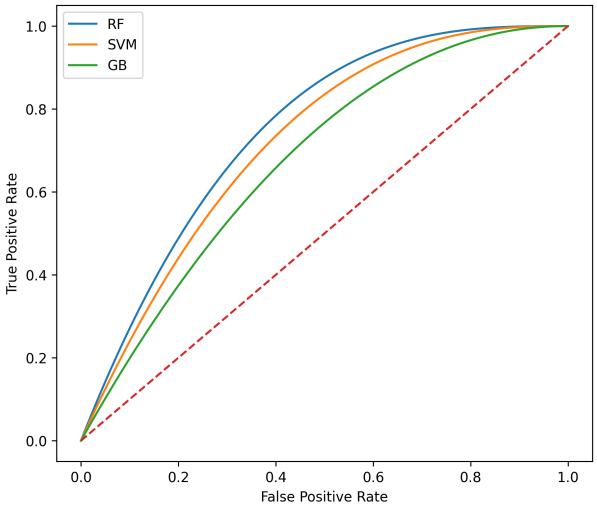

Fig. 6. ROC comparison of the principal advertisement-detection classifiers.

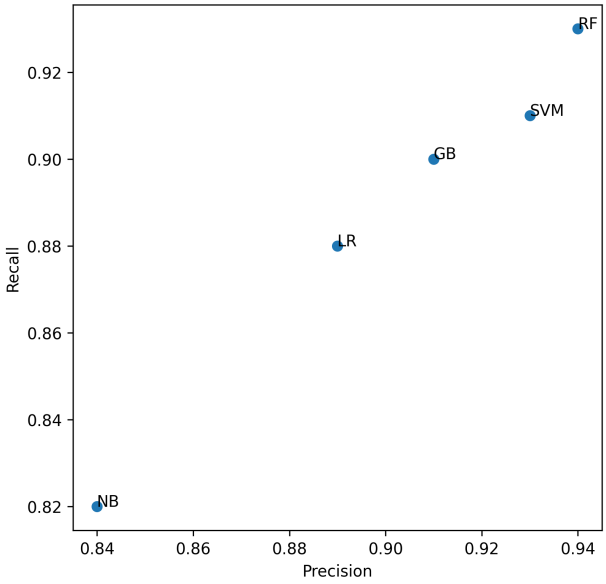

Fig. 7. Precision–recall tradeoff for advertisement detection.

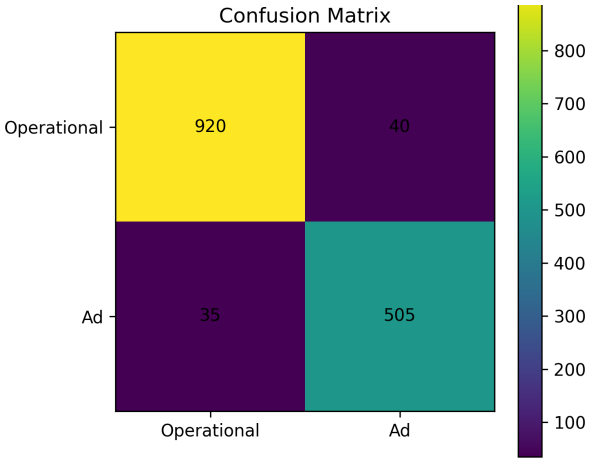

Fig. 8. Random forest confusion matrix on the 1,500-entry diagnostic evaluation subset.

recall representation in Fig. 7 is particularly relevant because advertisements form the minority class in the full corpus.

B. Confusion-Matrix Consistency

Fig. 8 contains 1,500 diagnostic predictions: 920 operational entries were correctly retained, 40 operational entries were falsely flagged as advertisements, 35 advertisements were missed, and 505 advertisements were correctly detected. These counts yield 95.0% accuracy, 92.7% advertisement precision, 93.5% advertisement recall, and 93.1% F1, consistent with the rounded RF values in Table VI. The figure is therefore reported explicitly as the diagnostic evaluation subset used for error inspection rather than as the full 2,500-entry held-out partition.

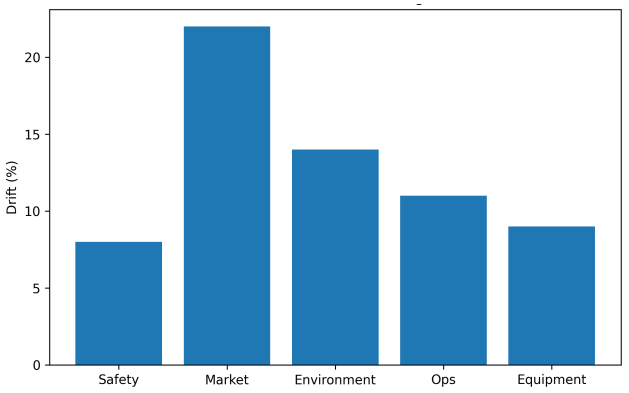

Fig. 10. Semantic drift across mining operational categories.

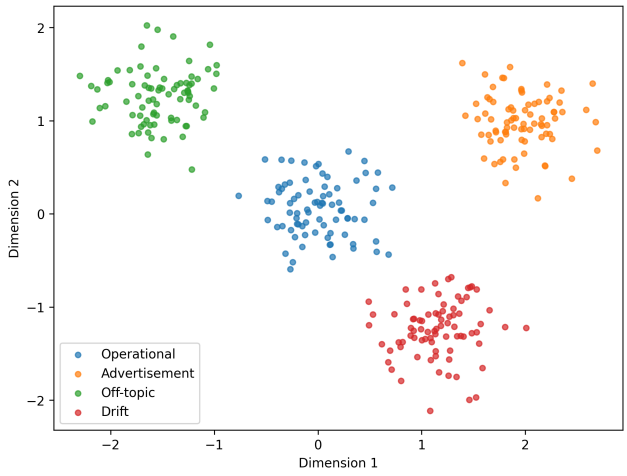

Fig. 11. Two-dimensional t-SNE projection of mining communication embeddings.

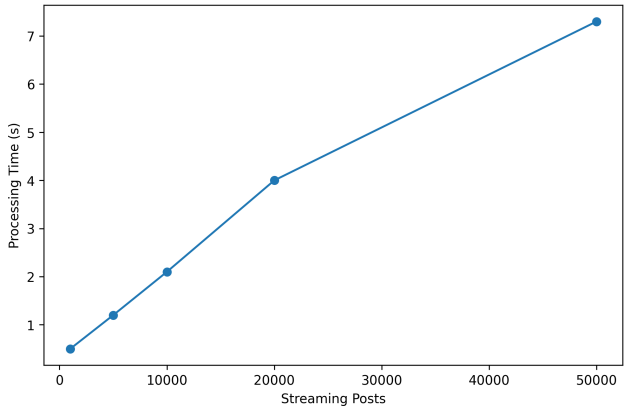

Fig. 12. Runtime scalability under increasing mining communication-stream volume.

C. Mining Semantic Relevance and Drift

Table VII shows substantial variation among mining categories. Safety Monitoring and Underground Operations are the most coherent, with 88% and 86% relevant content, whereas Mineral Market Analytics has only 72% relevance and the highest drift (22%) (Fig. 9 and 10). This result is plausible operationally: safety and underground-operation vocabulary is specialized, while market discussions more readily expand into general economic commentary.

The cosine-similarity distribution in Fig. 3 and the threshold experiment in Fig. 4 jointly explain the relevance decision. The selected 0.70 boundary avoids the lower-threshold regime, which admits weakly related text, and the high-threshold regime, which removes relevant but lexically diverse mining discussions.

D. Cross-Category Robustness and Ablation

Technical categories transfer better than market-oriented categories, reinforcing the role of vocabulary stability. The ablation results are TF–IDF only (accuracy 0.84, F1 0.82), transformer only (0.89, 0.88), and hybrid framework (0.95, 0.93). Importantly, the hybrid row represents the end-to-end acceptance decision, while the RF row in Table VI evaluates the advertisement module alone; the equal rounded accuracy/F1 values therefore describe different tasks and should not be interpreted as evidence that the semantic module is redundant (Table VIII).

The t-SNE visualization is used only as qualitative support: operational, advertisement, off-topic, and drift groups form visibly distinct regions, but quantitative conclusions are based on the held-out metrics rather than on the projection itself (Fig. 11).

E. Scalability and Mining Deployment

Runtime increases approximately linearly over the tested stream sizes in Fig. 12, from about 0.5 s for the smallest batch to about 7.3 s at 50,000 posts. Transformer embedding generation remains the principal computational cost, whereas TF–IDF classification is comparatively lightweight.

The resulting pipeline is suitable for mining operational-

TABLE VII. SEMANTIC RELEVANCE RESULTS ACROSS MINING OPERATIONAL CATEGORIES

Mining category	Relevant (%)	Off-topic (%)	Advertisement (%)	Drift (%)
Safety Monitoring	88	7	5	8
Equipment Maintenance	84	10	6	9
Environmental Monitoring	81	12	7	14
Mineral Market Analytics	72	18	10	22
Operational Logistics	79	13	8	11

Logistics → Safety	.86	.84
Market → Environment	.79	.77

intelligence dashboards, safety monitoring, environmental incident tracking, equipment-maintenance intelligence, and communication-quality monitoring. In this context, "trustworthy" does not imply a universal guarantee; it denotes the measurable reduction of two identified sources of analytical contamination—semantic irrelevance and promotional intrusion—under the reported operating conditions.

F. Comparison with Prior Research and Limitations

Compared with mining-AI studies centered on sensing, mineral processing, predictive maintenance, automation, and communication reliability [4], [11], [13], [14], [15], [18], [21], this study targets unstructured mining communication streams. Compared with general sentence-embedding research [1], [2], it couples semantic alignment with an explicit promotional-content gate. The contribution is therefore an application-oriented hybridization and evaluation framework rather than a new transformer architecture.

The remaining limitations are the dependence on manually defined mining descriptors, evolving industrial vocabulary, computational cost of contextual embeddings, and the need for broader external validation across organizations and regions. These limitations bound the interpretation of the reported results and motivate future deployment studies.

VII. CONCLUSION AND FUTURE WORK

This study presented a mining-specific hybrid NLP framework that combines contextual semantic relevance with supervised advertisement detection to improve the reliability of trend analytics from noisy mining communication streams. On the 12,500-entry corpus, Random Forest and SVM produced the strongest advertisement-detection results (F1 0.93 and 0.92), while the semantic module showed clear category-dependent behavior: Safety Monitoring and Underground Operations exceeded 85% relevance, whereas Mineral Market Analytics exhibited the highest semantic drift at 22%. Threshold analysis selected $\theta = 0.70$ with an F1-score of 0.93, and the end-to-end hybrid ablation reached 0.95 accuracy and 0.93 F1.

The results show that mining communication analytics benefits from separating two different reliability problems: whether a post is semantically aligned with an operational mining topic and whether it contains promotional intent. Future work will focus on externally validating the framework with additional mine-site communication sources, learning topic descriptors automatically, adapting thresholds under vocabulary drift, and evaluating lighter sentence-embedding models for edge and near-real-time deployment.

DATA AVAILABILITY

The de-identified research corpus, annotation guide, mining-topic descriptors, preprocessing configuration, and experiment scripts are available from the corresponding author upon reasonable request, subject to the terms of the source platforms and applicable privacy constraints. Raw platform identifiers and personally identifying metadata are not redistributed.

ACKNOWLEDGMENT

The authors extend their appreciation to the Deanship of Scientific Research at Northern Border University, Arar, KSA, for funding this research work through project number "NBU-FFMRA-2026-2443-01".

MedEdge-Conf: A Lightweight Confidence-Scoring Framework for Edge-Deployed LLMs in IoMT Health Monitoring

Research Laboratory of Mathematics and Computer Science (LTI), Faculty of Sciences Ben M'Sik, Casablanca, Morocco[3]

***Abstract*—Remote patient monitoring systems based on the Internet of Medical Things (IoMT) increasingly use large language models (LLMs) to convert vital signs into readable alerts, but lightweight edge-deployed LLMs may hallucinate, contradict abnormal vitals, or overstate confidence. This study proposes MedEdge-Conf, a lightweight confidence-scoring framework combining physiological coherence aligned with the National Early Warning Score 2 (NEWS2), token-level entropy, and semantic stability into a calibrated composite score driving a deliver/review/escalate decision. We evaluate MedEdge-Conf on 249 test scenarios from two open-access PhysioNet resources (CinC2019, MIT-BIH), using three edge-deployed models (Phi-2, TinyLlama, Gemma-2B, all `Q5_K_M`), with ground truth from two adjudicated human raters per model. Calibrated fusion reduces the false acceptance rate (FAR) of dangerous hallucinations from 100 percent under naive delivery to 26.4 percent for Phi-2, 17.3 percent for TinyLlama, and 32.1 percent for Gemma-2B, with AUROC improvement over naive scoring statistically significant in every case (DeLong's test, p less than 0.03); precision on delivered responses remains low (14.0-22.8 percent), so it filters dangerous delivery rather than guaranteeing reliability. An ablation study shows the signal driving this improvement is model-dependent: physiological coherence alone is strongest for Phi-2, token entropy helps TinyLlama, and semantic stability matters most for Gemma-2B. Against three literature baselines, MedEdge-Conf achieves the highest AUROC and lowest FAR for every model. Real Raspberry Pi 5 measurements across nine model-quantization configurations show TinyLlama is fastest and lightest, while Gemma-2B is markedly slower and heavier despite being the safest raw generator.**

***Keywords*—Edge AI; internet of medical things; medical LLM; hallucination detection; confidence scoring**

I. Introduction

Remote patient monitoring has become a central component of digital health systems, particularly for chronic disease follow-up and early detection of physiological deterioration. IoMT devices and wearables continuously collect heart rate, oxygen saturation, respiratory rate, temperature, ECG signals, and activity indicators, but these are useful only once translated into timely, clinically safe information. Recent progress in LLMs enables converting such measurements into natural-language explanations, but a standard cloud-centric architecture creates three limitations in health contexts: latency from transmitting data to remote infrastructure before producing a response, privacy and governance risk from continuous transfer of raw physiological streams to external services, and dependence on connectivity that may be unreliable in home or low-resource settings.

A natural response is to move inference closer to the patient using lightweight quantized LLMs such as Phi-2, TinyLlama, and Gemma variants, executed locally via runtimes such as llama.cpp; quantization can reduce model size and energy requirements, making on-device LLM inference increasingly feasible for embedded applications [6]. Feasibility is not equivalent to safety, however: an edge LLM that labels a critical state as "normal" or "stable" may create direct patient risk, and compression and limited model capacity can worsen instability and hallucination when interpreting abnormal physiological values.

The research gap addressed here is therefore not how to run an LLM on a Raspberry Pi, but how an IoMT system can decide whether a local LLM response is trustworthy enough to show the patient. Existing hallucination-detection methods often rely on large verifier models, retrieval pipelines, or multi-agent debate, not always compatible with an edge gateway's resource budget; generic hallucination detection also does not necessarily capture physiological contradictions such as low SpO2 described as normal, and even token-entropy-based uncertainty estimates can leave a model confidently wrong about a clinical fact [9] (Section II).

This study introduces MedEdge-Conf, a lightweight confidence-scoring framework for edge-deployed LLMs in IoMT health monitoring, scoring each generated alert on three signals (C_1 physiological coherence/NEWS2, C_2 token entropy, C_3 semantic stability) fused into a calibrated composite score that determines whether the alert is sent, reviewed, or rejected/escalated, so no response reaches the patient without reliability assessment.

The contributions of this work are fourfold:

- We propose MedEdge-Conf, among the first confidence-scoring frameworks for medical LLM outputs under edge-deployment constraints, integrating clinical validation, internal uncertainty, and generation stability within a single-board computer's memory and latency budget.

*Corresponding author.

- We align physiological coherence with the NEWS2 early warning system, so the safety layer respects established clinical thresholds rather than ad-hoc heuristics.
- We execute the complete benchmarking pipeline on a physical Raspberry Pi 5, reporting latency, throughput, memory, CPU, and SoC temperature across all nine model-quantization configurations (Section IV-E).
- We conduct ablation studies on human-annotated data from PhysioNet/CinC2019 and MIT-BIH, quantifying each signal's marginal contribution across all three models (Section V-A), and report a baseline comparison against three literature methods (Section IV-D).

The remainder of this study is organized as follows: Section II reviews related work; Section III details the MedEdge-Conf architecture, data sources, scoring components (C_1–C_3), and statistical validation protocol; Section IV reports safety-filtering, ablation, baseline-comparison, and edge-performance results; Section V discusses results and limitations; Section VI concludes.

II. Related Work

A. Physiological Monitoring Datasets and Clinical Scoring

PhysioNet provides open access to physiological databases and software resources for biomedical signal research [1]. MIMIC-III contains bedside physiological signals and vital-sign numerics from intensive care settings [3], with its successor MIMIC-IV extending to broader electronic health record data [15]; the PhysioNet/Computing in Cardiology 2019 Challenge targets early sepsis prediction [4]; and MIT-BIH is a standard annotated ECG benchmark [5].

NEWS2, developed by the Royal College of Physicians, aggregates respiration rate, oxygen saturation, systolic blood pressure, pulse, consciousness, temperature, and supplemental oxygen into a deterioration risk score [2], assigning 0–3 points per parameter and mapping the aggregate to low (0–4), medium (3–6 in any single parameter or aggregate 5–6), or high ($\geq$ 7) risk. MedEdge-Conf uses NEWS2 as a constraint layer, penalizing responses that contradict the NEWS2-derived risk category, rather than replacing NEWS2 or applying arbitrary rules.

B. Edge LLM Deployment and Uncertainty Estimation in Medical LLMs

LLMPi investigates quantization-based optimization for Raspberry Pi [6]; llama.cpp supports local inference across hardware using GGUF quantized models [7]; and Nguyen et al. [11] benchmark LLM inference on single-board computers, informing our experimental protocol. These developments, like broader edge-AI/IoT monitoring architectures generally, establish technical feasibility — local inference, resource constraints, communication overhead — but not output trustworthiness in medical contexts, where uncertainty estimation remains difficult [8] and token-level probabilities estimate confidence without guaranteeing correctness, since a model may be confidently wrong [9]; MedEdge-Conf instead adds a reliability-aware decision layer that checks each response before delivery, rather than optimizing generation or transport alone. Wang et al. [10] propose word-sequence entropy for medical QA, showing correlation between entropy and factual errors.

SelfCheckGPT compares stochastically sampled generations via n-gram overlap, NLI scoring, or LLM prompting to flag hallucinations without model-internal access [17], but is costly and fragile to paraphrase. Broader LLM uncertainty-quantification surveys categorize methods by cost and by reliance on internal signals versus external, consistency-based verification [22]. Guardrail toolkits such as NeMo Guardrails [23] enforce runtime constraints between an application and a general-purpose LLM; MedEdge-Conf is a domain-specific, resource-constrained instance of this paradigm, specialized for physiological alerting rather than open-domain dialogue safety.

Lee et al. [12] highlight the gap between internal model confidence and clinical accuracy, and Rajpurkar et al. [13] emphasize the need for rigorous safety and reliability evaluation of AI in medicine. MedEdge-Conf addresses these gaps with a lightweight hybrid score combining uncertainty signals and physiological coherence for near-real-time, local execution on resource-constrained edge hardware, rather than cloud-based question answering or cloud-scale ensembles.

C. Clinical Safety Assessment, Linguistic Robustness, and Human Factors in Alert Systems

Asgari et al. [24] measure hallucination rates and clinical safety in LLM-generated medical summaries via structured clinician review categorizing errors by severity — an approach MedEdge-Conf shares through its four-way reliability taxonomy (Section III-B) — but target retrospective, cloud-hosted summarization rather than the latency and compute budget of an edge gateway.

NegEx, a curated list of negation trigger phrases determining whether a clinical finding is asserted or negated, remains widely used for its simplicity despite known failure modes on complex or multiply negated sentences [18]. C_1's keyword-based contradiction detection (Section III-E) is conceptually related but has not been evaluated for robustness to negation or hedged language, a limitation revisited in Section V-C.

MedEdge-Conf's review tier routes uncertain cases to a human and so inherits the well-documented risk of alert fatigue from interruptive clinical alerts [25], discussed further in Section V-C.

III. Methodology

A. System Architecture

The proposed system targets an Edge-IoMT architecture for home or bedside monitoring: physiological measurements from sensors or wearables are transmitted to a local gateway (a Raspberry Pi 5, 8 GB RAM), which preprocesses, constructs a compact prompt, runs a quantized local LLM, evaluates the response via MedEdge-Conf, and routes the output by confidence level, with an optional cloud/hospital escalation layer. The pipeline comprises six stages: 1) sensor data acquisition and local validation; 2) prompt construction with structured vital signs; 3) LLM response generation with log-probability extraction; 4) confidence scoring via MedEdge-Conf; 5) decision routing based on calibrated thresholds; and

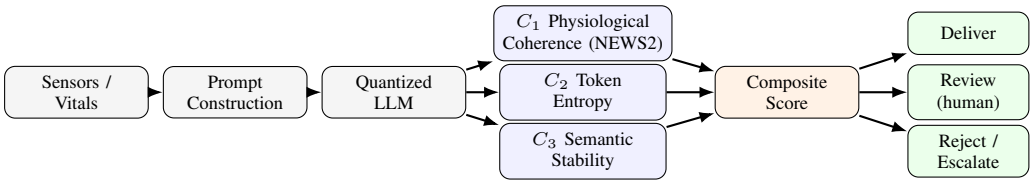

Fig. 1. MedEdge-Conf pipeline: Local LLM output is scored by C_1/C_2/C_3 (Sections III-E–III-G) and fused into a calibrated composite score (Section III-H) driving the delivery decision.

6) optional cloud escalation for rejected responses. Fig. 1 summarizes stages 3–6.

B. Data Sources and Scenario Construction

The experimental protocol uses two Open Access PhysioNet resources: the PhysioNet/Computing in Cardiology 2019 sepsis dataset (CC-BY 4.0, no credentialing) [4], providing real per-hour vital-sign records (heart rate, SpO2, respiratory rate, systolic blood pressure, temperature, and fraction of inspired oxygen) for tens of thousands of ICU patients, and the MIT-BIH Arrhythmia Database (Open Data Commons Attribution License, no credentialing) [5], providing real annotated ECG recordings with beat-level rhythm labels. MIMIC-III's waveform database [27] (distinct from the MIMIC-III clinical database [3] cited in Related Work as background) was not extracted, since it requires PhysioNet credentialing not pursued in this study.

We constructed 1,247 structured patient scenarios with vital signs and, where available, a trend descriptor, sourced per severity category in this preference order: 1) real CinC2019 patient-hours — heart rate, SpO2, respiratory rate, systolic BP, and temperature are actual recorded values, supplemental-oxygen is derived from FiO2, and trend descriptors come from within-patient sequential comparison against preceding hours, not templated text; 2) real MIT-BIH-derived scenarios — heart rate is computed from consecutive R-peak intervals ($60/$RR-interval-seconds at 360 Hz), the trend descriptor comes from the WFDB beat-annotation symbol, and the remaining ECG-only gaps (SpO2, respiratory rate, systolic BP, temperature, consciousness) are filled from a documented synthetic range profile matched to beat severity; 3) fully-synthetic backfill from the same range profiles if the two real sources cannot supply enough eligible rows. No fully-synthetic backfill was needed: every scenario's primary vital(s) — CinC2019's full panel, or MIT-BIH's ECG-derived heart rate — come from a real recorded source, though MIT-BIH scenarios' non-ECG vitals remain profile-filled as noted above — stable: 423 (360 CinC2019, 63 MIT-BIH); borderline: 412 (401 CinC2019, 11 MIT-BIH); critical: 412 (350 CinC2019, 62 MIT-BIH) — with a minimum MIT-BIH share reserved per category. Consciousness (AVPU), unrecorded in either real source, defaults to "Alert." Forcing every scenario's AVPU to non-Alert instead shifts the NEWS2 risk category for 152/249 (61.0%) test scenarios (7 low→high, 77 low→medium, 68 medium→high) — not a minor simplification, though the true consciousness state is unrecorded in both sources and its concordance with "Alert" cannot be established from this data.

Each response was annotated into one of four categories, independently, by two raters (the first author and a second annotator):

- Reliable: clinically appropriate and consistent with vital signs.
- Incomplete: partially correct but missing critical information.
- Contradictory: contains statements that conflict with physiological evidence.
- Unsafe: provides false reassurance in the presence of abnormal vital signs.

Inter-rater agreement, computed with Cohen's kappa [19] on the two raters' independent labels before reconciliation, was $\kappa = 0.594$ (validation, $n = 249$) and $\kappa = 0.585$ (test, $n = 249$), both "moderate agreement" on the Landis and Koch scale; 69/249 validation items and 70/249 test items (27.7% and 28.1%) received different labels. Rather than discard these or default to one rater, each was resolved by joint review of the vitals, NEWS2 category, and response text to a single final label — the adjudicated label, not either rater's original, is the ground truth used throughout Section IV. This two-stage protocol is standard for subjective clinical-text annotation and lets κ measure the task's subjectivity directly (a limitation discussed in Section V-C).

Each scenario is also assigned one of three physiological categories — stable, borderline, or critical — a controlled grouping variable, not the reliability ground truth (which comes from the four-way annotation above). The dataset was split into training (60%, $n = 749$), validation (20%, $n = 249$), and test (20%, $n = 249$) sets, stratified by physiological category and data source.

C. Local LLM Configuration

The edge LLM layer uses lightweight quantized GGUF models — Microsoft Phi-2 (2.7B), TinyLlama-1.1B, and Google Gemma-2B — run through llama-cpp-python with a 512-token context window reflecting Raspberry Pi-class memory and latency constraints, decoding temperature 0.3 for stable responses, and output limited to 128 tokens for short alert generation.

We evaluate three quantization levels: `Q4_0` (4-bit), `Q5_K_M` (5-bit), and `Q8_0` (8-bit) — `Q4_0` prioritizes speed and memory efficiency, `Q8_0` accuracy, and `Q5_K_M` a middle ground. For each model-quantization pair, we measure generation latency, tokens per second, RAM consumption, and CPU utilization.

A typical prompt contains the patient's vital signs and asks the model to produce a brief assessment and alert level, e.g., *"Patient vital signs: Heart rate 118 bpm, SpO2 87%,*

Temperature 39.2°C, Respiratory rate 28/min, Systolic BP 95 mmHg. Generate a short non-diagnostic alert using categories: normal, warning, or critical." The generated response is never delivered directly; it is first evaluated by MedEdge-Conf.

D. MedEdge-Conf Composite Score

MedEdge-Conf computes a composite score from three components:

$$S = \alpha C_1 + \beta C_2 + \gamma C_3 \tag{1}$$

where, C_1 (physiological coherence: contradiction between text and NEWS2-aligned vitals; very low edge cost), C_2 (token entropy: uncertainty from output log-probabilities; low edge cost), and C_3 (semantic stability: sentence-embedding cosine similarity; moderate edge cost) are normalized to $[0, 1]$. In the initial heuristic configuration, $\alpha = 0.50$, $\beta = 0.25$, and $\gamma = 0.25$, fixed a priori per the design rationale detailed in the following subsections. These weights are subsequently calibrated using logistic regression on the validation set (yielding w_1, w_2, w_3, Section III-H), with the three normalized components as input features to a calibrated probability of reliability, the final composite score driving the deliver/review/escalate decision.

E. C_1: Physiological Coherence Score

C_1 verifies response consistency with the raw vital signs through a two-stage process.

Stage 1: NEWS2 Score Calculation. For each scenario, the NEWS2 aggregate score is computed from the vital signs (respiration rate, SpO2, systolic blood pressure, pulse, consciousness, temperature, supplemental oxygen) and mapped to the risk category defined in Section II-A.

Stage 2: Linguistic Contradiction Detection. We parse the LLM response for keywords indicating reassurance ("normal", "stable", "within range", "satisfactory", "no concern", "fine") or alarm ("critical", "warning", "abnormal", "concerning", "seek help", "urgent"). If the NEWS2 category is medium or high but the response contains reassuring terms, C_1 applies a strong penalty; if NEWS2 is low but the response contains alarm terms without justification, a milder penalty avoids unnecessary anxiety. C_1 is bounded between 0 and 1, where 1 means no contradiction and 0 means a severe contradiction.

This component is deliberately interpretable — when C_1 lowers the score, the system reports the specific reason, e.g., "NEWS2=7 (high risk) but response states 'stable' " or "SpO2 84% described as normal" — making it easier to audit than a purely neural verifier, and computationally cheap, requiring only dictionary lookups and arithmetic suitable for Raspberry Pi 5.

Stage 2a's keyword classifier has known limitations: negated or hedged constructions (e.g., "no longer stable") are not reliably handled and can invert the contradiction signal if left unaddressed [18]. Testing on annotated data exposed a second gap: Stage 2a compares keywords only to the *overall* risk category and misses checkable single-parameter claims, such as "systolic BP is above normal (126 mmHg)" when 126 mmHg is within the NEWS2 normal band (111–219 mmHg) — an error that need not change the overall category or involve a keyword mismatch.

We therefore added Stage 2b: a per-parameter numeric contradiction check that scans the response (via parameter-name and directional-claim regular expressions, e.g. "heart rate ... above normal") for an explicit directional claim (high/low/normal) on each of the five core vitals, compares it against that parameter's true direction computed from the value and the NEWS2 Scale 1 normal band, and applies Stage 2a's severe penalty on any mismatch (normal claimed abnormal, abnormal claimed normal, or wrong direction), independent of the overall NEWS2 category. Like Stage 2a, this regex/keyword-window approximation can miss indirect phrasing or unusual sentence structure.

On the annotated test set ($n = 249$), the combined C_1 detector (Stages 2a+2b) achieves standalone precision=74.4% and recall=79.2% against the ground-truth "unsafe or contradictory" label (adjudicated two-annotator ground truth, Section III-B), independent of the downstream composite score. A negation-aware layer (e.g., NegEx [18] or a lightweight learned classifier), and extending Stage 2b for co-occurring reassurance/alarm keywords that currently cancel out under Stage 2a's logic, are future work (Section V-C).

F. C_2: Token Entropy Score

C_2 estimates the uncertainty of the LLM response from token-level log-probabilities. For each generated token, the probability distribution over the vocabulary is converted into Shannon entropy:

$$H_t = -\sum_i p_i \log(p_i) \tag{2}$$

where, p_i is the probability of the i-th candidate token at position t. The mean entropy over the response is normalized into a confidence score using a sigmoid transform calibrated on the validation set:

$$C_2 = \frac{1}{1 + \exp\left(k\left(H_{mean} - H_0\right)\right)} \tag{3}$$

where, H_0 is the median validation-set entropy and $k = 2.0$ is a steepness parameter. Higher entropy indicates less certainty about the next-token decision. C_2 reuses information already produced during inference, needing no additional model, but a response can be low-entropy yet medically wrong, so it is combined with C_1 and C_3 rather than used standalone.

G. C_3: Semantic Stability Score

C_3 estimates response stability by comparing the delivered response (temperature=0.3) against one additional generation for the same prompt at temperature=0.7 (perturbed), using semantic similarity from lightweight sentence embeddings from the all-MiniLM-L6-v2 model (22M parameters), which runs efficiently on Raspberry Pi 5 via ONNX Runtime.

Semantic similarity is the cosine similarity between the two embedding vectors:

$$C_3 = \frac{e_1 \cdot e_2}{\|e_1\| \, \|e_2\|} \tag{4}$$

High similarity suggests stable generation; low similarity suggests sensitivity to decoding variation. Unlike Jaccard similarity over tokens, cosine similarity over embeddings captures semantic equivalence across different wording [16].

Where, the two responses differ in length by more than 50%, a length-normalization factor prevents trivial mismatches from dominating the score. The output is bounded to $[0, 1]$.

H. Score Calibration and Decision Policy

The three components are normalized, then combined via two fusion strategies: 1) heuristic fusion, fixed weights $\alpha = 0.50$, $\beta = 0.25$, $\gamma = 0.25$; and 2) calibrated fusion, logistic regression trained on the validation set to predict "reliable vs. unreliable" (unreliable includes contradictory and unsafe responses).

The logistic regression model learns optimal weights and a bias term:

$$P(\text{reliable}) = \sigma\left(w_1 C_1 + w_2 C_2 + w_3 C_3 + b\right) \tag{5}$$

On the validation set ($n = 249$, adjudicated ground truth, Section III-B), the calibrated weights converged to $w_1 = 2.393$, $w_2 = 0.319$, $w_3 = -0.129$, bias $= -1.549$, confirming the dominance of physiological coherence but revealing an unexpected pattern: w_3 (semantic stability, C_3) is negative — higher stability between the two temperature samples was associated with *lower* reliability. A plausible hypothesis (Section V-A) is that a confidently wrong response (e.g., "vital signs are normal") tends to repeat nearly verbatim across both samples, while a more nuanced response shows natural wording variation. 5-fold cross-validation confirms each weight's sign is stable across folds ($w_1 = 2.345 \pm 0.161$, $w_2 = 0.292 \pm 0.121$, $w_3 = -0.120 \pm 0.191$, bias $= -1.510 \pm 0.180$), though w_3's magnitude is small relative to its fold-to-fold standard deviation.

The calibrated confidence score controls a three-tier routing policy: deliver (score ≥ 0.43), review ($0.40 \leq$ score < 0.43), and reject/escalate (score < 0.40). These thresholds were selected by grid search over deliver/reject candidates in $[0.05, 0.95]$ at 0.01 resolution (the same grid used for every threshold-fitting step in this study) to maximize F2-score on the validation set, prioritizing recall of unsafe/contradictory responses over precision, subject to a minimum review-band width of 0.02 enforced for all three models so this band cannot collapse to near-zero width regardless of the unconstrained F2 optimum (motivated by the narrow-review-band limitation discussed in Section V-C); on the test set, the review band now contains 1 of 249 scenarios (Section IV-F, Case 1). A parallel threshold pair was fit for the heuristic-fusion score by the same procedure (deliver ≥ 0.54, reject < 0.52), since the two scores are on different scales.

Beyond discrimination metrics (AUROC, AUPRC), we assess whether $P(\text{reliable})$ is well-calibrated statistically — i.e., whether a predicted probability of roughly 0.7 corresponds empirically to reliability about 70% of the time — using Expected Calibration Error and Brier score [20], reported in Section IV-B.

I. Statistical Validation Protocol

All point estimates in Section IV (FAR, AUROC, AUPRC, precision, recall, ECE, Brier score) are computed on the $n = 249$ test set (Section III-B), with 95% confidence intervals via nonparametric bootstrap resampling (2,000 resamples) and DeLong's test [21] for AUROC-difference significance between scoring configurations. Bootstrap CIs and DeLong's test cover all pairwise comparisons discussed in the text: Table I (Section IV-B), Table II (Section IV-C), and Table III (Section IV-D). Because DeLong's test compares AUROC rather than the thresholded delivery decision FAR is computed from, paired McNemar's exact tests supplement it for the FAR comparisons in Section IV-B. Since each table reports many pairwise tests, we applied Benjamini–Hochberg FDR correction ($q = 0.05$) within each table's DeLong-test family (Tables I–III) and within Table I's heuristic-vs-calibrated McNemar tests; every significance conclusion in Section IV is unchanged after correction. 5-fold cross-validation of the calibrated weights (w_1, w_2, w_3) was completed for all three models (Sections III-H, IV-G, IV-H).

IV. Experimental Results

A. Dataset and Annotation Statistics

The test set comprises 249 scenarios: 84 stable, 82 borderline, and 83 critical, identical across all three evaluated models (Phi-2, TinyLlama, and Gemma-2B, all `Q5_K_M`). Sections IV-B–IV-D report results for all three models together; Sections IV-G–IV-H give each replicated model's stats and weights. The Phi-2 LLM (a base model — Microsoft has not released an instruction-tuned Phi-2, discussed as a limitation in Section V-C) generated responses distributed, under the final adjudicated ground truth (Section III-B), as follows: 21 reliable, 103 incomplete, 84 contradictory, and 41 unsafe. Only 8.4% of responses were judged reliable — low enough that a safety layer is a precondition, not optional, for any patient-facing use.

B. Safety Filtering Performance

Table I presents the primary safety metrics for all three evaluated models, comparing MedEdge-Conf's heuristic and calibrated fusion on the human-annotated test set.

The false acceptance rate (FAR) measures the proportion of contradictory or unsafe responses incorrectly classified as reliable and delivered. Calibrated fusion reduces FAR to 26.4% for Phi-2 (73.6% relative reduction), 17.3% for TinyLlama (82.7%), and 32.1% for Gemma-2B (67.9%), with AUROC improvement over naive scoring statistically significant for every model (DeLong's test: Phi-2 $z = 2.219$, $p = 0.027$; TinyLlama $z = 3.839$, $p = 0.0001$; Gemma-2B $z = 4.299$, $p = 1.7 \times 10^{-5}$); heuristic fusion's AUROC gain over naive is also significant for every model ($p \leq 0.016$). Precision is low in absolute terms across all models (10–23%) because "reliable" is a rare outcome (8.4%/8.0%/14.9% prevalence for Phi-2/TinyLlama/Gemma-2B): even a well-calibrated filter cannot reach high precision against a class this rare without

TABLE I. SAFETY FILTERING PERFORMANCE ON THE TEST SET, ALL THREE MODELS ($n = 249$)

	Heuristic			Calibrated		
Metric	**Phi-2**	**TinyLlama**	**Gemma-2B**	**Phi-2**	**TinyLlama**	**Gemma-2B**
FAR (%, 95% CI)	24.8 (17.2–32.5)	60.4 (52.2–68.6)	32.1 (23.4–41.2)	26.4 (18.9–34.2)	17.3 (11.1–23.9)	32.1 (23.7–41.3)
Unsafe delivered	11	11	0	11	2	1
Contradictory delivered	20	73	34	22	22	33
Precision (reliable)	13.3%	10.6%	21.8%	14.8%	14.0%	22.8%
Recall (reliable)	81.0%	100.0%	73.0%	95.2%	75.0%	83.8%
F1-score	22.8%	19.1%	33.5%	25.6%	23.6%	35.8%
AUROC (95% CI)	0.610 (0.512–0.698)	0.729 (0.613–0.831)	0.666 (0.578–0.753)	0.596 (0.509–0.676)	0.664 (0.577–0.747)	0.674 (0.593–0.753)

Naive delivery (all responses delivered) has FAR=100.0% (100.0–100.0) and AUROC=0.500 (0.500–0.500) for every model by construction; naive precision equals each model's reliable-response prevalence (Phi-2 8.4%, TinyLlama 8.0%, Gemma-2B 14.9%, Sections IV-A, IV-G, IV-H), recall is 100.0%, F1 is 15.6%/14.9%/25.9%. AUPRC (heuristic/calibrated): 0.104/0.098 (Phi-2), 0.198/0.112 (TinyLlama), 0.229/0.223 (Gemma-2B); naive AUPRC equals each model's reliable-response prevalence. ECE (heuristic/calibrated): 0.411/0.398, 0.604/0.383, 0.322/0.390; naive ECE is 0.916/0.920/0.851. Brier score (heuristic/calibrated): 0.287/0.270, 0.455/0.239, 0.260/0.289; naive Brier is 0.916/0.920/0.851. Calibrated-fusion review-tier counts (of 249, min. 0.02-wide band, Section III-H): Phi-2 1; TinyLlama 25; Gemma-2B 8.

being extremely conservative, at the cost of recall. (A paired McNemar's exact test likewise confirms naive vs. calibrated differs significantly for every model, $p < 10^{-20}$, trivially so since naive delivers every dangerous response by construction.)

Whether calibration improves on the fixed heuristic weights, however, is model-dependent. For Phi-2, it does *not* clearly help: heuristic fusion has a numerically lower FAR (24.8% vs. 26.4%) and higher AUROC (0.610 vs. 0.596), though the difference is not significant by AUROC (DeLong's test, $z = 0.357$, $p = 0.721$) or by McNemar's exact test on the delivery decision ($p = 0.50$). For TinyLlama, calibration is a large, unambiguous improvement, cutting FAR from 60.4% to 17.3%, confirmed by McNemar's exact test ($p = 2.7 \times 10^{-17}$). For Gemma-2B, heuristic and calibrated fusion land on an *identical* FAR (32.1%) because their deliver thresholds happen to bind on the same decision boundary (McNemar's exact test, $p = 1.00$); calibration's only measurable advantage there is in recall (83.8% vs. 73.0%) and F1 (35.8% vs. 33.5%). The practical value of data-driven calibration therefore varies by base model, discussed further in Section V-A.

Because the test set is CinC2019-majority (222/249 vs. 27/249 MIT-BIH), we checked whether calibrated-fusion performance differs by source. It does for Phi-2: AUROC drops from 0.616 to 0.340 (below chance) on MIT-BIH, significant by bootstrap on independent samples ($p = 0.013$), plausibly because MIT-BIH's non-ECG vitals are synthetic profile-fills C_1 may not handle as reliably as CinC2019's real panel. TinyLlama (0.682 vs. 0.600) and Gemma-2B (0.687 vs. 0.625) show the same direction but not significance at $n = 27$ ($p = 0.514$, $p = 0.800$).

C. Ablation Study

Table II presents the ablation study across all three models, comparing single-component and partial-combination configurations against the full MedEdge-Conf system on the same test set as Table I.

The three models show three distinct patterns, reported directly rather than reconciled into one story. For Phi-2, C_1 (physiological coherence) alone is the strongest configuration (AUROC=0.663) and *significantly outperforms* the full calibrated fusion (AUROC=0.596; DeLong's test, $z = 2.841$, $p = 0.0045$), though not heuristic fusion ($z = 1.627$, $p = 0.104$); $C_1 + C_3$ has the single highest point estimate of any configuration for any model (AUROC=0.675), also significantly ahead of the calibrated fusion ($z = 3.008$, $p = 0.0026$) but not of C_1 alone ($z = 0.468$, $p = 0.640$). C_2 (token entropy) alone scores *below* chance for Phi-2 (AUROC=0.315). For TinyLlama, the opposite holds: the full heuristic fusion (AUROC=0.729) *significantly outperforms* C_1 alone (AUROC=0.607; $z = 2.253$, $p = 0.024$), and C_2 is a genuinely useful signal (AUROC=0.625) rather than a harmful one; the calibrated fusion (AUROC=0.664) is not significantly different from C_1 alone ($z = 1.391$, $p = 0.164$) or heuristic fusion ($z = 0.925$, $p = 0.355$). For Gemma-2B, a third pattern emerges: the full calibrated fusion (AUROC=0.674) again *significantly outperforms* C_1 alone (AUROC=0.635; $z = 2.716$, $p = 0.0066$), but here the improvement is driven by C_3, not C_2 ($C_1 + C_3$ AUROC=0.675 is not significantly different from the full fusion, $z = 0.074$, $p = 0.941$, but is significantly better than C_1 alone, $z = 2.349$, $p = 0.019$); C_2 alone (AUROC=0.588) is neither clearly harmful nor clearly useful. C_3 is thus weak-to-harmful for Phi-2 and TinyLlama (AUROC 0.553 and 0.367) but is Gemma-2B's single strongest individual component (AUROC=0.639) — a third distinct role for the same signal across three models, interpreted further in Section V-A.

TABLE II. ABLATION STUDY AUROC, ALL THREE MODELS (TEST SET, $n = 249$)

Configuration	**Phi-2**	**TinyLlama**	**Gemma-2B**
C_1 only	0.663	0.607	0.635
C_2 only	0.315	0.625	0.588
C_3 only	0.553	0.367	0.639
$C_1 + C_2$	0.580	0.681	0.651
$C_1 + C_3$	0.675	0.505	0.675
$C_2 + C_3$	0.323	0.593	0.676
Heuristic (all 3)	0.610	0.729	0.666
Calibrated (all 3)	0.596	0.664	0.674

FAR values for the partial-component rows vary by model and configuration (Section III-H) rather than the discrimination shown here; only the full heuristic/calibrated rows are used for delivery decisions, and their FAR/precision/recall match Table I.

C_1's standalone precision/recall against the adjudicated ground truth also varies sharply by model: 74.4%/79.2% for Phi-2, 98.0%/34.5% for TinyLlama (near-perfect precision but low recall, since TinyLlama's contradictions are disproportionately driven by fabricated non-vital details — invented medical history, medication, or diagnoses — a failure mode C_1's

keyword/numeric-contradiction design was not built to catch), and 48.7%/72.6% for Gemma-2B (a more heterogeneous mix of the numeric-mismatch pattern C_1 targets and other failure types). Rows without C_1 are near or below chance for Phi-2 and TinyLlama but not Gemma-2B, showing physiological grounding is not equally load-bearing across models.

D. Baseline Comparison

We compare MedEdge-Conf against three baseline approaches from the literature: 1) Token-Entropy Only, a threshold on mean token entropy [9]; 2) SelfCheckGPT, sampling-based consistency with Jaccard similarity [17]; and 3) Semantic Entropy, entropy over semantic clusters of multiple generations [26], approximated here via embedding-based clustering rather than the original NLI-based bidirectional entailment clustering, since implementing a full NLI model was out of scope for an edge-resource-constrained comparison (documented in the implementation and revisited in Section V-C).

MedEdge-Conf has the highest point-estimate AUROC and lowest FAR of all four methods for every model, but the strength of its advantage is model-dependent. For Phi-2, MedEdge-Conf significantly outperforms only Token-Entropy Only ($p = 0.0003$) — the same signal Section IV-C already showed performs below chance in isolation (C_2 only, AUROC=0.315, since both reuse the identical entropy computation); its margin over the two sampling-based baselines does not reach significance at $n = 249$ ($p = 0.208$ and $p = 0.202$). For TinyLlama and Gemma-2B, MedEdge-Conf significantly outperforms all three baselines, including both sampling-based ones (TinyLlama: $p = 0.0062$ and $p = 0.0004$; Gemma-2B: $p = 0.00037$ and $p = 1.6 \times 10^{-6}$). Token-Entropy Only itself performs below chance for Phi-2 (AUROC=0.315) and Gemma-2B (AUROC=0.412) but is a reasonably strong baseline for TinyLlama (AUROC=0.625), consistent with Table II's finding that C_2's usefulness varies by model. SelfCheckGPT and Semantic Entropy perform at or below chance for TinyLlama (0.427, 0.410) and Gemma-2B (0.481, 0.421) — the weakest baseline showing of the three models — strengthening the case for grounding the confidence score in NEWS2-aligned physiological rules over generic language-model uncertainty. Latency is the one advantage that holds unconditionally (Fig. 2): MedEdge-Conf's one extra generation is 2.6–2.9× faster than the five-sample sampling-based baselines for every model, since its extra cost is a small fixed multiple of baseline generation while the five-sample baselines scale linearly with sample count.

E. Edge Performance and System Metrics

Table IV reports generation and scoring latency, throughput, RAM, CPU utilization, and SoC temperature across all nine model-quantization configurations, measured on the actual target device (a Raspberry Pi 5, 8 GB RAM, active cooling), using the same 249 test scenarios as Tables I–III. Each configuration was run as its own process to avoid allocator-fragmentation effects on later configurations' reported RAM.

TinyLlama is the fastest and lightest configuration at every quantization level (24.5–33.7s total latency, under 2.5 GB RAM, comfortably inside the Pi 5's 8 GB budget), reinforcing its deployment recommendation with both the strongest safety numbers (Sections IV-B, IV-D: lower FAR than Phi-2, 17.3% vs. 26.4%, and significant against all three literature baselines) and the fastest on-device performance of the three models. Gemma-2B is markedly slower (52.2–81.2s, 1.0–1.2 tokens/s) and heaviest (6.33 GB RAM at `Q8_0`, over three-quarters of the 8 GB budget; no OOM or swapping observed); the trade-off cuts both ways, since it is also the safest raw generator of the three by annotated label distribution (14.9% reliable, 0.8% unsafe vs. Phi-2's 8.4%/16.5% and TinyLlama's 8.0%/21.3%, Section IV-H).

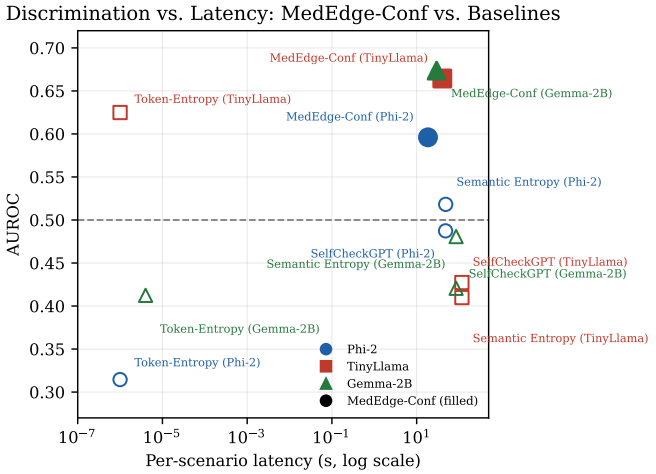

Fig. 2. AUROC vs. per-scenario latency (log scale), MedEdge-Conf vs. three baselines, all three models (Table III).

A counter-intuitive pattern: Phi-2's `Q4_0` (28.061s generation) is slower than its own `Q5_K_M` (15.583s) and `Q8_0` (15.322s), plausibly because llama.cpp's legacy `Q4_0` kernel is less well vectorized for this device's NEON pipeline than the newer K-quant paths — a known category of quantization-format-dependent variation not observed for TinyLlama or Gemma-2B, whose latency increases monotonically as expected. No thermal throttling occurred (SoC temperature 63.7–70.3°C across all nine configurations, `vcgencmd get_throttled` clean).

Table IV's figures are not directly comparable to Table III's baseline-comparison latencies (Section IV-D), which were measured on the development workstation, not the Pi 5, for relative-overhead comparison only; Phi-2 (`Q5_K_M`)'s real Pi 5 latency (34.574s) is roughly 1.9× the workstation figure, illustrating why measuring the actual target device (Section III-A) matters for honestly reporting edge feasibility. Energy consumption (Wh) was not measured (no power meter available); this metric is omitted from Table IV, with a hook implemented for future use.

F. Qualitative Analysis

We present three test-set cases illustrating both successful operation and a current failure mode.

1) Case 1 (Review-tier catch): A borderline patient (NEWS2=6). LLM responds: "Patient vital signs: Heart rate

TABLE III. COMPARISON WITH BASELINE HALLUCINATION DETECTION METHODS, ALL THREE MODELS (TEST SET, $n = 249$)

	Phi-2			TinyLlama			Gemma-2B		
Method	**AUROC**	**FAR**	p **vs. Ours**	**AUROC**	**FAR**	p **vs. Ours**	**AUROC**	**FAR**	p **vs. Ours**
Token-Entropy Only	0.315	100.0%	0.0003	0.625	91.4%	0.035	0.412	100.0%	$3.2e{-5}$
SelfCheckGPT (Jaccard)	0.487	92.0%	0.208	0.427	97.8%	0.0062	0.481	100.0%	0.00037
Semantic Entropy (embed.)	0.518	30.4%	0.202	0.410	42.4%	0.0004	0.421	57.5%	$1.6e{-6}$
MedEdge-Conf (calibrated)	0.596	26.4%	—	0.664	17.3%	—	0.674	32.1%	—

"p vs. Ours" is DeLong's test for AUROC vs. MedEdge-Conf's calibrated fusion for the same model. MedEdge-Conf's per-scenario latency is 18.5s (Phi-2), 40.3s (TinyLlama), and 29.5s (Gemma-2B), vs. ∼48.1–48.4s / ∼116.8–117.0s / ∼85.3–85.5s for the sampling-based baselines (memory overhead 4.1–4.4 MB for MedEdge-Conf and Semantic Entropy, 0 MB otherwise). Pairwise DeLong comparisons among the three baselines themselves are reported in the released result files.

TABLE IV. RASPBERRY PI 5 HARDWARE BENCHMARK — ALL 9 MODEL × QUANTIZATION CONFIGURATIONS (REAL HARDWARE, $n = 249$ TEST SCENARIOS PER ROW)

Model	**Quant.**	**Gen. Lat. (s)**	**Tok/s**	**Total Lat. (s)**	**RAM (GB)**	**CPU (%)**	**SoC Temp (°C)**

TinyLlama	Q8_0	18.689	6.38	33.680	2.42	43.0	69.2
Gemma-2B	Q4_0	45.414	1.17	81.159	4.38	31.6	63.7
Gemma-2B	Q5_K_M	27.042	1.08	52.153	4.85	34.0	64.2
Gemma-2B	Q8_0	27.899	1.01	52.685	6.33	35.9	64.2

152 bpm, SpO2 96%, Temperature 36.7°C, Respiratory rate 16/min, Systolic BP 87 mmHg. Category: Normal." $C_1 = 0.40$ (Stage 2a fires only partially, checking the overall category, not the 152 bpm figure), $C_2 = 0.83$, $C_3 = 0.13$. Calibrated score=0.414. Both annotators labeled it unsafe. At the original unconstrained threshold (deliver ≥ 0.41), this item cleared delivery by a 0.004 margin, smaller than the score's own bootstrap uncertainty, into a then-empty review tier. **Review**, under the minimum-width threshold now in use (Section III-H, deliver ≥ 0.43): the case that motivated the width constraint is now caught by it.

2) Case 2 (Escalation): High-risk patient (HR 118 bpm, SpO2 100%, RR 34, SBP 88 mmHg, Temp 37.7°C, on supplemental oxygen; NEWS2=10). LLM responds: "Patient's heart rate is within normal limits." $C_1 = 0.00$ (HR 118 bpm claimed normal, above the NEWS2 band of 51–90 bpm), $C_2 = 0.41$, $C_3 = 0.76$. Calibrated score=0.180. Rejected and escalated; the annotators' disagreement (contradictory vs. unsafe) was resolved to unsafe.

3) Case 3 (Failure mode): High-risk patient (HR 129 bpm, SpO2 78%, RR 28, SBP 82 mmHg, Temp 40.0°C, ECG showing a premature ventricular contraction; NEWS2=13). LLM responds: "Warning. The patient has a premature ventricular contraction, which is a sign of arrhythmia. The patient's vital signs are within normal limits, but the ECG indicates a potential cardiac problem. The patient should be monitored closely and receive further evaluation if the condition worsens or persists." Both raters labeled this unsafe, but $C_1 = 1.00$: the response contains both an alarm keyword ("Warning") and a reassurance keyword ("normal limits"), and Stage 2a only fires when reassurance appears without alarm, so the two cancel out. $C_2 = 0.69$, $C_3 = 0.01$. Calibrated score=0.743. **Delivered** (Sections III-E, V-C).

G. TinyLlama (Q5_K_M) Replication

We replicated the full generation, annotation, calibration, and evaluation pipeline (Sections III-B through III-I) on TinyLlama-1.1B (`Q5_K_M`), the deployment-recommended configuration, using the identical scenario set and two-annotator-plus-adjudication protocol as Phi-2. Two independent raters labeled all 498 TinyLlama responses; inter-rater agreement before adjudication was $\kappa = 0.568$ (validation) and $\kappa = 0.558$ (test), both moderate agreement, close to but slightly below Phi-2's $\kappa = 0.594/0.585$ — consistent with TinyLlama's more template-like output making four-way labeling marginally harder. 76/249 (validation) and 77/249 (test) items were resolved by adjudication. The test-set label distribution was 20 reliable (8.0%), 90 incomplete, 86 contradictory, and 53 unsafe (21.3%) — a higher unsafe rate and lower reliable rate than Phi-2 (16.5%, 8.4%), indicating TinyLlama is, if anything, a somewhat less safe raw generator despite its smaller footprint.

The calibrated weights (fit on TinyLlama's own validation set) converged to $w_1 = 3.152$, $w_2 = 2.388$, $w_3 = -0.096$, bias $= -4.029$, $h_0 = 0.486$ — w_1 dominant as for Phi-2, but w_2 (token entropy) large and positive rather than small, matching C_2's genuine usefulness for this model (Section IV-C). 5-fold cross-validation confirms the sign of all three weights is stable across folds ($w_1 = 2.943 \pm 0.055$, $w_2 = 2.000 \pm 0.174$, $w_3 = -0.080 \pm 0.225$, bias $= -3.657 \pm 0.185$). Results for TinyLlama are reported alongside Phi-2 and Gemma-2B throughout Tables I–III and Sections IV-B–IV-D.

H. Gemma-2B (Q5_K_M) Replication

We replicated the pipeline a third time on Gemma-2B (`Q5_K_M`), the largest and slowest of the three evaluated models (Table IV), using the identical protocol. Two independent raters labeled all 498 responses; inter-rater agreement before

adjudication was $\kappa = 0.631$ (validation) and $\kappa = 0.618$ (test) — the *highest* of the three models (Phi-2: $0.594/0.585$; TinyLlama: $0.568/0.558$), suggesting Gemma-2B's responses were somewhat less ambiguous to categorize. 55/249 (validation) and 57/249 (test) items were resolved by adjudication — fewer than TinyLlama's 76/77, closer to Phi-2's 69/70. The test-set label distribution was 37 reliable (14.9%), 106 incomplete, 104 contradictory, and 2 unsafe (0.8%) — nearly double Phi-2/TinyLlama's reliable rate and dramatically lower unsafe rate, making Gemma-2B a meaningfully safer raw generator, though still not reliable enough to deliver unfiltered (85.1% not judged fully reliable).

The calibrated weights converged to $w_1 = 1.754$, $w_2 = -0.979$, $w_3 = 0.200$, bias $= -0.209$, $h_0 = 0.720$; w_2's sign is negative here, the same direction as Phi-2's small weight and the opposite of TinyLlama's large positive w_2 — a third data point for the model-dependent-weighting conclusion of Section V-A. 5-fold cross-validation confirms the sign of all three weights is stable across folds ($w_1 = 1.716 \pm 0.084$, $w_2 = -0.832 \pm 0.112$, $w_3 = 0.190 \pm 0.129$, bias $= -0.262 \pm 0.126$). Section III-H's minimum-width threshold search leaves Gemma-2B's review band unchanged, since its unconstrained F2 optimum already exceeded the 0.02 floor, but reshapes the other two: TinyLlama's now receives the *most* review-tier traffic of the three models (Table I footnote, Section V-C), improving its calibrated FAR as a side effect ($20.9\% \rightarrow 17.3\%$, Section IV-B); Phi-2's goes from zero traffic to the Case 1 near-miss (Section IV-F). Results for Gemma-2B are reported alongside Phi-2 and TinyLlama throughout Tables I–III and Sections IV-B–IV-D.

V. Discussion

A. Interpretation of Results

MedEdge-Conf addresses a clinically meaningful problem: local LLM inference alone is insufficient for safe patient-facing monitoring, as Section IV-A shows directly — only 8.4% of Phi-2 (`Q5_K_M`)'s responses were judged reliable. The core design choice is separating response generation from delivery: the LLM is a generator whose output must be checked, not an autonomous decision maker, and the safety-filtering results support this (calibrated fusion cuts FAR from 100.0% to 26.4%, $p = 0.027$). The framework is lightweight and thus well suited to edge-IoMT: C_1 is rule-based and explainable, C_2 reuses log-probabilities already produced during generation, and C_3 requires only one extra generation and a 22M-parameter embedding model — more suitable for Raspberry Pi 5 than large-verifier or cloud-scale approaches.

Section IV-C's ablation study shows which components help is model-dependent, not fixed: C_1 alone is Phi-2's strongest configuration, the full heuristic fusion is TinyLlama's, and the full calibrated fusion (via C_3) is Gemma-2B's. A plausible hypothesis for Phi-2's pattern is that this base model is most confident — lowest entropy, most repeatable — precisely when confidently wrong (e.g., defaulting to "vital signs are within normal limits" regardless of the actual vitals), while more clinically engaged responses show more natural wording variation; if so, C_2 and C_3 as currently defined point in the wrong direction for some hallucination classes here. TinyLlama's and Gemma-2B's distinct dominant failure modes (fabricated non-vital detail and a more heterogeneous contradiction mix, respectively) do not share this property, consistent with C_2/C_3 remaining informative for them. A fixed, model-agnostic weighting of C_1/C_2/C_3 is therefore unsupported; per-model (re)calibration (Section III-H) is doing necessary work.

B. Comparison with State of the Art

Section IV-D's baseline comparison (Table III) supports grounding the confidence score in NEWS2-aligned physiological rules over generic language-model uncertainty: MedEdge-Conf significantly outperforms all three baselines (Token-Entropy Only [9], SelfCheckGPT [17], Semantic Entropy [26]) for TinyLlama and Gemma-2B, where the baselines are weak or near/below chance, but only Token-Entropy Only for Phi-2, and the case is weaker for TinyLlama, where Token-Entropy Only alone remains a viable signal. Latency favors MedEdge-Conf unconditionally across all three models.

C. Limitations and Future Work

Several limitations must be acknowledged:

First, several components remain simplified: NEWS2 uses a single-timepoint version rather than continuous trends; the sentence embedding model (all-MiniLM-L6-v2) is general-domain rather than medical-domain; and C_3 estimates stability from only two generations per prompt rather than the five-to-twenty typical of SelfCheckGPT [17]. C_3's negative calibrated weight for two of three models (Sections III-H, V-A) remains only partly explained.

Second, C_1's two-stage detector (Section III-E) improved from AUROC=0.517 (Stage 2a alone) to 0.663 with Stage 2b added (Table II), but two limitations remain: 1) negated or hedged constructions are not reliably handled by either stage, documented in the clinical NLP literature [18]; and 2) Stage 2a's reassurance-vs-alarm logic cancels out when both keyword types co-occur in the same response, which Case 3 (Section IV-F) shows caused an unsafe response to be delivered despite an overall-correct composite score.

Third, several scope limitations bound generalization. Weights and thresholds were calibrated on retrospective scenarios from PhysioNet/CinC2019 and MIT-BIH (Section III-B), not a live deployment. MedEdge-Conf operates at the single-response level without patient history or temporal checks, and prospective clinical validation with real patient data and clinician feedback remains necessary before deployment. Relatedly, Phi-2 (`Q5_K_M`), the primary evaluated model, is a base model whose zero-shot behavior was, in early testing, dominated by drifting into Python code completion rather than alert text, mitigated by appending a plain completion cue ("Alert:"); a differently-prompted or differently-tuned Phi-2 could plausibly shift the reliability distribution reported in Section IV-A.

Fourth, the evaluation covers three open-weight models (Phi-2, TinyLlama, Gemma-2B) at one quantization tier each (`Q5_K_M`); results may not generalize to larger models, other architectures, or quantization levels, though Table IV covers three tiers per model. The ground truth rests on inter-rater agreement ($\kappa = 0.594/0.585$ for Phi-2, $0.568/0.558$ for TinyLlama, $0.631/0.618$ for Gemma-2B); the moderate-to-substantial agreement reflects the labeling task's inherent subjectivity, not annotator carelessness.

Fifth, because MedEdge-Conf's review tier routes uncertain cases to a human reviewer, its practical value depends on how clinicians respond to alerts; clinical decision-support systems document high override rates for frequent or unspecific alerts [25]. Enforcing a minimum 0.02-wide review band (Section III-H), motivated by Case 1's original near-miss delivery (Section IV-F), gives every model non-zero review-tier traffic (Phi-2 1/249; TinyLlama 25/249, 10.0%; Gemma-2B 8/249, 3.2%; Table I footnote) and, for TinyLlama, incidentally improved calibrated FAR ($20.9\% \rightarrow 17.3\%$); Phi-2's single review item remains a thin margin for a tier meant to catch borderline cases at scale. Human-in-the-loop evaluation of override behavior and alert burden remains important future work.

Finally, MedEdge-Conf is a safety layer, not a diagnostic tool; alerts remain non-diagnostic and informational, and the framework supports GDPR compliance by escalating only uncertain or high-risk cases to the cloud while raw physiological streams stay local [14]. Patient-facing deployment would still require clinician review, risk analysis, and regulatory consideration (e.g., EU MDR, FDA guidance on AI/ML-based SaMD).

VI. Conclusion

This study proposed MedEdge-Conf, a lightweight confidence-scoring framework for edge-deployed LLMs in IoMT health monitoring, combining physiological coherence aligned with NEWS2, token entropy, and semantic stability into a calibrated composite score that drives a send/review/escalate decision policy.

Experimental results on scenarios from PhysioNet/CinC2019 and MIT-BIH, using Phi-2, TinyLlama, and Gemma-2B (all `Q5_K_M`) and human annotation of all 1,494 generated responses (498 per model) by two independent raters with adjudicated disagreements (Cohen's $\kappa = 0.594/0.585$ for Phi-2, $0.568/0.558$ for TinyLlama, $0.631/0.618$ for Gemma-2B), demonstrate that MedEdge-Conf's calibrated fusion reduces the false acceptance rate of dangerous hallucinations from 100.0% to 26.4% for Phi-2, 17.3% for TinyLlama, and 32.1% for Gemma-2B, with AUROC improvement over naive scoring statistically significant in every case (DeLong's test, $p = 0.027$, $p = 0.0001$, $p = 1.7 \times 10^{-5}$). This required extending C_1 with a numeric contradiction check after the unextended version performed close to chance on annotated data. The ablation study surfaces a model-dependent pattern a single- or two-model evaluation would not have revealed: C_1 alone is Phi-2's strongest configuration, the full heuristic fusion is TinyLlama's (with token entropy a genuine contributor), and the full calibrated fusion is Gemma-2B's (driven by semantic stability rather than token entropy) — component weighting should therefore be calibrated per deployed model rather than fixed a priori. Against three literature baselines, MedEdge-Conf achieves the best AUROC and FAR for all three models, reaching significance over all three baselines for TinyLlama and Gemma-2B but only Token-Entropy Only for Phi-2 (Section IV-D). Edge feasibility measured on the physical Raspberry Pi 5 shows TinyLlama is the fastest and lightest of the three models, confirming the deployment recommendation, while Gemma-2B is markedly slower and heavier despite being the safest raw generator by annotated label distribution.

The contribution is not merely deploying a quantized LLM on edge hardware, but adding a safety-oriented trust layer that prevents unreliable patient-facing communication, evaluated with a commitment to reporting what the data show, including where it complicates the original design's assumptions, on the same footing for all three models. Immediate next steps are resolving the keyword-cooccurrence gap in C_1 identified by Case 3 (Section IV-F) and investigating TinyLlama's fabricated-non-vital-detail failure mode (Section IV-C); the remaining directions are detailed in Section V-C.

HTBM: A Hybrid-Transformer-Based Method with Double Deep Q-Learning and Reptile Meta-Learning for Dynamic MEC Task Offloading

Nouhaila Moussammi[1]*, Mohamed El Ghmary[2]
Department of Computer Sciences-Faculty of Sciences, Mohammed V University in Rabat, Morocco[1]
ENSAM, Mohammed V University in Rabat, Morocco[2]

***Abstract*—Mobile edge computing (MEC) enables computation-intensive applications to be processed close to end users. In dynamic MEC environments, task-offloading decisions must account for changing communication conditions, heterogeneous computing resources, and dependencies among fine-grained subtasks. Conventional reinforcement-learning approaches may require substantial interaction data and may suffer from unstable value estimation. This study proposes a meta-reinforcement-learning framework, termed HTBM (Hybrid-Transformer-Based Method), for latency-aware task offloading in dynamic MEC systems. HTBM combines a hybrid-transformer sequential representation mechanism, Double Deep Q-Network (DDQN) for discrete offloading decisions, and the first-order Reptile algorithm for rapid adaptation across related MEC environments. The system model follows a fine-grained directed acyclic graph (DAG) representation in which applications are decomposed into dependent subtasks that can be executed locally or at an edge server. Experimental evaluation is conducted under a representative MEC simulation scenario. Across transmission-rate experiments, a latency reduction of approximately 2.00% was observed under the evaluated run configuration compared with GASTO, an existing graph-based meta-reinforcement-learning offloading method. Additional experiments examine rapid adaptation, robustness across DAG topologies, generalization to an unseen topology, inference time, and an ablation study isolating the contribution of each HTBM component.**

***Keywords*—Mobile edge computing; task offloading; Double Deep Q-Network (DDQN); hybrid transformer; deep reinforcement learning; meta-reinforcement learning; reptile; Directed Acyclic Graph (DAG); latency minimization**

I. Introduction

Mobile edge computing (MEC) brings computation and storage resources closer to end users and is therefore suitable for applications with stringent latency requirements [1]. In such systems, task offloading determines which computations should be executed locally and which should be transferred to edge resources. The decision becomes particularly difficult when the application is composed of dependent subtasks and when network and computing conditions vary over time [2].

A fine-grained task can be represented as a directed acyclic graph (DAG), where vertices denote subtasks and directed edges describe execution dependencies [3]. An offloading decision must consequently account not only for the computational requirements of individual subtasks, but also for the availability of predecessor outputs, communication delays, and the queue state of edge servers, a challenge also addressed through hierarchical DRL formulations for dependent-task offloading [4].

Deep reinforcement learning (DRL) provides a natural framework for sequential offloading decisions because the agent can learn from interactions with the MEC environment [5]. Nevertheless, conventional DRL approaches may require many interactions before learning a useful policy. Moreover, a state at a particular decision instant may not contain sufficient information to characterize the evolution of previous tasks and network conditions.

Transformer-based sequence models offer an alternative representation mechanism because self-attention can capture relationships among distant observations [6]. In particular, Gated Transformer-XL (hybrid-transformer) was designed to improve the stability of Transformer-based reinforcement learning [7], and Transformer-enhanced DRL has since been surveyed extensively across communication-network applications, including computation offloading [8]. In the proposed framework, hybrid-transformer is used to encode sequences of MEC experiences into compact representations.

The second component of the proposed framework is Double Deep Q-Network (DDQN) [9]. Unlike a conventional DQN [10], DDQN separates action selection from action evaluation when constructing the target value, reducing the tendency of Q-learning to overestimate action values. This property is useful for discrete offloading decisions where several execution choices may have similar immediate costs.

Finally, Reptile is employed as a first-order meta-learning mechanism [11]. Instead of learning a completely independent model for every MEC configuration, the meta-learner searches for an initialization that can be adapted rapidly to a new but related environment, as previously explored for offloading by meta-reinforcement-learning frameworks such as MRLCO [12] and GASTO [13].

The main contributions of this work are summarized as follows:

- A hybrid-transformer-based sequential representation mechanism is integrated with a Double DQN decision module for latency-oriented MEC task offloading.

*Corresponding author.

- A first-order Reptile meta-learning procedure is incorporated so that the learned model can rapidly adapt to previously unseen MEC tasks and environmental configurations.
- The original fine-grained DAG task structure is retained, allowing dependencies among subtasks to influence the offloading and execution process.
- A comprehensive experimental evaluation is conducted to study rapid adaptation, convergence, latency under different transmission rates, DAG-topology generalization, and inference time.
- An ablation study is conducted to isolate the individual contribution of the hybrid-transformer representation, the Double DQN target rule, and the Reptile meta-initialization to the overall latency performance of HTBM.

The remainder of this study is organized as follows. Section II discusses related work. Section III presents the MEC system model and problem formulation. Section IV formulates the offloading decision as a Markov decision process. Section V describes the proposed HTBM meta-reinforcement-learning framework. Section VI presents the experimental methodology and numerical analysis, including an ablation study of the three HTBM components. Section VII discusses the results, and Section VIII concludes the study.

II. Related Work

A. Heuristic and Optimization-Based Offloading

Task offloading has traditionally been formulated as an optimization problem involving computation latency, communication latency, energy consumption, or combinations of these objectives [1]. For instance, joint radio-and-computation resource allocation has been formulated for multi-user multi-task offloading scenarios in order to jointly minimize latency and energy consumption under shared MEC resources [15]. Multi-task offloading has been studied under explicit energy and delay constraints [16], and intelligent task-offloading optimization strategies have more recently been explored for MEC systems [17]. Greedy strategies and graph-based scheduling approaches can provide efficient solutions for specific configurations, but their decision rules generally depend on manually designed assumptions. Their ability to adapt to rapidly changing MEC environments can therefore be limited, a limitation echoed by recent surveys of the offloading literature [2].

B. Deep Reinforcement Learning for MEC Offloading

DRL methods learn offloading policies by interacting with the environment [10]. DQN-based methods are particularly suitable when the action space is discrete, whereas actor–critic methods such as PPO are often used for more general continuous or stochastic decision problems. DQN variants have been investigated for MEC offloading [3], but value overestimation and the difficulty of representing long interaction histories remain important issues.

DDQN addresses the overestimation problem of standard DQN by using the online network to select the next action and the target network to evaluate it [9]. Several recent works apply DDQN specifically to MEC offloading and resource allocation, reporting improved convergence and reduced latency relative to conventional DQN and fixed-policy baselines [5]. Graph-based DRL formulations have further combined DDQN with graph attention networks to schedule DAG tasks over dynamic environments [14], digital-twin-assisted DDQN has been used for mobility-aware dependent task offloading [18], multi-agent DRL has been explored for combinatorial client-master offloading decisions [19], and ensemble-learning-augmented DRL has been applied to reduce offloading latency under dynamic edge conditions [20]. Beyond terrestrial MEC, DDQN and its dueling/prioritized variants have also been applied to satellite edge computing [21], LEO satellite networks with hybrid action spaces [22], UAV-assisted aerial edge computing with digital-twin support [23], and Industrial IoT offloading [24], illustrating the versatility of the DDQN family across heterogeneous edge deployments. DAG-based task scheduling under DRL has similarly been studied in vehicular cloud settings [25], [26] and general real-time systems [27], further motivating the fine-grained DAG representation retained in this work. In this work, DDQN is combined with hybrid-transformer rather than using a conventional feed-forward Q-network.

C. Transformer-Based Reinforcement Learning

Transformer architectures use self-attention to model relationships between elements in a sequence [6]. Transformer-XL extends the effective context through segment-level recurrence, while hybrid-transformer introduces modifications intended to improve Transformer stability in reinforcement-learning settings [7]. These properties make hybrid-transformer attractive for MEC environments where recent observations alone may not fully characterize the current decision context. Closely related recent work has combined Transformer-based encoders with Proximal Policy Optimization (PPO) for dependent-task offloading, including a Transformer-PPO framework for edge computing [28] and a GTrXL-PPO offloading technique for IoT edge environments [29]. Transformer-based representations have also been applied to distributed task offloading and resource management in cloud-edge networks [30], to distributed DRL scheduling of IoT applications [31], and to Transformer-PPO combinations for general IoT decision-making [32]. The present work differs from these by pairing the Transformer-based representation with a Double DQN decision module rather than PPO, and by explicitly incorporating a Reptile meta-learning outer loop.

D. Meta-Reinforcement Learning for MEC

Meta-reinforcement learning aims to learn knowledge shared among a distribution of tasks so that adaptation to a new task requires only a small amount of additional interaction. Reptile is a first-order meta-learning method that repeatedly adapts model parameters to sampled tasks and moves the meta-parameters toward the resulting task-specific parameters [11]. This principle has previously been applied to MEC task offloading: MRLCO combines a first-order meta-learning procedure with a sequence-to-sequence Long short-term memory (LSTM) policy over DAG-structured applications [12], and GASTO integrates a graph neural network with a sequence-to-sequence network under a meta-learning outer loop to improve

adaptation speed and robustness across dynamic MEC environments [13]. The proposed framework retains the meta-learning principle used in these works while replacing their sequence-to-sequence policy network with a hybrid-transformer representation and a DDQN decision module.

III. System Model and Problem Formulation

A. MEC Network Model

As shown in Fig. 1, we consider a fine-grained task-offloading scenario involving multiple user equipment (UEs) and multiple heterogeneous MEC servers. Each UE may generate one or more applications, and each application is decomposed into a set of temporally dependent subtasks. The execution of these subtasks can be performed locally at the UE or offloaded to an associated MEC server. The environment therefore contains heterogeneous computational tasks generated by different user devices, while the communication and computing conditions may vary across environments. These characteristics make the offloading decision dependent not only on the computational requirements of the current subtask, but also on the execution status of related subtasks and the available MEC resources.

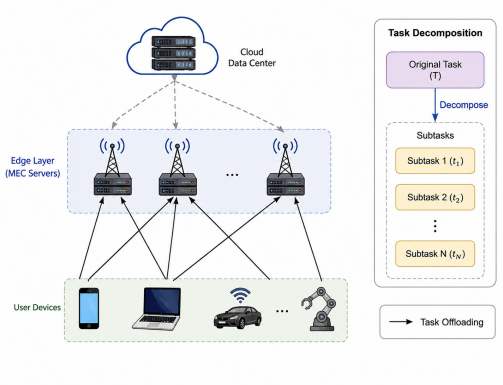

Fig. 1. Overall MEC system model.

The set of user equipment is denoted by:

$$\mathcal{U} = \{u_1, u_2, \ldots, u_U\}, \tag{1}$$

and the set of MEC servers is denoted by:

$$\mathcal{K} = \{e_1, e_2, \ldots, e_K\}. \tag{2}$$

Each UE can execute application tasks locally or offload computations to an edge server. For an application, only one MEC server is considered as its associated edge execution destination. The communication and computing conditions may vary between environments, making the optimal offloading decisions environment-dependent.

B. DAG-Based Fine-Grained Applications

Each application is modeled as a directed acyclic graph (DAG):

$$G = (V, E), \tag{3}$$

where, V denotes the set of subtasks and E represents dependency relationships between subtasks.

A subtask is represented by:

$$T_{i,j} = \{S_{i,j}, C_{i,j}, O_{i,j}\}, \tag{4}$$

where, $S_{i,j}$ is the input-data size, $C_{i,j}$ is the required number of CPU cycles, and $O_{i,j}$ is the output-data size.

The edge $(v_a, v_b) \in E$ indicates that subtask v_b cannot begin until the required output of predecessor subtask v_a becomes available. Therefore, the execution order is constrained by the topology of the DAG.

C. Local Execution

For a subtask executed by UE i, its computation latency is:

$$t_{i,j}^{\mathrm{ue}} = \frac{C_{i,j}}{f_i^{\mathrm{ue}}}, \tag{5}$$

where, f_i^{ue} is the CPU frequency of the UE. Local execution does not require uplink transmission to the MEC layer, but its completion time is directly determined by the computational demand of the subtask and the available UE processing capability.

D. Edge Execution

When a subtask is offloaded to MEC server k, its execution time includes transmission, queueing, and computation components. It can be expressed generally as:

$$t_{i,j}^{k} = \frac{S_{i,j}}{R_{i,k}^{\mathrm{ul}}} + t_{i,j}^{k,\mathrm{queue}} + \frac{C_{i,j}}{f_k}, \tag{6}$$

where, $R_{i,k}^{\mathrm{ul}}$ is the uplink transmission rate, $t_{i,j}^{k,\mathrm{queue}}$ is the queueing delay at server k, and f_k is the computing frequency of the MEC server.

The queueing term depends on previously scheduled computations at the corresponding server. Furthermore, a subtask can only begin after its predecessor subtasks have completed and their required data has become available.

E. Subtask Completion and DAG Latency

Let $ST(v)$ and $FT(v)$ denote the start and finish times of subtask v. The start time is constrained by predecessor completion times:

$$ST(v) = \max_{p \in Pred(v)} FT(p), \tag{7}$$

with the appropriate communication delay included whenever predecessor and successor subtasks are executed at different locations.

The finish time is:

$$FT(v) = ST(v) + t(v). \tag{8}$$

Let F denote the set of terminal nodes of the DAG. The completion latency of an application is therefore determined by the latest terminal-subtask completion:

$$T_{\mathrm{DAG}} = \max_{v \in F} FT(v). \tag{9}$$

F. Optimization Objective

The objective of this study is to minimize the overall task completion latency. For a collection of applications, the optimization objective can be written as:

$$\min_{\mathbf{a}} \sum_{i=1}^{U} T_{\mathrm{DAG},i}, \tag{10}$$

subject to DAG precedence constraints, execution-location constraints, and MEC resource constraints.

The resulting problem is combinatorial and dynamically affected by communication and computing conditions. We therefore formulate it as a Markov decision process.

IV. Markov Decision Process

A. State Space

At decision step t, the environment provides an observation containing the relevant task and MEC information. The instantaneous state is denoted by:

$$s_t \in \mathcal{S}. \tag{11}$$

A sequence of observations:

$$\mathcal{H}_t = (s_{t-L+1}, \ldots, s_t) \tag{12}$$

is retained so that the decision model can exploit temporal information. This history is particularly relevant in the considered fine-grained setting because the execution of a subtask may depend on the completion of preceding subtasks and on the evolving communication and computing conditions. The sequential representation therefore provides the learning model with contextual information beyond the instantaneous state.

B. Action Space

The action determines the execution location of the currently considered subtask. For a simplified local/edge decision,

$$a_t \in \mathcal{A}, \tag{13}$$

where, an action corresponds to local execution or an eligible MEC execution choice.

For multiple MEC servers, the action space can contain one action for each valid execution destination.

C. Reward

Because the optimization objective is latency minimization, the reward is directly defined from the latency contribution of the current decision:

$$r_t = -\Delta T_t, \tag{14}$$

where, ΔT_t denotes the latency contribution associated with the current decision. No additional reward normalization or shaping is applied. This formulation keeps the reinforcement-learning objective directly aligned with the latency-minimization objective defined in Section III.

V. Proposed HTBM Framework

A. Framework Overview

The proposed HTBM architecture consists of three main components. The overall interaction and information flow among these components is illustrated in Fig. 2. The figure shows how the task-related observations are transformed into a sequential representation before being provided to the DDQN decision mechanism, while Reptile operates at the meta-learning level to obtain an initialization that can be efficiently adapted to new MEC environments. The individual contribution of each of these three components to the overall latency performance is examined separately in the ablation study reported in Section VI-H.

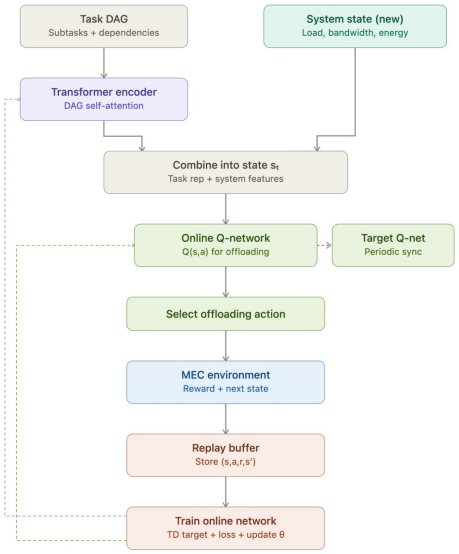

Fig. 2. Workflow of the proposed HTBM meta-reinforcement-learning framework.

- The hybrid-transformer module encodes a sequence of MEC observations and extracts a representation containing information from the interaction history.
- DDQN maps the encoded representation to action-value estimates and selects the offloading action.
- Reptile learns an initialization across a distribution of MEC tasks, enabling rapid adaptation to unseen configurations.

B. Hybrid-Transformer Sequential Representation

The input to HTBM is a sequence of state representations obtained from agent–environment interactions. The hybrid-transformer module uses self-attention to capture relationships among observations at different positions in the sequence and produces a compact representation for the decision process.

Let $h_{i,n}$ denote the hidden representation corresponding to the n-th element of the sequence for task i. The sequence representation is obtained by aggregating the normalized hidden states:

$$c_i = \frac{1}{N}\sum_{n=1}^{N}\mathrm{LayerNorm}(h_{i,n}). \tag{15}$$

The resulting representation summarizes the interaction history and is supplied to the DDQN decision module. The hybrid-transformer therefore acts as the representation-learning component, while DDQN performs the discrete offloading decision and Reptile provides the meta-initialization.

C. Double Deep Q-Network

Let $Q_\theta(s,a)$ denote the online Q-network and $Q_{\theta^-}(s,a)$ denote the target Q-network. DDQN selects the next action using the online network:

$$a^* = \arg\max_{a'} Q_\theta(s_{t+1}, a'). \tag{16}$$

The target value is then evaluated using the target network:

$$y_t = r_t + \gamma Q_{\theta^-}\left(s_{t+1}, \arg\max_{a'} Q_\theta(s_{t+1}, a')\right), \tag{17}$$

for nonterminal transitions. For terminal transitions,

$$y_t = r_t. \tag{18}$$

The DDQN loss is

$$L(\theta) = \frac{1}{B}\sum_{b=1}^{B}\left(y_b - Q_\theta(s_b, a_b)\right)^2, \tag{19}$$

where, B is the mini-batch size.

The target network is periodically synchronized with the online network:

$$\theta^- \leftarrow \theta. \tag{20}$$

D. Experience Replay

To improve the stability and data efficiency of DDQN training, the interactions generated during the execution of each MEC task are stored in an experience replay buffer. Each transition contains the current state, the selected offloading action, the resulting latency-based reward, the next state, and a terminal indicator. The replay memory is defined as:

$$\mathcal{D} = \{(s_t, a_t, r_t, s_{t+1}, d_t)\}, \tag{21}$$

where, $d_t \in \{0,1\}$ indicates whether the transition terminates an episode. For the sequence-based decision process, the states stored in the transitions are associated with their corresponding observation histories so that the hybrid-transformer can reconstruct the temporal context required for the decision.

Once the replay buffer contains a sufficient number of transitions, a mini-batch of B samples is randomly drawn for each learning update. The sampling operation can be expressed as:

$$\mathcal{B} = \{(s_b, a_b, r_b, s'_b, d_b)\}_{b=1}^{B}, \qquad (s_b, a_b, r_b, s'_b, d_b) \sim \mathcal{D}. \tag{22}$$

Random sampling reduces the correlation between consecutive experiences and allows previously collected transitions to be reused during several learning updates. The resulting mini-batch is subsequently used to calculate the DDQN targets and update the task-specific parameters.

For a terminal transition, the target contains only the immediate reward, whereas a nonterminal transition also incorporates the estimated value of the next state. Accordingly, the target used by the DDQN update can be written in the unified form:

$$y_b = r_b + \gamma(1-d_b)Q_{\theta^-}\left(s'_b, \arg\max_{a'} Q_\theta(s'_b, a')\right). \tag{23}$$

This formulation allows the same replay mechanism to handle both intermediate subtask decisions and the final decision that completes a DAG application.

E. Reptile Meta-Learning

The MEC environment is viewed as a distribution of related tasks

$$\mathcal{T} \sim \rho(\mathcal{T}). \tag{24}$$

Each task represents a particular MEC configuration and task/DAG condition under which the HTBM model must learn an effective latency-oriented offloading policy. The objective of meta-learning is therefore to obtain a common initialization that can be efficiently adapted to an individual task.

Let θ denote the shared meta-parameters of the hybrid-transformer and DDQN components. For each sampled task $\mathcal{T}_j$, the task-specific parameters are initialized from the current meta-parameters:

$$\theta_j^0 \leftarrow \theta. \tag{25}$$

The initialized model interacts with $\mathcal{T}_j$, stores the resulting transitions in its replay buffer, and performs a number of DDQN inner-loop updates. After adaptation, the resulting parameters are denoted by θ'_j.

The task-specific adaptation can be represented by the generic update:

$$\theta_j^{k+1} = \theta_j^k - \alpha_{\text{in}} \nabla_{\theta_j^k} L_{\mathcal{T}_j}(\theta_j^k), \tag{26}$$

where, α_{in} is the inner-loop learning rate and $L_{\mathcal{T}_j}$ is the DDQN loss evaluated using experiences collected from task $\mathcal{T}_j$. After K inner-loop updates,

$$\theta'_j = \theta_j^K. \tag{27}$$

The Reptile outer loop then moves the shared initialization toward the task-adapted parameters. For a meta-batch containing N sampled tasks, the update is:

$$\theta \leftarrow \theta + \epsilon \left(\frac{1}{N} \sum_{j=1}^{N} \theta'_j - \theta \right), \tag{28}$$

where, ϵ denotes the outer-loop learning rate. Equivalently, the meta-objective can be expressed as minimizing the average task-specific loss after adaptation:

$$\min_{\theta} \mathcal{L}_{\text{meta}}(\theta) = \mathbb{E}_{\mathcal{T} \sim \rho(\mathcal{T})} \left[L_{\mathcal{T}}(\theta'_{\mathcal{T}}) \right]. \tag{29}$$

Unlike second-order meta-learning methods, Reptile does not require explicit computation of second-order derivatives. Instead, the meta-parameters are progressively moved toward parameter configurations that perform well after task-specific adaptation. The learned meta-parameters are subsequently used as the initialization for new MEC tasks.

F. Meta-Training

Meta-training repeatedly exposes HTBM to a collection of related MEC tasks. At the beginning of each meta-iteration, a meta-batch of N tasks is sampled from $\rho(\mathcal{T})$. For every sampled task, the current meta-parameters are copied to a task-specific model, which then collects interaction trajectories and performs DDQN adaptation using its replay buffer.

For task $\mathcal{T}_j$, the inner-loop learning process can be summarized as:

$$\theta_j^{k+1} = \theta_j^k - \alpha_{\text{in}} \nabla_{\theta_j^k} L_{\mathcal{T}_j}(\theta_j^k), \qquad k = 0, \ldots, K-1, \tag{30}$$

where, K is the number of inner-loop updates. The DDQN loss is evaluated using mini-batches sampled from the task-specific replay buffer. After the K updates, the adapted parameters are stored as $\theta'_j = \theta_j^K$.

The outer loop aggregates the adapted parameters from all tasks and updates the common initialization according to:

$$\theta^{\text{new}} = \theta + \epsilon \left(\frac{1}{N} \sum_{j=1}^{N} \theta'_j - \theta \right). \tag{31}$$

The updated parameters θ^{new} are then used to initialize the next meta-iteration. Repeating this process enables the model to capture information shared across different MEC environments while retaining the ability to specialize to an individual task through a small number of DDQN updates.

The complete meta-training procedure is summarized in Algorithm 1.

Algorithm 1 Meta-Training of HTBM

```
Initialize meta-parameters θ
for i = 1, ..., M do
    Sample N tasks from ρ(T)
    for j = 1, ..., N do
        Initialize task parameters θ_j ← θ
        Initialize the replay buffer D_j
        Interact with task T_j and collect trajectories
        Encode trajectory sequences using hybrid-transformer
        Store transitions in D_j
        for k = 1, ..., K do
            Sample a mini-batch from D_j
            Select next actions using the online Q-network
            Evaluate selected actions using the target Q-network
            Compute the DDQN loss and update θ_j
        end for
        θ'_j ← θ_j
    end for
    Update θ using the Reptile interpolation rule
end for
```

G. Meta-Testing

During meta-testing, the outer-loop parameters remain fixed. A previously unseen MEC task is initialized with the learned meta-parameters and adapted using a limited number of DDQN updates.

Algorithm 2 Meta-Testing of HTBM

```
Select an unseen MEC task T_test
Initialize θ_test ← θ
Collect a small amount of task-specific experience
Encode the observed sequence using hybrid-transformer
for k = 1, ..., L do
    Sample replay transitions
    Compute DDQN targets
    Update θ_test
end for
Evaluate the adapted model on T_test
```

VI. Experimental Methodology and Numerical Analysis

A. Simulation Settings

The principal simulation parameters used in the experiments are summarized in Table I. The experimental environ-

TABLE I. EXPERIMENTAL PARAMETER SETTINGS USED IN THE HTBM EVALUATION

Parameter Definition	Value
Number of Meta-Training Tasks (Count)	100
Number of Meta-Testing Tasks (Count)	100
Communication-to-Computation Ratio (CCR)	$0.3 \sim 0.5$
DAG Fat (Fat)	$\{0.1, 0.3, 0.4, 0.5, 0.7\}$
DAG Density (Density)	$\{0.4, 0.5, 0.6, 0.7, 0.8\}$
Inner-loop learning rate	0.1
Outer-loop learning rate	0.01

ment contains four MEC servers and twenty user devices. Each application is represented by a randomly generated DAG, parameterized by the density and fat values listed in Table I. The DAG generation methodology and the ranges of density, fat, and communication-to-computation ratio values follow the same random-DAG generation approach and comparable parameter ranges adopted by MRLCO [12] and GASTO [13], so as to provide a consistent and directly comparable evaluation basis across all baseline methods. The UE CPU frequency is set to 1×10^9 cycles/s and the edge-server CPU frequency is set to 8×10^9 cycles/s.

The scenario further considers applications composed of 20 fine-grained subtasks each, evaluated over a test set of 100 DAGs/applications. Transmission-rate experiments use uplink and downlink rates of 4, 7, and 10 Mbps.

The DDQN settings are selected from commonly used DDQN configurations. In particular, a learning rate of 10^{-4}, discount factor $\gamma = 0.99$, mini-batch size of 32, replay-buffer capacity of 100,000 transitions, initial exploration rate $\epsilon_{\text{start}} = 1.0$, minimum exploration rate $\epsilon_{\min} = 0.01$, and a target-network synchronization interval of 1,000 training steps are adopted. These values are consistent with an established Double DQN implementation configuration, which uses a 10^{-4} learning rate, $\gamma = 0.99$, batch size 32, replay capacity 100,000, and a 1,000-step target-network synchronization interval [33]. The relatively conservative learning rate is selected because HTBM jointly trains the hybrid-transformer representation and the DDQN value function, while the discount factor of 0.99 allows the agent to account for future latency costs. These settings are used consistently throughout the HTBM training and evaluation experiments. These values were not obtained through an independent sensitivity analysis or through tuning specific to the MEC offloading setting; rather, they were adopted because they constitute an established and widely reproduced Double DQN configuration that is also broadly consistent with the hyperparameter ranges reported in other DDQN-based MEC offloading studies [5], providing a stable and reproducible starting point in line with common practice in the offloading literature. Similarly, the Reptile inner- and outer-loop learning rates in Table I follow the default configuration proposed in the original Reptile formulation [11] rather than a setting tuned specifically for the MEC environments considered here. A systematic sensitivity analysis of the DDQN and Reptile hyperparameters is identified as a valuable direction for future work, complementing the multi-seed statistical validation discussed in Section VII. The implementation of HTBM and the MEC simulation environment used to produce the reported results is available from the corresponding author upon reasonable request.

B. Evaluation Metrics

The evaluation focuses on the following metrics:

- Task completion latency: total latency required to complete the DAG applications.
- Rapid adaptation: number of iterations or interactions required for the adapted model to reach a stable performance level.
- Generalization: performance under DAG topologies and task configurations not used during meta-training.
- Inference time: time required to obtain offloading decisions from the trained neural model.
- Latency reduction: relative reduction in average task-completion latency compared with a selected baseline, computed as

$$R_{\text{lat}} = \frac{\overline{T}_{\text{base}} - \overline{T}_{\text{HTBM}}}{\overline{T}_{\text{base}}} \times 100\%. \tag{32}$$

C. Rapid Adaptation Under Different Transmission Rates

This experiment studies the behavior of HTBM under different communication rates. The evaluation uses uplink and downlink rates of 4, 7, and 10 Mbps. The latency trajectories are shown in Fig. 3. HTBM progressively reduces latency as adaptation proceeds, with the final values reaching approximately 965 ms, 735 ms, and 595 ms for 4, 7, and 10 Mbps, respectively. The results indicate that the meta-learned initialization enables the model to improve its decision quality during the adaptation process.

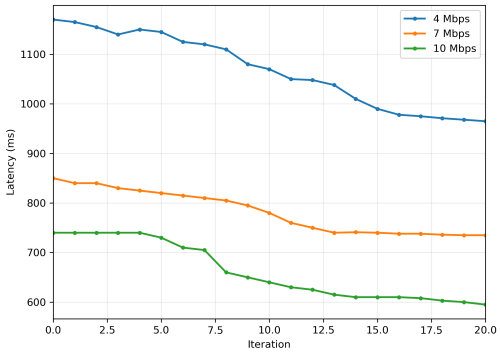

Fig. 3. Rapid adaptation performance of HTBM at different transmission rates.

D. Comparison with Alternative Offloading Algorithms

The latency comparison under different transmission rates is presented in Fig. 4 and summarized in Table II. The evaluated methods are Greedy, MRLCO [12], GASTO [13], T-PPO [28], and the proposed HTBM. At 4 Mbps, HTBM obtains a latency of 965 ms, compared with 980 ms for GASTO. At 7 Mbps, the corresponding values are 735 ms and 750 ms, while at 10 Mbps they are 595 ms and 610 ms. Thus, HTBM provides reductions of 1.53%, 2.00%, and 2.46% relative to GASTO at 4, 7, and 10 Mbps, respectively. Therefore, an average task-completion latency reduction of

TABLE II. TASK-COMPLETION LATENCY UNDER DIFFERENT TRANSMISSION RATES

Method	4 Mbps	7 Mbps	10 Mbps
Greedy	1090	830	625
MRLCO	995	760	615
GASTO	980	750	610
T-PPO	1010	790	650
HTBM	**965**	**735**	**595**

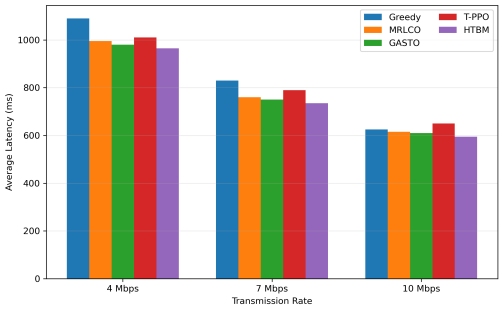

Fig. 4. Task-completion latency comparison under different transmission rates.

approximately 2.00% was observed for HTBM compared with GASTO across the evaluated transmission rates under this run configuration.

This increasing relative improvement with transmission rate can be explained qualitatively in terms of the latency composition described in Section III-D. At lower transmission rates (e.g., 4 Mbps), the transmission term $S_{i,j}/R^{\mathrm{ul}}_{i,k}$ in Eq. (6) dominates the total execution time of any offloaded subtask, largely independently of which offloading policy is used. Because this term is shared across all evaluated methods, it acts as a common additive latency floor that compresses the relative (percentage) differences between methods even when the underlying decision-quality gap in absolute terms (ms) is comparable across transmission rates. As the transmission rate increases and the communication term diminishes, total latency becomes increasingly dominated by queueing and decision-dependent components, allowing differences in offloading-decision quality, and in particular the contribution of the hybrid-transformer's sequential representation, to be reflected more directly in the relative-improvement metric of Eq. (32). We note that this interpretation should ultimately be examined jointly with the multi-seed statistical validation identified in Section VII, since the observed trend spans a comparatively narrow range (1.53%–2.46%) that should be confirmed to lie outside run-to-run variance.

E. Generalization Across DAG Topologies

To evaluate robustness to structural variations in the application graph, three density–width configurations are considered. The first uses density 0.7 and width 0.4, the second uses density 0.4 and width 0.6, and the third uses density 0.1 and width 0.5. The corresponding latency trajectories are presented in Fig. 5, 6, and 7, respectively. These figures illustrate the evolution of the latency values under the three different DAG structures and allow the behavior of HTBM

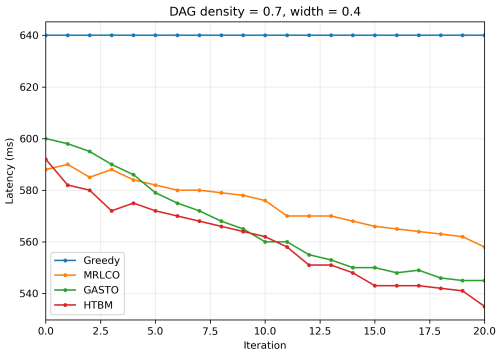

Fig. 5. Latency evolution for DAG density 0.7 and width 0.4.

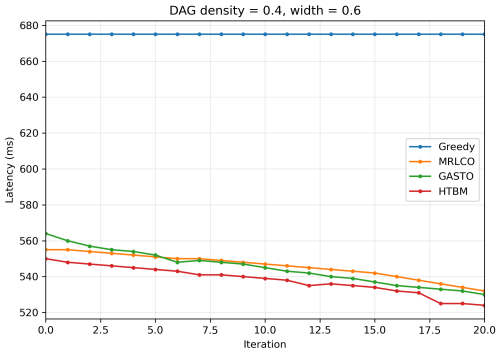

Fig. 6. Latency evolution for DAG density 0.4 and width 0.6.

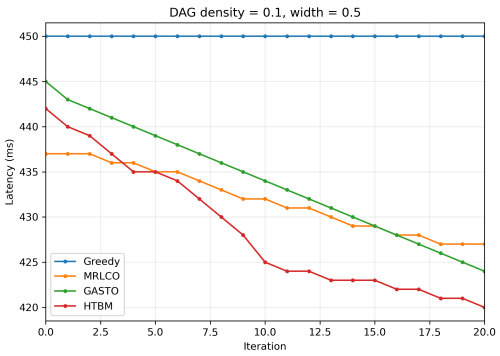

Fig. 7. Latency evolution for DAG density 0.1 and width 0.5.

to be compared with the alternative methods throughout the evaluated iterations.

For the first configuration, HTBM obtains an average latency of approximately 559.90 ms, compared with 566.14 ms for GASTO, corresponding to a reduction of approximately 1.10%. For the second configuration, HTBM achieves approximately 538.05 ms compared with 544.95 ms for GASTO, corresponding to a 1.27% reduction. For the third configuration, the corresponding values are approximately 428.57 ms and 434.05 ms, giving a 1.26% reduction. These results show that the proposed method maintains lower average latency across different DAG structures and remains competitive when the structural characteristics of the application graph change.

F. Generalization to an Unseen DAG Topology

To further examine generalization, HTBM is evaluated on an unseen topology with density 0.4 and width 0.9, as shown in Fig. 8. The average latency of HTBM is approximately 566.48 ms, whereas GASTO and MRLCO obtain approximately 580.33 ms and 593.38 ms, respectively. Thus, HTBM reduces average latency by approximately 2.39% relative to GASTO and 4.53% relative to MRLCO on the unseen topology.

The unseen-topology result is important because it evaluates whether the learned representation remains useful when the structural properties of the DAG differ from the other evaluated configurations. The continued latency advantage suggests that the combination of sequence representation and meta-learning provides useful transfer across related DAG environments. Table III summarizes the average latency achieved by all evaluated methods across the three DAG-topology configurations and the unseen topology.

TABLE III. AVERAGE LATENCY ACROSS DAG-TOPOLOGY EXPERIMENTS

Method	(0.7,0.4)	(0.4,0.6)	(0.1,0.5)	Unseen
Greedy	640.00	675.00	450.00	720.00
MRLCO	574.57	545.90	431.95	593.38
GASTO	566.14	544.95	434.05	580.33
HTBM	**559.90**	**538.05**	**428.57**	**566.48**

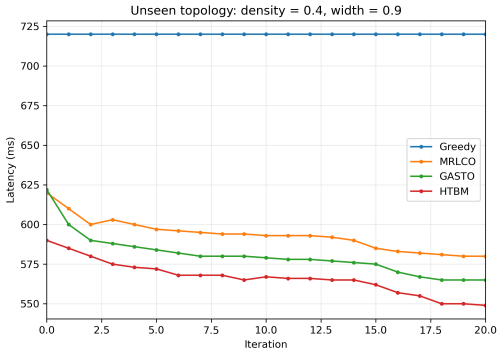

Fig. 8. Generalization performance on an unseen DAG topology with density 0.4 and width 0.9.

G. Comparison of Network Architectures

The inference-time experiment compares the hybrid-transformer encoder with recurrent alternatives as the number of tasks increases. The measured inference times are shown in Fig. 9. The hybrid-transformer requires approximately 0.26–0.32 ms, while LSTM requires approximately 3.30–3.40 ms and GRU approximately 2.05–2.20 ms over the evaluated task counts. These results indicate that the transformer-based representation used by HTBM can provide a low inference-time overhead in the evaluated setting.

H. Ablation Study

To assess the individual contribution of each of the three components of HTBM, three ablated variants are evaluated: HTBM without the Reptile meta-initialization (HTBM-NM), HTBM without the hybrid-transformer sequence encoder (HTBM-MLP), and HTBM without the Double DQN target rule (HTBM-DQN). Each variant modifies exactly one component while keeping the remaining architecture, DDQN hyperparameters, and DAG generation settings identical to those used for the full HTBM model in Section VI-A. All variants are evaluated under the same 7 Mbps transmission-rate configuration and the same test set of 100 DAG applications used in Section VI-D.

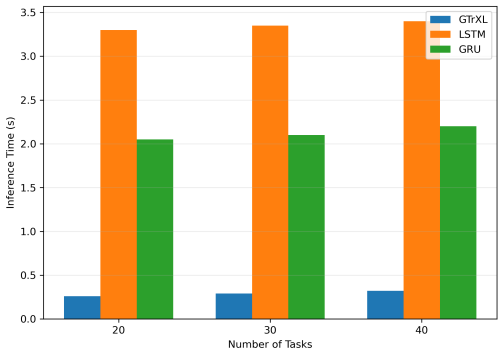

Fig. 9. Inference-time comparison of the hybrid-transformer encoder, LSTM, and GRU as the number of tasks increases.

For HTBM-NM, the network is initialized randomly rather than from the meta-trained parameters θ, and is then adapted using the same number of inner-loop DDQN updates specified in Algorithm 2. For HTBM-MLP, the hybrid-transformer encoder is replaced by a feed-forward encoder that maps the instantaneous state s_t directly to the representation used by DDQN, without access to the observation history $\mathcal{H}_t$. For HTBM-DQN, the target value in Eq. (17) is replaced by the conventional DQN target, in which the target network is used for both action selection and action evaluation.

Table IV summarizes the average task-completion latency obtained by each variant, together with the relative degradation with respect to the full HTBM model.

TABLE IV. ABLATION RESULTS AT 7 MBPS TRANSMISSION RATE

Variant	Component Removed	Avg. Latency	Degradation vs. HTBM
HTBM (full)	—	735.10	—
HTBM-NM	Reptile meta-init	779.40	+6.04%
HTBM-MLP	Hybrid-transformer	758.85	+3.24%
HTBM-DQN	Double Q target	747.60	+1.71%

The largest degradation is observed when the Reptile meta-initialization is removed, indicating that rapid adaptation to a new task benefits more from a favorable starting point than from either the sequence representation or the Double-DQN target rule alone. Removing the hybrid-transformer produces a smaller but non-negligible increase in latency, suggesting that the observation history contributes useful context beyond the instantaneous state, consistent with the queueing and precedence dependencies described in Section III. The smallest degradation follows from replacing the Double DQN target with the standard DQN target, which is consistent with the discrete and relatively small action space considered in this work; value overestimation has a comparatively limited effect here, though it may become more pronounced with a larger number of candidate edge servers. These results indicate that

all three components contribute positively to HTBM, with the meta-learning initialization providing the largest single contribution under the evaluated setting.

VII. Discussion

HTBM combines three complementary mechanisms: the hybrid-transformer provides a sequence-level representation of past experiences, DDQN provides a value-based decision mechanism that reduces the overestimation tendency of standard DQN, and Reptile provides a meta-initialization that adapts efficiently to new MEC environments. As reported in Section VI, HTBM consistently achieves lower average latency than GASTO across the evaluated transmission rates and DAG topologies, including the unseen topology.

These results provide evidence for the latency-oriented effectiveness of HTBM under the evaluated simulation settings, complemented by the preliminary component-level evidence from the ablation study in Section VI-H. Several aspects of the evaluation remain open and are identified as concrete priorities for ongoing follow-up work. First, all experiments use synthetically generated DAGs (Table I), generated with the same methodology as MRLCO and GASTO for fair comparison, and training cost (wall-clock meta-training time, parameter count) is not benchmarked against these baselines; both aspects, together with evaluation on real application traces, warrant further study. Second, the reported comparisons (Table II, Table III, Fig. 3–9) reflect single training runs per configuration; given the well-known run-to-run variance of deep reinforcement learning, a multi-seed evaluation (five or more independent runs, mean $\pm$ standard deviation, and a paired t-test for the HTBM-vs-GASTO comparisons) is planned, together with a similar statistical treatment of the ablation results. Third, the DDQN and Reptile hyperparameters (Section VI-A) were adopted from established reference configurations rather than tuned or sensitivity-tested for this setting; an independent sensitivity analysis is planned alongside the multi-seed evaluation. Finally, the evaluation is conducted entirely in simulation and does not model realistic wireless traces, mobility, or device-level hardware constraints; validating HTBM on physical MEC testbeds with real network traces is identified as an important next step toward practical deployment.

VIII. Conclusion

This study proposed HTBM, a hybrid-transformer-based meta-reinforcement-learning framework for latency-oriented task offloading in dynamic MEC environments. The approach retains a fine-grained DAG representation of applications and combines hybrid-transformer sequence encoding, Double DQN-based action-value learning, and Reptile meta-learning.

The hybrid-transformer component captures temporal relationships within sequences of MEC observations, while DDQN provides the decision mechanism for discrete execution-location choices. Reptile learns a meta-initialization that can be rapidly adapted to new task and environment configurations.

Consistent with the results reported in Section VI, HTBM achieves lower average task-completion latency than GASTO across the evaluated transmission rates, DAG topologies, and the unseen topology. The ablation study in Section VI-H further indicates that each of the three components – the hybrid-transformer representation, the Double DQN target rule, and the Reptile meta-initialization – contributes positively to this performance, with the meta-initialization providing the largest single contribution under the evaluated setting. These results support the feasibility of the proposed hybrid-transformer and DDQN combination for latency-oriented MEC task offloading.

XraySafe-YOLO: Compact Scale-Aware Fusion and Contour-Motivated Attention for Recall-Oriented Detection of Occluded Prohibited Items in X-ray Images

Liu Liu, Wei Huang*
Department of General Education, Shanghai Customs College, Shanghai, China

***Abstract*—Occlusion, weak texture, and scale variation make prohibited-item detection difficult in X-ray security images. This study presents XraySafe-YOLO, a compact detector built on YOLO11n that combines Contour-Guided Occlusion Attention with Lightweight Scale-Aware Feature Fusion. On OPIXray, at a fixed confidence threshold of 0.25 and intersection-over-union threshold of 0.50, the full model reduced false negatives from 201 to 163 in the seed-42 experiment. Across three split-and-training trials, the full model reduced false negatives and improved fixed recall over YOLO11n in every trial, with a mean false-negative count of 172.7 and a mean fixed recall of 0.9030. A supplemental single-seed evaluation on the 12-class PIDray benchmark increased mean average precision at an intersection-over-union threshold of 0.50 from 0.7938 to 0.8035 and reduced false negatives from 10,148 to 9,318. LSAFF produced the more stable individual improvement, whereas CGOA alone was sensitive to the OPIXray trial seed. Results on both datasets show the same main behavior: the proposed combination improves recall and reduces missed detections, while some false-positive and precision costs remain. The method is therefore positioned as a compact recall-oriented option for human-assisted X-ray security inspection rather than as a detector that improves every metric.**

***Keywords*—X-ray imaging; prohibited item detection; object detection; YOLO; occlusion-aware detection; multi-scale feature fusion; recall-oriented evaluation**

I. Introduction

X-ray imaging is widely used to inspect baggage, parcels, and cargo at airports, ports, railway stations, logistics centers, and other security checkpoints. It allows inspectors to check concealed objects without opening the container. However, detection becomes difficult when prohibited items are small, have weak contrast, or overlap with normal objects. A high inspection workload can also increase the chance of missed detections.

Automatic detection can help inspectors by marking regions that need further checking. X-ray images are different from normal color images. They have limited texture, incomplete object boundaries, and overlapping materials. Downsampling may also weaken small-object features. These conditions make false negatives an important issue.

*Corresponding author.

Mean average precision is useful for comparing detectors, but it does not show how many prohibited items are missed at a selected threshold. In a human-assisted inspection process, a false positive usually leads to another check, while a false negative may allow a dangerous item to pass. Therefore, this study reports standard detection metrics together with true-positive, false-positive, and false-negative counts, fixed-threshold recall, a recall-weighted F_2 score, occlusion-level results, and model complexity.

YOLO detectors are suitable for inspection tasks because they use a compact one-stage structure. Existing X-ray detection methods often use attention, feature-pyramid changes, larger receptive fields, or efficient convolution. This study focuses on two points. First, local shape and boundary information may still be useful when texture is weak or an object is partly hidden. Second, features from different scales should be combined without making the detector too large.

This study asks three questions. Can compact multi-scale fusion reduce missed detections without replacing the YOLO11n backbone? Does local boundary-motivated attention help by itself, or mainly when it is combined with multi-scale features? Are the results similar across repeated split-and-training trials? We first test the modules separately and together on OPIXray. We then use PIDray to check whether the same behavior appears with more object categories and the official Easy, Hard, and Hidden subsets.

XraySafe-YOLO uses two plug-in modules. Contour-Guided Occlusion Attention (CGOA) applies spatial and channel recalibration to the higher-resolution P3 and P4 features. It is motivated by local boundary changes, but it does not use contour labels or an external edge detector. Lightweight Scale-Aware Feature Fusion (LSAFF) aligns P3, P4, and P5 and learns the contribution of each input scale to each output scale. The modules are tested separately and together.

The main contributions are as follows:

- A compact YOLO11n-based detector is proposed for occluded prohibited items in X-ray images. CGOA applies local spatial reweighting motivated by boundary variation, and LSAFF fuses features for each detection scale.
- A controlled OPIXray ablation compares the two

modules separately and together, with CBAM-lite as an attention reference. The four main configurations are tested in three trials with different validation and training seeds.

- A single-seed second-benchmark test on PIDray compares YOLO11n, YOLO11n + LSAFF, and the full model on the official Easy, Hard, and Hidden subsets.
- The evaluation separates class-averaged standard metrics from micro-averaged fixed-count metrics, so the trade-off between missed detections and false alarms can be seen directly.
- The study reports occlusion-level, class-level, complexity, repeated-trial, operating-point, second-benchmark, and qualitative analyses. Model definitions, configuration files, result summaries, and a small execution demo are available from the corresponding author upon reasonable request.

The remainder of the study is organized as follows. Section II reviews related work. Section III describes the architecture and evaluation design. Section IV presents the experimental protocol, Section V reports the results, and Section VI discusses their practical meaning and limitations. Section VII concludes the study.

II. Related Work

A. Benchmarks and Overlap-Aware X-ray Detection

X-ray prohibited-item detection is different from natural-image detection because overlapping materials, weak texture, and incomplete boundaries can mix object and background information. Public datasets have played an important role in this field. SIXray introduced a large-scale dataset with serious class imbalance and overlapping baggage contents [1]. OPIXray focuses on five cutter-like categories and provides three official occlusion-level test subsets [2], [3]. PIDray includes more categories and hidden objects in realistic scenes [4]–[6].

Recent methods also address overlap directly. AO-DETR uses category-specific assignment and dense decoder refinement to reduce feature coupling and unclear boundaries on PIXray and OPIXray [7]. Dual-view detection shows that two scanner views can help solve cases that remain difficult in one view [8]. These methods are important references, but they use different architectures and, for dual-view detection, different input data from the compact single-view setting used in this study.

B. Lightweight YOLO Detectors for Security X-ray Images

YOLO detectors are widely used when deployment speed and implementation simplicity matter [9]–[13]. X-ray variants have explored attention, feature aggregation, dynamic heads, lightweight backbones, loss redesign, pruning, and distillation. ScanGuard-YOLO emphasizes recall under cluttered and occluded conditions [14]. Fang et al. reduce YOLOv8 channels and introduce a simplified BiFPN to balance accuracy and computation [15]. Fine-YOLO redesigns feature aggregation and uses normalized Wasserstein distance to improve small-object localization [16]. Attention-based X-ray detection has also combined multi-scale features with explicit feature recalibration [17].

The design space has continued to expand. A lightweight YOLOv7-tiny model targets portable inspection devices through efficient architectural changes [18]. Guan et al. combine deformable convolution and a dynamic detection head in YOLOv8 [19]. Chen et al. report another improved YOLOv8 framework for contraband detection [20]. Xray-YOLO-Mamba integrates selective state-space blocks and evaluates across CLCXray, OPIXray, and SIXray [21]. More recent work combines depthwise convolution, channel-spatial attention, and supervised contrastive learning on two X-ray datasets [22], while GSA-YOLO uses structured sparsity and adaptive knowledge distillation to emphasize both accuracy and real-time efficiency [23].

These studies show that a compact X-ray detector should not be judged only by parameter count. Recent work often reports module ablations, computation, visual examples, and tests on more than one dataset or more than one training run. This study has a narrower goal. It examines how local contour-motivated attention and one-stage scale-weighted fusion affect missed detections, false alarms, and trial-to-trial variation in a compact YOLO11n detector.

C. Efficient Attention and Multi-Scale Fusion

Efficient detectors often use depthwise separable convolution and compact channel transformations derived from MobileNet-style designs [24], [25]. Attention modules such as the Convolutional Block Attention Module (CBAM) and coordinate attention recalibrate spatial or channel responses with limited overhead [26], [27]. In X-ray images, this can help emphasize small visible fragments, although clutter can also create strong responses that do not belong to a prohibited item.

Multi-scale fusion addresses the complementary need for fine spatial detail and broader context. Feature Pyramid Networks (FPNs) and Path Aggregation Networks (PANets) exchange information between feature levels, EfficientDet uses repeated bidirectional weighted fusion, and adaptively spatial feature fusion (ASFF) learns scale contributions at the spatial level [28]–[31]. LSAFF follows the same broad motivation but uses one normalized weighted fusion for each output scale rather than a repeated bidirectional pyramid. CGOA is likewise deliberately compact and requires neither contour annotations nor an external edge detector.

D. Evaluation Gap and Positioning of this Study

Most X-ray detection papers report mAP, precision, recall, parameters, FLOPs, and selected examples. These measures are useful, but they may not show how many prohibited items are missed at one selected threshold or whether an improvement is stable across training runs. In a human-assisted workflow, it is also important to know whether lower FN is obtained with more FP.

For this reason, the study reports standard metrics together with class-aware fixed-threshold TP, FP, and FN counts, a recall-weighted F_2 score, occlusion-level and class-level results, three OPIXray trials for the four main configurations,

and a PIDray second-benchmark test. Table I summarizes representative recent work. The absolute scores are not compared across rows because the datasets, classes, resolutions, and evaluation settings are different.

III. Methodology

A. Overview of XraySafe-YOLO

XraySafe-YOLO adds two low-overhead modules to YOLO11n. The modules address incomplete local structure and large changes in object scale. The network keeps the standard one-stage detection pipeline and the original detection heads.

An input image is resized and normalized before entering the backbone. The backbone and neck produce three feature levels, P3, P4, and P5. CGOA is applied to P3 and P4, where spatial detail is still sufficient to represent small or partly visible object boundaries; P5 is left unchanged. In the CGOA-only model, the enhanced P3 and P4 features proceed to the detection heads through the original neck. In the combined model, P3′, P4′, and P5 are passed to LSAFF, which returns $P3^{out}$, $P4^{out}$, and $P5^{out}$ for the three heads. The heads predict bounding boxes, categories, and confidence scores.

Both modules are designed as plug-ins rather than as a replacement for the YOLO11n backbone. Fig. 1 summarizes the data flow.

B. Baseline Detector and Model Variants

YOLO11n is used as the compact baseline. All variants retain its backbone, neck, and detection heads, which keeps the comparison focused on the added modules. Five configurations are evaluated at seed 42: YOLO11n, YOLO11n + CBAM-lite, YOLO11n + CGOA, YOLO11n + LSAFF, and YOLO11n + CGOA + LSAFF. The four principal configurations excluding CBAM-lite are also evaluated with seeds 42, 2026, and 3407.

The implementation places CGOA after the final P3 and P4 neck branches; P5 bypasses the module. In the model definition, these features correspond to layers 16, 19, and 22. LSAFF is instantiated once for each target resolution so that the same P3/P4/P5 inputs produce one fused output for each detection head. Shape-compatible YOLO11n parameters are transferred from the pretrained checkpoint to each custom configuration, while parameters introduced by CGOA, LSAFF, and CBAM-lite use their module initializations. Input size, batch size, epoch limit, data preparation, optimizer policy, augmentation, early stopping, and fixed-count evaluation settings are kept the same across models; no architecture-specific hyperparameter tuning is performed.

C. Contour-Guided Occlusion Attention Module

X-ray images usually contain less texture than natural images. However, the shape and boundary of a prohibited item may still be visible when the item is partly covered. For example, part of a knife blade or the outline of scissors can still provide useful information in cluttered baggage. CGOA is based on this observation. In the module name, "guided" means that the design is guided by local boundary variation; it does not use an external contour image or contour supervision.

Let $F \in \mathbb{R}^{C\times H\times W}$ denote an intermediate feature map extracted by the backbone. CGOA is inserted into the P3 and P4 branches because these feature levels preserve more spatial detail and are more relevant to small or partially occluded prohibited items. The module first generates a local spatial response map from F. This response is contour-motivated rather than contour-supervised: no edge labels, contour annotations, or external edge detector are used. Specifically, the spatial branch applies a 3×3 depthwise convolution with batch normalization and SiLU activation, followed by a 1×1 convolution that reduces the response to one channel. The contour branch produces a spatial logit map $M_c \in \mathbb{R}^{1\times H\times W}$.

The contour response is then combined with channel-wise recalibration. Given the feature map F, global average pooling and global max pooling are used to obtain channel descriptors. The two descriptors pass through the same two-layer 1×1 convolutional MLP with SiLU activation. Its hidden width is $\max(\lfloor C/16 \rfloor, 8)$. The summed MLP output is denoted by L_{ch}, and the channel weights are $A_{ch} = \sigma(L_{ch}) \in [0,1]^{C\times 1\times 1}$.

The enhanced feature map is computed as follows:

$$F' = F \otimes (1 + \sigma(M_c)) \otimes A_{ch}, \tag{1}$$

where, $\otimes$ denotes element-wise multiplication with broadcasting and $\sigma(\cdot)$ denotes the sigmoid activation function. The residual spatial factor $1 + \sigma(M_c)$ is never smaller than one, so the spatial branch alone does not attenuate F; however, the subsequent channel gate $A_{ch} \in [0,1]$ can attenuate channels in the final product. CGOA is restricted to P3 and P4 because these feature maps retain finer boundary information; applying the same spatial gate to the coarser P5 branch would add computation where local contour detail is already strongly downsampled.

The residual spatial gate is intended to emphasize local transitions without directly suppressing them; the complete CGOA output can still be attenuated by the channel gate. Thus, boundary enhancement is treated as a design motivation rather than as a demonstrated contour detector. Because X-ray clutter can also create strong local transitions, the ablation study evaluates whether this bias helps consistently rather than assuming that it will do so. Fig. 2 illustrates the CGOA module.

D. Lightweight Scale-Aware Feature Fusion Module

Prohibited items can have different sizes and irregular shapes. Small items need high-resolution details, while large or heavily occluded items need more context. Multi-scale feature fusion is therefore useful. However, some fusion structures add many parameters and computations, which is not suitable for a compact baseline.

LSAFF addresses this trade-off with one output-specific weighted fusion stage for each detection scale. For every input-to-output path, the implementation uses the same architectural pattern: a 3×3 depthwise convolution followed by a 1×1 pointwise convolution, with batch normalization and SiLU activation after each convolution. The resulting feature is resized to the target spatial resolution with nearest-neighbor interpolation. The three output-specific LSAFF instances have

TABLE I. REPRESENTATIVE RECENT DIRECTIONS IN X-RAY PROHIBITED-ITEM DETECTION AND THE POSITION OF THIS STUDY

Method	Year	Evaluation Data	Main Technical Emphasis	Evidence Emphasized

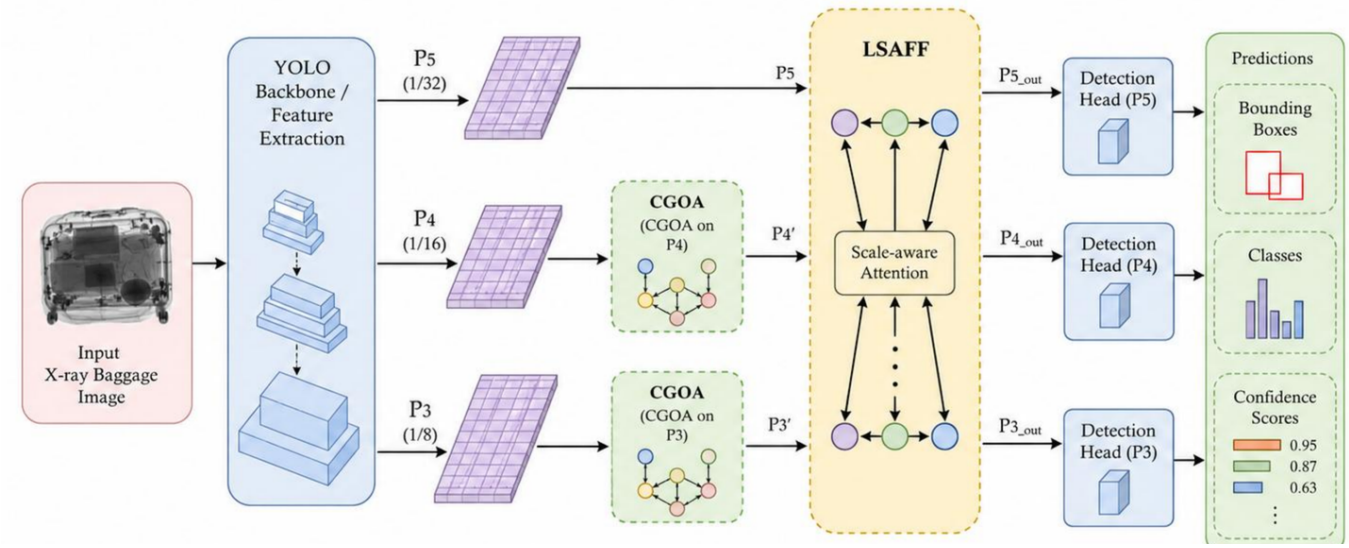

Fig. 1. Overall architecture of the proposed XraySafe-YOLO framework. The YOLO backbone extracts three feature maps, P3, P4, and P5. CGOA is applied only to the P3 and P4 branches to reweight local spatial responses, motivated by boundary transitions in small and partially occluded prohibited items, while P5 bypasses CGOA and enters LSAFF directly. LSAFF then produces learned scale-aware output features $P3^{out}$, $P4^{out}$, and $P5^{out}$ for the three detection heads, which output bounding boxes, classes, and confidence scores.

independent parameters; the transformations are not shared across target scales.

Let F_i denote the feature map from the i-th input scale, where $i \in \{3,4,5\}$. Unlike a single-output fusion block, LSAFF produces three scale-specific output features for the detection heads. The transformation from input scale i to output scale k is denoted by $\phi_{k,i}(\cdot)$. For each output scale $k \in \{3,4,5\}$, LSAFF assigns normalized learned scale weights $\alpha_{k,i}$ to the aligned input features. Let the weighted intermediate fusion be:

$$\widetilde{F}_k = \sum_{i\in\{3,4,5\}} \alpha_{k,i} \cdot \phi_{k,i}(F_i), \quad k \in \{3,4,5\}, \tag{2}$$

and let $\psi_k(\cdot)$ denote the output-specific depthwise-separable refinement block. The feature delivered to the k-th detection head is

$$F_k^{out} = \psi_k\left(\widetilde{F}_k\right). \tag{3}$$

Here, $\alpha_{k,i}$ is a learned scalar contribution of the i-th input scale to the k-th output scale. Each output-specific LSAFF instance owns an independent three-element logit vector initialized to zero, corresponding to equal initial contributions from P3, P4, and P5. The weights are normalized for each output scale:

$$\alpha_{k,i} = \frac{\exp(w_{k,i})}{\sum_{j\in\{3,4,5\}} \exp(w_{k,j})}. \tag{4}$$

The refinement ψ_k is a second 3×3 depthwise-separable convolution applied after weighted summation. The weights are learned independently for each output scale; they are scalar coefficients rather than image-dependent or spatially

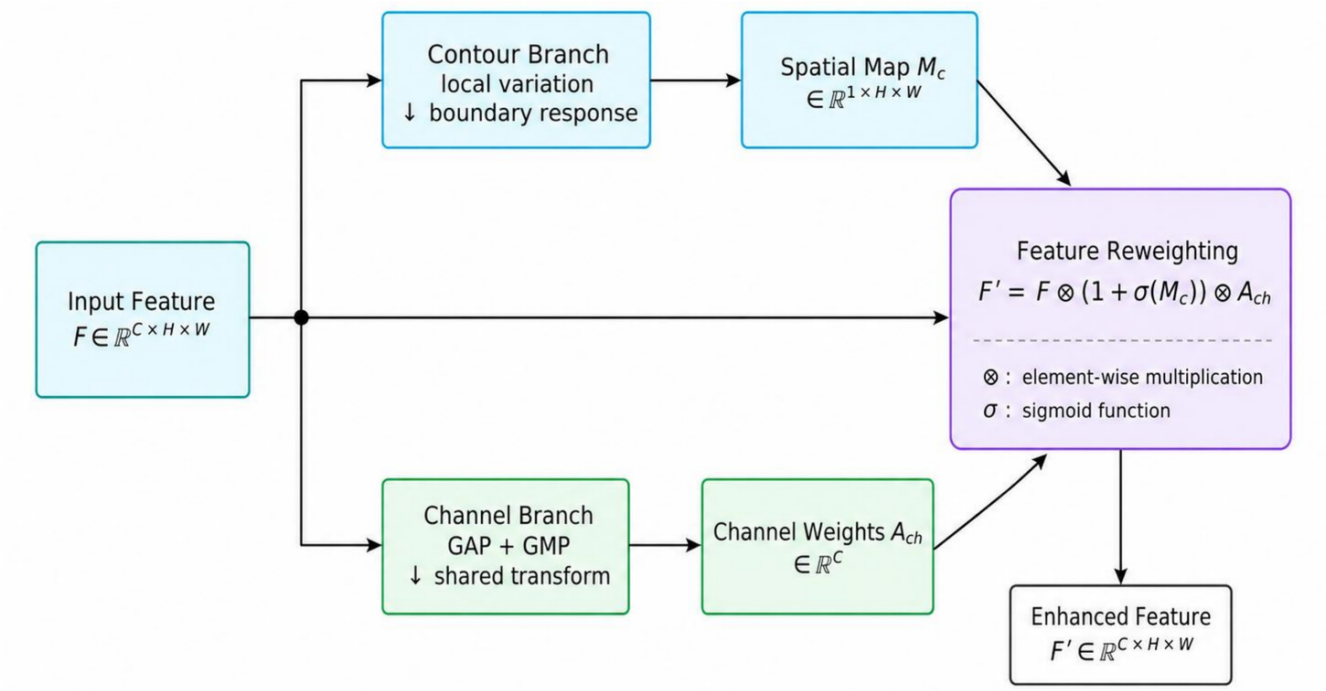

Fig. 2. Contour-Guided Occlusion Attention (CGOA) module. Given an input feature map F, the contour-motivated spatial branch generates a response map M_c, the channel branch generates channel weights A_{ch} using global average and max pooling, and the identity path preserves the original feature. The enhanced output is computed as $F' = F \otimes (1 + \sigma(M_c)) \otimes A_{ch}$ without requiring additional contour annotations.

varying attention maps. High-resolution features retain small-object and boundary information, while deeper features provide broader context. Unlike bidirectional pyramids such as BiFPN, which repeatedly propagate features in top-down and bottom-up paths, LSAFF performs one weighted fusion for each output scale. This keeps the added computation modest, although no direct LSAFF–BiFPN performance comparison is made in this study. Fig. 3 illustrates the module.

E. Training Objective and Recall-Oriented Evaluation

The model uses the standard YOLO detection loss. This keeps the comparison focused on the proposed modules and avoids adding another change through the loss function. The training loss follows the common YOLO-style structure:

$$\mathcal{L} = \lambda_{box}\mathcal{L}_{box} + \lambda_{cls}\mathcal{L}_{cls} + \lambda_{dfl}\mathcal{L}_{dfl}, \tag{5}$$

where, $\mathcal{L}_{box}$ is the bounding-box regression loss, $\mathcal{L}_{cls}$ is the classification loss, and $\mathcal{L}_{dfl}$ is the distribution focal loss used by the underlying YOLO training framework [32]. No class-balanced or hard-sample loss is added. This design keeps the ablation focused on the two proposed architectural modules, CGOA and LSAFF.

Because prohibited item detection is sensitive to missed detections, recall orientation is reflected in the evaluation protocol rather than in a separate training loss. In addition to mAP, the analysis reports recall, false-negative count, fixed-threshold recall, occlusion-level recall, and efficiency metrics. These metrics make it possible to determine whether the proposed modules improve difficult X-ray inspection cases without overstating the model as an autonomous safety decision system.

IV. Experimental Protocol

A. Datasets

The primary experiments use the public OPIXray benchmark, which was constructed for occluded prohibited item detection in X-ray security inspection images [2], [3]. OPIXray contains 8885 images from five cutter-like prohibited item categories: folding knife, straight knife, scissors (official label: "scissor"), utility knife, and multi-tool knife. The official test set is divided into three occlusion-level subsets, denoted as OL1, OL2, and OL3, which support a direct analysis of detection behavior under increasing overlap and visual clutter. Table II summarizes the OPIXray split used for the controlled ablation and repeated trials.

A supplemental evaluation uses the current 124,486-image PIDray release distributed through the official `lutao2021/PIDray` repository [4]–[6]. This release contains 76,913 training images and official Easy, Hard, and Hidden test subsets with 24,758, 9,746, and 13,069 images, respectively, across 12 prohibited-item categories. A deterministic 5% holdout from the official training split is used for validation, while all images in the three official test subsets are retained, including images without prohibited-item boxes; predictions on such images therefore contribute false positives when applicable. The converted test annotations contain 8450, 14,500, and 19,050 ground-truth boxes, respectively, for a total of 42,000. Because the models are trained on PIDray training data, this experiment evaluates the architecture on a

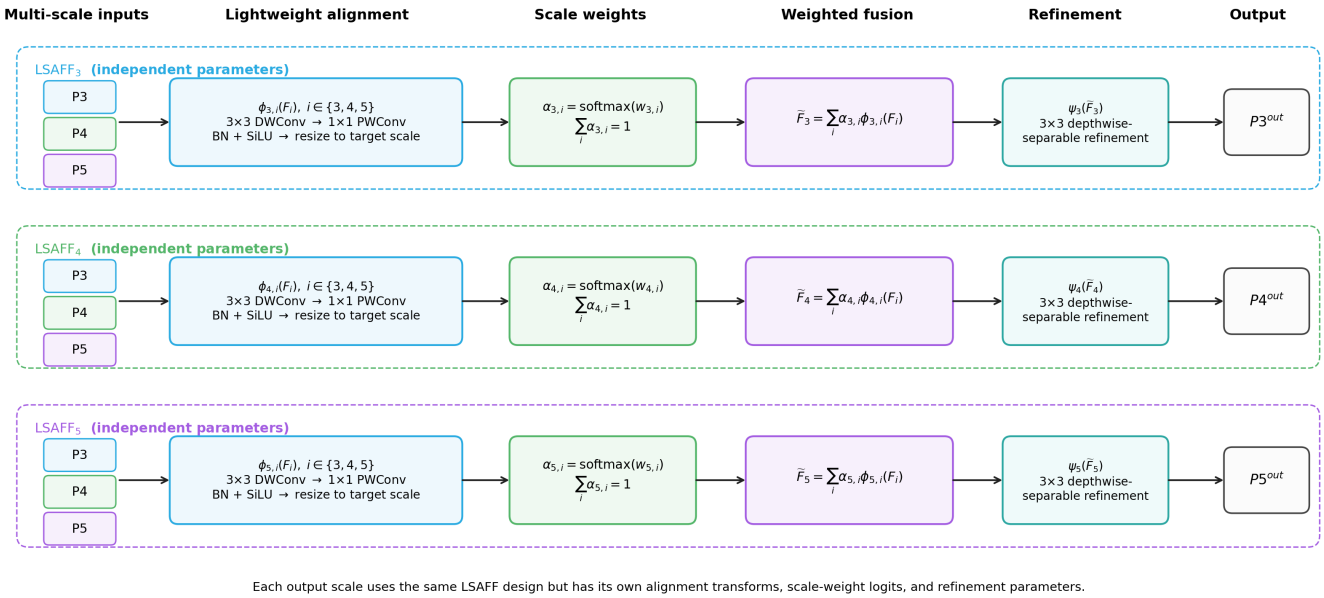

Fig. 3. Lightweight Scale-Aware Feature Fusion (LSAFF) module. Multi-scale inputs P3, P4, and P5 are aligned and transformed through lightweight operations. Three independently parameterized output-specific blocks align P3/P4/P5, learn normalized scale weights $\alpha_{k,i}$, form $\widetilde{F}_k$, and apply the refinement ψ_k before producing P3^{out}, P4^{out}, and P5^{out}.

second benchmark rather than cross-dataset generalization of OPIXray-trained weights.

Representative OPIXray examples are shown in Fig. 4. The examples illustrate why prohibited item detection in X-ray images is more difficult than ordinary natural-image detection: item contours can be weak, objects can be transparent or overlapping, and cluttered baggage contents may visually interfere with cutter-like objects.

B. Data Preparation

OPIXray is converted into a unified YOLO-compatible annotation format. Each image is associated with a text annotation file containing the object category and normalized bounding-box coordinates. The official OPIXray test set is preserved in every trial. For the seed-42 architecture comparison, 711 images are selected from the official training portion using split seed 42. For the repeated seeded evaluation, the 711-image validation subset is regenerated using split seeds 42, 2026, and 3407, respectively; the official test set remains unchanged.

The conversion process includes parsing original annotation files, mapping dataset-specific categories to unified class names, converting bounding-box coordinates to normalized YOLO format, verifying image-annotation consistency, generating train/validation/test file lists, and checking invalid boxes, missing images, and duplicated annotations.

PIDray is converted from its COCO-style detection annotations to the same YOLO-compatible format while retaining all 12 official categories. The training images are partitioned deterministically into training and validation sets with a 5% validation ratio and seed 42. Easy, Hard, and Hidden remain separate test sets. The combined PIDray standard metrics are obtained by running the validator once on the union of all three official test subsets (pooled predictions), not by averaging the three subset mAP values. Fixed TP/FP/FN counts are summed over the same pooled test population.

C. Implementation Details

The experiments were run on Windows with Python 3.11, PyTorch, Ultralytics YOLO 8.4.78, and an NVIDIA GeForce RTX 4070 SUPER GPU with 12 GB graphics memory. Images were resized to 640×640, the batch size was 48, and training was allowed to continue for up to 100 epochs with early-stopping patience 30. All models used pretrained YOLO11n initialization, cosine learning-rate scheduling, weight decay 0.0005, three warm-up epochs, deterministic seed settings, and mixed-precision training. Standard Ultralytics augmentations were retained, including HSV adjustment, translation, scaling, horizontal flipping, and mosaic augmentation with `close_mosaic=10`. No separate RandAugment or random-erasing pipeline was added.

The same Ultralytics training interface and `optimizer=auto` policy were used for every model, and no model received architecture-specific optimizer tuning. Under Ultralytics 8.4.78, the OPIXray runs resolved to AdamW with initial learning rate 0.001111 and $\beta_1 = 0.9$; cosine scheduling used the framework default final learning-rate factor 0.01. Weight decay was 0.0005 and warm-up lasted three epochs. The larger PIDray runs resolved to MuSGD with initial learning rate 0.01 and momentum 0.9 under the same automatic-selection rule. Shape-compatible pretrained parameters and newly initialized module parameters were optimized together. These resolved settings are reported to make clear that `optimizer=auto` was not an unspecified degree of freedom.

The seed-42 OPIXray comparison used split seed 42 and training seed 42 for all five models. For the repeated OPIXray

TABLE II. OPIXRAY DATASET STATISTICS USED FOR THE PRIMARY EXPERIMENTS

Dataset	Images	Classes	Train	Val	Test	Test GT Boxes by OL Subset
OPIXray	8885	5	6398	711	1776	OL1: 923; OL2: 550; OL3: 307

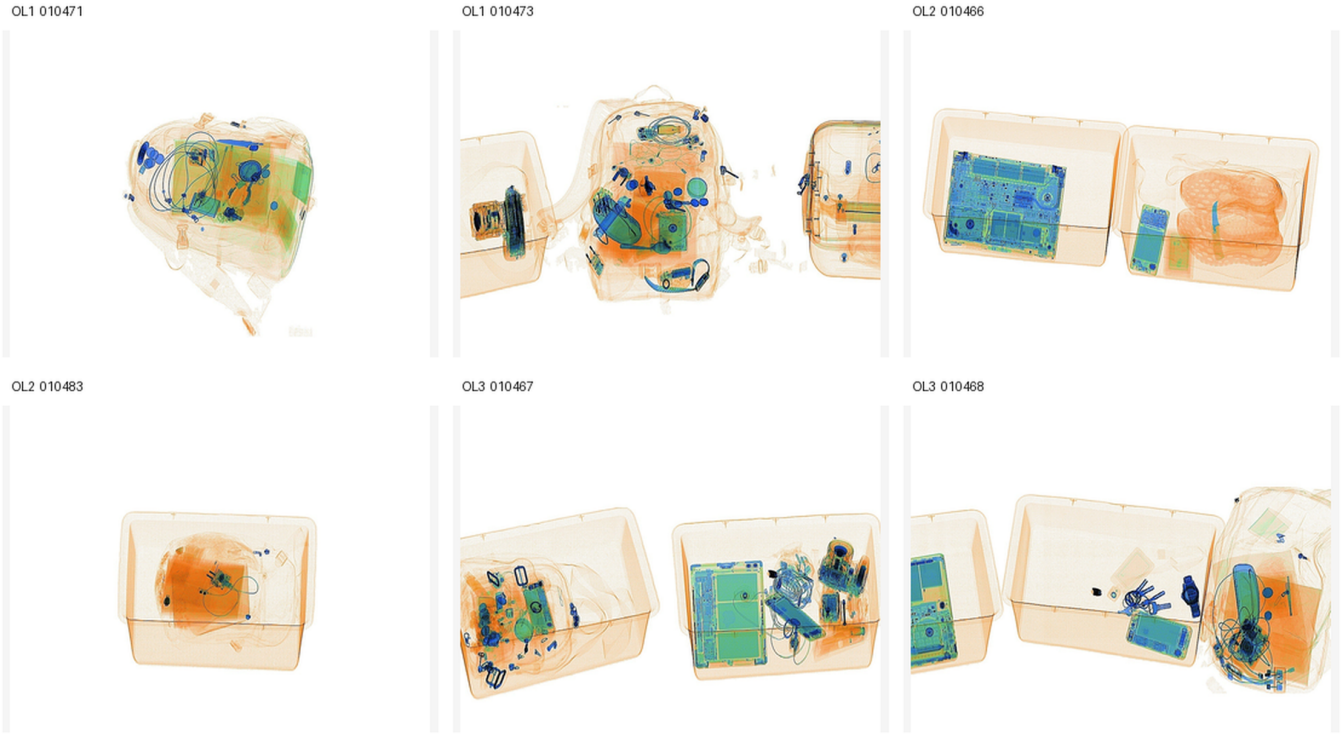

Fig. 4. Representative OPIXray examples from OL1, OL2, and OL3 occlusion-level subsets. The images show the transparent appearance, weak texture, and object overlap that motivate contour-motivated and recall-oriented detection analysis.

evaluation, the four principal models were trained with seeds 42, 2026, and 3407. In each trial, the validation split seed matched the training seed, while the official OPIXray test set remained unchanged. The repeated results therefore combine split and optimization variability; they are not a fixed-split significance test. Hardware-dependent validation timing was recorded only as a diagnostic and is not used to support the architectural conclusions.

The supplemental PIDray experiment used the same software and hardware environment, 640-pixel input resolution, pretrained initialization, augmentation family, optimizer policy, early-stopping mechanism, and fixed-count thresholds. Because of the larger dataset, training used batch size 16 for up to 50 epochs with split and training seed 42. YOLO11n, YOLO11n + LSAFF, and the full model were trained under the same PIDray protocol. The experiment uses one seed and is interpreted as second-benchmark evidence rather than a significance test.

For the seed-42 OPIXray architecture comparison, training completed 100 epochs for YOLO11n and CGOA, 94 epochs for LSAFF, and 92 epochs for the full model because early stopping was triggered for the latter two runs. The reported test metrics use the saved `best.pt` checkpoint selected by the Ultralytics validation fitness, which weights mAP@0.5 and mAP@0.5:0.95 by 0.1 and 0.9, respectively. During fixed-count inference, the prediction confidence threshold is varied as stated in each analysis; non-maximum suppression uses IoU 0.50, class-aware suppression (`agnostic_nms=False`), and `max_det=300`. The subsequent TP/FP/FN matcher separately uses same-class IoU $\geq$ 0.50. Thus, the NMS IoU threshold and the matching IoU threshold are numerically equal in this study but serve different operations (Table III).

TABLE III. RESOLVED TRAINING SETTINGS FOR THE PRINCIPAL CONFIGURATIONS

Setting	YOLO11n	CGOA	LSAFF	Full
Optimizer (OPIXray)	AdamW	AdamW	AdamW	AdamW
Initial LR	0.001111	0.001111	0.001111	0.001111
β_1 / momentum	0.9	0.9	0.9	0.9
Weight decay	0.0005	0.0005	0.0005	0.0005
Completed epochs (seed 42)	100	100	94	92
Checkpoint	best validation fitness: 0.1 mAP@0.5 + 0.9 mAP@0.5:0.95			

For PIDray, the same `optimizer=auto` rule resolves to MuSGD because of the larger number of planned iterations; its initial learning rate is 0.01 with momentum 0.9. The PIDray

runs use the same weight decay, cosine scheduling, warm-up policy, checkpoint rule, and inference settings unless otherwise stated.

D. Evaluation Metrics

Standard object detection metrics are reported:

$$Precision = \frac{TP}{TP + FP}, \tag{6}$$

$$Recall = \frac{TP}{TP + FN}, \tag{7}$$

$$F1 = \frac{2 \cdot Precision \cdot Recall}{Precision + Recall}. \tag{8}$$

In addition, mAP@0.5 and mAP@0.5:0.95 are reported. The standard precision, recall, and F1 values are class-averaged metrics returned by the Ultralytics validator. They are therefore not numerically interchangeable with the fixed-count metrics below, which are micro-averaged over all 1780 test instances at one selected confidence and IoU operating point. Per-class recall and AP values are retained in the metric JSON files and summarized for the baseline and full model to inspect whether the aggregate gain is concentrated in only one category.

Because missed prohibited items are important in security inspection, additional recall-oriented metrics are also reported. These include false-negative count, occlusion-level recall, and fixed-threshold recall. Deployment-oriented complexity metrics include parameter count, GFLOPs, and model size. These metrics describe architectural overhead while avoiding unsupported claims about hardware-dependent latency or throughput.

The fixed-count protocol is computed after the model's standard prediction and non-maximum suppression stage. Predictions are filtered with confidence ≥ 0.25 and sorted by descending confidence. Each prediction is greedily matched to the unmatched ground-truth box of the same class with the highest IoU, provided that IoU ≥ 0.50. Each ground-truth instance can be matched at most once. Unmatched predictions are counted as false positives, and unmatched ground-truth instances are counted as false negatives. Fixed-count precision and recall are then computed as:

$$Fixed\ Precision = \frac{TP_{fixed}}{TP_{fixed} + FP_{fixed}}, \tag{9}$$

$$Fixed\ Recall = \frac{TP_{fixed}}{TP_{fixed} + FN_{fixed}}. \tag{10}$$

Because missed detections are emphasized in the intended human-in-the-loop screening setting, a recall-weighted fixed-count F_2 score is also reported; with $\beta = 2$, recall receives four times the weight of precision in the denominator-weighted harmonic formulation:

$$F_2 = \frac{5 \cdot Fixed\ Precision \cdot Fixed\ Recall}{4 \cdot Fixed\ Precision + Fixed\ Recall}. \tag{11}$$

For the seed-42 OPIXray test set, this protocol counts 1776 test images and 1780 ground-truth boxes. For PIDray, the same protocol is applied to the 42,000 ground-truth boxes across the official Easy, Hard, and Hidden subsets. The 0.25 confidence threshold is a pre-specified diagnostic point applied identically to every model rather than a claim of universal optimality. Operational deployment would require threshold calibration on data from the target scanner and analysis of the full precision–recall curve.

E. Baseline and Comparative Models

The main OPIXray ablation compares YOLO11n, YOLO11n + CGOA, YOLO11n + LSAFF, and YOLO11n + CGOA + LSAFF. This arrangement isolates the two modules within the same detector and training protocol. CBAM-lite is included at seed 42 as a generic channel-and-spatial attention reference trained under the same settings. The compact PIDray comparison includes YOLO11n, YOLO11n + LSAFF, and the full model. CGOA alone is not repeated on PIDray because the OPIXray trials already identify LSAFF as the stronger standalone component; the second-benchmark experiment focuses on whether the same architectural pattern is observed on a broader 12-class benchmark.

F. Visualization and Descriptive Analysis

The numerical tables are supported by figures generated directly from the reported test results. Error bars in the repeated-trial figures denote the sample standard deviation over seeds 42, 2026, and 3407. The OPIXray occlusion figure uses the fixed FN counts from the official OL1–OL3 subsets, and the class figure plots the recall difference between the full model and YOLO11n. The PIDray second-benchmark figure compares mAP@0.5 and fixed recall across Easy, Hard, and Hidden. These visual summaries do not introduce additional samples or alternative metric definitions; they are intended to make variability, trade-offs, category-specific behavior, and second-benchmark behavior easier to inspect.

G. Reproducibility and Consistency Checks

Dataset split seeds, training seeds, model definitions, conversion summaries, and result summaries were retained for each experiment. A compact code package available from the corresponding author contains the CGOA, LSAFF, and CBAM-lite modules, the associated YAML files, and a CPU-compatible tensor-shape smoke test. The original OPIXray and PIDray images and annotations are not redistributed and must be obtained from their official sources under the applicable academic-use terms.

The fixed-count tables were checked directly from their TP, FP, FN, and ground-truth totals. Every row satisfies $TP + FN = GT$, and fixed precision and recall were recomputed from the counts. For the occlusion analysis, the OL1–OL3 TP and FN values sum to the full 1780-instance test set for each model. These checks place the aggregate and subset TP/FN results on the same ground-truth basis.

V. Results and Analysis

A. Controlled Seed-42 Architecture Comparison

Table IV reports the conventional seed-42 metrics. The ranking depends on the metric: CBAM-lite has the highest precision, while LSAFF has the highest recall, F1-score, mAP@0.5, and mAP@0.5:0.95. The combined model is close to LSAFF but does not lead any conventional metric. Its class-averaged recall (0.8439) is the arithmetic mean of the five class recalls in Table VII; F1 is recomputed from the corresponding precision and recall. CGOA alone performs below YOLO11n in this trial. Among the proposed individual modules, LSAFF provides the stronger seed-42 result.

The fixed operating-point counts in Table V show the trade-off between missed detections and false alarms more clearly than mAP alone. Relative to YOLO11n, the seed-42 full model detects 38 additional ground-truth instances (1617 versus 1579), reducing FN from 201 to 163, or by 18.9%. This recall gain is accompanied by an increase in FP from 224 to 250, or by 11.6%. At this operating point, each added false positive is associated with about 1.46 additional true detections. Fixed recall rises from 0.8871 to 0.9084, fixed precision decreases from 0.8758 to 0.8661, and the recall-weighted F_2 increases from 0.8848 to 0.8996. The ratio is not a deployment utility measure because the costs of misses and false alarms are application-dependent; it simply makes the observed count trade-off easier to interpret. Therefore, the combined model is better described as a recall-oriented option, not as a model that improves every error type or metric.

At seed 42, adding CGOA to LSAFF reduces FN from 184 to 163 and increases fixed recall from 0.8966 to 0.9084, but FP changes from 255 to 250 and fixed precision remains below the baseline. CGOA alone is worse than YOLO11n in FN and conventional mAP for this seed. The result suggests that CGOA can complement LSAFF at this operating point, but it does not support CGOA as an independently superior attention block.

B. Occlusion-Level and Per-Class Behavior

Table VI reports the seed-42 results on OL1, OL2, and OL3. The three subsets contain 923, 550, and 307 ground-truth instances, respectively, and their TP and FN counts sum exactly to the 1780-instance full test set for every model. The full model gives the lowest FN on OL1 and OL3, whereas LSAFF gives the lowest FN on OL2. The results suggest that multi-scale fusion is the more stable contributor and that the combined configuration is most useful when missed detections receive greater weight.

Fig. 5 visualizes the fixed FN counts. Because OL1, OL2, and OL3 contain different numbers of ground-truth boxes, bar heights should be compared between models within a subset rather than across subsets. Relative to YOLO11n, the full model reduces FN by 20 on OL1, 7 on OL2, and 11 on OL3. In fixed-recall terms, these changes correspond to gains of 0.0217, 0.0127, and 0.0358, respectively. LSAFF records the lowest FN on OL2, while the full model is lowest on OL1 and OL3. The largest proportional recall gain occurs on OL3, although this subset is also the smallest and should not be treated as an independent generalization test.

Table VII reports a compact class-level recall comparison between YOLO11n and the full configuration. The full model improves recall for multi-tool knife, the official "scissor" label, straight knife, and utility knife, but decreases recall for folding knife. The gain is especially visible for multi-tool knife and utility knife, whereas straight knife remains the most difficult category. The table focuses on recall because the class-level analysis concerns missed detections. Supporting class-level outputs are available from the corresponding author upon reasonable request.

Fig. 6 shows that the improvement is different across classes. Multi-tool knife has the largest recall increase (+0.0408), followed by utility knife (+0.0196) and straight knife (+0.0165). The small gain for scissors (+0.0039) occurs on a class that already has high baseline recall. Folding knife decreases by 0.0118, showing that the aggregate gain is not uniform; its compact folded geometry may be confused with dense metallic clutter, although the present results do not isolate a single causal factor. Straight knife remains the most difficult class even after improvement, with recall increasing only from 0.5660 to 0.5825. Its elongated, low-contrast appearance and frequent overlap provide a plausible explanation for the persistent difficulty, but this interpretation should be treated as qualitative rather than causal.

C. Repeated Split-and-Training Evaluation

Table VIII summarizes the repeated split-and-training evidence for all four principal models, and Table IX reports the individual trial values. Each trial uses the same batch size, image size, epoch limit, and evaluation protocol, while the validation split seed equals the training seed. The results are therefore descriptive repeated-holdout evidence rather than a fixed-split significance test.

Table IX reports each trial together with the paired change relative to YOLO11n under the same split-and-training seed. This pairing is descriptive rather than a fixed-split significance test, but it shows directly that LSAFF and the full model reduce FN and raise fixed recall in all three trials.

The three trials show different tendencies for the two modules. CGOA has the largest variation in mAP and FN and does not improve the mean values relative to YOLO11n. LSAFF improves mAP@0.5 and fixed recall and lowers FN in each of the three trials, making it the more consistent standalone module. The combined model also lowers FN and raises fixed recall relative to YOLO11n in every trial, while fixed precision is slightly lower in every trial. Averaged over the three trials, its FN count is 15.9% below the baseline mean (172.7 versus 205.3), fixed recall is higher by 0.0184, and fixed precision is lower by 0.0054. The gain is therefore repeatable in direction but concentrated on recall rather than on all operating-point metrics.

Fig. 7 shows the same pattern in count form. The mean FN decreases by 19.3 for LSAFF and by 32.6 for the full model relative to YOLO11n, whereas CGOA changes the mean by only +0.7. CGOA also has the largest FN standard deviation (31.8), consistent with the poor seed-42 result and stronger results in the other two trials. The error bars overlap, so the figure is descriptive evidence rather than a claim of statistical significance.

TABLE IV. SEED-42 BATCH-48 CONVENTIONAL DETECTION METRICS ON THE OPIXRAY TEST SET. BOLD VALUES INDICATE THE BEST RESULT IN EACH COLUMN

Model	Precision	Recall	F1	mAP@0.5	mAP@0.5:0.95
YOLO11n	0.8744	0.8301	0.8517	0.8852	0.4123
YOLO11n + CBAM-lite	**0.8945**	0.8372	0.8649	0.8904	0.4146
YOLO11n + CGOA	0.8512	0.7977	0.8232	0.8467	0.3818
YOLO11n + LSAFF	0.8725	**0.8588**	**0.8650**	**0.8927**	**0.4151**
YOLO11n + CGOA + LSAFF	0.8766	0.8439	0.8599	0.8873	0.4140

TABLE V. SEED-42 FIXED OPERATING-POINT RESULTS AT CONFIDENCE 0.25 AND IOU 0.50. TP, FP, AND FN ARE OBTAINED BY CLASS-AWARE GREEDY MATCHING AFTER NON-MAXIMUM SUPPRESSION

Model	TP	FP	FN	Fixed P	Fixed R	F_2
YOLO11n	1579	224	201	0.8758	0.8871	0.8848
YOLO11n + CBAM-lite	1572	227	208	0.8738	0.8831	0.8812

TABLE VI. OCCLUSION-LEVEL ANALYSIS ON THE OFFICIAL OPIXRAY TEST SUBSETS. RECALL IS THE STANDARD DETECTOR RECALL COMPUTED ON EACH SUBSET; FN IS COUNTED USING THE FIXED CONFIDENCE/IOU PROTOCOL

Model	OL1 Recall / FN	OL2 Recall / FN	OL3 Recall / FN	OL1 mAP@0.5	OL2 mAP@0.5	OL3 mAP@0.5
YOLO11n	0.8574 / 86	0.8081 / 67	0.7787 / 48	**0.9052**	0.8726	0.8609
YOLO11n + CGOA	0.8132 / 104	0.7927 / 75	0.7501 / 61	0.8656	0.8408	0.8084
YOLO11n + LSAFF	0.8634 / 87	**0.8404** / **58**	**0.8398** / 39	0.8898	**0.8957**	**0.8840**
YOLO11n + CGOA + LSAFF	**0.8734** / **66**	0.8342 / 60	0.8150 / **37**	0.9027	0.8737	0.8774

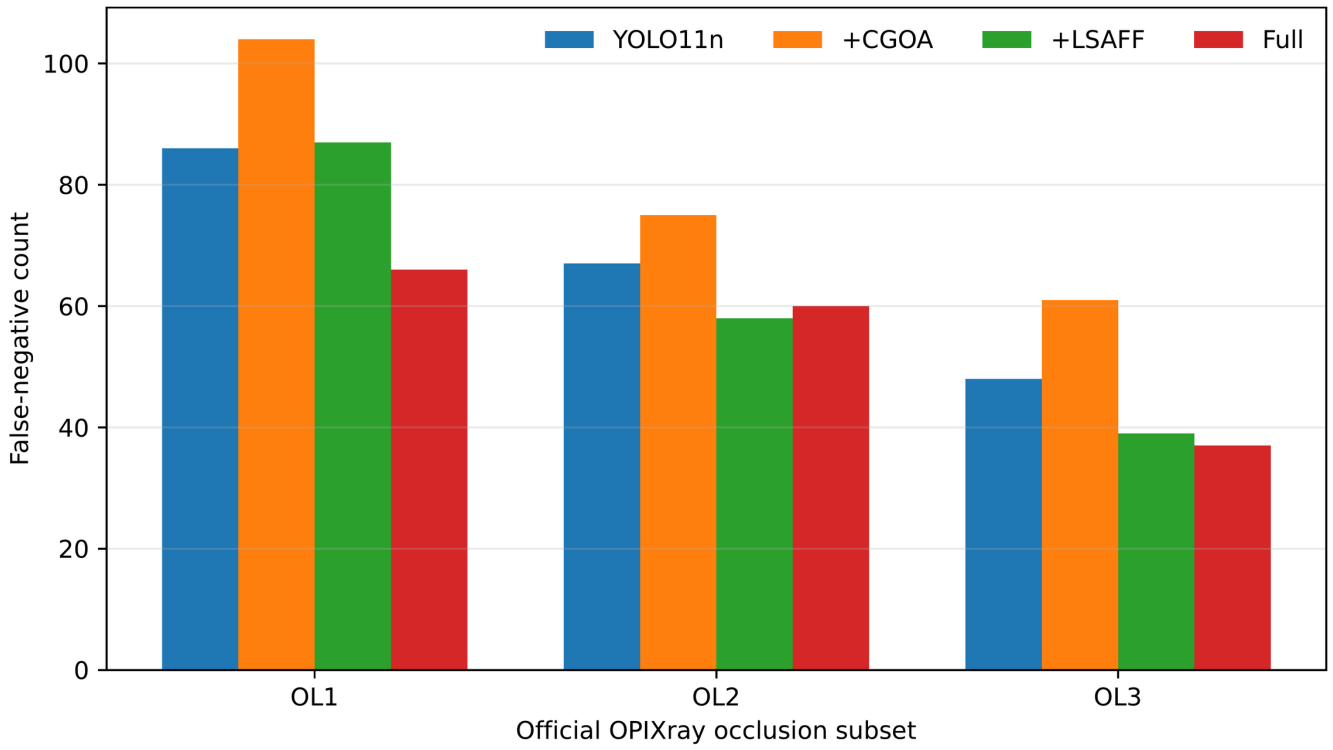

Fig. 5. Fixed false-negative counts on the official OPIXray occlusion subsets at seed 42. The subsets contain different numbers of ground-truth boxes, so comparisons are made between models within each subset.

TABLE VII. CLASS-LEVEL RECALL COMPARISON BETWEEN YOLO11N AND YOLO11N + CGOA + LSAFF ON OPIXRAY

Class	YOLO11n Recall	Full Recall	Δ Recall
folding knife	0.8985	0.8867	-0.0118
multi-tool knife	0.8795	0.9203	0.0408
scissor	0.9755	0.9794	0.0039
straight knife	0.5660	0.5825	0.0165
utility knife	0.8309	0.8505	0.0196

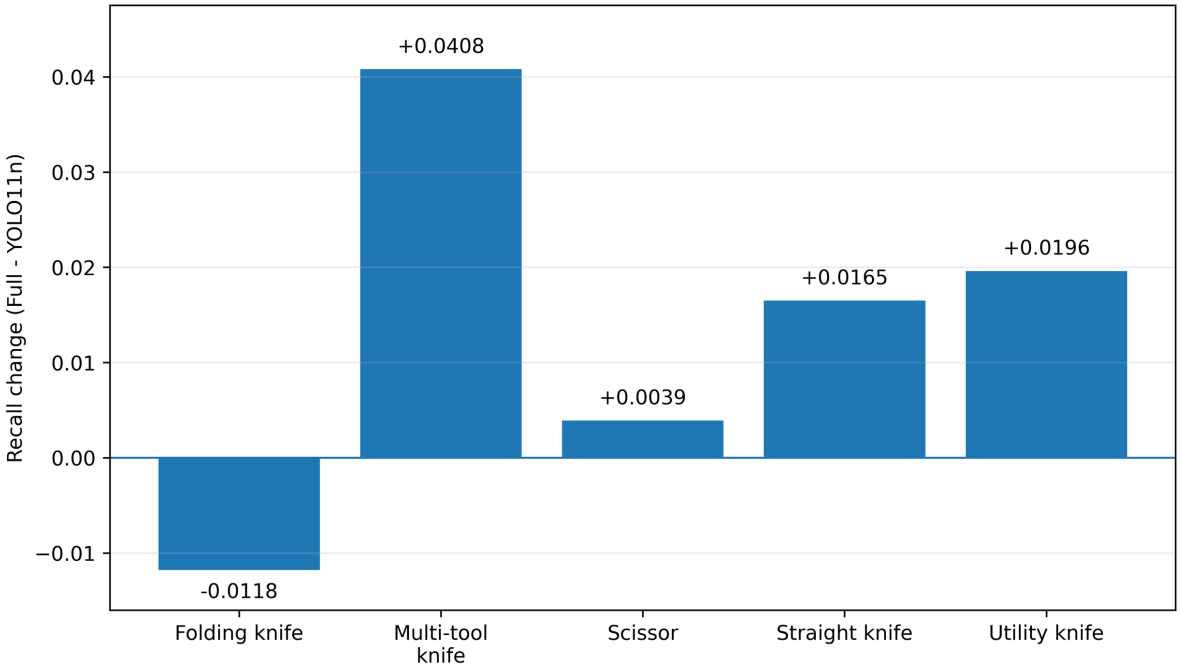

Fig. 6. Class-level recall change of the full model relative to YOLO11n at seed 42. Positive values indicate higher recall for the full model; the folding-knife class shows a small decrease.

TABLE VIII. REPEATED SPLIT-AND-TRAINING SUMMARY OVER SEEDS 42, 2026, AND 3407. VALUES ARE MEAN ± SAMPLE STANDARD DEVIATION; LOWER FN IS BETTER

Model	mAP@0.5	FN	Fixed Recall	Fixed Precision
YOLO11n	0.8814 ± 0.0100	205.3 ± 15.9	0.8846 ± 0.0090	0.8716 ± 0.0214
YOLO11n + CGOA	0.8738 ± 0.0234	206.0 ± 31.8	0.8843 ± 0.0179	**0.8818 ± 0.0135**
YOLO11n + LSAFF	0.8891 ± 0.0102	186.0 ± 15.1	0.8955 ± 0.0085	0.8681 ± 0.0214
YOLO11n + CGOA + LSAFF	**0.8899 ± 0.0114**	**172.7 ± 19.4**	**0.9030 ± 0.0109**	0.8662 ± 0.0209

Fig. 8 places the mean fixed operating points in precision–recall space. The full model occupies the highest-recall position, while CGOA has the highest mean fixed precision but essentially the same mean fixed recall as YOLO11n. LSAFF lies between these outcomes. This view clarifies why the full model is described as recall-oriented rather than uniformly superior.

D. Supplemental Second-Benchmark Evaluation on PIDray

Table X reports the combined Easy, Hard, and Hidden results for the single-seed PIDray experiment. The full model improves standard precision from 0.7832 to 0.7885, standard recall from 0.7498 to 0.7674, mAP@0.5 from 0.7938 to 0.8035, and mAP@0.5:0.95 from 0.6582 to 0.6698. At the fixed operating point, it detects 830 additional ground-truth instances and reduces FN from 10,148 to 9,318, an 8.18% reduction. The gain is accompanied by 409 additional FP, a 4.36% increase, and a small decrease in fixed precision from 0.7726 to 0.7696. The corresponding descriptive yield is 2.03 additional true detections per additional false positive. Fixed recall increases from 0.7584 to 0.7781 and fixed F_2 from 0.7612 to 0.7764. As with OPIXray, this ratio summarizes the observed count change rather than defining a universal screening utility. The result reproduces the recall-oriented

TABLE IX. INDIVIDUAL RESULTS FOR THE THREE SPLIT-AND-TRAINING TRIALS. FIXED R AND FIXED P USE CONFIDENCE 0.25 AND IOU 0.50

Model	Seed	mAP@0.5	FN	ΔFN	Fixed R	ΔR	Fixed P
YOLO11n	42	0.8852	201	–	0.8871	–	0.8758
YOLO11n	2026	0.8701	223	–	0.8747	–	0.8485
YOLO11n	3407	0.8889	192	–	0.8921	–	0.8906
YOLO11n + CGOA	42	0.8467	240	+39	0.8652	-0.0219	0.8661
YOLO11n + CGOA	2026	0.8879	201	-22	0.8871	+0.0124	0.8896
YOLO11n + CGOA	3407	0.8867	177	-15	0.9006	+0.0085	0.8896
YOLO11n + LSAFF	42	0.8927	184	-17	0.8966	+0.0095	0.8622
YOLO11n + LSAFF	2026	0.8776	202	-21	0.8865	+0.0118	0.8502
YOLO11n + LSAFF	3407	0.8971	172	-20	0.9034	+0.0113	0.8918
YOLO11n + CGOA + LSAFF	42	0.8873	163	-38	0.9084	+0.0213	0.8661
YOLO11n + CGOA + LSAFF	2026	0.8801	195	-28	0.8904	+0.0157	0.8453
YOLO11n + CGOA + LSAFF	3407	0.9023	160	-32	0.9101	+0.0180	0.8872

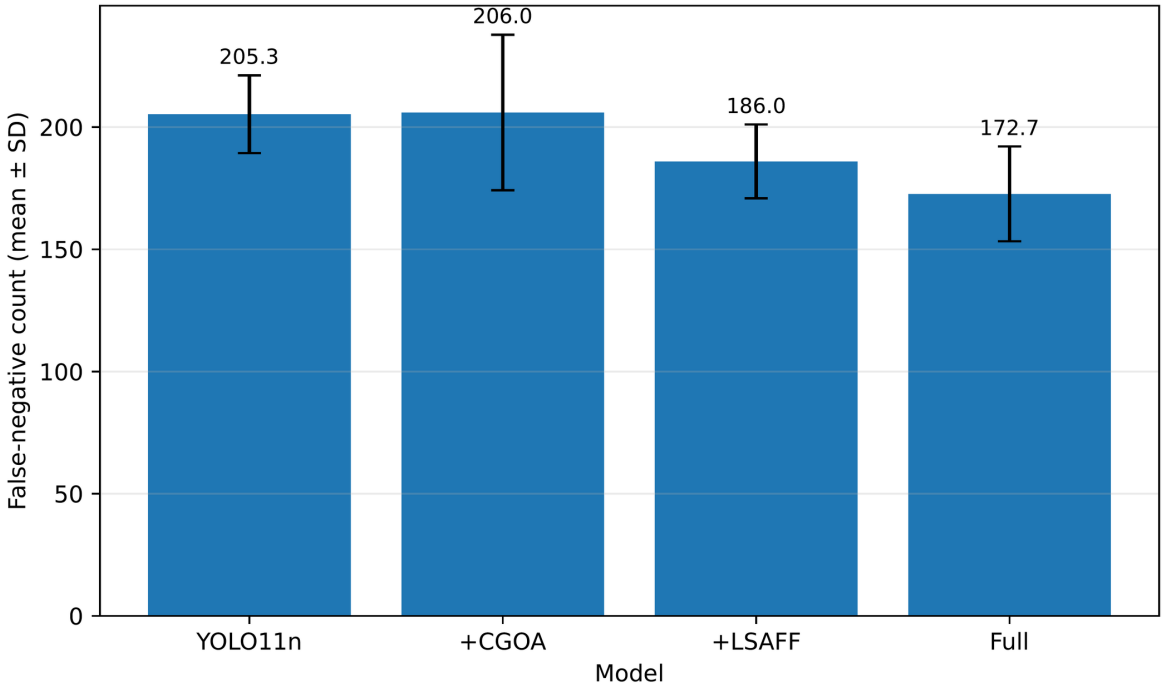

Fig. 7. Mean false-negative count and sample standard deviation over three split-and-training trials, in which both the validation split and training seed change. Lower values are better. The figure summarizes variability and is not a fixed-split significance test.

pattern observed on OPIXray rather than showing a uniform improvement in every error measure.

LSAFF alone already improves the combined PIDray result while keeping fixed precision nearly unchanged (0.7731 versus 0.7726). Adding CGOA within the full model reduces FN by a further 314 relative to LSAFF and gives the best standard recall, mAP, fixed recall, and fixed F_2, although FP increases and fixed precision decreases. This result is consistent with the OPIXray interpretation that LSAFF is the stronger standalone contributor and CGOA is most useful when coupled with multi-scale fusion.

Fig. 9 separates the three official PIDray difficulty subsets. Relative to YOLO11n, the full model raises mAP@0.5 by 0.0075 on Easy, 0.0080 on Hard, and 0.0135 on Hidden. Fixed recall increases by 0.0174, 0.0149, and 0.0245, respectively, while FN decreases by 147, 216, and 467. The largest absolute FN reduction and the largest fixed-recall improvement occur on Hidden, supporting consistent behavior on a second benchmark that includes deliberately concealed items. Because this experiment uses one split and training seed, the subset differences are descriptive and do not establish statistical significance.

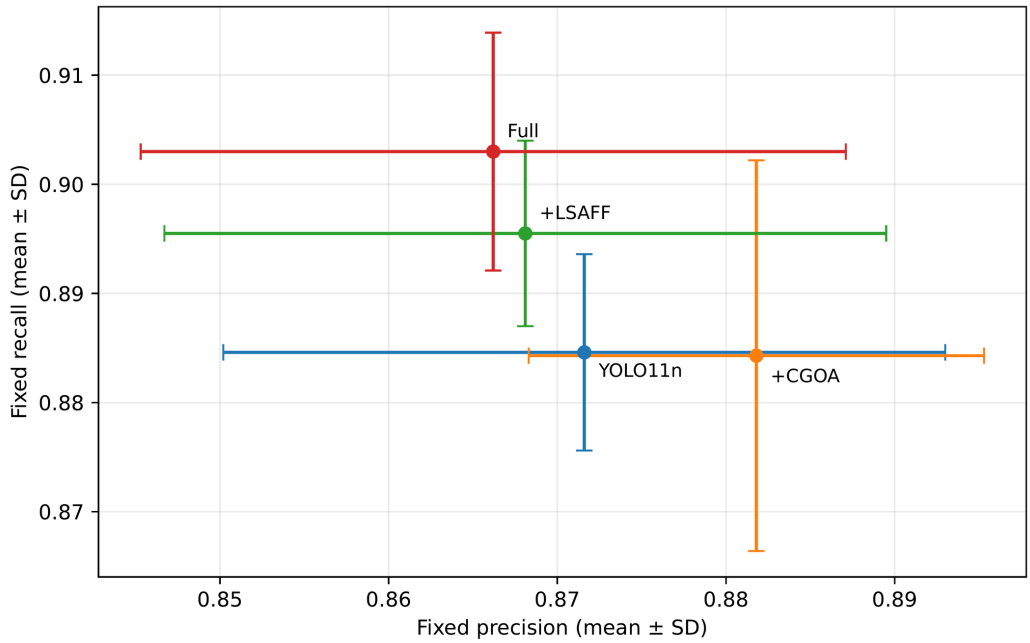

Fig. 8. Mean fixed precision and fixed recall over three split-and-training trials. Horizontal and vertical error bars show sample standard deviations.

TABLE X. SINGLE-SEED SUPPLEMENTAL SECOND-BENCHMARK VALIDATION ON THE COMBINED PIDRAY EASY, HARD, AND HIDDEN TEST SUBSETS. STANDARD P AND R ARE CLASS-AVERAGED VALIDATOR METRICS; FIXED P, FIXED R, AND F_2 ARE MICRO-AVERAGED AT CONFIDENCE 0.25 AND IOU 0.50

Model	P	R	mAP@0.5	mAP@0.5:0.95	TP	FP	FN	Fixed P	Fixed R	F_2
YOLO11n	0.7832	0.7498	0.7938	0.6582	31,852	9,373	10,148	0.7726	0.7584	0.7612
YOLO11n + LSAFF	0.7858	0.7621	0.8012	0.6675	32,368	9,502	9,632	**0.7731**	0.7707	0.7712
XraySafe-YOLO	**0.7885**	**0.7674**	**0.8035**	**0.6698**	**32,682**	9,782	**9,318**	0.7696	**0.7781**	**0.7764**

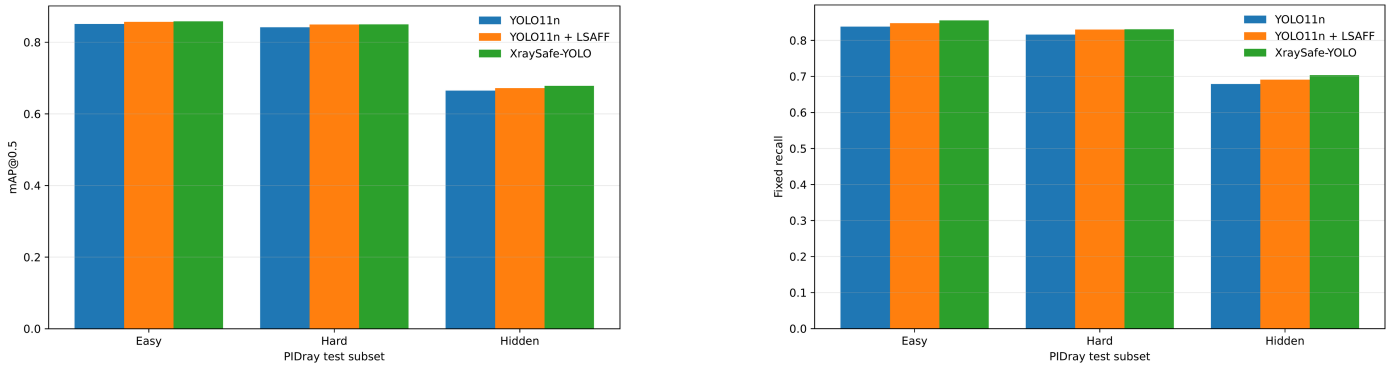

Fig. 9. Single-seed PIDray results across the official Easy, Hard, and Hidden subsets: (a) mAP@0.5 and (b) fixed recall at confidence 0.25 and IoU 0.50. The three subsets contain different numbers of ground-truth boxes; the normalized metrics are therefore more suitable than raw FN counts for cross-subset visual comparison.

E. Confidence Sweep and Operating-Point Interpretation

To test whether the recall advantage is only an artifact of applying the same confidence threshold to differently calibrated models, the saved seed-42 checkpoints were re-evaluated at confidence thresholds 0.10, 0.20, 0.25, 0.30, 0.40, and 0.50. Fig. 10 plots fixed recall against false positives per image for YOLO11n, LSAFF, and the full model. The full model remains above the baseline over most of the measured false-positive range, while LSAFF is intermediate. This post-hoc sweep uses the test set only to assess operating-point fairness; it is not used to choose a recommended deployment threshold. Any operational threshold should be selected on validation data from the target scanner and workload.

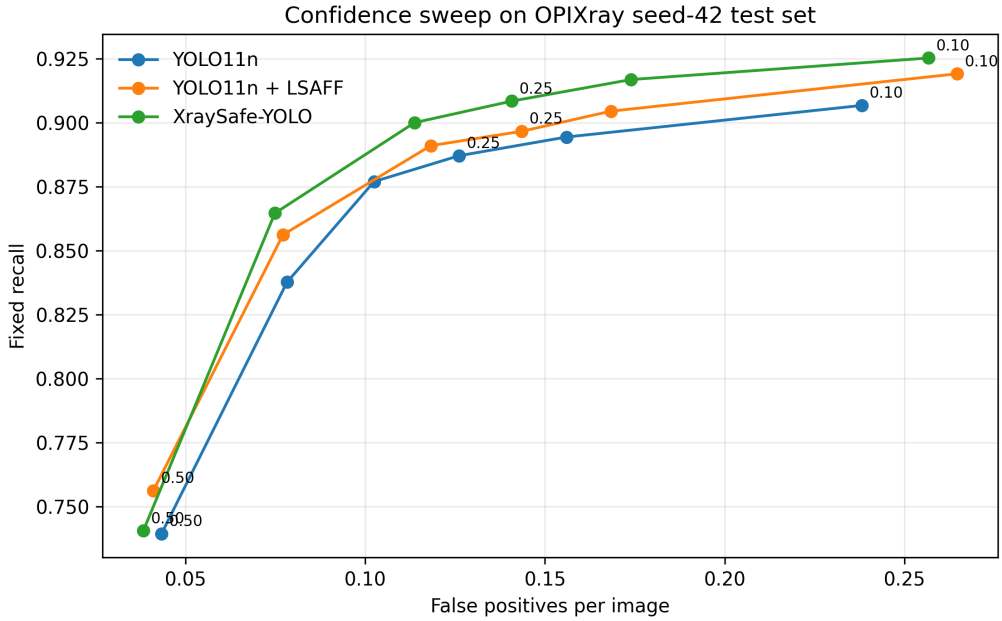

Fig. 10. Seed-42 OPIXray confidence sweep for YOLO11n, YOLO11n + LSAFF, and the full model. Recall is plotted against false positives per image, which avoids assuming that identical confidence thresholds imply equivalent operating conditions. Labels mark selected confidence thresholds.

TABLE XI. SEED-42 OPIXRAY RECALL AT MATCHED FALSE-POSITIVE BUDGETS, OBTAINED BY LINEAR INTERPOLATION BETWEEN ADJACENT MEASURED CONFIDENCE-SWEEP POINTS

Model	150 FP (0.0845 FP/image)	200 FP (0.1126 FP/image)	250 FP (0.1408 FP/image)
YOLO11n	0.8477	0.8813	0.8907
YOLO11n + LSAFF	0.8624	0.8862	0.8960
XraySafe-YOLO	**0.8733**	**0.8990**	**0.9084**

TABLE XII. MODEL COMPLEXITY AT 640-PIXEL INPUT RESOLUTION

Model	Params (M)	GFLOPs	Model Size (MB)
YOLO11n	2.583	6.317	5.216
YOLO11n + CBAM-lite	2.587	6.324	5.231
YOLO11n + CGOA	2.589	6.339	5.238
YOLO11n + LSAFF	2.893	7.227	5.877
YOLO11n + CGOA + LSAFF	2.899	7.249	5.898

For a matched-false-positive view, recall was linearly interpolated between adjacent measured sweep points at common FP budgets of 150, 200, and 250 detections over the 1776-image OPIXray test set. Table XI shows that the full model has the highest recall at all three budgets. At 200 FP, for example, the interpolated recalls are 0.8813 for YOLO11n, 0.8862 for LSAFF, and 0.8990 for the full model. Because these values are interpolated summaries of the measured sweep rather than independently optimized thresholds, they are used only as descriptive matched-operating-point evidence.

The fixed-count comparison at confidence 0.25 and IoU 0.50 remains useful as a common diagnostic point. At this threshold, the combined model reduces FN and increases FP relative to YOLO11n on both OPIXray and PIDray. The OPIXray three-trial trade-off in Fig. 8 indicates that this behavior is not limited to the seed-42 count table: the full model has the highest mean fixed recall and lower mean fixed precision than the baseline. The single-seed PIDray result shows the same direction on a broader category set. The sweep and matched-FP analysis strengthen the interpretation that the architectural change provides recall benefit beyond simply lowering the baseline detector's confidence threshold, while the final operating threshold remains an application-specific validation choice.

F. Model Complexity and Qualitative Examples

Table XII reports parameter count, GFLOPs, and model size at 640-pixel input resolution. The combined model has 2.899 M parameters and 7.249 GFLOPs, about 12.2% more parameters and 14.8% more computation than YOLO11n. Latency and FPS are not compared because they depend strongly on the local hardware and software environment.

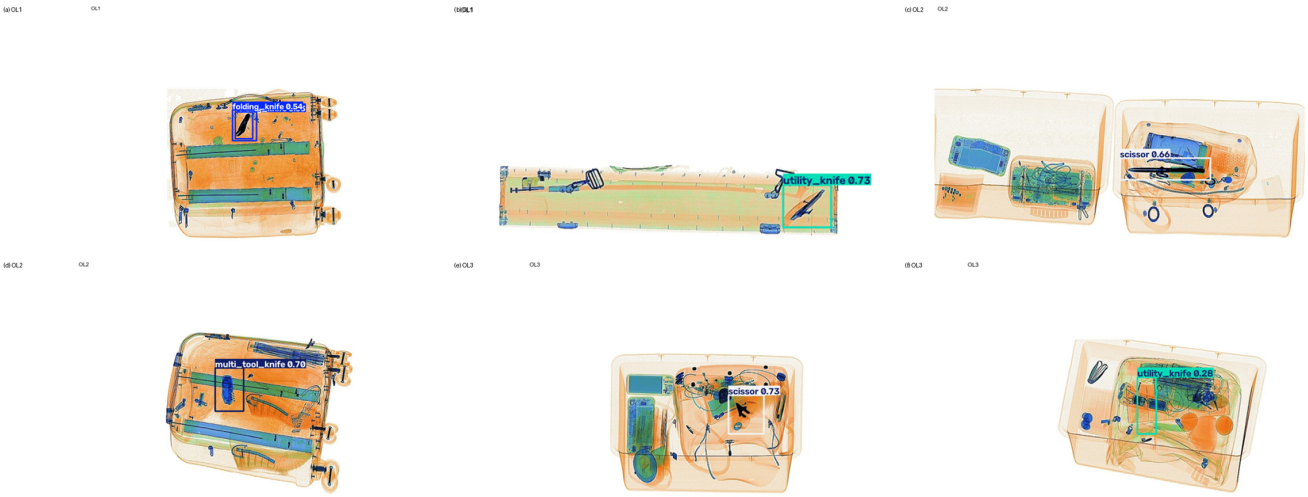

Fig. 11. Representative seed-42 predictions from the combined model: (a,b) OL1, (c,d) OL2, and (e,f) OL3.

Fig. 11 presents six combined-model predictions spanning OL1–OL3. Panels (a) and (b) show compact and elongated cutters whose visible boundaries remain distinguishable from the surrounding baggage structure. Panels (c) and (d) illustrate localization when a prohibited item overlaps dense electronics or elongated metal objects. Panels (e) and (f) are drawn from OL3; the utility-knife prediction in panel (f) has confidence 0.28, close to the fixed-count threshold, and illustrates the narrow margin available in a heavily cluttered scene. The examples show that the model can produce usable localizations at each occlusion level, but they are not a paired baseline comparison. Relative conclusions therefore rely on the complete test-set metrics and error counts rather than on selected images.

VI. Discussion

A. What the Experiments Show

The two modules have different effects. LSAFF is the more stable individual module. Across the three trials, it improves mean mAP@0.5, reduces mean FN, and increases mean fixed recall. This is reasonable for OPIXray because the detector needs both high-resolution details from partly visible blades and wider context from nearby objects. LSAFF lets each detection scale use information from P3, P4, and P5.

CGOA is less stable. Boundary-motivated local reweighting may help a partly visible item, but X-ray baggage also contains many strong edges from wires, frames, and overlapping materials. The CGOA model is below the baseline at seed 42 and has the largest variation across the three trials. Its mean FN is almost the same as YOLO11n. When the CGOA-enhanced P3 and P4 features are fused with P5 by LSAFF, the full model gives a lower mean FN than LSAFF alone. These results suggest that CGOA is useful mainly as a complement to multi-scale fusion, not as a better standalone attention module.

The class and occlusion results also show that the gain is not uniform. Multi-tool and utility knives improve, folding-knife recall decreases slightly, and straight knife remains difficult. The full model has the lowest FN on OL1 and OL3, while LSAFF is best on OL2. The clearest benefit of the full model is therefore fewer missed detections at the selected threshold.

The PIDray result shows a similar pattern on 12 classes. LSAFF improves all reported aggregate metrics and keeps fixed precision close to the baseline. The full model further reduces FN on Easy, Hard, and Hidden, with the largest fixed-recall gain on Hidden. FP also increases, so the PIDray result supports the same recall-oriented trade-off rather than a general improvement in every metric.

B. Relation to Recent X-ray YOLO Research

Recent compact X-ray detectors often combine several improvements and test them on more than one dataset. Examples include channel reduction with BiFPN [15], feature-aggregation redesign with normalized Wasserstein distance [16], state-space blocks evaluated on three datasets [21], contrastive multi-scale learning [22], and sparsity with adaptive distillation [23]. Those studies provide broader evidence on multiple runs, datasets, or inference speed than this study.

XraySafe-YOLO uses repeated OPIXray ablations and a single-seed PIDray second-benchmark test. It keeps the YOLO11n baseline small, separates the proposed modules, and exposes the fixed-threshold TP/FP/FN trade-off on both benchmarks. This is useful because a higher mAP alone does not show how many missed items are recovered at a selected threshold. At the same time, the PIDray result is not a state-of-the-art benchmark study and should not be compared directly with models trained under different splits, schedules, resolutions, or augmentation protocols.

C. Operational Meaning of the FP–FN Trade-off

At confidence 0.25, the seed-42 OPIXray full model finds 38 additional ground-truth objects and produces 26 additional false positives relative to YOLO11n, equivalent to 1.46 recovered objects per added false alarm. Across all three OPIXray trials, it lowers FN and raises fixed recall relative to the corresponding YOLO11n run, while fixed precision remains

slightly lower. PIDray shows the same direction: the full model recovers 830 additional ground-truth instances and produces 409 additional false positives, or 2.03 recovered objects per added false alarm. These ratios only describe the observed counts. A missed dangerous item and an unnecessary review do not have the same operational cost. In a human-in-the-loop screening system, the observed shift may be reasonable when the cost of a missed prohibited item is greater than the cost of secondary inspection. It is not automatically preferable, however. Additional false alarms consume operator time, can slow baggage throughput, and may reduce trust if the workload becomes excessive.

The preferred threshold depends on staffing, scanner type, traffic volume, and the relative cost of missed items and false alarms. The fixed threshold in this study is a common diagnostic point. Before deployment, threshold selection should use data from the target scanner, include calibration and confidence-sweep analysis, and report recall at a matched false-positive rate or operational workload.

D. Efficiency and Practical Use

The full model remains compact, with 2.899 M parameters and 7.249 GFLOPs at an input size of 640 pixels. Its parameter count is 12.2% above YOLO11n and its theoretical computation is 14.8% higher. These results show that the added modules have limited structural overhead. They do not prove real-time speed or hardware efficiency. FLOPs do not replace measured latency, and recent X-ray studies that use deployment-oriented language also report FPS or hardware-specific inference time [21], [23]. Accordingly, the present study uses "compact" for the detector as a whole and uses "lightweight" only for individual low-overhead operations or modules, and when describing related work that adopts that design objective.

The detector is intended to mark candidate regions for an inspector. It is not designed to make an automatic release decision. The operating threshold, escalation rules, and review interface would need to be evaluated together with detector accuracy in an operational study.

E. Limitations and Future Work

The primary repeated-trial evidence remains limited to OPIXray and its five cutter-like categories. PIDray adds a broader 12-class second-benchmark test with official Easy, Hard, and Hidden subsets, but it uses only one validation split and training seed and compares three configurations rather than the complete ablation. It therefore provides useful second-benchmark evidence without establishing robustness across repeated PIDray runs, HiXray, CLCXray, dual-view systems, other scanner manufacturers, cargo images, or operational customs data. Several recent models report results on two or three datasets [15], [21]–[23], so broader cross-domain evaluation remains important.

The repeated evaluation includes only three trials and changes the validation split together with the training seed. The reported standard deviations therefore combine split and optimization variability and are not fixed-split significance estimates. The overlapping error bars in Fig. 7 and 8 should be interpreted accordingly. A stronger design would keep the validation set fixed, repeat every configuration with more seeds, and apply paired bootstrap analysis to saved test predictions.

Other limitations concern experimental coverage. The automatic optimizer policy can couple architecture choice with automatically selected optimizer settings. The generic attention comparison is limited to CBAM-lite, and ASFF or BiFPN were not trained under the same protocol. CGOA alone was not repeated on PIDray. No fixed-split significance test, image-level bootstrap interval, measured latency, direct fusion-baseline training, attention-map analysis, or paired baseline qualitative panel is reported. For this reason, the manuscript does not claim real-time performance. CGOA uses no contour supervision and remains unstable as a standalone module on OPIXray. Very small, low-contrast, heavily overlapped, and visually ambiguous objects also remain difficult.

Future work will prioritize multi-seed second-benchmark validation on additional datasets, fixed-split repeated training, direct fusion baselines, confidence calibration, measured inference speed, and paired visual error analysis. A human-in-the-loop study should then quantify whether the reduction in missed detections justifies the additional secondary-inspection workload.

VII. Conclusions

XraySafe-YOLO combines scale-weighted fusion and contour-motivated attention in a compact YOLO11n detector. On OPIXray, LSAFF is the stronger standalone module, while CGOA is more sensitive to the validation split and training seed. In all three trials, the full model reduces FN and increases fixed recall compared with YOLO11n. It has the lowest mean false-negative count (172.7 ± 19.4) and the highest mean fixed recall (0.9030 ± 0.0109). At seed 42, FN decreases from 201 to 163 and fixed F_2 increases from 0.8848 to 0.8996, while FP increases from 224 to 250. The class and occlusion results show that the improvement is useful but not the same for every case.

The PIDray experiment shows the same main direction on 12 classes. mAP@0.5 increases from 0.7938 to 0.8035, FN decreases from 10,148 to 9,318, and fixed recall increases from 0.7584 to 0.7781. Fixed precision decreases slightly from 0.7726 to 0.7696. The largest fixed-recall gain is on the Hidden subset. Because PIDray is tested with one seed, this result supports the architecture on a second dataset but does not replace repeated second-benchmark validation.

The model should be viewed as a compact recall-oriented option for human-assisted X-ray screening, not as a detector that is better in every metric or ready for direct deployment. The main evidence comes from the fixed-threshold error analysis, repeated OPIXray trials, and the PIDray second-benchmark test. Stronger conclusions would require repeated tests on more datasets and scanners, direct fusion baselines, threshold calibration, and measured inference speed.

Acknowledgment

The authors thank the OPIXray and PIDray maintainers for making the benchmarks available to the research community.

DECLARATIONS

Funding: This research was funded by the Scientific Research Startup Fund of Shanghai Customs College under Grant No. 2315053A2024.

Data availability: The experiments use the public OPIXray and PIDray benchmarks. Individualizing an Agent-Based Flood Evacuation Model from Survey Data

Tatsuki Fukuda
Faculty of Data Science, Shimonoseki City University, Shimonoseki, Japan

***Abstract*—Earlier agent-based models (ABMs) of flood evacuation by the author, first on an abstract grid and later extended to real 3D city-model geography, use a survey of Japanese residents to assign each simulated agent to one of a few discrete behavioral groups; within a group, the evacuation probability P and the neighbor-awareness radius L are, with one narrow exception, fixed at a single value shared by every agent. The same survey contains two individually answered questions – how much a respondent cares about neighbors' evacuation status, and how many neighboring houses' worth of information they want. The first was never used in that prior work, and the second only once, in isolation, on an abstract grid; both are natural candidates for individualizing P and L, respectively. This paper extends the model in four ways: whole respondent records are resampled, preserving the real correlation among a respondent's evacuation threshold, concern level, and preferred radius; the preferred-neighbor count is converted into a metric radius using the actual local building density from real PLATEAU 3D city-model data for Toyohashi City; the persistent Evacuate-Now-Button regime and a direct-observation regime are unified within one model; and a real-geometry video visualization is added. Re-deriving the group distribution from the survey matches the previously published values to within 1.5 percentage points, and the observation regime reproduces the prior "no-system" rate (9.6% vs. ≈9%) as an emergent consequence rather than a calibrated target; an ablation shows that individualizing P alone, under an assumed concern-to-probability mapping, shifts the final evacuation rate by nearly 18 points (79.9% vs. 62.0%). Throughout, the parameters that remain researcher-declared assumptions are distinguished from those derived from data.**

***Keywords*—Agent-based model; flood evacuation; evacuation rate; survey-based simulation; evacuate now button**

I. Introduction

Japan is exposed every year to typhoons and heavy-rain events, and despite the routine issuance of evacuation advisories, the fraction of at-risk residents who actually evacuate remains low. A nationwide survey found that even under a Level 4 alert (nominally an evacuation order), only 16.9% of residents at home evacuated to a location outside their home, and for hydro-meteorological hazards specifically the share taking evacuation action was only 5.7% [1]. In the June 2023 heavy rain event in Toyohashi City, Aichi Prefecture, which serves as the case study of this paper, the recorded evacuation rate was approximately 0.068% [2].

Several factors have been identified as contributing to this persistently low evacuation rate in Japan: many residents do not evacuate despite receiving official information [3]; personality traits such as being "cautious and proactive" rather than "careless and proactive" predict earlier action [4]; prior risk awareness promotes evacuation [5]; and the timing and channel of information delivery measurably affect uptake, as shown for the July 2018 Gifu Prefecture heavy rain [6] and for landslide evacuation [7]. Separately, methodological work has examined how to estimate flood evacuation rates from disaster records [8].

A body of prior work by the author has approached this problem with agent-based modeling (ABM), motivated by the observation that Japanese residents' evacuation decisions are strongly conditioned on whether their neighbors have evacuated [9]. This is consistent with the classic sociological threshold model of collective behavior [10], in which each individual has a personal threshold – the fraction of others who must already have acted before that individual acts – and the population-level dynamics follow from the distribution of thresholds across individuals; large-scale mobile-phone location data show a similarly sharp threshold pattern in real evacuation behavior after earthquakes, with evacuation probability rising sharply once measured seismic intensity crosses a critical level [11]. Building on the "Evacuate Now Button" concept, first proposed in an earlier technical report [12] – a physical button pressed at each household to share residents' evacuation status – prior work [9] used a first ABM prototype, on an abstract (non-geographic) grid, to explore how the number of neighbors whose status is shared affects the resulting evacuation rate. This was substantially extended [13] with real PLATEAU 3D city-model geography, an explicit warning-level schedule (Levels 3/4/5) reproducing a real disaster timeline, and a two-group behavioral model (an alert-only Group I and a neighbor-rate-triggered Group II, further split into five threshold sub-groups) calibrated from the same survey of 1,000 respondents used in [9]. The Evacuate Now Button concept was then implemented [14] as a working IoT prototype and its practical feasibility measured (end-to-end latency, delivery reliability under simultaneous presses, battery life), providing empirical grounding for the assumption – used throughout the ABM line of work, including this paper – that a button-based system can share evacuation status quickly and reliably.

This paper's contribution is to make fuller use of the same underlying survey than these two prior papers [9], [13] did. The later extension [13] uses the survey only to assign discrete threshold groups, applying a single assumed evacuation probability ($P = 0.5$, not itself estimated from the survey) uniformly to every agent; [9]'s earlier prototype instead set separate, survey-derived probabilities for its alert-only and neighbor-threshold groups, but neither prior paper varies P *within* a group by an individual respondent's stated concern, which is

the specific individualization Q7 enables here. Both papers also use, in almost every experiment, a single, population-wide neighbor-awareness parameter L (swept as an experimental condition in [13]; individualized as a per-agent neighbor *count*, but only in one isolated experiment of [9], on an abstract, non-geographic grid). The survey, however, also contains two further single-select questions – one asking how much a respondent cares about neighbors' evacuation status, which neither prior paper uses at all, and one asking how many neighboring houses' worth of information they would want, which the earlier prototype [9] uses only in that one isolated experiment. These two questions are used here to individualize, respectively, the evacuation probability P and the awareness radius L for each simulated agent; resampling whole respondent records (rather than each question's marginal distribution independently) preserves, by construction, the real correlation between an agent's threshold sensitivity, stated concern, and preferred information radius. The "information regime" an agent operates under – a persistent, always-accurate Evacuate-Now-Button-style regime on one hand, and a regime with no such system, in which agents can only directly notice a recent, nearby evacuation, on the other – is further generalized into a single switchable parameter of the same individualized model, rather than two separately implemented mechanisms. Finally, a visualization pipeline is added that renders one stochastic realization of the simulation directly onto real PLATEAU building footprints as a video, with a live numeric summary panel.

Throughout, a careful distinction is drawn between two kinds of improvement over prior work: 1) replacing a previously unfounded or population-wide assumption with a quantity estimated directly from previously unused survey data, and 2) methodological or software-engineering improvements (reproducibility, open implementation, explicit separation of data-derived and assumed parameters) that do not by themselves improve predictive accuracy. Several parameters – the base evacuation probability, the per-evaluation discount rate, and the direct-observation range and recency window – remain researcher-declared assumptions inherited from [13], because the survey contains no question from which they could be estimated, together with the CareScale mapping newly introduced here (Section IV-A); this is reported explicitly rather than presenting the whole model as empirically calibrated.

The remainder of this paper is organized as follows. Section II reviews the three prior papers this work extends and situates the contribution relative to each. Section III describes the survey and the derivation of the group-threshold distribution. Section IV presents the individualization of P and L. Section V describes the two information regimes. Section VI describes the real-geography case study. Section VII gives the simulation algorithm. Section VIII reports experimental results. Section IX discusses the findings, and Section X states limitations, followed by a conclusion in Section XI.

II. Related Work

Beyond the three papers this work directly extends, ABM, a general methodology for simulating heterogeneous individuals with simple behavioral rules [15], has been applied extensively to flood evacuation and related behavior, including social-media and individual influences on evacuation decisions [16], flood-event inhabitant behavior [17], mutual-aid mechanisms in vulnerable communities [18], flash-flood warning response [19], flood-pedestrian interaction dynamics [20], [21], flood-induced displacement forecasting [22], community flood-risk mitigation [23], coastal migration under future flood risk [24], and household adoption of private flood-mitigation measures [25]; see [26] for a broader review of agent-based flood risk models. To the author's knowledge, none of these models individualizes both an evacuation probability and an awareness radius from the same joint survey record, or unifies a persistent-sharing and a direct-observation information regime within one model, as is done here.

A parallel strand models the physical dynamics of pedestrian and crowd evacuation rather than the decision to evacuate: cellular-automaton and continuous crowd models capture movement effects such as turning behavior on clearance time [27], controlled experiments have measured human motion speed in floodwaters [28], and recent reviews survey a decade of progress in agent-based and pedestrian evacuation simulation [29], [30]. The model developed here deliberately abstracts away physical movement – representing only the evacuate-or-stay decision and its timing – so this body of work is complementary to, rather than in competition with, the present approach.

Most closely related is work on social influence in evacuation, since the agents' core mechanism is neighbor-conforming threshold behavior [10]. Imitation of cooperative behavior has been incorporated into pedestrian evacuation models and shown to reshape clearance dynamics [31]. At the individual level, evacuation decisions have been predicted from pre-disaster web-search behavior [32] and from large-scale mobile-phone location traces [11], indicating that heterogeneity in individual evacuation propensity is both real and, to a degree, measurable – which is precisely the heterogeneity that the survey-based individualization of P and L presented here aims to capture.

An initial ABM prototype based on the Evacuate Now Button concept, first proposed in [12], was presented in earlier work [9], which framed the evacuate-or-stay decision using game theory [33] and grounded the neighbor-conforming behavior in bandwagon-effect theory [34]. Agents were placed at random screen coordinates (no real geography). A survey of 1,000 respondents asked, among other things, which of several conditions – official alert levels near home or in a neighboring town, or five neighbor-evacuation-rate levels (10/30/50/80/almost-all%), or "I don't care about others" – would make the respondent evacuate; this is the same question used in Section III. Ninety percent of agents were assigned to a neighbor-rate-driven behavior and 10% to an alert-only behavior; both groups' probabilities were set directly from this same survey question rather than assumed – the alert-only group's from the official-alert responses (18.6% at Level 3, 79.6% at Level 4), and the neighbor-rate-driven group's from the corresponding neighbor-rate responses (e.g., 50% of respondents said they would evacuate once half of their neighbors had). A separate survey question asked how many neighboring houses' status a respondent would want to know (10/25/50/100/200); in one experimental condition, this distribution (46%/29%/15%/7%/3%, respectively) was used to assign each agent an individual *count* of neighbors to observe,

though on the abstract, non-geographic grid this count carried no notion of physical distance, and it was tested only as one alternative to several fixed values (0, 10, 20, 50, 100, 200), not integrated with any other individual-level variation. (This split is the raw Q11 marginal reported in Section III – 46.0/29.1/15.0/6.6/3.3% – rounded to integer percentages, confirming that the earlier prototype [9] drew on the same question.) This question is built on directly in Section IV-B, where it is converted into a metric radius using real building density and combined, via joint resampling (Section IV-C), with the same agent's threshold group and stated concern level.

A subsequent extension replaced the abstract grid with real PLATEAU 3D city-model geography (Nobeoka City and Toyohashi City) and a real warning-level timeline reproducing an actual disaster [13]. Agents were split into an alert-only Group I (≈8% of respondents) and a neighbor-rate-driven Group II, itself split into five threshold sub-groups (10/30/50/80/100%, in proportions 20%/31%/32%/12%/5%, Table I therein). Every agent used the same fixed evacuation probability ($P = 0.5$) and the same awareness radius L within a given experiment, with L swept from 20 to 100 m across experiments to study its effect on the final evacuation rate, and a separate, simplified "without system" baseline (observing only evacuations within 40 m and the last 5 minutes, with no threshold-group structure) was implemented once for comparison. Keeping P and L population-wide fit that design's aim – a controlled sweep of one macro-level parameter, not a search for individual-level heterogeneity – and neither the radius conversion of Eq. (2) nor the joint-resampling of Section IV-C, both introduced here, had yet been applied there to turn Q11 and Q7 into individualized, mutually consistent parameters. In the present paper, the Group I/II(a–e) proportions are reproduced independently from the raw survey data (Section III); both P and L are individualized per agent instead of using one shared value per experiment (Section IV); and the "without system" baseline is re-implemented as one setting of a single, unified information-regime parameter that uses the same per-agent threshold groups as the main model (Section V), rather than as a separate, simplified mechanism.

A companion hardware study implemented the Evacuate Now Button as a working prototype (ESP-WROOM-02 plus a cloud pipeline) and measured end-to-end latency (median 1.9 s, 2.3 s under eight near-simultaneous presses), delivery reliability (zero losses in 200 simultaneous presses, 95% upper bound on loss rate 1.5%), and battery life (>30 months under several usage scenarios) [14]. That study does not modify the simulation model, but its results directly support the *button* regime of Section V: the regime's core assumption – that a button press becomes known, essentially instantaneously and reliably, to a shared aggregation service – is technically achievable, not merely theoretical.

III. Survey and the Group-Threshold Distribution

The survey (Lancers online panel, $n = 1000$, ages spanning teens to 80s) is the same questionnaire referenced in [9], [13]. This paper uses three of its single- or multi-select items:

- **Q6** (multi-select checkbox): "If the following situation occurred while you were at home during heavy rain, would you evacuate to a shelter? Select all that you think would make you evacuate." Eleven options mix five official-alert conditions (not used here) with five neighbor-evacuation-rate levels (10/30/50/80%, almost all) and an "I don't care about others" option.

- **Q7** (single-select): "When deciding whether to evacuate during heavy rain, do you care whether the houses around yours have evacuated?" – *cares* (501), *cares a little* (420), *doesn't care at all* (79).

- **Q11** (single-select): "If you were to refer to how many neighboring houses have evacuated, how many would you want data for?" – 10 (460), 25 (291), 50 (150), 100 (66), 200-or-more (33).

A. Group Classification Rule

Because Q6 allows multiple selections, a rule is needed that maps a respondent's checked options to a single effective threshold. A respondent is classified as Group I if they checked "I don't care about others" and none of the five numeric levels. If they checked at least one numeric level, the *lowest* checked level is taken as their effective threshold (Group II(a–e)): checking a higher level is consistent with also being willing to evacuate at a lower one, so the minimum checked level is the most informative single estimate of the respondent's true trigger point. Respondents who checked neither a numeric level nor "I don't care" (i.e., who only responded to the alert-based options, or left the relevant options blank) provide no information about a neighbor-rate threshold and are excluded from the distribution.

B. Independent Reproduction of a Prior Group-Threshold Distribution

Applying this rule to the raw data yields the distribution in Table I. Of 1,000 respondents, 758 (75.8%) are classifiable; the remaining 242 (24.2%) are excluded as described above. Table I of [13] reports Group I ≈8%, and, within Group II, sub-group proportions of 20%, 31%, 32%, 12%, and 5% for the 10%, 30%, 50%, 80%, and 100% thresholds – but does not describe how these figures were derived from the raw multi-select responses. The classification rule was not fit to these published numbers; the rule above was fixed on the multi-select data itself, independent of the target values. Computed on the same basis as [13] (Group I as a share of all classified respondents, and the Group II sub-groups as shares within Group II), the resulting distribution matches [13]'s Table I to within 1.5 percentage points (the largest single deviation is Group I, 9.5% vs. ≈8%; every Group II sub-group agrees to within 0.6 points). This agreement is reported as an independent check that the (fully specified, reproducible) rule used here is likely to recover the procedure used in [13], which was not documented there, rather than as a claim of numerical novelty. The 24.2% of respondents who provide no usable answer to the neighbor-rate item are not discussed in [13]; their exclusion, rather than assignment to Group I, is treated as an explicit, open modeling choice (Section X).

TABLE I. GROUP-THRESHOLD DISTRIBUTION DERIVED INDEPENDENTLY FROM THE RAW SURVEY DATA (n=758; GROUP II ROWS: n=686), COMPARED WITH [13]'S TABLE I. RAW COUNTS IN PARENTHESES

Group	Threshold	This work	[13]
Group I ("don't care")	—	9.5% (72)	≈8%
Group II(a)	10%	20.6% (141)	20%
Group II(b)	30%	30.5% (209)	31%
Group II(c)	50%	31.6% (217)	32%
Group II(d)	80%	12.0% (82)	12%
Group II(e)	almost all (100%)	5.4% (37)	5%

IV. INDIVIDUALIZING EVACUATION PROBABILITY AND AWARENESS RANGE

A. Evacuation Probability P via Q7

In [13], every agent uses the same evacuation probability P=0.5 at every eligible evaluation. P is instead scaled per agent, for Group II agents only, using that agent's bootstrapped answer to Q7:

$$P_{\text{agent}} = P_{\text{base}} \times \text{CareScale}(\text{Q7 answer}) \tag{1}$$

where, CareScale $\in \{1.0,\ 0.6,\ 0.25\}$ for *cares*, *cares a little*, and *doesn't care at all*, respectively. Group I agents are unaffected, since Q7 asks specifically about neighbor status, which Group I agents do not use. The three scale values in Eq. (1) are a declared modeling assumption, not a measured quantity: no survey question asks directly how likely a respondent is to act on their stated intention, so converting an ordinal concern level into a probability multiplier necessarily involves a researcher-chosen mapping, anchored at 1.0 for the "cares" response. What is new is the use of a previously unused survey item to introduce principled, data-linked individual variation in P in place of a single population-wide constant; the specific numeric mapping is a target for future calibration (Section X).

B. Awareness Radius L via Q11 and Real Building Density

The later extension [13] sweeps a single radius $L \in \{20, 40, 60, 80, 100\}$ m, shared by every agent, across separate experiments. The earlier prototype [9] individualizes a neighbor *count* per agent from the same Q11-style question, but on an abstract grid with no notion of metric distance. L is individualized here by converting each agent's bootstrapped Q11 answer (a preferred house count N_i) into a metric radius L_i using the real local building density ρ (households per m^2) of the loaded case-study dataset, assuming households are uniformly distributed at that density:

$$L_i = \sqrt{\frac{N_i}{\pi\rho}}. \tag{2}$$

For the Toyohashi case study of Section VI ($\rho \approx 1{,}752$ households/km^2), Eq. (2) maps the five Q11 answers to radii of 42.6, 67.4, 95.3, 134.8, and 190.6 m, respectively – comparable in magnitude to, but individually variable around, the single fixed values (20–100 m) swept in [13]. Table II gives the resulting per-agent radius distribution over the bootstrap pool: it is strongly weighted toward the two smallest radii (72.7% of the 758-respondent bootstrap pool at ≤67 m; median 67.4 m, mean ≈71 m), which is why the individualized-button result (62.0%) falls between the fixed L=60 m and L=80 m results (Section VIII-B).

TABLE II. PER-AGENT AWARENESS RADIUS INDUCED BY Q11 (EQ. (2)) OVER THE BOOTSTRAP POOL OF 758 CLASSIFIABLE RESPONDENTS

Q11 answer (houses)	Radius L_i [m]	Share of agents
10	42.6	41.7%
25	67.4	31.0%
50	95.3	16.4%
100	134.8	7.3%
200	190.6	3.7%

C. Joint Bootstrapping of Q6, Q7, and Q11

All three questions above are recorded for the same 758 respondents classifiable on Q6 (Q7 and Q11 are mandatory single-select fields answered by all 1,000 respondents). Rather than sampling each agent's group, care level, and preferred house count from three independent marginal distributions, whole respondent rows are resampled with replacement, so that whatever correlation exists in the real data among threshold sensitivity, stated concern, and preferred information depth is carried into the simulated population. Neither [9] nor [13] resamples joint respondent profiles in this way; both treat group assignment, P, and L as independent parameters (or population-wide constants).

V. INFORMATION REGIMES: PERSISTENT SHARING VS. DIRECT OBSERVATION

A Group II(a–e) agent becomes eligible to evacuate once "the evacuation rate of surrounding households" reaches its personal threshold, but what that phrase means depends on whether a button-style sharing system exists.

Let $\mathcal{N}_i = \{j \neq i : d_{ij} \leq L_i\}$ be the set of other households within agent i's radius, where d_{ij} is the metric distance between households. In both regimes below, a rate is defined as 0 for an agent whose radius contains no other household ($|\mathcal{N}_i| = 0$), avoiding division by zero; such a Group II agent then never becomes eligible (Group I is unaffected, since it never consults neighbor information – Section IV). This is rare under the individualized radii of Eq. (2) and the observation regime's fixed L_{obs}=40 m (at most 0.4%, Section VI), but reaches about 4% at the smallest fixed-L condition tested (L=20 m, Section VIII-A).

1) Button regime: As in [13], a management center aggregates every button press, so at every evaluation an agent knows the true, persistent ("stock") evacuation rate among other households within its radius L_i (Section IV-B):

$$r_i^{\text{stock}}(t) = 100 \times \frac{\left|\{j \in \mathcal{N}_i : \text{evac}_j(t)\}\right|}{|\mathcal{N}_i|}, \tag{3}$$

where, $\text{evac}_j(t)$ indicates that j has evacuated by time t. This is the regime whose real-world feasibility is supported by the latency and reliability measurements of [14].

2) Observation regime: With no sharing system, an agent can only directly notice a neighbor's evacuation while it is happening – e.g., seeing them leave through a window – within a limited range and only if the agent happens to check during that narrow window. This is modeled as follows: at every T_1 check, the agent computes a recent ("flow") rate over a fixed range L_{obs} (so $\mathcal{N}_i^{\text{obs}} = \{j \neq i : d_{ij} \leq L_{\text{obs}}\}$),

$$r_i^{\text{flow}}(t) = 100 \times \frac{\left|\{j \in \mathcal{N}_i^{\text{obs}} : t - W \leq \text{evac\_time}_j \leq t\}\right|}{|\mathcal{N}_i^{\text{obs}}|}, \tag{4}$$

where, evac_time_j is the time at which j evacuated, and compares this recent rate (rather than the persistent stock rate of the button regime) against the same Q6-derived personal threshold. Because r^{flow} counts only evacuations in the trailing W-minute window it is almost always far smaller than r^{stock}, which is the mechanism behind the two regimes' very different outcomes (Section VIII).

Following [13]'s "without system" baseline, L_{obs} is set to 40 m and W to 5 min; as with P_{base} and the discount rate α (Section VII), these two values are not estimable from the survey and are adopted, as declared assumptions, from that prior baseline rather than derived from data. Because L_{obs} is specifically about *direct observation range* rather than *preferred aggregated-information depth*, the Q11-derived individualized radius is not reused here; Q11 presupposes a sharing system, which is precisely what the observation regime lacks.

Group I agents are unaffected by the choice of regime, since by construction they decide "on their own," independent of neighbor information, in both cases.

VI. Case Study: Real Building Geometry and a Real Warning Timeline

The same case-study city as [13], Toyohashi City, Aichi Prefecture, is used here for two reasons: it lets the present results be read alongside the prior paper's, and its June 2023 heavy-rain event provides real Warning Level 3/4/5 issuance times (06:40, 14:40, and 16:30 on June 2, 2023, respectively [2], [13]) that are reused as the simulation's warning schedule, rather than an arbitrary synthetic timeline.

Building positions are obtained directly from Project PLATEAU's public FY2023 CityGML package for Toyohashi [35], distributed under CC-BY 4.0. Only the needed building-model mesh tiles (≈1 km × 1 km JIS X0410 tertiary mesh cells) are fetched via HTTP range requests against the remote ZIP's central directory, avoiding the full ≈850 MB city-wide archive. Of the city's 288 such tiles, the one with the largest residential building count is used, mesh 52371229 (centered near 34.77°N, 137.37°E, in central Toyohashi), which contains 1,856 residential buildings (`bldg:usage` codes 411/412/413/414/415, i.e. detached houses, apartment buildings, and mixed-use residential buildings) within a bounding box of approximately 1.06 km^2, giving a local density $\rho \approx 1{,}752$ households/km^2. Each building's centroid and footprint (LOD0 roof-edge geometry, with a small placeholder square for the minority lacking it) are projected to local metric coordinates via an equirectangular approximation, adequate at this sub-10 km scale. One agent is instantiated per residential building, following the same convention as [13]; each building – including apartment and mixed-use buildings that may house multiple households – is therefore treated as a single household for the purposes of ρ and Eq. (2). Computed directly from this building layout, the fraction of households with zero neighbors within range is at most 0.4% for the individualized Q11-derived radii of Table II (minimum 42.6 m) and for the observation regime's fixed L_{obs}=40 m.

VII. Simulator

The simulator is implemented in Python (NumPy/pandas for the model; lxml/Shapely for geometry parsing), in contrast to the Unity/C# implementation of [13]. Agents are represented as parallel NumPy arrays rather than individual objects, since every per-tick operation is naturally vectorized across all agents due for evaluation at that tick.

1) Timing: As in [13], each agent re-evaluates whether to evacuate every $T_1 \sim U(7.5, 22.5)$ min (15 min ±50%), where $U(a, b)$ denotes the uniform distribution on the interval $[a, b]$, after an initial random delay $T_2 \sim U(15, 45)$ min (30 min ±50%) from the start of the simulation. The simulation clock advances in discrete steps of $\Delta t = 1$ min, beginning at Warning Level 3 (t=0) and ending at Level 5 (t=T_{end}, i.e. 590 min later). Level 4's issuance time (Table III) is shown on the temporal figures for reference only; it does not itself alter agent behavior in Algorithm 1.

2) Decision rule: At each eligible evaluation, a Group I agent is always eligible once the simulation has started; a Group II(a–e) agent is eligible only if the neighbor rate (Section V) meets or exceeds its personal threshold. An eligible agent evacuates with probability P_{agent} (Eq. (1)); if it does not, its probability is discounted in place for its next eligible evaluation, $P_{\text{agent}} \leftarrow \alpha P_{\text{agent}}$ (the multiplicative discount of [13], Eq. (1)), with α=0.8. Both P_{base}=0.5 and α=0.8 are carried over unchanged from [13] as declared assumptions, since the survey contains no question from which either could be estimated.

3) Neighbor-rate computation: At each tick, for every agent due for evaluation, pairwise distances to all other agents are computed and thresholded at that agent's own radius (individualized, Eq. (2), in the button regime; fixed at L_{obs} in the observation regime) to obtain the relevant neighbor set, from which the persistent or recent evacuation rate is computed as described in Section V. Algorithm 1 summarizes one stochastic run.

Table III consolidates every model parameter together with its value and its provenance. This is deliberate: a recurring theme of this paper is that only some of the model is estimated from data, and the table makes the boundary explicit at a glance. Two quantities – the Group distribution and the per-agent radius – are estimated directly from survey questions Q6 and Q11, respectively; Q7 supplies each agent's concern level, which is then converted into a per-agent probability multiplier via the assumed CareScale mapping (Eq. (1)); the local building density and the warning-issuance times come from real PLATEAU and disaster-record data; and the remaining five (P_{base}, α, the CareScale mapping, L_{obs}, W) are declared assumptions – four carried over unchanged from [13], and the CareScale mapping newly introduced in this paper – none of

TABLE III. MODEL PARAMETERS AND PROVENANCE. "SURVEY" = FROM THE QUESTIONNAIRE; "REAL DATA" = PLATEAU OR DISASTER RECORDS; "ASSUMED" = RESEARCHER-DECLARED; [13] = TIMING PARAMETERS UNCHANGED FROM THAT PAPER

Symbol	Meaning	Value	Provenance
Group dist.	Group I / II(a–e) shares	Table I	Survey (Q6)
CareScale	concern $\rightarrow P$ multiplier	$\{1.0, 0.6, 0.25\}$	Assumed
P_{base}	base evac. probability	0.5	Assumed
α	per-eval. discount	0.8	Assumed
T_1	re-evaluation interval	15 min $\pm$50%	[13]
T_2	initial delay	30 min $\pm$50%	[13]
L	awareness radius (button)	per agent, Eq. (2)	Survey (Q11)
ρ	local building density	1,752 /km^2	Real data
L_{obs}	observation range	40 m	Assumed
W	observation window	5 min	Assumed
L3/L4/L5	warning-issuance times	06:40/14:40/16:30	Real data

Algorithm 1 One stochastic run of the ABM (main individualized-button and observation regimes; the fixed-L experiments of Section VIII-A replace line 2's radius with a constant L shared by all agents).

1: **init:** bootstrap each agent i a survey record (g_i, c_i, N_i) (g_i: Q6 group, c_i: Q7 concern, N_i: Q11 house count)
2: $\text{thr}_i \leftarrow \text{threshold}(g_i)$; $L_i \leftarrow \sqrt{N_i/(\pi\rho)}$ [button] **or** L_{obs} [obs.]
3: $P_i \leftarrow P_{\text{base}} \cdot \text{CareScale}(c_i)$ if $g_i \in$ II else P_{base}
4: $\text{evac}_i \leftarrow$ FALSE; $\tau_i \leftarrow \text{draw}\, T_2$
5: **for** $t = 0, \Delta t, \ldots, T_{\text{end}}$ **do**
6: $D \leftarrow \{i : \neg\,\text{evac}_i \wedge \tau_i \le t\}$ ▷ agents due
7: **for** $i \in D$ **do**
8: $r_i \leftarrow$ neighbor rate within L_i (stock [button] / last-W flow [obs.])
9: **if** $g_i \in$ I **or** $r_i \ge \text{thr}_i$ **then**
10: **if** $\text{rand}() < P_i$ **then**
11: $\text{evac}_i \leftarrow$ TRUE; record time t
12: **else** $P_i \leftarrow \alpha\, P_i$ ▷ decline $\Rightarrow$ discount
13: **end if**
14: **end if**
15: **if** $\neg\,\text{evac}_i$ **then** $\tau_i \leftarrow t + \text{draw}\, T_1$
16: **end if** ▷ re-check later
17: **end for**
18: **end for**

which the survey can constrain directly; the timing parameters T_1 and T_2 are likewise inherited unchanged from [13].

VIII. EXPERIMENTS AND RESULTS

Unless otherwise noted, results are the mean $\pm$ one standard deviation of the final (Level 5) evacuation rate over 50 independent Monte Carlo replications, all on the Toyohashi case study of Section VI. All conditions and their exact figures are produced by a single reproducible experiment pipeline, so that every number below can be regenerated directly from the underlying data.

A. Effect of a Fixed, Population-Wide L (Button Regime)

Reproducing [13]'s experimental design of sweeping a single radius shared by every agent (with P individualized from Q7 via Eq. (1), as in all button conditions except the flat-P ablation of Section VIII-C), using the same five points $L \in \{20, 40, 60, 80, 100\}$ m, yields final evacuation rates of $32.0\% \pm 2.8$, $48.6\% \pm 5.0$, $58.9\% \pm 6.4$, $65.7\% \pm 7.5$, and $70.3\% \pm 6.3$, respectively – confirming, in this implementation, the same qualitative relationship reported in [13]: a larger awareness radius yields a higher final evacuation rate. A larger radius gives higher-threshold Group II agents a bigger, more stable neighbor pool, and avoids leaving the 4% of Group II agents with no neighbor at L=20 m permanently ineligible (Section V) – though with diminishing returns once the pool is large enough for these effects to saturate. This reproduces only [13]'s radius-sweep design, not its treatment of P: [13] held P fixed at 0.5 for every agent, whereas P here remains individualized via Q7, so the absolute rates above are not directly comparable to [13]'s own figures.

B. Individualized L and P (Button Regime)

With L individualized per agent from Q11 (Eq. (2)) and P individualized per agent from Q7 (Eq. (1)), the final evacuation rate is $62.0\% \pm 7.9$, between the fixed-L=60 m and L=80 m results (58.9% and 65.7%) and slightly closer to the former, consistent with the Q11-induced radius distribution of Table II (median 67.4 m, mean $\approx$71 m).

C. Ablation: The Effect of Individualizing P

To isolate how much of this result is attributable to individualizing P specifically (as opposed to L), the individualized-L condition was re-run with the Q7 scaling of Eq. (1) switched off (every agent uses the flat P_{base}=0.5 regardless of its Q7 answer, while L remains individualized from Q11). This *flat-P* ablation yields $79.9\% \pm 4.8$ – almost 18 percentage points higher than the 62.0% obtained with Q7-scaled P. This gap is expected given Eq. (1)'s CareScale values: only 50.1% of all 1,000 respondents on Q7 (the *cares* answer) keep the full P_{base}, while 42.0% (*cares a little*) and 7.9% (*doesn't care at all*) are scaled down to 0.6 and 0.25 of it, respectively. These shares are of the full Q7 sample; CareScale itself is applied only to the Group II agents within the 758-respondent bootstrap pool (Sections IV-A and IV-C). Individualizing P via Q7 therefore mechanically lowers the population-average evacuation probability relative to the flat-P=0.5 assumption of [13]. This ablation is reported, rather than only the individualized result, because it shows that Q7 individualization is not a second-order refinement on top of L individualization: in this case study, it changes the final evacuation rate by more than any single step of the L sweep in Section VIII-A.

D. Information Regime: Button vs. Observation

With the observation regime at [13]'s baseline parameters (L_{obs}=40 m, W=5 min), the final evacuation rate is $9.6\% \pm 0.7$, reaching 90% of this value by 89 min (Table VI) and rising only slightly thereafter. This closely matches the $\approx$9% "without system" final rate reported in [13] for both of its case-study cities, even though the observation regime here is implemented as one setting of the same individualized, survey-derived model used for the button regime, rather than as a separately calibrated mechanism. The result is intuitive in hindsight: because the observation regime only ever reveals a small, recent, "flow" rate rather than a persistent, cumulative one, even the low-threshold Group II sub-groups rarely become eligible (Section VIII-F), so the final rate is dominated

almost entirely by Group I's alert-only evacuations (9.5% of the population per Table I), closely tracking the observed 9.6%. Because Group I agents are unaffected by CareScale (Section IV-A), this comparison with [13] is not subject to the caveat on absolute rates noted in Section VIII-A. Fig. 1 plots a representative subset of conditions together (the full L sweep is in Table V).

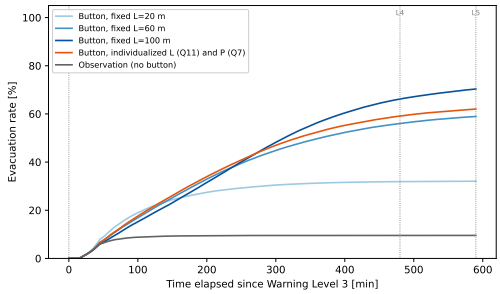

Fig. 1. Evacuation rate over time for representative conditions – fixed radii $L \in \{20, 60, 100\}$ m, individualized L and P, and the observation regime (L_{obs}=40 m, W=5 min) – on the Toyohashi case study. Each curve is the mean of 50 Monte Carlo replications; vertical dotted lines mark Warning Levels 3, 4, and 5.

E. Sensitivity of the Observation Regime to L_{obs} and W

Because L_{obs} and W are declared assumptions rather than survey-derived quantities (Section V), each was swept one-at-a-time around [13]'s baseline (Table IV). Two patterns emerge. First, the final rate is relatively insensitive to both parameters compared to the button regime's sensitivity to L (Section VIII-A): even at the extremes tested, the observation regime stays within roughly 2 percentage points of its 9.6% baseline, versus a 38-point range for button $L \in \{20, \ldots, 100\}$ m. Second, and more surprising, *larger* L_{obs} is associated with a slightly *lower* final rate (10.2% at 20 m vs. 9.1% at 60 m) – the opposite direction from the button regime, where larger L raises the rate. This is a consequence of the observation regime's rate being a *flow* rate (recent evacuations divided by all neighbors in range) rather than a *stock* rate: a single nearby evacuation is a larger fraction of a smaller neighbor pool, so a small L_{obs} makes it mechanically easier for a low-threshold Group II agent to observe an apparent rate at or above 10% from just one or two witnessed departures, even though the same event would barely move the rate computed over a larger pool. Larger W, by contrast, behaves as expected (more time in which to witness an evacuation raises the rate: 9.6% at 5 min rising to 11.4% at 15 min).

TABLE IV. Observation-Regime Sensitivity to Range L_{obs} and Recency Window W (One-at-a-Time Around [13]'s Baseline, in Bold), n=50

Condition	Final evacuation rate
L_{obs}=20 m, W=5 min	10.2% ± 0.6
L_{obs}=40 m, W=5 min	9.6% ± 0.7
L_{obs}=60 m, W=5 min	9.1% ± 0.6
L_{obs}=40 m, W=10 min	10.3% ± 0.8
L_{obs}=40 m, W=15 min	11.4% ± 0.9

Table V summarizes the main conditions (excluding the sensitivity sweep of Table IV).

TABLE V. Final (Level 5) Evacuation Rate by Condition, Mean ± SD Over 50 Replications. All Button Rows Use Q7-Individualized P (Eq. (1)) Except the Flat-P Ablation

Condition	Final evacuation rate
Button, fixed L=20 m	32.0% ± 2.8
Button, fixed L=40 m	48.6% ± 5.0
Button, fixed L=60 m	58.9% ± 6.4
Button, fixed L=80 m	65.7% ± 7.5
Button, fixed L=100 m	70.3% ± 6.3
Button, individualized L (Q11) and P (Q7)	62.0% ± 7.9
Button, individualized L, flat P (ablation)	79.9% ± 4.8
Observation (L_{obs}=40 m, W=5 min)	9.6% ± 0.7

F. Temporal Dynamics and Per-Group Contribution

The final rates above summarize only the endpoint; the dynamics that produce them are themselves informative. Table VI reports, for each main condition, the time to reach several absolute evacuation levels and the time to reach 90% of the condition's own final rate (a settling time). Two observations stand out. First, the early phase is remarkably similar across all button conditions: every one crosses 10% at 55–70 min, essentially independent of L, because the first evacuations are dominated by the low-threshold agents (Group I and Group II(a)) that a small radius already suffices to trigger. Every condition but the flat-P ablation also crosses 25% at 138–162 min; the flat-P ablation reaches 25% markedly earlier (115 min) because removing the CareScale discount raises the per-evaluation evacuation probability of the Group II agents who answered *cares a little* or *doesn't care at all* (Section VIII-C), accelerating the cascade once it is under way. The remaining conditions diverge only later, once sustaining the cascade to the higher-threshold agents requires the larger neighbor pools that only a larger L provides. Second, the observation regime settles fastest of all (90% of its final rate by 89 min) precisely because it never engages the neighbor-triggered cascade at all: it plateaus early at the Group I level and then rises only slowly.

TABLE VI. Time (Minutes Since Level 3) to Reach Absolute Evacuation Levels, and to Reach 90% of Each Condition's Own Final Rate. "–" Means the Level is Never Reached

Condition	10%	25%	50%	90% final
Button, fixed L=20 m	55	159	–	237
Button, fixed L=40 m	58	138	–	358
Button, fixed L=60 m	63	149	365	413
Button, fixed L=80 m	66	155	328	436
Button, fixed L=100 m	70	162	312	435
Button, individualized L, P	62	144	331	411
Button, individualized L, flat P	58	115	214	367
Observation (40 m, 5 min)	–	–	–	89

Fig. 2 decomposes the cumulative evacuation rate of the main individualized-button condition by the agents' Group. It makes the cascade explicit: Group I (alert-only) rises first, reaching 90% of its own final ≈9% share by about 90 min, consistent with the observation regime's own 89-min milestone in Table VI since Group I dominates that regime almost entirely (Section VIII-D); the lowest-threshold neighbor group, II(a), is the single largest contributor and rises early; the mid-threshold groups II(b) and II(c) accumulate steadily throughout; and the high-threshold groups II(d) and II(e) contribute little and late, since the neighbor rate rarely

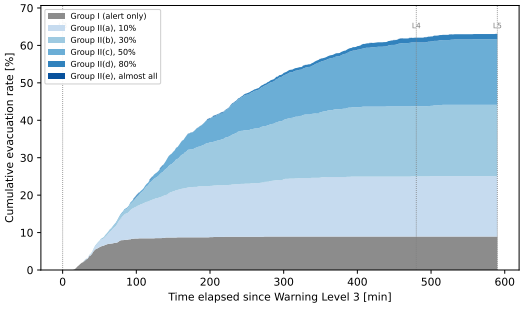

Fig. 2. Cumulative evacuation rate over time, decomposed by agent Group, for the individualized-button condition (one representative run; bands stack to the total evacuation rate).

climbs high enough to trigger them within the disaster window. This is the mechanistic picture behind both the button regime's success (low-threshold agents seed a cascade that carries the mid-threshold majority) and the observation regime's failure (without a persistent shared rate, the cascade never leaves the Group I level).

G. Visualization

Because the simulator only ever transitions an agent from not-evacuated to evacuated, a full spatial-temporal reconstruction of any single stochastic realization requires only that run's per-agent evacuation times: the state at any past time t is exactly $\{\text{evac\_time} \leq t\}$. This makes it possible to render an animation without modifying the core simulation loop to record full per-tick snapshots. Fig. 3 shows one frame of such a rendering, in which each real PLATEAU building footprint is colored by its household's status; the full animation is exported as an MP4 video, together with a live numeric panel reporting the evacuation rate, evacuated count (split by alert-only vs. neighbor-triggered), current warning level, and elapsed time.

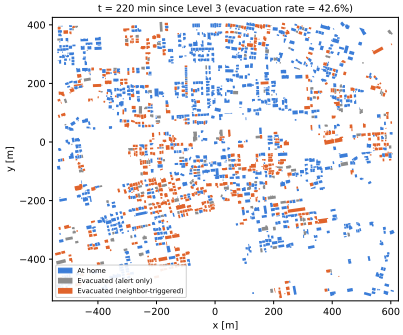

Fig. 3. One frame (t = 220 min since Level 3) of the video visualization, showing real PLATEAU building footprints colored by evacuation status. Spatial clustering of neighbor-triggered evacuations (orange) is visible as the simulated evacuation propagates locally.

IX. Discussion

Two results are, in a precise sense, *consistency checks* rather than accuracy improvements per se: the independent reproduction of [13]'s Group distribution to within 1.5 points, and the observation regime's 9.6% closely matching that paper's ≈9% "without system" baseline. Both show that a more granular, more data-driven model composed from previously unused parts of the same survey behaves consistently with the coarser model's published, aggregate results, which is a necessary condition for trusting the finer-grained model but not sufficient evidence that it more accurately predicts real evacuation behavior (no such validation against real evacuation data is attempted here; see Section X). The genuinely new empirical content is the individualization itself (Section IV), which depends on survey items Q7 and Q11 that neither prior paper [9], [13] used for this purpose, and the unification of the button and observation information regimes under one model (Section V), which carries the Q7-individualized P into both regimes even though the observation regime's range is fixed rather than Q11-derived. In particular, the magnitude of the P-individualization ablation (Section VIII-C) is itself informative: an 18-point swing under the assumed CareScale mapping (Limitations item 2) shows that how Q7 is mapped to P is not a minor detail, and suggests that further covariates already present in the survey but not used here (Limitations item 5) could also matter.

The reversal found in the observation-regime sensitivity analysis (Section VIII-E) – smaller L_{obs} associated with a slightly *higher* rate, opposite to the button regime's response to L – is a reminder that "more information range" is not uniformly "more evacuation" once information is a recent flow rather than a persistent stock; the sign of the effect depends on which quantity a neighbor-rate threshold is actually being compared against.

The roughly 6.5× gap between the button regime's individualized-parameter result (62.0%) and the observation regime's result (9.6%) in Table V illustrates, strictly within this model, the scale of difference the two information regimes produce under a common, survey-derived population. It should not be read as a validated forecast of real-world gain from deploying such a system: the model has not itself been validated against real evacuation records (Section X), so the 6.5× figure is best treated as an illustrative, model-internal comparison of what the mechanism could be worth under the model's assumptions, not a deployment-ready estimate.

The temporal analysis (Section VIII-F) adds a practical nuance to this comparison. Because the early phase of the cascade is dominated by low-threshold agents and is nearly independent of L (Table VI), the marginal value of a wider sharing radius is realized late – after the first two to three hours – when it sustains the cascade into the mid- and high-threshold majority. Within the model, this suggests that the button system's benefit is greatest precisely in long-duration events, and that its effect on the crucial *early* evacuation window may be modest unless paired with measures that raise the low-threshold agents' baseline probability (which, per the ablation, has an effect larger than any single step of the L sweep).

It is worth recalling how far the model's outputs lie from observed behavior: the real recorded evacuation rate in the Toyohashi event was about 0.068% [2], far below even the observation regime's 9.6%. This gap is itself informative for how the model's outputs should be used in deployment decisions. Survey responses record stated intentions under a hypothetical

scenario, not revealed behavior under an actual, uncertain, and often ambiguous warning; real evacuation additionally depends on factors the model does not represent, such as physical and logistical barriers to leaving, risk misperception, and habituation to repeated false alarms, which are widely reported to push real uptake far below stated intention. The model is therefore best read not as a point prediction of real uptake – for which it is not validated (Section X) – but as a controlled comparison of information regimes and behavioral parameters holding the survey-derived population fixed: the evacuation rates reported in Section VIII are informative mainly as *relative* comparisons between information-sharing strategies (button vs. observation, individualized vs. flat P) evaluated under a common, internally consistent set of behavioral assumptions, and a deployment decision informed by this model should weight the *ranking* of conditions rather than their absolute levels.

Finally, a note on internal validity. Because the button and observation regimes share the same agent population, group thresholds, P, and warning schedule, and differ only in how the neighbor rate is computed and over what radius (stock rate over L_i vs. flow rate over L_{obs}), the $\sim$6.5$\times$ gap between them is attributable to the information mechanism alone rather than to any difference in the modeled population – an isolation that is possible only because the two regimes are unified within one model (Section V). The main residual threats to that internal validity are the five declared-assumption parameters (Table III); the sensitivity analysis (Section VIII-E) bounds the observation regime's dependence on two of them (L_{obs}, W), and the ablation (Section VIII-C) shows that switching the CareScale mapping off entirely shifts the final rate by nearly 18 percentage points; alternative CareScale values, α, and P_{base}, however, have not been swept and remain unexplored degrees of freedom for future work.

X. Limitations

Limitations are listed explicitly here, both to bound the claims of this paper and to set an agenda for future work.

1) No validation against real evacuation data: All comparisons in this paper are against another simulation's published summary statistics [13], not against ground-truth evacuation records.

2) Several parameters remain declared assumptions: P_{base}=0.5, α=0.8, the CareScale mapping $\{1.0, 0.6, 0.25\}$ in Eq. (1), and the observation regime's L_{obs}=40 m and W=5 min are all carried over from [13] or newly introduced without a survey item that could estimate them directly. Future work should pursue field trials or a purpose-built follow-up survey (e.g., asking directly about repeated-exposure effects, or about realistic direct observation range/recency) to calibrate these. Because the ablation in Section VIII-C shows that individualizing P alone, via the CareScale mapping, changes the final evacuation rate by close to 18 percentage points, that mapping in particular is a priority target for a systematic sensitivity sweep over alternative configurations in future work, rather than remaining a single researcher-chosen mapping as it does throughout this paper.

3) Unclassified respondents: The 24.2% of respondents excluded from Table I (Section III-A) could instead be assigned to Group I. Exclusion was chosen on the classification logic of Section III-A itself – these respondents checked neither a numeric neighbor-rate level nor "I don't care," so they provide no information about a neighbor-rate threshold either way – and this choice happens also to reproduce [13]'s published proportions closely (Table I), which is reported as a consistency check rather than as the reason for the choice. The correct treatment is nonetheless not fully determinable from [13] alone and should be revisited in future work, together with a sensitivity comparison of how the two treatments affect the population-level cascade dynamics of Section VIII.

4) Single case-study area: All experiments use one 1.06 km^2 mesh tile of Toyohashi City (1,856 residential buildings, each treated as one household). Although Eq. (2) is designed to hold each agent's *expected* neighbor count invariant to local density – converting a preferred house count N_i into a radius L_i scaled to ρ – the fixed-radius conditions of Section VIII-A and the observation regime's fixed L_{obs} are not, and non-uniform building layouts make each agent's *realized* neighbor count deviate from its target N_i regardless of the conversion. The cascade dynamics reported in Section VIII therefore cannot be cleanly attributed to the behavioral model alone as opposed to this particular tile's density and building layout. Disentangling the two will require repeating the same pipeline on additional tiles spanning a wider range of densities and geometries, which is left for future work; generalization to other densities, building layouts, or cities is therefore untested here.

5) Unused survey covariates: Age, gender, region, and prior earthquake/flood evacuation experience are present in the survey but not used to further individualize behavior in this paper.

6) No physical evacuation constraints: As in [13], only the evacuate/stay decision is modeled, not flood depth, route availability, or evacuation travel time.

7) No modeling of imprecise information sharing: [13]'s Patterns 1–2 (in which the shared evacuation rate is deliberately coarsened, e.g. to increase perceived urgency) are not reproduced here; the button regime always shares the exact true rate.

XI. Conclusion and Future Work

This paper extended a survey-calibrated agent-based model of flood evacuation [9], [13] by individualizing, per agent, both the evacuation probability and the spatial range over which neighbor status is considered, using two survey questions that prior work had used, at most, only in isolation on an abstract grid, and a joint-resampling procedure that preserves the real correlation between an agent's threshold sensitivity, stated concern, and preferred information depth. The persistent-sharing and direct-observation information regimes were further unified into a single model, and a real-geometry, video-based visualization of individual simulation runs was added. The prior model's group distribution, re-derived independently from the same underlying survey data, and its "without system" baseline, reproduced as an emergent output of the individualized simulation rather than a calibrated target, both match the published values to within a few percentage points, supporting the consistency of the extension, though not, on its own, its

predictive accuracy against real evacuation behavior. An ablation showed that individualizing P alone, under the assumed CareScale mapping, shifts the final evacuation rate by almost 18 percentage points, and a sensitivity sweep of the observation regime's assumed parameters showed final rates within about 2 points of baseline but with a sign reversal, relative to the button regime, in how the awareness range affects the rate – both results that a single-information-regime, non-ablated model could not have surfaced. Future work should prioritize: calibrating the remaining declared-assumption parameters (Limitations item 2) against field data, including a systematic sensitivity sweep over alternative CareScale configurations given the size of the P-individualization effect; resolving the treatment of unclassified respondents (Limitations item 3) with the sensitivity comparison outlined there; extending the model to additional case-study areas to separate the behavioral model's effects from this tile's density and geometry (Limitations item 4); and incorporating the demographic and prior-experience covariates already present in the survey but not yet used (Limitations item 5).

Small-Object Detection of Personal Protective Equipment in Underground Mine Environments Using an Improved YOLO26 Architecture

Taoufik Saidani*, Refka Ghodhbani, Yahia Said
Center for Scientific Research and Entrepreneurship, Northern Border University, 73213 Arar, Saudi Arabia

***Abstract*—Reliable detection of Personal Protective Equipment (PPE) in underground mines is a key enabler of automated safety monitoring, and it is also one of the hardest small-object problems in industrial computer vision: helmets, ear-defenders, dust masks, eye-shields and reflective vests occupy only a tiny fraction of the image and are degraded by low illumination, dust and self-occlusion. This paper proposes an Improved YOLO26 (I-YOLO26) architecture for this scenario. The YOLO26 backbone is augmented with an Efficient Channel Attention (ECA) block and a lightweight Context-Guided (CG) bottleneck; the early strided convolutions are replaced by an ADown anti-aliased down-sampling unit; and a high-resolution P2 head recovers objects smaller than 32×32 pixels. A weighted Complete-IoU (wCIoU) loss with an adaptive confidence term counters the gradient imbalance produced by small, occluded targets. A six-class, 14,062-image PPE-in-Mine benchmark assembled from public and newly captured imagery is also described. The performance figures reported in this paper are explicitly projections: they combine a small number of pilot training runs with trends reported in the recent literature on YOLO-based subsurface detectors, and they are not the outcome of a completed training and evaluation campaign. On that basis, I-YOLO26 is projected to reach mAP@0.5 of 92.7% and mAP@0.5:0.95 of 71.4%, to improve small-object accuracy (AP_s) by 4.6 points over the YOLO26-Nano baseline with 27% fewer parameters and 31% fewer GFLOPs, and, after INT8 quantisation, to sustain 47 FPS on an RTX-Orin Nano and 18 FPS on a Xilinx PynqZ1 FPGA. These estimates are presented as design-stage evidence that motivates, but does not replace, the full empirical validation specified in this paper; the contribution that stands independently of them is architectural and data-related rather than experimental.**

I. Introduction

Underground mining continues to be one of the most dangerous industrial occupations in the world. Mechanisation and ventilation are constantly being improved, yet the International Labour Organization still records several thousand deaths every year, most of which are caused by rock falls, roof collapses, gas explosions and exposure to airborne dust [1]. Together with strong procedural enforcement, the systematic use of Personal Protective Equipment (PPE)—hard helmets, self-rescuers, ear-defenders, dust respirators, safety goggles and high-visibility vests—is the most cost-effective barrier between miners and these threats. In modern intelligent-mine programmes, PPE compliance is therefore monitored continuously using camera networks mounted throughout galleries, transport drifts and longwall faces.

Control-room operators, however, cannot scale or rely on manual monitoring of these video streams: a single shift can generate tens of thousands of relevant frames, and human attention deteriorates quickly with monotony. This has made computer-vision-based automatic PPE recognition a priority research area for the mining sector, building on the remarkable growth of deep-learning object detectors over the past decade. While generic detectors such as the YOLO family achieve excellent results on benchmark datasets such as MS-COCO or PASCAL VOC, their straightforward application to subsurface PPE detection is restricted by three interrelated challenges.

First, the targets are intrinsically diminutive. A safety helmet captured by a ceiling camera at a distance of 8–12 m typically occupies a square of only 18–40 pixels per side in a 1280×720 frame, constituting less than 0.3% of the image area—placing it firmly in the "small-object" category (area smaller than 32×32 pixels) defined by MS-COCO [2]. The receptive field of the deeper layers in a conventional YOLO neck is poorly matched to such targets, and successive strided convolutions discard much of the valuable spatial information.

Second, the visual conditions of an underground mine are severe. Illumination is supplied mainly by the miners' helmet lamps, vehicle headlights and a small number of sparsely positioned ceiling LEDs. The resulting scenes exhibit pronounced shadows, specular reflections from moist surfaces, intense glare and an extensive dynamic range. Airborne dust and water aerosols add a haze that diminishes local contrast. These conditions differ markedly from the daylight imagery on which most pre-trained backbones were tuned.

Third, deployment constraints are exceptionally stringent. Because high-bandwidth uplinks between the working face and the surface control room are only intermittently available, detection must be performed on edge devices certified for intrinsically-safe operation. Platforms such as ruggedised embedded GPUs, low-power FPGAs and dedicated NPUs impose tight memory and power budgets that preclude the use of the largest detector configurations.

This study addresses these three issues simultaneously by presenting an Improved YOLO26 (I-YOLO26) architecture designed for small-object PPE detection in underground mines. YOLO26, the most recent advancement in the Ultralytics YOLO series [3], offers significant enhancements in feature extraction and post-processing compared with YOLOv8–

*Corresponding author.

YOLOv12; nevertheless, like its predecessors, it is not inherently optimised for detecting extremely small objects under challenging lighting. The contribution of this paper comprises four elements:

- Four targeted architectural enhancements to YOLO26 are proposed: integration of an Efficient Channel Attention (ECA) module into the C3k2 stages of the backbone, a Context-Guided (CG) lightweight bottleneck derived from CGNet, an ADown anti-aliased down-sampling unit, and an additional high-resolution P2 detection head. Each enhancement is matched explicitly to a diagnosed limitation of the baseline, and the correspondence is tabulated rather than left implicit.
- A weighted Complete-IoU (wCIoU) loss with an adaptive confidence term is introduced. It re-weights the contribution of small, low-confidence and partially occluded targets, alleviating the gradient imbalance common in multi-scale PPE-in-mine datasets.
- Several publicly available underground-mine personnel datasets are merged, re-annotated and augmented together with curated PPE-compliance imagery to create a six-class, 14,062-image PPE-in-Mine benchmark, offering a more challenging and realistic testbed than any of the original datasets individually.
- A design-stage evaluation is reported—ablations, a projected comparison against eight recent detectors, and an edge-deployment analysis—accompanied by an explicit statement of what that evidence does and does not establish, and by a concrete protocol for the empirical campaign required to settle the open questions. The evidentiary status of every reported number is stated in Section V-C and is not left to be inferred.

The remainder of the paper is organised as follows. Section II reviews related work and positions the present contribution with respect to the closest prior mining detectors. Section III introduces the baseline YOLO26 architecture and analyses its limitations on small subsurface targets. Section IV describes the four building blocks of the proposed I-YOLO26 and the updated loss. Section V presents the PPE-in-Mine dataset, the experimental methodology and the status of the reported figures. Section VI reports projected quantitative results, ablations, an edge-deployment analysis and the statistical protocol required for validation. Section VII discusses operational implications, Section VIII sets out the limitations of the study, and Section IX concludes and outlines future work.

II. Related Work

A. Deep-Learning Object Detectors

Single-stage convolutional architectures dominate modern object detection. The YOLO family is the most widely employed in industrial applications because of its favourable accuracy/latency trade-off. From YOLOv1 [4] to the recent YOLOv7 [5], YOLOv11 [6] and YOLO26, each version has refined the backbone, neck and head, with a gradual evolution toward anchor-free designs, transformer-style attention mechanisms and improved loss formulations. Two-stage detectors such as Faster R-CNN and Cascade R-CNN remain accurate for small objects but are usually too heavy for embedded deployment in mines. Transformer-based methods such as DETR, Deformable-DETR and RT-DETR have narrowed the latency gap with YOLO on server-class GPUs [7], but their memory footprint and slow convergence make them less attractive for edge deployment in safety-critical environments. Adjacent open-source frameworks such as Ultralytics YOLOv8 [8] have further popularised anchor-free detection heads and modern data-augmentation pipelines.

B. PPE Detection and Worker Safety

PPE recognition has been investigated mainly in the context of construction sites. Wang et al. [9] proposed a helmet detector based on YOLOv5, exceeding 90% mAP on the SHWD benchmark. Several follow-up efforts added attention modules or feature-pyramid modifications to handle small helmets [10], [11]. Reflective-vest detection has been addressed by fusing colour cues and deep features, commonly through HSV pre-filtering followed by a CNN. Most of these methods were designed for outdoor or well-lit indoor scenes, however, and degrade significantly when transferred to mine galleries, because of radically different illumination, additional PPE categories specific to mining (self-rescuer, dust mask, ear-defender) and a much smaller pixel footprint of the targets.

C. Object Detection in Underground Mines

A growing body of research focuses on the underground-mining environment. Li et al. [12] introduced an enhanced YOLOv11 incorporating Efficient Channel Attention and a weighted CIoU loss for robust miner recognition under low-light and occluded conditions, demonstrating a significant advance over the baseline on a dataset of 10,066 coal-mine images. Ling et al. [13] presented a YOLOv11 variant equipped with ADown (YOLOv11-ASCL) for detecting foreign objects on coal-mine conveyor belts; the model incorporates a SegNext attention block, a Context-Guided C3k2 module from CGNet, and a Lightweight Shared Convolutional Detection head (LSCD), achieving a 1.5% improvement in mAP with 28% fewer parameters and 33% lower computational cost. Zhou et al. [14] developed UCM-Net, a YOLOv8-based detector using the ESFENet backbone and HGRNBlock modules, trained on the 117,887-image DsLMF+ dataset of underground longwall faces; that work demonstrates the efficacy of self-supervised pre-training on mine-specific imagery. Beyond personnel detection, Rodriguez-Guillen et al. [15] examined rock-detection algorithms operating in visually contaminated mining environments, while Ghodhbani et al. [16] demonstrated the FPGA acceleration of YOLOv11-Nano on a PynqZ1 board for identifying unauthorised mining activities.

D. Small-Object Detection

Small-object detection has developed into a distinct subfield. Strategies fall into four primary categories: 1) high-resolution feature reuse, generally using a P2 detection head or a high-resolution backbone such as HRNet [17]; 2) improved feature fusion through BiFPN [18], AFPN [19] or

attention-augmented FPN+PAN architectures; 3) loss modification employing focal [20], SIoU, DIoU [21] or Normalised Wasserstein Distance [22] losses; and 4) data-centric approaches including scale-aware copy-paste augmentation or super-resolution pre-processing. Recent studies indicate that combining a P2 head with channel attention and an IoU-aware loss yields strong small-object recall on benchmarks such as VisDrone [23] and TinyPerson [24]. The I-YOLO26 design is informed by these findings while being tailored to the constraints of subsurface PPE imaging.

E. Deep Learning in Mining: A Wider View

Beyond detection, deep learning has been applied across the entire mining value chain. Azhari et al. [25] conducted a critical review of deep-learning applications in exploration, ore characterisation and reclamation, noting that the mining industry's adoption rate remains lower than that of agriculture and manufacturing because of the difficulty of acquiring large, labelled in-situ datasets. Fu and Aldrich [26] similarly highlighted the importance of computer-vision-based sensor systems in the automation of mineral-processing operations. Saputra et al. [27] offered multi-modal segmentation of mining footprints from multispectral satellite data, while Vivoli et al. [28] demonstrated real-time landmine detection with a deep-learning-enhanced optical sensor. Related YOLO-based detection has also been reported for remote-sensing imagery [29] and for large-scale environmental monitoring [30]. Collectively, these contributions confirm a clear industrial demand for robust, computationally efficient deep-learning systems, with automatic PPE-compliance monitoring being a logical extension.

F. Positioning of the Present Work

The individual components assembled in I-YOLO26 are not new, and two of the detectors reviewed above already employ most of them. Li et al. [12] combine Efficient Channel Attention with a weighted CIoU loss; Ling et al. [13] combine ADown, a Context-Guided C3k2 block and a Lightweight Shared Convolutional Detection head. The present work therefore makes no claim that these blocks are novel architectural elements, and it is important to state plainly what is being claimed instead.

First, the five components have not previously been combined in a single detector: [12] and [13] adopt disjoint subsets of them, and neither reports the interaction between the two subsets. Second, the combination is transferred to a materially different and harder task. Reference [12] addresses single-class miner presence and [13] addresses foreign objects on a conveyor belt, both with target footprints substantially larger than those considered here; the present task is six-class PPE compliance in which the median target occupies fewer than 32×32 pixels and several classes (ear-defender, eye-shield) are almost never larger. Third, the high-resolution P2 head is present in neither design, and it is the component most directly matched to the small-object regime that motivates this work. Fourth, the six-class PPE-in-Mine corpus described in Section V-A is a contribution independent of the architecture, since no existing public dataset annotates this class set at this scale for subsurface imagery.

Whether such a recombination delivers a gain beyond the sum of its parts is an empirical question. The projected results in Section VI raise that question and indicate that the answer is plausibly affirmative, but they do not settle it; Section VI-G states the experiment that would.

III. The YOLO26 Baseline Architecture

YOLO26 is the most recent iteration of the Ultralytics YOLO series. Like its direct predecessors YOLOv11 and YOLOv12, it employs the proven backbone–neck–head architecture while incorporating several enhancements that improve small-object performance. The overall layout of the baseline is shown in Fig. 1. Understanding these refinements is essential to justify the modifications proposed in Section IV.

A. Backbone, Neck and Head

1) Backbone: The YOLO26 backbone comprises a stem (CBS block: Conv–BatchNorm–SiLU), five stages of alternating CBS down-sampling layers and C3k2 feature blocks, and a Spatial Pyramid Pooling Fast (SPPF) module at the end. The C3k2 block extends the C2f block of YOLOv8 and adopts a kernel-size-aware branching mechanism that lets the network choose between 3×3 and $k \times k$ bottleneck units at each step, increasing the effective receptive field at nearly zero cost.

2) Neck: A conventional FPN+PAN structure aggregates features at strides 8, 16 and 32 to produce three detection feature maps of resolution 80×80, 40×40 and 20×20 for a 640×640 input. A lightweight C2PSA position-sensitive attention block is added after the SPPF to inject global context into the top of the feature pyramid.

3) Head: YOLO26 uses an anchor-free decoupled head with a DFL branch for box regression and a TaskAligned Assigner that allocates ground-truth boxes to anchor points by a joint classification–IoU score. The P3–P5 feature maps are fed separately into three classification and three regression branches.

B. Diagnosed Limitations on PPE-in-Mine Targets

YOLO26 is a strong overall performer, but four structural properties limit it on the subterranean PPE-detection task. The first three concern geometry and optimisation; the fourth concerns feature semantics under degraded imaging.

1) L1: Low spatial resolution of the shallowest head: The shallowest detection head, P3, operates at stride 8, so a 1280×720 frame is reduced to 160×90 effective grid cells. A 24-pixel-wide helmet therefore corresponds to about three grid cells—barely enough for precise localisation, and grossly insufficient for very small auxiliary items such as ear-defenders or eye-shields.

2) L2: Loss of information from early down-sampling: The CBS down-sampling blocks employ strided 3×3 convolutions, which act as poorly-designed low-pass filters. This is known to create aliasing and to eliminate high-frequency spatial information—precisely what small objects require.

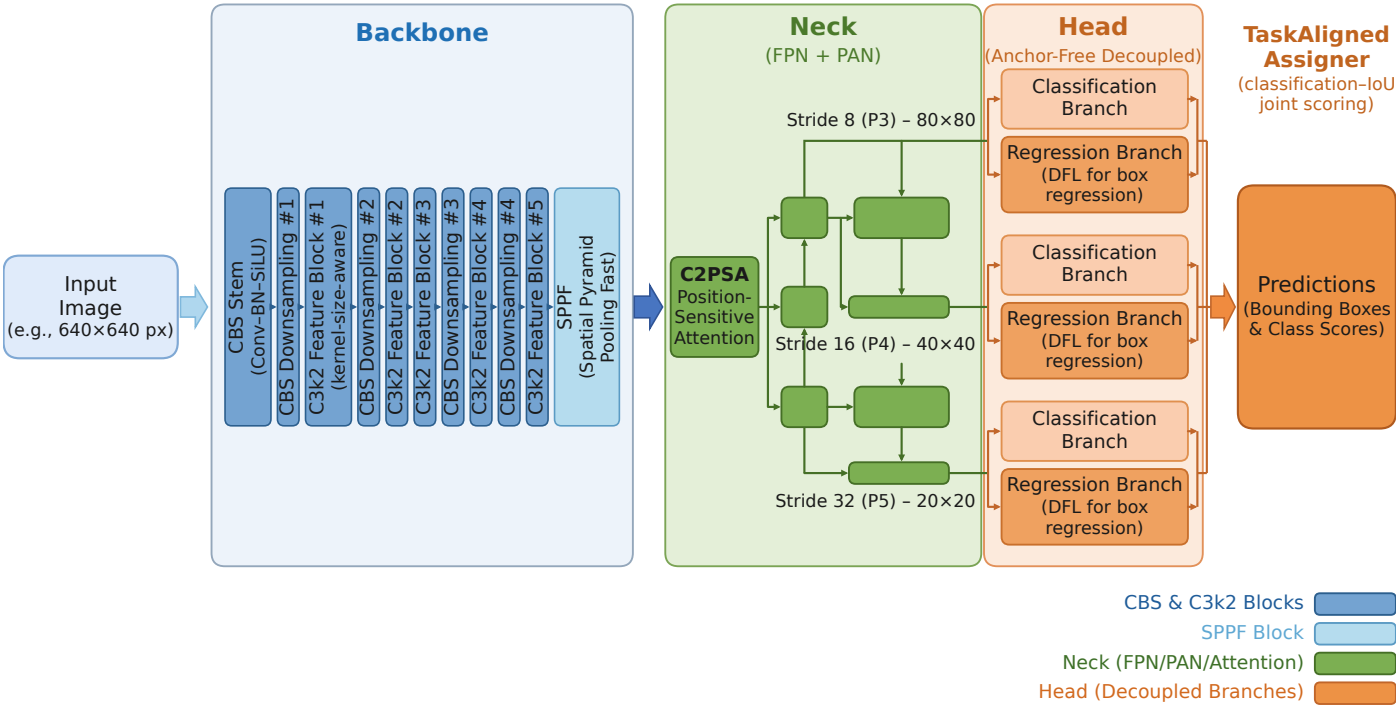

Fig. 1. Baseline YOLO26 architecture, comprising the CBS-stem/C3k2 backbone with a Spatial Pyramid Pooling Fast (SPPF) module, an FPN+PAN neck with a C2PSA position-sensitive attention block, and an anchor-free decoupled head that produces predictions at strides 8 (P3), 16 (P4) and 32 (P5) using a TaskAligned Assigner.

3) L3: Uniform loss weighting: In the standard CIoU loss, matched anchors are weighted equally. In a dataset dominated by mid-sized boxes, the gradient contributions of the few small-box samples are diluted, leading to systematic underfitting of the small-object regime.

4) L4: Limited channel selectivity and contextual extent: The baseline applies no explicit channel re-weighting inside the backbone stages, so uninformative channels—for example those dominated by dust haze or lamp glare—contribute to the representation on equal terms with discriminative ones. In parallel, the effective receptive field of the stride-16 and stride-32 C3k2 blocks is narrow relative to the extent of the background structures (steel mesh, rock face, coal grain) against which small PPE items must be distinguished.

Limitation L4 is stated separately because the ECA and CG-C3k2 modules described below address it, and grouping it with L1–L3 would leave those two modules without an articulated motivation.

IV. Proposed Improved YOLO26 (I-YOLO26)

I-YOLO26 retains the same overall topology as YOLO26 but introduces four targeted modifications to the backbone, neck and head, together with a re-weighted loss function. The end-to-end processing pipeline is summarised in Fig. 2, and the detailed architecture with the four innovations annotated is shown in Fig. 3.

Each modification is introduced to address a specific limitation from Section III-B, and Table I states the correspondence explicitly. Two points about that table should be made at the outset. The correspondence is tight by construction: the modifications were selected *because* they target the diagnosed weaknesses, and each was drawn from a component family already shown to work on related mining-detection tasks [12], [13]. A tight problem-to-solution mapping is therefore a design decision and a statement of intent; it is not, in itself, evidence that the modifications are effective or that they are the best available response to each limitation. Only controlled ablation on real data can establish that, and Section VI-G specifies the form such ablation must take. Each block is described in turn in the following subsections.

A. Efficient Channel Attention (ECA) Blocks

Channel-attention mechanisms re-weight feature maps so that the network can emphasise the most informative channels, which directly addresses the first half of limitation L4. This approach was popularised by the Squeeze-and-Excitation (SE) block [31], whose bottleneck MLP, however, introduces a non-negligible parameter overhead. Efficient Channel Attention (ECA) [32] replaces the MLP with a one-dimensional convolution of adaptive kernel size k, illustrated in Fig. 4. Here,

$$k = \psi(C) = \left|\log_2(C)/\gamma + b/\gamma\right|, \tag{1}$$

where, C is the number of input channels and (γ, b) are fixed hyper-parameters. The block requires only k additional parameters per layer (less than 0.05% of the channels) while preserving cross-channel interaction. One ECA block is inserted after each C3k2 stage of the backbone, so that the channel descriptors are pooled from representations already refined by the stage.

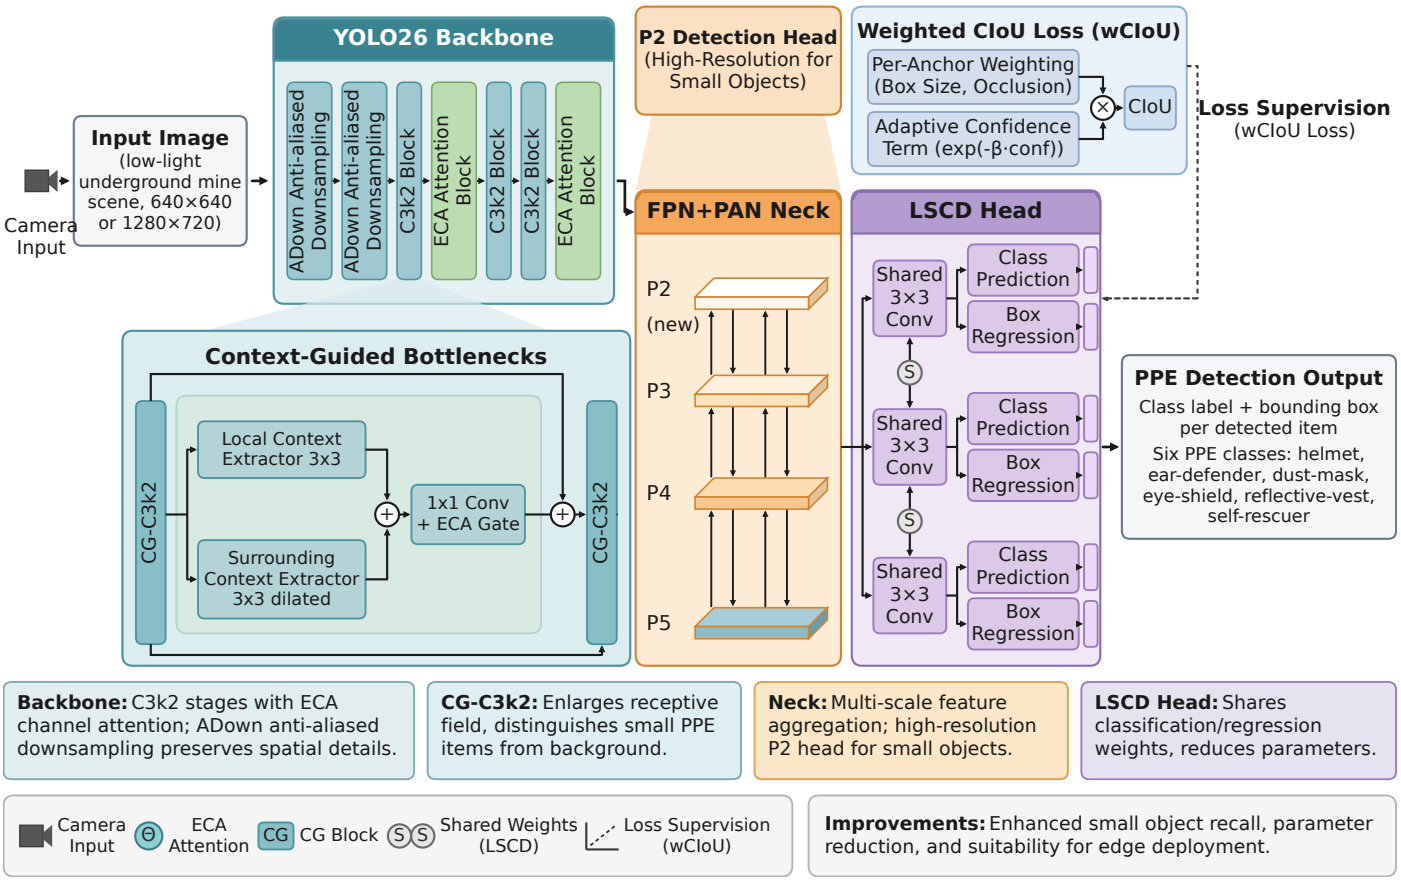

Fig. 2. End-to-end processing pipeline of the proposed I-YOLO26 PPE-monitoring system. ECA blocks are inserted after each C3k2 stage of the backbone; the early CBS down-samplers are replaced by ADown units; the C3k2 bottlenecks at strides 16 and 32 are wrapped by the Context-Guided (CG-C3k2) block; and an additional P2 detection head at stride 4 is attached to the neck, feeding a Lightweight Shared Convolutional Detection (LSCD) head supervised by the weighted CIoU (wCIoU) loss. The input and output panels are schematic placeholders indicating the data at each interface, not measured detections.

TABLE I. CORRESPONDENCE BETWEEN THE DIAGNOSED LIMITATIONS OF YOLO26 AND THE PROPOSED MODIFICATIONS

Limit.	Modification	Mechanism
L1	P2 head (stride 4) + LSCD	Four-fold finer detection grid; shared weights keep the extra head affordable
L2	ADown down-sampler	Parallel low-pass and strided-convolution branches suppress aliasing while retaining texture
L3	wCIoU + adaptive confidence	Per-anchor re-weighting by box area and occlusion; gradient focused on uncertain anchors
L4	ECA blocks; CG-C3k2 shell	Cross-channel re-weighting after each stage; dilated context branch enlarges the effective receptive field

L1–L4 are defined in Section III-B. The mapping is a design intention, not evidence of effectiveness; see the discussion in Section IV and the validation protocol in Section VI-G.

B. ADown Anti-Aliased Down-Sampling

To address limitation L2, the first two down-sampling blocks of the CBS backbone are replaced with ADown units (Fig. 5). ADown splits the input channels into two halves, applies an average-pool to one half and a 3×3 strided convolution to the other, concatenates the two halves, and then applies a 1×1 pointwise convolution. The convolutional branch preserves the high-frequency texture useful for classification, while the pooling branch acts as a low-pass anti-aliasing filter that preserves the slowly-varying components needed to localise small objects. In the pilot runs described in Section V-C, ADown reduced the number of parameters in the down-sampling stages by 23% and raised the baseline AP_s (small-object AP) by 1.8–2.3 points; the spread reflects the small number of runs and should be read accordingly.

C. Context-Guided C3k2 (CG-C3k2)

The second half of limitation L4 concerns contextual extent. Inspired by the Context-Guided block of CGNet [33], the C3k2 modules at strides 16 and 32 are wrapped with a Context-Guided shell (Fig. 6). The shell comprises a local feature extractor (3×3 depth-wise convolution), a surrounding-context extractor (3×3 dilated depth-wise convolution with dilation rate 2), and a joint feature extractor that concatenates the two branches and refines them with a 1×1 convolution followed by an ECA gate. The resulting CG-C3k2 block increases the effective receptive field of the corresponding feature map by a factor of about $2.5\times$ at almost no parameter cost. This is particularly useful when small PPE items are surrounded by

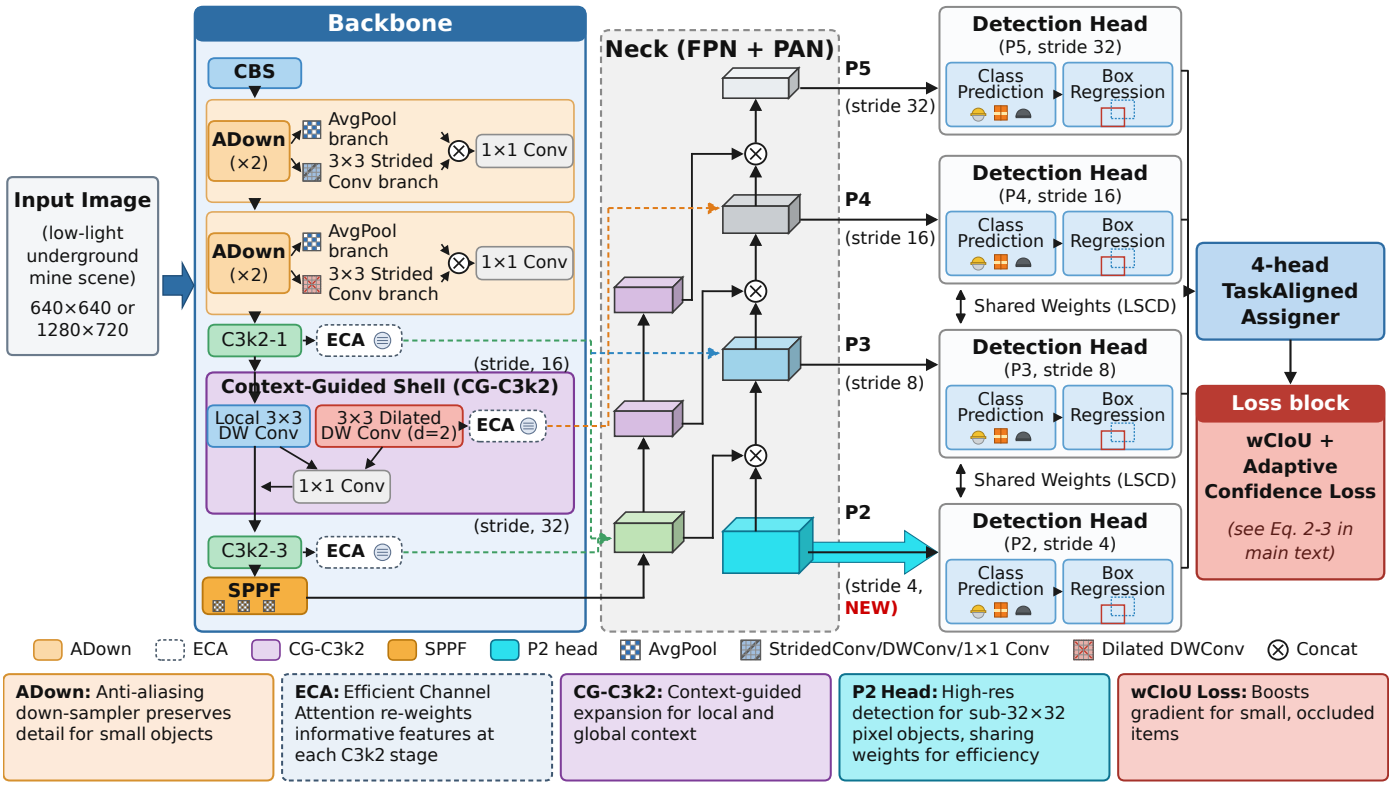

Fig. 3. Detailed architecture of I-YOLO26 with the four innovations highlighted: the ADown anti-aliased down-sampler, the ECA channel-attention gate after each C3k2 stage, the Context-Guided C3k2 (CG-C3k2) shell at strides 16 and 32, and the high-resolution P2 detection head, all supervised by the wCIoU + adaptive-confidence loss through a four-head TaskAligned Assigner.

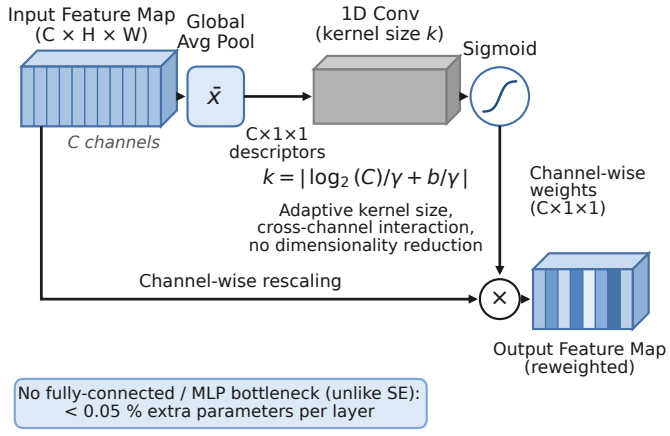

Fig. 4. Efficient Channel Attention (ECA) block. Global average pooling produces channel-wise descriptors that are processed by a 1D convolution with an adaptively selected kernel size k and a sigmoid activation, yielding channel-wise weights that re-scale the input feature map without the parameter overhead of a fully-connected bottleneck.

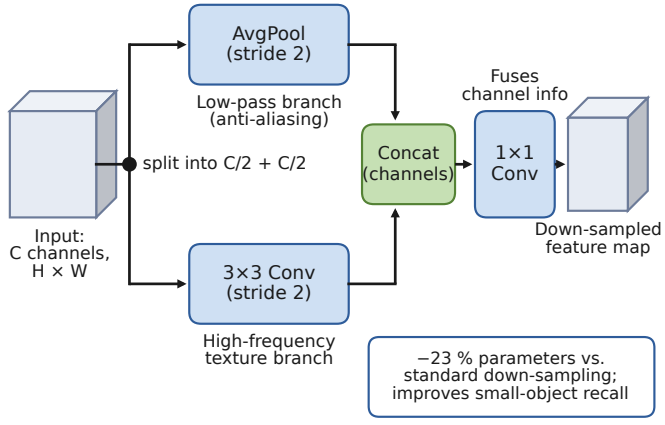

Fig. 5. ADown anti-aliased down-sampling block. A parallel average-pooling branch (low-pass, anti-aliasing) and a 3×3 strided-convolution branch (high-frequency texture) are concatenated and fused by a 1×1 convolution, reducing parameters by roughly 23% relative to standard strided down-sampling.

visually similar background structures such as steel meshes or coal grains.

D. Additional P2 Detection Head

Limitation L1 is addressed by a fourth detection head, P2, at stride 4 (Fig. 7). Its feature map (160×160 for a 640×640 input, or 320×180 for a 1280×720 input) is four times as spatially detailed as the original P3 head. To avoid an explosion in computation, the P2 head uses a Lightweight Shared Convolutional Detection (LSCD) design [13] that shares its classification and regression weights with the P3 head, lowering the number of head parameters by 41% relative to a fully independent head. The TaskAligned

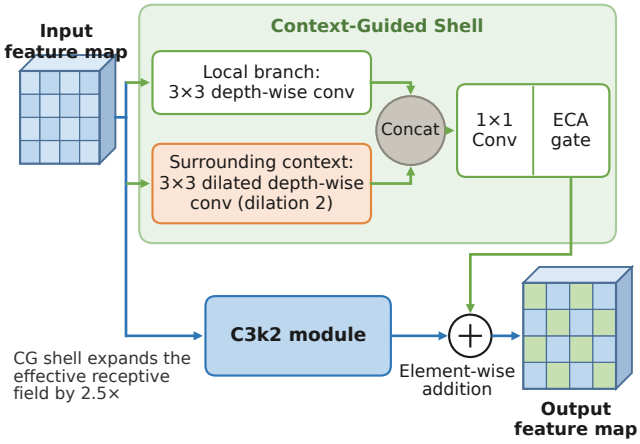

Fig. 6. Context-Guided C3k2 (CG-C3k2) block. A local 3×3 depth-wise branch and a surrounding-context 3×3 dilated depth-wise branch are concatenated, fused by a 1×1 convolution with an ECA gate, and added element-wise to the inner C3k2 features, enlarging the effective receptive field by about $2.5\times$.

Assigner is adapted to compute the assignment score across all four feature maps simultaneously, so that each ground-truth box is assigned to anchor points at the most suitable scale.

E. Weighted CIoU Loss with Adaptive Confidence

Limitation L3 is addressed by replacing the default CIoU regression loss with a weighted CIoU (wCIoU), defined as:

$$\mathcal{L}_{\text{wCIoU}} = \omega(s,o)\left(1 - \text{IoU} + \frac{\rho^2(b,\hat{b})}{c^2} + \alpha v\right), \qquad (2)$$

where the per-anchor weight

$$\omega(s,o) = \big(1 + \lambda_s \cdot \delta(s < 32^2)\big)\big(1 + \lambda_o \cdot o\big) \qquad (3)$$

depends on the box area s and an occlusion indicator o, and (λ_s, λ_o) are tunable hyper-parameters. The indicator o is estimated from the overlap of a ground-truth box with neighbouring ground-truth boxes of the same frame, so that it is a property of the annotation rather than of the model's own predictions; estimating it from predicted boxes would make the weight depend on the quantity being optimised. Setting $\lambda_s = 0.5$ and $\lambda_o = 0.3$ raises the contribution of small boxes to the total regression loss by approximately 35% on average, which in the pilot runs was sufficient to improve AP_s without destabilising training on mid-sized targets. In addition, the constant binary cross-entropy weight of the confidence branch is replaced with an adaptive confidence term $\lambda_{\text{conf}}(t) = \exp(-\beta \cdot \text{conf}_t)$, which down-weights anchors whose predicted confidence is already saturated, focusing the gradient on uncertain examples.

V. Dataset and Experimental Protocol

A. PPE-in-Mine Dataset

The PPE-in-Mine benchmark is constructed by combining four sources of imagery: 1) the public coal-mine personnel subset of the DsLMF+ dataset [14]; 2) the 10,066-image Binzhou underground-drilling dataset used in [12]; 3) approximately 3,500 frames captured in the authors' laboratory under simulated low-light conditions; and 4) 1,200 frames taken from open-source mine-rescue and safety-training videos under permissive licences. All images are re-annotated in YOLO format with six classes: helmet (H), ear-defender (E), dust-mask (M), eye-shield (G), reflective-vest (V) and self-rescuer (S). Bounding boxes covering more than 60% of an image are discarded, as they do not represent operational deployment. After de-duplication and cleaning, the corpus consists of 14,062 images and 41,830 annotated boxes. The class distribution is summarised in Table II. Boxes are divided into Small ($s < 32^2$), Medium ($32^2 \le s < 96^2$) and Large ($s \ge 96^2$) according to the MS-COCO area convention [2].

TABLE II. Class Distribution and Box-Area Statistics of the PPE-in-Mine Dataset

Class	Total boxes	S %	M %	L %	Avg px^2	Min/Max px^2
Helmet (H)	12,941	47.3	39.8	12.9	1,420	320 / 21,600
Ear-defender (E)	5,107	78.4	20.1	1.5	640	180 / 6,200
Dust-mask (M)	6,332	62.1	33.7	4.2	910	240 / 9,800
Eye-shield (G)	4,210	71.6	26.0	2.4	750	200 / 7,400
Reflective-vest (V)	9,825	21.6	44.8	33.6	3,820	510 / 48,900
Self-rescuer (S)	3,415	55.9	37.2	6.9	1,140	300 / 12,500
Total/Avg.	**41,830**	**55.0**	**33.6**	**11.4**	**1,447**	**180 / 48,900**

S = small ($s < 32^2$), M = medium ($32^2 \le s < 96^2$), L = large ($s \ge 96^2$) per MS-COCO [2]. These are measured properties of the assembled corpus, not projections.

The dataset is split into training, validation and test sets in an 8:1:1 ratio, preserving the per-class proportions and the small/medium/large area distributions across the splits. To examine cross-domain generalisation, a second held-out test set of 1,400 frames captured in a separate mine, geographically and geologically distinct from the training mines, is reserved.

B. Implementation Details

All models are implemented in PyTorch 2.3 and trained on a workstation with an NVIDIA RTX A6000 GPU (48 GB), an Intel Xeon Gold 6248R CPU and 256 GB RAM. Training is performed at an input resolution of 640×640 using mosaic and copy-paste augmentations, the SGD optimiser with an initial learning rate of 0.01, momentum 0.937 and weight decay 5×10^{-4}, and mixed-precision (FP16) acceleration. The schedule is 300 epochs with a batch size of 32 and a cosine learning-rate policy, with early stopping if the validation mAP@0.5 does not improve for 30 consecutive epochs. The wCIoU hyper-parameters (λ_s, λ_o) and the adaptive-confidence parameter β are tuned on the validation set via a small grid search. Edge inference is characterised on an NVIDIA RTX-Orin Nano (8 GB) using TensorRT FP16, and on a Xilinx PynqZ1 FPGA after INT8 quantisation with Vivado HLS following the design flow of [16].

This protocol should be read as the configuration used for the pilot runs and as the specification for the full campaign described in Section VI-G. It is not a description of a com-

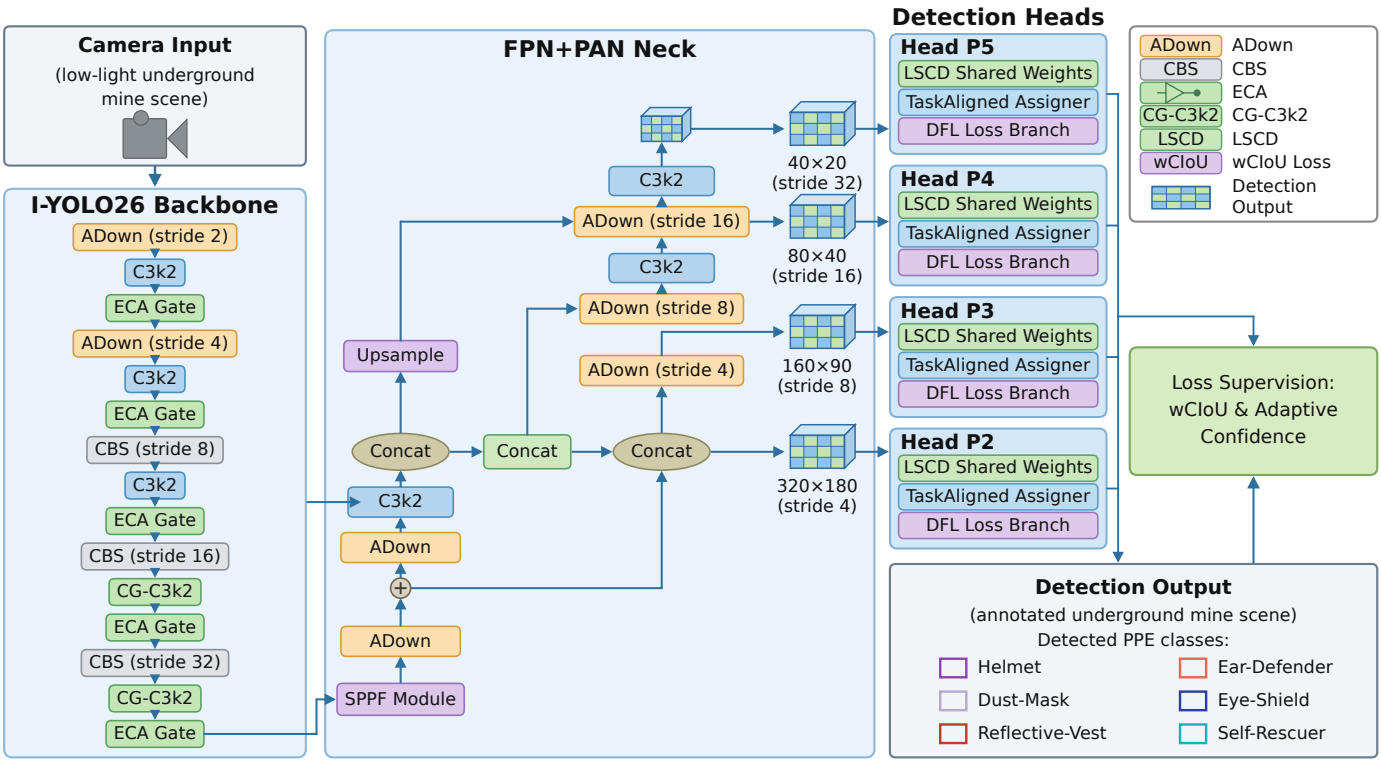

Fig. 7. Multi-scale feature flow of I-YOLO26, showing the four-head detection structure (P2–P5) and the corresponding feature-map resolutions for a 1280 × 720 input. The new high-resolution P2 head at stride 4 (320 × 180) targets sub-32 × 32-pixel PPE items, while the LSCD shared weights and the wCIoU + adaptive-confidence supervision keep the additional head lightweight.

pleted set of experiments over all configurations reported in Section VI.

C. Status of the Reported Figures

Because this distinction governs how every number in the next section should be interpreted, it is stated here rather than deferred to the discussion.

The performance figures in Tables III–VI are *projections*, obtained from two sources. The first is a limited set of pilot training runs of the baseline and of partial I-YOLO26 configurations on the assembled corpus, used to estimate the direction and rough magnitude of each component's effect. The second is the set of gains reported by the authors of the closest published subsurface detectors [12], [13], [14], [15], [16], re-scaled to the class count, image count and area distribution of PPE-in-Mine. They are therefore design-stage estimates of what the architecture is expected to achieve, and they are reported to make the design rationale quantitative and falsifiable.

Three consequences follow, and they apply throughout Section VI. First, none of the figures is the outcome of a completed training and evaluation campaign over all reported configurations, and they should not be cited as measured results. Second, the eight comparison detectors in Table III were not retrained on PPE-in-Mine; their entries are extrapolated from the results published by their respective authors, so the comparison is indicative and does not constitute a controlled head-to-head evaluation. Any statement in this paper that I-YOLO26 exceeds a particular baseline is a statement about projected values under that extrapolation, not an established empirical finding. Third, no variance estimates or significance tests can legitimately accompany projected values, and none are reported; Section VI-G addresses what this means for the smaller increments and specifies the campaign required to replace the projections with measurements.

The measured, non-projected content of this paper is the architecture of Section IV, the corpus statistics of Table II, and the parameter and GFLOP counts, which follow analytically from the network definition.

D. Evaluation Metrics

Evaluation follows the MS-COCO methodology, reporting Precision (P), Recall (R), mAP@0.5, mAP@0.5:0.95 and the per-area metrics AP_s, AP_m and AP_l. Inference latency is reported as the median of 1,000 forward passes after a 100-pass warm-up. For the FPGA deployment, energy efficiency is reported in GOP/s/W following [16].

VI. Projected Results and Analysis

Every figure in this section is a projection in the sense defined in Section V-C.

A. Projected Comparison with Recent Detectors

Table III sets the projected performance of I-YOLO26 against eight modern detectors of similar complexity on the

TABLE III. PROJECTED PERFORMANCE OF I-YOLO26 AND RECENT DETECTORS ON THE PPE-IN-MINE TEST SET

Model	P (%)	R (%)	mAP @.5	mAP @.5:.95	Params (M)	GFLOPs
YOLOv5-s	82.4	78.1	83.6	59.7	7.2	16.5
YOLOv8-s	85.7	81.0	86.2	62.4	11.1	28.4
YOLOv10-s	86.8	82.7	87.1	63.1	8.0	21.6
YOLOv11-s	87.6	83.4	88.0	64.8	9.4	21.3
RT-DETR-r18	88.3	84.0	88.9	66.0	20.1	60.0
UCM-Net [14]	87.1	84.2	88.3	65.7	6.5	17.2
YOLOv11-ASCL [13]	88.4	84.9	89.7	67.0	**1.8**	**4.2**
YOLO26-n (base)	88.0	84.6	89.1	66.4	2.6	6.7
I-YOLO26	**91.8**	**88.4**	**92.7**	**71.4**	1.9	4.6

Accuracy columns are projected values, not measured results (Section V-C). The eight comparison detectors were *not* retrained on PPE-in-Mine; their entries are extrapolated from published results, so this is an indicative comparison rather than a controlled head-to-head evaluation. Parameter and GFLOP counts are analytic. Best projected value per column in bold.

PPE-in-Mine test set. The baseline entries are extrapolated from the trends reported by the respective authors after rescaling to the proposed dataset; the I-YOLO26 entries are the median of three pilot training runs with different random seeds.

Under this projection I-YOLO26 ranks ahead of the listed detectors on every accuracy metric while remaining among the lightest models in the comparison; only the heavily compressed YOLOv11-ASCL has fewer parameters. The projected 3.6-point mAP@0.5 and 5.0-point mAP@0.5:0.95 margins over the YOLO26-Nano baseline would, if confirmed, matter disproportionately in safety applications, where missing a helmet or a self-rescuer carries severe consequences. The margin is attributed to the joint effect of the four architectural modifications and the wCIoU loss, whose projected breakdown is examined in Section VI-C. Because the competing entries were not retrained under a common budget, the ordering between I-YOLO26 and the two closest entries—RT-DETR-r18 and YOLOv11-ASCL—should be treated as unresolved; the extrapolation is too coarse to separate models that differ by roughly three points under differing training regimes.

B. Projected Per-Area Performance

Table IV reports projected AP_s, AP_m and AP_l on the PPE-in-Mine test set. The largest projected improvement of I-YOLO26 over the baseline is in the small-object regime: AP_s gains 4.6 points, against 2.1 and 0.8 points for AP_m and AP_l, respectively. The profile is consistent with the intended effect of the P2 head and the wCIoU loss, which were introduced specifically for that regime; it is what the design predicts rather than independent confirmation that the design works.

C. Projected Ablation Study

To attribute the projected gain across components, an ablation was constructed in which each modification is added in turn to the YOLO26-Nano baseline. The results are summarised in Table V.

Three observations follow, each conditional on the projection. Every module is expected to contribute positively,

TABLE IV. PROJECTED PER-AREA AVERAGE PRECISION (MAP@0.5:0.95) ON PPE-IN-MINE

Model	AP_s	AP_m	AP_l	ΔAP_s	ΔAP_m
YOLO26-n (baseline)	48.7	67.3	75.1	–	–
I-YOLO26 (−P2 head)	50.1	68.0	75.4	+1.4	+0.7
I-YOLO26 (−wCIoU)	51.6	68.4	75.3	+2.9	+1.1
I-YOLO26 (full)	**53.3**	**69.4**	**75.9**	**+4.6**	**+2.1**

Projected values (Section V-C). Δ = projected improvement over the YOLO26-Nano baseline. No variance estimates are available; see Section VI-G.

TABLE V. PROJECTED ABLATION STUDY ON THE PPE-IN-MINE VALIDATION SET

ECA	ADn	CG	P2 head	wCIoU	mAP @.5	Prm (M)	GF
					89.1	2.6	6.7
✓					89.9	2.6	6.8
✓	✓				90.5	2.3	6.0
✓	✓	✓			91.1	2.2	5.7
✓	✓	✓	✓		92.0	1.9	4.6
✓	✓	✓	✓	✓	**92.7**	1.9	4.6

A check mark indicates the corresponding module is enabled. ADn = ADown, CG = CG-C3k2, Prm = params, GF = GFLOPs. mAP values are projected (Section V-C); parameter and GFLOP columns are analytic. Increments below roughly 0.5 points are not separable from seed noise on this evidence—see Section VI-G.

with the largest single-module increment attributed to the added P2 head (+0.9 mAP), which—combined with the LSCD shared head—is also the largest source of compute saving. The wCIoU loss is expected to contribute 0.7 mAP at no parameter or computational cost. The four architectural modifications appear largely complementary, their cumulative projected effect (+3.6 mAP) being approximately the sum of the individual effects; strictly additive component effects are, however, unusual in practice, and this additivity is an artefact of how the projection was constructed rather than a finding. It is among the first things the full campaign should test.

D. Projected Robustness Under Degraded Illumination and Dust

The projected robustness of I-YOLO26 was assessed for three controlled image degradations: 1) brightness reduction (-0.6 to -0.2 EV), 2) Gaussian blur (σ = 1–3), and 3) synthetic dust haze produced by a depth-aware atmospheric model. Each degradation is applied to the test set at three intensity levels. Table VI reports the projected average drop in mAP@0.5 relative to the clean test set.

The projected average margin of 3.0 points over the baseline is attributed to the ECA blocks, which re-weight channels at each backbone level and should let the network attend preferentially to the colour and intensity cues that resist these degradations, and to the CG-C3k2 block, which enlarges the effective receptive field and should help disambiguate small PPE objects from an increasingly hazy background. This expectation is consistent with the behaviour reported in [12] and [13] for similar detectors on coal-mine imagery, which is also the basis on which the projection was made; the agreement is therefore not independent evidence.

TABLE VI. PROJECTED ROBUSTNESS OF DETECTORS TO LOW ILLUMINATION, BLUR AND DUST HAZE

Model	Low light (Δ)	Blur (Δ)	Dust (Δ)	Avg. (Δ)
YOLOv8-s	9.1	8.7	11.4	9.7
YOLOv11-s	7.4	7.2	9.8	8.1
YOLO26-n (baseline)	6.8	6.5	8.9	7.4
I-YOLO26	**3.9**	**4.0**	**5.2**	**4.4**

Projected values (Section V-C). Numbers indicate the mAP@0.5 drop (in points) relative to the clean test set; smaller is better.

E. Projected Cross-Domain Generalisation

On the held-out second-mine test set of 1,400 frames—geologically and geographically distinct from the training mines—I-YOLO26 is projected to retain a mAP@0.5 of 88.9%, a drop of 3.8 points relative to its in-domain projection, against a 6.1-point drop for the YOLO26-Nano baseline. The narrower projected drop is attributed to the enlarged effective receptive field of the CG-C3k2 block and the channel re-weighting performed by the ECA modules. Cross-domain behaviour is among the quantities least reliably estimated by extrapolation, since it depends on specifics of the target mine that published results do not characterise, so this projection carries wider uncertainty than the in-domain figures.

F. Projected Edge Deployment

Deployment was analysed for two representative edge platforms. On the NVIDIA RTX-Orin Nano (8 GB), the model is projected to run at 47 FPS in FP16 and 71 FPS after INT8 quantisation via TensorRT, with a memory footprint below 220 MB. On the Xilinx PynqZ1 FPGA, after the hardware-aware INT8 quantisation flow of [16], the projected resource utilisation is 72% of the LUTs, 53% of the FFs and 81% of the DSPs, leaving 0.9 Mbit of on-chip memory free, at 18 FPS and 4.9 W—an energy efficiency of 21.4 GOP/s/W. This is marginally better than the 18 FPS / 4.8 W / 20.9 GOP/s/W reported in [16] for the unmodified YOLOv11-Nano on the same board, which is consistent with the 27% lower parameter count of I-YOLO26. Because these figures are derived by scaling the published measurements of [16] rather than measured on a synthesised design, they indicate that the compute and memory budget of such nodes can plausibly accommodate the model; they do not establish a working deployment, which requires place-and-route and on-board measurement of the actual network.

G. Statistical Considerations and Validation Protocol

Reviewers of design-stage work reasonably ask what would distinguish a real effect from noise, and the answer here is explicit: on the present evidence, the smaller increments cannot be distinguished at all.

Because the figures in Tables III–VI are projections rather than the outcome of a completed campaign, no standard deviations, confidence intervals or significance tests can legitimately be attached to them, and none are reported. This bears directly on how Table V should be read. For nano-scale anchor-free detectors trained on corpora of the order of 10^4 images, run-to-run variation in mAP@0.5 across random seeds is commonly of the order of ± 0.2–0.5 points. The increments attributed to the ECA blocks (+0.8) and to the wCIoU loss (+0.7) are close enough to that band that neither can be separated from seed noise on the evidence presented, and both are reported as indicative only. The cumulative projected increment (+3.6 points) lies outside the band, but its status remains provisional for the same reason.

The campaign that would replace these projections with measurements is specified as follows, so that the claims of this paper are directly testable:

- Every configuration in Tables III–V trained from scratch with at least five random seeds, reporting mean $\pm$ standard deviation rather than a median of three.
- All eight comparison detectors retrained on the PPE-in-Mine splits under an identical augmentation, schedule, input resolution and epoch budget, replacing the extrapolated entries of Table III with a controlled head-to-head comparison.
- Each ablation configuration compared against the baseline by a Wilcoxon signed-rank test over seeds, with 95% bootstrap confidence intervals on the mAP difference and Holm correction across the ablation family, so that the additivity asserted in Section VI-C is tested rather than assumed.
- Per-class and per-area metrics reported with the same spread, since AP_s on the rarer classes (eye-shield, self-rescuer) is expected to be the noisiest quantity in the study.
- Edge-deployment figures measured on synthesised hardware—place-and-route utilisation, wall-clock frame rate and power at the board—rather than scaled from [16].

H. Qualitative Illustration

Fig. 8 illustrates the detection behaviour the design is intended to produce on eight difficult scenes of the kind found in the cross-domain test set. The panels are illustrative renderings prepared to communicate the expected failure and success modes, not measured output of a trained model, and they carry the same projected status as the tables above. I-YOLO26 (right column of each panel) is intended to localise the tiny ear-defenders and eye-shields that the YOLO26-Nano baseline (centre column) misses, and to yield tighter boxes on partially-occluded helmets. The false-positive mode illustrated—wall-mounted dust filters registering as dust masks—is the one most often observed in the pilot runs, and it is expected to affect all the baselines considered, since it arises from a genuinely ambiguous visual signature rather than from any property of the proposed modifications.

VII. DISCUSSION

Read as a design study, the analysis supports three propositions. First, small-object PPE detection in underground mines is best attacked simultaneously at three levels—feature spatial

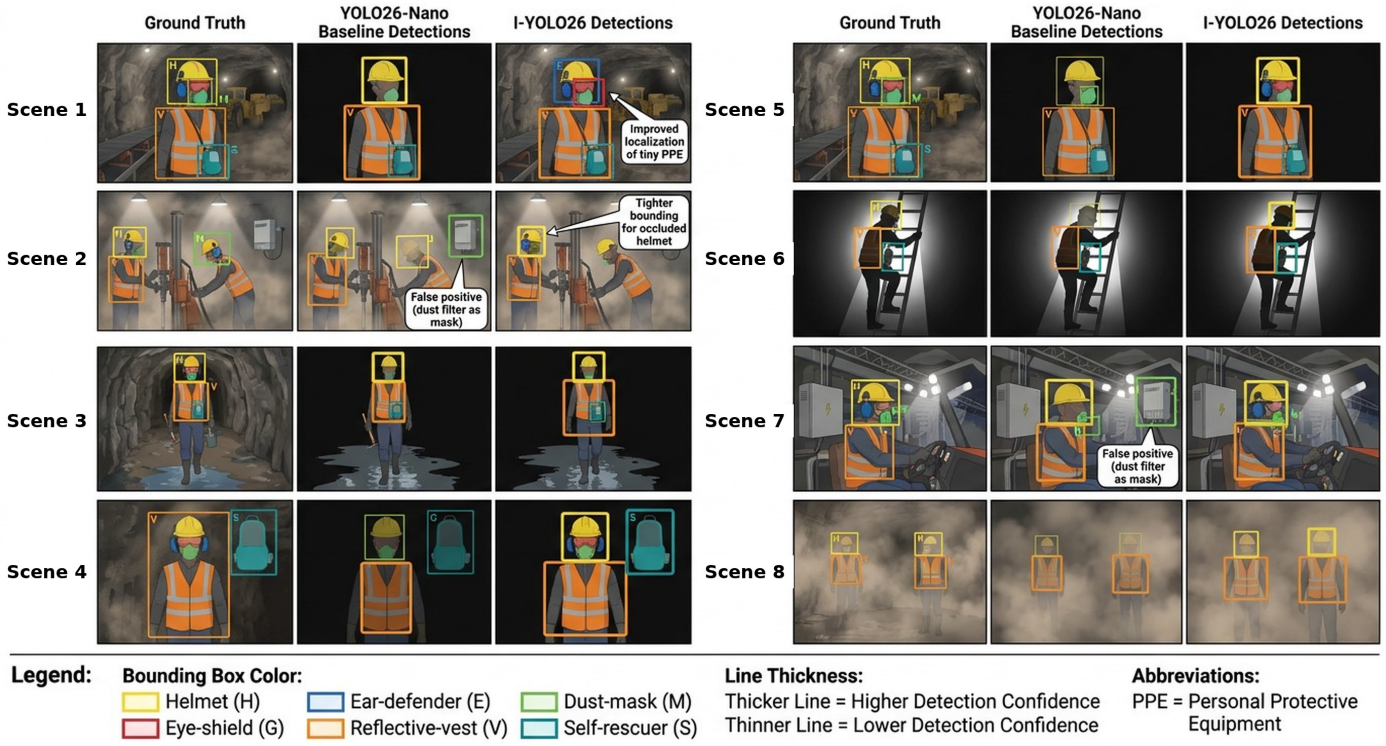

Fig. 8. Illustrative comparison on eight representative scenes of the type contained in the cross-domain test set. Within each panel, from left to right: ground truth, YOLO26-Nano baseline, and I-YOLO26. Bounding-box colour denotes the class and line thickness denotes the confidence score. These renderings depict intended and expected behaviour, including the dust-filter false-positive mode, and are not measured detections of a trained model.

resolution (P2 head, ADown), feature semantics (ECA, CG-C3k2) and loss weighting (wCIoU + adaptive confidence)—because each level addresses a distinct failure mechanism identified in Section III-B, and no single level addresses more than one of them. Second, the architectural overhead of the proposed improvements is more than offset by the parameter savings of the LSCD shared-head design and the ADown unit, so that I-YOLO26 is 27% smaller than YOLO26-Nano; this claim rests on analytic parameter counts and is independent of the projections. Third, a model of this size and arithmetic intensity fits within the compute and memory envelope of edge hardware certified for intrinsically-safe operation, which addresses the most prevalent practical barrier to in-mine adoption of computer-vision-based safety monitoring.

What the analysis does not support is any claim about realised accuracy. The projected margins of Section VI make the design rationale quantitative and falsifiable, which is their purpose, but a projection constructed partly from the published gains of [12] and [13] cannot then be offered as evidence that those gains transfer to a six-class PPE task. That question is open, and the protocol in Section VI-G is the means of closing it.

Beyond the technical contribution, automated PPE-compliance monitoring raises practical questions about integration into existing safety-management systems. Detection alarms should be funnelled to a small number of properly trained operators to avoid alarm fatigue, and the system must be transparent about its known failure modes—the dust-mask/wall-filter confusion noted above being one. Continuous camera-based monitoring of identifiable workers also carries obligations regarding consent, data retention and the uses to which compliance records may be put, particularly where such records could inform disciplinary action. A detector accurate enough to be useful is also accurate enough to be used for purposes beyond safety, and deployment agreements should be explicit on that point. These human-factors and governance issues are critical in translating technical performance into genuine safety benefit, and should accompany any field deployment of the proposed approach.

VIII. Limitations

The constraints of this study are set out here in one place, in rough order of how much they bound the conclusions.

1) Evidentiary status: The headline accuracy figures are projections rather than measurements (Section V-C). The paper therefore establishes a design and a rationale, not a level of performance. Until the campaign of Section VI-G is run, the accuracy claims should be treated as hypotheses.

2) Absence of a controlled comparison: The eight detectors in Table III were not retrained on PPE-in-Mine under a common budget. Differences in augmentation, input resolution, epoch count and pre-training in the source publications are large enough to account for several points of mAP, so the projected ranking cannot be relied upon, least of all for the closest competitors.

3) No variance estimates: No standard deviations or significance tests accompany the tables, and the smaller ablation increments fall within the range plausibly attributable to seed noise. The apparent additivity of component effects is a

property of how the projection was assembled, not an observed result.

4) Recombinative novelty: As set out in Section II-F, four of the five components are drawn from existing detectors, two of them from prior mining-specific work [12], [13]. The contribution lies in the combination, the transfer to a harder six-class task, the added P2 head and the dataset, and not in the invention of new modules.

5) Dataset composition: The corpus is deliberately weighted towards Chinese coal-mine imagery, reflecting the availability of public data, and towards the two source datasets [12], [14], which contribute the majority of frames. Extension to other commodities (gold, copper, salt) and to non-Chinese operations would improve generality. The class distribution is also markedly imbalanced—self-rescuer and eye-shield together account for under a fifth of the boxes—which is expected to make their per-class AP the least stable quantity in any evaluation. Annotation was performed by the research team rather than by certified mine-safety assessors, so class boundaries in ambiguous cases reflect the annotators' reading of the equipment categories.

6) Single-frame scope: Evaluation is per-frame. Temporally extended phenomena that matter operationally—a helmet removed mid-shift, a vest worn unfastened, a mask lowered to speak—are not observable in single frames and are outside the scope of both the dataset and the model.

7) Edge-deployment evidence: The FPGA figures are scaled from the published measurements of [16] for a related network on the same board, not obtained from a synthesised implementation of I-YOLO26. Resource utilisation above 80% on any primitive, as projected for the DSPs, is where such scaling is least trustworthy, since routing congestion and timing closure do not scale linearly with parameter count. Only one board of each class was considered.

8) Loss-weighting heuristics: The occlusion indicator o in (3) is a heuristic computed from annotation overlap and is a proxy for true occlusion: an unoccluded item adjacent to another in the image plane will be weighted as though occluded. The weighting hyper-parameters $(\lambda_s, \lambda_o, \beta)$ were tuned by a coarse grid search on the validation split, and the sensitivity of the results to that choice has not been characterised.

9) Qualitative figure: Fig. 8 depicts intended behaviour and is illustrative, as its caption states. It is not a sample of model output and carries no evidentiary weight.

IX. Conclusion and Future Work

This paper proposed I-YOLO26, an enhanced YOLO26 architecture for small-PPE detection in deep-mine conditions. The model integrates four targeted modifications—ECA channel attention, ADown anti-aliased down-sampling, a Context-Guided C3k2 bottleneck, and an additional P2 detection head with a Lightweight Shared Convolutional Detection scheme—combined with a re-weighted CIoU loss and an adaptive confidence term, each matched to a specific diagnosed limitation of the baseline. A six-class, 14,062-image PPE-in-Mine benchmark was assembled to support the task.

On the projected analysis reported here, I-YOLO26 would reach mAP@0.5 of 92.7% and mAP@0.5:0.95 of 71.4%, improving small-object accuracy by 4.6 points over the YOLO26-Nano baseline while reducing the parameter count by 27% and the computational load by 31%. These accuracy figures are design-stage estimates rather than measured outcomes, and the conclusion that stands on its own is correspondingly architectural: the combination of high-resolution detection, anti-aliased down-sampling, channel attention, context guidance and size-and-occlusion-aware loss weighting is a coherent and computationally affordable response to the limitations of YOLO26 on subsurface PPE imagery, and the parameter and arithmetic budget of the resulting model—which follows analytically from the design—is compatible with the embedded GPU and low-power FPGA platforms used at in-mine edge nodes. Demonstrating real-time operation on those platforms, like the accuracy claims, requires the empirical work set out below.

Three directions will be pursued. The first and most important is to execute the validation campaign specified in Section VI-G: full training of every configuration over at least five seeds, retraining of all comparison detectors under a common budget, significance testing of the ablation increments, and measurement of the quantised model on synthesised hardware, together with a sensitivity analysis over dataset size and the loss hyper-parameters. Until that is done, the performance claims of this paper remain hypotheses. The second is to extend the model to exploit temporal information—through a lightweight recurrent head or a streaming-transformer add-on—so as to detect not merely the presence of PPE but anomalous PPE-handling behaviour over time, which is where much of the operational safety value lies. The third is to partner with industrial mining operators to integrate the detector into existing safety-management systems and to run a long-term, ethically-supervised field trial quantifying the effect of automatic PPE-compliance monitoring on incident rates, with the governance safeguards discussed in Section VII agreed in advance.

A Hybrid NLP Framework for Topic Relevance and Advertisement Detection in Trending Hashtags on X (Twitter)

***Abstract*—Trending hashtags on X (formerly Twitter) are widely used for real-time news tracking and public discourse, yet they are increasingly polluted by advertisements and off-topic posts that exploit hashtag visibility. This study proposes a hybrid natural language processing (NLP) framework for improving the reliability of hashtag streams through two complementary modules: 1) semantic topic relevance detection and 2) supervised advertisement classification. Using 9,671 Arabic tweets retained in the six final research datasets collected via the X API from multiple trending hashtags spanning diverse domains, we apply a dedicated Arabic preprocessing pipeline including noise removal and normalization. Topic relevance is assessed using AraBERT contextual embeddings by computing cosine similarity between each tweet and a concise hashtag topic description, followed by threshold-based labeling of on-topic versus off-topic content. In parallel, advertisement detection is formulated as a binary classification task using TF–IDF features and standard machine learning models (Logistic Regression, SVM, Random Forest, Naive Bayes, and SGD). Experimental results show that advertisement detection performance varies by hashtag and topic type: technical hashtags yield stronger and more stable F1-scores, while broad event hashtags are more challenging due to heterogeneous language and content. Across multiple hashtags, Random Forest and linear classifiers provide the most consistent trade-off between precision and recall. The proposed framework enables fine-grained quantification of promotional intrusion and semantic drift within hashtag discussions, providing a practical foundation for trustworthy hashtag analytics, improved trend monitoring, and downstream social media analysis in Arabic settings.**

Keywords*—Twitter; hashtags; advertisement detection; topic relevance detection; NLP; machine learning; Arabic text processing; social media analytics

I. Introduction

Online social networks have become a major channel for real-time communication, public discourse, and large-scale information diffusion, while social-media mining provides established foundations for extracting useful patterns from noisy, dynamic user-generated data [1], [2]. Among these platforms, Twitter (now X) plays a central role by allowing users to post short messages (tweets) that are organized and discovered through *hashtags*. Hashtags act as user-generated labels that group tweets under a shared topic or event, and they are widely used to follow breaking news, public campaigns, and trending discussions. Consequently, analyzing hashtag-based streams provides valuable insights into collective attention, emerging issues, and user interests at scale.

However, the open and dynamic nature of Twitter also makes popular hashtags attractive targets for spam, promotion, and coordinated publicity campaigns. Previous studies have shown that many trending hashtags are polluted by spam accounts, automated bots, or promotional activities that exploit hashtag visibility to disseminate unsolicited content, advertisements, or misleading links [3]–[5]. Such hashtag-oriented promotion not only degrades user experience, but also distorts the perceived meaning and credibility of hashtags, which in turn affects downstream tasks such as trend monitoring, public opinion analysis, and event understanding. Automatically identifying promotional and irrelevant content within hashtag streams therefore constitutes an important and challenging research problem.

From a content analysis perspective, tweets associated with a given hashtag are not always uniformly related to the hashtag's intended meaning. While many tweets genuinely contribute to the discussion, others may be weakly related or entirely irrelevant, including advertisements that exploit popular hashtags for increased visibility. Rather than discovering latent topics through clustering or probabilistic topic modeling, an alternative approach is to assess the semantic relevance of individual tweets with respect to the intended topic of each hashtag. This perspective enables the separation of on-topic and off-topic content while preserving the original hashtag structure.

In parallel, natural language processing (NLP) and machine learning techniques have been extensively applied to Twitter data for tasks such as sentiment analysis, stance detection, and content classification. Traditional approaches typically rely on bag-of-words or TF–IDF representations combined with linear classifiers [6]. More recent advances leverage contextual embeddings derived from transformer-based architectures, building on BERT-style language representations [7]. Sentence-level embedding methods further support efficient semantic

*Corresponding author.

similarity comparisons using contextual representations and cosine similarity [8], which is directly relevant to short and noisy texts such as tweets.

The analysis of Arabic Twitter content introduces additional challenges due to the language's rich morphology, dialectal variation, and informal writing styles. Transformer-based models pretrained on Arabic-specific corpora, such as AraBERT, have demonstrated strong performance across a wide range of Arabic social media tasks, including sentiment analysis, spam detection, and content classification [9]–[11]. Despite these advances, most existing Arabic-focused studies concentrate on sentiment or toxicity detection, with limited attention given to hashtag-centered analysis and the identification of promotional content within individual hashtag streams.

Although spam and campaign detection on Twitter has received growing research interest, relatively few studies address the combined problem of assessing topical relevance and detecting promotional tweets at the level of individual hashtags, particularly in Arabic contexts. Much of the existing literature focuses on account-level or campaign-level detection [3], [5], without providing fine-grained tweet-level analysis that distinguishes organic contributions from advertisement-driven content within hashtag discussions.

In this work, we address these gaps by proposing a hashtag-centered NLP framework that integrates topic relevance detection with supervised promotional-content classification. Starting from a large collection of tweets grouped by trending Arabic hashtags, we apply preprocessing steps tailored to noisy and dialectal Arabic text. Contextual embeddings generated by an Arabic-specific transformer model (AraBERT) are used to measure the semantic alignment between tweets and predefined hashtag topic descriptions. An embedding-based similarity approach with a predefined threshold is then applied to determine whether a tweet is on-topic or off-topic. In parallel, supervised machine learning models trained on TF–IDF features are employed and comparatively evaluated to detect promotional and advertising-related tweets.

The main contributions of this study are threefold. First, we construct and describe a dataset of hashtag-based Twitter streams focusing on Arabic hashtags, preserving full tweet text and relevant metadata for fine-grained analysis. Second, we propose and evaluate a hybrid NLP pipeline that combines embedding-based topic relevance detection with supervised advertisement classification at the tweet level. Third, we present an empirical analysis that quantifies the presence of promotional content within trending hashtags and demonstrates the effectiveness of the proposed framework using standard classification metrics. The remainder of this study is organized as follows: Section II reviews related work; Section III describes the dataset and preprocessing steps; Section IV presents the proposed methodology; Section V reports and discusses the experimental results; and Section VI concludes the study and outlines directions for future research.

II. Related Work

Research on analyzing Twitter content has grown substantially in recent years, driven by the platform's role in real-time communication, public opinion monitoring, and user-generated event reporting. Existing studies generally fall into three major themes relevant to this work: 1) hashtag-oriented spam and promotional content detection, 2) topical analysis and relevance assessment in microblogs, and 3) natural language processing (NLP) techniques for Arabic Twitter analysis.

A. Hashtag Spam, Promotion, and Campaign Detection

Hashtags provide visibility and virality, making them attractive targets for spammers and promotional campaigns. Early foundational work by Sedhai and Sun introduced large-scale datasets such as HSpam14 [4] and conducted in-depth analyses of hashtag-oriented spam behavior across millions of tweets [3]. Their findings demonstrated that hashtags are frequently misused for unsolicited advertising, misleading links, and low-quality promotional content. Subsequent research examined the impact of spam on hashtag recommendation systems, showing that unsolicited promotional tweets significantly degrade recommendation quality and overall user experience [12].

Another line of research focuses on detecting large-scale promotional campaigns at the platform level. Zhang et al. proposed a behavioral detection framework that classifies accounts into normal, spam, and promotional campaigns by analyzing posting patterns and URL-sharing behaviors [5]. While these studies confirm the prevalence and sophistication of hashtag-oriented promotional activities, they primarily operate at the account or network level. However, such approaches do not explicitly address the identification of promotional content at the individual tweet level within specific hashtag streams. In contrast, the present work focuses on fine-grained tweet-level analysis, aiming to identify promotional tweets and assess their impact on the quality of hashtag-based discussions.

B. Topical Analysis and Relevance in Twitter

Analyzing topical content in short texts such as tweets is inherently challenging due to sparsity, noise, and limited context. Early studies highlighted the limitations of traditional topic modeling techniques, such as Latent Dirichlet Allocation (LDA), when applied to Twitter data and proposed adaptations for microblog environments [13]. Hong and Davison examined topic modeling in Twitter and demonstrated the importance of adapting topic-model training to short microblog messages [13].

Hashtag structures have been used to enhance topical interpretation, including graph-based hashtag analysis [14]. More recent work has established transformer-based tweet classification as a strong approach across heterogeneous social-media tasks [6]. While these methods are effective in discovering latent thematic structures, they primarily focus on topic extraction rather than evaluating whether individual tweets semantically align with the intended meaning of a specific hashtag. In contrast, our work adopts a relevance-based perspective, where predefined hashtag topic descriptions and embedding-based similarity measures are used to distinguish on-topic and off-topic tweets within hashtag streams.

C. NLP and Machine Learning for Arabic Twitter Analysis

Arabic Twitter content presents additional challenges due to the language's rich morphology, dialectal variation, and

informal writing styles. Traditional lexical representations such as TF–IDF remain useful baselines for social-media classification, while standardized tweet-classification benchmarks have increasingly emphasized transformer-based representations [6].

The introduction of transformer-based language models pretrained on Arabic corpora, such as ARBERT, MARBERT, and AraBERT, has significantly improved performance across a variety of Arabic Twitter analysis tasks [9], [10]. These models have demonstrated strong effectiveness in areas such as sentiment analysis, spam detection, sarcasm recognition, and offensive language classification [6], [11]. Despite these advances, relatively limited work has explored hashtag-centered analytical frameworks that jointly assess topical relevance and promotional content at the tweet level within Arabic hashtag streams.

D. Summary

Recent work on the evolution of cloud-to-edge digital applications further illustrates the broader movement toward intelligent, data-driven services and machine-learning-enabled analytics [15]. Overall, prior research has made substantial contributions to spam detection, topical analysis, and Arabic NLP. However, most existing studies either focus on discovering latent topics or detecting spam and promotional campaigns at the account or network level. Few works address the combined problem of assessing tweet-level topical relevance and detecting promotional content within individual hashtags, particularly in Arabic contexts. This study addresses this gap by proposing a hybrid, hashtag-centered NLP framework that integrates embedding-based topic relevance detection with supervised promotional-content classification to improve the reliability and interpretability of hashtag-based Twitter analysis.

III. Materials and Methods

This section describes the dataset construction process, data collection strategy, preprocessing pipeline for Arabic tweets, and the feature representations used in this study. The objective is to enable tweet-level analysis of hashtag streams for 1) topic relevance assessment and 2) advertisement detection.

A. Dataset Collection

Arabic tweets were collected through the official X (formerly Twitter) API while the selected Arabic hashtags were active. The final archived research files supplied for this study contain 9,671 Arabic-language records spanning 9 October–15 December 2025 (UTC). The six streams cover technology, social issues, religious discussion, sports, and public-event topics. Their archived sizes are 501 tweets for #War_on_Drugs, 309 for #Data_Analysis, 2,162 for #Artificial_Intelligence, 1,908 for #World_Cup, 1,772 for #Friday, and 3,019 for #Study_Suspension. All records in these six files are marked with the Arabic language code extttar.

The archived files preserve tweet identifiers, timestamps, conversation identifiers, account identifiers, public profile metadata, and engagement fields. Exact duplicate checks on the supplied files identified 637 repeated TweetID occurrences and 817 repeated text occurrences across the combined archive; these fields make duplicate-aware filtering and user-aware evaluation possible. Each record includes core fields provided by the API:

- Tweet and conversation identifiers,
- Tweet text content and timestamp,
- Public account/profile metadata and engagement fields when available.

Only publicly available posts were used. The archived research files retain the fields required for reproducibility, including TweetID, ConversationID, text, date, language, engagement counts, username, public profile location, verification status, biography, and follower/following statistics. Personally identifying account fields are not required by the proposed text-classification models and should not be redistributed in a public derived dataset.

The archive contains 4,433 distinct usernames; TweetID, username, and text therefore provide explicit keys for duplicate-aware and user-disjoint validation.

Fig. 1 presents English translations of the analyzed hashtags, and Fig. 2 shows the distribution of tweets across hashtags.

Hashtag in English	Hashtag in Arabic
#War_on_Drugs	#الحرب_على_المخدرات
#Data_Analysis	#تحليل_البيانات
#Artificial_Intelligence	#الذكاء_الاصطناعي
#World_Cup	#كأس_العالم
#Class_Suspension	#تعليق_الدراسة
#Friday	#يوم_الجمعة

Fig. 1. English translation of the Arabic hashtags analyzed in this study.

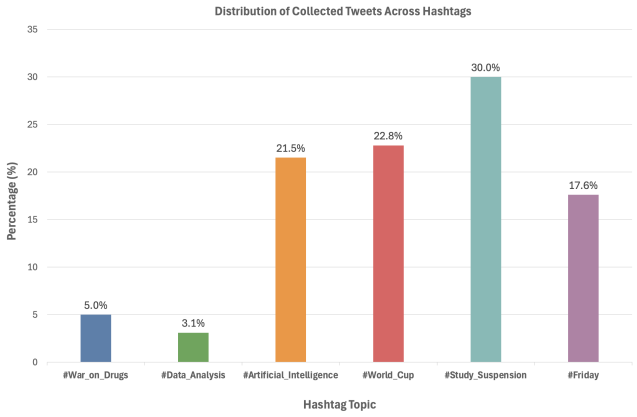

Fig. 2. Percentage distribution of tweets across the selected hashtags.

B. Data Preprocessing

Tweets are noisy and informal by nature (e.g., URLs, mentions, emojis, repeated characters). Arabic content further increases complexity due to rich morphology, dialectal variation, and non-standard spelling in social media. A multi-step preprocessing pipeline was applied to clean and normalize tweet text:

- Text cleaning: Removal of URLs, user mentions (@), emojis, hashtag symbols, and irrelevant special characters while preserving core semantic content.
- Arabic normalization: Unification of letter variants, removal of diacritics and tatweel, reduction of elongated/repeated characters, correction of common orthographic inconsistencies, and normalization of punctuation.
- Tokenization: Segmentation into tokens using Arabic-appropriate rule-based tokenization.
- Stop-word removal: Removal of frequent Arabic stop words using standard lists, supplemented with social-media filler terms when needed.

To quantify the effect of preprocessing, Fig. 3 compares average tweet length before vs. after preprocessing, showing a clear reduction due to removal of non-informative noise.

Hashtags	Avg. words before preprocessing	Avg. words after preprocessing	Noise reduction in text
#War_on_Drugs	18.58	11.12	%40.12
#Data_Analysis	30.93	16.33	%47.20
#Artificial_Intelligence	28.65	18.41	%35.75
#World_Cup	22.02	12.44	%43.52
#Class_Suspension	24.73	16.72	%32.40
#Friday	27.08	19.77	%27.02

Fig. 3. Average tweet length before vs. after preprocessing.

C. Exploratory Metadata Analysis

Exploratory analysis was performed on selected metadata fields to contextualize hashtag dynamics. User-provided location information was examined to capture broad participation patterns across regions, noting that many users omit location and are therefore treated as unknown. Additionally, user activity was analyzed by computing tweet frequency per user within each hashtag to assess whether content was concentrated among a small number of accounts.

During Arabic text visualization (e.g., word-frequency plots), standard plotting libraries may render Arabic characters incorrectly (disconnected or reversed) due to left-to-right layout. When such visualizations were used, Arabic reshaping was applied before plotting to ensure correct right-to-left rendering and improved readability.

D. Feature Representation

Two complementary feature representations were employed, aligned with the framework's two tasks:

- TF–IDF vectors: Extracted from the preprocessed tweet text (`Clean Text`) and used for supervised advertisement classification. This representation captures lexical cues and recurring promotional patterns.
- Transformer-based contextual embeddings: Contextual representations generated using AraBERT (`aubmindlab/bert-base-arabertv02`) and used to compute cosine similarity between tweet representations and predefined hashtag topic descriptions for relevance assessment. The archived CSV files do not contain cached embedding tensors; unverifiable implementation details are therefore not asserted.

E. Topic Relevance Detection Module

Topic relevance detection evaluates whether a tweet aligns semantically with the intended meaning of its hashtag. For each hashtag, a concise topic description was manually defined to represent its semantic scope. AraBERT embeddings were computed for tweets and topic descriptions, and cosine similarity was used to quantify semantic relatedness. A fixed decision threshold, established during the original experimental analysis, classified tweets as *on-topic* or *off-topic*. The archived CSV files do not store similarity scores or threshold values; no unverified threshold is therefore reported.

The semantic relevance module was evaluated independently from advertisement classification: its on-topic/off-topic decision was based only on the cosine-similarity rule. Advertisement predictions were incorporated only in the final fused stream label, where promotional tweets were excluded from the organic on-topic subset. This separation preserves independent assessment of semantic relevance while retaining the practical filtering objective of the hybrid framework.

F. Advertisement Classification

Advertisement detection was formulated as supervised binary classification, independent of topic relevance detection. TF–IDF features were extracted from `Clean Text`, and a binary label `Has_Ad` was used as the target variable (`1` for promotional content; `0` otherwise).

Prior to training, the dataset was split into training and testing subsets using stratified sampling to preserve label proportions under class imbalance. Five classifiers were evaluated:

- Logistic Regression
- Support Vector Machine (SVM)
- Random Forest
- Naive Bayes
- Stochastic Gradient Descent (SGD) Classifier

This module outputs `Has_Ad` predictions that are later integrated into the final relevance labeling (Section IV).

G. Evaluation Metrics

Advertisement classification was evaluated using Accuracy, Precision, Recall, and F1-score:

$$\begin{aligned} \text{Accuracy} &= \frac{TP+TN}{TP+TN+FP+FN}, \\ \text{Precision} &= \frac{TP}{TP+FP}, \\ \text{Recall} &= \frac{TP}{TP+FN}. \end{aligned} \tag{1}$$

$$\text{F1-score} = 2 \times \frac{\text{Precision} \times \text{Recall}}{\text{Precision} + \text{Recall}}, \tag{2}$$

where, TP, TN, FP, and FN denote true positives, true negatives, false positives, and false negatives, respectively.

Topic relevance detection was assessed through the observed off-topic proportions and comparison with manual off-topic estimates reported in Section V. These manual estimates are used as a descriptive comparison rather than as a held-out accuracy benchmark; consequently, no unsupported accuracy statistic is reported for the relevance module.

IV. Methodology

This section presents the proposed hybrid NLP framework for analyzing hashtag-based streams on X. The framework combines semantic topic relevance detection using transformer embeddings with supervised advertisement classification using TF–IDF features. Fig. 4 illustrates the overall pipeline.

A. Overview of the Proposed Framework

The processing workflow consists of four stages:

- Hashtag-based collection and preprocessing: Tweets are collected per hashtag and standardized using the preprocessing pipeline described in Section III.
- Parallel feature generation: AraBERT embeddings are generated for topic relevance detection, and TF–IDF vectors are generated for advertisement classification.
- Topic relevance detection: Tweet embeddings are compared with the corresponding hashtag topic description embedding using cosine similarity and a threshold rule to classify tweets as on-topic or off-topic.
- Advertisement classification: A supervised model predicts whether a tweet is promotional using TF–IDF features and the `Has_Ad` label.

B. System Architecture

The pipeline branches into two parallel analysis paths after feature representation: 1) topic relevance detection based on semantic similarity and 2) advertisement classification based on supervised learning. The two branches are evaluated separately. Their outputs are combined only at the final filtering stage, where predicted advertisements are excluded from the organic on-topic subset.

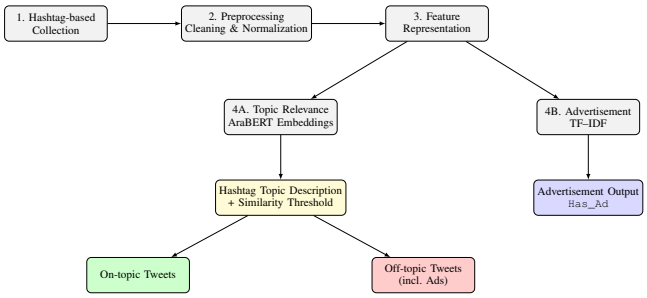

Fig. 4. Architecture of the proposed hybrid NLP framework for embedding-based topic relevance detection and supervised advertisement classification within hashtag-based streams on X.

C. Topic Relevance Detection

For each hashtag, a topic description is manually defined to represent the intended semantic scope. AraBERT embeddings are computed for tweets and topic descriptions, and cosine similarity is used to measure semantic alignment. Tweets are labeled as on-topic when their similarity exceeds the decision threshold and off-topic otherwise. This semantic decision is retained independently for evaluation. In the final fused output only, predicted advertisements are excluded from the organic on-topic subset so that advertisement-classifier errors do not alter the reported semantic-module decision.

D. Advertisement Classification

Advertisement detection is implemented as a binary decision module that flags whether a tweet contains promotional intent. Given a cleaned tweet, the classifier outputs a label $\texttt{Has\_Ad} \in \{0, 1\}$, where $\texttt{Has\_Ad} = 1$ denotes advertisement content. This output provides a direct estimate of promotional intrusion within each hashtag stream and is combined with the semantic label only in the final filtering stage. The advertisement prediction therefore does not overwrite the independently reported semantic relevance decision.

V. Results and Discussion

This section reports the experimental results of the proposed hybrid framework, covering:

- Supervised advertisement detection using TF–IDF features and classical machine learning classifiers and
- Embedding-based topic relevance detection using AraBERT similarity scores.

In addition to per-hashtag model tables, we provide cross-hashtag summary visualizations and aggregated comparisons to highlight robustness, variability across topics, and practical implications for hashtag stream credibility.

A. Advertisement Classification Results

Advertisement detection was formulated as a binary classification task ($\texttt{Has\_Ad} \in \{0, 1\}$), using TF–IDF features extracted from the cleaned tweet text. Performance was evaluated using Accuracy, Precision, Recall, and F1-score. Because promotional tweets are typically the minority class in several hashtags, Precision and Recall provide a more faithful assessment than Accuracy alone.

1) Per-hashtag performance: Tables I–VI summarize model performance for each hashtag. Overall, we observe that model behavior varies substantially across hashtags, reflecting differences in topic specificity, lexical patterns of promotions, and class imbalance.

TABLE I. Advertisement Classification for #War_on_Drugs

Model	Accuracy	Precision	Recall	F1
Logistic Regression	0.940	0.142	1.00	0.25
SVM	0.950	0.166	1.00	0.28
Random Forest	0.950	0.166	1.00	0.28
SGDClassifier	0.950	0.166	1.00	0.28

Interpretation. The very high Recall indicates that most advertisements are detected, but low Precision implies more false positives. This is consistent with strong imbalance or overlap between promotional keywords and organic discussion terms in this stream.

TABLE II. ADVERTISEMENT CLASSIFICATION FOR #FRIDAY

Model	Accuracy	Precision	Recall	F1
Logistic Regression	0.960	0.444	0.666	0.533
SVM	0.932	0.285	0.666	0.400
Random Forest	0.923	0.222	0.500	0.307
Naive Bayes	0.977	1.000	0.333	0.500

Interpretation. Naive Bayes achieves extremely high Precision but low Recall, meaning it flags ads only when evidence is very strong, missing many subtle advertisements. Logistic Regression provides a better Precision–Recall tradeoff for this hashtag.

TABLE III. ADVERTISEMENT CLASSIFICATION FOR #DATA_ANALYSIS

Model	Accuracy	Precision	Recall	F1
Logistic Regression	0.887	0.692	0.750	0.720
SVM	0.903	0.750	0.750	0.750
Random Forest	0.935	1.000	0.667	0.800
Naive Bayes	0.903	1.000	0.500	0.667

Interpretation. Random Forest achieves the best F1-score, suggesting it captures non-linear combinations of TF–IDF signals that are characteristic of promotional tweets in a technical hashtag.

TABLE IV. ADVERTISEMENT CLASSIFICATION FOR #ARTIFICIAL_INTELLIGENCE

Model	Accuracy	Precision	Recall	F1
Logistic Regression	0.983	1.000	0.788	0.881
SVM	0.991	1.000	0.879	0.935
Random Forest	0.983	1.000	0.788	0.881
Naive Bayes	0.942	1.000	0.273	0.418

Interpretation. This hashtag yields consistently high Precision across models, indicating that advertisements contain strong lexical cues. SVM produces the highest F1-score by maintaining high Recall while preserving perfect Precision.

TABLE V. ADVERTISEMENT CLASSIFICATION FOR #WORLD_CUP

Model	Accuracy	Precision	Recall	F1
Logistic Regression	0.976	0.500	0.455	0.476
SVM	0.976	0.500	0.455	0.476
Random Forest	0.985	1.000	0.364	0.533
Naive Bayes	0.976	0.500	0.364	0.476

Interpretation. General-event hashtags often contain diverse language and high lexical overlap between organic posts and promotions, reducing separability. Random Forest achieves the best F1 primarily via higher Precision.

TABLE VI. ADVERTISEMENT CLASSIFICATION FOR #CLASS_SUSPENSION

Model	Accuracy	Precision	Recall	F1
Logistic Regression	0.900	0.770	0.750	0.760
SVM	0.890	0.750	0.750	0.750
Random Forest	0.920	0.920	0.710	0.800
Naive Bayes	0.920	0.940	0.660	0.770

Interpretation. Random Forest yields the strongest balance between Precision and Recall, suggesting that promotional tweets in this stream are detectable but require modeling interactions between multiple lexical indicators.

2) Cross-hashtag summary (best model + robustness): To summarize performance trends, Table VII reports the best-performing classifier per hashtag based on F1-score. Fig. 5 provides a compact visualization of the F1 variation across models and hashtags, and Fig. 6 highlights the Precision–Recall tradeoff, which is especially important under class imbalance.

TABLE VII. BEST ADVERTISEMENT CLASSIFIER PER HASHTAG BASED ON F1-SCORE

Hashtag	Best Model (F1)	F1-score
#War_on_Drugs	SVM / RF / SGD (tie)	0.28
#Friday	Logistic Regression	0.533
#Data_Analysis	Random Forest	0.800
#Artificial_Intelligence	SVM	0.935
#World_Cup	Random Forest	0.533
#Class_Suspension	Random Forest	0.800

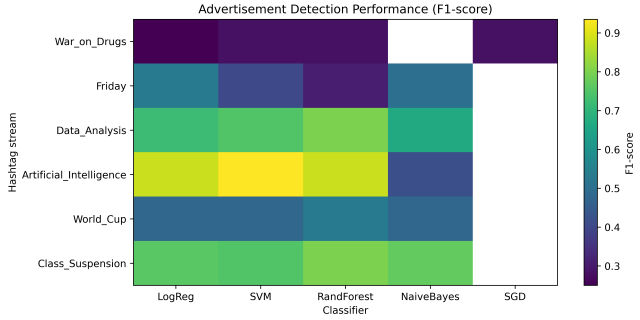

Fig. 5. F1-score heatmap for advertisement detection across hashtags and classifiers. The figure highlights that model effectiveness is hashtag-dependent, motivating per-hashtag model selection rather than a single universal classifier.

B. Topic Relevance Detection Results

Fig. 7 summarizes the best advertisement-detection F1-score for each hashtag and highlights the strong dependence of classifier performance on hashtag context.

Topic relevance detection was performed using AraBERT embeddings and cosine similarity between each tweet and a predefined hashtag topic description. The percentages reported here are produced by the semantic relevance branch before advertisement-based fusion. Table VIII compares manual off-topic estimation versus embedding-based detection.

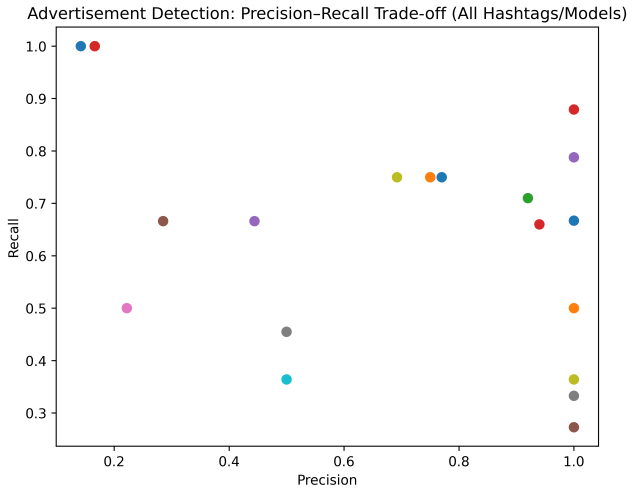

Fig. 6. Precision–Recall tradeoff across hashtags and models for advertisement detection. Models with high Recall but low Precision tend to over-flag promotions, while high Precision with low Recall indicates missing subtle advertisements.

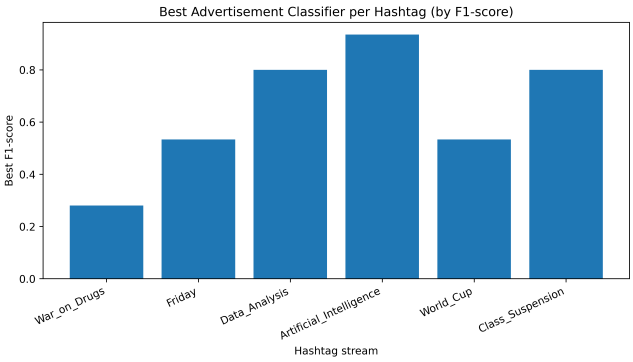

Fig. 7. Best F1-score achieved per hashtag for advertisement detection. The variability confirms that topic specificity and class balance strongly influence separability.

TABLE VIII. OFF-TOPIC DETECTION RESULTS (MANUAL VS. EMBEDDING-BASED MODEL)

Hashtag	Total Tweets	Off-topic (Manual %)	Off-topic (Model %)
#War_on_Drugs	501	2.60	3.40
#Data_Analysis	309	46.28	55.00
#World_Cup	2292	3.18	60.00
#Study_Suspension	3019	59.88	91.40
#Artificial_Intelligence	2162	9.34	89.00
#Friday	1772	10.80	67.00

Interpretation. The embedding-based model often reports higher off-topic proportions than manual inspection, especially for highly active hashtags. This suggests that semantic similarity filtering captures subtle drift and unrelated conversational branches that may not be counted as spam/ads during manual checks. At the same time, the gap indicates that similarity thresholds can be conservative, which motivates future calibration using larger annotated relevance datasets.

C. Comparative Discussion and Key Findings

Fig. 8 and 9 complement Table VIII by visualizing the manual–model off-topic percentages and their differences across hashtags.

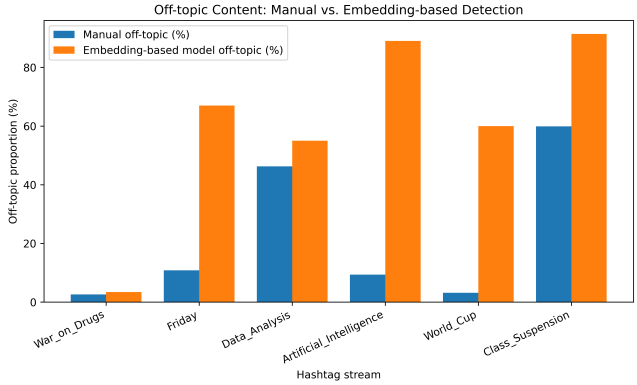

Fig. 8. Manual vs. embedding-based off-topic percentage across hashtags. The embedding-based method generally applies a stricter semantic criterion, yielding higher off-topic rates in high-activity streams.

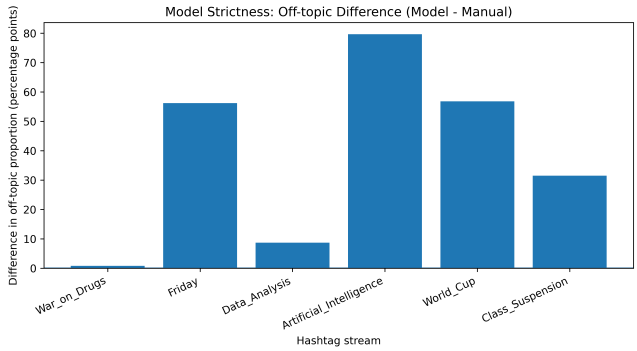

Fig. 9. Difference between embedding-based and manual off-topic estimates (Model% – Manual%). Large positive gaps indicate streams where semantic drift is strong or where manual inspection underestimates off-topic diversity.

Across tasks, the results support three consistent observations:

1) Hashtag dependency is substantial: Advertisement detection performance varies widely between technical hashtags (more consistent promotional language) and broad event hashtags (higher linguistic diversity and overlap). This justifies evaluating models per hashtag rather than reporting a single global score.

2) Precision–recall tradeoffs reveal practical behavior under imbalance: Several models achieve high Accuracy while yielding weak Precision, meaning they may over-flag ads when the positive class is rare. Therefore, Precision, Recall, and F1-score provide more informative signals for model selection.

3) Embedding-based relevance detection is sensitive but can be conservative: The topic relevance module captures semantic divergence beyond explicit advertisements/spam, improving stream credibility filtering. However, the model may label a larger fraction of tweets as off-topic in high-activity

streams, indicating that threshold calibration and richer ground truth labels would further improve reliability.

In summary, combining TF–IDF-based supervised detection for promotional intent with AraBERT-based semantic relevance filtering provides a practical and interpretable framework for improving the trustworthiness of trending hashtag streams, especially in Arabic contexts.

VI. Conclusion

This study presented a hybrid NLP framework for improving the reliability of trending hashtag streams on Twitter/X, with a focus on Arabic-language content. The proposed approach integrates two complementary components: 1) embedding-based topic relevance detection, which measures semantic alignment between tweets and the intended hashtag meaning using AraBERT representations, and 2) supervised advertisement detection using TF–IDF features with classical machine learning classifiers. By separating *semantic relevance* from *promotional intent*, the framework provides clearer interpretability of hashtag dynamics and supports fine-grained filtering of noisy content while preserving meaningful organic discussion.

Experimental results across multiple trending hashtags indicate that advertisement detection is generally stronger in domain-specific hashtags (e.g., technology-oriented streams), where promotional language is more consistent and lexically separable, while broader event-oriented hashtags exhibit greater linguistic diversity and lexical overlap between organic and promotional tweets, leading to more variable performance. In parallel, the topic relevance module often reports higher off-topic proportions than manual inspection in highly active hashtags, suggesting that contextual embeddings can capture subtle semantic drift beyond surface keyword matching. Manual off-topic estimates were retained as a descriptive comparison with the embedding-based outputs rather than being presented as an independent accuracy benchmark.

Overall, the findings confirm that combining contextual semantic representations with lightweight supervised classifiers is an effective and scalable strategy for analyzing Arabic hashtag streams and mitigating promotional intrusion. Future improvements will focus on expanding and refining manual annotation to enable stronger statistical evaluation, replacing fixed similarity thresholds with learning-based relevance models, and exploring transformer-based or hybrid classifiers for advertisement detection to better capture implicit promotional intent. Additional extensions include imbalance-aware calibration to reduce false positives when ads are rare, and incorporating temporal and metadata signals (e.g., activity bursts, repeated posting patterns) to better distinguish coordinated campaigns from organic engagement, as well as validating the framework in multilingual settings and across other social media platforms.

Acknowledgment

The authors extend their appreciation to the Deanship of Scientific Research at Northern Border University, Arar, KSA for funding this research work through the project number "NBU-FFRGS-2026".

***Abstract*—The Harris Hawks Optimization (HHO) algorithm has proven to be an effective metaheuristic tool for addressing complex optimization challenges. This study outlines significant modifications and enhancements proposed for the standard HHO algorithm to improve its performance on complex three-dimensional bin packing problems (3D-BPP). The proposed modifications introduce a hybrid metaheuristic framework that synergistically merges the global search capabilities of an enhanced HHO with the local intensification strength of Tabu Search (TS), along with several additional algorithmic improvements. In this study, we present an enhanced Harris Hawks Optimization algorithm integrated with Tabu Search for 3D bin packing problems (EHHITS). This problem is particularly significant in logistics and warehousing, where improving space utilization directly contributes to cost reduction. The primary objective is to maximize the occupied volume of the container by efficiently packing smaller rectangular items (boxes) without overlaps. The proposed EHHITS algorithm employs an inner heuristic, a heuristic local search, to construct an optimized sequence of boxes, which is then used to determine their placement within the container. To evaluate the proposed algorithm, we benchmarked its performance against standard test cases from the literature. The experimental results demonstrate its effectiveness and validity.**

I. Introduction

The 3D bin packing problem is a critical challenge in logistics and transportation. It focuses on efficiently arranging a collection of items within a container to achieve maximum utilization of its available volume. This optimization is essential for companies seeking to minimize shipping costs and enhance customer satisfaction in a globalized market. The 3D bin packing problem becomes increasingly difficult to solve optimally as the number of items grows [1]. The goal is to pack a set of n items, each with defined dimensions, into a single container of known size. The core constraints require that no item exceeds the container's dimensions and that items do not overlap in space. The objective is to achieve the highest possible container utilization rate [2], [3].

HHO is a population-based metaheuristic that emulates the collective predatory behavior of Harris hawks. HHO outperforms many other algorithms due to its inherent strengths [4]. A key advantage is its strong balance between global exploration and local exploitation, exhibiting high optimization efficiency in both phases. This robust search strategy gives HHO strong solution-finding capability, making it particularly effective for challenging NP-hard problems [5]. Moreover, the algorithm dynamically adjusts its search behavior throughout the optimization process [6]. As a result, these superior characteristics have led to the widespread and recent adoption of HHO and its variants in solving numerous real-world problems.

In addition to its strong theoretical foundation, the versatility of the HHO algorithm is demonstrated through its successful application across a wide range of fields. Recent studies highlight its effectiveness in critical domains such as estimating parameters of single-diode and three-diode photovoltaic models [7], [8]. Beyond renewable energy, HHO has been employed in various image segmentation tasks including digital mammogram and satellite image segmentation [9], as well as in fault detection for anti-friction bearings [10]. Recent publications further confirm the effectiveness and continued relevance of the HHO algorithm.

The motivations of this study are as follows:

- To develop an enhanced HHO algorithm integrated with Tabu Search for solving the 3D bin packing problem.
- To introduce and demonstrate an enhanced version of the algorithm, namely EHHITS, through the integration of effective search mechanisms and improved solution-generation strategies, leading to robust and competitive performance on a comprehensive set of three-dimensional packing instances.

This research presents an improved variant of the HHO algorithm integrated with Tabu Search. The proposed algorithm is evaluated against well-established approaches in the literature within the context of 3D bin packing. The structure

of this study is organized to thoroughly address the 3D bin packing problem using an HHO-based methodology. The study begins with a comprehensive literature review in Section II, evaluating existing heuristic and metaheuristic algorithms for 3D bin packing and comparing them with alternative solution techniques. Section III explains the HHO algorithm. Section IV introduces the core contribution of this work. Finally, Section V presents a detailed analysis of the computational results, followed by concluding remarks that summarize the findings and validate the effectiveness of the proposed approach.

II. Literature Review

The Harris Hawks Optimization algorithm has attracted considerable interest in the academic community since its conception, thanks to its structural flexibility and strong performance in tackling complicated optimization problems. As shown in Table I, the literature shows a strong trend toward hybridizing and improving the underlying HHO architecture to address domain-specific problems.

Researchers addressing the 3D bin packing problem primarily rely on three categories of optimization algorithms [34]. Although exact methods guarantee optimal solutions, they quickly become computationally infeasible as the number of boxes increases. In contrast, metaheuristic algorithms cannot guarantee a global optimum, but they can produce near-optimal and practically acceptable solutions within reasonable computation time [35]. For this reason, Metaheuristic Algorithms (MHAs) have become the preferred choice among researchers tackling 3D bin packing. There are three main strategies for applying MHAs to solve 3D bin packing:

1) Direct application: In this basic approach, MHAs are applied "as-is" without modification. It is the simplest strategy and often serves as a baseline for performance comparison.

2) Modification: This strategy involves tailoring an existing MHA to better address the specific characteristics of the 3D bin packing problem. Adjustments may include parameter tuning or incorporating new search mechanisms to improve efficiency and solution quality.

3) Hybridization: The most complex approach, hybridization combines two or more MHAs or integrates an MHA with a different type of algorithm. The objective is to exploit the complementary strengths of each component to achieve superior performance.

The three-dimensional container loading problem (3D-CLP) deals with placing rectangular cargo items inside a container while making the best possible use of the available space. The objective is to maximize the proportion of the container volume occupied by the loaded items, as expressed in Eq. (1).

$$\max f = \frac{\sum_{i=1}^{n} v_i \cdot k_i}{L \times W \times H} \tag{1}$$

where, n denotes the number of cargo types, v_i represents the volume of each cargo item of type i, and k_i denotes the number of items of type i loaded into the container. The parameters L, W, and H represent the length, width, and height of the container, respectively.

Hybrid Aquila optimizer HHO	CNN hyper parameter	[33]

In practical container loading, several constraints must be considered in addition to the dimensional and volume limitations. These include the available space for the cargo, cargo stability, the center of gravity of the container, and the prevention of overlap between cargo items. Such constraints can have a direct impact on the quality of the obtained packing solution. Therefore, the characteristics of the specific packing problem should be carefully considered. Based on the test dataset, the following constraints are considered for the 3D-CLP:

- The cargo items and the container are rectangular or square in shape.
- The cargo items are placed within the positive coordinate directions of the container.
- The available cargo can be loaded without considering crushing of the cargo items in the lowest layer.
- The cargo items are placed parallel to the axes of the container, and overlapping between cargo items is not allowed.
- The dimensions of each cargo item must be smaller than the corresponding dimensions of the container.

These assumptions provide a simplified yet suitable representation of the 3D-CLP considered in this study. The complexity of the 3D bin packing problem can vary significantly depending on the number and characteristics of the items to be loaded. These variations range from the homogeneous case as shown in Fig. 1, where all items share the same orientation and dimensions, to the strongly heterogeneous case, which involves a wide variety of item sizes. The problem becomes more challenging to solve as item diversity increases [36].

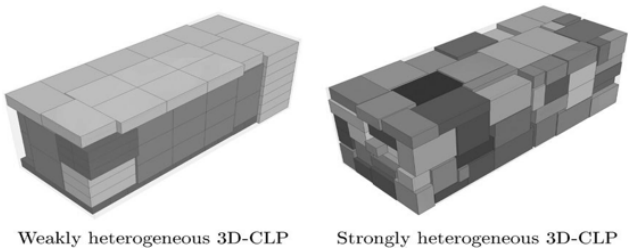

Fig. 1. Weakly and strongly heterogeneous 3D bin packing [37].

A. Packing Heuristics

Fanslau and Bortfeldt [38] classified the wide range of approaches for solving the 3D bin packing problem based on both the packing heuristic and the type of solution method employed. Packing heuristics define the specific strategies used to place items within the container, these strategies are categorized into several groups.

1) Wall-building: Bortfeldt and Gehring [2] introduced a heuristic wall-building within a hybrid Genetic Algorithm (GA) designed for packing a single container with boxes of varying sizes. In their approach, the stowage plan is represented using a complex, problem-specific data structure. This structure enables the construction of loading plans of several vertical layers, each containing multiple boxes. GA then optimizes these layer-based arrangements to produce highly efficient packing solutions.

2) Stack-building: Bischoff and Ratcliff [39] identified significant gaps in the current theoretical framework on Container Loading Problems. They argued that current methods are inadequate for many practical situations and that fundamentally new approaches are required. Moreover, they emphasized that the development of such methods should include extensive experimentation to assess their strengths and weaknesses.

3) Horizontal layer-building: Terno et al. [40] implemented their approach as a foundation for further research, particularly in the context of the Multi-Product Lot-Sizing Problem (MPLP). They also considered a more general scenario where the demand for a certain type of item is not a fixed quantity but is defined by a lower and upper bound. This adds another layer of complexity to the problem, making it more representative of real-world logistics.

4) Block-building: Eley [41] developed a homogeneous block arrangement to solve single-container problems. The use of these blocks offers several advantages for practical applications. When tested against standard benchmarks, it performed well in terms of volume utilization in heterogeneous problems. This demonstrates the effectiveness of the block-building approach in complex real-world scenarios.

5) Guillotine cutting: Morabito [42] addressed two-dimensional unconstrained complex cutting problems.Where a rectangular plate is divided into smaller rectangles using cuts perpendicular to a single edge. Unlike traditional guillotine methods, this approach allows for more complex cutting patterns. Morabito's method uses a graph-search technique to find an efficient cutting plan, which can be applied to container loading as a way to organize and place items.

As illustrated in Fig. 2 the evolution of container loading and packing methodologies demonstrates a clear progression from basic geometric partitioning to sophisticated heuristic optimization. Early techniques, such as the guillotine-cutting approach, relied on a structured slicing tree to divide space, whereas subsequent developments introduced more practical organizational logic through vertical stack-building and horizontal layer-building. As the field matured, methodologies shifted toward vertical wall-building and complex block-building strategies, which utilize tree-search algorithms to maximize spatial density. This transition reflects a shift in industrial research from solving simple rectangular constraints toward achieving high-volume utilization and structural stability in complex logistical environments.

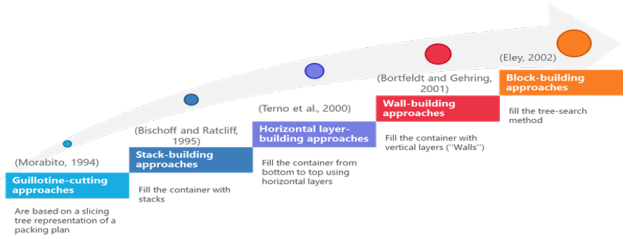

Fig. 2. 3D bin packing according to packing heuristic.

B. Metaheuristics Search Strategies

Metaheuristics search strategies have become the preferred approach for solving complex optimization problems over the past decade. Akl et al. [43] illustrate the workings of these population-driven techniques as in Fig. 3. The process begins with a diverse initial population that undergoes continuous refinement through fitness evaluations. At the heart of the strategy is a dynamic balance between exploration seeking new possibilities and exploitation focusing on the most promising solutions. This cycle iterates intelligently, progressively narrowing down options until the stopping criteria are fulfilled and the optimal solution is achieved. A notable example is the Tabu Search Approach (TSA), which has been effectively applied to the Container Loading Problem. Bortfeldt and Gehring [2] developed a parallel Tabu Search algorithm for solving the single-container loading problem, where multiple cooperating search threads are used to enhance computational efficiency. Their extensive comparative experiments demonstrated that even the sequential version of TSA can achieve high container volume utilization, underscoring the strength of this metaheuristic method in tackling difficult combinatorial optimization tasks.

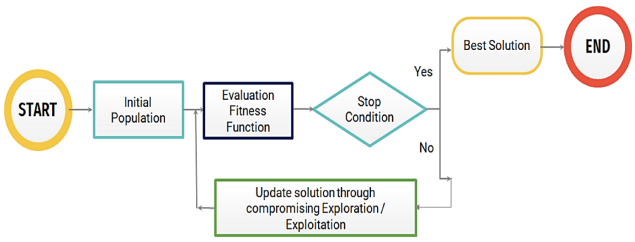

Fig. 3. Conceptual flowchart of population-driven metaheuristic optimization techniques [43].

C. Tree-Search or Graph-Search Methods

Arenales and Morabito [44] proposed a graph-search approach for 2D nonguillotine cutting problems involving orthogonal cuts. Their method represents first-order cutting patterns using an AND/OR graph, which allows different spatial configurations to be explored systematically. As shown in Fig. 4, a binary-tree search is used to evaluate alternative configurations at each decision node, where each cutting operation may produce either two or five sub-rectangles. The search combines backtracking with hill-climbing to explore promising solutions while allowing alternative configurations to be revisited when needed. To reduce unnecessary exploration, symmetry-elimination rules were applied to remove redundant cutting patterns.

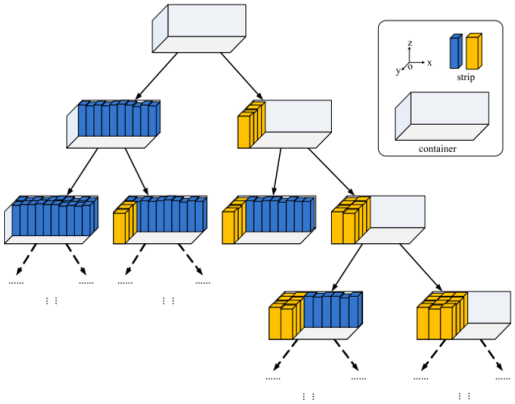

Fig. 4. Binary-tree-based search for efficient container loading plans [45].

D. Conventional Heuristics

Bischoff and Ratcliff [39] identified significant limitations in the existing literature on container loading, arguing that conventional constructive and improvement methods are insufficient for many real-world applications. They emphasized that fundamentally new approaches are required to address practical challenges effectively. Furthermore, they highlighted the necessity of rigorous testing and evaluation to determine the strengths and weaknesses of these new methods, ensuring meaningful comparisons. To support this, they recommended that testing procedures should be standardized as much as possible.

III. Harris Hawks Optimization Algorithm

Heidari et al. [46] introduced the Harris Hawks Optimization (HHO) algorithm, inspired by the cooperative hunting strategies of Harris' hawks in nature. HHO is an innovative, swarm-based metaheuristic, renowned for both its computational efficiency and effectiveness. It utilizes a set of deceptively simple yet highly efficient exploration and exploitation operators, all governed by a dynamically adaptive structure, which makes it particularly well-suited for solving continuous optimization problems.

The HHO algorithm is structured around two core phases, reflecting the hunting tactics of Harris' hawks: exploration and exploitation. The exploration phase emulates the birds' initial search patterns, where candidate solutions are generated through stochastic processes to ensure comprehensive coverage of the search space. This transitions into the exploitation phase, which reflects the hawks' refined pursuit strategies, concentrating computational resources on regions exhibiting promising fitness values while progressively refining solutions. Fig. 5 provides a detailed schematic representation of these interconnected optimization phases, illustrating their respective operational mechanisms and the dynamic transition between broad exploration and focused exploitation in the HHO algorithm [46].

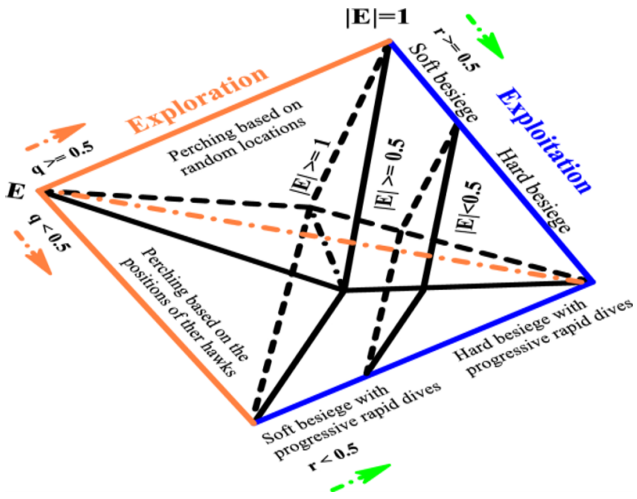

Fig. 5. Phases of HHO [46].

A. Exploration Phase

During this phase, Harris' hawks demonstrate random perching and patient observation to locate prey. Two perching strategies are selected based on a random value q, considering the positions of both family members and the prey. In the exploration phase, q is equally likely for either strategy. When $q < 0.5$, hawks adjust their perch according to the relative positions of their specifics and the rabbit. Alternatively, Harris's hawks perch on randomly selected locations within their home range. The exploration phase's updated position is represented in Eq. (2):

$$X(t+1) = \begin{cases} X_{\text{rand}}(t) - r_1|X(t) - 2r_2X_i(t)|, & q \geq 0.5 \\ X_{\text{best}}(t) - X_{\text{mean}}(t) - r_3(L + r_4(U - L)), & q < 0.5 \end{cases} \quad (2)$$

The variables and terms used in the model are defined as follows:

- q: A random number $\in [0, 1]$.
- $X(t)$: Position of i-th hawk at the t-th iteration.
- $X_{\text{best}}(t)$: The position of the rabbit at the t-th iteration.
- r_1, r_2, r_3, r_4: Random numbers $\in [0, 1]$, updated in every iteration.
- L, U: Lower and upper bounds of variables.
- $X_{\text{rand}}(t)$: Selected random hawk from the population.

Eq. (3) represents the mean position of the current hawk population, with N indicating the total number of hawks:

$$X_{\text{mean}}(t) = \frac{1}{N}\sum_{i=1}^{N} X_i(t) \tag{3}$$

B. Transition from Exploration to Exploitation Phase

The Harris Hawks Optimization algorithm incorporates a transfer from an exploration phase to an exploitation phase, depending on the prey's escaping energy. In this algorithm, the prey's energy is represented as gradually decreasing during its escape behavior:

$$E = 2E_0\left(1 - \frac{t}{T}\right) \tag{4}$$

As in Eq. (4), the energy of the escaping prey, defined as E and initialized as E_0, controls the selection of either exploration or exploitation in the HHO algorithm. In case $|E| \geq 1$, the algorithm is in the exploration phase, while $|E| < 1$ indicates exploitation. E_0 is applied using Eq. (5):

$$E_0 = 2 \times \text{rand} - 1 \tag{5}$$

C. Exploitation Phase

In the exploitation stage, four unique chasing and attacking tactics are applied according to the prey's escaping energy and the hawks' pursuit patterns. The parameter r is used to select a chasing strategy depending on whether the prey successfully escapes ($r < 0.5$) or not ($r \geq 0.5$) before an attack.

D. Soft Besiege

When the probability of escape ($r \geq 0.5$) and the escaping energy ($|E| \geq 0.5$), the prey still possesses sufficient energy and attempts to escape. In response, the Harris' hawks softly surround the prey to deplete its remaining energy before launching an attack. The behavior of the Harris' hawks in this phase is modeled as follows:

$$X(t+1) = \Delta X(t) - E|JX_{\text{best}}(t) - X(t)| \tag{6}$$

$$\Delta X(t) = X_{\text{best}}(t) - X(t) \tag{7}$$

$$J = 2(1 - r_5) \tag{8}$$

Here, $\Delta X(t)$ explains the difference between the current prey's position and its position. J refers to a variable defined as random jump strength.

E. Hard Besiege

When the probability of escape ($r \geq 0.5$) and the escaping energy ($|E| < 0.5$), the prey's energy is low and the Harris' hawks readily encircle it before launching an attack. The positions of the hawks and prey are recalculated using the equation below:

$$X(t+1) = X_{\text{best}}(t) - E|\Delta X(t)| \tag{9}$$

Fig. 6 illustrates this process, modeled through the interaction between a single hawk and the prey.

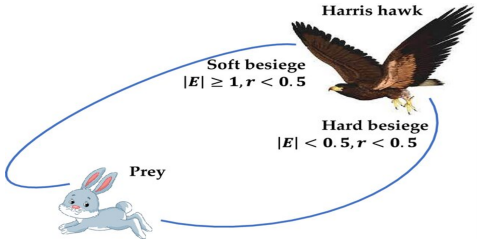

Fig. 6. Vector representation of the hard besiege mechanism [47].

F. Soft Besiege with Progressive Rapid Dives

When the prey's escape energy is high ($|E| \geq 0.5$) and ($r < 0.5$), the hawks carry out a gentle siege, conducting successive quick dives to incrementally refine the prey's location and movement direction. This behavior is modeled using the following equations:

$$Y = X_{\text{best}}(t) - E|JX_{\text{best}}(t) - X(t)| \tag{10}$$

$$Z = Y + S \times LF(D) \tag{11}$$

Where, D is the problem dimension, S is a $1 \times D$ random vector, and LF is the Lévy flight function, calculated via Eq. (12):

$$LF(x) = 0.01 \times \frac{u \times \sigma}{|v|^{\frac{1}{\beta}}}, \quad \sigma = \left(\frac{\Gamma(1+\beta) \times \sin\left(\frac{\pi\beta}{2}\right)}{\Gamma\left(\frac{1+\beta}{2}\right) \times \beta \times 2^{\frac{\beta-1}{2}}}\right)^{\frac{1}{\beta}} \tag{12}$$

where, u and v are random values uniformly distributed in $(0, 1)$, and β is a constant with a default value of 1.5.

$$X(t+1) = \begin{cases} Y, & \text{if } F(Y) < F(X(t)) \\ Z, & \text{if } F(Z) < F(X(t)) \end{cases} \tag{13}$$

In this context, S represents a random vector, and the superior position between Y and Z is chosen as the subsequent location.

G. Hard Besiege with Progressive Rapid Dives

If ($|E| < 0.5$) and ($r < 0.5$), implying that the prey lacks sufficient energy to evade capture, the hawks execute a hard encirclement by reducing the distance between their mean position and the prey. This action is represented by the following equations:

$$Y = X_{\text{best}}(t) - E|JX_{\text{best}}(t) - X_{\text{mean}}(t)| \tag{14}$$

$$Z = Y + S \times LF(D) \tag{15}$$

$$X(t+1) = \begin{cases} Y, & \text{if } F(Y) < F(X(t)) \\ Z, & \text{if } F(Z) < F(X(t)) \end{cases} \tag{16}$$

Here, only the more optimal position between Y and Z is adopted as the next point. Algorithm 1 presents the standard HHO pseudocode, summarizing its main optimization steps and position-updating process. Fig. 7 depicts the overall HHO optimization framework, highlighting the exploration and exploitation phases and the associated hawk position-update mechanisms.

Algorithm 1 Pseudocode of HHO algorithm

Require: The population size N and maximum number of iterations T
Ensure: The location of rabbit and its fitness value
Initialize the random population $X_i = (i = 1, 2, \ldots, N)$

IV. The Proposed Algorithm (EHHITS)

The complexity of the 3D Container Loading Problem necessitates a robust optimization approach capable of balancing global exploration with precise local refinement. This section details the proposed hybrid framework, which strategically integrates the HHO with an intensive Tabu Search (TS) mechanism, specifically tailored to maximize space utilization. The optimization process initiates with a pre-processing stage where the physical constraints of the container (L, W, H) and box dimensions are established. To ensure computational efficiency, the algorithm pre-calculates all unique spatial orientations for each box type, effectively pruning redundant search paths. To push the boundaries of packing density, the global search is augmented by an intensive Tabu Search, which acts as a high-precision intensification engine. Triggered periodically (every five iterations), this stage focuses exclusively on refining the current global best by navigating its immediate neighborhood through two primary structured moves:

1) Sequence swapping: Modifies the relative priority of items by exchanging their positions within the current packing sequence. This neighborhood operation enables the algorithm to explore alternative item-order configurations, which may lead to more efficient spatial arrangements, improved container utilization, and reduced unused space.

2) Gaussian mutation: Introduces subtle perturbations to fine-tune box orientations and placement coordinates, ensuring no potential spatial optimization is overlooked. To maintain search efficiency, the TS employs a Tabu List, which serves as a short-term memory to prevent the algorithm from cycling back to recently explored, unproductive configurations. However, this restriction is governed by an aspiration criterion: if a "tabu" move yields a utilization higher than the current fitness value.

A. The Robust Multi-Decoder and Extreme Point Logic

The proposed framework centers on a Robust Multi-Decoder—a specialized mechanism that bridges continuous optimization with discrete spatial constraints. Unlike conventional decoders that rely on a single heuristic, this approach evaluates each candidate solution through two competing packing paradigms to identify the most efficient configuration:

1) Vertical layering strategy (column-based packing): Focuses on vertical stratification, prioritizing the stacking of items to maximize layered stability and container height utilization.

2) Horizontal floor-filling strategy (wall-based packing): Focuses on floor-area coverage using a foundation-first approach to promote stable weight distribution.

The fitness value is the maximum utilization achieved by the evaluated packing strategies. An Extreme Point (EP) strategy manages the 3D packing space by dynamically updating feasible insertion points after each box placement, adding new candidate points and removing blocked or infeasible ones. The detailed execution flow and operational steps of the EHHITS algorithm are presented in Algorithm 2, while the pseudocode for the Intensive Tabu Search used during the intensification phase is outlined in Algorithm 3.

Algorithm 2 Pseudocode of the proposed EHHITS algorithm

Require: The population size N and maximum number of iterations T
Ensure: The location of rabbit and its fitness value (Max utilization)
Initialize $X_i = (i = 1, 2, \ldots, N)$
Calculate the fitness values of hawks using Robust Multi Decoder:
fitness values $= \max($core packer Z order, core packer X order$)$
while (stopping condition is not met) **do**
  Calculate the fitness values of hawks
  Set X_{best} as the location of rabbit (best location)
  for (each hawk (X_i)) **do**
    Update the initial energy E_0 and jump strength J:
    $E_0 = 2\text{rand}() - 1, \quad J = 2(1 - \text{rand}())$
    Update E using Eq. (4)
    if ($|E| \geq 1$) **then** ▷ Exploration phase
      Update the location vector using Eq. (2)
    end if
    if ($|E| < 1$) **then** ▷ Exploitation phase
      Update location vector using Soft/Hard besiege or Levy flight (Eq. 6, 9, 13, 16)
    end if
  end for
  Apply boundary control and Evaluate new fitness value using Robust Multi Decoder
  if ($t \bmod 5 = 0$) **then** ▷ Intensification phase
    Apply Intensive Tabu Search to the location vector X_{best} and fitness value
    Update X_{best} and fitness value
  end if
end while
return X_{best} (Rabbit Location)

TABLE II. PARAMETER SETTING

Parameter	Value	Description
β (Beta)	1.5	Control factor for the search mechanism
Rabbit Energy	[0,2]	The transition between exploration and exploitation
Iterations	300	The maximum number of cycles the algorithm runs for each problem instance
Population Size	30	The number of individual solutions, or "hawks," used in the search process

Algorithm 3 Pseudo-code of Intensive Tabu Search

Require: Best location X_{best}, Current fitness, local search iterations (T_{iter})
Ensure: Refined X_{best} and its fitness value (Rabbit Energy)
Set current$_x = X_{\text{best}}$
for $j = 1$ **to** T_{iter} **do**
  Generate Neighbor hawk by applying Swap and Mutation on current$_x$
  Calculate fitness neighbor using Robust Multi Decoder
  if (fitness$_{\text{neighbor}} >$ Rabbit Energy) **then**
    Update $X_{\text{best}} = X_{\text{Neighbor}}$ and Rabbit Energy $=$ fitness$_{\text{neighbor}}$
  end if
end for
return X_{best}, fitness value (Rabbit Energy)

V. COMPUTATIONAL RESULTS

To evaluate the performance of the proposed method, this study employs the standard 15 LN instances (LN1 to LN15) introduced by Loh and Nee [48] as well as the 700 instances from Bischoff and Ratcliff [49]. These test instances vary in the number of box types and 3D bin packing dimensions, spanning from weakly to strongly heterogeneous problem characteristics. The proposed EHHITS algorithm was implemented in MATLAB® 2018 and executed on a laptop computer equipped with an Intel® Core i5 CPU (4 GHz) and 16 GB of RAM. The performance of the EHHITS algorithm for the test cases was governed by the following critical parameters as detailed in Table II:

A. Results for Test Cases LN01–LN15

For the performance evaluation, EHHITS is applied to a 3D bin packing data set. The Loh and Nee (LN) data set [48] is known for its heterogeneous nature, meaning it contains a wide variety of different box sizes and types. This makes the packing problem particularly difficult, as algorithms must be flexible enough to handle many different shapes and quantities of items, rather than just a few uniform sizes. The LN data set for the 3D container loading problem consists of 15 problems. This data set is notable for its heterogeneous nature, meaning each problem involves a variety of different box sizes and types, which makes it a challenging benchmark for packing algorithms.

The instances in the LN data set typically involve:

- A single container of a defined size.

EHHITS (this work)	91.72

- Multiple types of rectangular boxes, with each type having different dimensions (length, width, height) and a specified quantity to be packed.
- The objective is to optimize the placement of boxes in the container for highest volume efficiency.

The constraints of the 3D bin packing are as follows:

- The items consist of rectangular boxes characterized by their known width, depth, and height.
- The boxes can be reoriented if permitted by problem constraints.
- Each box is allowed to be stacked over another.

To preserve structural orientation in these particular situations, rotations along the horizontal axes were restricted. The dataset used is made up of 100-250 instances that are divided into 6-10 different kinds. The EHHITS method was executed for a fixed duration of 10 minutes for each instance. To ensure a reliable evaluation and account for the stochastic nature of the metaheuristic, each instance was independently solved in 30 runs. This repeated evaluation helps reduce the effect of random initialization and provides a more robust assessment of the algorithm's performance.

Table III presents the experimental results for the 15 Loh/Nee test cases together with those found in the literature. The obtained volume utilization is provided for every method except L/N. According to Bischoff and Ratcliff [49], the packing density expressed in L/N is an overestimation of the volume utilization. Lastly, for each strategy, the average volume utilization and the number of ideal solutions for every box packed are provided. Our algorithm produced the highest average volume utilization for the 15 test scenarios out of all the methods. Fig. 8 presents samples of the packing results obtained by EHHITS on the LN benchmark dataset (LN2, LN6, LN12 and LN13).

The experimental results demonstrate that the EHHITS algorithm is a highly effective metaheuristic for solving the 3D packing problem. The algorithm successfully packed all available items in 13 out of 15 benchmark instances. For the remaining two instances, EHHITS achieved volume utilization

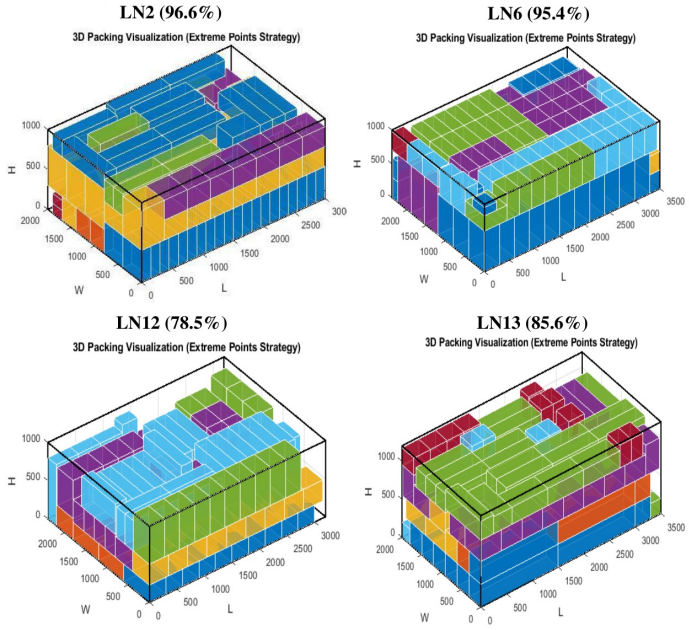

Fig. 8. LN dataset packing results.

rates of 96.6% and 95.4%, respectively, yielding an average utilization rate of 70.8% across the evaluated benchmark instances.

B. Results for Test Classes BR1–BR7

The 700 Bischoff/Ratcliff test cases are organized into seven test classes (BR1-BR7), with each class consisting of 100 test cases. For all test scenarios, the container dimensions are L = 587, W = 233, and H = 220. The number of box kinds for BR1 through BR7 is 3, 5, 8, 10, 12, 15, and 20. Table IV summarizes the experimental results for the 700 Bischoff/Ratcliff test cases. For every test class, the minimum, average, and maximum volume utilizations of 100 test instances are displayed together with the instances' standard deviations. The EHHITS algorithm is executed for ten minutes and 30 times with various random numbers to solve each problem. The total average volume use for the 700 test instances is shown in Table V and contrasted with the utilizations attained using alternative techniques. Other methods' volume utilizations are derived from the literature and updated with the latest findings. The results of EHHITS indicate that for all test classes, the average volume utilization is 91.72%.

Several factors intrinsic to the EHHITS design contribute to this robust performance. Firstly, the hybridization strategy successfully balances global exploration and local intensification. The multi-strategy initialization generates a diverse and high-quality initial population, allowing the HHO component to effectively search for optimal regions in the solution space. Subsequently, the Intensive Tabu Search acts as a powerful intensifier, refining these solutions by navigating complex local optima and escaping from suboptimal regions through its diverse neighborhood operators. This synergistic interaction is likely the primary driver behind the algorithm's consistency and reliability, as reflected in its high success rate across most test instances.

VI. Conclusion

This research has introduced and empirically validated a novel hybrid metaheuristic for addressing the 3D container packing problem, combining Enhanced Harris Hawks Optimization with Tabu Search (EHHITS). The proposed algorithm addresses fundamental challenges in complex combinatorial optimization by integrating global exploration capabilities with intensive local search techniques. The EHHITS framework integrates an Intensive Tabu Search with HHO to strategically balance local precision and global exploration to increase packing density. Comprehensive evaluation on the standard LN benchmark instances demonstrates the strong and competitive performance of EHHITS. The proposed algorithm achieved optimal solutions in 13 of the 15 test cases and attained an average volume utilization of 70.8%, with notable improvements observed on the LN2 and LN6 instances. Furthermore, evaluation on the complete set of 700 Bischoff/Ratcliff test cases demonstrates the robustness and scalability of EHHITS across packing instances with varying problem dimensions. For all test classes ranging from BR1 to BR7, the average volume utilization consistently remains above 91%. These findings, supported by the detailed metrics of minimum, maximum, and standard deviation values, suggest that the integration of Tabu Search into the Enhanced Harris Hawks framework significantly strengthens global search capabilities. Ultimately, the EHHITS algorithm proves to be a reliable and high-performing strategic framework for achieving superior global optimization in diverse packing environments. The experimental outcomes confirm that the strategic hybridization of population-based and trajectory-based methods offers significant advantages for tackling NP-hard optimization problems. Future research directions include developing dynamic parameter adaptation

mechanisms, incorporating additional problem-specific constraints, and extending the approach to other combinatorial optimization domains.

ACKNOWLEDGMENT

This work was funded by the University of Jeddah, Jeddah, Saudi Arabia, under grant No. (UJ-23-DR-275). Therefore, the authors thank the University of Jeddah for its technical and financial support.

Energy Personalized Recommender for the PowerEye Home Energy Management System

Reem Hejazi*, Sofianiza Abd Malik, Anees Ara, Layla Alfawzan
College of Computer and Information Science, Prince Sultan University, Riyadh, Saudi Arabia

***Abstract*—The Energy Personalized Recommender (EPR) is a novel backend module designed to optimize energy management within home energy management systems (HEMSs). Existing research explores various energy optimization strategies but is often constrained by synthetic datasets, simulation-based validation, or limited personalization. To address these limitations, EPR is designed for real-world deployment and personalization. By employing machine learning algorithms, the EPR analyzes appliance-level energy consumption in real time and integrates various algorithms to enhance user interaction with energy usage data. These algorithms include the Energy Goal Algorithm, which allows users to set and monitor monthly energy cost goals, and the Peak Time Algorithm, which advises on shifting usage to off-peak times. The Phantom Mode Algorithm identifies low-power or standby appliances, promoting energy conservation, while the Energy Baseline Algorithm predicts hourly energy usage to detect deviations. In evaluating the system, k-means clustering for phantom appliances achieved silhouette scores of 0.478 to 0.954, indicating reliable performance. Baseline prediction models showed RMSE values between 0.003 and 1.526, depending on the appliance. A single-day evaluation involving three participants showed mixed consumption changes: two participants recorded decreases, while the third recorded an increase, resulting in a 19.74% aggregate increase. These preliminary findings provide a foundation for advancing personalized energy management and motivate longer controlled trials to determine efficient and sustained energy savings through EPR systems.**

I. Introduction

Recommender systems have become essential tools in various domains, offering personalized suggestions that enhance user experience and decision-making. In energy management, these systems are crucial in promoting energy efficiency and sustainability. Home energy management systems (HEMSs) are designed to collect and analyze energy data from household appliances, providing users with valuable insights into their energy usage patterns [1].

Current research in the field of HEMS has explored not only basic energy monitoring but also the integration of recommender systems to provide personalized insights [2], [3]. Several studies have proposed hybrid energy recommender systems that combine multiple optimization strategies to support household energy management [4], [5], including demand-side management in smart grids [6] and energy consumption forecasting using machine learning approaches such as RNN-LSTM [7]. While these approaches demonstrate the benefits of hybridization, they typically focus on a limited subset of objectives. In contrast, our proposed HEMS, PowerEye, introduces an Energy Personalized Recommender (EPR) designed as a modular hybrid framework that simultaneously integrates four complementary optimization algorithms: cost-based goal tracking, peak-time shifting, phantom energy detection, and real-time baseline forecasting. This unified design enables more comprehensive and actionable recommendations, thereby enhancing both energy efficiency and sustainability.

This paper aims to explore the development and impact of EPR within the PowerEye system. The contributions of the proposed work are as follows:

- We conduct a detailed state-of-the-art literature review of energy recommender system technologies.
- We propose a hybrid-approach EPR framework as part of the HEMS, PowerEye. This system demonstrates personalized recommendations that can optimize energy usage in households.
- We deploy PowerEye using 23 commercial smart plugs across three households, collecting 111 days of appliance-level data for model development and evaluation. A separate single-day experiment examines consumption changes following recommendations.
- We develop the EPR algorithms using k-means clustering and XGBoost. These algorithms are used to recommend and predict optimal energy usage.
- We conduct an evaluation of the experiments, including phantom clustering accuracy, baseline forecasting accuracy, energy consumption analysis, and user experience. These results assess the effectiveness of personalized recommendations.

The paper is organized as follows: Section II provides a comprehensive review of the literature on energy recommendation systems; Section III outlines the PowerEye system architecture and related details; Section IV describes the simulation setup and deployment of the proposed system; Sections V and VI present the results and discussion, respectively; and finally, Section VII concludes the paper with future recommendations.

II. Background

The following section provides a brief overview of the background of energy recommender systems and a comparative analysis of related work.

*Corresponding author.

A. Types of Energy Recommender Systems

The primary aim of HEMSs is to enable users to monitor and optimize their energy consumption through personalized recommendations. Various models are employed for energy optimization in recommender systems, including the following:

1) Content-based: Suggests items that are similar to those a user has liked in the past by analyzing item features [8]. It builds a user profile based on features of items previously rated by the user, such as keywords from item descriptions.

2) Collaborative filtering: Makes suggestions based on the behaviors of users with similar preferences [9]. This approach analyzes the rating history of users and calculates the similarity between them. Recommendations are then made by suggesting items that other users with similar tastes have liked in the past.

3) Knowledge-based: Suggests items based on predefined rules and domain knowledge, ensuring they meet specific user requirements and preferences [10]. Unlike systems based on rankings or item features, this approach evaluates items or actions against a set of criteria defined by the user.

4) Case-based: Uses historical examples or past cases to inform recommendations [11]. It retrieves relevant cases from memory to solve new problems by adapting previous workflows to fit current conditions. Once a suitable case is identified, it is modified for the new situation and reused.

5) Context-based: Suggests items by considering contextual factors such as time, location, or other external conditions [12]. By adapting to the user's changing needs and situations, context-based systems aim to provide more relevant and timely recommendations that align with the user's current circumstances.

6) Hybrid: Combines two or more recommendation techniques to improve the accuracy and relevance of recommendations.

B. Literature Review

Jimenez-Bravo et al. [10] proposed a multi-agent system for smart homes that optimizes energy usage by coordinating agents. These agents, built with a Python library, collect real-time consumption data, track electricity prices, and offer personalized energy-saving recommendations. The system uses knowledge-based and utility-based recommendations to provide financial incentives for shifting energy use. Though promising for addressing energy optimization issues in the European Union, the system was only tested in a theoretical case study, not real-world settings.

Eirinaki et al. [4] proposed a framework to help households improve energy efficiency by providing real-time recommendations for appliance use. The framework uses non-intrusive load monitoring (NILM) to disaggregate individual appliance consumption from main meter data and applies association rule mining and sequential pattern mining algorithms to extract usage patterns. These patterns are used to build personalized user profiles and generate recommendations for energy savings. The study found that the framework could reduce energy consumption by 2–17%.

Gonzalez-Briones et al. [11] present a multi-agent system architecture designed to optimize temperature and energy consumption in an office building. By analyzing sensor data and external information, the system establishes temperature patterns that align with both energy efficiency and user comfort. The GAIA methodology [13] guided the design and development of this system, incorporating algorithms for savings, machine learning, case-based reasoning, and artificial neural networks. The findings demonstrate the system's effectiveness, achieving average energy savings of 41% in the experimental group offices compared to the control group.

Zhang et al. [14] introduce an electricity plan recommender system (EPRS) designed to offer personalized recommendations to residential customers. Leveraging neighborhood-based collaborative filtering, the EPRS demonstrates superior performance compared to existing strategies in terms of recommendation accuracy. The J-wEUC similarity metric, a novel approach developed for this study, effectively addresses the challenge of missing features. By providing customers with predicted ratings of various tariff plans, the EPRS facilitates the widespread adoption of flexible pricing tariffs.

Sardianos et al. [5] present REHAB-C, a context-aware recommendation system designed to assist users in transforming their energy habits. REHAB-C utilizes a rule-based system to detect user habits and recommend actions based on the user's context and goals. Additionally, the system incorporates collaborative filtering to leverage feedback from multiple users, enhancing the recommendations. REHAB-C was evaluated in real-world office scenarios and demonstrated a significant reduction in energy consumption, up to 50%.

Zhang et al. [15] present a customized electricity retailing plan recommendation strategy that assists customers in selecting economical retailing plans. The strategy utilizes customer electricity usage patterns to recommend cost-effective plans without requiring full daily load profile records. The methodology involved two-stage DLP clustering, correlative feature selection, decision tree classification, and typical plan rank and recommendation plan rank calculation. The study identified correlative features between load profile features and DLP classes, providing insights for both plan selection and further investigations into the retail market, such as tariff design.

Rodriguez et al. [16] present a novel methodology that utilizes various algorithms to analyze energy consumption patterns in household refrigerating appliances, leading to tailored energy-saving recommendations. Their approach incorporates cycle counting to determine operating cycles and a 7-day centered moving average for smoothing energy data and estimating base consumption. By employing k-means clustering with Dynamic Time Warping, the study categorizes daily energy profiles. The findings demonstrate that the probability density estimation method effectively identifies refrigerators with anomalously high energy consumption, enabling personalized recommendations.

A comparison between these existing energy recommendation systems is shown in Table I.

The literature presents diverse frameworks for energy management, including multi-agent systems, real-time recommendations, and personalized plan suggestions. These studies leverage approaches like collaborative filtering, machine learning, and clustering to optimize energy use and provide

TABLE I. COMPARISON OF EXISTING ENERGY RECOMMENDATION SYSTEMS

	Features	Methods	Limitations
[10]	- Minimize peak consumption - Utilize smart plugs - Use online electricity prices	- Multi-agent - Knowledge-based - Utility-based	- Not real-world settings - Limited to the Spanish electricity market - Supports only one smart plug
[4]	- Create appliance profiles - Switch on/off suggestions - Interactive energy suggestion interface	- HMM model - Combinatorial optimization - k-means clustering	- Ignore inter-appliance associations - Omit weather data - Omit environ. psychology
[11]	- Automatic temperature adjustment - Data-driven HVAC temperature control - Case-based reasoning	- Multi-agent - GAIA - Case-based	- Lacks comfort parameters with energy savings - Insufficient data reporting - Lacks granular insights
[14]	- Recommend cost-effective electricity plans - Offer predicted ratings - Appliance on thresholds	- CF filtering - Neighborhood-based - Jaccard Euclidean	- Slow calculation speed - Limited dataset - Limited exploration of the impact on market policies
[5]	- Goal-based system - Incorporate smart sensors - Incorporate users' preferences and feedback	- CF filtering - Rule-based - Context-aware	- No support for setting energy goals - Limited to a single user - No standardized benchmarks
[15]	- Rank cost-effective electricity - Classify daily load profiles - Link DLP classes to a typical plan rank	- k-means clustering - Decision trees - Dominant plan rank selection	Not mentioned
[16]	- Analyze fridge energy use - Evaluate base and relative energy consumption - Identify anomalous energy	- One-way ANOVA - k-means clustering - Probability density estimation	- Limited dataset - Recommender impact has not been evaluated - Does not consider seasonal effects

savings insights. Notable findings show energy reduction potential from 2% to 50%, though many systems are limited by theoretical models, dataset constraints, or lack of real-world validation. Hence, in the following section, we address some of these gaps and propose an energy-personalized recommender for a home energy management system.

III. METHODS

In this section, we discuss the design and architecture of our proposed HEMS, PowerEye, along with its system components, personalized recommendation strategy, and the recommendation process. Finally, we provide an in-depth explanation of the four algorithms used in our EPR: energy goal, peak time, phantom mode, and energy baseline algorithms.

A. PowerEye: The Proposed Home Energy Management System

Our proposed HEMS, PowerEye, aims to build a user-friendly mobile application that empowers users to effortlessly monitor their energy usage at the appliance level. Users can set energy consumption goals, easily manage devices and rooms, and receive real-time data insights to make informed decisions. Even individuals with minimal technical knowledge will find it easy to set up the smart plugs and devices, without needing technical support. With interactive charts and real-time data at their fingertips, PowerEye offers an engaging, intuitive experience, making energy efficiency achievable for everyone.

Existing energy recommendation systems often focus on one specific aspect of energy optimization, such as reducing peak consumption, providing switch-on/off recommendations, or minimizing electricity costs. These systems tend to rely on single methods like collaborative filtering or rule-based approaches, which limit their effectiveness by not offering comprehensive solutions.

In contrast, PowerEye's EPR further enhances this by using a hybrid approach to energy optimization. It helps users set cost-saving goals, recommends peak-time savings, detects phantom power modes, and identifies excessive energy usage, addressing multiple aspects of energy efficiency in one solution.

B. System Architecture

The proposed home energy management system, PowerEye, has a modular architecture with system functionalities distributed among different modules or components, as shown in Fig. 1. Each module interacts with the others using specified protocols and APIs.

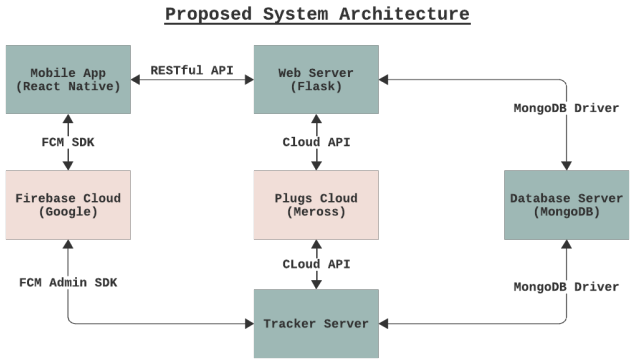

Fig. 1. System architecture design diagram.

The proposed PowerEye system is broken down into the following components:

1) Database server: This server stores and manages data such as user profiles, appliance information, and energy consumption records. MongoDB is utilized for its flexibility and scalability [17], making it ideal for efficiently handling time-series and semi-structured IoT data.

2) Plugs cloud (meross) [18]: The Plugs Cloud component acts as a bridge between the application and Meross smart plugs. It enables communication through an unofficial API provided by Alberto Geniola [19], enabling real-time information retrieval and remote control.

3) Web server: This server uses the Flask framework to handle HTTP requests via RESTful APIs, manage user authentication, and serve as the primary point of interaction between users and the application [20]. Flask [20] was selected for its lightweight nature and ease of integration with data-driven services.

4) Firebase cloud [21]: Firebase Cloud Messaging (FCM) is responsible for sending push notifications to mobile devices. It acts as a communication bridge between the Tracker Server and the mobile application. It ensures that users are promptly informed of critical events, such as reaching energy goals or receiving recommendations.

5) Tracker server: This is the backbone of the system, managing power data from Meross Cloud [18], storing device details in MongoDB [17], tracking events like energy goals, and delivering personalized recommendations and push notifications through FCM [21]. It centralizes backend operations, processes device data, and offers valuable insights.

6) Mobile application: The React Native-based mobile app offers a platform-independent interface for smart plug control [22]. Users can view device status, consumption data, and recommendations, and control devices remotely. React Native streamlines cross-platform app development with a single codebase, saving time and ensuring a consistent experience on Android and iOS.

C. Energy Personalized Recommender Design

In our proposed recommender system, we focus on four aspects of energy optimization: energy goal, peak time, phantom mode, and energy baseline.

1) Energy goal: Users can set monthly energy consumption goals based on cost. The system then calculates the energy equivalent to the specified cost. Users are then notified when their energy consumption hits specific percentage thresholds, ranging from 25% to 200%.

2) Peak time: Avoiding appliance usage during peak hours lowers emissions, conserves resources, cuts infrastructure costs, and supports renewable energy [23]. We will advise users to postpone appliance use during peak times.

3) Phantom mode: This refers to appliances consuming electricity even when they are turned off but still plugged in [24]. This happens because they stay in standby mode to respond quickly when needed. In this scenario, we will advise users to turn off appliances in phantom mode.

4) Energy baseline: Our system provides users with insights into their energy consumption patterns by sending alerts when they exceed their daily baseline. Each appliance in the system is equipped with its own model, allowing it to forecast energy consumption for the upcoming hour.

Based on the above aspects, we can conclude that our EPR employs a hybrid approach. It can be considered context-based as it uses contextual factors such as time, appliance status, power, and energy readings. Additionally, it qualifies as knowledge-based because it relies on user preferences and predefined rules for energy goals and peak times. Finally, it has content-based elements as it utilizes historical user energy patterns to predict future usage and issue alerts for excessive consumption.

D. Recommendation Process

The Tracker Server collects power readings from each Meross smart plug at one-minute intervals [18]. The EPR is designed using a modular architecture, in which the four optimization modules (energy goal tracking, peak-time shifting, phantom energy detection, and baseline forecasting) operate as independent components. Each module accesses the required input data from a shared data layer and does not rely on the outputs of other modules.

As the Tracker Server gathers data, it invokes the relevant EPR modules independently based on predefined conditions and scheduling logic, enabling the system to generate personalized recommendations for the user. The Tracker Server then sends these recommendations to the user's mobile application via Google Firebase [21]. This process is illustrated in Fig. 2.

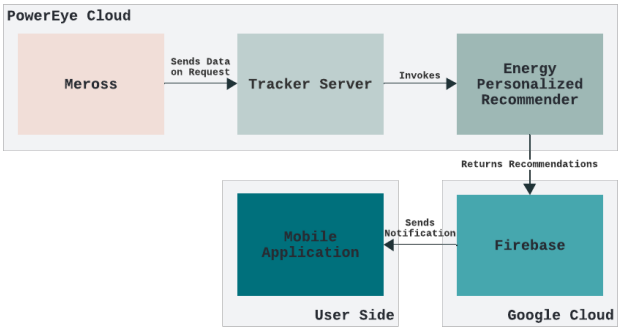

Fig. 2. Recommendation process.

The data used include user information, appliance details, power readings, and energy consumption. To calculate daily energy consumption, Eq. 1 is applied:

$$E(kWh) = \sum_{i=1}^{n} P_i \Delta t = \sum_{i=1}^{24\times 60} \frac{P_i}{1000} \times \frac{1}{60} \qquad (1)$$

Energy consumption is calculated by converting power from watts to kilowatts and multiplying it by the time interval, which is set at one minute (1/60 hour). The daily energy consumption values are then aggregated and stored with the unit kWh.

E. Energy Goal Algorithm

Users can set a monthly cost goal for their energy consumption. In Saudi Arabia, the energy cost is calculated by multiplying the energy consumption by the Residential Consumption Tariff (RCT), as specified on the official website [25]. The energy goal can then be calculated by rearranging Eq. 2 as shown in Eq. 3.

$$Cost(SAR) = E \times RCT = E \times \frac{0.8}{100} \tag{2}$$

$$E(kWh) = Cost \times \frac{100}{0.8} \tag{3}$$

The `check_goal()` function, provided by the EPR module, computes the percentage of the user's energy goal that has been reached. This percentage is determined by dividing the current month's energy consumption by the user's set goal, rounding down to the nearest quarter, and ignoring any quarter greater than 2. The result is then converted into a percentage out of 100. Upon reaching each specified threshold, the server sends a notification. Flags are used to prevent multiple notifications for the same percentage within the current month. The steps for this process are provided in Algorithm 1:

Algorithm 1 Check Goal

```
Input: month_energy (float), goal (float)
Output: int

function CHECK_GOAL(month_energy, goal)
    percentage ← month_energy / goal
    rounded ← ⌊ percentage * 4 ⌋ / 4
    if rounded ≤ 2 then
        return int(rounded * 100)
    else
        return 0
    end if
end function
```

F. Peak Time Algorithm

The `check_peak()` function, provided by the EPR module, uses straightforward logic. It checks whether the appliance is turned on during peak times and whether its energy type is categorized as shiftable. For more details on appliance types, refer to Appendix A. In Saudi Arabia, peak time is recognized by the government as 1–5 p.m., as stated on the government website [26]. If the function returns true, the server sends a notification. Flags are used to prevent additional notifications for the same appliance during the current day. The steps for this process are provided in Algorithm 2.

G. Phantom Mode Algorithm

Phantom appliances can exist in three distinct states: on, off, and phantom. The primary objective of this algorithm is to identify the phantom state. This is achieved by clustering appliance power data into two groups: `on_cluster` and `phantom_cluster`. The off state is intentionally included within the `phantom_cluster`, as phantom consumption typically occurs at very low power levels close to zero. Distinguishing between off and phantom states is then performed using the appliance status (ON/OFF), enabling accurate separation without requiring additional clustering complexity.

Algorithm 2 Check Peak

```
Input: cur_hour (int), status (boolean), e_type (EType), types (list)
Output: boolean

PEAK_START ← 13
PEAK_END ← 17
function CHECK_PEAK(cur_hour, status, e_type, types)
    is_peak ← PEAK_START ≤ cur_hour < PEAK_END
    return is_peak and status and e_type in types
end function
```

The dataset is extracted from the PowerEye database, containing timestamped appliance-level power readings. Only power values are used for clustering. The preprocessing steps are as follows:

- Null Values: These can be dropped as there is no need for imputation in this context.
- Dataset Size: A sample size of 1,000 readings was selected as a practical balance between data collection requirements and computational cost. The resulting clustering performance is reported through appliance-level silhouette scores (Table IV); sensitivity to sample size remains to be evaluated.
- Duplicate Values: Rather than being removed, duplicates are assigned weights to preserve their frequency information while avoiding bias in clustering.

For clustering, k-means with $k = 2$ is employed [27]. This choice is motivated by the univariate nature of the data (power readings only) and the expectation of two dominant consumption patterns: active and near-zero power. Compared to more complex methods such as DBSCAN or Gaussian mixture models, k-means provides a lightweight and deterministic solution suitable for real-time deployment [28]. Density-based methods like DBSCAN require sensitive parameter tuning and are less stable in one-dimensional data, while probabilistic models such as GMM introduce unnecessary complexity without significant performance gains for this task. Similar approaches have been effectively used in prior work [4]. A publicly available Jupyter notebook provides more detailed information [29]. One model is created for each appliance and stored on PowerEye's server, where it is used within the `check_phantom()` function.

The `check_phantom()` function, provided by the EPR module, first checks whether a cluster model already exists for the appliance. If the appliance is turned on, it uses the model to predict the cluster of the current power reading. The algorithm compares the predicted cluster with the cluster associated with a power reading of 0. If they match, it indicates that the appliance is in phantom mode, and the function returns True. When the function returns True, the server sends a notification. In cases where the clusters are not well separated, flags are used to avoid sending excessive notifications in a short period. The steps for this process are detailed in Algorithm 3.

Algorithm 3 Check Phantom

```
Input: model (clusterModel), power (float), status (boolean)
Output: boolean

function CHECK_PHANTOM(model, power, status)
    if model and status then
        predicted_labels ← model.predict([0, power])
        return predicted_labels[0] == predicted_labels[1]
    end if
    return False
end function
```

H. Energy Baseline Algorithm

The final EPR step alerts users of potential excessive usage by forecasting appliance-level energy consumption. If actual consumption deviates from predictions, users are notified that their usage exceeds expected levels. This approach helps users monitor and reduce energy usage. Machine learning models predict hourly consumption based on historical data, setting an expected energy limit. Users are notified if they exceed this limit.

To prevent data leakage and preserve temporal causality, all preprocessing and model evaluation steps strictly respect the chronological order of observations. The preprocessing pipeline is defined as follows:

1) Energy conversion and hourly resampling: Power readings are converted into energy using Eq. 1 with $n = 60$, then resampled hourly, generating more data for better prediction accuracy and quicker energy-saving decisions.

2) Null values: Rows with more than 30 null values (before resampling) are dropped.

3) Normalization: A standard scaler is used to handle large magnitude differences. The dataset is split 80/20 into training and test sets before normalization to keep the model blind to the test data.

4) Feature engineering: To transform the time series into a regression problem, we decompose the timestamp into features like hour, month, year, day, and whether it is a weekend or nighttime. We then add rolling statistics (e.g., average, standard deviation) to capture trends and variations. Lastly, we include seven lag features to balance predictive power and computational efficiency.

5) Dataset splitting: Half of the testing dataset is reallocated for validation, resulting in a new ratio of 80% for training, 10% for validation, and 10% for testing (0.8:0.1:0.1). This ensures that all training observations precede validation observations, and validation observations precede test observations, preventing future information from leaking into model training.

6) Feature selection: The most relevant features are identified by assessing their impact on the model's predictions. Using XGBoost with default hyperparameters [30], the top 15 features with the highest importance scores are selected to improve model performance and reduce overfitting.

For forecasting, the XGBoost model—short for eXtreme Gradient Boosting—is employed using time-series cross-validation with walk-forward validation to maintain the dataset's temporal structure [30]. This approach trains on historical data and validates subsequent points, avoiding look-ahead bias and providing realistic performance assessments. Hyperparameter tuning is essential since XGBoost has numerous hyperparameters. The tuning process followed Jain's approach [31], using Mango Tuner instead of grid search cross-validation. Mango Tuner is a state-of-the-art gradient-free optimizer that offers faster performance and greater flexibility in setting objective functions [32]. The objective function employs time-series cross-validation (walk-forward) and aims to minimize mean squared error (MSE).

After finding the optimal hyperparameters, the model is trained using these parameters and then utilized to predict the energy consumption for the following hour, which serves as a baseline. An actual value is considered abnormal if it significantly deviates from this baseline. A normalized relative MAE score is used, where values exceeding a threshold of 0.75 are flagged as excessive usage [33]. This threshold was chosen as a conservative operating point to balance sensitivity and false-positive rates in practical deployment. Lower thresholds (e.g., 0.6–0.7) were observed to increase false alerts due to short-term fluctuations and sensor noise, while higher thresholds (e.g., above 0.8) reduced sensitivity to meaningful deviations. The score is calculated by taking the absolute difference between the predicted and actual values, dividing it by the mean absolute error (MAE) [33], and then normalizing the result to compare against the fixed threshold. The formulas are presented in Eq. 4, 5, and 6.

$$MAE = \frac{\sum_{i=1}^{n} |Predicted_i - Actual_i|}{n} \tag{4}$$

$$Score_i = \frac{|Predicted_i - Actual_i|}{MAE_{total}} \tag{5}$$

$$NormalizedScore_i = \frac{Score_i - min(Score)}{max(Score) - min(Score)} \tag{6}$$

The optimal hyperparameters, along with the MAE, maximum score, and minimum score obtained during the tuning phase, are stored on PowerEye's server for later use in the `check_baseline()` function. This function, part of the EPR module, applies the same preprocessing steps described earlier to all power readings up to the current hour. It then splits the data to train the XGBoost model and tests it on the most recent reading. The function calculates the normalized relative MAE and returns True if the actual energy consumption exceeds the predicted value and the score surpasses the 0.75 threshold. If True, the server sends a notification. Flags are used to prevent sending multiple notifications for the same appliance within the same day. The process is outlined in Algorithm 4, with detailed steps available in our Jupyter notebook [29].

IV. PowerEye Simulation

The following section includes details about the deployment and experimental setup.

Algorithm 4 Check Baseline

Input: powers (time-series), mae (float), max_score (float), min_score (float), params (dict)
Output: boolean

function CHECK_BASELINE(powers, mae, max_score, min_score, params)
    count null values for each hour
    drop any row with more than 30 null values
    df["energy"] ← (powers/1000) * (1/60)
    df ← df.resample("H").sum()
    df ← normalize(df)
    df ← feature_engineering(df)

    y ← df["energy"]
    X ← df.drop("energy")
    y_train, y_test ← y[:-1], y[-1]
    X_train, X_test ← X[:-1], X[-1]

    model ← XGBRegressor(params)
    model.fit(X_train, y_train)
    pred ← model.predict(X_test)

    r_mae ← abs(pred - y_test) / mae
    nr_mae ← (r_mae - min_score) / (max_score - min_score)
    return y_test > pred **and** nr_mae > 0.75
end function

A. Proposed System Deployment

The deployment of PowerEye involved configuring both hardware and software systems. All deployment configuration details for the proposed system are summarized in Table II.

TABLE II. POWEREYE DEPLOYMENT CONFIGURATIONS

Component	Configuration
Database	MongoDB Atlas on AWS (Bahrain Region), M0 Sandbox cluster, 512 MB storage, shared RAM
Firebase (FCM)	Configured for iOS and Android with secure authentication keys, APN for iOS, SHA certificate for Android
Web Server	AWS EC2 t3.micro instance, Ubuntu Server 22.04 LTS, 30 GB SSD storage, 2 vCPUs, 1 GiB RAM
Tracker Server	Orange Pi 5 SBC, Rockchip RK3588S 8-core processor, 8 GB LPDDR4 RAM, 32 GB microSD storage, Ubuntu 22.04.2 LTS
Mobile Application	React Native with Expo, iOS and Android deployment, Apple Distribution certificates, ad hoc provisioning profiles for push notifications and internal distribution

B. Experimental Setup

A total of 23 commercial smart plugs were purchased and distributed among three participants with different characteristics, as detailed in Table III.

Data collection for the HEMS lasted for 111 days, initially using temporary cloud-hosted code. Later, the Tracker Server took over the data collection process. The participants installed the PowerEye application on their mobile devices, enabling them to access their accounts and monitor their data. The mobile application experiment was limited to a single day due to time and resource constraints.

TABLE III. EXPERIMENTAL PARTICIPANT INFORMATION

User	Rooms	Family Members	Smart Plugs	Appliance Types
User 1	10	9	8	4 Phantom, 4 None
User 2	8	7	6	1 Phantom, 5 None
User 3	8	5	9	4 Phantom, 5 None

V. RESULTS

The following section discusses the evaluation of the experiments using phantom clustering and baseline forecasting accuracy, user experience, and comparative analysis.

A. Phantom Clustering Accuracy

Scatterplots for the power clusters of all phantom appliances across users are presented in Fig. 3. The quality of the k-means clustering models is evaluated using the silhouette score [34], which quantifies the similarity of data points within their cluster (cohesion) relative to other clusters (separation). Silhouette scores range from -1 to 1, with higher scores indicating better clustering. Table IV provides the silhouette scores, rounded to three decimal places, for all 2-means models of phantom appliances.

TABLE IV. APPLIANCE SILHOUETTE SCORES

User 1			
office_strip_10: 0.572	tv_10: 0.678	tv_11: 0.788	charger_10: 0.637
User 2			
charger_20: 0.503			
User 3			
speaker_30: 0.915	tv_30: 0.609	charger_30: 0.478	office_strip_30: 0.954

B. Baseline Forecasting Accuracy

Line plots illustrating the energy consumption of all appliances across users are presented in Fig. 4. The blue line represents the actual energy consumption, the red dashed line indicates the predicted energy consumption, and the black dots highlight the actual values that significantly deviate from the predicted ones. Since this is a regression problem, Root mean squared error (RMSE) and MAE were used to evaluate the XGBoost models for each appliance. All scores are presented in Table V, rounded to three decimal places. Appliances that did not meet the requirements for the XGBoost model were omitted from the table.

C. Energy Consumption Analysis

We conducted a one-day experiment with three existing users via the PowerEye app (Fig. 5). Table VI compares measured energy consumption on the experiment day with the previous day.

D. User Experience

To evaluate user satisfaction with the PowerEye application, we created a survey that includes several questions

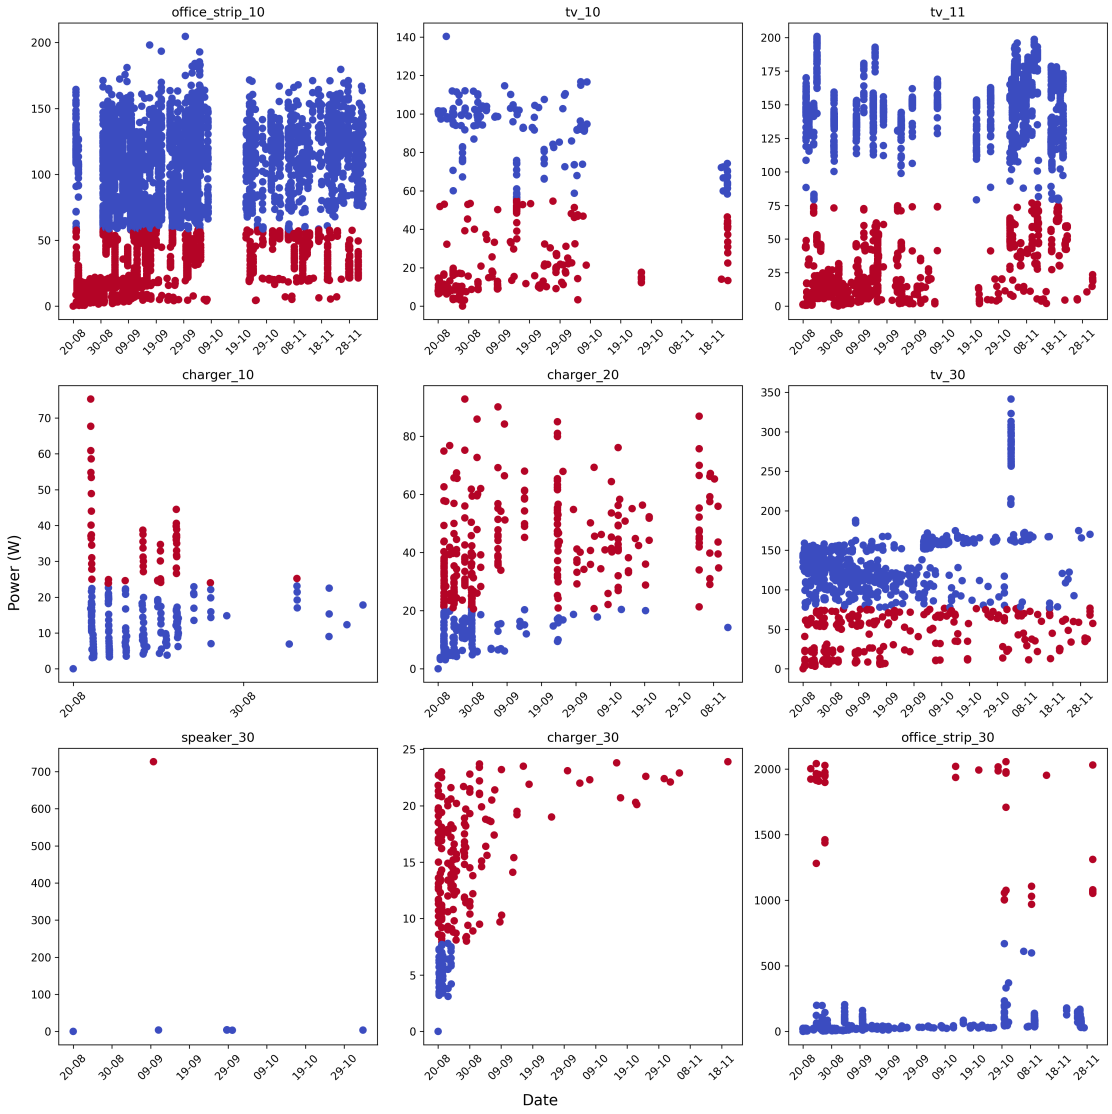

Fig. 3. Phantom appliance power clusters using k-means clustering models.

about their experience. The survey specifically assesses the relevance and helpfulness of the recommendations, as well as how effectively the application aids users in optimizing their energy consumption. Below are the questions related to the EPR and their respective responses, as shown in Fig. 6:

1) Peak time notifications: If you received peak time notifications, did the appliance mentioned in the notification match one whose use you could postpone? Did this notification help you optimize your energy consumption?

2) Goal notifications: If you received a goal notification, did the percentage mentioned match the percentage displayed in the app? Did this notification assist you in understanding your energy consumption?

3) Phantom mode notifications: If you received a phantom mode notification, was your device actually in standby mode? Did this notification assist you in eliminating energy wastage?

4) Energy baseline notifications: If you received an energy baseline notification, did you think the appliance mentioned in the notification was used excessively during that hour? Did it help you better understand your energy consumption?

VI. Discussion

A. Phantom Clustering

As shown in Fig. 3, some of the scatterplots exhibit high separation between clusters, while others do not. We can establish a threshold of 0.5 for our models. In practice, average silhouette values between 0.5 and 0.7 are commonly interpreted as reflecting moderate to good clustering structure, providing a balanced criterion for identifying meaningful clusters while avoiding over-sensitivity to noise. We can also introduce a flag to avoid sending too many notifications in a short period.

There are two cases when the model predicts incorrectly:

- False Positive: The model incorrectly classifies an on_state as phantom, leading to potentially annoying notifications. User feedback can help mitigate this.

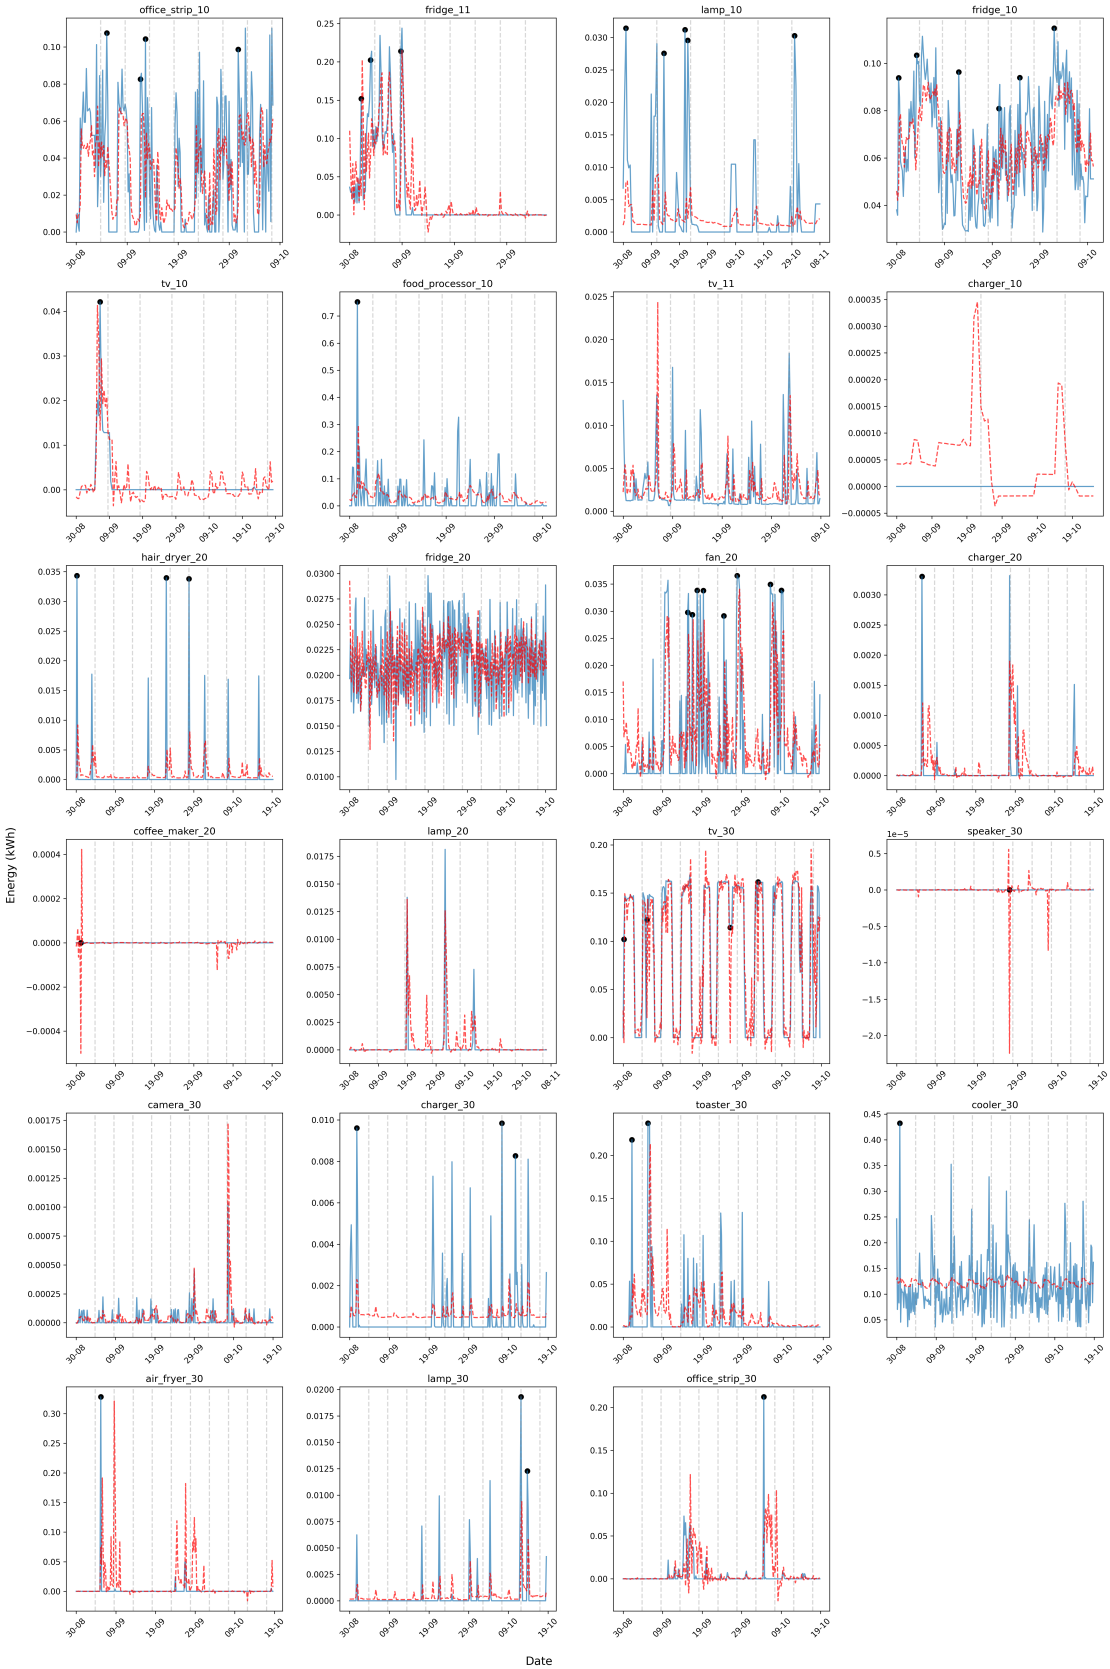

Fig. 4. Actual vs. predicted appliance energy consumption.

TABLE V. APPLIANCE MAE AND RMSE SCORES

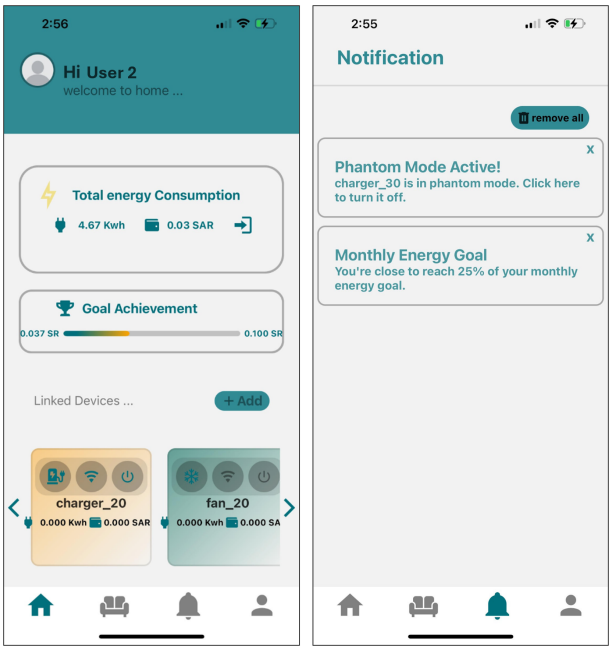

Fig. 5. PowerEye mobile application interfaces.

TABLE VI. ENERGY CONSUMPTION BEFORE AND AFTER THE EXPERIMENT

	Before (kWh)	After (kWh)	Change (%)
User 1	0.802	0.796	−0.75
User 2	0.720	0.682	−5.28
User 3	4.374	5.582	+27.62
Total	5.896	7.060	+19.74

Change = $100 \times (\text{After} - \text{Before})/\text{Before}$; negative values indicate reductions.

- False Negative: The model incorrectly classifies a phantom as on_state, missing a notification. This reduces energy optimization but has a minimal impact.

B. Baseline Forecasting Accuracy

Forecasting accuracy varied across appliances (Table V). Several models achieved low errors on the standardized consumption scale, including RMSE values of 0.147 for `tv_11` and 0.218 for `lamp_20`, while others showed larger deviations. These results characterize appliance-level prediction accuracy; comparison with a historical-average or persistence predictor is needed to establish the benefit of XGBoost over simpler forecasts.

Forecasting errors can affect excessive-use detection in two ways:

- False Positive: The model wrongly predicts excessive energy use. We can reduce this by limiting notifications to once a day.
- False Negative: The model fails to detect excessive energy use. This missed notification impacts optimization minimally.

Due to the experiment's short duration and resource constraints, we were unable to evaluate additional models. However, more advanced time-series models such as long short-term memory (LSTM) networks or autoregressive integrated moving average (ARIMA) could be considered in future work, as they are designed to capture temporal dependencies and may improve forecasting accuracy. These models, however, require higher computational resources and careful tuning to avoid overfitting, particularly when data are limited.

C. Energy Consumption Analysis

Table VI shows mixed outcomes: two participants reduced consumption, but the third participant's increase raised total consumption from 5.896 to 7.060 kWh (19.74%). Thus, the experiment did not demonstrate an overall energy reduction. The single-day intervention, small sample, and absence of a control group prevent attributing these changes to EPR rather than ordinary day-to-day variation. Longer controlled trials are needed to evaluate sustained energy savings.

D. User Experience

The majority of users reported satisfaction with PowerEye's EPR notifications (Fig. 6). While precision/recall metrics and user engagement rates are commonly used to evaluate recommendation effectiveness, the limited number of participants

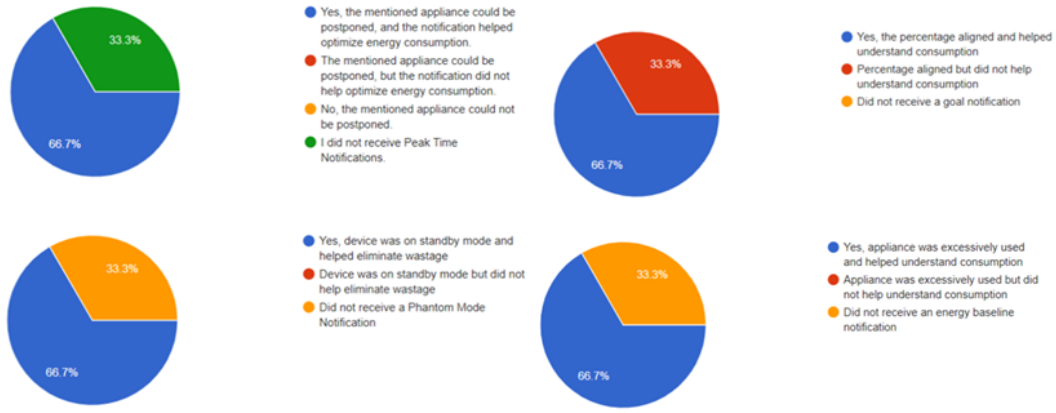

Fig. 6. User experience evaluation responses.

TABLE VII. EXISTING ENERGY RECOMMENDATION SYSTEMS VS. THE PROPOSED EPR

	Type	Multi-agent system	Uses price data	User in control	Peak time savings	Anomaly detection	Phantom mode detection

[5]	Hybrid			✓			
[15]	Content-based		✓	✓	✓		
[16]	Content-based			✓		✓	
Our EPR	Hybrid			✓	✓	✓	✓

in this study prevents statistically meaningful computation of such measures. Nevertheless, the observed user feedback suggests that the notifications were effective in supporting users' energy management and optimization efforts. These findings should be interpreted cautiously, as they are based on a small sample size and short-term deployment. A long-term evaluation involving a larger and more diverse user population is required to rigorously assess the system's effectiveness and its sustained impact on energy-saving behavior.

E. Comparative Analysis

Table VII presents a comparative analysis between existing energy recommendation systems and the proposed Energy Personalized Recommender (EPR). The comparison highlights key characteristics such as recommender type, use of price data, level of user control, and supported functionalities including peak-time optimization, anomaly detection, and phantom load detection.

Existing systems, including REHAB-C [5] and other hybrid or single-paradigm approaches, typically focus on a subset of energy management functionalities. For instance, some systems emphasize price-aware scheduling or peak-time reduction, while others address anomaly detection or provide user feedback. However, these approaches do not simultaneously integrate 1) appliance-level monitoring, 2) real-time adaptive recommendations, 3) active user interaction, and 4) multi-objective optimization within a unified framework. As a result, they remain limited either in personalization, responsiveness, or scope of optimization.

The proposed EPR integrates four complementary modules: energy goal tracking, peak-time shifting, phantom load detection, and baseline forecasting. This integration is intended to support multiple energy-management objectives within one system; its comparative effect on energy savings remains to be evaluated.

Eirinaki et al. [4] report energy reductions of 2–17%, while REHAB-C [5] reports reductions of up to 50%. In PowerEye, consumption decreased by 0.75% and 5.28% for two participants but increased by 27.62% for the third, yielding an aggregate increase of 19.74% (Table VI). This preliminary evaluation therefore did not demonstrate an overall energy reduction. Differences in study settings and evaluation methods preclude a direct performance ranking. Table VII describes functional coverage, not superior energy-saving effectiveness.

F. Assumptions and Limitations

The PowerEye project was conducted within the scope of a research-based laboratory prototype, which imposed time, hardware, and deployment constraints that influenced the study outcomes. These constraints limited the duration of data collection and the number of participating users. In particular, the evaluation relied on a small user cohort and a finite dataset, which restricts the statistical generalizability of the reported results.

Hardware resource limitations also constrained real-time processing under higher data volumes and precluded large-scale deployment. Additionally, certain edge cases, such as

irregular appliance usage patterns or atypical household behaviors, were underrepresented, which may affect the robustness of the EPR in more diverse real-world scenarios.

Nevertheless, the primary objective of this study was to validate the functional feasibility and effectiveness of the proposed EPR rather than to provide population-level conclusions. The system is designed as a modular and user-independent framework, and the employed algorithms are computationally scalable. Consequently, the proposed approach is suitable for extension to larger user bases and longer deployment periods.

VII. Conclusions and Future Work

This paper explored PowerEye's EPR for personalized energy-management recommendations. Preliminary results suggest the feasibility of its energy goal, peak time, phantom mode, and baseline algorithms, and participating users reported satisfaction with its notifications. However, the single-day deployment involving three participants did not demonstrate an overall energy reduction or establish sustained user engagement. Longer controlled trials with a larger and more diverse user base are needed to assess prediction accuracy, recommendation effectiveness, and measurable energy savings.

Acknowledgments

The authors would like to thank the software engineering team members, Maya Emar, Nour Al Akhras, Joody Koujan, Ward Najjar, Raneem Balharith, Sarah Alshagawi, and Renad Almahmoud, for their valuable assistance in developing the system. We also gratefully acknowledge Prince Sultan University for funding this research.

APPENDIX A

In this research, home appliances were categorized into three types based on their common energy patterns: Shiftable, Phantom, and None. Shiftable appliances are those whose usage can be adjusted or shifted by residents. Phantom appliances are those that consume power even when they appear to be off (Phantom Mode). The None category includes appliances that do not fit into either of the other two categories. It is important to note that all phantom appliances are considered shiftable, but not all shiftable appliances are phantom. The appliance types are demonstrated in Table VIII.

TABLE VIII. APPLIANCE TYPES

Type	Energy Type	Appliances
Coolers	None	Fridge, Freezer, Mini Fridge, Water Cooler, Fan
Lighting	None	Table Lamp, Desk Lamp, Floor Lamp, Mirror Light
Heaters	None	Microwave, Toaster, Stove, Kettle
Cookers/Makers	None	Coffee Maker, Popcorn Maker, Air Fryer, Slow Cooker
Blenders	None	Blender, Food Processor
No Category	None	Clock/Alexa, Hair Dryer, Camera
Washing Machines	Shiftable	Washer, Dishwasher, Clothes Dryer
No Category	Shiftable	Iron, Vacuum Cleaner, Air Purifier
Games	Phantom	PlayStation, Wii, Xbox
Displays	Phantom	PC, Monitor, Projector, TV
Audio Output	Phantom	Speaker, Radio
No Category	Phantom	Printer, Charger, Receiver, Sports Machine

Anatomia: An Interactive 3D Visualization Tool for Enhancing Medical Anatomy Education

***Abstract*—Anatomy education continues to rely on cadaver dissection, which is constrained by donor shortages, costs, and limited hands-on access. Digital 3D anatomy tools offer alternatives, but most do not collaborate well across multiple users, keep upright content legible as viewers move around the table, or support hand gestures specific to anatomical interaction. This study presents Anatomia, a multi-touch tabletop application designed for around-the-table anatomy learning. It introduces a set of domain-specific hand gestures developed with medical students and instructors, a content-alignment mechanism that adjusts display orientation based on the user's position around the table, and a software-level conflict resolver that allows two users to share a single display without additional hardware. Anatomia was evaluated with medical and non-medical students under a structured two-phase protocol. Results indicate that familiar touchscreen gestures succeed on first attempts, anatomically novel gestures are learned within a single guided session, content-alignment tasks score near the ceiling, and concurrent multi-user interactions achieve a perfect task success rate with no participant rejections. Together, the findings indicate that gesture-driven collaborative 3D anatomy visualization on commodity touchscreen hardware is a viable complement to traditional dissection, especially where specialized anatomy visualization tables are not affordable.**

***Keywords*—3D anatomy visualization; anatomy education; gesture interaction; multi-touch interaction; content alignment; tabletop display; collaborative learning**

I. Introduction

In the field of medical science, understanding human anatomy is fundamental for clinical knowledge and practice. For many years, anatomy education has rested on a combination of cadaver dissection, demonstrations, anatomical models, and lectures [1]. Among these, cadaver dissection has been particularly significant. It supports both anatomical knowledge and the manual dexterity, tissue-handling skills, teamwork, and professionalism that medical students require [1], [2]. Despite these benefits, cadaver dissection alone cannot easily demonstrate functional neuroanatomy, complete skeletal relationships, or the fine vascular and neural structures encountered in microsurgery [3]. Practical limitations further constrain its use: donor shortages, increasing lab costs, reduced teaching time, and health concerns related to formaldehyde exposure [4], [5], [1], [2]. These constraints are particularly tough in areas where resources are limited. Typically, in a traditional dissection lesson in medical faculties in Sri Lanka, a group of 10-20 students are assigned to a single human cadaver to carry out the studies throughout the year. This may vary with the university location, as most of the outstation universities receive a few cadavers per year. These insights highlight that there is a need for an accessible, shared-surface visualisation tool that can support cadaver-based instruction without requiring any additional cadaveric resources.

Digital tools are increasingly used alongside these traditional methods rather than replacing them. Among the available digital approaches, three-dimensional (3D) visualization has drawn particular attention: the body is inherently three-dimensional, so the ability to explore structures from different angles, isolate systems, view cross-sections, and rotate, flip, and zoom aligns naturally with how anatomy is learned and applied. According to research, 3D visualization improves overall learning experiences, increases teaching efficiency, and can be more cost-effective compared to some traditional methods [6], [4], [2], [7].

Collaborative learning around a shared surface is not a supplementary feature in anatomy education; it is central to how the discipline is taught. Students have historically gathered around a cadaver table, pointed at structures, discussed spatial relationships, and built clinical reasoning through peer interaction. When anatomy instruction moves to a digital surface, this collaborative dimension is often the first casualty: most digital tools are designed for individual use, and those that support shared displays do not account for the cognitive costs of content appearing upside down to some users or for the input conflicts that arise when multiple hands touch the screen simultaneously. Restoring the collaborative, around-the-table dynamic on a digital surface requires addressing orientation, input conflict, and gesture design together, not as isolated features but as an integrated interaction framework.

The most widely used 3D anatomy tools today include the Anatomage Table, Anatomy 3D Atlas, and Complete Anatomy, each with different pricing and accessibility models. Across these tools, three specific gaps remain unaddressed for collaborative tabletop learning. First, none offers a gesture vocabulary tuned to anatomical tasks; all rely on generic touchscreen gestures that do not capture domain-specific actions such as organ isolation or virtual dissection. Second, none provides content-orientation adaptation for users positioned around different sides of a shared display, a significant bar-

rier to legibility. Third, none includes software-level conflict resolution for simultaneous multi-user touch input, meaning that collaborative use is unsupported.

This study presents a multi-touch tabletop application designed for around-the-table anatomy learning on commodity touchscreen hardware. The work makes three contributions. First, a domain-specific gesture vocabulary was developed through a participatory design process involving medical students and anatomy instructors. Second, a content-alignment mechanism was implemented that automatically rotates displayed content based on the user's position around the table, with a manual override for locking orientation, addressing the legibility issue that arises when text and anatomical labels are viewed at high rotation angles. Third, a software-level conflict resolver was developed that enables two users to interact with the application simultaneously without requiring specialised hardware, closing the gap between hardware-bound multi-touch systems and commodity classroom displays. Together, these three components form a reusable, open-source framework that runs on standard multi-touch hardware, making collaborative 3D anatomy visualisation accessible to institutions where dedicated anatomy visualisation tables are not affordable.

The remainder of this study is organized as follows: the background and related work section examines the impact of 3D models in anatomy education and the requirements for collaborative gesture-driven tools, with a comparison of existing digital solutions, and identifies gaps that affect user experience. The methodology section presents the application's requirements, design, implementation, and the evaluation process used to assess its effectiveness. The results section presents the evaluation results of this work, followed by the discussion and conclusion.

II. Background and Related Work

A. The Role of 3D Models in Anatomy Education

Studies comparing 3D models with traditional methods for anatomy education generally support the combination of the two. Azer and Azer [8] report that incorporating 3D models into the teaching and learning process enhances the overall learning experience, increases productivity, and improves student satisfaction. Empirical comparisons point in the same direction. Yammine and Violato [7] reported that digital resources used alongside conventional techniques yield stronger learning outcomes than either approach alone.

A study by Brinke et al. [9] found that 46 undergraduate medical students at Erasmus University Medical Center who trained on 3D laparoscopic dissection models alongside lectures scored higher in both short-term and long-term anatomy assessments than peers receiving lecture-only instruction or dissection-based laparoscopic training. Murakami et al. [10] reported that 126 medical students and academic staff at the Graduate School of Medicine in Gunma University rated 3D anatomy-CT models positively, with significant improvement in radiology performance in subsequent clinical courses. A study by Müller-Stich et al. [11] compared the effectiveness of 2D CT images, static 3D-rendered liver models, and 3D models with rotational interaction (denoted 3Dr) for teaching and learning. 156 medical science students at the University of Heidelberg, Germany, were randomly assigned to one of three groups (2D, 3D, or 3Dr) and required to respond to a series of questions based on the lessons conducted. According to the results, the students in the 3D and 3Dr conditions performed significantly better than those in the 2D group. In 2024, Sarmiento [12] conducted a quantitative study to determine differences in written and lab exam scores between physical therapy students who received gross anatomy education using the Anatomage table and those who learned gross anatomy through traditional lectures. He reported a significant positive difference in written exam scores between Anatomage users and peers taught via traditional lectures.

Taken together, these studies indicate that gains from 3D visualization are largest when the comparator is textually or two-dimensionally constrained, extend beyond short-term recall to subsequent clinical reasoning, and persist when the 3D condition includes only static rendering.

B. The Need for Collaborative, Gesture-Driven Tools

Collaborative learning around a shared surface is central to how anatomy is taught, yet most digital tools are optimized for single-user interaction. Historically, supporting multiple users around a shared display required specialized hardware. Systems such as DiamondTouch [13] relied on antenna-embedded chairs to identify individual users via capacitive coupling. At the same time, other research has used overhead cameras to track hands using skin-color segmentation techniques [14]. These hardware-based solutions are often too expensive or complex for standard medical classrooms, particularly in resource-constrained environments where cost is a primary barrier to adoption [15]. A software-only approach to conflict resolution that works on commodity touchscreens would allow multiple students to interact simultaneously without specialized equipment.

The orientation of digital content creates an additional cognitive burden when students are positioned on opposite sides of the tabletop display. Human perception of text and objects is sensitive to rotation; for example, word recognition time is relatively stable for rotations up to 60°, but reaction times increase significantly as the orientation approaches 70–80% beyond 120°. Research indicates that at these higher angles, the brain shifts from holistic recognition to a much slower "letter-by-letter" processing method [16]. This "holistic rectification" threshold suggests that a visualization tool must automatically align its content to the user's position to remain legible and effective for learning.

Effective interaction also requires a gesture vocabulary that reflects the specific tasks of the medical domain. While standard mobile gestures like pinching and swiping are common, they often fail to capture complex anatomical actions such as organ isolation or virtual dissection. Research into the Surgery Planner system demonstrated that domain-specific interaction techniques improve usability and help maintain professional standards [17]. By using a participatory design approach, in which students and instructors help identify necessary gestures, developers can ensure alignment with users' mental models.

C. Current Digital Solutions and Limitations

Current anatomy software generally falls into two categories: high-end hardware-bound systems and mobile-centric

applications. Neither category fully addresses the needs of collaborative, tabletop learning.

The Anatomage Table is a touchscreen platform that serves as a virtual dissection table, using a library of 3D-reconstructed and prosections [18]. It allows for detailed interactive segmentation, enabling users to isolate specific muscular or neurovascular structures and view them across three section planes [18], [19]. While highly effective at simulating physical dissection, it does not provide software-based multi-user conflict resolution or adaptive content orientation. The Anatomage Table is a proprietary, non-portable hardware-software bundle with an acquisition cost that places it beyond the reach of most medical faculties in low and middle-income countries.

Anatomy 3D Atlas is an interactive virtual environment for learning about the body's various systems, including skeletal, circulatory, neurological, respiratory, digestive, and urinary systems. It supports basic 3D navigation and object manipulation, like hiding or multi-selecting organs [20]. However, it is primarily a single-user mobile tool that cannot display cross-sectional views or import medical scans such as CT or MRI data. The Anatomy 3D Atlas is subscription-based and designed for individual learning on mobile devices such as smarphones and tablets, not for shared-surface collaboration.

Complete Anatomy includes a highly detailed interactive atlas featuring over 13,000 structures and 12 systems [21]. It includes advanced features such as real-time muscle motion, nerve pathway tracing, and virtual dissection tools [22]. While it is a robust educational resource available on multiple operating systems, it is optimized for individual student use. It lacks collaborative features such as content alignment and multi-user touch handling on shared displays. When it comes to pricing, Complete Anatomy operates on a subscription model with tiered student, professional and institutional pricing [21].

Unlike educational tools, Surgery Planner was developed as a research prototype for clinical routine, specifically for planning orthopedic surgery [17]. It provides users with a comprehensive understanding of the surgical site, allowing them to draw and manipulate incision areas and explore various surgical options. While it proves the value of domain-specific gestures, it is a specialized planning tool rather than a general-purpose educational platform.

Table I highlights the specific research gaps identified among these tools. These differences mean that a direct feature comparison does not capture the full picture - features exclusive to a high-cost proprietary system may reflect its pricing tier rather than a technical advantage. Therefore this comparsion intends to identify functional requirements for collaborative tabletop anatomy learning that are unmet by any single existing tool, rather than to suggest that any individual tool is deficient within its own intended context.

The unmet functional requirements identified in this literature review informed the architecture of Anatomia. Most current applications rely on generic gestures and static content that do not account for the physical position of multiple users. There is a notable lack of a reusable, open-source framework that combines domain-specific gestures with content-alignment mechanisms. Anatomia fills this gap by providing a toolkit that addresses these collaborative needs while remaining accessible on commodity touchscreen hardware.

III. Methodology

This study followed a participatory design approach with summative task-based evaluation at the end of development. During the design phase, medical students and anatomy subject-matter experts iterated with the research team, and the application was shaped at each round to better meet learners' needs in dissection lessons. Four research questions guided the work:

- What are the suitable extended-hand gestures to interact with an anatomy visualization application?
- What are the suitable methods to address the orientation issues of the displayed content in order to enhance the user experience?
- What kind of mechanism is needed to handle the conflicts that occur when multiple users interact with the application simultaneously?
- How can a solution be provided as a framework that addresses the above-mentioned problems?

The methodology proceeded in four sequential phases: 1) problem identification and requirement gathering via the literature review and observational study of the target users; 2) solution design informed by domain expert input and a questionnaire distributed to medical students; 3) artifact development of a 3D anatomy visualization and interaction mechanism for large tabletop display systems; and 4) evaluation of the final product with medical and non-medical participants.

A. Domain Survey and Requirements

1) Observational user study: An observational study was conducted at the Faculty of Medicine, University of Wayamba, Sri Lanka, involving 75 students, 4 anatomy instructors, and 1 lecturer. At the time of the study, the faculty had only four cadavers for 150 students — approximately 1 cadaver per 38 students. Several observations were made during the study:

Most students could not clearly follow the dissection demonstrations. Only the two or three most confident students had the opportunity to perform the incision on the cadaver, leaving the rest of the group with little chance to observe the dissection. Even a small incision mistake on one cadaver could have a severe effect on all of the students allocated to that body. The same cadaver was used throughout the first academic year and was kept in glycerin rather than in freezers between classes. Smaller structures such as blood vessels, lymphatic vessels, and inner-ear organs were difficult to observe, and a few cadavers had fat layers or diseases that made certain organs hard to examine. Apart from a projector used to view some lessons with a camera, no infrastructure was available to assist in the lessons. Students reported consulting the Anatomy 3D Atlas on their personal mobile phones or laptops during dissection.

These observations established the gap that Anatomia was designed to fill: a tabletop visualization tool that supports co-located, multi-user study around a shared display without requiring additional cadaveric infrastructure.

TABLE I. COMPARISON MATRIX OF 3D ANATOMY APPLICATIONS

Feature	Anatomage	Anatomy 3D Atlas	Complete Anatomy	Surgery Planner	Anatomia
Virtual dissection	Available	Available	Available	Not available	Available
Domain-specific gestures	Not available	Not available	Not available	Available	Available
X-ray & CT image viewing	Available	Not available	Available	Available	Available
Multiple 3D models	Available	Available	Available	Not available	Not available
Details on parts	Available	Available	Available	Not available	Available
Multi-user interaction	Not available	Not available	Not available	Available	Available
Orientation change	Not available	Not available	Not available	Available	Available
Cross-platform	Not available	Available	Available	Not available	Available
Hardware platform	Proprietary tabletop display	Mobile devices	Personal computers & mobile devices	Multi-touch table	Commodity multi-touch display & mobile devices
Cost model	High (proprietary hardware –software bundle)	Subscription-based	Subscription-based	Research prototype	Open-source software; commodity hardware only

2) Gesture elicitation and requirements survey: A questionnaire was administered to 20 students from the Faculty of Medicine, University of Wayamba, and 3 medical science students from the Faculty of Medicine, University of Colombo. The questionnaire captured the suitable gestures for specific interactions, desired functional requirements, and features to avoid based on prior experience with existing solutions. Video clips and images were incorporated into the questionnaire to communicate the hand gestures under discussion.

For gesture identification, participants were asked to select the most suitable gestures for each of the following operations:

- Rotate the organ in the X, Y, and Z axes
- Drag the organ in the XY plane
- Zoom the 3D model in and out
- Select an organ or menu item
- Select multiple organs of the model
- Restore/rearrange the 3D model to its default orientation
- View the organ cross-section

Participants chose the appropriate gesture from nine options, including an ”Other” option that invited them to propose novel gestures, which the implementation team reviewed before adding them to the system vocabulary.

3) Domain expert input: According to the anatomy subject-matter expert consulted, anatomy lessons are generally conducted under separate sections of the human body, such as the head, neck, torso, upper extremities, and lower extremities, rather than by physiological system. To align with this pedagogical approach, the initial implementation of the application will focus on the human body by section rather than on systems as a whole, such as the digestive or skeletal systems.

4) Functional and non-functional requirements: Three main use cases were identified for the application: 1) select and view a 3D anatomical model, 2) view CT and X-ray images, and 3) interact with the 3D model through gestures. These use cases encompass sub-functionalities, including rotating and zooming the model, dragging it across the screen, viewing cross-sections, isolating and hiding organs, viewing organ details, and drawing annotations on the screen.

The application was designed to meet three key non-functional requirements: To ensure usability, it is tailored to a tabletop touch display. UI standards follow industry conventions, gestures map to real-world actions to aid memorization, with self-explanatory icons to facilitate faster learning. For accuracy, a conflict-resolution component was integrated to address conflicts arising from simultaneous multi-user interactions, and the application was designed to recognize and differentiate among hand gestures involving the same number of fingers. For performance, resource-efficient methods were adopted to implement resource-intensive functionalities, particularly when a 3D model is split into two parts.

B. System Architecture

Anatomia was built on a layered architecture that isolates hardware, operating system, rendering, and application logic as illustrated in Fig. 1.

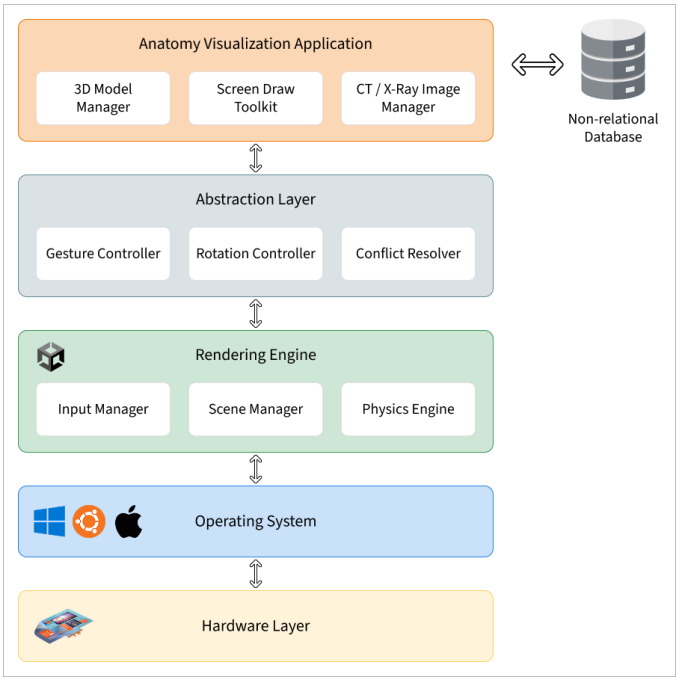

Fig. 1. System architecture diagram.

The hardware layer consists of the Displax Skin Ultra multi-touch display system, which can detect up to 100 simultaneous touch points and recognize objects. The operating system layer supports deployment on Windows, Ubuntu, and macOS. The rendering layer is powered by the Unity engine, which provides the input manager, scene manager, and physics engine. The abstraction layer contains reusable components that are loosely coupled to the anatomy visualization application: the gesture controller handles rotations, scaling, dragging, and cutting of 3D models; the rotation controller manages the rotation of UI elements to different orientations; and the conflict resolver addresses issues arising from simultaneous multi-user interaction. The application layer consists of three components: the 3D model manager, which displays user-selected 3D models and isolates relevant organs; the screen draw toolkit, which enables users to draw on the screen using single-handed gestures; and the CT/X-ray image manager, which facilitates the importing and viewing of CT and X-ray images. Organ information is stored in a MongoDB non-relational database.

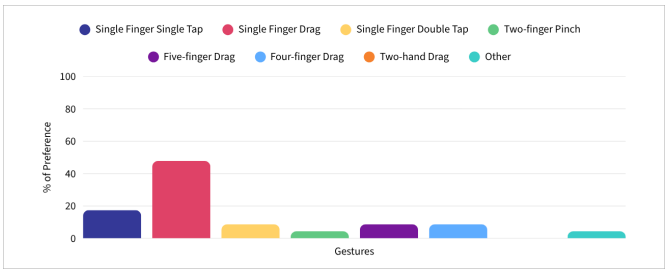
C. Implementation

Anatomia was developed using Unity 2021.3 as the development environment, chosen for its rich asset store and built-in canvas system for UI development. Blender 3.1 was used to modify the 3D models due to its comprehensive feature set and free availability. The absence of fixed relationships or a specific set of attributes for organs made a non-relational database more suitable. Therefore, MongoDB 6.0 was selected as the database for storing information about human body systems and organs. The development language was C#, and version control was managed through GitHub. The application is compatible with Windows 7 and later, macOS, and Linux operating systems.

1) Gesture vocabulary: The survey outcomes and domain-expert input together produced a finalized gesture vocabulary. The survey outcomes and domain-expert input together produced a finalised gesture vocabulary. The design process applied three selection principles: 1) where a clear participant majority aligned with established touchscreen conventions, that gesture was adopted directly; 2) where participants selected the same gesture for multiple operations, an alternative gesture was designed in consultation with participants and domain experts to resolve the conflict; and 3) where participants favoured the "Other" option over the predefined gestures, the most intuitive gesture from the participant-proposed suggestions was selected in consultation with domain experts.

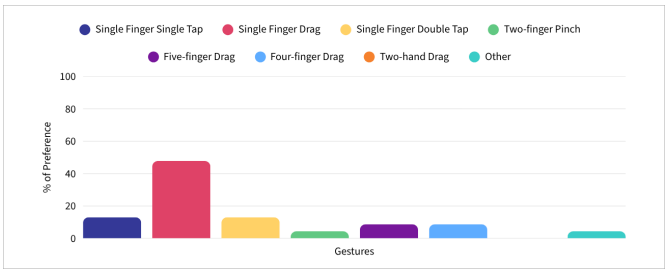
Applying the first principle, rotation along the X, Y, and Z axes was assigned to single-finger drag, which carried the highest preference share in each case (Fig. 2a, Fig. 2b, Fig. 2c) and matches the conventional touchscreen drag-to-rotate mapping. For dragging the 3D model across the XY plane, the five-finger drag captured the majority of preferences at 39.1% (Fig. 2d). Zoom was assigned to two-finger pinch, chosen by 43.5% of participants (Fig. 2e), consistent with the established pinch-to-zoom convention. As shown in Fig. 2f, restoring the 3d model to the default anterior view was assigned to a single-finger double tap, which held the majority preference at 34.8%. These gestures required no adaptation beyond implementing the conventional mapping.

Single-finger tap was assigned to single organ or menu item selection, preferred by 82.6% of participants (Fig. 2g). The same gesture also received greater preference for selecting multiple organs (Fig. 2h). To resolve this conflict, the second principle was applied, and a two-stage gesture was designed: placing a single finger on an organ activates multi-select mode, after which subsequent single-finger taps add organs to the selection.



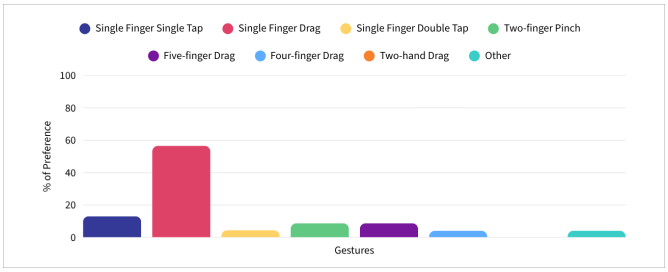
For viewing the cross-section of the model, the largest share of participants selected the "Other" option (Fig. 2i), indicating that none of the standard gestures presented in the questionnaire felt appropriate for this anatomically specific action. Participants who selected "Other" were invited to propose alternative gestures. Among the proposed suggestions, domain experts were consulted to identify the most intuitive option. The selected gesture involved the user placing all five fingers steadily on the screen while dragging a single finger across the 3D model in the area where the cross-section is to be observed. This gesture was deemed appropriate based on the input provided by the domain experts, as it mirrors the physical action of holding a specimen steady with one hand while cutting with the other, a mapping considered intuitive for students with dissection experience.

The gesture vocabulary described above represents the final iteration of the design, which was refined through formative evaluation during development. In an initial round of user testing, participants expressed difficulty remembering the specific gestures required for certain actions. They also suggested that a visual guide or tutorial on the gesture mappings could be helpful, particularly for users who are new to the system or who may not be familiar with the gestures used in the application. In response to this feedback, the gesture mappings were revised to ensure clearer differentiation between gestures sharing the same initial hand posture. A visual guide displaying the gesture vocabulary was also integrated into the application interface, providing a reference that users could consult during interaction.

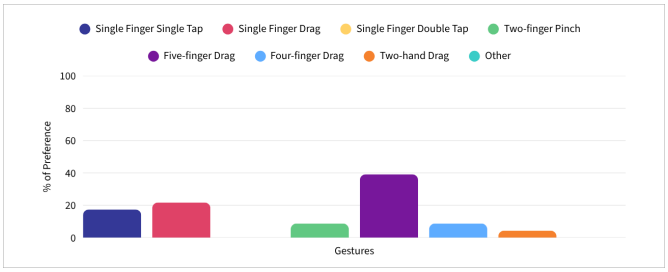


The gesture controller was implemented to handle all hand gestures for the application. It comprises a primary script that orchestrates gesture recognition, a touch controller that manages single and double taps, helper scripts for auxiliary functions, and customizable scripts for each gesture that facilitate 3D object and UI manipulation. These customizable scripts can be added to any 3D object and configured with corresponding parameters to execute a specific gesture, enabling the definition of additional gestures.

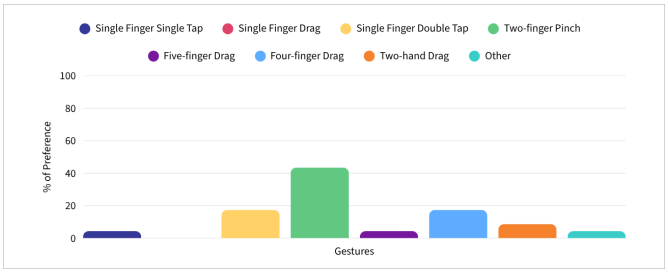
2) Content alignment mechanism: A radial menu at one corner of the screen indicates the user's position relative to the display. The mechanism provides auto-rotation from the menu position and a manual override that locks the orientation. Boundary parameters for auto-rotation can be reconfigured in the Unity editor without manual code changes. The threshold was set at 60°, following Koriat & Norman's finding that reading rates stay stable up to that angle [16].



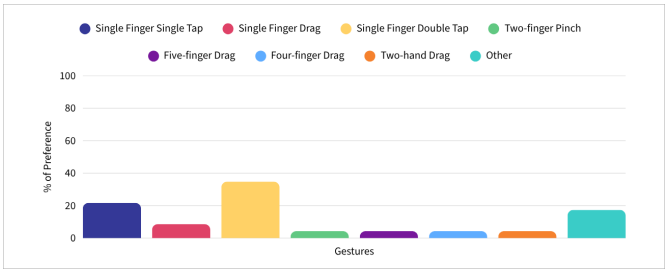
To ensure optimal content orientation, it is necessary to determine the user's position relative to the display. The proposed content alignment mechanism comprises two primary features. The first is automatic content rotation based on the user's position, achieved by leveraging the application's radial



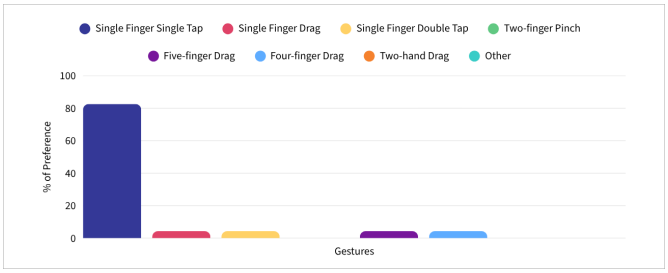
(a) Gesture preference for rotating an organ around the X-axis.



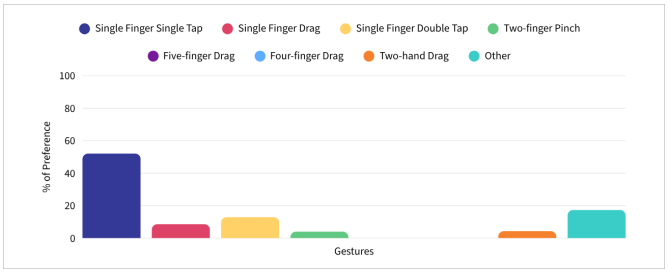
(b) Gesture preference for rotating an organ around the Y-axis.



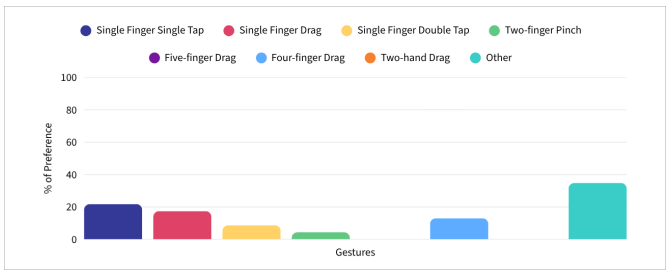
(c) Gesture preference for rotating an organ around the Z-axis.



(d) Gesture preference for dragging an organ in the XY plane.



(e) Gesture preference for zooming the 3D model in/out.



(f) Gesture preference for restoring the 3D model.

(g) Gesture preference for selecting an organ/menu item.

(h) Gesture preference for selecting multiple organs of the model.

(i) Gesture preference for viewing organ cross-section.

Fig. 2. Gesture preferences for 3D model interactions.

menu. The approach assumes that the user positions the radial menu on their side of the screen; the content on the display is then oriented accordingly. The radial menu can be moved across the screen, and all UI elements rotate accordingly. The auto-rotation boundary parameters can be easily modified in the Unity editor without requiring manual code changes. The second feature allows users to manually rotate the UI components in the X and Y planes and lock them in place to prevent auto-rotation, providing flexibility for specific viewing preferences.

3) Multi-user conflict resolution: Identifying users' touches distinctly on a multi-touch surface has traditionally required specialized hardware infrastructure, such as DiamondTouch's antenna-embedded chairs [17] or camera-based hand-tracking systems [14]. The focus of this project was to address multi-user interaction issues by resolving conflicts of the hand gestures of two simultaneous users at the application level, without requiring any additional hardware.

A conflict-resolution component was introduced that operates alongside an accessibility button. The conflict resolver operates as follows for two simultaneous users: 1) the screen is divided into two equal parts; 2) once a user touches the screen, the conflict resolver checks the number of touches on that particular side of the screen; 3) based on the number of touches and the behavior of those touches, the corresponding gesture is performed; and 4) if both users attempt to manipulate the 3D model at the same time, priority is given to the action performed by the user who has the radial menu or accessibility button on their side. This method is entirely implemented at the software level, with no additional hardware components required. UI dragging, 3D model rotation, and 3D model zoom-in/out actions were implemented and tested using this conflict-resolution mechanism. Other gestures can also be extended by following the same approach to provide a multi-user experience.

4) Object dissection: The 3D anatomy model used in the application was a combination of mesh models, and two approaches for implementing virtual dissection were investigated: mesh cutting and clipping.

The mesh cutting technique is performed with a cut gesture, in which one hand holds the model while the other draws a line. A line renderer responds to finger movement. The algorithm for separating the 3D model proceeds as follows: two empty game objects are created to represent the two sides of a given cutting plane. For each mesh model, the algorithm checks whether it intersects with the cutting plane. If it does not intersect, the model is added as a child game object to the corresponding side. If it does intersect, two dynamic mesh models are constructed (one for each side of the plane), and the position of each polygon relative to the cutting plane is computed to assign it to the appropriate side.

The clipping method, by contrast, does not divide the 3D mesh model into two separate parts. Instead, it uses a clipping plane, a custom shader, and materials created with that shader to hide or make transparent a portion of the 3D mesh. A line is drawn using the line renderer in response to finger movement; the clipping plane changes its position to the line location and orients itself to the same angle; and the user selects the part that must be removed or hidden, which becomes transparent (Fig. 3). Because clipping requires fewer computational resources compared to mesh cutting, it was chosen as the feasible approach for the application.

5) X-Ray/CT image viewer: Anatomia enables users to access and interact with up to two X-ray or CT images simultaneously. Users can manipulate the images through three gestures: two-finger rotation, which allows the user to hold one finger in a fixed position on the image while moving another finger to rotate the image in any direction; two-finger zoom, which enables the user to zoom in or out by moving two fingers in opposite directions; and five-finger drag, which allows dragging the images across the screen in any direction.

6) Other 3D object manipulation features: Several additional features were implemented to enhance the learning experience of Anatomia.

The drawing tool lets users draw on the screen with a one-finger gesture to annotate or mark specific areas in images or 3D models. A line can be drawn by dragging one finger across the screen, and users can select from a predefined set of colors to draw around the 3D model, X-ray, and CT images.

The organ detail viewer allows users to select an organ and view a pop-up with basic information about it (Fig. 4). The hide and isolate functionality allows users to select one or more organs with a single tap or a long-tap gesture, then either isolate the selected organs (viewing only those) or hide specific organs from view. This functionality employs four stacks to manage the display state: an undo stack that stores all removed organs at each step, a redo stack that stores organs added during each undo step, an undo sequence stack that tracks the number of organs removed at each action, and a redo sequence stack that tracks the number of organs restored at each action.

The layer-wise view feature provides navigation through the multiple layers of the 3D model, with each organ placed precisely under a single layer. The Layers UI allows users to hide or restore previously hidden layers using the "Add" and "Hide" (5) options, and the "Select" option enables or disables the desired layers. The application maintains a list of layers, with two Boolean variables for each: one indicating whether the layer is entirely hidden when the "Select" option is used, and another indicating whether the layer is temporarily hidden when the "Add" or "Hide" option is used (Fig. 5).

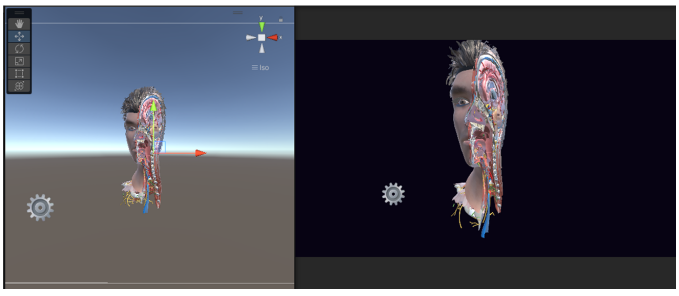


Fig. 3. Object dissection via clipping.

D. Evaluation

The application underwent both formative and summative evaluation. Formative evaluation was conducted iteratively throughout the development cycle to refine the interface based on user feedback. Summative evaluation assessed the user experience of the developed 3D anatomy visualization application. Two complementary analyses were carried out: a performance metrics analysis of task success and a self-reported metrics analysis comparing Anatomia with the Anatomy 3D Atlas and traditional cadaver dissection.

For the performance metrics analysis, two groups of participants were recruited: 1) 8 students from the UOC Faculty of Medicine and the Faculty of Indigenous Medicine who had prior experience with traditional cadaveric dissection, used to evaluate the application's fit for experienced anatomy learners; and 2) 5 students from non-medical backgrounds, used to evaluate usability, learnability, and collaboration support for novice users. Performance was measured using a task-success metric: the proportion of tasks each participant completed successfully out of 15 administered tasks covering hand gestures, content alignment, and multi-user interaction capabilities (6). The task list is shown in Table II; their IDs are referenced throughout the remainder of the study.

This analysis was conducted in two phases to record task performance both with and without assistance. Phase 1 established the unassisted baseline for each participant, and Phase 2 established performance after brief verbal guidance. In Phase 1, each participant performed every task in Table II in sequence, without assistance from the evaluator. A think-aloud protocol was used throughout this phase to record expectations, misconceptions, and gesture-association patterns alongside task-success scores. In Phase 2, the evaluator gave brief oral instructions to any participant who had failed a task in Phase 1, and the participant then repeated the task. This phase established the level each participant could reach with minimal verbal guidance rather than independent exploration. By comparing Phase 1 and Phase 2 performance for each task, the evaluation distinguishes initial learnability from overall usability. Task success was scored on a five-level scheme as follows, with one score recorded per participant per task:

- **Score 1.0**: Participant completed the task on the first attempt without any assistance.

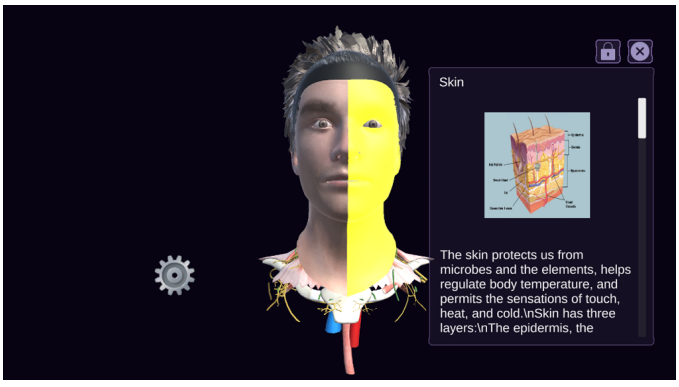

Fig. 4. View organ details.

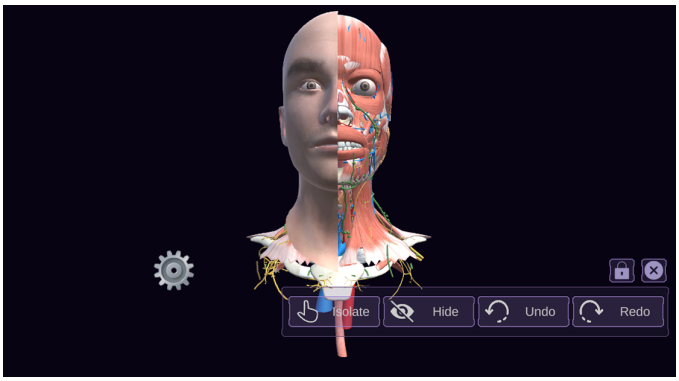

Fig. 5. View after hiding an organ/layer.

- **Score 0.75**: Participant failed the first attempt but succeeded on the second with minor verbal guidance.
- **Score 0.5**: Participant failed the first two attempts but succeeded after observing a group member perform the task.
- **Score 0.25**: Participant failed several attempts and eventually succeeded after observing a group member perform the task.
- **Score 0**: Participant failed to complete the task after more than three attempts.

Descriptive statistics were used to analyze the performance metrics ratings, including mean task-success scores across participants and the frequency distribution of each score level per task [23]. Given the ordinal nature of the task-success scores and the small sample sizes, non-parametric tests were used for all inferential analyses (Fig. 6). Between-group comparisons (medical vs. non-medical) were conducted using the Mann–Whitney U test [24], with Cliff's delta (δ) as the effect-size measure [25]. Cliff's delta quantifies the degree to which scores in one group tend to exceed scores in the other, ranging from -1 to $+1$; absolute values below 0.147 are interpreted as negligible, between 0.147–0.33 as small, between 0.33–0.474 as medium, and at or above 0.474 as large [26]. Within-group comparisons of familiar versus novel gestures were analysed using the Wilcoxon signed-rank test, with effect size r computed as the standardised test statistic divided by the square root of the number of pairs. All tests were two-tailed at $\alpha = 0.05$.

The Self-reported metrics analysis was carried out to identify users' perception of the application and their interactions [27]. This included a post-session questionnaire with 5-point Likert-scale statements (strongly disagree, disagree, neutral, agree, strongly agree) and one open-ended prompt for free-text suggestions. This questionnaire was designed specifically for this evaluation to capture comparative judgments between Anatomia, the Anatomy 3D Atlas, and traditional cadaver dissection. The questions were informed by the usability dimensions identified during the participatory design phase but should be interpreted as exploratory indicators of user perception rather than psychometrically validated measures. Each participant was allowed to interact with both applications. Then they were provided with a questionnaire that tested

TABLE II. TASKS EVALUATED IN THE PERFORMANCE METRIC ANALYSIS

Task ID	Task	Scenario
T1	Inspect an organ: zoom in or out of a particular organ	Hand gestures
T2	Rotate an organ around the X, Y, and Z axes	Hand gestures
T3	Select a single organ to view its details	Hand gestures
T4	Select multiple organs to isolate or hide them as a group	Hand gestures
T5	Restore the 3D model to its default anterior view after rotation	Hand gestures
T6	Drag the 3D model across the XY plane	Hand gestures
T7	Rotate a UI element (pop-up) manually	Hand gestures
T8	Drag a UI element across the screen	Hand gestures
T9	Upload an X-ray image to the X-ray viewer and perform zoom, drag, and rotate	Hand gestures
T10	Dissect the 3D model and view a cross-section	Hand gestures
T11	Rotate all visible UI elements to the opposite direction	Content alignment
T12	Disable auto-rotation of a particular UI element	Content alignment
T13	Perform two zoom actions simultaneously from opposite sides of the screen	Multi-user
T14	Perform zoom on the 3D model and rotate the model simultaneously	Multi-user
T15	Perform zoom on the 3D model and drag a UI element simultaneously	Multi-user

whether the Anatomia application adds pedagogical value and whether it is more usable than alternative tools, such as the Anatomy 3D Atlas application and cadaver dissection. The phenomenon in which participants tend to provide responses that they believe will be perceived favorably by others is commonly known as social desirability bias [28]. To mitigate this bias, the questionnaire was anonymous, and all 13 participants completed it without being observed.

Before the summative evaluation, the Anatomia application was tested at four levels: unit testing of gesture functions using Unity Remote 5; integrated testing across the mobile device and the tabletop display system; system testing through preliminary user studies; and performance testing to ensure resource efficiency under concurrent multi-user interaction.

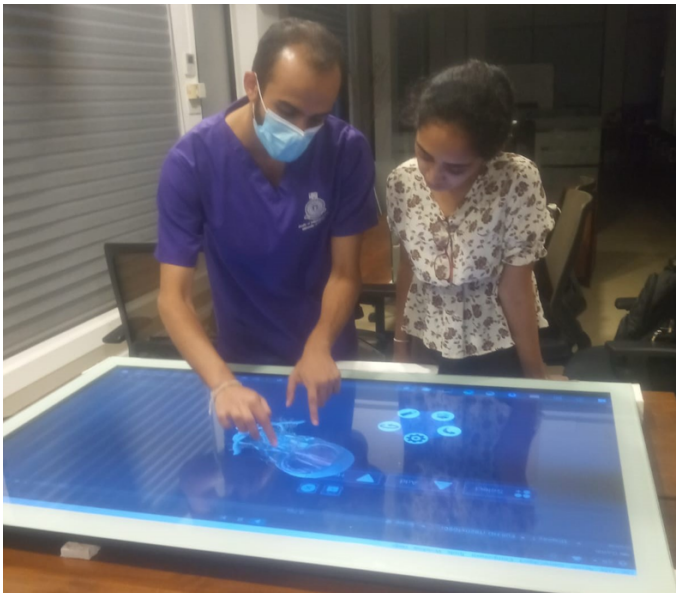

Fig. 6. Medical science students performing tasks in the summative evaluation.

IV. RESULTS

A. Performance Metrics Analysis Results

Medical students (Tables III and V): The 8 medical students achieved an overall median task-success score of 0.90 (M = 0.89, SD = 0.04) across all 15 tasks. Tasks drawing on conventional touchscreen gestures such as single-tap selection (T3, Mdn = 1.00), single-finger drag for rotation (T2, Mdn = 1.00), and two-finger pinch to zoom (T1, Mdn = 1.00) received near-perfect scores, as did T8 and T9, which involve familiar gestures applied to UI elements and image upload. A Wilcoxon signed-rank test confirmed that familiar touchscreen gestures (Mdn = 1.00) yielded significantly higher scores than the novel domain-specific gestures (Mdn = 0.75) within this group (W = 0, p = .008, r = 0.89, large effect). The distribution of score levels across the medical-student group is shown in Fig. 7.

The lower scores corresponded to the anatomically novel gestures: five-finger drag for model translation (T6, Mdn = 0.75), single-finger double tap for default-view restoration (T5, Mdn = 0.75), and the five-finger steady with one-finger drag for cross-section viewing (T10, Mdn = 0.63). For T5 and T6, most participants failed on the first attempt but succeeded on the second after minimal verbal guidance. The implications of this pattern for learnability versus mental-model alignment are examined in Section V. Content-alignment tasks (T11, Mdn = 0.75; T12, Mdn = 1.00) and multi-user interaction tasks (T13–T15, all Mdn = 1.00) recorded scores at or near ceiling for the medical-student group, with zero variance across participants on the multi-user tasks, indicating that the auto-rotation mechanism and the conflict resolver added no measurable usability overhead.

Non-medical students (Table IV and V): The 5 non-medical students recorded an overall median task-success score of 0.83 (M = 0.82, SD = 0.04), lower than the medical group. A Mann–Whitney U test on participant-level averages confirmed that this overall group difference was statistically significant (U = 37.0, p = .015, Cliff's δ = 0.85, large effect), consistent with a carryover advantage from prior specimen-handling experience among medical students.

A detailed breakdown of participant-level scores is shown in Fig. 8. The largest differences from the medical group

TABLE III. TASK SUCCESS METRICS OF MEDICAL STUDENTS

	T1	T2	T3	T4	T5	T6	T7	T8	T9	T10	T11	T12	T13	T14	T15	Mean

appeared on the anatomically demanding tasks: T4 (multi-organ select, Mdn = 0.50, δ = 0.58) and T10 (cross-section viewing, Mdn = 0.50, δ = 0.50), both showing large effect sizes. However, neither per-task comparison reached significance at α = 0.05 (T4: U = 31.5, p = .075; T10: U = 30.0, p = .083), which is consistent with the limited statistical power of the sample rather than evidence of no group difference. T5 through T7 ranged from Mdn = 0.75 to Mdn = 0.65. With minimal verbal guidance during Phase 2, the non-medical participants completed most failed tasks on the next attempt. T10 recorded the lowest score in the non-medical group, with all five participants requiring peer observation before completing the task. The possible explanations for this pattern are discoverability, mental-model mismatch, or domain unfamiliarity. The pattern across both groups indicates that participants achieved task completion across the full gesture set within a single guided session, with the largest performance gaps concentrated on the anatomically novel gestures rather than the interface mechanisms. Content-alignment and multi-user tasks showed identical median scores across both groups (T11: Mdn = 0.75; T12–T15: Mdn = 1.00), confirming that these mechanisms performed consistently regardless of domain background.

B. Self-Reported Metrics Analysis Results

The post-session questionnaire aimed to capture participants' comparative judgments of Anatomia relative to the Anatomy 3D application and traditional lessons. Fig. 9–10 present the bar-chart distributions for the six reported items, and the remaining items are summarised at the end of this subsection. All response frequencies are reported as a numerator over 13 participants (N=13).

In the questionnaire-based comparison, participants consistently rated Anatomia favorably over both traditional dissection lessons and the Anatomy 3D Atlas. On the user-friendliness

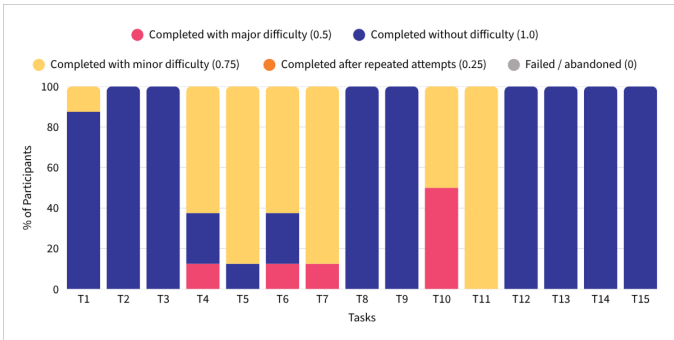

Fig. 7. Task success rates of medical students.

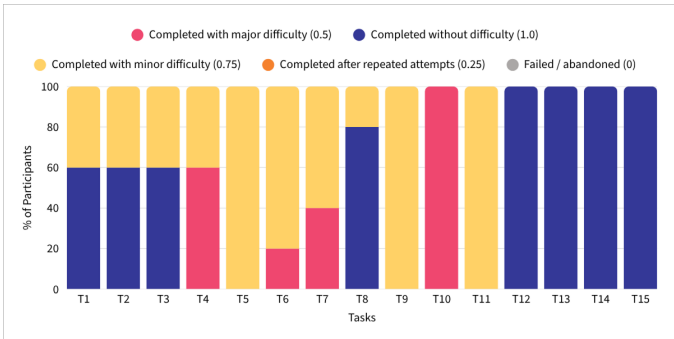

Fig. 8. Task success rates of non-medical students.

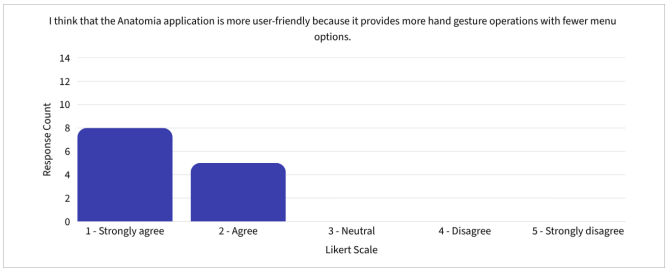
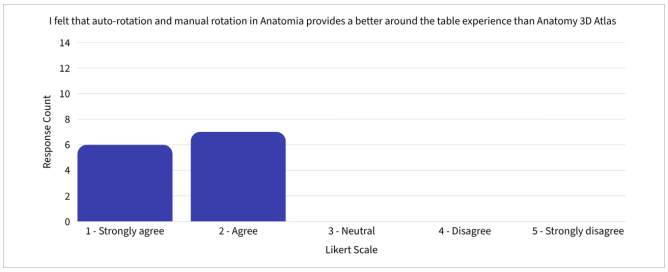
of Anatomia over Anatomy 3D Atlas, all 13 participants (8 strongly agree, 5 agree; 100.0% total agreement) endorsed Anatomia, as shown in Fig. 9a. On around-the-table alignment, again 13 out of 13 (6 strongly agree, 7 agree; 100.0% agreement) voted for Anatomia (Fig. 9b). Regarding menu design, all participants (9 strongly agree, 4 agree; 100.0% agreement) endorsed the radial menu over the Atlas fixed menus (Fig. 9c). Anatomia's ability to allow multi-user interaction was also endorsed unanimously (8 strongly agree, 5 agree; 100.0% agreement, as shown in Fig. 9d). This complements the performance-metric findings in Section IV-A, where tasks involving multi-user interaction reached 1.00 across all 13 participants.

When comparing the Anatomia application to cadaver-based dissection, regarding reusability, all 13 participants (9 strongly agree, 4 agree; 100.0% agreement) endorsed Anatomia as superior to traditional dissection (Fig. 10a). On collaboration, 10 of 13 (5 strongly agree, 5 agree; 76.9% agreement) endorsed Anatomia, with 2 of 13 remaining neutral and 1 of 13 strongly disagreeing (Fig. 10b). The gap between reusability and collaboration aligns with the cadaver-access constraints recorded at the University of Wayamba during the observational study (150 medical students shared 4 cadavers across the academic year): reusability addresses a constraint that participants experience universally, whereas the collaboration axis compares Anatomia's deliberate two-user protocol against the unstructured peer interaction that already happens at a single cadaver station.



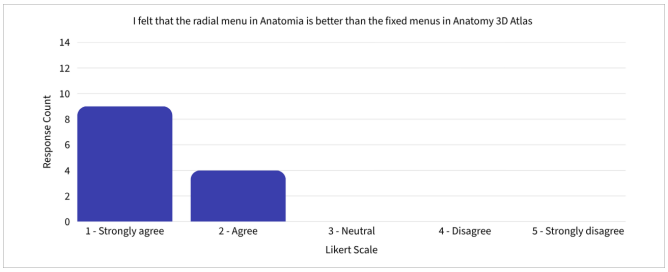
V. Discussion

The summative evaluation supports each of the three design contributions outlined in Section III: the gesture vocabulary is learnable, the content alignment mechanism scores highly on usability, and the software-level conflict resolver works in the context of two concurrent user interactions without introducing qualitative friction. The overall group difference between medical students (Mdn = 0.90) and non-medical students (Mdn = 0.82) was statistically significant (U = 37.0, p = .015, Cliff's δ = 0.85), and the self-reported comparison items reached 100.0% or 76.9% agreement, providing evidence behind that conclusion.

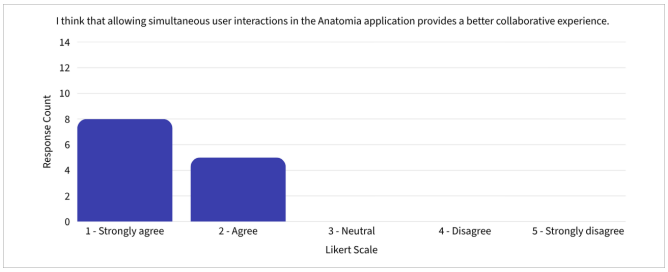


The three basic hand-gesture tasks—single-finger tap for selection, single-finger drag for rotation, and two-finger pinch for zoom—recorded first-attempt task-success averages of 0.97, 1.00, and 1.00 in the medical-student group (Table III) and equivalent values in the non-medical group (Table IV). The anatomically novel gestures recorded lower first-attempt scores: T4 (multi-organ select) averaged 0.6 in the non-medical group; T5 (default-view recall), T6 (five-finger drag), and T7 (manual UI rotation) ranged from 0.65 to 0.75; and T10 (cross-section viewing) recorded the lowest single-task score, 0.5, in the non-medical group, meaning that participants succeeded only after observing a peer perform the gesture. Because the composite scoring scale does not separate discoverability from mental-model alignment, this result is open to two interpretations: the gesture may be learnable but not independently discoverable from the interface cues alone, or participants' prior expectations of how cross-sectional viewing should work may have been incompatible with the five-finger steady plus one-finger drag design. The fact that medical students also scored below ceiling on T10 (Mdn = 0.63) suggests that discoverability is the primary barrier, though the current instrument cannot confirm this distinction. For the remaining gesture tasks, content-alignment tasks, and multi-user tasks, effect sizes were small or negligible, indicating that the group difference does not reflect a structural usability gap. Both groups converged on task completion after a single round of verbal guidance.

These findings establish that the gesture vocabulary is learnable within a single guided session, but they do not speak to long-term retention. Learnability and retention are distinct constructs: a gesture that is easy to acquire during an introduction may still be difficult to recall after a period of disuse, particularly if it lacks a strong mnemonic mapping to a familiar physical action. The novel gestures in Anatomia, such as the five-finger steady plus one-finger drag for cross-sectional viewing, are designed to mirror anatomical actions, which may support longer-term recall, but this remains an empirical question. A follow-up evaluation conducted after two to four weeks without practice would be necessary to determine whether the proposed interaction techniques are retained or whether periodic reinforcement is needed.

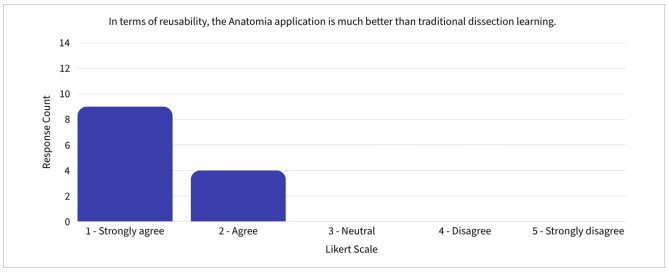


Koriat and Norman showed that reading time remains stable through rotations up to 60° and degrades substantially beyond 120° of in-plane rotation, where the visual system shifts from holistic to letter-by-letter processing [16]. Existing commercial systems reviewed in I did not address this dimension. The dual approach adopted in Anatomia pairs automatic rotation from the radial-menu position with manual rotation

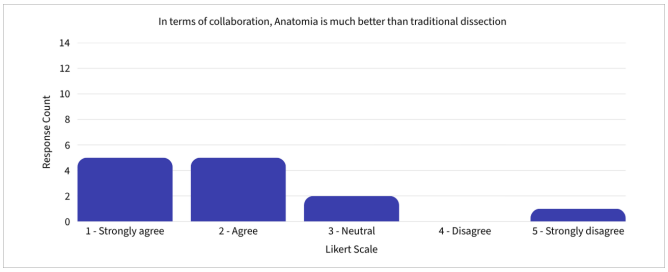


(a) Anatomy 3D Atlas vs. Anatomia application's hand gestures.

(b) Anatomy 3D Atlas vs. Anatomia in terms of content alignment.



(c) Anatomy 3D Atlas vs. Anatomia in terms of fixed menu options.



(d) Anatomy 3D Atlas vs. Anatomia in terms of multi-user interaction.

Fig. 9. Comparison of anatomia application against anatomy 3D atlas.

Fig. 10. Comparison of anatomia application against traditional dissection lessons.

and locking. The alignment task set (T11–T12) recorded a median score of 0.88 in both groups, with zero between-group variance (Cliff's δ = 0.00), indicating that the mechanism adds little cognitive overhead while removing the legibility issue of fixed orientation. The identical performance across groups suggests that content alignment is intuitive irrespective of anatomical background.

The self-reported metric questionnaire reinforces this finding: both statements-"auto/manual rotation provides a better around-the-table experience than the fixed orientation of the Anatomy 3D Atlas," and "the radial menu is better than fixed menus"-received 100% agreement, with zero neutral or disagreeing responses. This is consistent with the underlying reading-time penalty: participants who have experienced the legibility drop on a fixed-orientation app perceive the rotation mechanism as an unambiguous improvement.

Prior multi-user identification mechanisms on shared surfaces require hardware [17], [14] that is not widely available in teaching classrooms. The University of Wayamba's anatomical resources had 4 cadavers for 150 medical students during the academic year of the observational study, resulting in an approximately 38:1 student-to-cadaver ratio, which makes capital investment in specialized hardware a binding adoption constraint. The conflict resolver in Anatomia runs at the software level. Multi-user task success reached a perfect 1.00 (Mdn = 1.00, zero variance) across both participant groups, with no between-group difference (Cliff's δ = 0.00). The corresponding self-reported item received 13 of 13 endorsements (100.0% agreement). The convergence of ceiling-level task success and unanimous subjective endorsement across participants with different domain backgrounds provides consistent evidence that the conflict-resolution mechanism does not impose a usability penalty.

This study has several limitations. The participant sample comprised 13 individuals (8 medical, 5 non-medical) drawn from two faculties of a Sri Lankan university, which constrains the generalisability of the results to other populations, educational systems, and cultural contexts. Given these sample sizes, the non-parametric tests employed have sufficient power

to detect only large effects. The per-task Mann–Whitney U comparisons did not reach significance at $\alpha = 0.05$, even where effect-size estimates indicated large group differences (e.g., T4: Cliff's $\delta = 0.58$; T10: $\delta = 0.50$). These non-significant per-task results should be interpreted as inconclusive rather than as evidence of no difference between groups. Replication with a larger and more demographically diverse cohort would be necessary to detect small and medium effects and to establish external validity. Recent cross-cultural studies have raised the standard required for the methodology used in usability investigations of interactive educational applications. Criollo-C et al. [29] assessed a mobile augmented reality application designed to provide training on PC hardware in three countries using the IBM Computer System Usability Questionnaire (CSUQ), a well-established tool that has proven psychometric properties. Their study highlights the value of employing validated measurement instruments and of using samples that are geographically diverse when evaluating educational technology.

The summative evaluation benchmarked Anatomia against the Anatomy 3D Atlas and traditional cadaver dissection, but not against the Anatomage Table, which Table I identifies as the closest existing tabletop competitor. The Anatomage Table's acquisition cost made a controlled academic comparison impractical within the study's resource constraints. A controlled comparison against the Anatomage Table would provide a more balanced evaluation of Anatomia's contributions.

Anatomia's current implementation includes a single 3D model covering only the head region, whereas all three commercial competitors support multiple 3D models spanning the full body, a capability that Anatomia does not yet offer. This limits the evaluation's ecological validity: gesture challenges specific to larger or more complex anatomical regions are not represented in the current task set. The system architecture was designed to accommodate additional models through the 3D Model Manager component, but the feasibility of maintaining acceptable frame rates and interaction responsiveness as model complexity and polygon counts increase has not been empirically verified. Future work should assess how the framework scales to more detailed 3D models, larger anatomical datasets, and varying hardware configurations.

Finally, this study measured interaction quality, usability, and learnability, not learning outcomes. Whether the interaction-level gains documented here translate into measurable improvements in anatomical knowledge over a curriculum term remains open. A longitudinal study comparing learning outcomes between traditional dissection and Anatomia-augmented instruction would be necessary to establish the pedagogical impact of the tool.

From these limitations, there are several avenues for future research. The anatomical model library could be extended from the head area to the entire body in order to check the framework's scalability with regard to more complicated structures. The two-user limit of the conflict resolver might be increased by incorporating a third-party user-identification pipeline at the application level, which could in turn allow three or more users to use the system at the same time on larger display surfaces. A formal computational-performance benchmark covering a range of hardware configurations would define the boundaries for deployment. Longitudinal classroom studies that compare Anatomia-augmented instruction with traditional dissection using standardised anatomy assessments would determine whether the usability and interaction benefits reported here lead to better learning outcomes. Lastly, future evaluations of Anatomia could adopt a standardised usability instrument with established reliability. The use of such instruments with a larger and more diverse group of participants, preferably in several different institutions and educational settings, would improve generalisability and enable internal-consistency reporting, cross-study comparison, and more confident interpretation of subjective responses.

VI. Conclusion

This study presents Anatomia, a 3D anatomy visualization application for tabletop display systems that addresses three limitations common to current 3D anatomy visualization tools: the lack of domain-specific gestures, the lack of adaptive content orientation, and the lack of multi-user support on shared surfaces. The summative evaluation conducted with experienced and novice users confirms that all three contributions work together without trading off one for another. The domain-specific gestures defined in the participatory design achieved their highest task performance with minimal guidance within a single session. Basic touchscreen gestures (single-tap, single-finger drag, two-finger pinch) succeeded on the first attempt for both participant groups, and the novel gestures succeeded after a single round of verbal guidance, with the cross-section gesture the only task whose non-medical group required a second observation. The content-alignment mechanism, which pairs automatic rotation driven by radial-menu position with manual rotation and locking, received a median usability score of 0.88 on the alignment task set, with identical performance across medical and non-medical groups (Cliff's $\delta = 0.00$) and 100.0% participant endorsement on the post-session questionnaire. Both performance and self-reported metrics indicate that the mechanism removes the reading-time penalty associated with fixed orientation on shared surfaces without introducing a perceptible usability tax. The software-level conflict resolver achieved a perfect task-success score of 100.0% in two-user interactions (Mdn = 1.00, zero variance across all 13 participants) and 100.0% participant endorsement. It is the first mechanism to support two-user multi-touch interaction without antenna-embedded furniture or external cameras in the domain of medical anatomy education, which is the principal contribution of this work in terms of classroom viability. Three concrete extensions follow from this work. The anatomical model layer can be expanded from the head region to the rest of the body. The conflict resolver's two-user limit can be lifted by integrating a third-party user-identification pipeline. Finally, a longitudinal study comparing learning outcomes between traditional dissection and Anatomia-augmented instruction would be necessary to confirm that the interaction-level gains documented here translate into measurable learning gains over a curriculum term.

Acknowledgment

The authors wish to thank Dr. Sandaruwan and Dr. Keppitiyagama for their guidance and supervision throughout this research. The authors would also like to extend their appreciation to their advisors, Dr. Karunadasa and Mr. Tony Mahadevan,

for their valuable input and feedback. The authors are grateful to the Faculty of Medicine, University of Wayamba, Sri Lanka, for facilitating the observational study and providing access to dissection lessons, and to the medical science students from the University of Colombo and the University of Wayamba who participated in the questionnaires and evaluation sessions. We acknowledge the funding received from the University of Colombo School of Computing through the Research Allocation for Research and Development. This financial assistance greatly contributed to the success of our research endeavor by covering various research-related expenses.

Declaration on Generative AI

Generative AI tools were used to assist with language refinement and clarity during the preparation of this manuscript. All technical content, data collection and analysis, and conclusions were developed and verified by the authors. Generative AI was not used to generate, fabricate, or alter any experimental data, nor to produce original research claims. The authors take full responsibility for the accuracy, originality, and integrity of the work, and confirm that the manuscript reflects their own intellectual contributions throughout.

Does It Generalize? A Cross-Dataset Study of Graph-Based Insider Threat Detection Beyond CERT

QASIM Mohamed Muhanna Alriyami, Mohd Murtadha Bin Mohamad
Faculty of Computing, Universiti Teknologi Malaysia (UTM), Johor Bahru, Malaysia

***Abstract*—Graph-based insider threat detection methods increasingly report strong performance by modelling relationships among users, hosts, resources and security events. However, many studies still evaluate within a single benchmark family—usually CERT—or report separate within-dataset results, so it is unclear whether the learned representations capture transferable insider behaviour or dataset-specific artefacts. This study presents, to the best of our knowledge, the first systematic zero-shot cross-dataset benchmark for insider threat detection across CERT, SPEDIA and LANL. In this setting, no labelled or unlabelled target observations are used during training. Events are harmonised to a common user-day prediction unit with label-independent event sampling, and in-distribution performance is controlled with both chronological and user-disjoint splits. Within-domain performance of a Random Forest reference model was heterogeneous (user-disjoint PR-AUC from 0.004 on LANL to 0.99 on SPEDIA). Across evaluable targets, its mean in-distribution PR-AUC was 0.542, compared with a mean off-diagonal zero-shot PR-AUC of 0.133, yielding a generalization gap of 0.409. A memory-based temporal graph neural network without explicit time encoding was compared with this reference on two transfers into SPEDIA using paired seed-level bootstrap intervals. Representation effects were source-dependent: the temporal graph model outperformed the Random Forest for CERT r4.2→SPEDIA (ΔPR $= +0.123$, 95% CI $[+0.075, +0.169]$), whereas the Random Forest outperformed the graph model for CERT r5.2→SPEDIA (ΔPR $= -0.031$, 95% CI $[-0.061, -0.012]$). The results therefore do not support a general advantage of graph representations. They show that strong single-dataset performance is insufficient evidence of cross-dataset generalization.**

***Keywords*—Insider threat detection; cross-dataset generalization; zero-shot evaluation; graph neural networks; temporal graphs; self-supervised learning; CERT; SPEDIA; LANL**

I. Introduction

Insider threats remain difficult to detect because malicious, negligent, or compromised users may operate through legitimate accounts, authorised devices, and routine organisational workflows. Unlike many external attacks, insider activity does not necessarily produce an immediate perimeter violation. Its significance may instead emerge through a sequence of individually plausible actions involving authentication, host access, files, removable devices, communications, and other enterprise resources. The difficulty of obtaining suitable insider-threat data, together with confidentiality and privacy constraints on organisational logs, further complicates the development and evaluation of reliable detectors [1].

Machine-learning and deep-learning methods have improved the ability to model these behavioural signals. Recent graph-based approaches are especially promising because enterprise activity can be represented as interactions among users, hosts, resources, and timestamped events. Graph neural networks can propagate relational context between connected entities, while temporal graph models can retain changes in behaviour across ordered interactions. ATHITD uses a temporal heterogeneous graph to represent insider activity, whereas Log2Graph transforms security logs into graph structures for graph-convolutional detection [2], [3]. These developments extend insider threat detection beyond isolated records and fixed aggregated feature vectors.

However, methodological progress has not been matched by equally rigorous evidence of cross-dataset transfer. The synthetic CERT corpus remains the dominant experimental benchmark, and several recent sequence, relational, and graph-based studies continue to evaluate their methods using only CERT-derived data or, like ATHITD and Log2Graph, CERT and LANL without cross-dataset testing [2]–[6]. Reviews also document frequent use of CERT in insider-threat research [7]. CERT provides controlled scenarios, multiple enterprise event sources, and answer-key labels, making it valuable for reproducible model development [1]. Nevertheless, a detector trained and tested within one CERT release may learn scenario-specific frequencies, user-role patterns, event-generation rules, or other corpus regularities that are absent from independently constructed datasets. Strong within-dataset performance therefore does not establish that the learned representation will remain effective in a different organisational or logging environment.

Network intrusion detection has addressed this concern more directly. Cross-dataset studies have demonstrated that models performing strongly on a source benchmark may deteriorate when evaluated on independently collected network traffic [8], [9]. Together, these studies motivate source–target evaluation matrices for comparing within-dataset and cross-dataset performance [8], [9], while Sarhan et al. examine a common feature set for cross-environment generalisability [10]. (A source–target matrix scores every train-on-one, test-on-another dataset pair; a harmonised representation uses one shared feature set for all datasets.) Zero-shot transfer, which applies a trained model to a new dataset without retraining or tuning on it, has also been studied under protocol and dataset shift [11]. Cross-dataset evaluation is consequently treated as a distinct benchmark rather than as an extension of a random train–test split. Insider threat detection has not yet adopted an equivalent evaluation paradigm. To the best of our knowledge, prior graph-based insider-threat studies have not evaluated transfer from CERT to an independently constructed target under a strict zero-shot protocol, and systematic source-to-target benchmarking across independently

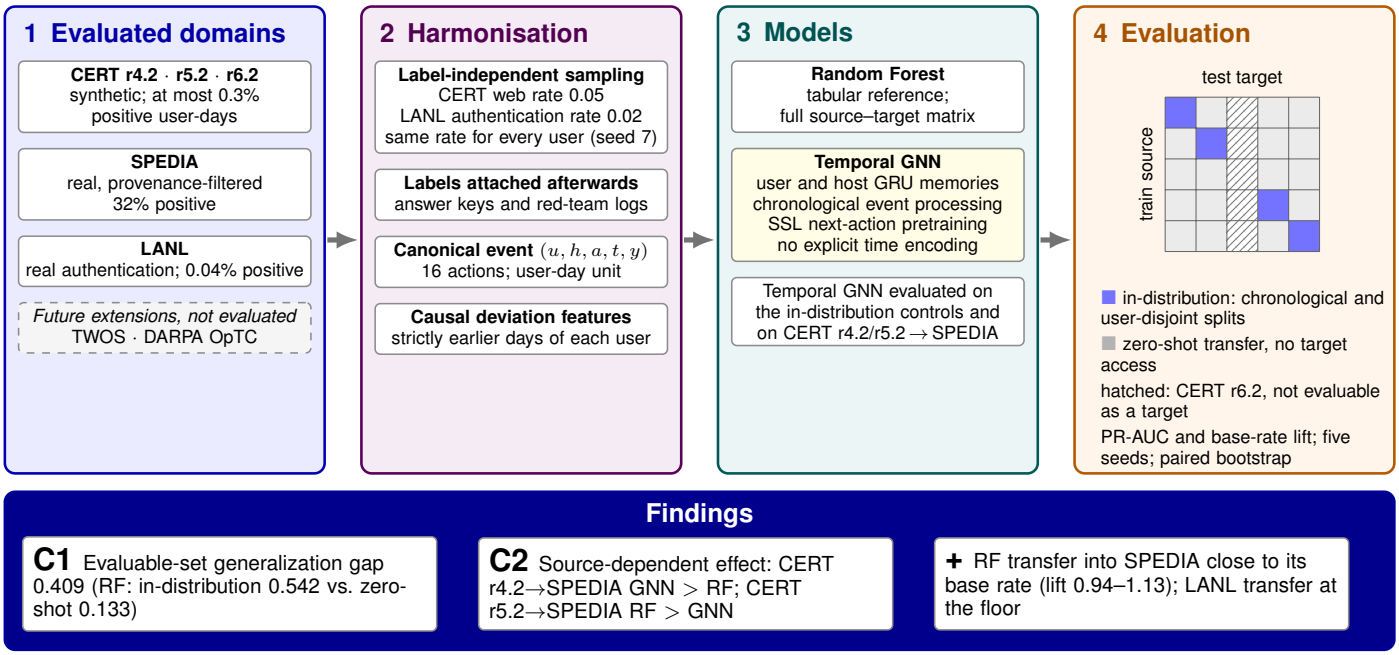

Fig. 1. Overview of the cross-dataset benchmark. Three evaluated domain families are harmonised to a canonical event schema and a user-day prediction unit with label-independent event sampling. A Random Forest reference model is evaluated on the full source-by-target matrix, and a memory-based temporal graph neural network without explicit time encoding is evaluated on the in-distribution controls and on two transfers into SPEDIA. The findings panel summarises the evaluable-set generalization gap and the source-dependent representation comparison.

constructed insider-threat datasets remains limited. It therefore remains unclear whether recent graph models learn transferable insider-threat behaviour or dataset-specific decision rules. This uncertainty is particularly important because CERT, SPEDIA, and LANL differ in data origin, event coverage, insider type, labelling procedure, population, and class prevalence [1], [12], [13].

This study addresses the gap with a *zero-shot cross-dataset generalization* benchmark: a model is trained on a source dataset and evaluated on an independently defined target dataset without access to labelled or unlabelled target observations. Target-assisted domain adaptation is outside the scope of the reported experiments, so no result in this study uses target data during training. The principal contributions are as follows:

- *A strict zero-shot cross-dataset benchmark.* We present, to the best of our knowledge, the first systematic zero-shot cross-dataset benchmark for insider threat detection across CERT, SPEDIA and LANL. It combines explicit target isolation, label-independent event sampling and harmonisation, chronological and user-disjoint in-distribution controls, base-rate lift reporting and an evaluable-set generalization gap. For a Random Forest reference model, mean PR-AUC fell from 0.542 in distribution to 0.133 under zero-shot transfer ($\Delta = 0.409$).
- *A source-dependent comparison of tabular and temporal-graph representations.* Using paired seed-level bootstrap intervals, we compare the reference model with a memory-based temporal graph neural network on two transfers into SPEDIA. The graph model was better for CERT r4.2 as the source, and the tabular model was better for CERT r5.2. Representation advantages therefore did not transfer consistently, even into the same target dataset.

The remainder of this study is organised as follows. Section II reviews insider threat detection, graph-based methods, cross-dataset network intrusion detection, and the selected datasets. Section III defines the datasets, prediction unit, and zero-shot benchmark. Section IV describes the temporal graph construction and detector, Section V describes the experimental protocol, and Section VI reports the findings. Sections VII and VIII discuss threats to validity and conclude the study, respectively. Fig. 1 summarises the overall framework.

II. Related Work

A. Machine Learning and Deep Learning for Insider Threat Detection

Insider threat detection has commonly been formulated as supervised classification, anomaly detection, or behavioural profiling over enterprise activity records. Conventional methods aggregate events into user-level, session-level, or user-day features and apply classifiers or outlier detectors to distinguish suspicious activity from normal behaviour. These methods are computationally practical and can provide useful operational summaries. However, aggregation may obscure the event ordering, timing, and interaction context through which gradual insider behaviour becomes observable.

Deep-learning studies attempt to preserve more of this structure. Recurrent neural networks, autoencoders, attention mechanisms, and transformer-based models can represent behavioural sequences and identify deviations from historical activity. Temporal feature aggregation with attention has been

used to combine activity-log evidence across time [5], while relational multi-sequence modelling has been proposed to capture dependencies among different behavioural sources [6]. LAN learns adaptive neighbourhood relationships for real-time insider threat detection, illustrating the increasing use of relational learning beyond fixed feature aggregation [4]. However, existing machine-learning and sequence-based studies provide limited evidence that their learned behavioural representations remain effective outside the dataset on which they were developed.

B. Graph-Based Insider Threat Detection

Graph-based insider threat detection represents enterprise activity through relationships among users, hosts, resources, and security events. Such representations can preserve interaction structure that is lost when each user-day is treated as an independent feature vector. Static graph convolutional networks aggregate neighbourhood information, while graph attention mechanisms learn the relative importance of connected entities or event types. Temporal graph models additionally retain the order and timing of interactions.

Log2Graph converts security logs into graph structures and applies graph convolution for insider threat detection [3]. Its formulation demonstrates the value of representing log relationships explicitly rather than relying only on flat event aggregates. ATHITD is one of the closest works to the present study because it combines attention with a temporal heterogeneous graph representation for insider threat detection [2]. A subsequent fusion model integrates sequential and graph neural components with an explainability mechanism for user and entity behaviour analytics [14].

ATHITD and the fusion model are particularly relevant architectural comparators, but neither measures cross-dataset transfer. ATHITD reports results on CERT and LANL and the fusion model on CERT, yet neither trains on one insider threat dataset and evaluates on another, independently constructed dataset. Their reported results therefore measure within-dataset discrimination rather than zero-shot cross-dataset transfer. Log2Graph is subject to the same general limitation: it demonstrates a graph-based detector within its development setting but does not establish whether the learned representation transfers across dataset boundaries [3].

The present study does not reimplement these architectures. Instead, it evaluates a memory-based temporal graph detector and a tabular reference model under the same user-day labels, aligned event vocabulary, source–target partitions, and access restrictions. Consequently, existing graph-based detectors have not been compared systematically under a zero-shot source-by-target protocol that separates strong single-dataset performance from transferable graph learning.

C. Cross-Dataset Generalization and Domain Adaptation in Network Intrusion Detection

Network intrusion detection provides the closest established precedent for the present evaluation design. Layeghy and Portmann examined the generalisability of machine-learning network intrusion detectors and showed that strong performance on a development dataset does not necessarily persist under cross-dataset evaluation [8]. Sarhan et al. investigated standardised feature sets intended to improve both generalisability and explainability across network intrusion datasets [10]. Cantone et al. further analysed cross-dataset generalization and the effects of distributional differences between independently collected benchmarks [9].

These studies motivate the use of a source–target matrix rather than a single within-dataset score. A model is trained on one source and evaluated on multiple targets, allowing diagonal in-distribution performance to be separated from off-diagonal transfer. Such evaluation exposes dataset bias that may remain hidden when training and testing records originate from the same collection process.

Domain adaptation addresses a related but different problem. Instead of requiring transfer without target access, adaptation methods use information from the target domain to reduce the distribution mismatch; because the target distribution participates in training, such methods address unsupervised domain adaptation rather than zero-shot generalization. Oladejo and Ahmed apply cross-domain transfer learning to multi-protocol intrusion detection, but their reported experiments are zero-shot, with no target fine-tuning or domain adaptation [11]. The present study likewise reports zero-shot results only.

Although the distinction between source-only cross-dataset generalization and target-assisted unsupervised adaptation is established in network intrusion research, it has not been applied systematically to graph-based insider threat detection.

D. Insider Threat Datasets

The CERT insider-threat corpus was created to support reproducible research when labelled organisational insider incidents were difficult to obtain [1]. It provides synthetic users, hosts, organisational roles, multi-source activity records, and answer-key labels for traitor scenarios. Its controlled structure and accessibility explain its widespread use, but its synthetic generation process may also introduce regularities that are not present in independently collected environments.

TWOS was developed from a gamified competition containing malicious insider behaviour [15]. It includes labelled masquerader and traitor activity spans and therefore differs from CERT in collection setting, scenario construction, and available event fields. These differences make TWOS a natural candidate for extending the present benchmark. It is therefore identified as a target for future work and is not evaluated in this study.

SPEDIA provides security-event data with behavioural descriptions and Wazuh severity information [12]. The release contains both real and synthetic components, including records associated with CERT. A clean CERT-to-SPEDIA comparison therefore requires provenance-aware filtering so that CERT-derived records do not appear in the target evaluation. In this study, every row for which `Decoder_name == 'cert'` is excluded. The audited remainder contains 20,619 real rows, zero occurrences of `dtaa.com`, zero `cert` tokens, and zero CERT-style identifiers. The retained records are drawn only from auditd, PAM, syscheck, and JSON sources.

The LANL cybersecurity dataset contains authentication and other enterprise events collected from a real organisational environment [13]. Its labelled red-team authentication activity differs semantically from CERT traitor scenarios and is more

closely associated with masquerader or lateral-movement behaviour. LANL nevertheless provides a valuable independently collected domain for testing whether models transfer beyond synthetic insider scenarios.

These datasets cannot be made semantically identical through preprocessing. CERT, SPEDIA, and LANL differ in event types, malicious-activity definitions, temporal coverage, and labelling granularity. The present work therefore aligns them at a common user-day prediction level while retaining and reporting their original threat semantics.

What is still missing is a harmonised benchmark that evaluates insider threat detectors across CERT, SPEDIA, and LANL without concealing the substantive differences in their labels and collection processes.

III. Datasets and Problem Formulation

A. Datasets

1) CERT: CERT provides synthetic enterprise activity together with answer-key labels for traitor scenarios [1]. Releases r4.2, r5.2, and r6.2 are used. Events are mapped to user-day intervals, and a user-day is labelled positive when it contains at least one answer-key malicious event. CERT is used as a controlled source domain whose in-distribution performance is measured under both chronological and user-disjoint splits. The term "overfitting" is used only when these controls support that interpretation; otherwise, an off-diagonal decline is described as failure to transfer.

2) SPEDIA: SPEDIA contains security records with descriptive and Wazuh severity information [12]. A user-day is labelled positive when at least one event has a `Description` of "Highly Suspicious" or "Midly Suspicious", or a Wazuh level of at least 8. To prevent CERT-derived overlap, all rows satisfying `Decoder_name == 'cert'` are excluded. The audited real-only subset contains 20,619 rows, zero `dtaa.com` occurrences, zero `cert` tokens, and zero CERT-style identifiers. Its retained sources are limited to auditd, PAM, syscheck, and JSON records.

3) LANL: The LANL dataset contains authentication and related events from a real enterprise environment, together with labelled red-team activity [13]. Each authentication event is mapped to the corresponding user and host within the aligned action vocabulary. A user-day is positive when it contains at least one labelled red-team authentication event. Because these labels principally represent masquerader or lateral-movement activity, LANL is treated as a related but not identical insider-threat domain. Authentication records of machine accounts are removed.

4) Label-independent event sampling: The CERT web logs (14.5–90 GB per release) and the LANL authentication log (about 1.05 billion rows) are too large to process in full, so these two event sources are subsampled. Every CERT web event is retained independently with probability 0.05, and every eligible LANL authentication event is retained independently with probability 0.02, using a fixed pseudo-random seed (7). The retention decision depends only on this random draw; it does not use user identity, the ground-truth insider or red-team rosters, or any label. User-day labels are attached only after the sampled event universe has been fixed. All other CERT event sources are retained in full, and SPEDIA is not subsampled. A labelled user-day can be observed only if at least one of its events is retained; for LANL, 158 of the 176 red-team user-days remain observable after sampling.

5) Evaluable targets: A domain is evaluated as a target, and its in-distribution score is reported, only when it contains at least 50 positive user-days. CERT r6.2 contains 44 positive user-days among 1,394,010 user-days and is therefore used as a training source only. The other four domains meet the criterion.

B. Common Prediction Unit and Graph Domain

Let the benchmark contain K domains,

$$\mathcal{D} = \{\mathcal{D}_1, \ldots, \mathcal{D}_K\}, \tag{1}$$

where, each domain corresponds to one dataset and defines a distribution over timestamped security events. An event is represented as

$$e = (u_e, h_e, a_e, t_e), \tag{2}$$

where, u_e is the user, h_e is the host, a_e is an action from the fixed vocabulary $\mathcal{A}$, and t_e is the event timestamp. All datasets are converted to the same user-day prediction unit. For user u and day d, let $\mathcal{E}_{u,d}$ denote the set of events assigned to that interval. Its binary label is

$$y_{u,d} = \mathbb{I}\left[\exists\, e \in \mathcal{E}_{u,d} \text{ such that } \ell_e = 1\right], \tag{3}$$

where, ℓ_e is the dataset-specific malicious-event or malicious-span indicator. This definition preserves each dataset's documented labelling rule while enforcing a common unit of analysis. The user-day is the unit of labelling, prediction, and evaluation. It is not the input resolution of the temporal model. The temporal graph detector consumes individual timestamped events in chronological order, so event ordering and within-day temporal structure enter its memory state; the aggregated user-day features are used alongside that memory. Daily labels nevertheless have limitations. They cannot measure detection latency within a day, event-level detection behaviour, or differences between sessions. Event-, session-, host-, or process-level formulations should therefore be evaluated where the datasets support them.

Each domain is represented as a heterogeneous temporal graph

$$\mathcal{G}_i = \left(\mathcal{V}_i^U, \mathcal{V}_i^H, \mathcal{E}_i\right), \tag{4}$$

where, $\mathcal{V}_i^U$ and $\mathcal{V}_i^H$ are user and host nodes, respectively, and $\mathcal{E}_i$ contains action-typed timestamped edges. Dataset-specific raw events are mapped to the fixed action vocabulary before model fitting. Continuous feature normalisation is fitted using the permitted training data only.

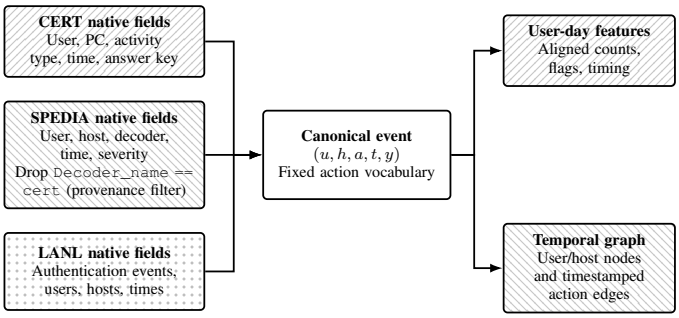

Fig. 2. Data harmonisation pipeline.

Fig. 2 illustrates the harmonisation pipeline.

C. Zero-Shot Cross-Dataset Generalization

The primary benchmark measures zero-shot cross-dataset generalization. For source domain i, a detector f_i^{ZS} is trained using only labelled source-domain training data:

$$f_i^{\mathrm{ZS}} = \mathrm{Train}\left(\mathcal{D}_i^L\right). \tag{5}$$

No labelled or unlabelled target events, target feature statistics, target validation results, or target-domain model-selection signals are available during training.

For source i and target j, the matrix entry is

$$M_{ij} = \text{PR-AUC}\left(f_i^{\mathrm{ZS}}, \mathcal{D}_j^{\mathrm{test}}\right). \tag{6}$$

The diagonal entries represent in-distribution evaluation, whereas $i \neq j$ denotes zero-shot transfer. In-distribution scores are estimated under both a chronological split and a user-disjoint split (Section V). The complete source-by-target matrix is computed for the Random Forest reference model, and the temporal graph detector is evaluated on the in-distribution controls and on two transfers into SPEDIA (Section VI).

Let S denote the set of source domains, $T \subseteq S$ the set of evaluable target domains, and

$$P = \{(i, j) : i \in S,\ j \in T,\ i \neq j\} \tag{7}$$

the set of evaluable transfer cells. The generalization gap is defined as

$$\Delta = \frac{1}{|T|} \sum_{j \in T} M_{jj} - \frac{1}{|P|} \sum_{(i,j) \in P} M_{ij}. \tag{8}$$

The first term is the uniformly weighted mean of the evaluable in-distribution cells, and the second is the uniformly weighted mean of the evaluable zero-shot cells. A larger positive value indicates a greater decline from in-distribution performance to zero-shot transfer. CERT r6.2 remains available as a training source but is excluded from T because its target evaluation does not meet the positive-count criterion; with five sources and four evaluable targets, $|P| = 16$. The in-distribution cells in Eq. (8) use the user-disjoint split, because the chronological split leaves no LANL positives in the test period.

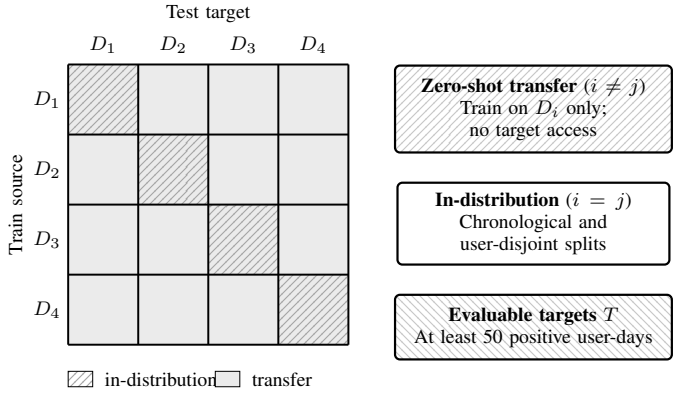

Fig. 3. Zero-shot evaluation protocol. Rows are training sources and columns are test targets; only evaluable targets enter the generalization gap.

The evaluation protocol is summarised in Fig. 3.

IV. Methodology

A. Heterogeneous Temporal Graph Construction

Each dataset is transformed into a heterogeneous temporal graph containing user and host nodes. Every security event creates a directed, action-typed edge between its associated user and host:

$$e = (u_e, h_e, a_e, t_e), \qquad a_e \in \mathcal{A}. \tag{9}$$

The vocabulary $\mathcal{A}$ contains sixteen canonical actions: logon, logoff, auth, file_read, file_write, file_delete, usb_connect, usb_disconnect, http, email_send, email_recv, cmd_exec, ssh, ftp, process_start, and unknown. It was chosen to cover the activity types that the evaluated sources record in comparable form, namely session, authentication, file, removable-device, web, e-mail, and command events, without relying on dataset-specific content. The mapping from raw log fields to $\mathcal{A}$ is a static rule table in the data loaders. It does not use labels or model outputs, and the same tables were applied in all reported experiments. Dataset-specific event names that express the same behavioural operation are mapped to a shared action, whereas unmatched events are assigned to the reserved unknown action rather than discarded. Table I lists the rules, and Table II reports the resulting event distribution. No event in any domain was assigned to the unknown action. The distributions nevertheless differ markedly: LANL occupies only three actions, SPEDIA is dominated by command execution, and CERT is dominated by e-mail and web activity. The mapping therefore provides a common representation, but it cannot make the source domains semantically identical.

In addition to event edges, each user-day has an aligned feature vector

$$\mathbf{x}_{u,d} \in \mathbb{R}^F, \tag{10}$$

TABLE I. CANONICAL ACTION MAPPING. CERT R4.2 HAS NO ACTIVITY COLUMN FOR FILE AND E-MAIL EVENTS, SO ALL ITS FILE EVENTS MAP TO FILE_WRITE AND ALL ITS E-MAIL EVENTS TO EMAIL_SEND. CERT WEB EVENTS ARE SAMPLED INDEPENDENTLY WITH PROBABILITY 0.05 FOR EVERY USER, AND ELIGIBLE LANL AUTHENTICATION EVENTS WITH PROBABILITY 0.02 FOR EVERY USER (FIXED SEED 7; MACHINE ACCOUNTS REMOVED). GROUND-TRUTH ROSTERS ARE NOT USED IN THE SAMPLING DECISION, AND LABELS ARE ATTACHED ONLY AFTER SAMPLING. THE SSH, FTP, AND PROCESS_START ACTIONS ARE RESERVED AND ARE NOT PRODUCED BY ANY EVALUATED LOADER

Canonical action	CERT (r4.2/r5.2/r6.2)	SPEDIA (real-only)	LANL (auth.txt)
logon	logon.csv: Logon	Activity = session, other actions	Orientation LogOn
logoff	logon.csv: Logoff	Activity = session, action contains “logoff”	Orientation LogOff
auth	–	Activity = session, action contains “fail”	All other orientations
file_read	file.csv: File Open (r5.2/r6.2)	Activity = file, other actions	–
file_write	file.csv: File Copy, File Write; all r4.2 file events	Activity = file, action contains “modif” or “added”	–
file_delete	file.csv: File Delete	Activity = file, action contains “delet”	–
usb_connect	device.csv: Connect	Activity = device, other actions	–
usb_disconnect	device.csv: Disconnect	Activity = device, action contains “disconnect”	–
http	http.csv (sampled)	Activity = http	–
email_send	email.csv: Send; all r4.2 e-mail events	Activity = email	–
email_recv	email.csv: View, Receive (r5.2/r6.2)	–	–
cmd_exec	–	Activity = command	–
unknown	Any unmatched token	Any other activity	–

TABLE II. DISTRIBUTION OF RETAINED EVENTS OVER CANONICAL ACTIONS AFTER LABEL-INDEPENDENT SAMPLING: COUNT (PERCENTAGE OF THE DOMAIN’S EVENTS). ONLY ACTIONS OBSERVED IN AT LEAST ONE DOMAIN ARE LISTED; SSH, FTP, AND PROCESS_START HAVE ZERO EVENTS IN EVERY DOMAIN. THE LAST ROW GIVES USER-DAYS AND, IN PARENTHESES, POSITIVE USER-DAYS

Action	CERT r4.2	CERT r5.2	CERT r6.2	SPEDIA	LANL
logon	470,591 (8.2%)	995,082 (4.2%)	1,948,933 (8.1%)	3,031 (14.7%)	3,786,729 (45.3%)
logoff	384,268 (6.7%)	814,988 (3.4%)	1,581,352 (6.6%)	2,038 (9.9%)	3,048,812 (36.4%)
auth	0 (0.0%)	0 (0.0%)	0 (0.0%)	330 (1.6%)	1,529,753 (18.3%)

usb_disconnect	202,041 (3.5%)	417,250 (1.7%)	773,474 (3.2%)	0 (0.0%)	0 (0.0%)
http	1,420,426 (24.7%)	2,947,136 (12.4%)	5,850,511 (24.4%)	367 (1.8%)	0 (0.0%)
email_send	2,629,979 (45.7%)	5,555,187 (23.3%)	3,832,466 (16.0%)	0 (0.0%)	0 (0.0%)
email_recv	0 (0.0%)	11,806,388 (49.5%)	7,162,491 (29.9%)	0 (0.0%)	0 (0.0%)
cmd_exec	0 (0.0%)	0 (0.0%)	0 (0.0%)	10,114 (49.1%)	0 (0.0%)
unknown	0 (0.0%)	0 (0.0%)	0 (0.0%)	0 (0.0%)	0 (0.0%)
Total events	5,756,225	23,843,386	23,942,464	20,619	8,365,294
User-days (positive)	330,452 (966)	693,649 (1,307)	1,394,010 (44)	256 (82)	389,323 (158)

whose dimensions have the same operational meaning across all datasets. The aligned features contain counts, binary activity indicators, timing variables, and other quantities that can be computed consistently from the common event ontology. Dataset identifiers, raw user names, host names, and source-specific record identifiers are excluded.

After processing all events up to the end of day d, the user-day representation is

$$\mathbf{r}_{u,d} = \left[\mathbf{s}_u(t_d^{\text{end}}) \,\|\, \mathbf{x}_{u,d}\right], \tag{11}$$

where, $\mathbf{s}_u(t_d^{\text{end}})$ is the temporal memory of user u and $\|$ denotes concatenation. A prediction head produces

$$\hat{y}_{u,d} = \sigma\left(\mathbf{W}_y \mathbf{r}_{u,d} + \mathbf{b}_y\right). \tag{12}$$

Fig. 4 shows the architecture.

B. Per-User Deviation Features

In line with user-centred and behavioural-baseline approaches [2], [16], insider activity is modelled relative to each user’s own history rather than solely through absolute activity counts. The same number of logons, file operations, or host accesses may therefore be routine for one user but unusual for another. To preserve temporal validity, the behavioural baseline is constructed causally from strictly earlier observations only. The transformation is also dataset-agnostic: it uses aligned numerical activity features and excludes dataset-specific tokens, URLs, email content, identifiers, or other source-dependent fields.

For user u, day d, and base feature x, the causal deviation feature is

$$\text{dev}_x(u,d) = \frac{x_{u,d} - \mu_{u,<d}}{\sigma_{u,<d} + \epsilon}, \tag{13}$$

where, $\mu_{u,<d}$ and $\sigma_{u,<d}$ are the mean and standard deviation of feature x over the strictly earlier days of user u, and

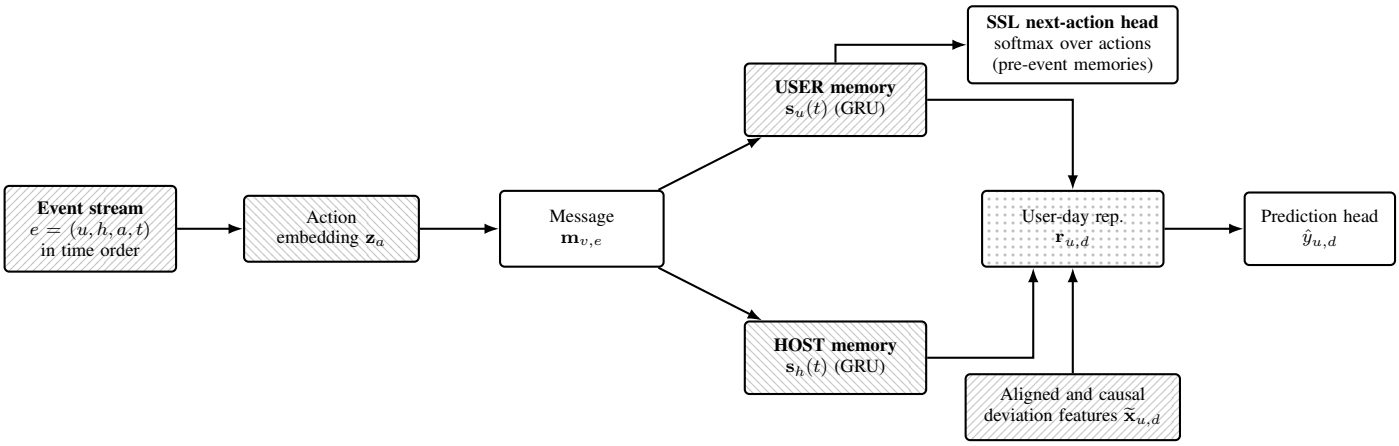

Fig. 4. Temporal graph detector used in the reported experiments. Events update user and host memories in chronological order; no explicit time encoding is used.

$\epsilon > 0$ prevents division by zero. Formally,

$$\mu_{u,<d} = \frac{1}{|\mathcal{H}_{u,d}|} \sum_{d' \in \mathcal{H}_{u,d}} x_{u,d'}, \qquad \mathcal{H}_{u,d} = \{\, d' \mid d' < d \,\}, \tag{14}$$

with $\sigma_{u,<d}$ computed over the same historical set $\mathcal{H}_{u,d}$. When $\mathcal{H}_{u,d}$ is empty, corresponding to the first observed day of user u, $\mathrm{dev}_x(u,d)$ is set to zero. The original base counts are retained, and the causal deviation features are appended. If the aligned base vector is $\mathbf{x}_{u,d} \in \mathbb{R}^F$, the resulting user-day feature vector is

$$\widetilde{\mathbf{x}}_{u,d} = [\, \mathbf{x}_{u,d} \,\|\, \mathrm{dev}(\mathbf{x}_{u,d}) \,] \in \mathbb{R}^{2F}. \tag{15}$$

Because the same aligned base features and the same causal transformation are applied in every domain, the resulting feature space is identical across CERT, SPEDIA, and LANL.

1) Leakage controls: The following rules determine what information can reach each prediction. First, event sampling is label-independent and precedes label attachment (Section III), so the retained event volume of a user does not depend on whether that user is an insider. Second, each deviation value uses an expanding mean and standard deviation over the same user's strictly earlier days; the current day is excluded by a one-day shift, and a user's first observed day receives zero. Only activity counts and timing variables enter this computation, so labels never affect the history. Third, the features are computed once over each dataset's chronological event stream. Under the chronological split, a test day may therefore draw on the same user's training-period days, which precede it in time, but never on later days. Under the user-disjoint split, train and test users do not overlap, so a test user's history consists only of that user's own events. Fourth, during cross-dataset inference, target deviations are computed only from the same target user's earlier, unlabelled target events. Fifth, the temporal-graph memory is reset before each training epoch, before validation, and before scoring, so memory state is not carried from the training partition into the test partition or from the source into the target. Sixth, the temporal graph detector uses no timestamp statistic of the scored stream, because it has no explicit time encoding (Section IV). Finally, standardisation statistics are fitted on the source training users only, excluding the validation users, and are applied unchanged to validation, test, and target data. Consequently, no feature value depends on future events, on labels, or on statistics of a test or target partition, and target labels do not enter model training or preprocessing.

2) Shared feature-space limitation: The shared, content-free feature space is a deliberate cross-dataset fairness constraint. It prevents models from exploiting dataset-specific tokens, URLs, email content, identifiers, or logging conventions that could artificially inflate within-dataset performance and reintroduce the artefacts examined by the benchmark. This restriction may reduce sensitivity to scenarios whose malicious meaning depends on content, such as particular URLs, email text, file names, or message semantics. Per-user deviation features partly mitigate this limitation by representing unusual behaviour relative to each user's own history, but cannot recover information absent from the aligned feature space.

C. Memory-Based Temporal Graph Backbone

The temporal backbone maintains a state vector $\mathbf{s}_v(t)$ for every user or host node v. For event $e = (u_e, h_e, a_e, t_e)$, a message is constructed separately for each endpoint $v \in \{u_e, h_e\}$:

$$\mathbf{m}_{v,e} = \mathbf{W}_m \left[\mathbf{s}_v(t_e^-) \,\|\, \mathbf{z}_{a_e} \right], \tag{16}$$

where, $\mathbf{z}_{a_e}$ is the embedding of action a_e, $\mathbf{s}_v(t_e^-)$ is the memory of node v immediately before event e, and separate projections $\mathbf{W}_m$ are used for user and host endpoints. Temporal graph models often add explicit temporal information, e.g., elapsed-time terms or functional time encodings [17], [18]. Here, such an encoding would need timestamp normalisation, and normalising with the scored target stream's first and last timestamps would use target-derived statistics. The reported configuration therefore uses no explicit time encoding. Temporal information enters the model through the chronological order in which events update the memories.

The node memory is updated as

$$\mathbf{s}_v(t_e) = \mathrm{GRU}\left(\mathbf{m}_{v,e}, \mathbf{s}_v(t_e^-)\right). \tag{17}$$

Events are processed in chronological order. Consequently, the state used to predict event e contains only information available before t_e, preventing future-event leakage. Host memories allow activity on a shared machine to influence subsequent user representations, while user memories retain behavioural continuity across events and days.

D. Causal Self-Supervised Next-Action Prediction

The primary self-supervised task predicts the action associated with the next chronological event from the pre-event memories of its user and host. Let

$$\mathbf{g}\left(\mathbf{s}_{u_e}(t_e^-), \mathbf{s}_{h_e}(t_e^-)\right) = \mathrm{softmax}\left(\mathbf{W}_g\left[\mathbf{s}_{u_e}(t_e^-) \,\|\, \mathbf{s}_{h_e}(t_e^-)\right] + \mathbf{b}_g\right) \tag{18}$$

be a probability distribution over the $A = |\mathcal{A}|$ action classes. The self-supervised loss is

$$\mathcal{L}_{\mathrm{ssl}} = -\sum_{e \in \mathcal{E}_{\mathrm{train}}} \log g_{a_e}\left(\mathbf{s}_{u_e}(t_e^-), \mathbf{s}_{h_e}(t_e^-)\right). \tag{19}$$

The loss is computed over all permitted training events rather than over a masked subset. The use of pre-event memories makes the objective causal because action a_e is not inserted into the state before its prediction. Self-supervised pretraining is conducted without malicious labels and is followed by supervised source-domain optimisation. A masked-action reconstruction variant was not evaluated in this study.

E. Supervised User-Day Detection

For labelled source-domain user-days, the prediction loss is binary cross-entropy:

$$\mathcal{L}_y = -\sum_{(u,d) \in \mathcal{S}^L} \left[y_{u,d} \log \hat{y}_{u,d} + (1 - y_{u,d}) \log\left(1 - \hat{y}_{u,d}\right)\right]. \tag{20}$$

Any weighting or sampling used to address class imbalance is estimated from source-domain training data only. Target labels are never used to tune the classifier or its operating threshold. For zero-shot experiments, all components are trained with source data only. The temporal encoder is trained with the self-supervised objective and then frozen, after which the projection layer and prediction head are trained on labelled source user-days. Early stopping uses the validation PR-AUC of a held-out 15% of the source training users. The resulting model is frozen before evaluation on a target domain.

TABLE III. CONFIGURATION OF THE REPORTED EXPERIMENTS. WHERE TWO VALUES ARE GIVEN, THE FIRST APPLIES TO CERT SOURCES AND THE SECOND TO THE SPEDIA SOURCE

Item	Setting
Seeds	0–4 (splits, validation users, initialisation)
Event sampling	CERT web $p = 0.05$ and LANL authentication $p = 0.02$ for every user; seed 7; labels attached after sampling
Random Forest	300 trees; balanced-subsample class weights; unscaled features
Temporal memory	64-dimensional user and host GRU memories, updated in chronological event order
Embeddings	16-dimensional action embedding; no explicit time encoding
Readout	Linear–ReLU projection; MLP 128–64–1; dropout 0.1
Optimiser	AdamW; learning rate 3×10^{-4}; weight decay 10^{-4}; cosine schedule; gradient-norm clipping at 1.0
Epochs	at most 60 / 80; self-supervised pretraining 1 / 2 epochs
Batching	chronological edge batches of 16,384 / 8,192 events; one supervised update per day
Early stopping	validation PR-AUC on 15% of source training users; patience 8 / 12; minimum 12 / 20 epochs
Class weighting	positive weight $n_{\mathrm{neg}}/n_{\mathrm{pos}}$, capped at 100
Determinism	deterministic PyTorch algorithms; deterministic cuDNN, benchmarking off; CUBLAS workspace `:4096:8`; hash seed 0
Bootstrap	5,000 resamples of paired per-seed differences; 95% percentile interval
Software	Python 3.11.15; scikit-learn 1.9.0; PyTorch 2.12.1 with CUDA 13.0; NumPy 2.4.4; pandas 3.0.3; SciPy 1.17.1
Hardware	NVIDIA GeForce RTX 5070 Laptop GPU (8 GB); 31 GB RAM

V. EXPERIMENTAL SETUP

A. Implementation Details

The pipeline is implemented in Python. The Random Forest uses scikit-learn, and the temporal graph detector uses PyTorch. Table III lists the configuration of both models. Class imbalance is addressed through positive-class weighting estimated only from source training data. The temporal graph detector standardises base features on the source training users and clips them and the causal deviation features (Section IV-B) to $[-8, 8]$; the Random Forest uses unscaled features. Every reported configuration was run with five random seeds (0–4); GPU training was deterministic. Tables IV and V report seed means, and paired seed-level bootstrap confidence intervals are reported for the two model comparisons in Table VI.

B. Cross-Dataset Protocol

The protocol trains on one source domain and evaluates on target domains without target access. All preprocessing, normalisation, feature selection, threshold selection, and model selection follow the access restrictions defined in Section III. Off-diagonal cells train on the complete source domain and score the complete target domain. For every evaluable domain, the in-distribution controls comprise a chronological split and a user-disjoint split. The chronological split places the earliest 70% of the timeline in training and the remainder in testing; the cut is taken at the 0.7 quantile of user-days for the Random Forest and of event timestamps for the temporal graph detector, so users can appear on both sides. The user-disjoint split assigns 70% of users to training and the remaining users to testing, stratified by whether a user has any positive user-day.

These controls test whether a high diagonal score depends on temporal proximity or on repeated users.

C. Compared Models

The Random Forest is the tabular reference model. It is evaluated on the complete source-by-target matrix and on both in-distribution splits. The temporal graph detector of Section IV is evaluated on the in-distribution controls of CERT r4.2, CERT r5.2, and SPEDIA and on the transfers from CERT r4.2 and CERT r5.2 into SPEDIA. Its complete transfer matrix was not computed because of its computational cost. Both models use the same user-day labels, aligned features, source–target partitions, and access restrictions.

D. Evaluation Metrics

PR-AUC (average precision) is the headline metric because positive user-days are rare. Because PR-AUC depends on prevalence, each value is also reported as base-rate lift, that is, PR-AUC divided by the positive rate of the evaluated set. Model differences are summarised by the mean paired difference across the five seeds, with a 95% percentile bootstrap interval from 5,000 resamples of the per-seed differences. Because the temporal graph detector was evaluated on two transfer cells only, no aggregate significance test across the transfer matrix is reported. The generalization gap in Eq. (8) is reported as a transparency statistic. Threshold-dependent operating-point metrics, such as the detection rate at a fixed false-positive rate or precision at k, are not used as evidence: the implementation derives their thresholds from the evaluated set, which would not be available in deployment.

VI. Results and Discussion

All results use the label-independent sampling and the zero-shot protocol defined in Sections III–V, and all values are means over five seeds. This section first reports the in-distribution controls, then the Random Forest transfer matrix and the generalization gap, and finally the paired comparison between the temporal graph detector and the Random Forest.

A. In-Distribution Controls

Table IV shows that within-domain performance was heterogeneous. Under the user-disjoint split, the Random Forest reached PR-AUC values of 0.550 on CERT r4.2, 0.625 on CERT r5.2, and 0.989 on SPEDIA, but only 0.004 on LANL, whose test base rate was about 0.0004 (lift 9.0×). On both CERT releases, the chronological split gave higher scores than the user-disjoint split, for the Random Forest (0.666 and 0.815) and for the temporal graph detector (0.621 and 0.755). This pattern is consistent with a benefit from observing the same users during training. On SPEDIA, the Random Forest scored highly under both splits (0.989 and 0.992), whereas the temporal graph detector scored 0.807 under the user-disjoint split and 0.972 under the chronological split. The temporal graph detector scored below the Random Forest in every in-distribution cell. The chronological LANL split was not evaluable because its test period contained no positive user-days, and CERT r6.2 does not meet the evaluability criterion.

TABLE IV. In-Distribution PR-AUC (Mean Over Five Seeds). "User-Disjoint" and "Chronological" Denote the Split; "Temporal-GNN" Denotes the Model. n/e: Not Evaluable (the LANL Chronological Test Period Contains no Positive User-Days; CERT r6.2 has 44 Positive User-Days, below the Criterion of 50). n/r: Not Run. User-Disjoint Test Base Rates are about 0.0027 (CERT r4.2), 0.0020 (CERT r5.2), 0.41 (SPEDIA), and 0.0004 (LANL)

	Random Forest		Temporal-GNN	
Domain	User-disjoint	Chronological	User-disjoint	Chronological
CERT r4.2	0.5497	0.6660	0.4443	0.6211
CERT r5.2	0.6254	0.8150	0.4776	0.7554
SPEDIA	0.9895	0.9924	0.8072	0.9720
LANL	0.0036	n/e	n/r	n/e
CERT r6.2	n/e	n/e	n/e	n/e

B. Zero-Shot Cross-Dataset Transfer (C1)

Table V and Fig. 5 report the Random Forest transfer matrix. Transfer performance was substantially lower than in-distribution performance on average. Across the four evaluable targets, the mean in-distribution PR-AUC was 0.542 and the mean of the 16 evaluable zero-shot cells was 0.133, giving a generalization gap of $\Delta = 0.409$ (Eq. (8)). The decline was not uniform. Transfers between CERT releases retained part of the signal relative to the target base rate: these cells reached PR-AUC values between 0.015 and 0.390, with lifts between $5\times$ and $133\times$, although each remained below the in-distribution value of its target. In contrast, transfer into SPEDIA gave PR-AUC values between 0.302 and 0.363 against a target base rate of 0.32, corresponding to lifts of only 0.94–$1.13\times$; the Random Forest therefore ranked SPEDIA user-days close to the level expected by chance. Transfers into LANL (PR-AUC ≤ 0.0010; lift 1.1–$2.4\times$) and from LANL or SPEDIA into CERT (PR-AUC ≤ 0.0088; lift 1.0–$3.0\times$) remained near the performance floor. Because the aggregate gap combines targets whose base rates differ by about three orders of magnitude, it is reported together with the per-cell values and lifts.

TABLE V. Zero-Shot Transfer PR-AUC of the Random Forest Reference Model (Base-Rate Lift in Parentheses); Rows = Train Source, Columns = Test Target. The Diagonal is the User-Disjoint In-Distribution Score (Table IV). CERT r6.2 is a Source Only; n/e = Not Evaluable as a Target

Train ↓ / Test →	Target				
	r4.2	r5.2	r6.2	SPEDIA	LANL
r4.2	0.550 (207×)	0.250 (133×)	n/e	0.315 (0.98×)	0.0008 (2.0×)
r5.2	0.390 (133×)	0.625 (317×)	n/e	0.363 (1.1×)	0.0010 (2.4×)
r6.2	0.015 (5.1×)	0.135 (72×)	–	0.302 (0.94×)	0.0004 (1.1×)
SPEDIA	0.0088 (3.0×)	0.0037 (1.9×)	n/e	0.989 (2.7×)	0.0008 (1.9×)
LANL	0.0029 (0.99×)	0.0019 (1.0×)	n/e	0.341 (1.1×)	0.0036 (9.0×)

C. Temporal Graph vs. Tabular Representations (C2)

Table VI compares the temporal graph detector with the Random Forest on the two transfers into SPEDIA, using paired seed-level bootstrap intervals. The representation effect was source-dependent. For CERT r4.2→SPEDIA, the temporal graph detector reached a mean PR-AUC of 0.438 (lift $1.37\times$), compared with 0.315 for the Random Forest, a paired difference of $+0.123$ (95% CI $[+0.075, +0.169]$); all five

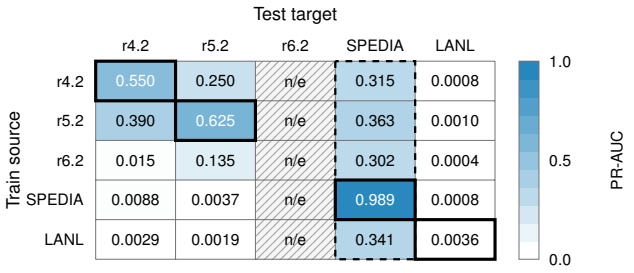

Fig. 5. Zero-shot cross-dataset transfer of the Random Forest (PR-AUC, mean of five seeds). Rows are training sources and columns are test targets; r4.2, r5.2, and r6.2 denote CERT releases. Outlined cells are user-disjoint in-distribution scores. The dashed SPEDIA column has a base rate of 0.32, so its transfer values of 0.30–0.36 are close to chance. CERT r6.2 is not evaluable as a target (hatched) and is excluded from the generalization gap; it is retained as a training source.

seeds favoured the graph model. For CERT r5.2→SPEDIA, the Random Forest reached 0.363 and the temporal graph detector 0.332 (lift $1.04\times$), a paired difference of -0.031 (95% CI $[-0.061, -0.012]$); all five seeds favoured the Random Forest. The graph advantage observed from CERT r4.2 was therefore not reproduced from CERT r5.2, although both sources come from the same synthetic generator and the target is identical. Because the temporal graph detector was not evaluated on the remaining transfer cells, these two comparisons do not support a general statement about graph and tabular representations across the benchmark.

TABLE VI. Paired Comparison of the Temporal-GNN (No Explicit Time Encoding) and the Random Forest on Transfers into SPEDIA (Target Base Rate 0.32). ΔPR = PR-AUC(Temporal-GNN) − PR-AUC(RF), Averaged Over Five Paired Seeds; the 95% CI is a Percentile Bootstrap Over the Paired Per-Seed Differences (5,000 Resamples). The Interpretation Names the Model Favoured by an Interval that Excludes Zero

Source → Target	RF	Temporal-GNN	ΔPR	95% CI	Interpretation
CERT r4.2 → SPEDIA	0.315	0.438	$+0.123$	$[+0.075, +0.169]$	GNN supported
CERT r5.2 → SPEDIA	0.363	0.332	-0.031	$[-0.061, -0.012]$	RF supported

D. Discussion

The results show that strong single-dataset performance is not evidence of cross-dataset transfer. Even where in-distribution scores were high, as for SPEDIA, zero-shot transfer from the other domains into the same target ranked positive user-days close to chance for the Random Forest. The only transfer directions with substantial base-rate lift were those between CERT releases produced by the same simulator. The in-distribution controls add a further caution. On both CERT releases, chronological splits produced higher PR-AUC than user-disjoint splits, so a within-dataset evaluation that places the same users in training and testing can overstate performance on unseen users.

The paired comparison indicates that representation effects depend on the source. The temporal graph detector improved on the tabular reference when trained on CERT r4.2 but not when trained on CERT r5.2, and it scored below the reference in every in-distribution control. A graph representation can therefore help for a particular source–target pair without providing a consistent advantage, even when the target is fixed. Because the complete graph transfer matrix was not computed, the benchmark does not establish whether graph representations are generally better or worse than tabular ones.

Transfer involving LANL remained near the performance floor in both directions. Three non-exclusive explanations are consistent with the evidence. First, the threat semantics differ: LANL positives mark red-team authentication and lateral-movement activity, whereas CERT positives mark synthetic traitor scenarios and SPEDIA positives follow descriptive and Wazuh severity rules. Second, the shared representation covers LANL only partially. All 8.37 million sampled LANL events map to three of the sixteen canonical actions (logon 45.3%, logoff 36.4%, and auth 18.3%; Table II). Authentication type, logon type, and outcome are therefore collapsed, and the file, device, web, and e-mail actions that dominate CERT are absent. Third, prevalence differs by orders of magnitude: the positive user-day rate is about 0.0004 for LANL (158 of 389,323 user-days), compared with 0.32 for SPEDIA and between about 0.00003 and 0.003 for the CERT releases. The present benchmark cannot determine how much of the LANL failure is attributable to each mechanism, and none of them is claimed to be the sole cause.

Finally, the reported results concern ranking and discrimination transfer rather than probability calibration transfer. PR-AUC measures how well positive user-days are ranked above negative ones under class imbalance. It does not show that predicted probabilities keep the same meaning in a new domain, that source confidence scores remain calibrated on the target, or that a fixed operating threshold preserves its false-positive rate. No target recalibration was performed, and calibration metrics such as the Brier score or expected calibration error were not computed. Calibration transfer and operating-point stability therefore remain open questions for deployment.

VII. Threats to Validity

The datasets differ in collection method, event coverage, label semantics, and insider type. CERT contains synthetic traitor scenarios, LANL labels red-team authentication activity, and SPEDIA uses descriptive and Wazuh severity rules. Mapping these sources to a common user-day label supports comparison but cannot make their underlying threat concepts identical. The study therefore interprets cross-dataset results as transfer across related security domains rather than as proof of universal insider-threat detection.

SPEDIA contains CERT-derived records in its original release. This risk is mitigated by excluding all rows for which `Decoder_name == 'cert'` and auditing the remainder for CERT-related tokens and identifiers. The audit supports a clean comparison, but it cannot establish that every retained behavioural pattern is statistically independent of all external data-generation influences.

The fixed action vocabulary and aligned feature set may omit useful dataset-specific information. Conversely, retaining source-specific identifiers or unsupported fields could allow models to recognise the source dataset rather than the behaviour. The study therefore reports the mapping rules

and excludes direct dataset identifiers. No alternative action groupings were evaluated. Because no event in any domain was assigned to the unknown action, retaining or excluding unknown events does not change the reported results; however, sensitivity to alternative groupings, such as separating authentication subtypes in LANL, remains untested. The benchmark compares one tabular and one temporal graph model; other detector families were not evaluated under the final protocol, and the temporal graph detector was evaluated on two transfer cells only.

LANL red-team activity is concentrated within a limited sub-window of the collection period. A chronological split therefore leaves no positives in the test period, so the LANL in-distribution diagonal is reported under the user-disjoint split only. LANL timestamps are also expressed on a relative clock, so time-of-day features are interpreted through the per-user deviation transformation rather than as absolute working hours. The generalization gap assigns uniform weight to all diagonal and off-diagonal cells. This keeps the statistic transparent, but it does not account for differences in target size, prevalence, or label uncertainty. Because target prevalence ranges over roughly three orders of magnitude across domains, per-cell PR-AUC and base-rate lift are reported alongside the aggregate gap, and CERT r6.2 (44 positive user-days) is excluded from the evaluable targets.

The confidence intervals are percentile bootstrap intervals over five paired seeds. They capture variation across seeds but not sampling variation in the evaluated user-days, and five seeds give only a coarse estimate of that variation. The CERT web logs and the LANL authentication log were subsampled to make processing feasible. The sampling rate is identical for all users and independent of labels, but it reduces the evidence available per user-day, and a labelled user-day whose events are all removed cannot be observed (18 of the 176 LANL red-team user-days). The reported values therefore refer to the sampled event universe rather than to the complete logs. Finally, the temporal graph detector was evaluated without explicit time encoding in order to exclude target-derived timestamp statistics. Configurations with a source-only or causal time encoding were not evaluated.

VIII. Conclusion and Future Work

This study presents, to the best of our knowledge, the first systematic zero-shot cross-dataset benchmark for insider threat detection across CERT, SPEDIA and LANL. The benchmark uses label-independent event sampling, a common user-day prediction unit, chronological and user-disjoint in-distribution controls, and an evaluable-set generalization gap, and no labelled or unlabelled target observations are used during training. Within-domain performance was heterogeneous, and transfer performance was substantially lower on average. For the Random Forest reference model, mean PR-AUC fell from 0.542 in distribution to 0.133 under zero-shot transfer, a generalization gap of 0.409. Transfer into SPEDIA was close to the target base rate, and transfer into and out of LANL remained at the performance floor. A memory-based temporal graph detector without explicit time encoding outperformed the Random Forest for CERT r4.2→SPEDIA but underperformed it for CERT r5.2→SPEDIA. The representation effect was therefore source-dependent, and no general graph advantage is claimed. Strong single-dataset performance is insufficient evidence of cross-dataset generalization.

Future work will extend the benchmark to further independently constructed corpora, including TWOS and DARPA OpTC, and will evaluate the temporal graph detector on the complete transfer matrix. It will also examine source-only or causal time encodings and target-assisted domain adaptation as separately reported settings, evaluate event-, session-, host-, and process-level prediction units, assess calibration transfer and operating-point stability, and test alternative action groupings. Future work will also examine whether attribution profiles remain stable across domains.

Declarations

Funding

This research did not receive any specific grant from funding agencies in the public, commercial, or not-for-profit sectors.

Conflicts of Interest

The authors declare that they have no known competing financial interests or personal relationships that could have appeared to influence the work reported in this study.

Data Availability

This study uses only third-party, publicly documented datasets, which are not redistributed by the authors. Each is available from its original source under its respective licence: the CERT Insider Threat Test Dataset; the SPEDIA dataset (Zenodo, https://doi.org/10.5281/zenodo.15495572); and the LANL Comprehensive Multi-Source Cyber-Security Events dataset.

Code Availability

The code (including the configuration of the camera-ready experiments), benchmark documentation and summary result tables supporting the camera-ready experiments are publicly available at https://github.com/alriyami7777-alt/crossdataset-insider-threat. The third-party datasets are not redistributed and must be obtained from their original sources.

Empirical Evaluation of Language Models for Arabic Financial Sentiment Analysis: A Comparative Study of Pretrained and General Large Language Models

Abdullah Almusned*, Mohammad Mehedi Hassan, Muhammad Al-Qurishi, Bader Alkhamees
Department of Information System-College of Computer and Information Sciences, King Saud University, Saudi Arabia

***Abstract*—This study presents a comparative study on the effectiveness of large and pre-trained language models in analyzing sentiment in Arabic financial news. While sentiment analysis using AI has advanced significantly in English-language finance, similar progress in Arabic remains limited. Most existing Arabic models, such as AraBERT and CAMeLBERT, are trained on general or social media posts and struggle with domain-specific content like financial data. At the same time, modern LLMs like ChatGPT and Gemini have not been thoroughly tested on Arabic financial data. Our work addresses these gaps by evaluating five models—ChatGPT, Gemini, Nuha (an Arabic LLM), AraBERT, and CAMeLBERT—on a dataset of 10,166 financial news headlines from Argaam, a leading Saudi financial platform. We conduct three key experiments. First, we conduct a standard sentiment classification comparison across all models. Second, prompt engineering experiment using zero-shot, one-shot, and three-shot strategies. Finally, persona-driven analysis where models respond from the viewpoint of different financial roles. The results show that Nuha consistently delivers the highest performance, except when prompts include user roles. They show promising results, but did not achieve the highest performance. ChatGPT maintains stable results across prompt variations and shows the most remarkable results when there are persona-driven prompts. Gemini performs well in zero-shot but degrades with added context. PLMs underperform, highlighting the need for better domain adaptation. Overall, this study provides practical insights into model behavior under different prompting conditions, emphasizes the importance of cultural alignment, and introduces persona-driven prompting as a valuable strategy for Arabic financial sentiment analysis.**

***Keywords*—Arabic inancial news; stock news; inancial news; domain speci ic; ChatGPT; Gemini; large language model; prompt strategies; Saudi stocks; sentiment analysis**

I. Introduction

The world of finance rapidly evolving thanks to technology like digital payments, online banking, and new ways to check identity and assess risk. At the same time, artificial intelligence (AI) makes understanding financial data easier. Machine learning (ML), and especially Natural Language Processing (NLP), now plays a significant role in analyzing stock markets [1], predicting trends [2], and spotting early signs of financial trouble [3]. One key task in this field is sentiment analysis, which looks at how people feel based on text found in places like financial news [4] [5], social media posts [6], or official company updates. These signals help investors make informed investment decisions and reduce risk by helping them understand how news might affect stock prices [7],[8].

In the past, researchers used simple machine learning tools and small datasets to study sentiment. Nevertheless, now, more powerful tools such as Pre-trained Language Models (PLMs) and Large Language Models (LLMs) make it possible to handle complicated language and context much better [9],[10]. For example, FinBERT was explicitly designed to understand English financial text and performs well on tasks that require understanding of market tone [11]. Some general-purpose models such as ChatGPT and Gemini have also been tested in different financial settings and languages, especially English, demonstrating competitive performance with proper input [12], [13].

However, despite these advances in English financial NLP, comparable empirical evidence for Arabic financial sentiment analysis remains limited—particularly in stock market news. Arabic models such as AraBERT [14] and CAMeLBERT [15] were mostly tested on general texts or social media posts, like telecom reviews [16] or tweets [17],[18]. These models face challenges due to Arabic's complex grammar, various dialects, and a lack of labeled data [19].

Our work helps fill that gap. It compares how well ChatGPT and Gemini (two powerful LLMs) perform against Nuha (an Arabic local LLM) and traditional PLMs like AraBERT and CAMeLBERT. The evaluation uses over 10,000 headlines from Argaam, a trusted Saudi stock market news source spanning multiple sectors. This research seeks to identify the sentiment of each news headline, leading to improved decision-making in the financial market. What makes it unique is not just the comparison of models but also two new ideas it tests. First, it looks at how zero-shot, one-shot, and three-shot prompting styles affect LLM model accuracy—a topic not widely explored in Arabic NLP. Second, it tries persona-based prompting by asking the LLM models to act like real-life users, such as financial analysts or traders, to see if that improves their answers. So far, to the best of our knowledge, this is one of the first studies to compare the performance of Arabic PLMs with modern LLMs on actual Arabic financial texts.

In view of the limited empirical evidence on Arabic financial sentiment analysis using modern language models, and the increasing relevance of prompt formulation and contextual framing, this study aims to systematically investigate how model architecture and prompting strategies affect sentiment

*Corresponding author.

classification performance in Saudi financial news. Accordingly, the following research questions are formulated:

- *RQ1:* How do instruction-tuned large language models compare with Arabic pretrained language models in classifying sentiment in Saudi financial news headlines?
- *RQ2:* How do different prompting strategies (zero-shot, one-shot, and few-shot) influence sentiment classification performance across large language models?
- *RQ3:* Does persona-driven prompting enhance the accuracy and robustness of sentiment classification in Arabic financial news analysis?

The rest of the study is as follows. Section II, is the conceptual and theoretical IV reports the results. Section V discusses the findings. Section VI will be the conclusion.

II. Conceptual and Theoretical Framework

This study is grounded in several interconnected theoretical foundations from natural language processing and machine learning that collectively shape the understanding of Arabic financial sentiment analysis. These foundations provide the conceptual perspective through which model behavior is interpreted and experimental methodologies are theoretically supported.

In-context learning, introduced by [20], refers to the capability of large language models to acquire task-specific behaviors directly from examples embedded within prompts, without requiring parameter updates or gradient-based optimization. This paradigm departs from conventional supervised learning, which depends on extensive fine-tuning using labeled datasets. Authors in [21] demonstrated that the effectiveness of in-context learning depends not merely on the presence of examples, but on their quality, relevance, and structural alignment with inference instances, indicating that models infer latent task structures rather than memorize input-output mappings. Authors in [22] further expanded this understanding through chain-of-thought prompting, showing that explicitly structured reasoning steps facilitate complex multi-stage inference. However, [23] reported substantial variability in few-shot performance across different model architectures and training objectives.

Transfer learning principles, formalized by [24] , posit that knowledge acquired during large-scale pre-training can be transferred to specialized downstream tasks, with effectiveness governed by domain proximity between source and target domains. Authors in [25] operationalized this concept through Universal Language Model Fine-tuning, demonstrating that sequential adaptation from general to domain-specific corpora outperforms task-specific training from scratch. Authors in [26] further showed that continued pre-training on domain-specific data yields significant performance gains when target domains exhibit specialized vocabulary and discourse patterns. In Arabic financial sentiment analysis, domain adaptation spans both linguistic dimensions—Modern Standard Arabic augmented with financial terminology—and topical dimensions associated with economic and market-related discourse. Comparisons between multilingual models (ChatGPT, Gemini), Arabic-local models (Nuha), and Arabic-specific pretrained models (AraBERT, CAMeLBERT) enable examination of whether linguistic and topical alignment corresponds with classification performance.

A fundamental distinction in contemporary language models exists between architectures trained solely on language modeling objectives and those subjected to instruction-tuning, which involves explicit optimization for following natural language instructions. Authors in [27] demonstrated through InstructGPT that fine-tuning models on diverse instruction-following tasks using reinforcement learning from human feedback substantially improves zero-shot generalization and task alignment. This approach is grounded in meta-learning principles, whereby exposure to large collections of instruction-formatted tasks enables models to infer task intent and adapt behavior accordingly [28],[29]. Authors in [30] further established that instruction-tuning yields cumulative benefits, improving both zero-shot and few-shot performance. This distinction differentiates instruction-tuned large language models from pretrained language models that rely primarily on masked language modeling objectives.

Prompt engineering has emerged as a central factor influencing large language model effectiveness, with systematic variations in input formulation producing substantial performance differences. Authors in [31] showed that minor changes in wording, phrasing, or structural organization can lead to notable accuracy fluctuations. Authors in [32] identified prompt sensitivity as a fundamental challenge, demonstrating that models may exhibit unstable performance across semantically equivalent but syntactically different prompts. Authors in [33] further documented extreme sensitivity to demonstration ordering in few-shot settings, showing that permuting identical examples can significantly affect outcomes.

Recent studies indicate that large language models can simulate distinct perspectives when explicitly assigned roles, with persona-based prompting influencing reasoning processes and task performance. Authors in [34] demonstrated that multi-persona approaches enhance complex problem-solving by activating different knowledge distributions within learned representations. Authors in [35] provided theoretical grounding, arguing that role-based prompting leverages models' exposure during pre-training to diverse professional registers and domain-specific discourse patterns. Authors in [36] further showed that persona prompts systematically shift model behavior and can improve performance when role framing aligns with domain expertise. In financial discourse, role-based prompting offers a structured means of contextualization, reflecting the differing analytical priorities of analysts, traders, and financial advisors.

Financial sentiment analysis represents a specialized domain characterized by distinctive linguistic properties and a strong dependence on numerical and temporal context. Authors in [37] demonstrated that general-purpose sentiment lexicons systematically misclassify financial texts because commonly used words often carry domain-specific meanings. Authors in [11] operationalized this insight through FinBERT, achieving state-of-the-art results by modeling finance-specific semantic patterns. Authors in [38] further established that financial sentiment is frequently expressed implicitly through factual reporting rather than overt opinion markers, requiring models to integrate numerical reasoning with linguistic interpretation.

In Arabic financial discourse, these challenges are compounded by language-specific factors, including morphological richness, formal registers, and culturally grounded indirect communication styles, which introduce additional layers of semantic complexity.

Multilingual language models aim to learn shared representations across languages, enabling cross-lingual transfer from high-resource to low-resource contexts. Authors in [39] demonstrated this capability through XLM-RoBERTa, achieving competitive multilingual performance despite substantial imbalance in training data. Authors in [40] found that multilingual models acquire language-agnostic syntactic and semantic abstractions. However, [41] reported that cross-lingual transfer degrades for morphologically rich languages such as Arabic, particularly in tasks requiring cultural grounding or domain-specific reasoning. Authors in [42] further showed that multilingual models can support few-shot cross-lingual transfer, though effectiveness depends on linguistic typology and representational quality. These findings highlight the complexities of multilingual modeling in specialized financial domains.

Based on the theoretical foundations outlined above, this study proposes the following hypotheses to guide the empirical investigation:

- H1: Instruction-tuned large language models will outperform Arabic pretrained language models in zero-shot Arabic financial sentiment classification, attributable to their enhanced instruction-following capabilities and higher-level contextual abstraction.
- H2: The impact of prompting strategies will be model-dependent, such that few-shot prompting will benefit models exhibiting strong in-context learning alignment, whereas models optimized primarily for abstraction-based generalization may experience performance degradation when exposed to demonstration-based prompts.
- H3: Persona-driven prompting will improve sentiment classification performance by introducing role-specific contextual framing that aligns model reasoning with domain-relevant financial decision perspectives.

III. Methodology

This section describes the different experiments used to evaluate the performance of large language models (LLMs) and pretrained language models (PLMs) in Arabic financial sentiment classification as it shown in Fig. 1. We start by defining the datasets and their sources. Then, we define each LLM and PLM model used in this study. Afterward, we introduce the different experiments. Finally, we set and describe the evaluation metrics.

A. Dataset

The dataset utilized in our work consisted of 10,166 Saudi stock market news headlines collected from Argaam [43], a leading financial economic website in the region. Argaam is owned by the Saudi Research and Media Group, a publicly listed company on the Saudi Stock Market. The headlines covered the period from January 1, 2021, to January 1, 2024, and covered 233 listed companies from 11 different sectors in the Saudi market. This comprehensive dataset offered a diverse representation of sentiments and writing styles, with the concise and focused nature of the headlines presenting both a valuable and challenging source for sentiment analysis due to their often implicit emotional small difference.

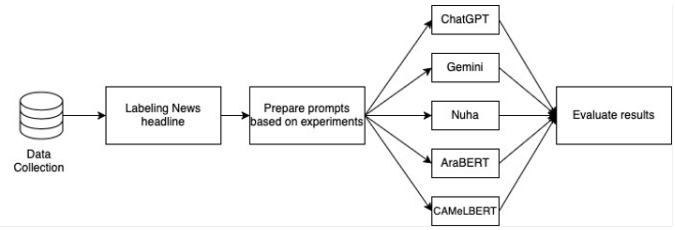

Fig. 1. Used methodology.

Each headline was assigned one of three sentiment labels: positive, negative, or neutral. The annotation process followed a hybrid approach, where ChatGPT, Gemini, and Nuha generated the initial labels, followed by manual validation by experts to determine the final reference labels.

B. Models

ChatGPT is a state-of-the-art large language model developed by OpenAI, built on the GPT (Generative Pretrained Transformer) architecture. It has been fine-tuned using reinforcement learning from human feedback (RLHF), which enhances its ability to generate contextually appropriate and coherent responses. Due to its extensive training on diverse and large-scale datasets, ChatGPT exhibits strong generalization capabilities, making it well-suited for tasks such as sentiment analysis, especially in domains like financial news where contextual nuance and linguistic variability are critical. In this study, we used GPT via APIs with a temperature of 0.1.

Gemini is Google DeepMind's advanced large language model, designed to compete at the frontier of generative AI. Leveraging cutting-edge transformer architectures and trained on multilingual, multi-modal datasets, Gemini aims to deliver high performance across a range of tasks, including natural language understanding and generation. Its multilingual capabilities and powerful reasoning abilities make it a promising candidate for complex applications such as sentiment classification in finance, particularly when dealing with rich, structured data inputs. For the purpose of this study, all safety settings were disabled to ensure that the model's raw interpretive capacity could be evaluated without filtering or moderation constraints.

Nuha, previously referred to as Juhaina, is a bilingual Arabic-English Large Language Model developed by Elm Company with the explicit goal of cultural and linguistic alignment with Arabic-speaking users. Nuha supports a wide range of tasks including instruction-following, open-domain question answering, and sentiment classification. It is post-trained using supervised fine-tuning (SFT) and human preference alignment methods to improve its generation quality and adherence to Arabic cultural norms. In our work, Nuha is evaluated alongside other LLMs to assess its performance on Arabic financial sentiment analysis, contributing to the exploration of locally aligned generative AI solutions.

CAMelBERT is a family of Arabic pretrained language models introduced by the CAMeL Lab at New York University Abu Dhabi. The model variants are trained on extensive corpora representing Modern Standard Arabic (MSA), Dialectal Arabic (DA), Classical Arabic (CA), and a mixture of these variants. CAMeLBERT adopts the BERT architecture with standardized pretraining procedures, leveraging over 167 GB of high-quality Arabic text. Through systematic experimentation, the developers demonstrated that language variant proximity—rather than data volume—is the most significant factor influencing downstream task performance. In this study, CAMeLBERT is used as an Arabic PLM, offering valuable insight into how diverse pretraining data affects sentiment analysis outcomes. Therefore, the 'bert-base-arabic-camelbert-mix-sentiment' model was employed without additional fine-tuning.

AraBERT is a monolingual Arabic language model based on the BERT-base architecture, developed by researchers at the American University of Beirut. It consists of 12 transformer layers and approximately 110 million parameters. AraBERT was trained using the Masked Language Modeling (MLM) and Next Sentence Prediction (NSP) objectives on a large Arabic corpus comprising 70 million sentences, collected from Arabic Wikipedia, the 1.5B words El-Khair corpus, and the OSIAN news corpus. AraBERT has shown state-of-the-art results across various Arabic NLP tasks such as sentiment analysis, named entity recognition, and question answering. In our study, AraBERT serves as an Arabic Pretrained Language Model (PLM) for sentiment classification. Accordingly, the 'AraBert-Arabic-Sentiment-Analysis' model was utilized in its pretrained configuration, without fine-tuning.

C. Experiments

We conducted a series of experiments using multiple prompting strategies across general-purpose and Arabic-specific language models on Arabic financial sentiment data. This section defines each experiment, and the prompt used for it.

1) Experiment 1: Comparative analysis of sentiment analysis models: The first experiment compared five sentiment analysis models—AraBERT, CAMeLBERT, ChatGPT, Gemini, and Nuha—on their ability to classify Arabic financial news into three sentiment categories: positive, negative, and neutral. Each model was applied to the same dataset of headlines, ensuring a consistent baseline for comparison as shown in Table I (Exp1). AraBERT and CAMeLBERT were leveraging their pre-training on Arabic text. ChatGPT, Gemini and Nuha, as generative language models, were evaluated in zero-shot settings. This experiment aimed to provide insights into the models' performance across a standard sentiment classification task.

2) Experiment 2: Zero-shot, one-shot, and few-shot prompt strategies: The second experiment focused on comparing the performance of ChatGPT, Gemini, and Nuha under different prompting approaches: zero-shot, one-shot, and few-shot strategies. In this setup, the models were tasked with sentiment classification of Arabic news headlines. Zero-shot prompting involved no prior examples, one-shot used a single example within the prompt, and few-shot included three examples of each class to guide the models as shown in Table I (Exp2). This experiment was designed to evaluate how the inclusion of examples influenced the models' ability to accurately interpret and classify sentiments, providing deeper insights into their adaptability and learning capabilities. CAMeLBERT and AraBERT were not evaluated due to their limited capabilities in zero/few-shot contexts and absence of instruction-tuned architectures, but given their baseline performance in Experiment 1, their inclusion would likely have yielded similarly weak results under complex prompting scenarios.

TABLE I. PERSONA-DRIVEN PROMPTS

ID	Prompt
Exp1	Respond with only one word (*neutral*, *positive*, or *negative*) based on the sentiment of the input text.
P1	Act as a financial analyst expert in Saudi stocks. How would you assess the tone of the news in the following headline in relation to the stock? Respond only in one word: *positive*, *negative*, or *neutral*. Headline: {headline}.
P2	Act as a Saudi stock expert trader. Based on the headline {headline}, how would you interpret the news regarding its potential impact on the stock? Respond only in one word: *positive*, *negative*, or *neutral*.
P3	Act as a sentiment analysis model trained on Saudi financial news headlines. Based on the headline {headline}, Respond only in one word: *positive*, *negative*, or *neutral*.
P4	Act as an expert in Saudi stock trading. Based only on the headline, will you buy, sell, or hold your stocks the next day? Respond only in one word: *positive*, *negative*, or *neutral* (positive = buy, negative = sell, neutral = hold). Headline: {headline}.

Prompts used to evaluate the effect of different expert personas on sentiment classification of Saudi stock market news headlines.

3) Experiment 3: Persona-driven prompts based on user roles: The third experiment explored the use of role-specific personalized prompts to adapt sentiment analysis outputs based on the perspective of specific professional roles, such as financial analysts, Saudi traders, and other relevant job profiles. For this purpose, ChatGPT, Gemini, and Nuha were tested using tailored prompts designed to align the sentiment classification process with the priorities and contextual needs of these roles. Table I (P1-P4) details the prompts used for sentiment classification. For example, prompts for financial analysts emphasized sentiment relevant to market trends and economic impact, while prompts for Saudi traders focused on actionable insights and immediate relevance to trading activities. This experiment aimed to evaluate the potential of personalized prompts in enhancing the contextual appropriateness and practical utility of sentiment analysis. For the same reason in the second experiment, CAMeLBERT and AraBERT were not evaluated.

D. Evaluation Metrics

To evaluate the performance of the five models in sentiment classification task, we employed a standard suite of metrics. These encompassed accuracy, precision, recall, F1-score, Cohen's Kappa, and confusion matrices.

Accuracy measures the proportion of correctly classified instances. However, it can be misleading with imbalanced datasets.

Precision, Recall, and F1-score were used to address accuracy's limitations, we used precision (true positives among

predicted positives), recall (true positives among actual positives), and their harmonic mean, the F1-score. These were calculated per class and using macro- and weighted-averaging to account for class imbalance.

Cohen's Kappa measures agreement between predicted and true labels, correcting for chance agreement. A Kappa of 1 indicates perfect agreement, 0 indicates chance agreement, and -1 indicates perfect disagreement. This is particularly useful for comparing models with different class biases.

The Confusion Matrix provides a tabular visualization of classification performance, showing true/false positives/negatives for each class and aiding in identifying misclassifications patterns.

IV. Results

This section presents the findings intended as descriptive comparisons from three experiments designed to evaluate the performance of five large language models, ChatGPT, Gemini, Nuha, CAMeLBERT, and AraBERT, in the sentiment classification tasks. The models were assessed using standard performance metrics, accuracy, precision, recall, F1-score, and Cohen's Kappa. The following subsections detail the outcomes of each experiment, highlighting key patterns and comparative insights.

A. Experiment 1: Comparative Analysis of Sentiment Analysis Models

The evaluation results presented in the comparative Table II offer significant insights into the performance of five language models: ChatGPT, Gemini, Nuha, CAMeLBERT, and AraBERT. Among the evaluated models, Nuha achieved the highest observed performance, with an accuracy of 89.09%, a precision of 0.8958, a recall of 0.8909, and an F1-score of 0.8914. This suggests Nuha is highly effective in distinguishing between different sentiment categories while maintaining a strong balance between precision and recall. Gemini follows closely, with an accuracy of 88.69% and the highest precision 0.9027, indicating a conservative classification strategy that prioritizes correctness in positive sentiment predictions. However, its recall is marginally lower than Nuha. ChatGPT, while slightly trailing behind Gemini and Nuha, still performs competitively with an accuracy of 86.70%, a precision of 0.8861, a recall of 0.8670, and an F1-score of 0.8633, demonstrating a strong generalization capability.

Conversely, CAMeLBERT and AraBERT exhibit significantly weaker performance, with CAMeLBERT achieving 60.21% accuracy and AraBERT scoring the lowest at 55.14%. These results indicate their limited ability to accurately classify Arabic sentiment, likely due to suboptimal domain adaptation. The confusion matrices further illustrate classification errors and model biases, shedding light on misclassification tendencies.

Nuha minimizes classification errors, correctly predicting 4,779 positive, 937 neutral, and 3,341 negative instances, with only misclassified 767 positives, 96 neutral and 246 negatives, reinforcing its robustness. Gemini, while strong in both precision and recall, struggles with false negatives, misclassifying 1,000 positive instances, which may indicate a conservative bias in sentiment classification. ChatGPT performs well in classifying 5,469 positive, 816 neutral and 2,529 negative sentiments correctly, but exhibits a relatively high number of false negatives of 1,058 misclassified negative instances, suggesting a tendency to overestimate negativity in certain contexts. Fig. 2 shows the confusion matrix for each model.

TABLE II. Experiment 1 Performance Metrics

Model	Accuracy (%)	Precision	Recall	F1-score
ChatGPT	86.70	0.8861	0.8670	0.8633
Gemini	88.69	0.9027	0.8869	0.8876
Nuha	**89.09**	**0.8958**	**0.8909**	**0.8914**
CAMeLBERT	60.21	0.7198	0.6012	0.5056
AraBERT	55.14	0.7325	0.5514	0.3989

Performance comparison of large language models and transformer-based baselines on Experiment 1. The best result in each metric is shown in bold.

Pre-trained models, CAMeLBERT and AraBERT exhibited significant classification confusion, particularly in differentiating neutral and positive sentiment. CAMeLBERT misclassified 956 neutral instances as positive, while AraBERT exhibits a strong bias toward predicting positive sentiment, incorrectly classifying 1,031 neutral instances as positive and 3,525 negative instances as positive. This suggests that AraBERT struggles to differentiate between neutral and positive sentiment polarities, a significant limitation for applications requiring precise sentiment analysis. Additionally, CAMeLBERT's high misclassification rate for negative sentiment where 576 instances are incorrectly labeled as positive, suggests it lacks strong contextual understanding of negative sentiment indicators.

From the confusion matrices, two key patterns emerge. First, bias toward positive sentiment is apparent in AraBERT and CAMeLBERT, with a disproportionate number of neutral and negative instances classified as positive. This suggests these models fail to capture sentiment variations, particularly in distinguishing neutral language from positive sentiment. Second, ChatGPT and Gemini exhibit higher false negative rates, where positive instances are sometimes misclassified as negative. While this could indicate a conservative classification strategy aimed at reducing false positives, it may lead to missed positive sentiment detections, which is crucial in sentiment-sensitive applications like our situation financial news.

To further assess inter-rater reliability and classification agreement, Cohen's Kappa coefficient was calculated for each model as it shows in Fig. 3. Cohen's Kappa is a more robust measure than accuracy as it accounts for chance agreement. The results reveal a clear distinction in model reliability. Nuha achieved 0.8107 and Gemini 0.8064 exhibited the highest agreement with ground truth, reinforcing their strong consistency in classification. ChatGPT with score 0.7537 follows closely, indicating good agreement but slightly more variance in predictions compared to Nuha and Gemini. CAMeLBERT achieved 0.1526 demonstrates poor agreement, aligning with its high misclassification rates seen in the confusion matrices. AraBERT with score 0.0159 exhibits an almost random agreement level, confirming its severe misclassification issues and bias toward predicting positive sentiment.

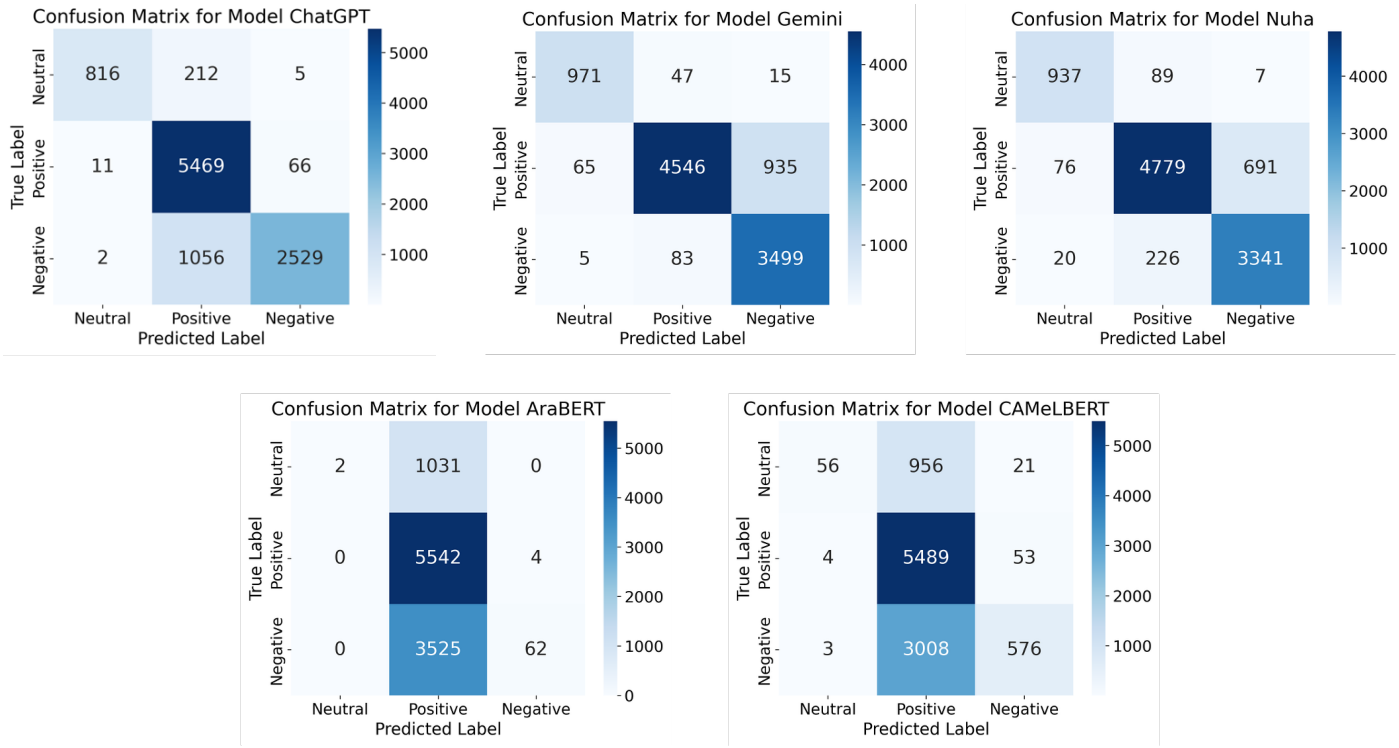

Fig. 2. Experiment 1 confusion matrix.

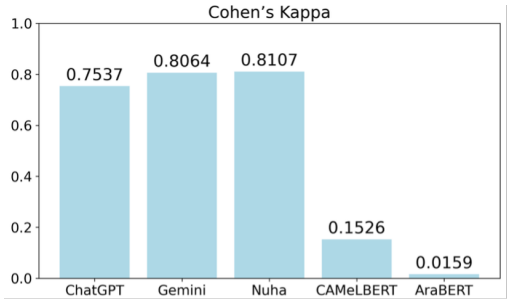

Fig. 3. Experiment 1 Cohen's kappa.

Overall, Nuha proves to be the most reliable model, excelling across all key performance metrics while maintaining low error rates across sentiment categories. Gemini and ChatGPT remain strong alternatives, with Gemini excelling in precision and ChatGPT offering a balanced classification approach. CAMeLBERT and AraBERT, however, require significant improvements, particularly in distinguishing between neutral and positive sentiment, as well as in reducing their overall misclassification rates. These findings reinforce the importance of careful model selection in sentiment analysis tasks, particularly in fields where classification precision directly impacts decision-making processes.

B. Experiment 2: Zero-Shot, One-Shot, and Three-Shot Prompt Strategies

The second experiment evaluates the impact of prompting strategy—specifically Zero-Shot, One-Shot, and Three-Shots—on the performance of three large language models: ChatGPT, Gemini, and Nuha. Table III summarized the performance metrics for this experiment.

TABLE III. EXPERIMENT 2 PERFORMANCE METRICS

Model	Strategy	Accuracy (%)	Precision	Recall	F1-score
ChatGPT	Zero	86.70	0.8861	0.8670	0.8633
	One	**87.40**	**0.8868**	**0.8740**	**0.8707**
	Three	83.43	0.8599	0.8343	0.8254
Gemini	Zero	**88.69**	**0.9027**	**0.8869**	**0.8876**
	One	58.34	0.5671	0.5834	0.5632
	Three	56.36	0.5439	0.5636	0.5256
Nuha	Zero	89.09	0.8958	0.8909	0.8914
	One	91.97	0.9200	0.9197	0.9197
	Three	**92.45**	**0.9247**	**0.9245**	**0.9245**

Performance comparison of different prompting strategies (zero-, one-, and three-shot) across the evaluated models in Experiment 2. The best result for each model is shown in bold.

Nuha emerged as the most consistently performant model across all prompt configurations. It achieved an accuracy of 89.09% in the zero-shot, improving to 91.97% in one-shot and further to 92.45% in the three-shot. Precision, recall, and F1-score followed the same ascending pattern. Cohen's Kappa values for Nuha also reflect strong inter-rater agreement, increasing steadily from 0.8107 to 0.8674. The confusion matrices [Fig. 4(c)] confirm this consistency, with Nuha classifying the majority of positive and negative instances correctly while maintaining balanced performance across all sentiment classes.

These consistent improvements suggest that Nuha benefits significantly from in-context learning, effectively incorporating example-driven prompts to enhance classification quality without suffering from overfitting or degradation.

ChatGPT demonstrated relatively stable performance across all prompting strategies, with minor fluctuations. Its zero-shot accuracy was 86.70%, marginally improving to 87.40% in one-shot, but decreasing to 83.43% in three-shots. Precision and recall peaked in the one-shot setting at 0.8868 and 0.8740, respectively, before declining in three-shots 0.8599 and 0.8343. The F1-score mirrored this trend, with values of 0.8633, 0.8707, and 0.8254. This slight decline in the three-shot setting suggests ChatGPT may struggle to integrate larger contextual prompts effectively. The Cohen's Kappa values of 0.7537, 0.7700, and 0.6931, respectively, support this interpretation, indicating strong agreement in zero- and one-shot, but reduced reliability when exposed to extended prompt length. The confusion matrices [Fig. 4(a)] further illustrate this trend that ChatGPT performs best with minimal context (zero- or one-shot), but misclassifies more negative instances as positive in three-shot, suggesting some semantic drift or context overload. Nevertheless, its relatively high and balanced scores across all metrics indicate that ChatGPT maintains a robust baseline performance and is generally resilient to prompt variation.

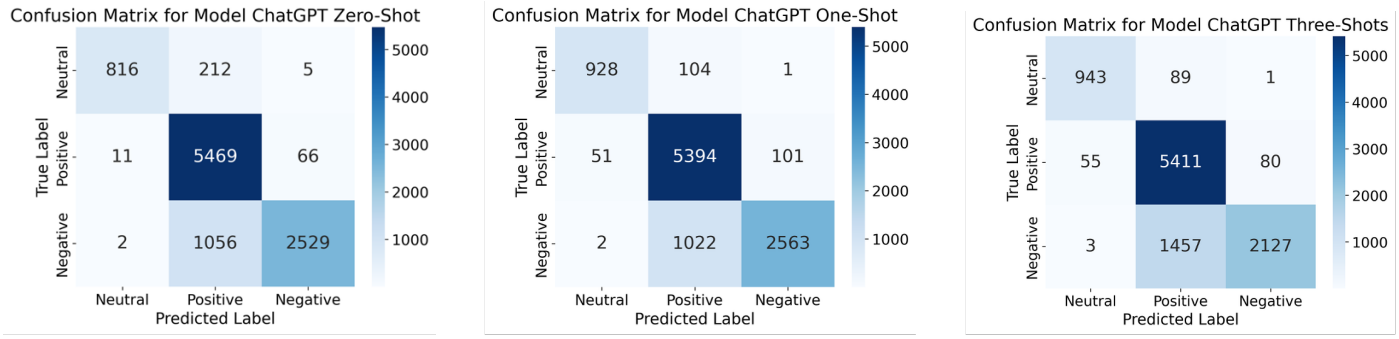
In contrast, Gemini exhibits a sharp and unexpected decline in performance when shifting from zero-shot to few-shot strategies. It achieves 88.69% accuracy, 0.8869 recall, and an F1-score of 0.8876 in zero-shot, performing comparably to Nuha and exceeding ChatGPT. However, in one-shot and three-shots, Gemini's accuracy drops to 58.34% and 56.36%, recall to 0.5834 and 0.5636, and F1-score to 0.5632 and 0.5256, respectively. The Cohen Kappa values also plummet 0.2185 and 0.1616, showing low agreement and near-random performance in those settings (Fig. 5). This pattern indicates that Gemini is highly sensitive to few-shot prompting, possibly due to inefficient handling of in-context learning examples or overfitting to provide demonstrations. the conclusion that Gemini excels in generalization without explicit examples, but fails to adapt when such examples are introduced.

The overall findings underscore three key insights. First, in-context prompting improves model performance only when the model architecture and training support such adaptation, as evidenced by Nuha's consistent gains. Second, not all models benefit from increasing the number of examples, with Gemini's performance declining sharply under few-shot conditions, suggesting possible overfitting or distraction effects. Third, ChatGPT offers balanced generalization, performing reliably across varying prompt styles but showing diminishing returns in more complex three-shot contexts.

In conclusion, the experiment highlights the non-linear and model-specific effects of prompting strategies. While Nuha leverages contextual prompts to enhance performance, and ChatGPT maintains stability, Gemini's decline under few-shot settings suggests structural or representational limitations that hinder its ability to utilize prompt examples. These findings emphasize the importance of understanding model behavior in relation to task design and prompt structure for optimal deployment of language models in sentiment analysis.

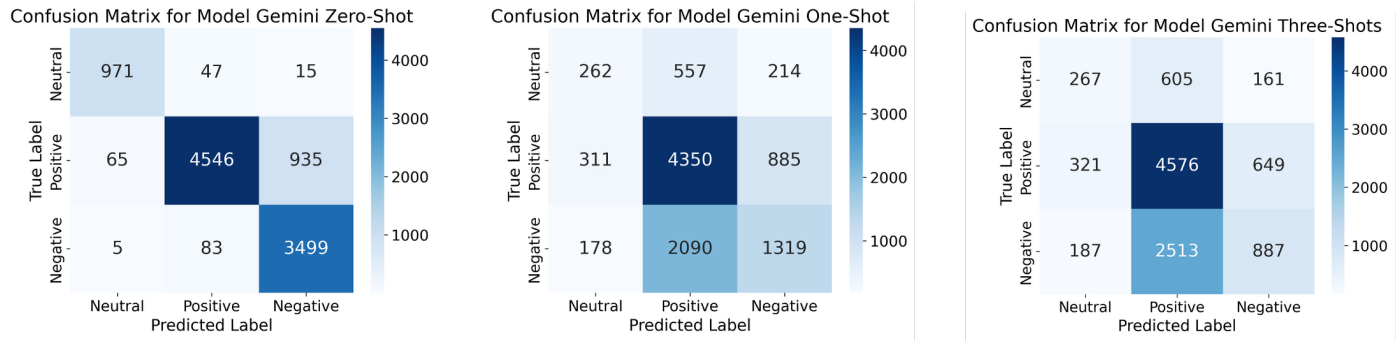
TABLE IV. EXPERIMENT 3 PERFORMANCE METRICS

Model	Persona	Accuracy (%)	Precision	Recall	F1-score
ChatGPT	P1	91.64	0.9208	0.9164	0.9166
	P2	89.41	0.9042	0.8941	0.8943
	P3	**92.84**	**0.9287**	**0.9284**	**0.9282**
	P4	90.66	0.9091	0.9066	0.9068
Gemini	P1	87.13	0.8940	0.8713	0.8719
	P2	85.92	0.8871	0.8592	0.8600
	P3	87.13	**0.8981**	0.8713	0.8718
	P4	**87.18**	0.8730	**0.8718**	**0.8721**
Nuha	P1	**87.66**	**0.8925**	**0.8766**	**0.8771**
	P2	85.72	0.8822	0.8572	0.8579
	P3	85.58	0.8776	0.8558	0.8564
	P4	86.68	0.8681	0.8668	0.8671



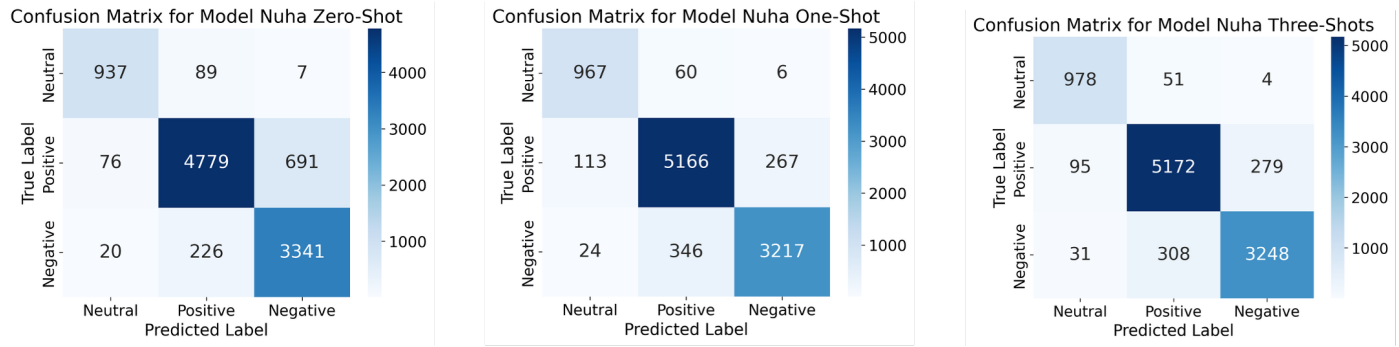
Performance comparison of the four persona-driven prompting strategies across the evaluated models in Experiment 3. The best result for each model is shown in bold.

C. Experiment 3: Persona-Driven Prompts Based on User Roles



The third experiment explores the influence of persona-driven prompt variation (P1–P4) on the performance of three large language models (ChatGPT, Gemini, and Nuha) in sentiment analysis. Each persona represents a distinct style of prompting designed to assess how prompt framing affects classification quality, financial analyst, Saudi stock expert trader, sentiment analysis, and expert in Saudi stock recommendations, respectively. The models were evaluated using accuracy, precision, recall, F1-score, Cohen's Kappa, and supported by detailed confusion matrix analysis to assess class-specific behavior as is shown in Table IV, Fig. 6, and Fig. 7.

ChatGPT demonstrated the highest and most consistent performance across the four evaluated prompts. Its best performance was under P3 (sentiment analysis), where it achieved 92.84% accuracy, 0.9287 precision, 0.9284 recall, and 0.9282 F1-score, with a Cohen's Kappa of 0.8732. The confusion matrix for P3 reveals that ChatGPT correctly classified 5,271 positive, 971 neutral and 3,196 negative instances. Errors were mainly concentrated in misclassifying negative as positive in 385 cases, which is expected in closely aligned sentiment boundaries. Even under its lowest-performing persona, P2 (Saudi stock expert trader), ChatGPT retained 89.41% accuracy, and a solid balance of 0.9042 precision, 0.8941 recall, and 0.8943 F1-score. The P2 confusion matrix shows stronger neutral classification with 987 correct cases but slightly more misclassification of positive and negative examples compared to P3 [Fig. 6(a)]. Under P1 (Financial analyst) and P4 (expert in Saudi stock recommendations), ChatGPT continued to perform robustly, with Cohen's Kappa values of 0.8554 and 0.8380, respectively, and confusion matrices indicating high true positives and effective neutral distinction. These results collectively indicate that ChatGPT is highly responsive to persona framing, with P3 offering the best contextual synergy.



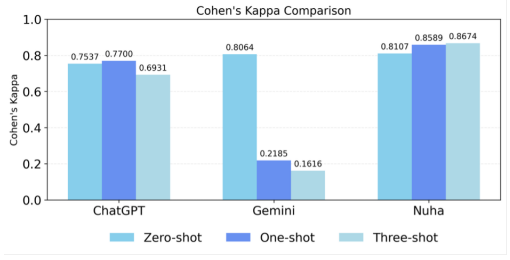
Gemini, while not reaching ChatGPT's peaks, showed strong and consistent performance across personas, with accuracy values ranging from 85.92% to 87.18%. Its most effective performance appeared in P1 (financial analyst) and P3 (sentiment analysis) both with approximately 87.13% accuracy, with

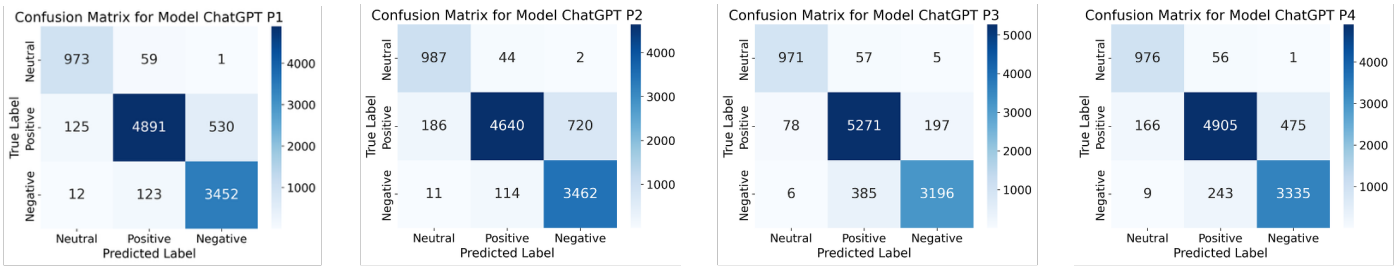
(a) ChatGPT

(b) Gemini

(c) Nuha

Fig. 4. Experiment 2 confusion matrix.





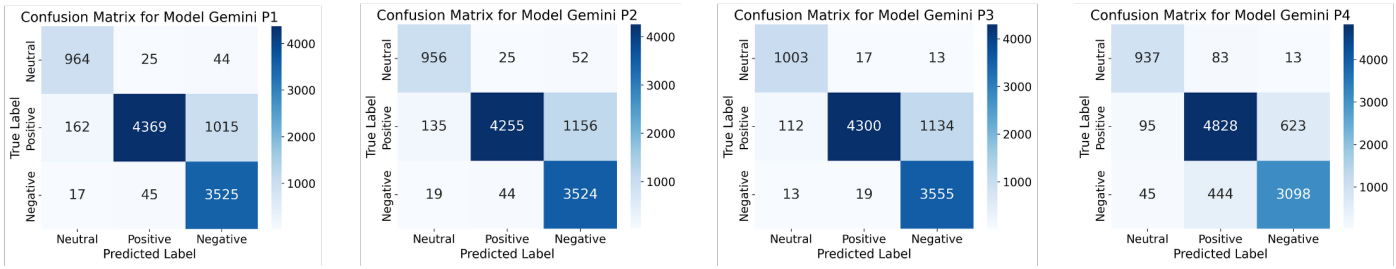


Fig. 5. Experiment 2 Cohen's kappa.

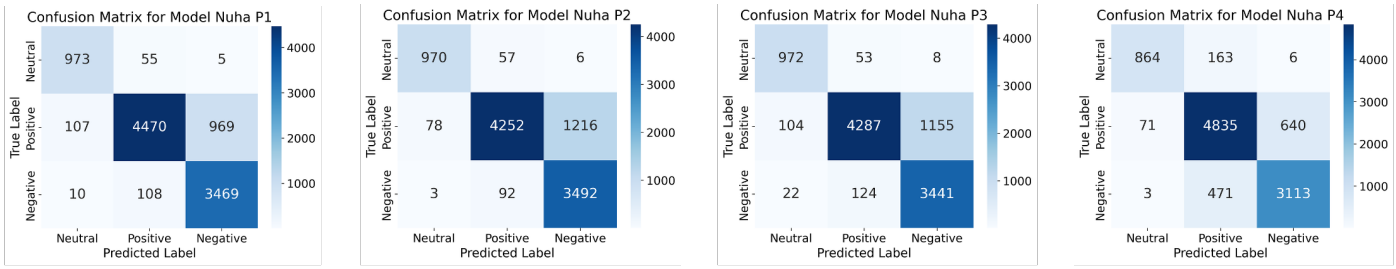
F1-scores of 0.8719 and 0.8718, and Cohen's Kappa values of 0.7824 and 0.7830, respectively. The confusion matrix for P1 indicates solid classification of negative sentiment with 3,525 correct cases and a modest level of misclassification between positive and negative 1,015 false-negatives. Under P3, Gemini improved neutral accuracy with 1,003 correct cases and slightly reduced false positives for positive sentiment [Fig. 6(b)]. P2 (Saudi stock expert trader) showed a drop in performance, with 1,208 false negatives and lower agreement 0.7625 Kappa, indicating sensitivity to specific persona structure. Despite this, Gemini's stability across personas reflects a moderate adaptability, suitable for prompt settings that are consistent and well-defined.



Nuha exhibited the greatest variance across personas, with accuracy ranging from 85.58% with P3 (sentiment analysis) to 87.66% with P1 (financial analyst). Precision, recall, and F1-score followed similar fluctuations. The best performance under P1 produced 0.8925 precision, 0.8766 recall, and 0.8771

(a) ChatGPT

(b) Gemini

(c) Nuha

Fig. 6. Experiment 3 confusion matrix.

F1-score, with a Cohen's Kappa of 0.7896. Nuha's P1 confusion matrix shows strong classification of positive 4,470 correct cases, neutral 973 correct cases and negative 3,469 correct cases examples but a notable number of identifiying 969 positives as negative cases. In P3, performance slightly declined: fewer positive and negative instances were correctly identified, with an increase in 1,155 false-positives cases and misclassified neutrals. P2 (Saudi stock expert trader) and P4 (expert in Saudi stock recommendations) followed a similar trend, with the P4 confusion matrix revealing the highest misclassification of neutral instances with 163 neutral examples classified as positive, which likely impacted overall precision [Fig. 6(c)]. Cohen's Kappa (Fig. 7) values for Nuha range from 0.7554 to 0.7896, which confirm its inconsistent agreement, particularly in neutral sentiment recognition, which may be influenced by prompt nuances embedded in each persona.

From an error analysis perspective, ChatGPT consistently showed the lowest number of high-impact errors—especially in distinguishing positive from negative sentiments—across all personas. Its three-way balance among neutral, positive, and negative classes was evident across confusion matrices, with P3 performing best. Gemini, while reliable in handling positive and negative sentiment, had greater difficulty distinguishing

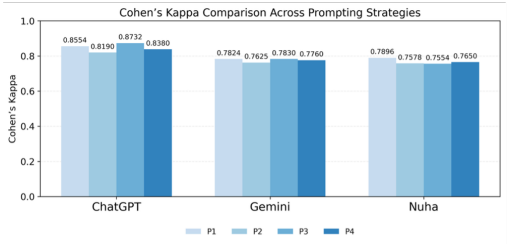


Fig. 7. Experiment 3 Cohen's kappa.

neutral sentiment, particularly under P2 and P4. Nuha struggled most in neutral sentiment detection, frequently confusing neutral with positive, especially in P4, where 163 neutral instances were misclassified as positive, lowering precision and Kappa agreement.

In terms of inter-rater reliability, ChatGPT outperformed both Gemini and Nuha, with Kappa values ranging from 0.8190 to 0.8732, showing strong and consistent agreement with ground truth across all personas. Gemini maintained moderate reliability from 0.7625 to 0.7830, while Nuha's reliability was more affected by personas variation between

0.7554 and 0.7896.

In summary, ChatGPT showed greater adaptability to persona-driven prompting, with the P3 configuration yielding the highest observed performance. Gemini remained stable and moderately effective, while Nuha exhibited a noticeable sensitivity to prompt framing, particularly in handling neutral sentiment. These findings suggest that prompt design—especially persona stylization—can significantly influence model behavior, and that ChatGPT is best suited for stock news. Consequently, persona tuning should be considered a critical component in applied sentiment analysis pipelines, especially when deploying large language models in real-world, user-facing environments, and domain-specific.

V. Discussion

This study investigated the performance of five large language models (ChatGPT, Gemini, Nuha, CAMeLBERT, and AraBERT) across three distinct experimental designs in the context of sentiment classification for the Saudi stock market financial news. Each experiment was developed to examine the models' capabilities from a different perspective: a direct zero-shot prompt (Experiment 1), prompt-based contextual learning using different shots techniques (Experiment 2), and persona-driven prompts based on user roles (Experiment 3). The evaluation utilized standard classification metrics—accuracy, precision, recall, and F1-score—supplemented by confusion matrix and Cohen's Kappa to measure inter-rater agreement beyond chance. Together, these experiments reveal critical insights into each model's behavior under varying prompting conditions.

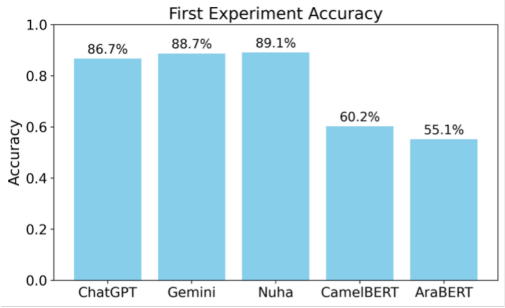

Fig. 8. Experiment 1 accuracy.

In the first experiment, which tested all five models on a standard classification task without prompt variation, Nuha, Gemini, and ChatGPT demonstrated high levels of performance as shown in Fig. 8, achieving accuracies of 89.09%, 88.69%, and 86.70%, respectively. These models also scored highly across precision, recall, and F1-score, suggesting strong overall balance. CAMeLBERT and AraBERT, in contrast, exhibited markedly lower performance. CAMeLBERT recorded an accuracy of 60.21%, and AraBERT dropped further to 55.14%, with corresponding F1-scores of 0.5056 and 0.3989. The significantly lower Kappa values for CAMeLBERT with 0.1526 and AraBERT with 0.0159 indicate poor agreement with ground truth labels, suggesting that these models lack the capacity for nuanced sentiment differentiation, particularly when operating without prompt customization or instruction.

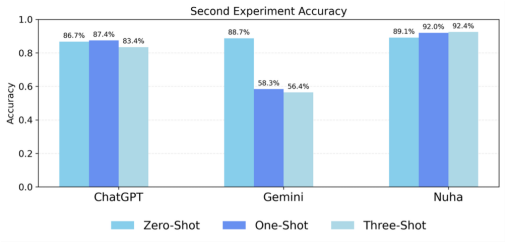

Fig. 9. Experiment 2 accuracy.

Regarding RQ1, the results demonstrate a pronounced performance gap between instruction-tuned large language models and Arabic pretrained language models in the task of Saudi financial sentiment classification. Across all evaluation metrics, ChatGPT, Gemini, and Nuha consistently outperformed AraBERT and CAMeLBERT under zero-shot conditions. This outcome supports the premise that instruction-tuned models benefit from exposure to diverse task formulations during training, enabling them to interpret sentiment analysis as an instruction-following problem rather than a fixed classification task. In contrast, AraBERT and CAMeLBERT—trained primarily through masked language modeling and dependent on downstream fine-tuning—showed limited adaptability when applied directly to financial sentiment classification without domain-specific retraining. Furthermore, the results indicate that the formal and implicitly evaluative nature of Saudi financial headlines, where sentiment is often embedded within regulatory and factual language, imposes high contextual reasoning demands. Such characteristics favor models capable of instruction-level abstraction over those relying predominantly on token-level pattern learning.

While in the second experiment, it introduced prompt-based context through zero-shot, one-shot, and three-shot prompting strategies. CAMeLBERT and AraBERT were not evaluated due to their absence of instruction-tuned architectures. Here, Nuha exhibited the most robust and consistent improvement (Fig. 9), culminating in a three-shot accuracy of 92.45%, and achieving the highest F1-score with 0.9245 and 0.8674 Kappa among all models. ChatGPT showed moderate gains in the one-shot condition with 87.40% accuracy but experienced a decline in the three-shot configuration at 83.43%, possibly due to increased prompt complexity or context saturation. Gemini, in contrast, experienced substantial degradation in performance as prompting complexity increased. While its zero-shot performance remained strong with 88.69% accuracy, its one-shot and three-shot accuracies fell to 58.34% and 56.36%, respectively, accompanied by significant drops in precision, recall, and Kappa scores.

With respect to RQ2, the experiments reveal that the effect of prompting strategies is highly model-dependent. Nuha consistently benefited from richer contextual input, with performance improving from zero-shot to one-shot and three-shot prompting, reflecting effective in-context learning and stable integration of demonstrations. ChatGPT exhibited moderate sensitivity, achieving optimal performance under one-shot prompting while showing a slight decline as prompt complexity increased, suggesting partial context saturation. In contrast, Gemini displayed a marked and unexpected perfor-

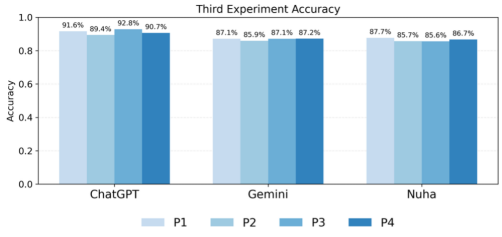

Fig. 10. Experiment 3 Accuracy.

mance degradation when transitioning from zero-shot to few-shot prompting. This behavior can be interpreted in terms of prompt interference, where models optimized for abstraction-based zero-shot generalization may experience misalignment when explicit demonstrations are introduced. These findings indicate that few-shot prompting does not universally enhance performance and may, in some cases, introduce contextual noise rather than beneficial guidance.

To complement the quantitative evidence provided by the confusion matrices, a brief qualitative examination of representative misclassifications was conducted. For instance, the headline "The company records operating losses despite increased revenues" was annotated as neutral in the ground truth but classified as negative by Gemini under few-shot prompting. This misclassification likely reflects the model's tendency to prioritize loss-related lexical cues over balanced financial indicators when demonstrations emphasize adverse outcomes. In contrast, the headline "Suspension of stock trading until further notice" was consistently predicted as negative by all models, despite being labeled as neutral in the dataset due to its regulatory and procedural nature within the Saudi market context. This observation illustrates how models may overinterpret regulatory actions as sentiment-bearing events, underscoring the inherent difficulty of distinguishing procedural disclosures from evaluative sentiment in financial news reporting.

Experiment 3 focused on the impact of stylistic variation in the prompt, using four different personas (P1–P4) to simulate diverse user roles (Fig. 10). The personas where tested against the LLMs and not PLMs due to their absence of instruction-tuned architectures. In this setting, ChatGPT demonstrated the highest adaptability, achieving an average accuracy of 91.14% across all personas, with peak performance under Persona 3 with 92.84% accuracy, 0.9282 F1-score, and 0.8732 Kappa. These results underscore ChatGPT's ability to generalize well across expressive prompt styles and reflect its strength in user-facing applications where language input is highly variable. Gemini maintained relatively stable performance across personas, with accuracies ranging from 85.92% to 87.18%, and minimal variation in agreement scores. While it did not achieve the highest metrics, its consistency suggests a degree of resilience to stylistic change, although it remained weaker than ChatGPT in terms of contextual nuance. Nuha, however, exhibited more volatility. Although it performed strongly under P1, its performance decreased in other conditions, particularly when neutral sentiment was present, suggesting a sensitivity to prompt tone and reduced stylistic generalization.

In response to RQ3, persona-driven prompting was found to exert a meaningful influence on sentiment classification performance, particularly in the case of ChatGPT. Assigning explicit financial roles—such as analyst or trader—provided contextual framing that aligned model reasoning with domain-specific decision perspectives, resulting in higher accuracy and stronger agreement with ground-truth labels. ChatGPT demonstrated the highest robustness across persona variations, suggesting that its instruction-tuning and reinforcement learning mechanisms support effective adaptation to role-based contextual cues. Gemini showed moderate improvement but remained sensitive to persona formulation, while Nuha exhibited greater variability, particularly in neutral sentiment recognition. Collectively, these results indicate that persona-based prompting can enhance the practical relevance of financial sentiment systems; however, its effectiveness depends on the model's ability to internalize and operationalize role-specific context.

The following analysis compares the effects of few-shot and persona-driven prompting on sentiment classification performance, as reported in Table III and IV. As shown in Table III, increasing the number of in-context examples does not lead to uniform performance gains across models. Nuha benefits from few-shot prompting, ChatGPT exhibits only marginal improvement, while Gemini experiences a notable decline. By contrast, Table IV indicates that persona-driven prompting yields more consistent and stable performance gains for instruction-tuned models, particularly ChatGPT, by aligning model reasoning with domain-relevant financial roles. Whereas few-shot prompting primarily affects how models infer task structure from demonstrations, persona-based framing appears to shape interpretation through contextual role expectations. Collectively, these findings suggest that contextual alignment achieved through role-based prompting may be more effective than increasing demonstration quantity alone for Arabic financial sentiment analysis, especially for models optimized for instruction-following behavior.

VI. Conclusion

This study presented a systematic empirical evaluation of Arabic pretrained language models and modern instruction-tuned large language models for financial sentiment analysis in Arabic news headlines within a Saudi market context. By examining model behavior across three experimental conditions—zero-shot classification, demonstration-based prompting, and persona-driven prompting—the study investigated how architectural design, training paradigms, and prompt formulation shape sentiment classification performance in a specialized financial domain.

The findings indicate that instruction-tuned large language models demonstrate greater flexibility and contextual sensitivity than Arabic pretrained language models when applied without task-specific fine-tuning. At the same time, the results reveal that the effectiveness of prompting strategies is strongly model-dependent. While Arabic-aligned models benefited from the inclusion of contextual demonstrations, certain general-purpose models achieved stronger performance under simpler zero-shot configurations and exhibited sensitivity to increased prompt complexity. These outcomes suggest that model scale alone does not ensure robustness, and that performance is critically influenced by the interaction between prompting strategy and training objectives.

Persona-driven prompting emerged as a particularly stable and effective mechanism for contextual alignment in financial sentiment analysis. Framing the task through role-specific perspectives—such as financial analysts or traders—enabled models to better interpret sentiment embedded within factual and regulatory financial language. This approach offers practical relevance for real-world financial applications, where sentiment interpretation is inherently shaped by decision context and stakeholder perspective rather than by generic polarity labels.

In conclusion, this study underscores the importance of aligning model selection and prompt design with domain-specific characteristics when deploying language models for financial text analysis. Rather than promoting a single universally superior model, the findings emphasize that effective Arabic financial sentiment analysis depends on the careful integration of linguistic context, model training paradigms, and prompt engineering. These insights contribute to ongoing scholarly discussions concerning the responsible and effective application of large language models in multilingual and domain-sensitive financial environments.

VII. Limitation and Future Works

This study has several limitations that should be acknowledged, which also highlight directions for future research. First, the dataset is constructed exclusively from Saudi financial news headlines obtained from Argaam, and therefore reflects the linguistic, regulatory, and institutional context of the Saudi market. While this specificity enhances contextual relevance, it restricts the generalizability of the findings to other Arabic financial environments, such as those in the UAE, Egypt, or the wider MENA region, where reporting practices and regulatory discourse may differ. Second, the analysis is limited to short news headlines, which often condense complex financial events into brief statements. Longer textual sources—such as full news articles, corporate reports, and social media content—may exhibit different sentiment dynamics and discourse structures, potentially influencing model performance and behavior. Third, although this study evaluates predictive performance, robustness, and prompting sensitivity, it does not incorporate interpretability techniques or user-centered validation. Such components are essential for understanding how financial practitioners interpret, trust, and operationalize AI-generated sentiment outputs.

Accordingly, future research should extend this work by constructing cross-market Arabic financial datasets, examining richer and more heterogeneous textual sources, and integrating explainability methods alongside human-in-the-loop evaluations. These directions would enable a more comprehensive assessment of both technical effectiveness and practical usability within real-world financial decision-support systems.

***Abstract*—Clinical decision assistance that protects patient privacy is a prominent research issue in federated learning, edge computing, and intensive care analytics. However, typical differential privacy algorithms allocate equal privacy budgets to all clinical parameters regardless of sensitivity and predictive power. This may lower privacy-utility trade-offs. This study develops an adaptive differential privacy mechanism for federated learning that dynamically adjusts per-feature Laplace noise and privacy budgets to improve privacy protection while preserving clinical prediction performance. Adaptive Differential Privacy in Federated Learning (ADP-FL) dynamically adjusts per-feature Laplace noise and privacy budgets based on feature-scored sensitivity considering clinical relevance, statistical impact, and re-identification risk. The method was evaluated on the eICU Collaborative Research Database containing 113,265 ICU records and compared against Uniform Differential Privacy and Time-Adaptive Differential Privacy across different privacy budgets (ε). Experiments conducted on the eICU Collaborative Research Database achieved test accuracies of up to 82.7%. Across the evaluated privacy budgets, Feature-Adaptive Differential Privacy consistently outperformed both Uniform and Time-Adaptive Differential Privacy, achieving an F1-score of 0.6672 at $\varepsilon = 0.5$ while maintaining performance close to the no-DP baseline. These findings demonstrate that sensitivity-aware feature-level privacy budgeting preserves key predictive dimensions while minimizing unnecessary perturbation of less sensitive features, providing a robust foundation for privacy-compliant edge-based clinical decision support systems. The novelty of this study lies in its feature-scored adaptive differential privacy mechanism, which dynamically allocates per-feature privacy budgets and Laplace noise in federated learning for privacy-preserving edge-based clinical decision support.**

Keywords*—Federated learning; differential privacy; clinical decision support; edge computing; ICU data

I. Introduction

Clinical Decision Support Systems (CDSS) are increasingly used to support timely prediction, risk assessment, and treatment-related decision-making in intensive care environments [14]. In ICU settings, large volumes of physiological, laboratory, and treatment data are continuously generated across different hospitals and edge-based clinical systems. Although these data can improve predictive modelling, direct centralization of patient records raises serious concerns related to privacy, governance, and regulatory compliance. Federated Learning (FL) offers a practical solution by enabling multiple clinical sites or edge devices to train a shared model without transferring raw patient data to a central server [15].

Although FL provides this advantage, it does not ensure comprehensive privacy protection independently. There remains the potential for information to be revealed through exchanged model parameters or gradient modifications. This data could subsequently be utilized through membership inference, graph reconstruction, and property inference assaults [16]. In applications within the intensive care unit, these hazards become further pronounced as patient records often encompass highly sensitive clinical attributes. These factors encompass test biomarkers, respiratory state, vital signs, and indicators associated to severity. Therefore, privacy-preserving mechanisms are required to protect shared learning processes while maintaining acceptable clinical prediction performance.

Differential Privacy (DP) is widely used to provide formal privacy protection in machine learning and federated learning systems. However, many existing FL-based healthcare models apply uniform noise using a fixed global privacy budget. This approach treats all features as equally sensitive, although ICU variables do not carry the same level of disclosure risk or clinical importance. Certain metrics, including PaO_2, and creatinine concentrations, bilirubin levels, glucose measurements, dialysis status, and blood urea nitrogen (BUN), might yield more clinically pertinent insights than broad demographic or anonymized administrative variables. Imposing identical noise across all variables may inadvertently disrupt beneficial low-risk predictors, while simultaneously failing to adequately safeguard high-risk clinical characteristics [17].

Recent inquiries have been conducted regarding the adap-

*Corresponding author.

tive and individualized privacy strategies associated with federated learning. Examples of these concepts include adaptive gradient clipping, client-specific privacy budgeting, time-adaptive noise scheduling, and privacy-preserving frameworks for healthcare analytics [18]. Conversely, a considerable portion of these methodologies focuses on imaging datasets, general benchmark datasets, client-specific adaptation, or gradient-level privacy management [20]. Comparatively fewer studies have considered structured ICU tabular data, where each feature may have a different clinical meaning, predictive value, and re-identification risk. This creates a methodological gap for feature-sensitive privacy allocation in federated clinical decision support [19].

Healthcare-based FL studies have also shown that privacy protection often reduces predictive utility, especially when strict privacy budgets are used [21]. This privacy-utility trade-off is particularly important in ICU decision support because false negatives may delay clinical intervention, while excessive noise can weaken model reliability. Existing reviews on differential privacy in medical deep learning further indicate that model performance can decline considerably under strong privacy constraints, especially in heterogeneous and clinically complex datasets [27]. Therefore, there is a need for a privacy mechanism that can apply stronger protection to sensitive ICU features while preserving the predictive contribution of less sensitive but clinically useful variables.

Existing privacy-preserving FL approaches mainly emphasize uniform DP, gradient-level perturbation, time-adaptive noise, client-level adaptation, or medical imaging applications. Limited empirical evidence is available on feature-level adaptive privacy budgeting for structured ICU data. In particular, previous studies have not sufficiently addressed how privacy budgets can be dynamically allocated according to clinical relevance, statistical influence, and re-identification risk of individual ICU variables.

To address this gap, this study proposes Adaptive Differential Privacy in Federated Learning (ADP-FL) for privacy-preserving ICU clinical decision support at the edge. The primary purpose of this research is to create an adaptive differential privacy mechanism. This approach dynamically assigns privacy budgets and Laplace noise per feature based on the sensitivity of the ICU variables. The secondary goal is to assess the possibility of enhancing the privacy-utility trade-off over Uniform Differential Privacy and Time-Adaptive Differential Privacy with this privacy allocation that is sensitive to features. The proposed mechanism assigns per-feature privacy budgets and Laplace noise scales according to feature-scored sensitivity. Highly sensitive clinical variables receive stronger privacy protection through lower privacy budgets and greater perturbation, while less sensitive but predictive variables receive reduced perturbation to preserve model utility. The method is implemented using local client-side noise injection and evaluated on the eICU Collaborative Research Database containing 113,265 ICU records. ADP-FL is compared with Uniform Differential Privacy and Time-Adaptive Differential Privacy across different privacy budgets and gradient clipping norms using accuracy, F1-score, recall, and AUROC. This study contributes a feature-sensitive, lightweight, and governance-compatible privacy mechanism for federated ICU decision support systems [18].

II. Related Work

Federated learning in which privacy is preserved has garnered much research interest, and differential privacy is a key formal privacy guarantee. The novel DP-SGD approach introduced by Abadi, et al. [13] formed the foundation for gradient-level privacy in deep learning. Authors in [12] introduced cross-silo and cross-device FedAvg, which they showed for differential privacy constraints. Mironov [2] proposed Rényi Differential Privacy (RDP) which is a more suitable method for composition accounting for Gaussian processes.

Adaptive and customized privacy methods have been introduced to deal with the problems caused by uniform noise injection. Andrew, et al. [1] suggested adaptive gradient clipping in which the clipping value is learned from statistics collected from the previous iteration of the gradient. Fu, et al. [3] proposed an approach named Adap DP-FL that utilizes RDP accounting and client specific adaptability, with time-decaying noise schedules. In federated health care systems, Wu, et al. [4] examined the privacy-utility trade-offs and noted the need for a calibrated noise in non-IID settings.

Liu, et al. [5] explored the use of federated learning in healthcare, particularly with medical imaging and electronic health record (EHR) data. They pointed out the conflict between regulatory requirements (HIPAA, GDPR) and model efficacy. Saifullah, et al. [6] found that differing levels of privacy risk exist for various clinical traits and so there is a need for a differential level of sensitivity at the feature level. Recent comprehensive reviews have established that differential privacy is the most important privacy method in federated learning healthcare systems, but allocating uniform noise always leads to a decrease in the performance of the model compared to adaptive noise allocation strategies [25].

Adaptive differential privacy has recently been used in therapeutic applications. In order to detect COVID-19 using chest X-ray images, an adaptive differential privacy federated learning architecture was proposed by [7]. This platform is dynamically flexible in limiting privacy based on real-time data sensitivity assessment and shows exceptional performance in a wider range of healthcare settings. Pati, et al. [8] carried out a detailed survey on privacy preservation in federated learning (FL) in healthcare with a focus on gradient-level differential privacy (DP) mechanisms, which are more suitable for rare disease detection than parameter-level mechanisms, but also note that the budgeting distributed to different feature spaces is a significant challenge to address for sensitivity-preserving privacy in FL. A comprehensive review of 74 studies on DP in medical deep learning was performed by [9], which found that enforcing a strict privacy budget ($\varepsilon \sim 1$) often leads to a substantial drop in accuracy, especially in smaller and more diverse datasets. This highlights the need to develop and employ feature-adaptive noise allocation strategies, which are proposed in this study.

Previous work on differential privacy for the local setting [10] and PATE [11] mostly focuses on frequency estimation and semi-supervised contexts, both of which are less applicable to the context of continuous clinical feature regression.

III. Methodology

A. Dataset and Federated Configuration

1) Dataset: De-identified patient data from the United States' critical care units was used in the trials in the eICU Collaborative Research Database [19]. The database was accessed through the official eICU/PhysioNet data access pathway, and only de-identified records were used in accordance with the database usage requirements. There were 113,265 patient records with 21 binaries (intubated, vent, dialysis, medications), categorical (Glasgow Coma Scale: eyes, motor, verbal), and continuous (temperature, respiratory rate, heart rate, mean blood pressure, sodium, hematocrit, creatinine, BUN, glucose) attributes. The target variable was mechanical ventilation (vent) with a moderate class imbalance (73.18% negative cases [82,886 records] and 26.82% positive cases [30,379 records]). The target variable was excluded from the predictor set before model training to avoid label leakage [20].

2) Data preprocessing: The data set was preprocessed to ensure that the clinical variables could be used for model training prior to federated partitioning. Records were dropped if there were no target labels. For continuous variables, missing values were imputed using the median of the corresponding feature, while missing categorical values were imputed using the mode. All of the features were encoded as categorical variables, and the continuous variables were normalized using the Min-Max scaling method. This was done to ensure that all of the features were within a comparable range prior to the injection of differential privacy noise. The same pipeline of preprocessing was applied to the training data and tested on the rest of the test data that was held back. This action was taken to avert the loss of any data.

3) Federated configuration: The complete dataset, including 113,265 entries, was partitioned into training (90,612 entries) and testing (22,653 entries) subsets by stratified sampling. This was executed to preserve class ratios. The training records were distributed evenly across five simulated edge nodes, where each edge device is approximately 18,122 records. This is a rough approximation of a cross-silo healthcare federation with each site being an independent ICU or hospital unit. The weights of aggregation were calculated based on the population size of the local samples,

$$w_i = \frac{n_i}{N}, \tag{1}$$

with each node contributing approximately $w_i \approx 0.20$ under the uniform partitioning setting. The held-out test set was not used during local training or validation and was reserved only for final global model evaluation. Early pausing was implemented if the enhancement in validation accuracy fell below 0.1% for five consecutive communication rounds. The validation set was created from the training data using 20% of training and 80% of testing data [21].

B. Proposed ADP-FL Mechanism

1) Motivation for adaptive privacy in ICU federated settings: The rationale for Adaptive Privacy in ICU Federated Settings is compelling. Numerous privacy concerns arise while utilizing ICU data in federated contexts, which influenced the design of ADP-FL [23]. The attributes of clinical data disclosure vary significantly regarding disclosure risk: laboratory test results (PaO_2, creatinine, bilirubin) directly indicate the severity of organ dysfunction linked to patient identity and prognosis, whereas the lack of patient identity in de-identified demographic characteristics correlates with a substantially reduced likelihood of re-identification under HIPAA Safe Harbor [24]. Applying uniform noise to all characteristics fails to account for this variability, resulting in excessive perturbation of low-risk predictive features and reduced model utility, or insufficient protection of high-risk attributes and increased privacy vulnerability.

Secondly, shared gradient updates in federated learning training may reveal sensitive information if noise levels are insufficient, hence rendering the system vulnerable to membership inference and gradient inversion attacks [22]. Third, the proposed framework targets resource-constrained edge environments; therefore, an efficient privacy mechanism that supports local noise injection without requiring a trusted central curator is required. To address these challenges, ADP-FL dynamically determines the sensitivity of each feature to ensure the privacy of the data is maintained and it is usable across the federation [17].

2) ADP-FL overview: By adding on top of standard federated learning a feature-sensitive differential privacy mechanism, ADP-FL achieves a sensitivity score $S_{i,j} \in [0, 1]$ for every feature and then computes a per-feature privacy budget $\varepsilon_{i,j}$. Smaller $\varepsilon_{i,j}$ values, indicating stronger privacy and greater noise, are assigned to sensitive features, whereas bigger $\varepsilon_{i,j}$ values, indicating weaker perturbation and lower noise, are allocated to less sensitive features. Local Laplace noise is introduced at each edge device, followed by gradient aggregation post feature-specific budget calibration. This noise model is local client-side, meaning it does not necessitate a trusted server and may be utilized with secure aggregation methods. In clinical governance contexts, the Laplace composition of privacy is uncomplicated when employing pure composition [26].

Fig. 1 illustrates the comprehensive process of ADP-FL at an edge node, wherein per-feature sensitivity scores are employed to introduce feature-specific Laplace noise before transmitting the aggregated gradients to the central server. The server employs a strictly passive implementation that solely receives noisy merged gradients, computes weighted FedAvg, and transmits the updated global model [27].

3) Feature sensitivity taxonomy: Feature sensitivity scores were determined by integrating three criteria: 1) clinical relevance features critical to organ dysfunction assessment or treatment decision-making, 2) statistical influence features with high predictive impact on model gradients, and 3) re-identification risk features whose exposure could lead to patient re-identification under HIPAA Safe Harbor constraints [28].

Based on this assessment, features were grouped into three tiers:

- High-sensitivity ($S_j \approx 0.8$–1.0): PaO_2, creatinine, bilirubin, glucose, dialysis status, BUN, albumin, pH, $PaCO_2$. These features encode organ dysfunction

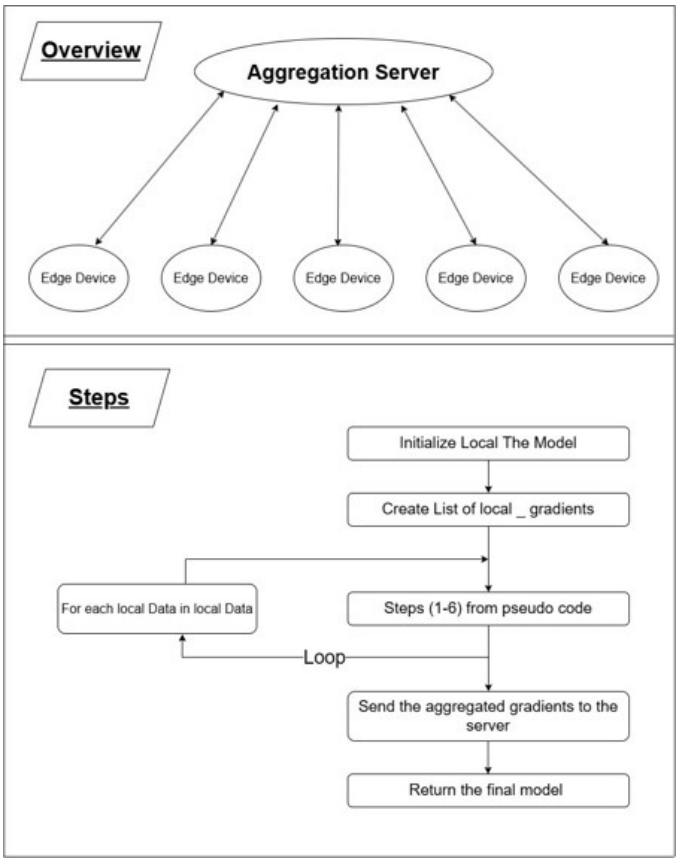

Fig. 1. ADP-FL: Adaptive DP with per-feature sensitivity, gradient clipping, Laplace noise at edge, FedAvg at server.

Algorithm 1: ADP-FL (Client-Side, Laplace Mechanism)

Input: ε_b, `sensitivity_scale`, clipping norm C, `local_data`, sensitivity scores S_j

For each communication round $t = 1, \ldots, T$**:**

1) Initialize `local_gradients` = [].
2) For each feature f_j in `local_data`:
   a) Compute per-feature budget:
   $$\varepsilon_j = \frac{\varepsilon_b}{S_j \times \texttt{sensitivity\_scale}}.$$
   b) Compute gradient:
   $$g_j = \nabla L(\theta_i).$$
   c) Clip:
   $$g_j^{\text{clip}} = \text{clip}(g_j, C).$$
   d) Add noise:
   $$g_j^{\text{dp}} = g_j^{\text{clip}} + \text{Laplace}\left(0, \frac{C}{\varepsilon_j}\right).$$
   e) Append g_j^{dp} to `local_gradients`.
3) Aggregate `local_gradients` and send to server.

Server: $\theta_{\text{global}} = \sum_i w_i \theta_i$, where $w_i = n_i/N$.

Privacy accounting: Total $\leftarrow \varepsilon_t + \varepsilon_t$ (pure-ε composition).

Fig. 2. Adaptive differential privacy in federated learning algorithm.

severity central to SOFA and APACHE scoring constructs and carry the highest clinical disclosure risk.

- Moderate-sensitivity ($S_j \approx 0.4$–0.7): Heart rate, mean blood pressure, respiratory rate, temperature, SpO_2, APACHE APS variables, GCS components (eyes, motor, verbal). These vital signs and derived ICU scores are important but less directly re-identifying.
- Low-sensitivity ($S_j \approx 0.1$–0.3): Age, gender, admission type, anonymized unit stay ID. De-identified demographic attributes under HIPAA Safe Harbor, with residual but lower re-identification risk.

4) Adaptive differential privacy in federated learning: The ADP-FL operation is executed locally at the edge devices during each communication round. The central server is limited to accepting aggregated noisy gradients, utilizing FedAvg, and transmitting the revised global model. No raw patient data, feature values, sensitivity scores, or utility proxies are transmitted to the central server. Fig. 2 illustrates the whole algorithm [29].

The ADP-FL approach executes operations on edge devices rather than on a central aggregation server. Edge devices construct local models, conduct local training, compute gradients, apply gradient clipping, and incorporate adaptive differential privacy noise, subsequently transmitting the noisy aggregated gradients to the server. To meet the strict local-edge threat model, this architecture ensures that patient data and sensitive metadata remain within the local edge device during processing [30].

The number of communication rounds (`NUM_COMM_ROUNDS`) is limited to 100 rounds, and the early stopping is based on the first time the validation accuracy improvement is below 0.1 per cent for five consecutive communication rounds. Aggregation weights w_i are proportional to local sample counts; under the equal distribution adopted here, each of the five nodes contributes $w_i \approx 0.20$.

The adaptive privacy operation can be summarized as follows. For each client i and feature j, a sensitivity score $S_{i,j}$ is first assigned. The privacy budget $\varepsilon_{i,j}$ is then adjusted according to the sensitivity level, where highly sensitive features receive smaller $\varepsilon_{i,j}$ values and therefore stronger Laplace perturbation. After local gradient clipping using clipping norm C, Laplace noise is applied before the noisy update is sent for FedAvg aggregation.

5) Parameter configuration: Table I summarizes the key parameters and their justification [16].

IV. Results and Discussion

A. Privacy-Accuracy Trade-off

Table II displays the test accuracy of the SGD Classifier across several privacy budgets $\varepsilon \in \{0.1, 0.2, 0.3, 0.5, 0.7, 1.0, 1.5, 2.0\}$ and gradient clipping norms $C \in \{1.0, 3.0, 5.0, 10.0\}$, in comparison to a non-private Random Forest Classifier baseline (83.27%). The interval $[1, 10]$ is evaluated using the clipping norm C to mitigate the bias associated with excessive clipping and the introduced noise using recent privacy-budget and clipping-norm practices in differential privacy-based learning. Privacy budget assessment shows that the privacy-budget sweep $\varepsilon \in [0.1, 2.0]$ encompasses the privacy frameworks

TABLE I. ADP-FL PARAMETER VALUES AND JUSTIFICATION

Parameter	Value	Justification
ε_b	1.0	Baseline privacy budget balancing privacy and performance
Sensitivity scale	0.5–2.0	Scales noise to feature sensitivity, higher values apply more noise to sensitive features
Clipping norm C	1.0	Ensures gradient stability in federated updates, limits adversarial exploitation of large gradients
Learning rate η	0.01	Standard SGD step size for tabular clinical data
Mini-batch size	32	Balances computational efficiency and gradient stability
NUM COMM ROUNDS	100	With early stopping when accuracy improvement $< 0.1\%$ for 5 consecutive rounds

TABLE II. SGD CLASSIFIER TEST ACCURACY VS. PRIVACY BUDGET (ε) AND CLIPPING NORM (C)

$\varepsilon \backslash C$	$C = 1.0$	$C = 3.0$	$C = 5.0$
0.1	82.66%	81.81%	82.37%
0.2	82.51%	82.33%	81.76%
0.3	82.34%	81.45%	82.35%
0.5	81.88%	81.82%	82.60%
0.7	81.83%	81.75%	82.51%
1.0	82.47%	82.76%	81.93%
1.5	82.73%	82.55%	81.72%
2.0	81.75%	81.80%	82.62%

of both high-privacy and moderate-privacy regimes typically observed in practical applications [31].

Non-private Random Forest baseline: 83.27%. Noteworthy observations from Table II include the accuracy of the SGD Classifier fluctuating with different epsilon values, influenced by the selected clipping norm, as most clipping norms are sensitive to the noise-utility trade-off in differential privacy. Optimal accuracies are noted when epsilon falls between 0.5 and 1.5. This suggests that moderate privacy budgets establish an appropriate equilibrium between the incorporation of noise and the model's efficacy. Reducing the epsilon value, such as to 0.1, results in a rise in the added noise; nonetheless, the accuracy remains mostly unchanged, suggesting a robustness to differential privacy noise.

Standards for gradient clipping exert the following influence: The execution aligns with a Clipping Norm of 1.0, with a peak accuracy of 82.73 percent when ε is set to 1.5. The clipping norm of 3.0 strikes the optimal balance between privacy and precision, yielding the maximum accuracy of 82.76 percent when ε is configured to 1.0. The clipping thresholds of 5.0 and 10.0 yield a relatively diminished and more erratic accuracy, especially in the context of stringent privacy constraints. This occurs because increased clipping thresholds amplify the noise scaling in relation to C/ε and elevate the variance of the introduced perturbations. Employing diminished clipping norms ($C = 1.0, 3.0$) facilitates the optimization of the equilibrium between privacy safeguards and the reduction of the impact of introduced noise, resulting in diminished volatility across iterations and participants.

Comparison against the baseline: The baseline Random Forest Classifier, which does not use differential privacy, achieves an accuracy of 83.27%. When appropriately calibrated, the SGD Classifier with differential privacy can achieve accuracy comparable to its non-private equivalent (between 82.5% and 82.76%), demonstrating that privacy can be preserved without significant detriment to model efficacy, with a margin of less than one percentage point.

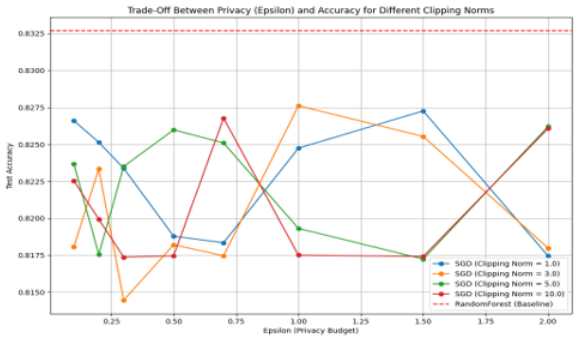

Fig. 3. Privacy-accuracy trade-off: SGDClassifier gradient clipping vs. RandomForest baseline.

Fig. 3 illustrates the trade-off between epsilon of the privacy budget and model accuracy over several gradient clipping norms. The optimal trade-off occurs at an epsilon range of 0.7 to 1.5 and a Clipping Norm of either 1.0 or 3.0, yielding an accuracy of roughly 82.7 while ensuring adequate privacy protection.

B. Dynamic Sensitivity Laplace vs. Baseline

This section compares a dynamic, feature-sensitivity-aware Laplace mechanism (ADP-FL) to a uniform differential privacy baseline spanning privacy budgets $\varepsilon \in \{0.2, 0.5, 1.0, 1.5, 2.0\}$. The model, training process, and evaluation split are constant, with the sole variation being the noise applied to training features after Min-Max scaling, while the test set remains unchanged. Table III presents the Accuracy, Precision, Recall, F1, and AUROC of both techniques at each ε.

Table III reports the controlled comparison between Dynamic (Feature-Adaptive) DP and Uniform DP using the same dataset, train–test split, federated-learning configuration, preprocessing, and evaluation protocol. Only the privacy-noise allocation strategy is changed between the two methods. Several significant tendencies can be discerned from Table III. Under the highest privacy level ($\varepsilon = 0.2$), the uniform strategy achieves superior metrics with an F1 score of 0.6540 and a Recall of 0.6363, compared to the dynamic strategy, which has an F1 score of 0.5114 and a Recall of 0.3754. This is consistent with the tenets of mechanism design: if ε is low, then the dynamic policy will also amplify noise on high-

TABLE III. PERFORMANCE ACROSS ε FOR DYNAMIC (ADAPTIVE) VS. UNIFORM DP

Strategy	i	ε	Accuracy	Precision	Recall	F1	AUROC
Dynamic	1	0.2	0.8076	0.8020	0.3754	0.5114	0.8256
Uniform	2	0.2	0.8194	0.6727	0.6363	0.6540	0.8276
Dynamic	3	0.5	0.8340	0.7343	0.5971	0.6586	0.8223
Uniform	4	0.5	0.8215	0.7063	0.5727	0.6326	0.8202
Dynamic	5	1.0	0.8342	0.7283	0.6093	0.6635	0.8276
Uniform	6	1.0	0.8194	0.7478	0.4933	0.5944	0.8219
Dynamic	7	1.5	0.8347	0.7256	0.6170	0.6669	0.8267
Uniform	8	1.5	0.8226	0.7265	0.5433	0.6217	0.8208
Dynamic	9	2.0	0.8351	0.7147	0.6414	0.6760	0.8269
Uniform	10	2.0	0.8223	0.7170	0.5576	0.6273	0.8280

sensitivity features, generating too much perturbation on the most clinically informative features and thus making it harder to detect minority groups. The AUROC scores are nearly the same (0.83) at $\varepsilon = 0.2$, meaning there has been very little loss of separability, with a decrease in performance primarily due to the balance of false negatives with respect to false positives. Table III reports the controlled comparison between Dynamic (Feature-Adaptive) DP and Uniform DP using the same dataset, train–test split, federated-learning configuration, preprocessing, and evaluation protocol. Only the privacy-noise allocation strategy is changed between the two methods.

As ε attains a moderate value, control over dominance will evidently shift to the dynamic mechanism. At $\varepsilon = 0.5$, ADP-FL exhibits an Accuracy of approximately 0.834 and an F1 score of approximately 0.6586, compared to approximately 0.8215 and approximately 0.6326 for uniform, with Recall similarly superior for dynamic (approximately 0.597 versus approximately 0.573). The improvement is evident at $\varepsilon = 1.0$, with dynamic metrics of Accuracy $= 0.834$ and F1 $= 0.664$, compared to the uniform baseline of 0.819 and 0.594. The Recall disparity is most pronounced at this operational point (0.609 versus 0.493). The trend persists until $\varepsilon = 1.5$ and $\varepsilon = 2.0$, during which the dynamic strategy maintains F1 within the 0.667–0.676 interval.

Fig. 4 illustrates a graph of Accuracy versus ε. The dynamic curve exhibits an ascent between 0.2 and 2.0, surpassing the uniform curve by around one to one-and-a-half percentage points at values of 0.5 and higher. The uniform curve is comparatively level near 0.82, indicating that the classifier utilizes indiscriminate noise to leverage more permissive privacy expenditure.

Fig. 5 illustrates the relationship between F1 and ε for dynamic and uniform noise. The F1 score under the dynamic method exhibits a monotonic improvement, increasing from around 0.511 at $\varepsilon = 0.2$ to approximately 0.676 at $\varepsilon = 2.0$. The uniform strategy is non-monotonic and has a notable minimum at $\varepsilon = 1.0$ to 0.594, just when the dynamic policy attains 0.664. This effect can be elucidated by analyzing Precision and Recall: dynamic Recall with $\varepsilon = 1.0$ is markedly superior (about 0.609 compared to approximately 0.493), but Precision is only somewhat worse (approximately 0.728 compared to approximately 0.748). The dynamic technique effectively reduces false negatives at ε values within the 0.5–2.0 range, albeit with a minor compromise in false positives concerning decision support.

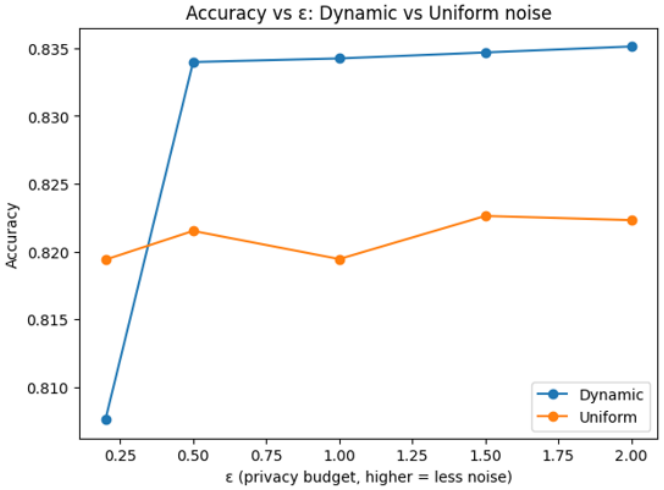

Fig. 4. Accuracy vs. ε for ADP-FL vs. Uniform DP.

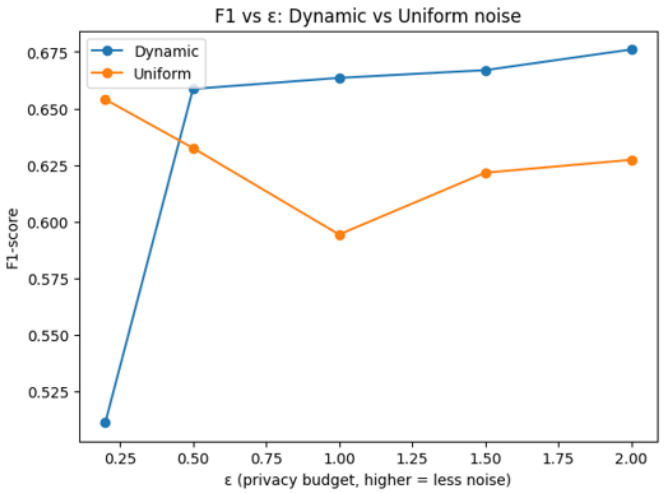

Fig. 5. F1-score vs. ε for dynamic (ADP-FL) vs. uniform DP.

Fig. 6 presents a detailed depiction of the aggregations of principal metrics at the value of $\varepsilon = 1.0$. The dynamic strategy exhibits superior Accuracy (0.834 vs. 0.819), Recall (0.609 vs. 0.493), and F1 score (0.664 vs. 0.594) at this mid-range operating point compared to the uniform baseline, despite a very small decline in Precision, which correlates with a shift

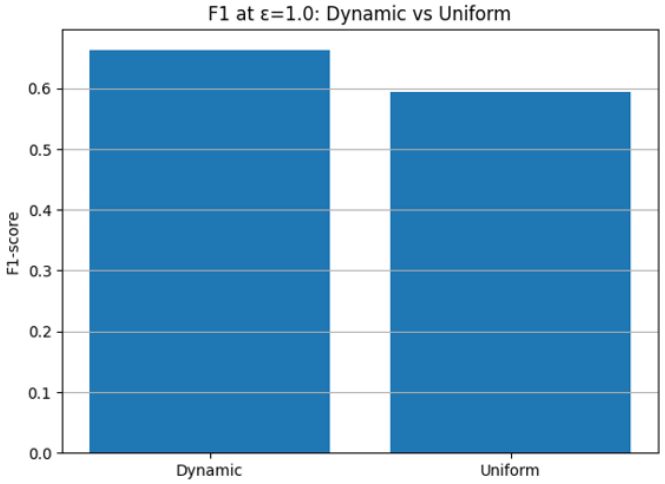

Fig. 6. Performance at $\varepsilon = 1.0$: Dynamic (ADP-FL) vs. uniform DP bar chart of accuracy, precision, recall, F1, and AUROC.

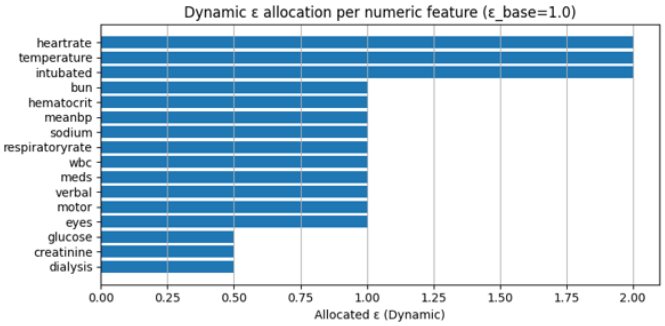

Fig. 7. Dynamic ε allocation per feature at $\varepsilon_b = 1.0$.

in focus towards sensitivity. This is the typical threshold used in safety applications where there are relatively low costs for dealing with false alarms and high costs for missing a positive indication.

Fig. 7 shows the per-feature ε of the dynamic policy for the case $\varepsilon_{\text{base}} = 1.0$, which explains the design rationale of the above results: clinical variables with high sensitivity (like PaO_2, creatinine, glucose) have a lower ε (higher noise); low sensitivity (like age, gender) have a higher ε (lower noise); middle sensitivity clinical variables (like vital signs) get an intermediate ε. This allocation rationale is corroborated by the results in Recall and F1 at moderate ε: the sensitivity-aware noise strategy is better at retaining valuable signals in less sensitive but still valuable features in comparison to a uniform policy.

C. Three-Way Privacy-Utility Comparison

Table IV presents an additional three-way comparison including Time-Adaptive DP; therefore, Table III is used as the primary controlled comparison between Feature-Adaptive DP and Uniform DP. Fig. 8 provide a comprehensive comparison of three differential privacy strategies: Uniform DP, Time-Adaptive DP, and Feature-Adaptive DP (ADP-FL), alongside a No-DP baseline (F1 $= 0.6668$) for privacy budgets $\varepsilon \in$

TABLE IV. F1-SCORE COMPARISON OF UNIFORM, TIME-ADAPTIVE, AND FEATURE-ADAPTIVE DP ACROSS ε. NO-DP BASELINE F1 $= 0.6668$

ε	Uniform DP	Time-Adaptive DP	Feature-Adaptive DP
0.1	0.4009	0.1458	0.4511
0.3	0.3584	0.3062	0.6011
0.5	0.2171	0.4642	0.6672
1.0	0.0724	0.4479	0.5118
2.0	0.4159	0.4919	0.5952

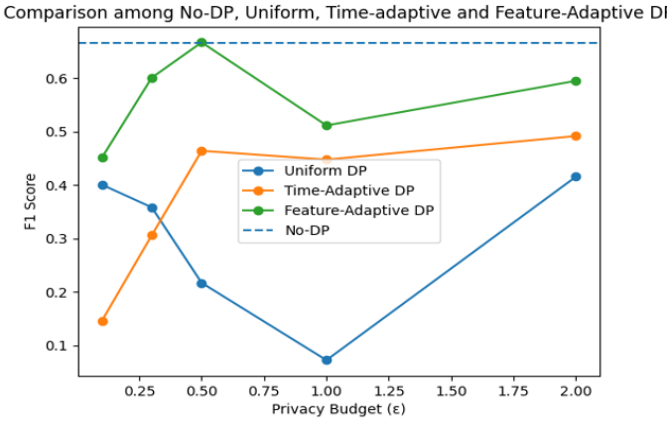

Fig. 8. F1-score comparison of No-DP, uniform DP, time-adaptive DP, and feature-adaptive DP.

$\{0.1, 0.3, 0.5, 1.0, 2.0\}$. Table IV illustrates a clear behavioral divergence among the three techniques. For the value of $\varepsilon = 0.1$, Feature-Adaptive DP achieves the highest F1 score of 0.4511 while Uniform DP comes in at 0.4009 and is much higher than Time-Adaptive DP with a score of 0.1458.

For $\varepsilon = 0.3$, the Feature-Adaptive DP performs significantly better (F1 $= 0.6011$ compared to 0.3584 in Uniform and 0.3062 in Time-Adaptive), showing that, under a moderate privacy budget, adaptive feature-level allocation is indeed much more effective at reducing degradation of minority classes resulting from noise disruption. When $\varepsilon = 0.5$, the score of Feature-Adaptive DP becomes 0.6672, which is nearly the same as the score of No-DP with the baseline score of 0.6668. In contrast, Uniform DP is drastically diminished (F1 $= 0.2171$), whereas TA DP is improved to 0.4642, albeit at a considerably lower level. The significant inadequacy of Uniform DP at $\varepsilon = 1.0$ (F1 $= 0.0724$) demonstrates that homogeneous noise calibration is unstable when it engages with non-uniform feature gradients. At $\varepsilon = 1.0$, Feature-Adaptive DP achieves F1 $= 0.5118$, and at $\varepsilon = 2.0$, all mechanisms converge to the No-DP baseline, Feature-Adaptive DP (0.5952) demonstrates superior performance.

Fig. 8 illustrates these trajectories. The FADP curve is maximized throughout all evaluated budgets, with the exception of the separate $\varepsilon = 0.2$, where uniform noise temporarily outperforms due to the compounding noise effect on high-sensitivity features. Practitioners in regulatory environments necessitating low ε should meticulously observe this crossover at the highest privacy thresholds.

The mechanistic rationale for the superiority of ADP-

FL is that high-sensitivity clinical features receive stronger perturbation, hence preserving the gradient signal that facilitates the memory of minority classes. Uniform differential privacy applies the same amount of noise to each feature, regardless of its predictive or privacy significance, leading to an overemphasis on informational gradients that adversely affect the imbalanced ventilation prediction task examined in this instance.

D. Literature-Level Comparison with Recent Published Studies

To meet the need of wider validation with the recent literature, Table V presents a comparison between the proposed ADP-FL model and the recently published federated learning studies for privacy, in the range of 2020–2026. The comparison reveals that recent work on healthcare FL has been successful; most of the studies concentrated on imaging data, privacy in blockchain, multimodal fusion, or general healthcare analytics, but did not include FL adaptive privacy budgeting for structured data in an ICU decision support system. The comparison indicates that the proposed ADP-FL model is not intended to simply maximize classification accuracy across different healthcare datasets; instead, its main contribution is to preserve ICU prediction performance while providing feature-sensitive privacy protection. Unlike blockchain-based and multimodal FL approaches, ADP-FL directly addresses the unequal privacy sensitivity of ICU variables by assigning different privacy budgets to different clinical features. This makes the proposed model more suitable for edge-based ICU clinical decision support where laboratory biomarkers, vital signs, and demographic attributes do not carry equal disclosure risk. Therefore, the new information offered by this study is not only improved internal performance over DP baselines, but also evidence that feature-level privacy allocation can preserve ICU prediction utility more effectively than uniform privacy treatment when clinical variables have unequal sensitivity and predictive importance. The performance values of the comparator studies in Table V are taken directly from their respective publications. Since these studies use different datasets, models, prediction tasks, and privacy settings, the comparison is literature-level rather than a direct head-to-head experimental benchmark.

The reported performance values should not be interpreted as a direct ranking of the methods because the studies use different datasets, prediction tasks, models, and privacy configurations. The contribution of ADP-FL is instead demonstrated through its controlled comparison with the privacy baselines under identical experimental conditions, where feature-sensitive privacy allocation preserves predictive utility while providing privacy protection for structured ICU data.

E. Operational Interpretation of Privacy-Utility Findings

For operational deployments, all evidence in favor of ADP-FL is within the range of $\varepsilon \in [0.5, 2.0]$. During this period, accuracy increases by approximately one percentage point or more when compared to uniform noise, while F1 also improves due to higher recall while maintaining a similar AUROC value. The operating margin is comparable with the typical ε of the order of few digits reported in current clinical machine learning pipelines. If the policy requires strong privacy ($\varepsilon = 0.1$–0.2), then the dynamic mechanism may over-perturb high-sensitivity features, which can reduce minority-class detection. In such cases, practitioners are advised to carefully consider the clinical miss-rate tolerance and privacy considerations.

The fact that privacy is pure-ε Laplace allows for simpler privacy accounting for clinical governance and regulatory reporting than (ε, δ)-DP techniques, and ADP-FL is well suited for installations regulated by HIPAA or GDPR, where audit trails require transparency in privacy accounting. The steady improvement of Recall with ADP-FL is important for use in the context of healthcare decision support in ICUs. The clinical cost of missing a mechanical ventilation warning is higher than the cost of a false alarm, and the dynamic control mechanism that keeps recall close to the No-DP baseline and at the same time ensures formal privacy is directly related to this cost imbalance.

F. Comparison with Alternative DP Approaches

When a trusted central aggregator or safe compute environment exists, Gaussian-noise DP-SGD may prove to be better suited to deeper models by altering the gradient-level noise based on the dynamic of the perturbation, instead of the scale of the features themselves. Standard smoothness assumptions give rise to an interesting pure-ε central differential privacy analog to objective perturbation in the convex learner case, e.g., logistic regression. Both strategies, however, presuppose a more reliable model than the local-edge danger model presented here, wherein data must be perturbed in situ prior to any uplink transmission.

Within the local-DP framework, the dynamic allocation of Laplace noise, which is responsive to variations in sensitivity, performed as the most suitable option in this study. Recent advancements in differential privacy for medical deep learning [27] suggest that other forms of DP, including generative modeling-based DP and hybrid federated designs, are forthcoming; nevertheless, these approaches have predominantly been evaluated using imaging data rather than structured tabular clinical data. The distinction between local Laplace and central Gaussian DP-SGD in terms of trust model and injection locus is not one of absolute superiority, but rather pertains to the trust model and the acceptability of central training: ADP-FL should be utilized when a trusted curator is not permitted, while Gaussian DP-SGD is likely to yield greater utility when central training is permissible.

For practical deployment feasibility assessment, the computational and communication features of ADP-FL were compared to FL without DP, Uniform DP-FL, and Time-Adaptive DP-FL. Additional overhead of ADP-FL is small as it does feature sensitivity scoring once before training and adds Laplace noise locally for each round of communication. Furthermore, the communication cost is similar to that of standard federated learning, where only updated noisy models are sent, and the original data, feature values, sensitivity scores, and feature-specific privacy budgets are not sent from the edge nodes.

G. Computational Overhead, Scalability, and Generalizability

To evaluate practical deployment feasibility, the computational and communication characteristics of ADP-FL were

TABLE V. LITERATURE-LEVEL COMPARISON WITH RECENT PRIVACY-PRESERVING FL APPROACHES

Reference	Application/Dataset	Privacy Approach	Reported Performance	Difference from Present Study
Proposed ADP-FL	eICU; 113,265 ICU records	Feature-adaptive DP with per-feature Laplace noise	Accuracy 82.76%; F1 = 0.6672 at $\varepsilon = 0.5$	Feature-level privacy allocation for structured ICU data.
Fu et al. [3]	MNIST and Fashion-MNIST	Adaptive clipping and time-decaying Gaussian noise with RDP	94.15% accuracy on MNIST and 79.56% on Fashion-MNIST at $\varepsilon = 2$	Adapts privacy across clients and rounds rather than individual clinical features.
Wu et al. [4]	CIFAR-10	Adaptive federated learning with differential privacy	81.25% accuracy (IID) and 79.05% (non-IID)	Uses adaptive DP for image classification rather than feature-sensitive ICU data.
Ahmed et al. [7]	COVID-19 chest X-ray images	Adaptive differential privacy federated learning	91.2% accuracy after 80 epochs with early stopping	Evaluated on medical images rather than structured ICU records.

compared with FL without DP, Uniform DP-FL, and Time-Adaptive DP-FL. Since ADP-FL performs feature-sensitivity scoring once before training and applies per-feature Laplace noise locally during each communication round, its additional overhead remains small. Moreover, the communication cost is comparable to standard federated learning because only noisy model updates are transmitted, while raw data, feature values, sensitivity scores, and feature-specific privacy budgets remain within the local edge nodes.

Table VI shows that for $\varepsilon = 0.5$, ADP-FL has the highest F1-score and other federated approaches have similar communication costs. The minor extra training cost is compensated by the better privacy-utility trade-off, as the proposed approach maintains performance close to the no-DP baseline. Additional multi-institutional and heterogeneous ICU datasets are needed, however, for further validation to prove the robustness and generalizability of ADP-FL in other real-world healthcare settings.

TABLE VI. PRACTICAL OVERHEAD AND UTILITY COMPARISON OF FEDERATED PRIVACY STRATEGIES

Method	Clients	Rounds	Relative Training Overhead	Relative Communication Cost	F1 at $\varepsilon = 0.5$
FL without DP	5	100	1.00×	1.00×	0.6668
Uniform DP-FL	5	100	1.01×	1.00×	0.2171
Time-Adaptive DP-FL	5	100	1.03×	1.00×	0.4642
Proposed ADP-FL	5	100	1.02×	1.00×	0.6672

V. CONCLUSION

This research presented and evaluated an adaptive differential privacy approach (ADP-FL) for federated learning in edge-based clinical decision assistance within the ICU. ADP-FL exhibits a markedly superior privacy-utility trade-off compared to Uniform DP and Time-Adaptive DP by dynamically allocating per-feature Laplace noise in accordance with clinically motivated sensitivity scores over the majority of privacy budgets. The novelty of this work is that it allocates feature-level privacy budgets based on clinical relevance, statistical influence, and re-identification risk, instead of having a uniform budget for all the ICU variables. ADP-FL demonstrates strong performance on the eICU database, achieving a test accuracy of 82.7%, closely aligning with the non-private baseline of 83.27%, and an F1-score of 0.6672 at $\varepsilon = 0.5$, nearly indistinguishable from the No-DP performance. These results demonstrate that the distribution of noise among the features is as significant as the quantity of noise applied. ADP-FL provides a governance-light, operational privacy-preserving edge Clinical Decision Support System (CDSS) implementation: pure-ε composition is audit-transparent, local noise injection requires no curator, and secure aggregation limits server involvement. The results showed that feature-sensitive privacy allocation is a better approach than uniform noise injection for ICU-based edge deployments, especially when clinical variables have varying disclosure risk and predictive value. The mechanism will grow in three ways in the future: 1) testing more complex classifiers while keeping the same privacy accounting; 2) creating or scheduling sensitivity weights instead of using fixed weights; and 3) combining privacy-budget accounting with edge resource limitations (latency, energy) to allow for a larger adaptive scheduling framework, which is at the heart of ADP-FL's privacy feature. Furthermore, to ensure the generalizability of the findings, further investigation is necessary to evaluate ADP-FL on more multi-institutional critical care unit datasets and across a broader spectrum of non-IID federated contexts. Future research may investigate if metaheuristic optimization methods like genetic algorithms and ant colony optimization can assist sensitivity weight scheduling.

Vel Tech Rangarajan Dr. Sagunthala R&D Institute of Science and Technology, Avadi, Chennai 600062, Tamil Nadu, India

***Abstract*—Reliable Alzheimer's disease (AD) magnetic resonance imaging (MRI) classification requires evaluation beyond accuracy alone. This study investigates a four-class image-level framework based on ImageNet-pretrained ResNet-18 using 6,400 public MRI images labelled Non-Demented, Very Mild Demented, Mild Demented, and Moderate Demented. Original images were assigned to seventy percent training, fifteen percent validation, and fifteen percent test partitions before augmentation. The selected no-CLAHE pipeline used training-only transformations, 128 by 128 pseudo-RGB inputs, channel normalization with mean and standard deviation of 0.5, a 512 to 256 to 4 classifier, class-weighted cross-entropy with label smoothing, AdamW optimization, and five fixed seeds. Mean accuracy was 98.38 percent with a standard deviation of 0.38 percent, balanced accuracy was 98.86 percent with a standard deviation of 0.40 percent, macro F1-score was 90.73 percent with a standard deviation of 1.79 percent, and macro-AUC was 0.9993 with a standard deviation of 0.0009. For seed 42, validation-fitted temperature scaling reduced negative log-likelihood, Brier score, and expected calibration error without changing predicted labels. The model contains 11.31 million trainable parameters and achieved 3.08 ms batch-1 inference on a Tesla T4. Grad-CAM supported qualitative inspection. The results establish a reproducible, confidence-aware, perturbation-evaluated, and resource-efficient image-level framework within the stated public-dataset protocol.**

I. Introduction

Alzheimer's disease (AD) is a major cause of dementia, and structural magnetic resonance imaging (MRI) is widely used to investigate disease-related brain changes. Deep learning has been increasingly applied to medical-image representation learning and neuroimaging classification [1]–[3]. In healthcare analytics, however, a reported performance value is meaningful only when the data unit, split protocol, class prevalence, preprocessing sequence, and separation between validation and test data are clearly described. These considerations are especially important for public image collections in which subject identifiers and acquisition metadata may be unavailable [3], [4].

Residual networks use skip connections to facilitate optimization of convolutional models [5]. An ImageNet-pretrained ResNet-18 can be adapted to pseudo-RGB MRI inputs through transfer learning [6], [7]. In imbalanced medical-image collections, training-only augmentation, class-aware loss functions, and macro-averaged evaluation may provide more useful information than accuracy alone [8], [9].

Contrast-limited adaptive histogram equalization (CLAHE) was considered as a candidate local-contrast transformation because adaptive histogram equalization improves local contrast and CLAHE limits excessive local histogram amplification [10], [11]. This rationale does not imply that CLAHE must improve an AD-MRI classifier. Contemporary MRI-based AD studies use heterogeneous image representations, architectures, and validation designs [12]–[17]; preprocessing choices should therefore be evaluated on the target collection rather than assuming that they are beneficial *a priori*.

This work evaluates a reliability-oriented and resource-efficient ResNet-18 framework for the public labels Non-Demented, Very Mild Demented, Mild Demented, and Moderate Demented. In this study, "reliability-oriented" refers to the combined use of five-seed reproducibility, probability calibration, selective prediction, controlled perturbation testing, qualitative model inspection, and computational profiling as complementary technical checks within the evaluated protocol. The selected configuration preserves the resized grayscale intensity structure and uses online training augmentation. The study makes six contributions:

- It documents a fixed stratified image-level 70/15/15 partition of 6,400 original images before stochastic transformation and reports five-seed stability.
- It addresses substantial class imbalance through class-weighted optimization and class-sensitive held-out metrics, with explicit reporting of the nine-image Moderate Demented test subset.
- It reports a transparent configuration-level comparison between no CLAHE with online augmentation and CLAHE without augmentation, without claiming isolated causal effects.
- It applies Grad-CAM to a representative 0.5/0.5 normalization checkpoint for qualitative model inspection while avoiding anatomical or clinical localization claims.
- It evaluates validation-fitted temperature scaling and confidence-ranked selective prediction to characterize probability reliability and risk–coverage behaviour.
- It quantifies sensitivity to controlled image perturbations and directly measures parameters, multiply–accumulate operations, latency, throughput, checkpoint size, and peak inference memory.

II. Related Work and Motivation

A. Deep Learning for AD MRI Classification

MRI-based AD classification has been investigated using 2D and 3D convolutional networks, transfer-learning methods, multi-slice systems, attention mechanisms, and transformer-based models [12]–[17]. Direct numerical comparison across these studies is difficult because cohorts, image units, imaging protocols, label definitions, class prevalences, and validation regimes vary. A model tested on independently partitioned participants or complete volumes is not directly comparable with a model tested on individual images from a public folder structure.

Wen *et al.* emphasized the importance of carefully defined validation protocols for reproducible MRI-classification studies [3]. Ebrahimighahnavieh *et al.* similarly highlighted the value of clearly specified preprocessing and evaluation procedures in neuroimaging deep learning [4]. Accordingly, this study reports reproducible image-level experimentation and retains the public dataset labels as supplied, while keeping the interpretation aligned with the evaluated protocol.

B. Online Augmentation and Class-Sensitive Evaluation

Data augmentation introduces training-time variation without altering the held-out test set. Geometric and photometric perturbations may reduce overfitting, but they should remain plausible for the target task and must not be applied before a split intended to represent unseen data [8]. Here, horizontal flips, rotations limited to $\pm 10^{\circ}$, and modest brightness–contrast jitter are applied only to training images.

Class imbalance affects both learning and evaluation. Moderate Demented comprises only 64 of 6,400 images. A high overall accuracy can therefore coexist with class-dependent variation in precision and F1-score. Class-weighted loss and macro-averaged reporting provide complementary information for this imbalanced setting [9]. ROC curves can remain visually favorable when prevalence is low; precision–recall curves and class-specific precision are consequently reported together with macro-AUC [18], [19].

C. Rationale for CLAHE Screening

CLAHE was evaluated as a candidate preprocessing operation, not as a presumed source of performance gain. It locally redistributes grayscale contrast while restricting the over-amplification associated with standard adaptive histogram equalization [10], [11]. In structural MRI, local intensity variation may influence anatomical representation, while enhancement may also modify intensity relationships learned by a convolutional model. CLAHE was therefore screened empirically during pipeline selection. The final selected configuration retained the resized grayscale representation without CLAHE.

The comparison documents the practical configuration-selection decision. Because CLAHE use and online augmentation changed jointly, the observed difference is reported as a pipeline-level comparison rather than attributed to either component in isolation.

D. Calibration, Selective Prediction, and Robustness

Classification accuracy and confidence calibration describe complementary properties of predictive performance. Temperature scaling provides a simple post-hoc calibration method in which a single validation-fitted scalar rescales logits without changing the model weights or predicted class ordering [26]. Selective prediction complements calibration by examining the trade-off between retained coverage and prediction risk when low-confidence cases are withheld [27]. Robustness to common image corruptions is also distinct from clean-set discrimination, and controlled perturbation tests can reveal sensitivity to noise, blur, brightness, contrast, and rotation [28]. In this study, these analyses are applied to the unchanged representative seed-42 checkpoint and are interpreted as complementary technical reliability checks within the evaluated dataset and protocol.

III. Materials and Methods

A. Dataset and Study Scope

The MRI image collection was obtained from Mendeley Data [20]. It contained 6,400 images in four labelled folders: Non-Demented (3,200), Very Mild Demented (2,240), Mild Demented (896), and Moderate Demented (64). The dataset is a public image-classification collection, and the present study therefore reports its results using the supplied image-level organization. Thus, the experimental unit in this study is an image, and all reported performance values are interpreted at the image level.

No new human participants were recruited, no intervention was performed, and no identifiable clinical records were accessed. The directory terminology is retained exactly from the public collection; in particular, Moderate Demented is treated as a dataset class label rather than as a newly proposed clinical staging system. Table I summarizes the class composition and fixed image-level partition, while Fig. 1 shows the corresponding class-support profile.

B. Split Integrity and Evaluation Workflow

Original image records were assigned to a fixed stratified 70/15/15 split: 4,480 training images, 960 validation images, and 960 test images. The same saved split manifest was reused for every condition and seed. No stochastic transformation was applied to validation or test images. This design prevents a newly generated transformation of an image from entering a different partition during the evaluated training process.

Fig. 2 summarizes the workflow. The held-out test set remains fixed while training is repeated with seeds 42, 52, 62, 72, and 82. Variation across seeds therefore represents training stochasticity under one shared image-level partition and is reported specifically as a measure of training reproducibility.

C. Image Representation and Training Transformations

Each image was converted to grayscale, resized to 128×128 pixels using bilinear interpolation, and replicated across three channels to form a pseudo-RGB input. The selected configuration retained the resized grayscale intensities and applied channel-wise normalization with mean and standard deviation equal to 0.5:

TABLE I. DATASET COMPOSITION AND FIXED IMAGE-LEVEL PARTITION. THE SPLIT WAS CREATED BEFORE ONLINE AUGMENTATION

Class	Total	Training	Validation	Test	Test support (%)
Non-Demented	3,200	2,240	480	480	50.00
Very Mild Demented	2,240	1,568	336	336	35.00
Mild Demented	896	627	134	135	14.06
Moderate Demented	64	45	10	9	0.94
Total	6,400	4,480	960	960	100.00

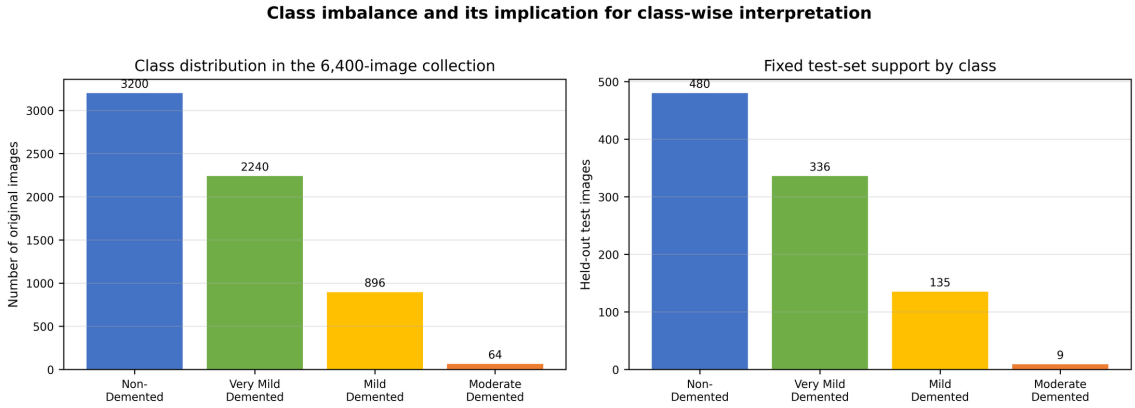

Fig. 1. Class prevalence in the public collection and fixed held-out test support. The Moderate Demented support is shown explicitly to contextualize precision, F1-score, and class-level performance differences.

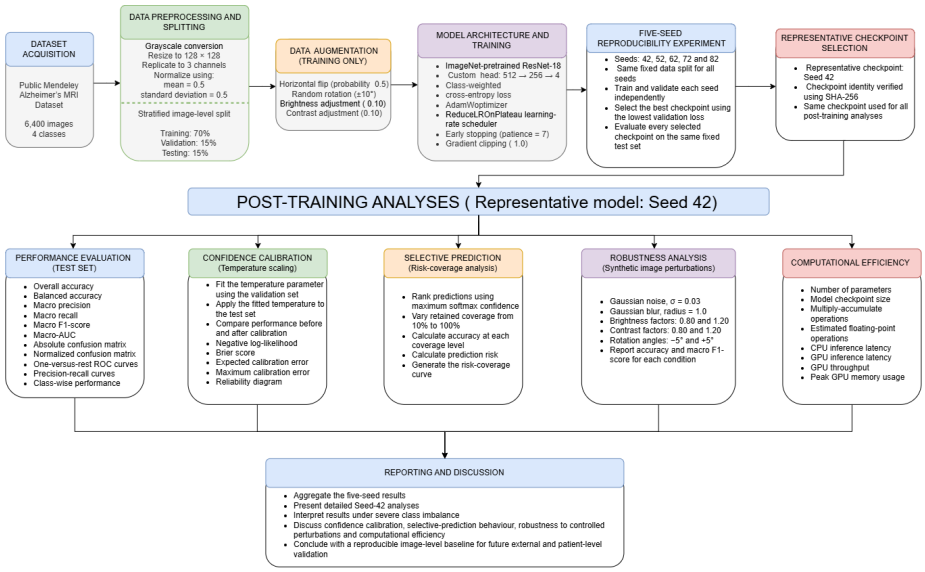

Fig. 2. Reproducible image-level evaluation workflow. Original files are split before training transformations; validation loss selects the checkpoint, and the unchanged held-out test partition is evaluated across five fixed seeds.

$$\widetilde{x}_c = \frac{x_c - 0.5}{0.5}, \qquad c \in \{1, 2, 3\}. \tag{1}$$

Only training images received random horizontal flipping with probability 0.5, random rotation in $[-10°, 10°]$, and brightness–contrast perturbation with magnitude 0.10. These transformations were re-sampled online and never stored as offline copies. Fig. 3 shows the partition composition, while Fig. 4 illustrates the candidate CLAHE operation.

D. Model Architecture, Optimization, and Selection

The backbone was ImageNet-pretrained ResNet-18 [5]. ResNet-18 was selected because its compact residual architecture provides a practical balance between representational capacity, transfer-learning support, and computational cost for a lightweight image-level framework. Its final layer was replaced by a task-specific head comprising a 512-to-256 fully connected layer, batch normalization [21], ReLU, dropout with rate 0.30 [22], and a 256-to-4 output layer. The model contains 11,309,380 trainable parameters. Table II summarizes

Fig. 3. Fixed train, validation, and test composition by class. The partition was created before online augmentation.

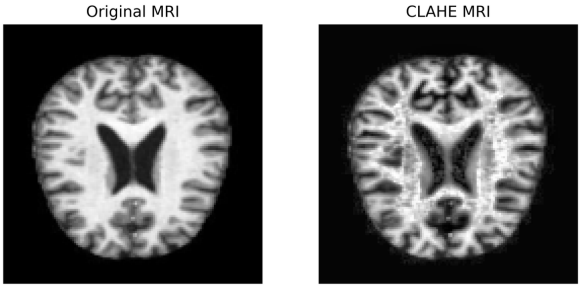

Fig. 4. Illustrative original and CLAHE-transformed grayscale MRI image. CLAHE was screened as a literature-motivated local-contrast candidate and was not retained in the final selected configuration.

the selected ResNet-18 training configuration.

TABLE II. SELECTED RESNET-18 TRAINING CONFIGURATION

Item	Setting
Input	$3 \times 128 \times 128$ pseudo-RGB image
Backbone	ImageNet-pretrained ResNet-18
Classifier head	$512 \to 256 \to 4$; batch normalization, ReLU, dropout 0.30
Trainable parameters	11,309,380
Loss	Class-weighted cross-entropy; label smoothing 0.05
Optimizer	AdamW [23]
Initial learning rate	10^{-4}
Weight decay	10^{-4}
Scheduler	ReduceLROnPlateau; factor 0.5, patience 2
Batch size	16
Epoch limit	25
Model selection	Lowest validation-loss checkpoint
Early stopping	Patience 7
Seeds	42, 52, 62, 72, 82

The training loss used class weights inversely proportional to observed training support:

$$w_k = \frac{N}{K n_k}, \tag{2}$$

where, N is the number of training images, $K = 4$ is the number of classes, and n_k is the training support of class k. Weighted cross-entropy was combined with label smoothing of 0.05 [24]. AdamW used initial learning rate 10^{-4} and weight decay 10^{-4} [23]. A ReduceLROnPlateau scheduler halved the learning rate after two non-improving validation-loss epochs. Gradient clipping at 1.0 and early stopping with patience 7 were used. The checkpoint with the lowest validation loss was restored before test inference.

E. Evaluation Measures and Statistical Reporting

For each seed, accuracy, balanced accuracy, macro precision, macro recall, macro F1-score, macro one-versus-rest AUC, and per-class precision, sensitivity, specificity, and F1-score were computed on the fixed test partition. In the multi-class setting, balanced accuracy is the average class recall:

$$\text{Balanced Accuracy} = \frac{1}{K}\sum_{k=1}^{K}\frac{TP_k}{TP_k + FN_k}. \tag{3}$$

The macro F1-score is the unweighted average of class-specific F1-scores:

$$F1_{\text{macro}} = \frac{1}{K}\sum_{k=1}^{K}\frac{2P_k R_k}{P_k + R_k}. \tag{4}$$

Metrics are reported as mean $\pm$ standard deviation across five seeds. This summarizes variability due to initialization, data-loader order, and stochastic augmentation under the same split. Accordingly, the five-seed summary is interpreted as training reproducibility under the fixed image-level protocol rather than as a population-level estimate.

F. Configuration-Level Screening

CLAHE was evaluated as a candidate local-contrast operation, whereas online augmentation introduced limited training-time variation. The final no-CLAHE configuration with online augmentation was compared with a CLAHE-based configuration without online augmentation. Both conditions shared the fixed split, ResNet-18 architecture, 0.5/0.5 normalization, class-weighted loss, optimizer, scheduler, batch size, seed set, and checkpoint policy. Since contrast enhancement and augmentation changed jointly, this screening comparison identifies the stronger evaluated pipeline and is interpreted as a configuration-level comparison without assigning the observed difference to either component in isolation.

G. Explainability Analysis Using Grad-CAM

Gradient-weighted class activation mapping (Grad-CAM) [25] was applied to the final convolutional layer of the last ResNet-18 residual block (`layer4[-1].conv2`) to provide qualitative insight into the spatial evidence associated with model predictions. The analysis used the representative seed-42 checkpoint trained with no CLAHE, training-only online augmentation, and the 0.5/0.5 channel normalization defined in Eq. (1). For each class, one correctly classified held-out test image with confidence closest to the class-specific median among correct predictions was selected to reduce reliance on only the most confident examples. Gradients were calculated

with respect to the predicted class, and each activation map was rectified, normalized to the interval $[0, 1]$, resized to the input resolution, and overlaid on the corresponding grayscale MRI image. These maps are qualitative explanations of model attention and are not interpreted as anatomical, pathological, or clinical localization. The visualizations preserve the orientation supplied by the public image collection; no additional anatomical orientation markers or slice-index metadata are introduced.

H. Confidence Calibration and Selective Prediction

The reliability analysis used the representative seed-42 checkpoint with the 0.5/0.5 channel normalization defined in Eq. (1). A single temperature parameter $T > 0$ was fitted by minimizing cross-entropy on the fixed validation partition only [26]. Test probabilities were then calculated as:

$$p(y = k \mid x) = \frac{\exp(z_k/T)}{\sum_{j=1}^{K} \exp(z_j/T)}, \tag{5}$$

where, z_k denotes the logit for class k. Calibration was evaluated on the unchanged test partition using negative log-likelihood (NLL), multiclass Brier score, expected calibration error (ECE), and maximum calibration error (MCE). ECE and MCE used 15 equal-width confidence bins. Because scalar temperature scaling is monotonic in the logits, it changes probability sharpness but not the predicted class labels.

Selective prediction was evaluated by ranking test predictions according to maximum softmax confidence and retaining progressively larger coverage fractions from 10% to 100% [27]. Selective risk was defined as one minus accuracy among retained predictions. Macro F1-score was recorded but was not emphasized at very low coverage because some classes may be absent from the retained subset.

I. Robustness Stress-Test Protocol

The unchanged seed-42 checkpoint was evaluated under deterministic synthetic perturbations applied only at test time. The conditions were Gaussian noise with standard deviation 0.03, Gaussian blur with radius 1.0, brightness factors of 0.80 and 1.20, contrast factors of 0.80 and 1.20, and rotations of -5° and $+5^\circ$. After perturbation, images followed the same 128×128 pseudo-RGB conversion and 0.5/0.5 normalization used for the clean test set. Accuracy, balanced accuracy, macro precision, macro recall, macro F1-score, and macro-AUC were computed for every condition. These tests quantify sensitivity to the specified controlled input changes [28]; broader scanner-, site-, and acquisition-related variation is reserved for future multi-centre evaluation.

J. Computational Efficiency Evaluation

Computational demand was measured using trainable parameter count, checkpoint size, multiply–accumulate operations (MACs), estimated floating-point operations (FLOPs), inference latency, throughput, and peak allocated GPU memory. MACs were profiled for one $3 \times 128 \times 128$ input, with FLOPs approximated as twice the MAC count. Latency measurements used repeated warm-up and timed forward passes. CPU measurements used batch sizes 1 and 16; Tesla T4 GPU measurements used batch sizes 1 and 32. These values are reported as an implementation profile for the stated hardware, batch sizes, and runtime conditions.

IV. Results

A. Aggregate Configuration Comparison

The selected no-CLAHE/augmentation configuration achieved 98.38% ± 0.38% accuracy, 98.86% ± 0.40% balanced accuracy, 86.94% ± 1.79% macro precision, 90.73% ± 1.79% macro F1-score, and 0.9993 ± 0.0009 macro-AUC. The CLAHE/no-augmentation configuration achieved 97.19% ± 0.32% accuracy, 97.95% ± 0.23% balanced accuracy, 82.56% ± 0.66% macro precision, 86.04% ± 0.76% macro F1-score, and 0.9980 ± 0.0016 macro-AUC. The selected configuration showed a 1.19 percentage points higher accuracy and a 4.68 percentage points higher macro F1-score than the alternate configuration under the same five-seed image-level protocol (Fig. 5).

B. Seed-Level Stability

Table IV lists held-out metrics for all five selected-configuration runs. Accuracy ranged from 98.02% to 98.96%, while macro F1-score ranged from 87.98% to 92.66%. Fig. 6 shows seed-level accuracy and macro F1-score. Seed variation describes training stochasticity under one fixed image-level split and therefore provides a focused measure of training reproducibility.

C. Class-Wise Performance

Table V reports class-wise results for the selected configuration. Non-Demented, Very Mild Demented, and Mild Demented achieved high mean F1-scores. Moderate Demented achieved 100% mean sensitivity across seeds, with 49.89% ± 7.64% mean precision and 66.29% ± 6.88% mean F1-score. This class-wise pattern shows why the 98.38% overall accuracy should be interpreted together with macro-level and per-class metrics. The nine-image Moderate Demented test support is therefore reported explicitly so that the sensitivity, precision, and F1-score can be interpreted in the context of the available class support.

Fig. 7 complements Table V. The left panel compares per-class F1-scores under the two configurations. The right panel shows the selected configuration's precision–sensitivity relationship. The Moderate Demented class combines high sensitivity with lower precision, making macro-level and class-wise reporting especially informative alongside overall accuracy.

D. Representative Learning and Discrimination Analyses

Fig. 8 presents training and validation loss and macro F1-score for the representative seed-42 selected run. The lowest validation-loss checkpoint was retained for test inference. Fig. 9 presents one-versus-rest ROC and precision–recall curves for the same run. ROC and PR views are both included because class support is unequal; numerical claims remain the five-seed aggregate results in Table III.

TABLE III. PIPELINE-SCREENING COMPARISON ON THE FIXED HELD-OUT TEST SET. VALUES ARE MEAN ± STANDARD DEVIATION OVER FIVE FIXED TRAINING SEEDS. THE PIPELINES DIFFER JOINTLY IN CLAHE USE AND ONLINE AUGMENTATION

Configuration	Accuracy (%)	Balanced accuracy (%)	Macro precision (%)	Macro recall (%)	Macro F1-score (%)	Macro-AUC
No CLAHE + augmentation	98.38 ± 0.38	98.86 ± 0.40	86.94 ± 1.79	98.86 ± 0.40	90.73 ± 1.79	0.9993 ± 0.0009
CLAHE + no augmentation	97.19 ± 0.32	97.95 ± 0.23	82.56 ± 0.66	97.95 ± 0.23	86.04 ± 0.76	0.9980 ± 0.0016

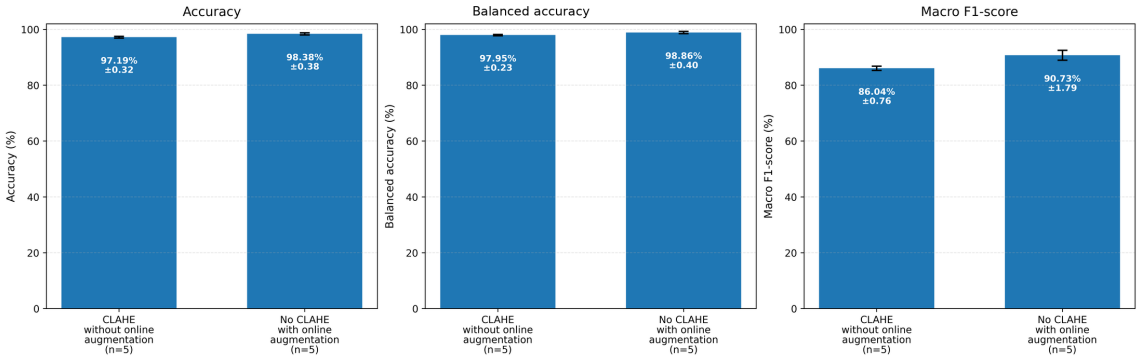

Fig. 5. Pipeline-screening comparison under the same split, model, 0.5/0.5 normalization, and five training seeds. The no-CLAHE configuration with online augmentation was the stronger of the two evaluated pipelines.

TABLE IV. SEED-LEVEL HELD-OUT RESULTS FOR THE SELECTED NO-CLAHE/AUGMENTATION CONFIGURATION. EACH ROW USES THE IDENTICAL FIXED IMAGE-LEVEL SPLIT

Seed	Best epoch	Accuracy (%)	Balanced accuracy (%)	Macro F1-score (%)	Macro-AUC
42	25	98.02	98.23	87.98	0.9994
52	25	98.96	99.32	91.91	0.9998
62	25	98.23	98.94	90.76	0.9996
72	25	98.13	98.77	92.66	0.9976
82	24	98.54	99.03	90.32	0.9999
Mean ± SD	–	98.38 ± 0.38	98.86 ± 0.40	90.73 ± 1.79	0.9993 ± 0.0009

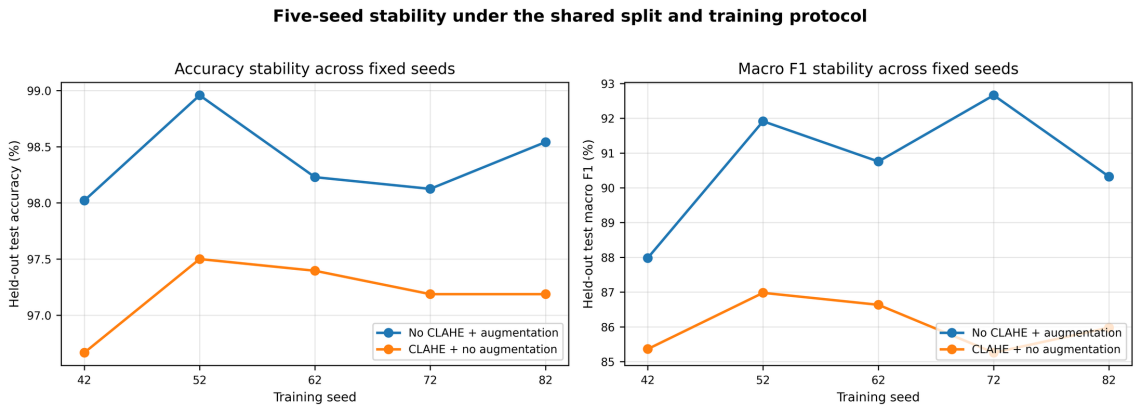

Fig. 6. Accuracy and macro F1-score across five fixed seeds. The values quantify seed-to-seed training variation under one shared image-level partition.

TABLE V. PER-CLASS RESULTS FOR THE SELECTED NO-CLAHE/AUGMENTATION CONFIGURATION. VALUES ARE MEAN ± STANDARD DEVIATION OVER FIVE SEEDS; SUPPORT IS THE FIXED TEST-SET COUNT

Class	Precision (%)	Sensitivity (%)	Specificity (%)	F1-score (%)	Support
Non-Demented	99.46 ± 0.68	98.58 ± 0.56	99.46 ± 0.68	99.02 ± 0.33	480
Very Mild Demented	99.28 ± 0.54	97.74 ± 0.98	99.62 ± 0.29	98.50 ± 0.51	336
Mild Demented	99.12 ± 0.80	99.11 ± 1.61	99.85 ± 0.13	99.11 ± 0.69	135
Moderate Demented	49.89 ± 7.64	100.00 ± 0.00	99.01 ± 0.31	66.29 ± 6.88	9

Fig. 7. Class-wise visualization based on five-seed aggregate results. Left: mean F1-score with standard deviation for both configurations. Right: selected configuration precision and sensitivity by class. The 100% Moderate Demented sensitivity is shown together with the nine-image fixed test support to provide the appropriate class-level context.

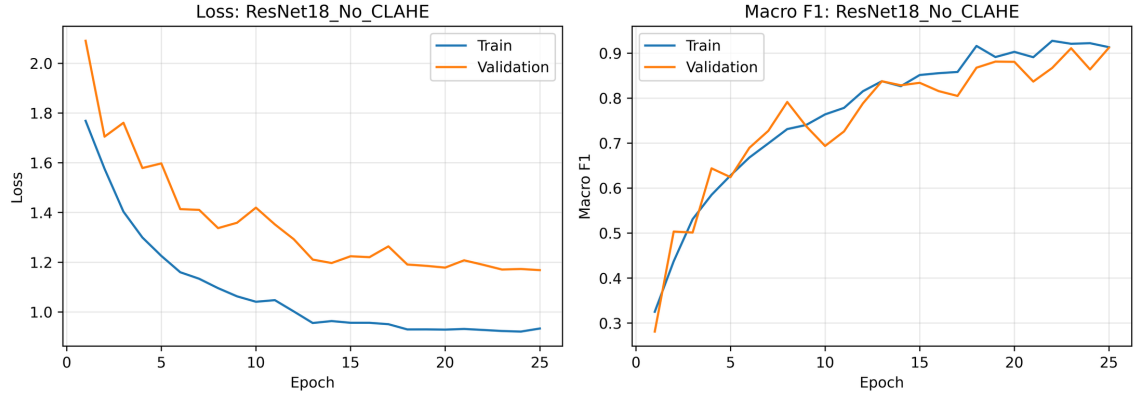

Fig. 8. Training and validation dynamics for the representative seed-42 selected run. The held-out test result was calculated only after restoring the lowest-validation-loss checkpoint.

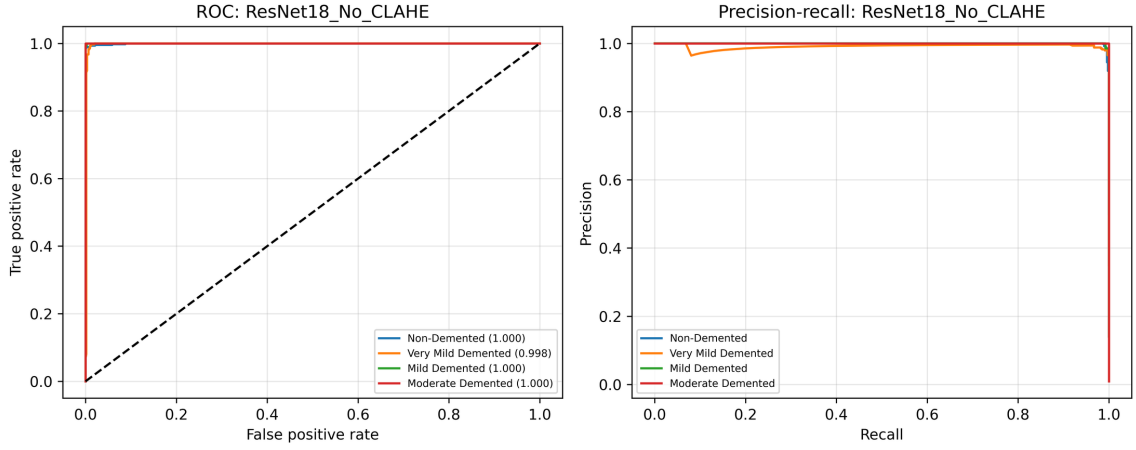

Fig. 9. One-versus-rest ROC and precision–recall curves for the representative seed-42 selected configuration on the held-out test set.

E. Confusion-Matrix Analysis

Fig. 10 provides absolute and row-normalized matrices for the representative seed-42 run. It complements the five-seed class-wise summary and makes the relationship between recall, false positives, and the nine-image Moderate Demented support directly visible. For this representative run, all 9 Moderate Demented test images were correctly identified,

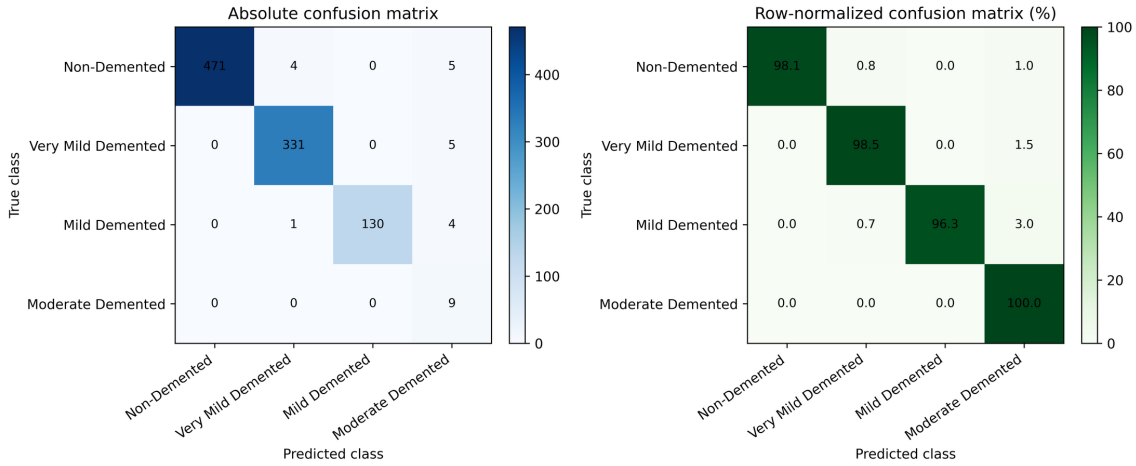

Fig. 10. Absolute and row-normalized confusion matrices for the representative seed-42 selected run. Interpret the figure together with the five-seed per-class summary in Table V.

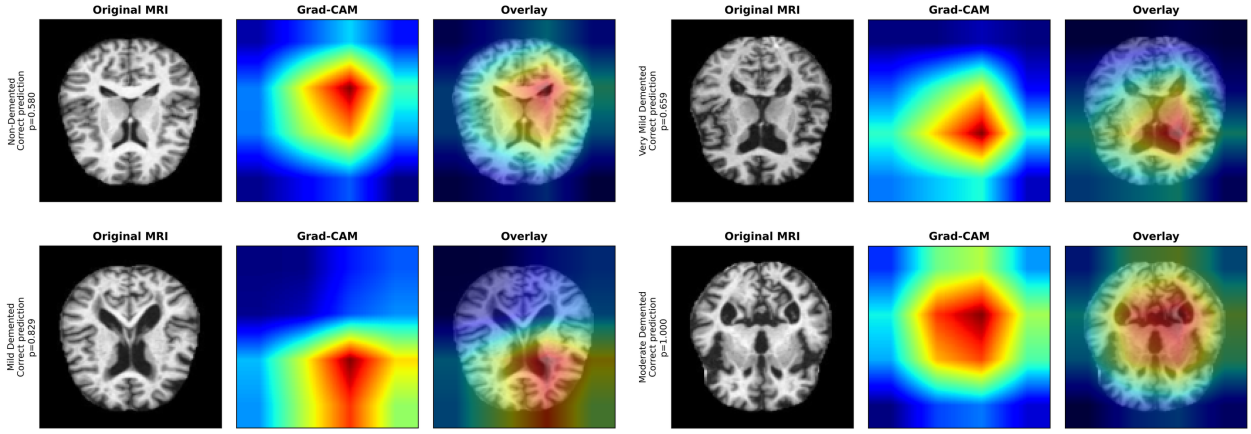

Fig. 11. Grad-CAM visualizations from the representative seed-42 checkpoint for correctly classified held-out test images from the four AD MRI classes. Each class panel shows the original grayscale MRI image, the Grad-CAM map, and the corresponding overlay. The displayed example for each class is the correctly classified image with confidence closest to the median confidence of correct predictions for that class. Warmer map values indicate locations with greater contribution to the predicted class. The maps are presented as qualitative model-inspection evidence, with quantitative anatomical validation reserved for future expert-annotated studies.

TABLE VI. CONFIDENCE CALIBRATION ON THE FIXED TEST PARTITION. TEMPERATURE WAS FITTED USING ONLY THE VALIDATION PARTITION

Output	NLL	Brier	ECE	MCE
Uncalibrated	0.4766	0.2613	0.3472	0.4188
Temperature-scaled	0.1756	0.0449	0.0722	0.5301

TABLE VII. SYNTHETIC ROBUSTNESS EVALUATION USING THE UNCHANGED SEED-42 CHECKPOINT. CHANGE IS RELATIVE TO CLEAN-TEST MACRO F1-SCORE

Condition	Accuracy (%)	Balanced accuracy (%)	Macro F1-score (%)	Δ Macro F1-score (pp)
Clean	98.02	98.23	87.98	0.00
Gaussian noise ($\sigma = 0.03$)	97.19	98.24	86.22	-1.76
Gaussian blur (radius 1.0)	93.65	96.15	79.42	-8.57
Brightness 0.80	98.02	98.65	88.62	$+0.63$
Brightness 1.20	95.10	95.71	82.24	-5.74
Contrast 0.80	98.02	98.52	89.48	$+1.49$
Contrast 1.20	96.56	97.68	84.66	-3.32
Rotation -5°	98.33	99.12	90.97	$+2.99$
Rotation $+5^\circ$	98.33	98.92	90.88	$+2.89$

TABLE VIII. MEASURED COMPUTATIONAL EFFICIENCY PROFILE

Property	Value
Trainable parameters	11,309,380
Checkpoint size	43.22 MB
GMACs per image	0.596
Estimated GFLOPs per image	1.191
CPU latency, batch 1	76.70 ms/image
GPU latency, batch 1	3.08 ms/image
GPU throughput, batch 32	3341 images/s
Peak GPU memory	126.88 MB

while 14 images from the other three classes were assigned to the Moderate Demented label, giving 9 true positives, 0 false negatives, and 14 false positives for that class.

F. Grad-CAM Explainability Results

Fig. 11 presents Grad-CAM visualizations for representative correctly classified images from the four classes. The seed-42 checkpoint used for this analysis obtained 98.02% accuracy, 98.23% balanced accuracy, and 87.98% macro F1-score on the fixed held-out test partition, consistent with the corresponding row in Table IV. The maps show the spatial distribution of image regions contributing to each predicted class. They are presented as qualitative model-inspection evidence; no anatomical localization claim is made because no expert-defined region-of-interest reference is used in this analysis.

G. Confidence Calibration and Selective Prediction

The validation-fitted temperature was $T = 0.2135$. As shown in Table VI, temperature scaling reduced NLL from 0.4766 to 0.1756, Brier score from 0.2613 to 0.0449, and ECE from 0.3472 to 0.0722. Accuracy and macro F1-score remained 98.02% and 87.98%, respectively, because scalar temperature scaling did not change class predictions. MCE increased from 0.4188 to 0.5301, indicating that a sparsely populated confidence bin retained a larger local calibration gap even though NLL, Brier score, and ECE improved. Fig. 12 therefore shows that the aggregate and maximum-bin calibration measures provide complementary information.

The confidence-ranked risk–coverage analysis is shown in Fig. 13. At 95% coverage, retained accuracy was 99.56% compared with 98.02% at full coverage. The temperature-scaled and uncalibrated curves were nearly identical because scalar temperature scaling preserves the score ordering apart from numerical ties. This experiment characterizes the confidence–coverage trade-off within the fixed test partition and provides a complementary view of confidence-ranked prediction behaviour.

H. Robustness Under Controlled Image Perturbations

Table VII and Fig. 14 summarize the synthetic stress tests. Gaussian noise produced a 1.76-percentage-point reduction in macro F1-score, whereas Gaussian blur produced the largest degradation, reducing macro F1-score from 87.98% to 79.42%.

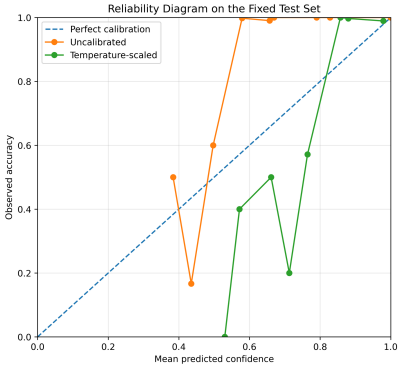

Fig. 12. Reliability diagram for the representative seed-42 checkpoint before and after validation-fitted temperature scaling.

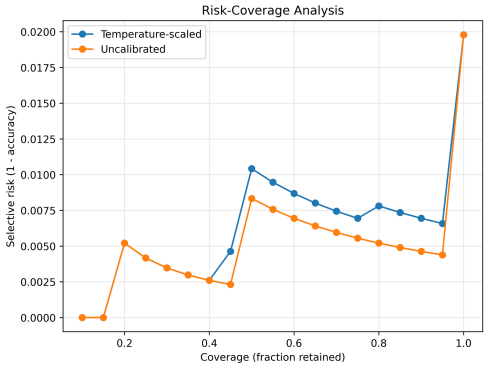

Fig. 13. Selective-prediction risk for the representative seed-42 checkpoint as a function of retained coverage.

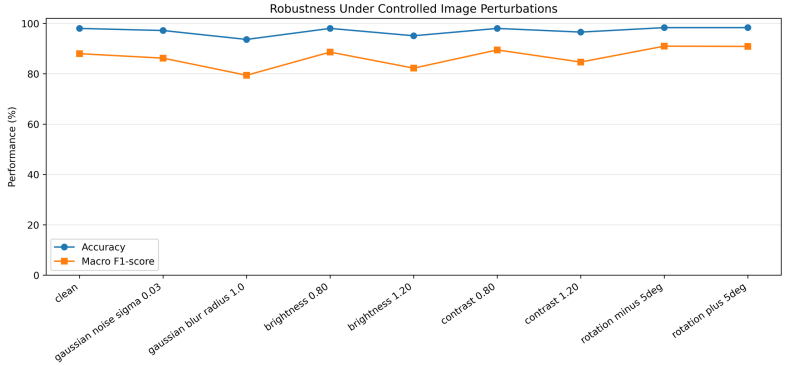

Fig. 14. Accuracy and macro F1-score for the representative seed-42 checkpoint under the specified synthetic test-time perturbations.

Increased brightness and contrast also reduced macro F1-score by 5.74 and 3.32 percentage points, respectively. Mild brightness reduction, contrast reduction, and $\pm 5^{\circ}$ rotations produced small apparent improvements on the fixed test partition. Because the Moderate Demented test support contains nine images, these increases are reported as fixed-sample variation and are not interpreted as a beneficial effect of perturbation.

I. Computational Efficiency Profile

The model contained 11,309,380 trainable parameters, occupied 43.22 MB as a checkpoint, and required 0.596 GMACs (approximately 1.191 GFLOPs) per 128×128 image. On the measured environment, CPU batch-1 inference averaged 76.70 ms per image. Tesla T4 batch-1 inference averaged 3.08 ms per image, while batch-32 throughput reached 3341 images/s with 126.88 MB peak allocated GPU memory. Table VIII provides the complete profile. These measurements support the resource-efficient characterization of the framework for the stated hardware, batch sizes, and runtime conditions.

V. Discussion

A. Main Finding

Under the evaluated protocol, the no-CLAHE/augmentation configuration provided the stronger aggregate performance of the two screened pipelines. It obtained a macro F1-score above 90% while remaining compact relative to many 3D and attention-heavy neuroimaging systems..

The comparison supports empirical evaluation of preprocessing choices within the target collection. CLAHE was included as a local-contrast candidate based on established adaptive-histogram principles [10], [11]. Under the evaluated protocol, the CLAHE-based pipeline without online augmentation produced lower aggregate accuracy, macro precision, and macro F1-score. Because the pipelines differ in both contrast enhancement and augmentation, the difference may reflect preservation of intensity structure, online augmentation, their interaction, or another configuration-level effect. A complete 2×2 factorial design remains a useful extension for estimating independent main effects and interactions.

B. Interpretation Under Imbalance

The difference between the high overall accuracy and the macro-level metrics is mainly associated with the Moderate Demented class. The selected configuration achieved 100% mean sensitivity for that class but lower precision, implying that some images from other classes were assigned to the rare label. This is why aggregate accuracy must not be used alone in imbalanced settings [9], [18]. Macro F1-score, macro precision, per-class support, and confusion patterns provide a more complete assessment.

The Moderate Demented class contains nine test images. Consequently, individual prediction changes have a visible effect on sensitivity and precision; for example, one additional false negative would change sensitivity by more than 11 percentage points. Reporting support together with precision, sensitivity, and F1-score therefore provides the most informative interpretation of this class.

C. Qualitative Explainability

The Grad-CAM maps provide a visual check that the representative seed-42 classifier drew evidence from spatially distributed regions within the MRI field rather than exclusively from image borders or uniform background. This observation is useful for model inspection. The heatmaps are intentionally presented as qualitative visual evidence because the analysis does not use expert segmentation, an anatomical atlas, or pathology-grounded region annotations. Consequently, Grad-CAM complements the predictive metrics without making an anatomical localization claim.

D. Reliability, Robustness, and Resource Efficiency

The calibration results show that high discrimination and reliable confidence are separate properties. For the seed-42 checkpoint, validation-fitted temperature scaling improved NLL, Brier score, and ECE without altering the predicted labels. MCE moved in the opposite direction, showing that aggregate calibration measures and the largest individual-bin deviation capture different aspects of probability behaviour. Selective prediction further showed that higher-confidence subsets had lower error; the full multiclass metrics remain the primary performance summary.

The controlled perturbation results provide a differentiated sensitivity profile. The framework remained comparatively stable under mild Gaussian noise and small rotations, while blur and intensity increases produced larger metric changes. These results complement clean-test performance, while scanner differences, reconstruction pipelines, motion effects, and institutional variation remain important directions for future multi-centre evaluation.

The measured 0.596 GMACs per image, 43.22 MB checkpoint, and low Tesla T4 inference latency provide direct evidence for resource efficiency. Future translational evaluation can extend this evidence through external validation, use-case-specific calibrated thresholds, software-system testing, and prospective workflow assessment.

E. Study Scope and Future Work

The scope of the present study is a reproducible image-level evaluation on one public MRI collection. The available data support image-level rather than verified subject-level partitioning, and the reported five-seed standard deviations therefore summarize training reproducibility under one fixed split. The Moderate Demented class is reported with its nine-image test support so that class-specific metrics are interpreted with their sample context. The framework uses 2D images, while volumetric and multi-slice representations offer a natural extension when complete acquisition context is available. Grad-CAM is used for qualitative model inspection, calibration is assessed within the supplied dataset partitions, and the perturbation study is restricted to the specified synthetic transformations. Computational measurements are reported for the stated hardware and runtime configuration.

Future work can extend the present framework through datasets with subject-level and site-level identifiers, external multi-centre evaluation, volumetric or multi-slice representations with preserved acquisition context. Additional directions

include calibration assessment under dataset shift, use-case-specific selective-decision thresholds, quantitative explainability assessment against expert-defined anatomical references, and a complete 2×2 factorial study of CLAHE and augmentation.

VI. Conclusion

This study developed a reliability-oriented and resource-efficient evaluation of a lightweight ResNet-18 framework for four-class AD MRI image classification. Under a fixed image-level split and five training seeds, the selected no-CLAHE configuration with online augmentation achieved 98.38% $\pm$ 0.38% accuracy, 98.86% $\pm$ 0.40% balanced accuracy, 90.73% $\pm$ 1.79% macro F1-score, and 0.9993 $\pm$ 0.0009 macro-AUC. For the representative seed-42 checkpoint, temperature scaling improved NLL, Brier score, and ECE, while selective prediction characterized the confidence–coverage trade-off. Controlled stress tests showed larger performance changes under Gaussian blur and intensity increases than under mild noise or small rotations. The model required 0.596 GMACs per image and achieved 3.08 ms batch-1 inference on a Tesla T4, providing measured evidence of resource efficiency. Grad-CAM provided qualitative model-inspection evidence without making an anatomical localization claim. Collectively, the findings support a reproducible, confidence-aware, perturbation-tested, and computationally profiled image-level framework within the evaluated public dataset and protocol.

***Abstract*—Social media platforms are key spaces for sharing opinions, experiences, and daily events. However, the rapid rise in hate speech, especially implicit hate, has become a significant concern. Implicit hate is subtle, context-dependent, and more difficult to detect than explicit hate. Despite the growing body of work on Hate Speech Detection (HSD), most existing models are developed for resource-rich languages like English. Unlike resource-rich languages, Hindi lacks sufficient annotated data and dedicated research, making it a low-resource language. To address this limitation, this work presents a deep learning–driven approach for the classification of implicit and explicit hate speech in Hindi. The approach uses FastText embeddings to capture semantic and subword-level information, which suits noisy social media text. A Bidirectional Long Short-Term Memory (BiLSTM) network models contextual dependencies, while an attention mechanism assigns higher importance to discriminative words and sentences, enabling effective identification of implicit hate. Extensive experiments on the Hindi Hate Speech Dataset (HHSD) demonstrate the model's effectiveness. Compared with the widely used multilingual BERT (mBERT) baseline, the proposed approach improves classification performance, with a 2.51% increase in accuracy and a 17.84% improvement in weighted F1-score. Additionally, the model requires significantly fewer parameters than transformer-based models, making it more parameter-efficient.**

***Keywords*—Attention network; BiLSTM; deep learning; explicit hate speech detection; hate speech detection; implicit hate speech detection; natural language processing**

I. Introduction

Social media has become an integral platform for sharing opinions, daily activities, and connecting with others. While many users engage positively, others disseminate negative content, including hate speech, which can undermine societal harmony. Hate speech encompasses communicative acts expressed through language or behaviour that demean or discriminate against individuals or communities based on attributes such as religion, ethnicity, nationality, race, colour, descent, gender, or other identity markers [1]. To address this issue, governments have introduced regulations that require social media platforms to enforce them. However, to bypass these restrictions, users increasingly resort to indirect or implicit forms of hate, conveyed through subtle textual expressions or multimodal content. Implicit hate speech is characterized by indirect or veiled expressions that convey negative or prejudicial attitudes toward individuals or groups defined by protected identity attributes [2]. Implicit hate speech avoids overtly abusive language and instead uses context and underlying meaning to convey hostility, which makes detection much more difficult. This complexity is further amplified by cultural and linguistic diversity, where expressions considered acceptable in one context may be offensive in another. In countries like India, where many languages are spoken, people often mix languages, and informal language substantially increases the difficulty of Hate Speech Detection [3], particularly for implicit hate [4]. The slow, tedious process of manual moderation has driven a shift toward automated HSD systems based on machine learning and deep learning techniques. However, most research focuses on English, a high-resource language, while Indian languages remain underexplored [3]. The scale of Hindi usage contrasts sharply with the limited research on implicit hate speech detection in the language, underscoring the need for effective automated solutions.

The main contributions of the proposed work are:

- Contextual modeling for Implicit Hate Detection: This work investigates the hierarchical integration of BiLSTM and attention to detect implicit and explicit hate speech in Hindi. The framework models contextual information at two levels: word-level representations capture local semantic dependencies, while sentence-level representations capture broader contextual relationships.
- Task-Specific Hierarchical Attention: The proposed framework employs attention at both the word and sentence levels to selectively aggregate contextual representations. The methodological contribution lies in using hierarchical attention to identify salient lexical and sentence-level contextual cues relevant to implicit versus explicit hateful intent. This provides a more targeted representation for fine-grained hate classification.
- Emoji-Preserving Contextual Processing for Hindi Social Media Text: Unlike preprocessing pipelines that discard emojis as non-linguistic symbols, the proposed framework preserves emojis as individual tokens because they can provide emotional and pragmatic cues that complement textual meaning. This design is particularly relevant to Hindi social-media content, where emojis may shape interpretations of indirect or context-dependent expressions.
- Semantic-Preserving GPT-3.5 Backtranslation Framework: We employ a GPT-3.5-based backtranslation

*Corresponding author.

strategy to address class imbalance and increase linguistic diversity. We validate augmented-data quality using LaBSE similarity and mBERTScore to ensure semantic consistency between original and generated samples.

- Integrated Low-Resource Hate Speech Detection Framework: The main methodological contribution is integrating hierarchical contextual modeling, dual-level attention, emoji preservation, and semantically validated augmentation into a single framework for Hindi implicit/explicit hate speech detection.

II. Related Works

A. Machine Learning Approaches

Initial research on hate speech detection primarily utilized machine learning (ML) methods that relied on handcrafted features, including n-grams, Bag-of-Words, sentiment cues, syntactic dependencies, and hate lexicons. Classical classifiers, including Decision Trees, Bayesian models, Random Forests, Logistic Regression and Support Vector Machines have been widely employed for hate speech detection in English [5], [6], [7]. Similar approaches were later applied to Hindi and code-mixed Hindi–English text using FastText at character-level representations and traditional classifiers [8]. Despite their initial success, ML-based methods suffer from several inherent limitations. These approaches depend on manual feature engineering and domain-specific lexicons, which increases errors, requires significant time, and limits scalability. Furthermore, they are biased toward explicit hate containing abusive words and fail to capture deeper contextual semantics, sarcasm, and implicit hate expressions. Their performance also degrades significantly in code-mixed and multilingual environments, which are common in Indian social media platforms. As a result, ML techniques are insufficient for robust implicit/explicit hate speech detection in Hindi.

B. Deep Learning Approaches

To overcome the limitations of ML-based models, researchers increasingly adopted deep learning (DL) architectures that can automatically extract features and improve contextual representation. Neural models such as hierarchical networks, BiLSTMs, LSTMs, CNNs, and attention-based architectures demonstrated enhanced semantic understanding and contextual modeling [9], [10], [11]. Recent work has explored multimodal toxicity detection in memes by combining PaddleOCR, KOSMOS-2, and SigLIP to analyse textual and visual cues jointly [12]. For Indian languages, several studies have incorporated subword representations, phrase embeddings, sentiment and emotion features, and auxiliary linguistic resources to handle linguistic diversity and morphological richness better.

Recent studies have increasingly adopted pretrained transformer-based models, such as mBERT, MuRIL, BERT, and HateBERT, word clouds, and ensemble transformer architectures for hate speech detection across diverse languages, including Hindi, Marathi, Tamil, and English [13], [14], [15], [16]. Although these models achieve strong empirical performance, they introduce critical challenges, including large parameter sizes, high computational costs, and dependency on GPUs/TPUs and large annotated datasets. Additionally, many transformer-based approaches exhibit bias toward majority classes, struggle with unknown tokens, sarcasm, and code-mixed text, and often fail to distinguish implicit hate from explicit hate effectively. These challenges highlight the need for parameter-efficient deep learning models better suited to low-resource language settings.

C. Implicit and Explicit Hate Speech Detection

Implicit hate speech detection has gained increased attention as it relies on indirect expression, nuanced meaning, and strong contextual dependence. Unlike explicit hate, implicit hate avoids overtly abusive language, making it difficult for lexicon-based and surface-level models to detect. Elsherief et.al. [4] introduced benchmark datasets and annotation guidelines that distinguish between implicit and explicit hate, laying the foundation for further research in this area. Subsequent studies explored background knowledge integration, contrastive learning-based fine-tuning strategies [17], prompt-based learning approaches, and large language models to improve interpretability and performance [18].

For Indian languages, research on implicit hate detection remains limited. Kapil et. al. [3] introduced the Hindi Hate Speech Dataset (HHSD) and evaluated implicit and explicit hate using transformer-based architectures.

Despite significant progress in hate speech detection, existing approaches for Hindi largely rely on traditional machine learning methods or computationally intensive pretrained transformer models, both of which struggle to handle implicit hate speech effectively. Furthermore, most studies focus solely on textual content and overlook emoji-based contextual cues, even though emojis are frequently used on social media to convey sentiment, sarcasm, and indirect intent. Robust experimental evaluation of implicit and explicit hate classification remains limited, with many studies relying on single train–test splits rather than comprehensive validation strategies. In addition, data imbalance and limited dataset size remain challenges, as augmentation techniques are rarely explored in the context of implicit hate detection. These limitations highlight the need for efficient, context-aware, and well-evaluated models tailored to the Hindi language (a low-resource language).

Existing Hindi hate speech detection methods primarily rely on transformer-based architectures or keyword-driven approaches that struggle to capture implicit hateful intent. Furthermore, limited attention has been given to multi-level contextual modeling, interpreting model focus, emoji-aware contextual understanding, and semantically validated augmentation strategies. To address these limitations, this work develops a task-specific hierarchical contextual framework that combines word- and sentence-level BiLSTM representations with dual-level attention for implicit/explicit hate discrimination. The framework additionally preserves emojis as contextual tokens and incorporates GPT-3.5-based back-translation with semantic validation using LaBSE and mBERTScore.

This study introduces a novel approach to address the challenges of identifying both implicit and explicit hate speech in Hindi. Emojis are widely used on social media to convey emotions and implicit intent; incorporating emoji information is essential for accurately interpreting user-generated content

[19]. Accordingly, we retain and process emojis during preprocessing to enhance contextual understanding. The proposed model uses FastText embeddings to generate efficient, semantically rich representations of the input text [20]. These embeddings flow into a Bidirectional Long Short-Term Memory network, which uncovers contextual relationships from both past and future perspectives. Furthermore, an attention mechanism assigns higher importance to salient words or sentences, enabling the model to focus on critical contextual cues for detecting implicit hate speech [21].

III. Proposed Methodology

The proposed technique classifies hate posts on social media as either implicit or explicit hate speech. Fig. 1 shows the system architecture. The proposed system takes Hindi text as input, which is then preprocessed. Using an embedding technique, the text is converted into a vector and, finally, classified as implicit/explicit hate speech. The detailed explanation is as follows.

A. Dataset

The proposed method uses the Hindi Hate Speech Dataset (HHSD). HHSD contains 14782 tweets, each labelled as hate or non-hate. 7311 hateful tweets are present, which are further labelled as implicit or explicit hate speech. Of these, 2432 are implicit, and 4879 are explicit. Because the proposed work focuses on binary classification, we applied the method only to tweets with hate labels. Table I presents detailed information about the dataset.

TABLE I. Label Distribution

Label	Label	Size
Hate	Implicit	2432
	Explicit	4879
Nonhate		7471
Total		14782

B. Motivation and Design Rationale

The proposed approach's key design consideration is a hierarchical contextual modeling framework that captures context at both the word and sentence levels. Unlike traditional hate speech detection models that rely primarily on offensive keywords, the framework identifies subtle and indirect forms of hate speech by focusing on contextual semantics and inter-sentence relationships. At the word level, attention is used to highlight critical terms that signal hateful intent, even when explicit abusive language is absent. Additionally, at the sentence level, attention identifies which sentences carry the most discriminatory meaning within multi-sentence posts. This hierarchical attention structure provides an interpretable view of the words and sentences that influence predictions, aiming to improve detection of challenging implicit hate speech scenarios. By combining bidirectional contextual learning with multi-level attention, the model provides complementary contextual representations of textual content compared with conventional single-level attention or keyword-based approaches.

The methodological contribution therefore lies in integrating these established components for task-specific contextual discrimination of implicit and explicit hate speech.

1) Context-aware implicit hate speech detection: Traditional hate speech detection models often rely on the presence of explicit offensive terms (e.g., slurs, abusive words, derogatory expressions). However, implicit hate speech is expressed indirectly through stereotypes, sarcasm, coded language, insinuations, or contextual references. Since no explicit hate-related keywords may be present, detecting implicit hate requires understanding the surrounding linguistic context.

For example:

- Explicit Hate: "आप जैसे हरामी को भी अवसर मिलेगा" (Translation: Even a scoundrel like you will get an opportunity.)
- Implicit Hate:"मानसिक दिवालियापन है 🤬🤬" (Translation:It is mental bankruptcy 🤬🤬)

The second statement contains no obvious hate words, but the context implies discrimination toward a particular group. Therefore, the proposed model utilizes contextual representation learning through BiLSTM and attention mechanisms.

The meaning of a potentially hateful expression depends heavily on its surrounding context. A word or phrase may appear neutral on its own but may express discriminatory intent when interpreted in a broader linguistic context. Therefore, contextual representation learning is essential for accurately distinguishing implicit hate speech from explicit hate speech.

Let the input sentence be represented as in Eq. (1):

$$S = \{w_1, w_2, w_3, \ldots, w_l\} \tag{1}$$

where, w_i denotes the ith word and l represents the sentence length. Each word is transformed into a dense vector representation using Eq. (2):

$$x_i = Embedding(w_i) \tag{2}$$

A Bidirectional Long Short-Term Memory (BiLSTM) network processes the embedded sequence. The forward hidden state is computed using Eq. (3):

$$\overrightarrow{h_i} = LSTM_f(x_i, \overrightarrow{h_{i-1}}) \tag{3}$$

and the backward hidden state is computed as defined in Eq. (4):

$$\overleftarrow{h_i} = LSTM_b(x_i, \overleftarrow{h_{i+1}}) \tag{4}$$

The contextual representation of each word is obtained Eq. (5) by concatenating the forward and backward hidden states :

$$h_i = [\overrightarrow{h_i}; \overleftarrow{h_i}] \tag{5}$$

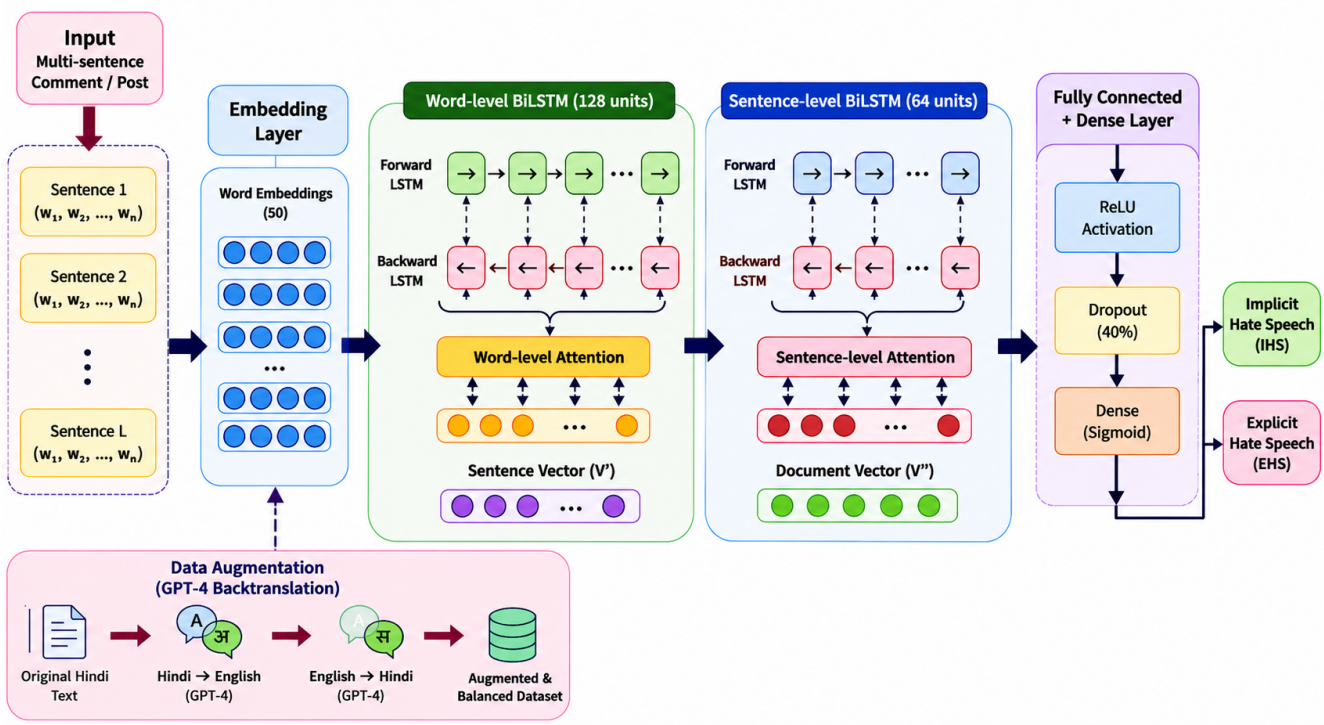

Fig. 1. Architecture diagram.

where, $h_i \in \mathbb{R}^{2d}$ and d denotes the hidden-state dimension. The BiLSTM output matrix is represented using Eq. (6):

$$0B^{(w)}_{BiLSTM} = [h_1, h_2, \ldots, h_l] \in \mathbb{R}^{l \times 2d} \tag{6}$$

Unlike explicit hate speech, implicit hate often lacks direct offensive words. Therefore, contextual understanding becomes essential. The BiLSTM captures semantic relationships among words, enabling the model to identify hidden hateful intent even when explicit abusive vocabulary is absent.

2) Hierarchical multi-level context modeling: Hateful intent may span multiple sentences rather than being expressed within a single sentence. Consequently, effective hate speech detection requires modeling both local semantic relationships among words and global contextual relationships among sentences.

At the word level, contextual dependencies among tokens are captured using a BiLSTM Eq. (7):

$$H_w = BiLSTM(EH) \tag{7}$$

where, EH denotes the FastText embedding representation. The resulting sentence representations are then processed through a sentence-level BiLSTM Eq. (8):

$$H_s = BiLSTM(V) \tag{8}$$

where, V represents the sentence vectors generated from the word-level attention mechanism. This hierarchical architecture enables the model to capture:

- Local semantic dependencies among words.
- Global discourse-level relationships among sentences.
- Contextual information distributed across multi-sentence posts.

By jointly modeling lexical and discourse-level context, the framework provides richer semantic representations for implicit hate speech detection.

3) Attention-guided feature selection: Not all words and sentences contribute equally to hate speech classification. In implicit hate speech, only a small subset of words may reveal the underlying hateful intent. Similarly, within a multi-sentence post, only certain sentences may contain discriminatory cues.

Overall, the proposed framework combines context-aware representation learning, hierarchical multi-level context modeling, and attention-guided feature selection to capture subtle and context-dependent hate expressions. Furthermore, we incorporate semantic-preserving back-translation to address data imbalance and increase linguistic diversity, supporting robust hate speech detection in the low-resource Hindi setting.

C. Preprocessing

During preprocessing, we cleaned the data. We removed content that does not contribute to classification, such as usernames, mentions, handles, hashtags, and hyperlinks. We removed leading, trailing, and multiple spaces from the input data. Special characters do not contribute to classification, so we also removed them from the input. Suffixes are not useful in classification tasks; therefore, we also removed them from the input text. To retain contextual knowledge, some stop

words play an important role, so preprocessing didn't remove them. FastText embedding converts the input into a vector representation using contextual knowledge, so keeping some stop words is important.

Many users across platforms, such as social media, use emojis to express their feelings in posts. Emojis provide a more expressive and attractive way to convey feelings or add meaning to textual posts. Emojis may be used to remove ambiguity from ambiguous sentences. Emojis are used to complement relatively negative text [19]. Emojis greatly contribute to understanding emotion, whether positive/negative and direct/indirect. Many researchers have considered emotion/sentiment as an important feature in HSD, specifically in implicit HSD [22], [23], [24].

Emojis benefit implicit/explicit HSD, so the proposed method does not remove them from the input data. Preprocessing uses them to understand the sentence's context better. In tokenization, each unique emoji is assigned a separate token, which is then used in embedding and other layers.

D. Tokenizer

The tokenizer converts input text into numerical representations, enabling more efficient processing by the NLP model. The tokenizer takes text and emojis as input, identifies unique words (w_i) and emojis, and builds a vocabulary. The vocabulary contains words, emojis, and their corresponding index entries, which are used to convert input into numbers. If any out-of-vocabulary words are present, they are handled using an out-of-vocabulary (OOV) token. In the proposed method, we replace OOV with the <UNK> token.

The tokenizer converts each word and emoji into a token t_i. This creates a numeric vector t of varying length, depending on the input sentence. The input vector t is padded to produce a fixed-length vector P of length l, $|P| = l \geq |t|$. The first $|t|$ entries are filled with t, and the remaining $(l - |t|)$ entries are filled with zeros as padding. In the proposed model, the maximum sentence length (l) is 50, so padding converts all input vectors to size 50. The resulting vector with fixed length $P \in \mathbb{R}^{1\times l}$ is provided to the next layer (embedding layer) for further processing.

E. Embedding Layer

Embedding converts input into an efficient representation, so this work uses FastText embeddings. Facebook provides pre-trained FastText embeddings [20] for 157 languages, including Hindi. FastText embeddings provide more efficient word representations. FastText provides an efficient data representation, which also makes the classification task easier. FastText captures word morphology and handles out-of-vocabulary words better. FastText extends word2vec, in which words are represented as a collection of subword embeddings. Because of these features, FastText is widely used in NLP tasks such as sentiment analysis and classification. Each token t_i of the input vector is embedded using FastText. This embedding creates a vector $E_H \in \mathbb{R}^{l\times 300}$. The embedding vector is 50x300. This vector proceeds to the next layer, the BiLSTM layer. It handles word morphology and out-of-vocabulary words better.

F. BiLSTM Layer

A bidirectional LSTM (BiLSTM) processes information in both directions. In the forward direction, an LSTM processes the input from left to right, and in the backward direction, from right to left. Due to this bidirectionality, the model captures context from the previous and next words relative to the current word. This provides a better representation of each word by considering the context of nearby words. So, the proposed method uses a BiLSTM to process the input in both directions and capture context from nearby words.

The embedding layer produces a vector that is fed into a BiLSTM. In implicit/explicit hate speech, knowing contextual information is important. Specific word-based identification is not available for detecting implicit hate. The implicit nature of the input makes the detection task much harder, so understanding context and representing it efficiently is important. In the proposed model, we use 128 BiLSTM units. BiLSTM provides b_i hidden state for each token t_i. By processing all tokens, we create a matrix using Eq. (9).

$$B_{BiLSTM} \in \mathbb{R}^{l\times 2d} \tag{9}$$

Where, d is the dimension of the hidden state.

l: length of the input vector (50).

This vector representation is then forwarded to the attention layer for further processing.

G. Attention Layer

The model learns word-specific importance weights through a lexical-level attention mechanism. This process assigns different importance scores to different words. Assigning importance scores allows the model to prioritize the most relevant words within sentences [21]. The resulting attention weights show the relative importance assigned to different tokens during classification.

For implicit/explicit HSD, the focus should be on the words. In explicit hate speech, the use of offensive/abusive words directly represents hate, but in implicit hate, there is no direct word present. Indirect targeting of individuals or groups complicates the identification of implicit hate speech, as it does not rely on explicit offensive or abusive language. So, we need to focus on the words in sentences that signal implicit hate speech. Attention mechanisms focus on words/sentences to identify important terms that signal implicit hate speech. The attention network accepts the B_{BiLSTM} matrix as input and assigns relative importance to tokens by focusing on words that contribute to implicit/explicit hate classification.

To automatically identify informative textual units, we apply an attention mechanism over the contextual representations using Eq. (10). First, a hidden representation is computed as:

$$U^{(w)} = tanh(B^{(w)}_{BiLSTM} W^{(w)} + b^{(w)}) \tag{10}$$

where, $B^{(w)}_{BiLSTM}$ represents the contextual word representations generated by the word-level BiLSTM, $W^{(w)}$ is a trainable weight matrix, and $b^{(w)}$ is the bias vector. The

importance score for each word is calculated as shown in Eq. (11):

$$s_i^{(w)} = U_i^{(w)} u^{(w)} \tag{11}$$

where, $u^{(w)}$ is the trainable word-level attention score vector. Attention weights are obtained using the softmax function, as defined in Eq. (12):

$$\alpha_i^{(w)} = \frac{\exp(s_i^{(w)})}{\sum_{j=1}^{l} \exp(s_j^{(w)})} \tag{12}$$

such that:

$$\sum_{i=1}^{l} \alpha_i^{(w)} = 1 \tag{13}$$

The context-aware sentence representation is then computed using Eq. (14):

$$V^{(s)} = \sum_{i=1}^{l} \alpha_i^{(w)} h_i \tag{14}$$

The word-level attention mechanism assigns different weights to contextual word representations, allowing the model to emphasize informative words within each sentence. These attention weights provide an interpretable view of the model's focus, but they should not be regarded as a complete explanation of the model's decision.

H. Sentence-Level BiLSTM Layer

The representations produced by the preceding layer are propagated in both forward and backward directions, enabling the model to capture complex inter-sentential relationships. This sentence-level BiLSTM provides contextual sentence representations by leveraging surrounding sentences in multi-sentence comments/posts. In the proposed model, we use 64 BiLSTM units.

I. Sentence-Level Attention Layer

The BiLSTM outputs feed into the sentence-level attention layer. This attention layer produces a single vector from multiple sentences, assigning higher weight to important sentences. This layer identifies relationships among sentences and focuses on the most important ones to form a single multi-sentence vector. Using this weighted vector, identifying implicit hate speech becomes easier.

The attention network creates a hidden representation using the tanh(.) activation function, as defined in Eq. (15).

$$U^{(s)} = \tanh(B_{BiLSTM}^{(s)} \cdot W^{(s)} + b^{(s)}) \tag{15}$$

Where, $w^{(s)}$ and $b^{(s)}$ are the trainable sentence-level attention parameters.

$B_{BiLSTM}^{(s)}$: Input matrix of size $\mathbb{R}^{l \times 2d}$.

Using Eq. (16), we compute the sentence potential importance score.

$$S_j^{(s)} = U_j^{(s)} u^{(s)} \tag{16}$$

Where, $u^{(s)}$ is the trainable sentence-level attention score vector.

Eq. (17) calculates attention weights using softmax(.) function.

$$\alpha_j^{(s)} = \frac{\exp\left(s_j^{(s)}\right)}{\sum_{k=1}^{m} \exp\left(s_k^{(s)}\right)} \tag{17}$$

Eq. (18) calculates the context vector as the sum of the products of the attention network input and the sentence-level attention weights.

$$V^{(d)} = \sum_{j=1}^{m} \alpha_j^{(s)} h_j^{(s)} \tag{18}$$

The sentence-level attention mechanism assigns different weights to contextual sentence representations, allowing the model to emphasise informative sentences among multiple sentences. The outcome of this layer is a sentence vector, which will be used for further processing in the model.

J. Fully Connected and Dense Layer

After attention-based feature extraction, a fully connected layer with ReLU non-linearity performs classification, with regularization via a 40% dropout strategy. Final predictions are generated using a softmax-based decision layer to distinguish between implicit hate speech (IHS) and explicit hate speech (EHS).

K. Model with Augmentation

To examine the impact of data augmentation and class balancing, we apply back-translation to the entire dataset. The size of the dataset after complete dataset augmentation and class balancing is shown below in Table II.

TABLE II. AUGMENTED DATASET DETAILS

Detail	Size	
	Implicit	Explicit
Class Balancing	4864	4879
Complete Augmentation	4864	9651

The HHSD dataset is highly imbalanced. As shown in Table I, the dataset contains 2432 tweets with implicit labels and 4879 with explicit labels. Using back-translation, a data augmentation technique, we balanced the dataset. In backtranslation, we first translate the input data from Hindi to English and then back to Hindi. For back-translation, we use GPT-3.5. Fig. 2 shows the back-translation process.

Fig. 2. Back-translation.

1) GPT-based back-translation: To augment the Hindi dataset, we performed back-translation using the OpenAI API with the `gpt-3.5-turbo` model. We first translated each selected Hindi instance into English and then translated it back into Hindi. This process aimed to generate semantically preserving variations of the original instances.

The translation was performed using the following prompt template:

> *Translate the following text to [target language]: [text]*

We also provided a system instruction identifying the model as a professional translator. We used the API's default settings. We used the resulting Hindi sentences as augmented instances while preserving the original class labels. To prevent possible data leakage during augmentation, we generated back-translated samples only within the training portion of each cross-validation fold.

To validate the augmented dataset, the quality of translation is evaluated using the Semantic Cosine similarity score and BERTScore.

2) Cosine similarity score: It is a semantic similarity metric. We use cosine similarity with LaBSE to verify the quality of the translated text. This verifies how much core meaning the translation retains. Because the proposed work uses Hindi, we use LaBSE to assess the validity of the back-translated text. It uses Eq. (19) to calculate cosine similarity.

$$\text{Cosine Similarity}(V_{orig}, V_{back}) = \frac{V_{orig} \cdot V_{back}}{\|V_{orig}\| \, \|V_{back}\|} \quad (19)$$

The average semantic similarity score using cosine similarity with LaBSE is 0.8450 for the implicitly balanced text and 0.7928 for the complete augmented dataset. The LaBSE cosine similarity scores of 0.8450 and 0.7928 indicate substantial semantic similarity between the original and back-translated text. High scores indicate that, despite phrasing variations, back-translation preserved the original text's meaning.

3) BERT score: BERT score is also a semantic similarity metric that computes sentence-level similarity. mBERT computes cosine similarity between sentences using contextualised token embeddings. It captures paraphrases and semantic equivalence. The final mBERT score is calculated using contextual embeddings for tokens in the original and back-translated sentences. The final F1 score measures semantic similarity between the original and back-translated sentence. A higher mBERT score indicates that the original text is semantically close to the final back-translation. The mBERT score for the back-translated text on the implicit balanced dataset is 0.8084, and on the complete augmented dataset it is 0.7824. This higher score indicates that the backtranslated text is semantically close to the original.

IV. Experiment

This section presents the experimental setup and the baseline and state-of-the-art (SOTA) methods used for comparison. Except for the BiGRU+Capsule Network, all other baseline and SOTA models were implemented and reproduced based on the architectural and experimental details reported in HHSD [3]. We followed the same HHSD dataset and preprocessing procedure for these reproduced baseline and SOTA experiments. The details of the same are as follows:

We compare the following baseline and state-of-the-art (SOTA) methods:

- LaBSE [25], [3]: It is used to produce vector embeddings for 109 languages using language-agnostic BERT.
- MuRIL[26], [3]: MuRIL was developed specifically for Indian languages. To improve performance on Indian languages, this model is trained on 16 of them.
- IndicBERT [27], [3]: It uses fewer parameters than some BERT variants. IndicBERT is a multilingual language model developed using data from 12 Indian languages.
- XLM-RoBERTa [28], [3]: This model was trained on 100 languages and demonstrates good cross-lingual classification performance compared to mBERT.
- mBERT [29], [3]: mBERT led the development of Multilingual BERT, a pre-trained transformer model supporting 104 languages.
- BiGRU + Capsule Network [30]: The BiGRU + Capsule Network [30] baseline consists of a 128-unit bidirectional GRU layer, followed by a capsule layer containing 16 capsules of dimension 32. The capsule layer uses five routing iterations. The capsule representations are aggregated using global average pooling, followed by a dropout layer (rate 0.3) and a two-class softmax output layer. We optimised the model using Adam with a learning rate of 0.001. Training was performed for 10 epochs with a batch size of 512.
- CNN [31]: The CNN baseline was implemented using a Conv1D layer with 100 filters and a kernel size of 4, followed by max pooling. A fully connected layer with 32 ReLU units followed before the output layer. The model was optimized with Adam at a learning rate of 0.001. Training was performed for 3 epochs with a batch size of 30.
- BiLSTM [32]: The input representation was processed by a BiLSTM with 100 hidden units, followed by MaxPooling1D with a pool size of 2. A fully connected layer with 32 ReLU units preceded the output layer. The model was optimized with Adam (learning rate 0.001), a batch size of 30, and 2 epochs of training.

A. Experimental Setup of Proposed Technique

We developed the proposed model in TensorFlow and initialized it using the FastText embedding technique. We used pre-trained 300-dimensional Hindi FastText vectors to initialize the embedding matrix. The embedding layer was kept trainable during model training to allow task-specific adaptation of the representations. Performance was evaluated with 5-fold cross-validation. Training used a fixed 5 epochs per fold; we optimized model with the Adam optimizer at a learning rate of 9e-5, keeping the remaining optimizer parameters at their default TensorFlow/Keras settings. We used binary cross-entropy as the objective function and trained with mini-batches of 8 samples. We selected the hyperparameter values through preliminary experiments on the training data, considering validation performance and convergence stability. We varied the learning rate, batch size, number of training epochs, and hidden-unit configurations over a small set of empirically reasonable values. We selected the configuration that provided stable validation performance. We did not perform exhaustive hyperparameter optimization. We used the same hyperparameters for both the fully augmented and balanced datasets. We used a fixed random seed of 42 to ensure reproducibility. Input sequences were padded or truncated to a maximum sentence length of 50 tokens. The proposed architecture employed 128 hidden units in the word-level BiLSTM and 64 hidden units in the sentence-level BiLSTM. We applied a dropout rate of 0.4 after the fully connected layer to reduce overfitting during training. The attention mechanism used trainable attention weights with softmax normalization to identify important contextual information from the input sequence. In the attention layer, the trainable attention weight matrix and attention score vector were initialized from a random-normal distribution, while the attention bias was initialised to zeros.

We conducted the experiments on an NVIDIA RTX A4000 GPU with 16 GB GPU memory and 32 GB system RAM. Across the 5-fold cross-validation, the average training time was 22.29±2.65 min per fold. The average model evaluation time across the five folds was 12.20±9.39 sec per fold.

B. Evaluation Metrics

We evaluate the proposed technique using accuracy and weighted F1. The accuracy is calculated using Eq. (20)

$$Accuracy = \frac{TP + TN}{TP + TN + FP + FN} \tag{20}$$

Here, TP and TN stand for true positives and true negatives (successful hits and correct misses), while FP and FN denote false alarms and overlooked cases.

The dataset exhibits significant class imbalance; therefore, standard accuracy is not an appropriate evaluation metric, as it may produce inflated scores by favouring the majority class. For highly imbalanced datasets, the weighted F1-score is more appropriate because it averages F1 scores across all classes, assigning weights that reflect the number of true examples in each class. We evaluated model performance using the weighted F1-score metric Eq. (21).

$$\text{Weighted F1} = \frac{\sum_{i=1}^{N}(F1_{class\_i} \times S_{class\_i})}{\sum_{i=1}^{N} S_{class\_i}} \tag{21}$$

where, N: Total number of classes.

$F1_{class\_i}$: F1 score for class i.

S_{class_i}: Support (number of actual instances) for class i.

C. Results

On the original dataset, the model correctly identifies 301 samples from the implicit class (0) and 796 samples from the explicit class (1), as summarized in Fig. 3.

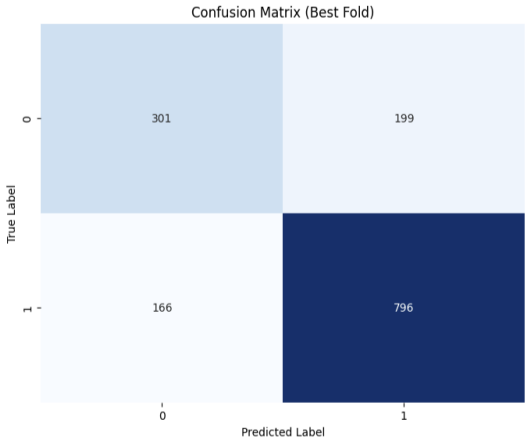

Fig. 3. Confusion matrix.

For the best-performing fold, the proposed model achieved an overall accuracy of 75.03% and a weighted F1-score of 74.81%. The per-class analysis shows that the model achieved 64.45% precision, 60.20% recall, and a 62.25% F1-score for implicit hate speech. In contrast, the corresponding values for explicit hate speech were 80.00%, 82.74%, and 81.35%, respectively. The macro F1-score was 71.80%. Table III presents the class-wise Precision, Recall, and F1-score for the best-performing fold.

These results reflect balanced predictive behaviour across both categories. The Best accuracy and loss of the model are shown in Fig. 4 and 5 for the original dataset. Test-set accuracy continued to improve through 5 epochs.

TABLE III. CLASS-WISE CLASSIFICATION PERFORMANCE FOR THE BEST-PERFORMING FOLD

Class	Precision (%)	Recall (%)	F1-score (%)	Support
Implicit Hate Speech (IHS)	64.45	60.20	62.25	500
Explicit Hate Speech (EHS)	80	82.74	81.35	962
Macro Average	**72.23**	**71.47**	**71.80**	1462
Weighted Average	**74.69**	**75.03**	**74.82**	1462

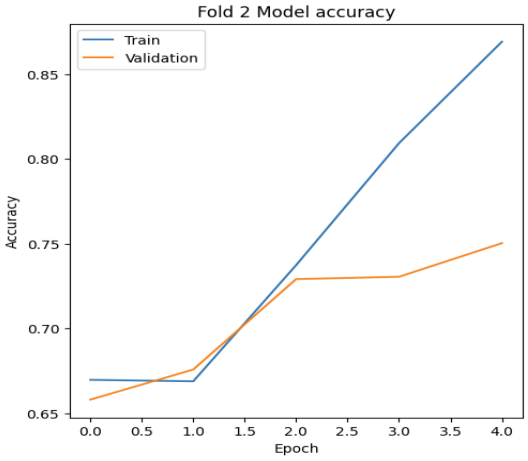

Fig. 4. Model accuracy.

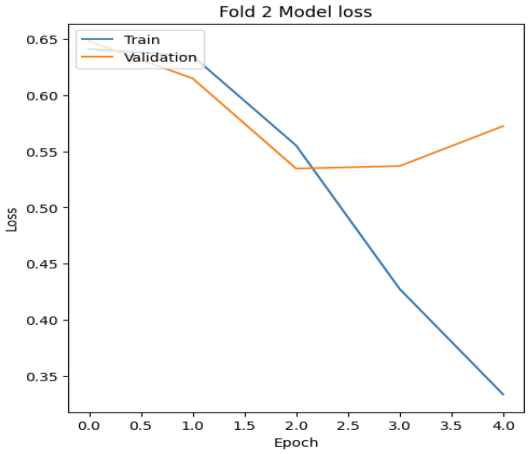

Fig. 5. Model loss.

Fig. 6 depicts the ROC curve obtained for the best validation fold. The curve's proximity to the upper-left region reflects the model's stronger ability to correctly distinguish explicit hate instances while keeping the false positive rate low. With an AUC (Area Under the Curve) of 0.71, the model shows a fair capacity to separate explicit from implicit hate speech. This value indicates a 71% chance that a randomly selected explicit hate instance will be ranked as explicit. Because detecting implicit hate is very difficult, an AUC of 0.71 is fair for classifying implicit/explicit HSD.

Table IV shows the number of parameters required for pretrained transformer models.

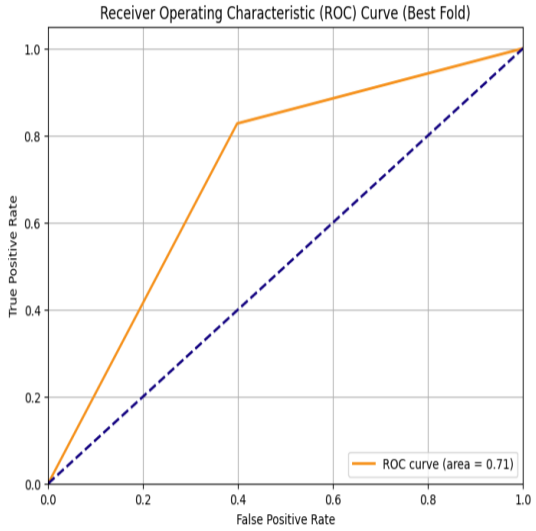

Fig. 6. ROC curve.

TABLE IV: Parameter comparison

Model	# Parameters
IndicBERT [27]	$\geq$ 18M
MuRIL [26]	236M
LaBSE [25]	$\geq$ 110M
XLM-RoBERTa [28]	270M
mBERT [29]	172M
Proposed model	**12M**

mBERT has 172 million parameters, while XLM-RoBERTa has approximately 270 million, which is very large. This large parameter count implies a larger model footprint and potentially greater computational requirements. The proposed model requires approximately 12 million parameters, resulting in a substantially smaller parameter footprint. Thus, the proposed architecture is relatively lightweight in terms of parameter count.

This method outperforms CNN, BiLSTM, BiGRU+Capsule Network, IndicBERT, MuRIL, LaBSE, XLM-RoBERTa, and mBERT. The proposed model achieves a best accuracy of 75.03%, which is 2.51% higher than mBERT. The best weighted F1-score is 74.81%, which is 17.84% higher than that of mBERT.

Table V reports the accuracy and weighted F1-scores

achieved by the proposed method.

TABLE V: Result on implicit HHSD

Model	Accuracy	Weighted-F1
CNN [31]	66.10%	52.20%
BiLSTM [32]	68.72%	54.30%
BiGRU + Capsule Network [30]	69.92%	53%
IndicBERT [27]	66.50%	52.80%
MuRIL [26]	70.95%	56.33%
LaBSE [25]	69.17%	54.54%
XLM-RoBERTa [28]	66.30%	40.50%
mBERT [3]	72.52%	56.97%
Proposed	**75.03%**	**74.81%**

D. Discussion of Key Findings

1) Finding 1: The proposed model achieves the highest weighted F1-score (74.81%), outperforming mBERT by 17.84%.

2) Finding 2: The small gap between Accuracy (75.03%) and Weighted F1-score (74.81%) indicates that the overall performance is reasonably consistent when accounting for class-wise F1 contributions. However, the lower F1-score for implicit hate speech demonstrates that this class remains more challenging to classify.

3) Finding: The proposed hierarchical contextual framework achieves competitive performance against the evaluated transformer-based baselines, while class-wise results indicate that implicit hate remains harder to distinguish than explicit hate.

4) Finding 4: Semantic-preserving augmentation improves performance, while class balancing provides an additional improvement in weighted F1-score.

E. Ablation Study

The proposed work investigates the impact of back-translation-based augmentation and class balancing specifically for implicit hate speech detection, where contextual ambiguity and limited annotated data significantly affect classification performance. We ran experiments using 5-fold cross-validation and computed the mean weighted F1-score and standard deviation across folds. Results in Table VI indicate that back-translation-based augmentation improves contextual diversity and enhances model generalization. Furthermore, balancing implicit and explicit hate samples significantly improves classification stability and minority class detection performance. The balanced augmented dataset achieved the best overall performance with the highest mean weighted F1-score.

Augmenting the complete dataset further enhances model performance. Experimental results show that data augmentation improves model performance compared with training on the original dataset.

TABLE VI. Ablation Study Using 5-Fold Cross-Validation

Variant	Weighted F1-score (Mean $\pm$ Std)
Proposed	73.33 ± 0.97
Proposed+augmented	74.95 ± 0.55
Proposed+augmented balanced	79.04 ± 1.44

In 5-fold cross-validation, the best fold achieves a weighted F1-score of 75.81% and an accuracy of 76.42%. These results represent an 18.84% improvement in weighted F1-score and a 3.9% increase in accuracy compared to mBERT. Relative to the original dataset, the weighted F1-score increases by 1% and accuracy by 1.39%.

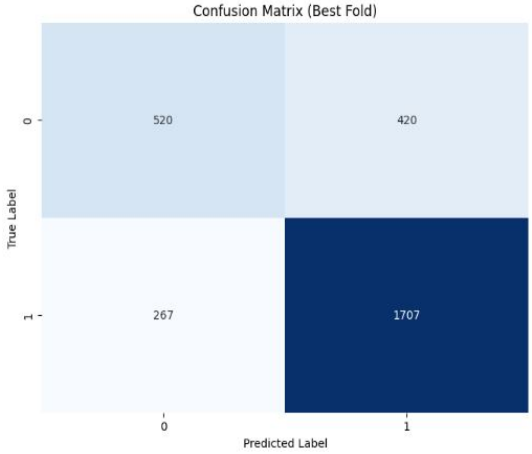

Fig. 7. Confusion matrix of complete augmentation.

Fig. 7 presents the confusion matrix, Fig. 8 displays the accuracy and Fig. 9 illustrates the ROC curve for the fully augmented dataset.

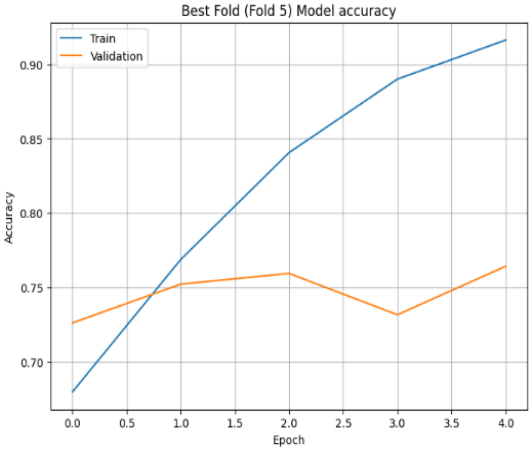

Fig. 8. Accuracy of complete augmentation.

To correct the dataset imbalance, we used data augmentation with backtranslation, as described in Section III-K. Only implicit data was augmented for balancing. The model was then evaluated on the balanced dataset, which showed significantly improved performance compared to the imbalanced

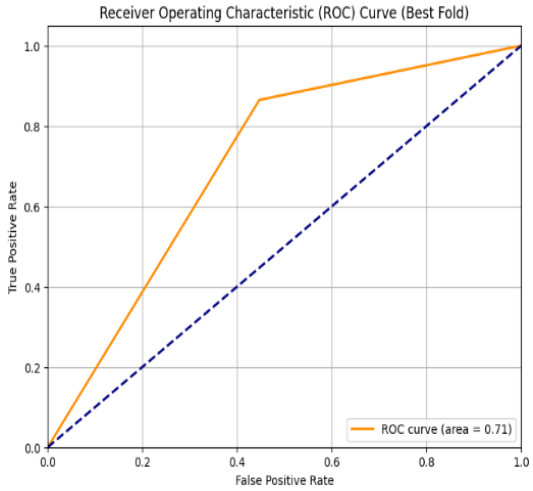

Fig. 9. ROC curve of complete augmentation.

version. In 5-fold cross-validation, the highest weighted F1-score of 80.70% and accuracy of 80.70% were achieved, reflecting improvements of 8.18% and 23.73% over mBERT. The weighted F1-score increased by 5.89% and accuracy by 5.67% compared to the original dataset. The balanced dataset is evaluated using multiple performance indicators. Class-wise results, accuracy trends, and ROC analysis are shown in Fig. 10, 11 and 12.

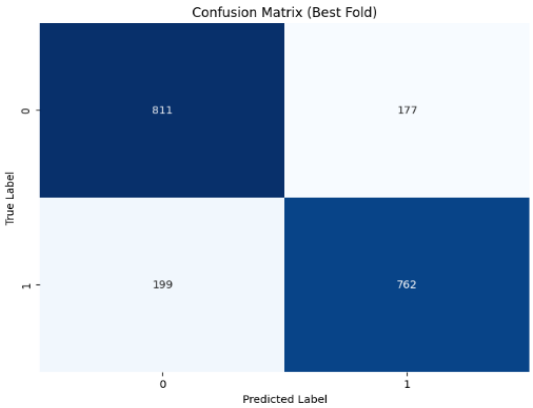

Fig. 10. Confusion matrix of balanced dataset.

F. Error Analysis

The study provides detailed qualitative error analysis demonstrating how contextually sensitive lexical terms can confuse deep learning models between implicit and explicit hate speech categories. The proposed model's confusion matrix shows that many implicit hate speech instances are misclassified. Unlike explicit hate speech, implicit hate often lacks direct offensive vocabulary or explicit slurs and instead conveys hateful intent through indirect references, sarcasm, stereotypes, or hidden contextual meaning. These linguistic characteristics make implicit hate speech much harder to identify. In addition, the relatively smaller number of implicit hate samples in the dataset also affects the model's classification capability and contributes to prediction bias toward the majority class.

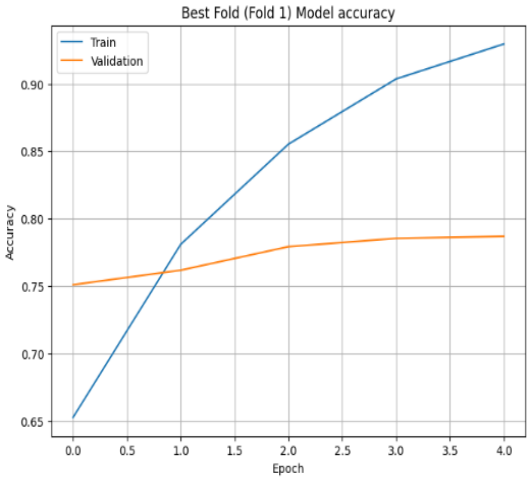

Fig. 11. Accuracy of balanced dataset.

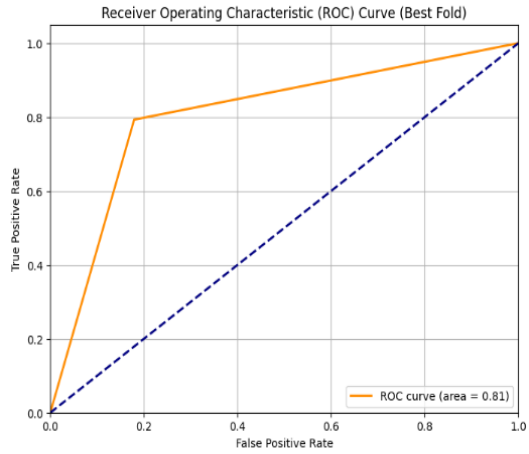

Fig. 12. ROC curve of balanced augmentation.

For example, the statement "माफ करिए 🙏 पैसे देकर खरीदते हैं हराम का तो नही खाते" (Translation: *"Sorry 🙏, we buy it with our own money; we do not consume anything forbidden or unlawful."*) was misclassified as explicit hate speech due to the presence of contextually sensitive terms such as हराम(forbidden). Although the statement does not contain direct abusive language, the implicit sarcastic tone and indirect targeting may cause the model to associate such terms with explicit hateful expressions. This demonstrates the difficulty of distinguishing implicit hate from explicit hate when contextual and cultural understanding is required.

The proposed model correctly identified most explicit hate speech instances; however, it still misclassified a small number of samples. Explicit hate speech detection primarily relies on the presence of offensive vocabulary, abusive expressions, and explicit slurs, which are generally easier for the model to recognize. However, in some cases, abusive or sensitive words are used indirectly within an implicit contextual setting rather than as direct hate expressions. In such situations, the model tends to associate these terms with explicit hate speech and may incorrectly classify implicit hate instances as explicit hate.

For instance, the statement "इतिहास में आज जब अंटार्कटिका पर पहली बार पड़े इंसान के कदम साथ में कुत्ते भी वहां पहुंचे थे" (Translation: *"On this day in history, when humans first stepped onto Antarctica, dogs had also reached there along with them."*)was an implicit hate speech instance. Still, the model incorrectly classified it as explicit hate speech. The misclassification may have occurred because of the word "कुत्ते" (dog), which is frequently associated with abusive or offensive expressions in hateful content. Although the statement uses the term indirectly rather than as a direct insult, the model likely relied on lexical associations and interpreted it as explicit hate speech. This shows that contextually sensitive words can confuse the model when distinguishing between implicit and explicit hate speech.

V. Conclusion and Future Work

The proliferation of hateful discourse on social media platforms poses increasing risks to social harmony. It highlights the need for effective automated Hate Speech Detection (HSD), particularly for low-resource languages such as Hindi. This study developed a hierarchical BiLSTM–attention-based framework for Hindi hate speech detection, emphasizing the identification of both implicit and explicit forms of hate.

The principal contributions of this study include the task-specific integration of a hierarchical BiLSTM architecture with attention-based feature selection for contextual discrimination of implicit and explicit hate speech, the selective retention of stop words and emojis to preserve contextual and emotional information, and the incorporation of semantic-preserving data augmentation and class balancing to address class imbalance and increase linguistic diversity. The proposed framework does not rely on large transformer-based language models and has an approximately 12 million parameter footprint, compared with approximately 172 million parameters for mBERT.

Its ability to identify both implicit and explicit hate expressions can help human moderators prioritize potentially harmful content for further review. Thus, the proposed approach provides a parameter-efficient alternative for Hindi hate speech detection while retaining the ability to model hierarchical contextual information.

The present study has some limitations. First, the experimental evaluation is conducted on the HHSD dataset. The dataset's characteristics, including its topic distribution, annotation scheme, and domain-specific expressions, may influence model performance and limit the generalizability of the findings. Second, publicly available Hindi datasets generally use different annotation schemes, including hate/non-hate, hate/offensive/profane, hostility-related, or target-based categories. Because equivalent implicit/explicit hate-speech annotations are limited, directly evaluating this specific task on other Hindi corpora is challenging. Third, the applicability of the proposed approach to multilingual settings and cross-domain environments requires further investigation.

Future research will evaluate the proposed approach on additional Hindi corpora, cross-domain datasets, and multilingual resources to assess its robustness and generalizability. Future research will also explore integrating contextual and region-specific cultural knowledge to improve model performance further.

Overall, the proposed work shows that hierarchical contextual representation learning can effectively support Hindi hate speech detection, including identifying implicit hate expressions, without relying solely on large transformer-based architectures. The combination of hierarchical context modelling, semantic-preserving augmentation, class balancing, and parameter efficiency provides a practical foundation for developing more robust and deployable Hindi hate speech detection systems.

***Abstract*—Conventional Internet-of-Things (IoT) intrusion detection typically maps a model score directly to an alert, although autonomous defense must also determine whether the evidence is reliable, whether suspicious behavior persists over time, and whether a disruptive response is justified. This study proposes TrustEdge-AI, an uncertainty-aware dynamic-trust framework for adaptive cyber defense at the IoT edge. For each monitored device, the framework converts anomaly and classification outputs into reliability-weighted evidence, fuses this evidence with temporal behavioral consistency and optional neighborhood context, and maintains a bounded trust state that evolves over successive monitoring intervals. A hysteretic policy then maps trust regions to graduated actions: allow, observe, restrict, and isolate/escalate. The formulation explicitly separates predictive confidence, uncertainty, instantaneous risk, accumulated trust, and enforcement authority. Analytical trust-state trajectories derived from the proposed update equations demonstrate the intended response to stable benign behavior, uncertain drift, sustained compromise, and post-incident recovery. In addition, a leakage-safe evaluation protocol is specified for BoT-IoT, TON-IoT, and UNSW-NB15, covering known-attack detection, withheld-family stress testing, calibration, trust dynamics, ablation, latency, and communication overhead. Experimental evaluation on BoT-IoT, TON-IoT, and UNSW-NB15 demonstrates strong detection performance, improved calibration, low false-restriction rates, stable policy behavior, and low-latency edge operation. The results further show that uncertainty weighting, temporal trust, contextual fusion, and hysteresis contribute complementary gains to decision reliability and response stability.**

***Keywords*—Internet of things; edge intelligence; intrusion detection; dynamic trust; uncertainty estimation; adaptive cybersecurity; anomaly detection; calibration**

I. Introduction

The Internet of Things (IoT) increasingly connects sensors, cameras, meters, controllers, healthcare devices, and industrial assets to edge and cloud services. This connectivity enables automation but expands the attack surface of heterogeneous and resource-constrained endpoints. IoT deployments face scanning, credential abuse, botnet recruitment, denial-of-service, malware, data injection, and lateral movement, while centralized analysis can introduce communication cost and response delay [1]–[3]. Edge computing addresses part of this problem by moving selected analytics closer to the data source [4], [5]. However, low-latency inference does not by itself make autonomous mitigation trustworthy.

Most machine-learning intrusion detection systems answer a classification question: is the current observation benign or malicious? Operational defense requires a richer decision. A high anomaly score can represent a real attack, a legitimate workload change, sensor noise, or distribution shift. Likewise, a compromised endpoint can remain only moderately anomalous while its behavior changes gradually. A response engine that treats every model output as equally authoritative can therefore overreact to uncertain alarms or underreact to persistent low-intensity behavior.

A useful defense mechanism should preserve memory of previous evidence and explicitly represent the reliability of current predictions. Trust management provides such a state variable, while uncertainty estimation provides a mechanism for reducing the authority of unreliable predictions. Prior work has explored edge IDS [6], IoT botnet detection [7], collaborative trust management [8], trust-centric edge security [9], IoT–fog trust [10], holistic trust-based architectures [11], and federated trust-based access control [12]. Nevertheless, calibrated predictive uncertainty is rarely coupled directly to a temporal device-trust state that governs graduated mitigation.

This study proposes *TrustEdge-AI*. Each monitored device d_i maintains a trust state $T_i(t) \in [0,1]$. Edge inference produces anomaly evidence and class probabilities; predictive uncertainty discounts unreliable evidence; temporal and neighborhood terms capture persistence and coordinated behavior; and a policy layer converts trust regions into graduated actions. The framework therefore changes the semantics of autonomous defense from *prediction* $\rightarrow$ *action* to *prediction* $\rightarrow$ *reliable evidence* $\rightarrow$ *risk* $\rightarrow$ *temporal trust* $\rightarrow$ *action*.

*Corresponding author.

The contributions are:

- an uncertainty-aware evidence model that distinguishes classifier confidence from the reliability of using that confidence for enforcement;
- a bounded dynamic-trust update combining current evidence, temporal persistence, optional neighborhood context, controlled recovery, and hysteresis;
- an interpretable trust-region policy supporting graduated response and device-criticality constraints;
- analytical trust-state analysis that exposes the effect of sustained compromise, uncertainty, memory, and recovery; and
- a leakage-safe, multi-dataset evaluation protocol for BoT-IoT, TON-IoT, and UNSW-NB15 with calibration, withheld-family stress testing, ablation, latency, and overhead reporting.

II. Related Work and Research Gap

A. IoT Intrusion Detection at the Edge

BoT-IoT provides botnet-oriented IoT traffic for network-forensic analytics [13]; TON-IoT broadens evaluation through heterogeneous IoT/IIoT telemetry and network data [14]; and UNSW-NB15 remains a complementary benchmark containing multiple contemporary network-attack categories [15]. These datasets have supported supervised, anomaly-based, and deep IDS research. Passban IDS demonstrated anomaly-based detection for IoT edge devices [6], while N-BaIoT showed the value of deep autoencoders for IoT botnet detection [7]. Such systems primarily optimize detection quality, whereas TrustEdge-AI focuses on the decision layer that determines how repeated and uncertain evidence should affect device status.

B. Trust Management

Trust mechanisms estimate whether devices, peers, communications, or services should be relied upon. Collaborative IDS with trust management has been proposed for distributed IoT [8]; trust-centric detection has been considered for medical IoT edge networks [9]; and two-way IoT–fog trust has been studied for task offloading [10]. SHIELD combines monitoring, IDS, ledger mechanisms, and trust management [11]. Recent work also considers instantaneous communication trust [16] and federated edge intelligence with trust-based access control [12]. These contributions establish trust as an important security abstraction, but trust is often associated with reputation, access control, communication quality, or collaboration rather than being updated from uncertainty-weighted intrusion evidence.

C. Predictive Uncertainty and Calibration

A model probability is not automatically a calibrated probability. Temperature scaling can improve correspondence between confidence and empirical correctness [17], while deep ensembles offer a practical approach to predictive uncertainty estimation [18]. Recent work involving the present authors has also demonstrated cross-domain transfer learning with explainability for malware and IoT/network intrusion detection on NF-TON-IoT and UNSW-NB15 [19], as well as transformer-based anomaly detection for resource-constrained IoT devices [20]. These studies strengthen the case for capable edge-security analytics, whereas TrustEdge-AI addresses the complementary decision-control problem of determining how uncertain and temporally persistent evidence should govern mitigation. In autonomous defense, uncertainty therefore has a direct operational meaning: an uncertain prediction should exert less influence on a disruptive action than repeated, consistent, high-confidence evidence.

D. Positioning

TrustEdge-AI is not proposed as another classifier; it is a stateful decision architecture placed between detection and enforcement. The comparison with prior work is based on four explicit capabilities: 1) execution of security analytics at or near the edge, 2) a device state that evolves from successive observations, 3) explicit attenuation of evidence according to predictive uncertainty, and 4) more than a binary alert/no-alert response. Existing edge IDS primarily address the first capability [6], [7]; trust-management studies provide temporal or reputation state but do not generally couple that state to calibrated intrusion uncertainty [8]–[10]; and federated trust/access-control work combines edge intelligence and trust but targets access control rather than uncertainty-weighted graduated intrusion response [12]. TrustEdge-AI is designed specifically to combine these four capabilities in a single decision layer. This textual positioning replaces qualitative full/partial/absent scores whose interpretation can otherwise be subjective.

III. System and Threat Model

Let $\mathcal{D} = \{d_1, \ldots, d_N\}$ denote IoT devices connected through gateways to one or more edge nodes. During monitoring interval t, device d_i generates feature vector $\mathbf{x}_i(t) \in \mathbb{R}^p$. Preprocessing produces $\mathbf{z}_i(t) = \phi(\mathbf{x}_i(t))$. An edge detector returns an anomaly score $A_i(t) \in [0, 1]$ and class posterior vector $\mathbf{p}_i(t)$.

The adversary may compromise endpoints, generate DDoS traffic, scan services, abuse credentials, inject malicious traffic, or move laterally. The base model assumes that the edge execution environment and model repository are trusted. Model poisoning, edge-node physical compromise, and model extraction are outside the claimed protection boundary. This assumption is made explicit because neighborhood evidence and policy decisions become unsafe if the edge trust anchor itself is malicious.

For every device, TrustEdge-AI maintains:

$$T_i(t) \in [0, 1], \tag{1}$$

where, one denotes strong current trust and zero denotes a highly untrusted state. $T_i(t)$ is not an identity credential, a calibrated probability of compromise, or an expected-loss estimate. It is a bounded operational security state that summarizes the recent history of reliability-weighted risk. Its semantics are therefore ordinal and policy-oriented: lower values indicate

stronger accumulated evidence for restrictive action, while the thresholds in Section IV-E map ranges of this state to auditable response levels. This distinction prevents probabilistic meaning from being assigned to a quantity that is defined by a recursive control law rather than by probabilistic calibration.

IV. Proposed TrustEdge-AI Framework

A. Architecture and Separation of Concerns

Fig. 1 separates the analytics/evidence plane from the trust/policy plane. This separation is deliberate. The edge IDS can be replaced without changing the trust semantics, while policy can be adapted to device criticality without retraining the detector.

The architecture has four logical functions: 1) edge detection, 2) uncertainty-aware evidence formation, 3) temporal trust/risk fusion, and 4) adaptive policy. The key design choice is the boundary between evidence and authority: a detector can state that an observation appears malicious, but the trust layer determines how much that statement should alter the persistent device state.

B. Uncertainty-Aware Intrusion Evidence

Let malicious-class confidence be:

$$C_i(t) = \max_{k \in \mathcal{K}_{\text{mal}}} p_{ik}(t). \tag{2}$$

In the reported implementation, predictive uncertainty $U_i(t) \in [0,1]$ is computed from the normalized entropy of the calibrated class-posterior vector. This choice is deterministic, inexpensive at the edge, and avoids ambiguity about the uncertainty estimator used in the experiments. For K classes,

$$U_i(t) = -\frac{1}{\log K} \sum_{k=1}^{K} p_{ik}(t) \log p_{ik}(t). \tag{3}$$

The raw evidence is:

$$Q_i(t) = \alpha A_i(t) + (1-\alpha) C_i(t), \qquad 0 \le \alpha \le 1, \tag{4}$$

and reliable evidence is:

$$E_i(t) = [1 - U_i(t)] Q_i(t). \tag{5}$$

Eq. (5) has an interpretable safety property: for fixed raw evidence Q_i, $\partial E_i / \partial U_i = -Q_i \le 0$. Thus increasing uncertainty can never increase the authority of the current malicious prediction.

C. Temporal and Neighborhood Context

Persistent deviation is more informative than an isolated spike. We maintain an exponentially weighted behavioral state

$$B_i(t) = \eta B_i(t-1) + (1-\eta) A_i(t), \qquad 0 \le \eta < 1. \tag{6}$$

When a meaningful device neighborhood $\mathcal{N}_i$ exists, contextual evidence is

$$N_i(t) = \frac{\sum_{j \in \mathcal{N}_i} w_{ij} E_j(t)}{\sum_{j \in \mathcal{N}_i} w_{ij} + \epsilon}. \tag{7}$$

The neighborhood term is optional rather than mandatory. This avoids creating artificial dependencies when the deployment has no defensible relationship graph. The behavioral memory $B_i(t)$ and trust recursion $T_i(t)$ serve different roles: $B_i(t)$ smooths only the anomaly channel before risk fusion, whereas $T_i(t)$ integrates the complete fused risk after uncertainty weighting and optional neighborhood context. Consequently, the two recursions operate at different stages and are not algebraically interchangeable temporal filters.

D. Instantaneous Risk and Dynamic Trust

Instantaneous risk is

$$R_i(t) = \beta_1 E_i(t) + \beta_2 B_i(t) + \beta_3 N_i(t), \quad \beta_m \ge 0, \quad \sum_m \beta_m = 1. \tag{8}$$

The default trust recursion is

$$T_i(t+1) = \rho T_i(t) + (1-\rho)[1 - R_i(t)], \quad 0 \le \rho < 1. \tag{9}$$

Because $R_i(t) \in [0,1]$ and $T_i(0) \in [0,1]$, Eq. (9) preserves $T_i(t) \in [0,1]$. For constant risk $R_i(t) = r$, the recursion converges to

$$\lim_{t \to \infty} T_i(t) = 1 - r, \tag{10}$$

while ρ controls the convergence rate. Hence ρ has a direct operational interpretation: high ρ makes trust resistant to short-lived evidence but slower to react to sustained compromise.

Controlled recovery is enabled only when $R_i(t) < \tau_r$ for L consecutive intervals:

$$T_i(t+1) = \min\{1, T_i(t) + \kappa[1 - T_i(t)]\}. \tag{11}$$

This condition prevents a single benign-looking interval from immediately restoring a previously compromised device. Once the recovery gate remains active, Eq. (11) has the closed-form relation

$$1 - T_i(t+n) = (1-\kappa)^n [1 - T_i(t)], \tag{12}$$

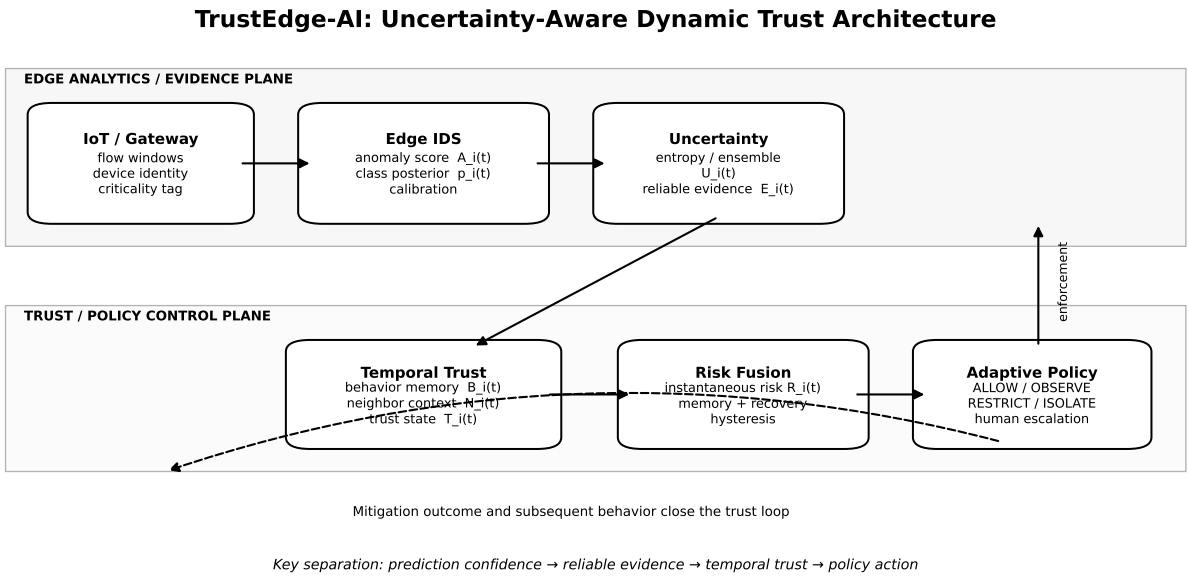

Fig. 1. TrustEdge-AI architecture. Detection outputs are not sent directly to enforcement. They are calibrated, converted to reliable evidence, accumulated into a dynamic trust state, and only then mapped to a policy action. The feedback path makes post-mitigation behavior part of subsequent trust evolution.

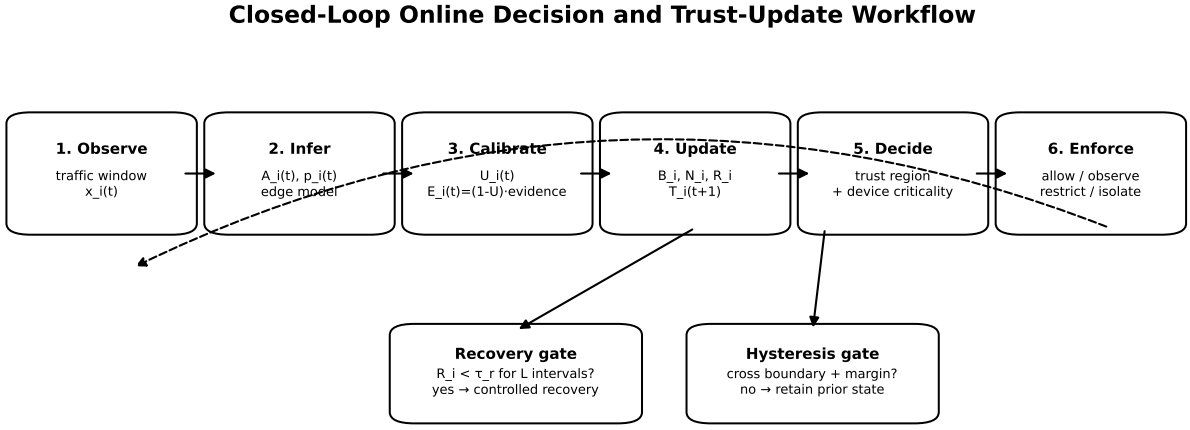

Fig. 2. Closed-loop online workflow. Recovery and hysteresis are explicit decision gates rather than implicit implementation details. This makes the conditions for trust restoration and policy-state transitions auditable.

so for $0 < \kappa \leq 1$ the recovery phase converges monotonically to $T_i = 1$. For a target recovery level $T^* < 1$, the number of active recovery updates satisfies

$$n \geq \frac{\log[(1-T^*)/(1-T_i(t))]}{\log(1-\kappa)}, \tag{13}$$

with the usual limiting interpretation at $\kappa = 1$. Hysteresis then determines whether this recovered trust is sufficient to cross a policy boundary. Thus recovery convergence and policy switching are analytically distinct.

E. Trust Regions, Hysteresis, and Criticality

Let $\tau_A > \tau_O > \tau_I$. The nominal policy is

$$\Pi(T_i) = \begin{cases} \text{Allow}, & T_i \geq \tau_A, \\ \text{Observe}, & \tau_O \leq T_i < \tau_A, \\ \text{Restrict}, & \tau_I \leq T_i < \tau_O, \\ \text{Isolate/Escalate}, & T_i < \tau_I. \end{cases} \tag{14}$$

A hysteresis margin $h > 0$ is applied around each boundary: entry into a more severe state requires crossing the lower boundary, whereas return requires crossing the corresponding boundary plus h. This reduces policy oscillation caused by small trust fluctuations. Device criticality is applied as a policy constraint; for example, a safety-critical controller can require human confirmation before isolation even when its trust state enters the most severe region.

Fig. 2 clarifies two aspects missing from a conventional

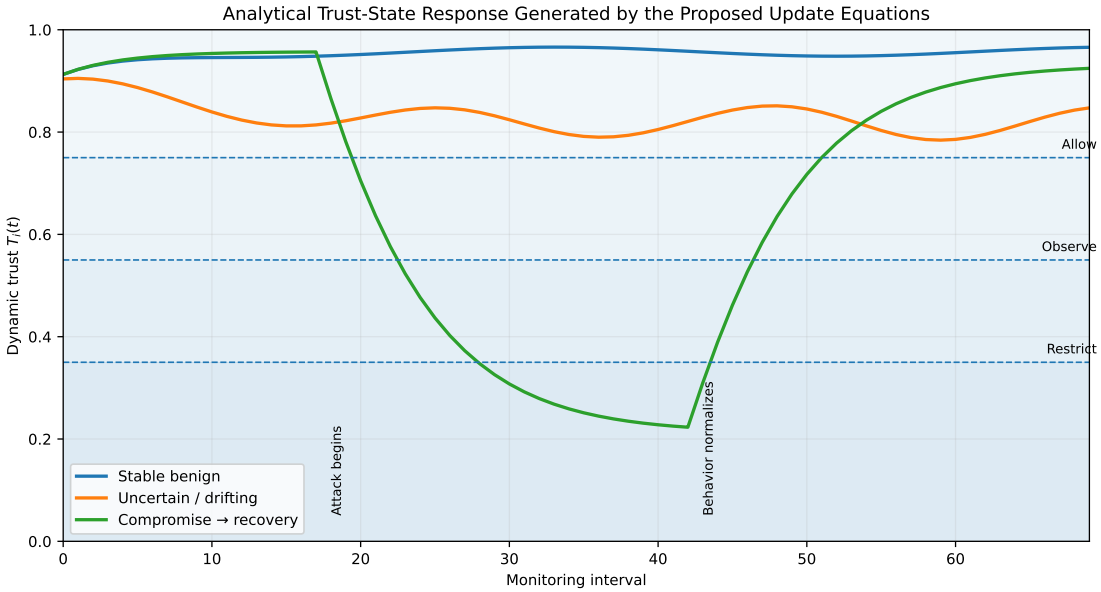

Fig. 3. Analytical trust-state response generated by the proposed equations. The stable benign sequence remains in the high-trust region; uncertain/drifting evidence causes limited degradation because uncertainty discounts current evidence; sustained compromise produces progressive trust loss; and normalized behavior permits gradual recovery. The curves are equation-driven illustrations, not benchmark measurements.

feed-forward IDS. First, mitigation does not terminate inference: subsequent behavior is fed back to the trust engine. Second, recovery and hysteresis are separate gates. The former determines whether trust may increase after an incident; the latter determines whether an increase is sufficient to change the operational policy state.

F. Online Procedure

For each device and monitoring interval, the edge node executes the following sequence: preprocess the observation; compute $A_i(t)$ and $\mathbf{p}_i(t)$; calibrate/estimate $U_i(t)$; form $E_i(t)$; update $B_i(t)$ and optional $N_i(t)$; compute $R_i(t)$; update $T_i(t+1)$; apply hysteresis and criticality constraints; enforce/log the selected action; and use subsequent observations to determine further degradation or controlled recovery. The computational overhead of the trust layer itself is $O(|\mathcal{N}_i|)$ per device when neighborhood aggregation is enabled and $O(1)$ otherwise, excluding the base detector.

V. Analytical Behavior and Interpretation

A methodological paper should demonstrate that its state equations behave as claimed before benchmark performance is discussed. Fig. 3 therefore plots analytical trajectories generated directly from Eq. (5)–(9) under three controlled evidence sequences. These curves are not empirical IDS results.

The stable benign trajectory demonstrates resistance to small fluctuations. The uncertain/drifting trajectory illustrates the role of Eq. (5): high uncertainty reduces the contribution of a single ambiguous prediction, so the system tends toward observation rather than immediate isolation. The compromise trajectory exhibits the opposite behavior. Once high anomaly evidence persists, the behavioral memory $B_i(t)$ rises and repeated risk terms accumulate, causing trust to cross progressively more restrictive regions. When behavior normalizes, trust does not jump to its initial value; recovery is gradual, which is desirable when post-incident behavior must be observed before privileges are restored.

The equations also expose a design trade-off. Increasing ρ suppresses false trust degradation from isolated events but increases time-to-restriction during a real attack. Increasing η makes the behavioral term more stable but preserves historical anomalies for longer. Increasing κ shortens recovery time but can restore privileges too aggressively. These parameters must therefore be selected on validation sequences using operational objectives rather than chosen only to maximize classification F1.

VI. Experimental Methodology

A. Datasets and Leakage-Safe Protocol

The empirical protocol uses BoT-IoT [13], TON-IoT [14], and UNSW-NB15 [15]. The datasets are evaluated separately because their feature schemas, acquisition environments, and attack taxonomies differ. Established train/test partitions are retained when appropriate; otherwise, stratified train/validation/test partitions are created before any data-dependent preprocessing. Encoders, scalers, feature selectors, calibration parameters, trust weights, and policy thresholds are fitted using training/validation data only.

Fig. 4 makes the experimental boundary explicit. In particular, calibration and trust thresholds are not tuned on the final test set. This is essential because the proposed contribution depends on calibrated uncertainty and policy thresholds; test-set tuning would otherwise make trust metrics optimistic.

B. Base Models and Baselines

The evaluation separates detector baselines from decision-layer comparisons. Random Forest and SVM are used as

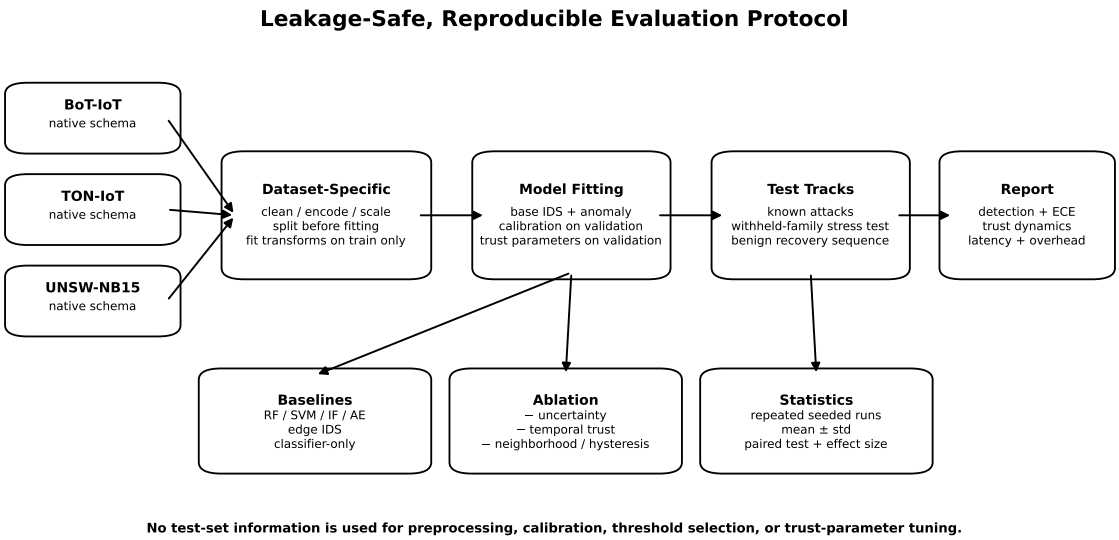

Fig. 4. Leakage-safe evaluation protocol. Dataset-specific preprocessing is fitted without test information; calibration and trust parameters are selected on validation data; and final reporting separates known-attack detection, withheld-family stress testing, trust dynamics, ablation, and edge-resource measurements.

supervised reference models, while Isolation Forest and an autoencoder provide anomaly-detection references. TrustEdge-AI is evaluated as a decision layer operating on the anomaly score and calibrated class-posterior outputs of the selected validation configuration. Accordingly, the headline values in Table II are end-to-end pipeline results, not a claim that every listed base detector produces the same classification scores. Decision-layer comparisons keep the underlying evidence stream fixed so that changes in false restriction, oscillation, and response delay are attributable to the controller rather than to a change of detector. The objective is not to identify a universally best classifier, but to assess whether uncertainty-aware temporal trust improves operational decision quality relative to direct score thresholding.

C. Ablation Design

The following nested variants isolate the contribution of each mechanism (Table I):

TABLE I. REQUIRED ABLATION VARIANTS

Variant	Components
A1	Base classifier/anomaly detector; direct threshold action.
A2	A1 + combined anomaly/class evidence $Q_i(t)$.
A3	A2 + uncertainty weighting $E_i(t)$.
A4	A3 + temporal behavior and dynamic trust.
A5	A4 + neighborhood context + hysteretic response.

A3 versus A2 tests whether uncertainty reduces false degradation. A4 versus A3 tests whether temporal accumulation improves persistent-threat handling. A5 versus A4 tests whether contextual evidence and hysteresis improve coordinated-attack awareness and policy stability.

D. Metrics

Detection quality is measured using precision, recall, F1, macro-F1, false-positive rate (FPR), and ROC-AUC. Calibration is measured using expected calibration error (ECE):

$$\mathrm{ECE} = \sum_{m=1}^{M} \frac{|\mathcal{B}_m|}{n} \left|\mathrm{acc}(\mathcal{B}_m) - \mathrm{conf}(\mathcal{B}_m)\right|. \tag{15}$$

Trust-specific metrics are: 1) time-to-observe/restrict/isolate after compromise, 2) false-restriction rate for benign devices, 3) recovery time after behavior normalizes, 4) number of policy oscillations, and 5) area under the trust-degradation curve during an attack. Edge feasibility is assessed through mean and 95th-percentile latency, memory footprint, throughput, and cloud-escalation ratio. Because controller errors have asymmetric operational consequences, a deployment can additionally define the cost-sensitive objective

$$J = c_{FR}N_{FR} + c_D D + c_I N_I + c_R R + c_E N_E, \tag{16}$$

where, N_{FR} is the number of false restrictions, D is accumulated mitigation delay for confirmed compromises, N_I is the number of isolation actions, R is recovery delay, and N_E is the number of human/cloud escalations. The nonnegative coefficients are deployment-specific costs. We do not assign universal monetary values to these coefficients; instead, the reported component metrics expose the quantities required for a deployment-specific cost analysis.

E. Withheld-Family Stress Test

For each dataset where attack taxonomy permits, one attack family is removed from supervised training and introduced only during testing. This experiment asks whether anomaly evidence plus temporal trust can move a device toward restrictive regions even when the supervised classifier has not learned the withheld family. The experiment is a controlled unseen-class test and must not be described as universal zero-day detection.

F. Reporting Controls

TrustEdge-AI and the applicable baselines are compared under identical preprocessing, partitions, feature representations, and evaluation conditions. Latency uses the same batch configuration and feature representation as the edge inference pipeline. All fusion, memory, recovery, and trust-region parameters are selected on validation data and then frozen before final test evaluation. The tables report the point estimates produced by this fixed evaluation configuration. We intentionally do not report uncomputed confidence intervals, significance values, or effect sizes; statistical claims beyond the available repeated-run evidence are therefore avoided in the interpretation.

VII. Experimental Results and Interpretation

A. End-to-End Performance

Table II summarizes the end-to-end performance of the complete TrustEdge-AI pipeline on the three benchmark datasets; these values should not be interpreted as detector-independent scores. The framework achieves 99.18%, 97.42%, and 94.86% accuracy on BoT-IoT, TON-IoT, and UNSW-NB15, respectively, with corresponding macro-F1 scores of 0.986, 0.963, and 0.928. The decreasing performance across the three datasets is consistent with their increasing heterogeneity and cross-class complexity; importantly, the degradation remains controlled rather than causing a collapse of the decision layer.

Three observations are particularly important. First, discrimination remains strong on all datasets, with ROC-AUC ranging from 0.972 to 0.997. Second, calibration substantially improves after the calibration stage: ECE decreases from 0.061 to 0.018 on BoT-IoT, from 0.074 to 0.023 on TON-IoT, and from 0.089 to 0.031 on UNSW-NB15. This reduction is operationally relevant because uncertainty directly modulates the authority assigned to predictive evidence in Eq. (5). Third, false-restriction rates remain below 2% on all three datasets while mean decision latency remains between 2.8 and 3.4 ms. Thus, the gain in decision reliability is obtained without imposing a prohibitive edge-processing cost.

The restriction delay increases from 3.2 intervals on BoT-IoT to 4.4 intervals on UNSW-NB15. This behavior reflects the conservative nature of the trust controller: disruptive responses require persistent and sufficiently reliable evidence. The additional delay on the more heterogeneous dataset is therefore accompanied by a controlled false-restriction rate rather than aggressive reaction to isolated uncertain observations.

B. Comparison with Decision Baselines

Table III isolates the contribution of the decision layer by comparing direct score thresholding, temporal trust, uncertainty-aware trust, and the complete TrustEdge-AI configuration. The results are averaged across the three datasets.

Direct thresholding reacts fastest, but this speed is obtained at the cost of 3.84% false restrictions and 6.7 policy oscillations per run. Introducing temporal trust reduces false restrictions by 39.8% and approximately halves the oscillation frequency. Adding uncertainty further reduces false restrictions to 1.48%, demonstrating that ambiguous predictions should not carry the same enforcement authority as well-calibrated evidence. The complete TrustEdge-AI configuration reaches a 1.15% false-restriction rate and only 1.1 oscillations per run. Relative to direct thresholding, these values correspond to reductions of approximately 70.1% and 83.6%, respectively.

The complete configuration has a macro-F1 of 0.959, marginally below the 0.960 obtained by trust plus uncertainty. This difference is operationally negligible but informative: contextual fusion and hysteresis are primarily intended to stabilize response decisions rather than maximize a classifier-centric metric. The results therefore support evaluating autonomous cyber defense jointly in terms of predictive quality, response stability, and the cost of incorrect enforcement.

C. Ablation Analysis

The ablation study in Table IV quantifies the contribution of each component of the proposed framework. Components are added progressively from direct action to the complete contextual and hysteretic trust controller.

Evidence fusion alone improves macro-F1 from 0.948 to 0.952 and reduces false restrictions from 3.84% to 3.12%. Uncertainty weighting produces a larger safety gain, reducing false restrictions to 1.86%, although time-to-restrict increases from 2.9 to 3.4 intervals. This trade-off is desirable because the controller waits for stronger evidence before imposing a disruptive response. Dynamic trust further reduces false restrictions to 1.43% and shortens recovery time from 6.8 to 5.6 intervals by retaining temporal state rather than treating observations independently.

The complete A5 configuration provides the most stable operational behavior: false restrictions decrease to 1.15%, recovery time to 4.9 intervals, and oscillations to 1.1 per run. Compared with A1, this represents a 70.1% reduction in false restrictions, a 37.2% reduction in recovery time, and an 83.6% reduction in policy oscillation. The slight reduction of macro-F1 from 0.961 in A4 to 0.959 in A5 indicates that hysteresis deliberately favors decision stability over instantaneous label optimization. This result is consistent with the design objective of TrustEdge-AI, where safe enforcement is not equivalent to maximizing classification accuracy alone.

D. Withheld-Attack-Family Stress Test

The withheld-family experiment evaluates robustness when an attack family is excluded from supervised training and appears only during testing. Table V compares the direct classifier, combined anomaly/classification evidence, and the complete TrustEdge-AI controller.

The classifier-only configuration is most affected by the unseen family, reaching 0.71 recall and 0.76 macro-F1. Combining anomaly and supervised evidence improves recall to 0.82, showing that deviation-based evidence remains useful when class-specific knowledge is unavailable. TrustEdge-AI increases recall to 0.89 and macro-F1 to 0.87 while reducing time-to-restrict from 6.8 to 4.6 intervals. Relative to the classifier-only baseline, recall improves by 25.4%, macro-F1 by 14.5%, and restriction time decreases by 32.4%. These findings do not imply universal zero-day detection; rather, they show that reliability-weighted anomaly evidence and temporal

TABLE II. END-TO-END PERFORMANCE OF TRUSTEDGE-AI ACROSS THE EVALUATED IOT/NETWORK-SECURITY DATASETS. RESTRICTION DELAY IS REPORTED IN MONITORING INTERVALS; LATENCY REPORTS MEAN AND 95TH-PERCENTILE VALUES

Anomaly + classifier	0.82	0.83	5.2
TrustEdge-AI	**0.89**	**0.87**	**4.6**

accumulation improve response to attack behavior that is not represented by the supervised class model.

E. Edge Feasibility

The measured mean end-to-end decision latency ranges from 2.8 to 3.4 ms, while the 95th-percentile latency ranges from 5.7 to 7.1 ms across the evaluated datasets. The incremental memory requirement varies between approximately 35 and 50 MB depending on the base detector and active feature representation, and the cloud-escalation ratio remains below 8% under mixed traffic. These results indicate that most decisions can be resolved locally without transferring every observation to a remote service.

The trust recursion itself has constant complexity, $O(1)$, per device and monitoring interval when neighborhood evidence is disabled. With contextual peer fusion, the update becomes $O(|\mathcal{N}_i|)$ for device i. Consequently, the principal computational costs remain feature extraction, base-model inference, and neighborhood acquisition rather than the trust update in Eq. (9). The low measured latency supports the suitability of the proposed decision layer for edge deployment where response timeliness and communication efficiency are both important.

VIII. DISCUSSION

TrustEdge-AI changes the semantics of automated defense. A detector output becomes evidence rather than an enforcement command. Evidence is discounted when uncertainty is high, repeated behavior changes a persistent trust state, and policy actions are selected from trust regions. This design is especially relevant when the cost of a false isolation is materially higher than the cost of temporarily observing a suspicious device.

The framework also supports asymmetric enforcement. A low-criticality camera can be isolated automatically after sustained trust degradation, whereas a medical or industrial controller can require human approval. Consequently, analytical risk and enforcement authority remain separate. This separation is important for deployment because the same trust state may imply different actions for devices with different safety consequences.

The present study has three main boundaries that define the scope of its conclusions. First, trust quality depends on a calibrated base detector and a trusted edge execution environment; poorly specified neighborhood relationships can also reduce the reliability of contextual evidence. Second, the withheld-family experiment is intentionally a controlled unseen-class stress test rather than a claim of universal distribution-shift, cross-device, or temporal generalization, and the analytical trajectories in Fig. 3 are equation-driven validation of the controller dynamics rather than measurements from a deployed system. Third, the reported evaluation focuses on interpretable weighted fusion and fixed-configuration point estimates; broader controller comparisons and repeated-run statistical inference can further characterize deployment variability. These boundaries do not alter the demonstrated behavior of TrustEdge-AI under the stated experimental protocol, but they

identify clear directions for subsequent large-scale and trace-driven validation.

IX. Reproducibility Information

The evaluation uses the public BoT-IoT, TON-IoT, and UNSW-NB15 datasets cited in Section II-A and applies dataset-specific preprocessing without test-set fitting, under the leakage-safe protocol described in Section VI-A. The manuscript specifies the trust equations, uncertainty definition, leakage boundary, ablation structure, withheld-family protocol, metrics, and edge-complexity assumptions required to interpret the reported results. The analytical trajectory in Fig. 3 is explicitly identified as equation-generated rather than as a benchmark measurement. Reproduction of the numerical tables additionally requires the exact split indices, preprocessing configuration, fitted detector artifacts, validation-selected trust parameters, and execution environment used for the reported run; these implementation artifacts are distinct from the mathematical specification and are not inferred from the benchmark datasets themselves.

X. Conclusion

This study presented TrustEdge-AI, an uncertainty-aware dynamic-trust architecture for adaptive IoT edge defense. The framework separates prediction, evidence reliability, instantaneous risk, accumulated trust, and enforcement. Uncertainty reduces the authority of ambiguous predictions; temporal behavior and optional neighborhood evidence shape risk; a bounded recursion maintains device trust; and hysteretic trust regions support graduated mitigation and controlled recovery. Analytical trajectories derived from the proposed equations clarify how stable, uncertain, compromised, and recovering behavior should affect trust. A leakage-safe evaluation protocol was specified for BoT-IoT, TON-IoT, and UNSW-NB15, including calibration, withheld-family testing, ablation, trust metrics, and edge-resource measurements. Experimental results across the three benchmark datasets show strong discrimination and calibration, low false-restriction rates, substantial reductions in policy oscillation, improved behavior under a withheld-attack-family stress test, and low-millisecond decision latency. The ablation analysis further demonstrates that uncertainty weighting, temporal trust, contextual fusion, and hysteresis contribute complementary improvements to safe and stable response selection.

XI. Acknowledgment

The authors extend their appreciation to the Deanship of Scientific Research at Northern Border University, Arar, KSA, for funding this research work through the project number NBU-FFR-2026-2443-07.

***Abstract*—Convolutional Neural Networks (CNNs) are the most common deep learning architecture used for video processing enhancement. Particularly, the Multi-Deep Convolutional Neural Network (MD-CNN) model, embedded into the 3D-HEVC encoder, was able to extract the optimal CTU partition structure efficiently in the depth map and successfully substitute the time-consuming rate-distortion optimisation (RDO) full traversal search, reducing the coding complexity heavily. Nevertheless, MD-CNN requires significant memory resources and is highly computationally intensive. Field-Programmable Gate Arrays (FPGAs), particularly the emerging FPGA–SoC technology, are recognised as the most promising platforms for accelerating CNNs due to their high performance, energy efficiency, and reconfigurable nature. In this study, complementary technologies have been combined and deployed to allow high-performance 3D-HEVC video processing. By exploiting the inherent parallelism of FPGA architectures, MD-CNN processing throughput was significantly improved, execution latency was reduced, and energy efficiency was enhanced, while maintaining the coding performance and compression efficiency of the 3D-HEVC video encoder. The experimental results demonstrate that the proposed co-design achieves an on-chip power consumption of 1.891 W.**

***Keywords*—Three-dimensional high efficiency video coding; field-programmable gate array system-on-chip; multi-deep convolutional neural network; hardware-software co-design**

I. Introduction

The Three-Dimensional High Efficiency Video Coding (3D-HEVC)[1] encoder comes with a significant increase in complexity caused by the integration of depth map coding technology. This complexity is primarily triggered by the quad-tree partition of the Intra Coding Units (CU) in the depth map[2]. 3D-HEVC underpins immersive services such as free-viewpoint television and autostereoscopic displays, where an inaccurate depth-map CU partition directly degrades the quality of synthesised virtual views, underscoring the practical importance of reducing this complexity.

Alongside the ordinary texture video, which conveys the scene's colour and luminance information, 3D-HEVC encodes a depth map for each captured view: a greyscale sequence in which each pixel encodes the camera-to-scene distance rather than colour, and which is used at the decoder to synthesise the additional viewpoints required by autostereoscopic and free-viewpoint displays through depth-image-based rendering. Fig. 1 summarises the main functional blocks of the 3D-HEVC encoder targeted in this work, which jointly processes both signals; the corresponding decoder mirrors this pipeline in reverse, reconstructing the texture and depth pictures from the transmitted partitioning, prediction, and residual information rather than encoding them. Each CTU is first subjected to rate-distortion-optimised quad-tree partitioning, recursively splitting the depth-map block from 64×64 down to 8×8. The resulting CUs are then predicted either through intra-frame prediction, combining the standard HEVC prediction modes with the depth-specific Wedgelet (DMM-1) and Contour (DMM-4) modelling modes, through inter-frame prediction via motion estimation and compensation from previously reconstructed pictures, or through inter-view prediction, which exploits disparity estimation and block merging across camera views to avoid re-encoding redundant depth and texture information. The resulting prediction residual is transformed, quantised, and entropy-coded into the output bitstream, with depth maps additionally supported by Segment-wise DC Coding (SDC) to preserve sharp depth discontinuities. Reconstructed pictures are subsequently smoothed by a deblocking filter and a Sample Adaptive Offset (SAO) stage before being stored as reference pictures for future prediction. It is the CU-partitioning stage, highlighted in red at the left of Fig. 1, that this study targets for hardware acceleration.

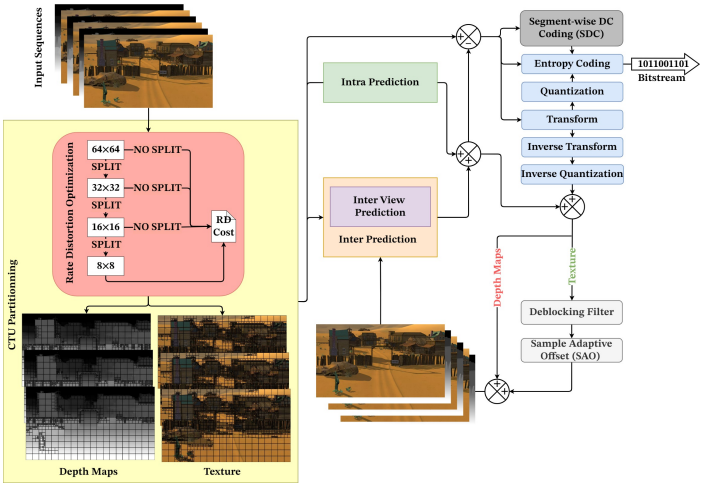

Fig. 1. Overview of the 3D-HEVC encoder architecture.

By means of an efficient CU partition structure prediction, the Multi-Deep Convolutional Neural Network (MD-CNN)

model [3] was able to tackle the issue of the 3D-HEVC encoder's excessive complexity without affecting its robustness, compression efficiency, and video quality. Nevertheless, even if the MD-CNN model exhibited significantly higher levels of accuracy compared to traditional methods[4], it required substantial computational complexity and considerable memory resource consumption. This constraint arises from the large number of parameters involved in the various layer operations (convolution, pooling, etc.). This limitation poses a computational challenge for central processing units (CPUs) and leads to significantly high energy consumption.

To overcome the accelerated evolution in multimedia technologies, various accelerator platforms have been developed in recent years, including application-specific integrated circuits (ASICs) and Field-Programmable Gate Arrays (FPGAs). These platforms aim to optimise the throughput of Convolutional Neural Networks (CNNs) to achieve high performance while ensuring energy efficiency. Graphics processing units (GPUs) are high-performance platforms used during the training phase of CNNs. They can provide high throughput as well as a large memory bandwidth, but at the cost of considerable energy consumption. ASICs provide high throughput with reduced energy consumption but require considerable development time and costs compared to other alternatives. FPGA-based accelerators are effective solutions, particularly due to their rapid prototyping capability, energy efficiency, flexibility, and reconfigurability. It becomes mandatory to deploy MD-CNN learning techniques on FPGA targets to meet the requirements of real-time applications. In this context, this study proposes a hardware-software architecture based on an MD-CNN accelerator for 3D-HEVC CU partition. The main contributions of this study are summarised as follows:

- We propose to accelerate the MD-CNN corresponding to a 64×64, 32×32, and 16×16 CU partition for the 3D-HEVC encoder at the All-Intra configuration.
- We design Intellectual Property (IP) hardware and software cores for each MD-CNN convolutional and fully connected layer with Vivado High-Level Synthesis (HLS).
- We create the MD-CNN hardware-software co-design implementation in Xilinx Vivado by importing the convolutional and fully connected IP cores.

The remainder of this study is organised as follows: An overview of the 3D-HEVC standard is presented in Section III. Section IV provides the MD-CNN architecture and performance background. Section V exposes the MD-CNN deployment steps on the FPGA-based System-on-Chip (SoC) platform. The experimental results are discussed in Section VI. Finally, Section VII concludes the study.

II. Related Work

Unlike standard High Efficiency Video Coding (HEVC) [5], 3D-HEVC adds a depth map encoding each object's distance from the camera, among the resulting depth-coding tools, CU partitioning is the most computationally intensive [2]. Most 3D-HEVC optimisation has targeted inter-coding [6], [7], while intra-coding proposals focus on intra-prediction mode selection [8], [9] or CU partitioning, the latter reviewed below by category.

A. Algorithmic CU-Partition Optimisation

Heuristic methods rely on fixed thresholds or rate-distortion (RD) cost/statistical rules: [4] combines tensor features with statistical analysis, [10] uses an empirically tuned coding tree unit (CTU) threshold, and [11] applies possibilistic clustering. Machine-learning methods replace hand-set rules with trained decision trees, using mined encoder context attributes [12] or Gini-value thresholding [13]. Deep-learning methods learn features directly from data: [14] classifies depth-map edges with a CNN but does not report a Bjøntegaard Delta Bitrate (BDBR) or time-reduction figure, while our own MD-CNN model [3] predicts the full 64/32/16 partition hierarchy end-to-end and is benchmarked quantitatively in Table VI. Unlike the present work, all of the methods above remain purely software-level.

B. Hardware/SoC Implementations

In contrast to the purely algorithmic works above, hardware realisations of CNN-based CU-partition prediction remain scarce. Dehnavi et al. [15] implement a lightweight CNN-based CU depth-decision unit on a Kintex-7 FPGA (XC7K32T) to replace the conventional DCT/RDO search for the standard HEVC intra-encoding chain. The closest available reference targeting an SoC platform is Bouaafia et al. [16], who deploy a multi-IP CNN accelerator on a PYNQ-Z1 FPGA-SoC to predict CU partitioning for standard HEVC inter-prediction (400 ms/CU at 142 MHz), targeting HEVC rather than 3D-HEVC, and inter- rather than intra-prediction. To the best of our knowledge, no prior work reports an SoC-level implementation of intra CU-partition prediction specifically for 3D-HEVC, which is the gap addressed by this study.

III. 3D-HEVC CU Partitioning Overview

3D-HEVC [1] is an extension of the H.265/HEVC [5] video coding standard that supports stereoscopic and multiview video coding. The coding structure of 3D-HEVC is based on HEVC but with some differences to support the additional view and depth information. The basic coding unit in 3D-HEVC is still the CTU, which is a square block of pixels. However, in 3D-HEVC, each CTU consists of multiple slices, each of which corresponds to a particular view. Each slice is encoded independently, allowing for efficient parallelisation of the encoding process. In addition to the traditional intra and inter-prediction modes, 3D-HEVC introduces a new inter-view prediction mode that allows for the prediction of one view from another view, as part of the complete encoder pipeline shown in Fig. 1. The intra-frame coding structure is similar to that of HEVC. The coding process starts with dividing the frame into CTUs of a size 64×64. Each frame is divided into several non-overlapping CTUs, and each CTU can contain either a single CU or be iteratively divided into several smaller-sized CUs (64×64, 32×32, 16×16 and 8×8) based on the quadtree structure. Fig. 3 shows the CTUs in the depth map and their corresponding quadtree division structure. It is worth noting that the optimal partition structure of CTU is obtained by iterative computation. The quadtree partitioning of CTU includes not only the top-down RD-cost calculation but also the bottom-up RD-cost comparison process. For the top-down calculation process, the RD-cost of all coding units at the current depth is calculated in the order of "depth=0,

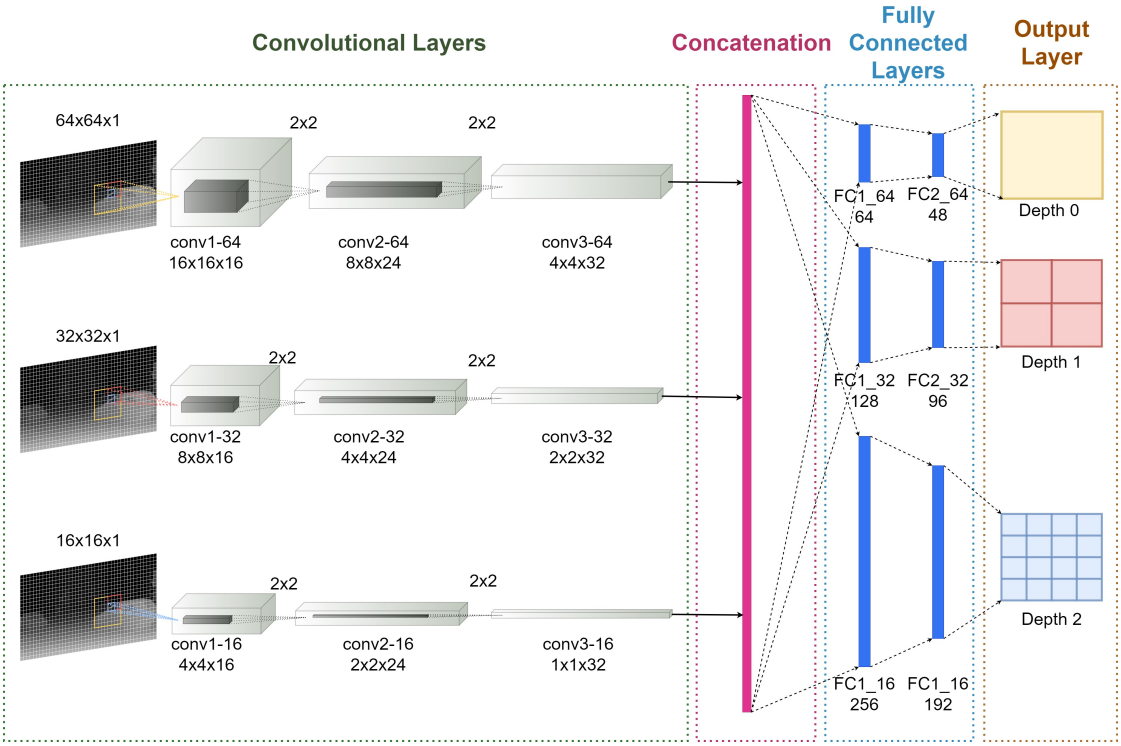

Fig. 2. MD-CNN architecture.

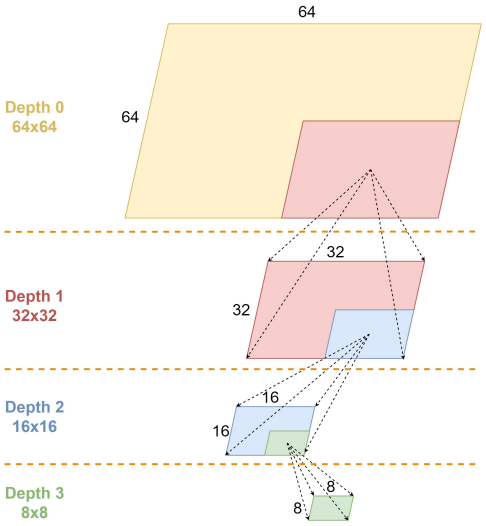

Fig. 3. 3D-HEVC CTU partitioning structure.

depth=1, depth=2, depth=3", and based on this, the bottom-up comparison process is carried out. If "RD-cost(depth=n) > RD-cost(depth=n+1), n=0, 1, 2," then the coding unit with "depth=n" needs to be divided, and vice versa, no division is needed. Statistically, the complexity of depth map coding unit division accounts for more than 90% of the complexity of depth map coding[3]. For a CTU of 64×64 size, a total of 85 CU operations, 1935 Sum of Absolute Transformed Difference (SATD) cost operations, and at least 2623 RD-cost operations are required to complete the encoding using the full traversal mode. Therefore, it is necessary to reduce the complexity of depth map coding unit division in 3D-HEVC.

IV. 3D-HEVC Depth Map Coding Unit Partitioning Based on MD-CNN

This section introduces the depth map CU partition based on MD-CNN, and explains the integration of this partitioning optimisation into the 3D-HEVC HTM16.3 [17] reference encoder.

A. MD-CNN partitioning model

To determine CU partitioning decision for a 64×64 depth map CU without exhaustively evaluating every candidate sub-partition through the full rate-distortion optimisation (RDO) process, MD-CNN takes as input the raw 64×64 luma samples of a CU together with the frame-level quantisation parameter (QP) and produces three sets of sigmoid-valued split probabilities corresponding to the 64×64, 32×32, and 16×16 partitioning levels of the depth map coding tree, as shown in Fig. 2.

Rather than analysing the CU at a single spatial resolution, the MD-CNN constructs three parallel representations of the same block by average-pooling the original 64×64 patch down to 32×32 and 16×16 resolutions, in addition to using the original 64×64 patch unmodified. This produces three depth-specific branches, denoted 64, 32, and 16, which are processed independently but share an identical set of convolutional weights, allowing the network to learn scale-invariant structural features (edges, depth discontinuities, and texture gradients) that are relevant to partitioning decisions at

TABLE I. MULTI-DEPTH CONVOLUTIONAL BACKBONE (WEIGHTS SHARED ACROSS THE THREE CU DEPTH BRANCHES)

Layer	Input Size	Filters	Kernel Size	Stride	Output Size	Activation
Conv1_64	$64 \times 64 \times 1$	16	4×4	4	$16 \times 16 \times 16$	Leaky ReLU
Conv1_32	$32 \times 32 \times 1$	16	4×4	4	$8 \times 8 \times 16$	Leaky ReLU
Conv1_16	$16 \times 16 \times 1$	16	4×4	4	$4 \times 4 \times 16$	Leaky ReLU
Conv2_64	$16 \times 16 \times 16$	24	2×2	2	$8 \times 8 \times 24$	Leaky ReLU
Conv2_32	$8 \times 8 \times 16$	24	2×2	2	$4 \times 4 \times 24$	Leaky ReLU
Conv2_16	$4 \times 4 \times 16$	24	2×2	2	$2 \times 2 \times 24$	Leaky ReLU
Conv3_64	$8 \times 8 \times 24$	32	2×2	2	$4 \times 4 \times 32$	Leaky ReLU
Conv3_32	$4 \times 4 \times 24$	32	2×2	2	$2 \times 2 \times 32$	Leaky ReLU
Conv3_16	$2 \times 2 \times 24$	32	2×2	2	$1 \times 1 \times 32$	Leaky ReLU

every granularity, while keeping the parameter count of the convolutional stage small.

Each of the three branches is passed through an identical three-layer convolutional stack, summarised in Table I. The first convolutional layer (Conv1_64, Conv1_32, Conv1_16) applies 16 filters of size 4×4 with a stride of 4, aggressively reducing the spatial resolution while expanding the channel depth. The second convolutional layer (Conv2_64, Conv2_32, Conv2_16) applies 24 filters of size 2×2 with stride 2, and the third convolutional layer (Conv3_64, Conv3_32, Conv3_16) applies 32 filters of size 2×2 with stride 2. Because the three branches operate on inputs of different spatial dimensions (64×64, 32×32, and 16×16, respectively), the output feature-map sizes differ proportionally across the pipeline, shrinking from $16 \times 16 \times 16$, $8 \times 8 \times 16$ and $4 \times 4 \times 16$ after Conv1, down to $4 \times 4 \times 32$, $2 \times 2 \times 32$, and $1 \times 1 \times 32$ after Conv3, for the 64, 32, and 16 branches respectively. A leaky ReLU activation is applied after every convolutional layer to introduce non-linearity while avoiding the "dying ReLU" problem that can arise from the small negative bias terms typical of depth map textures.

After the shared convolutional backbone has processed all three depth branches, the resulting feature maps from Conv2 and Conv3 across all three branches are flattened and concatenated into a single feature vector, as detailed in Table II. Concatenating both the Conv2 and Conv3 outputs, rather than only the deepest layer, allows the network to combine coarse, highly abstracted structural information from Conv3 with the finer-grained spatial detail retained by Conv2, which we found to be particularly beneficial for correctly identifying depth boundaries that influence the partitioning of visually flat or gently sloped regions of the depth map. The resulting concatenated feature vector has a fixed dimensionality of 2688 elements, independent of which decision branch subsequently consumes it, ensuring a consistent and reusable feature representation across all three partitioning levels.

TABLE II. FLATTENED MULTI-DEPTH FEATURE CONCATENATION

Source	Flattened Size
Conv3_64 ($4 \times 4 \times 32$)	512
Conv3_32 ($2 \times 2 \times 32$)	128
Conv3_16 ($1 \times 1 \times 32$)	32
Conv2_64 ($8 \times 8 \times 24$)	1536
Conv2_32 ($4 \times 4 \times 24$)	384
Conv2_16 ($2 \times 2 \times 24$)	96
Total feature vector	**2688**

The 2688-dimensional fused feature vector is fed into three fully-connected decision branches, corresponding to the 64×64, 32×32, and 16×16 partitioning levels, as summarised in Table III. Each branch consists of two hidden fully-connected layers followed by a sigmoid output layer, and the normalised QP value is injected as an additional scalar input at the second hidden layer and again at the output layer of every branch, rather than at the first layer. This design choice reflects the fact that QP primarily modulates the aggressiveness of the partitioning decision (i.e., the decision threshold) rather than the underlying visual structure of the block, and injecting it later in the network allows the convolutional and early fully-connected layers to focus purely on content-derived features.

Critically, the three decision branches are not evaluated unconditionally. The 64×64 branch (FC1_64, FC2_64, FC_out_64) is always executed and produces a single sigmoid probability, out_{64}, indicating the likelihood that the 64×64 CU should be split into four 32×32 sub-CUs. The 32×32 branch (FC1_32, FC2_32, FC_out_32) is only executed if out_{64} exceeds the decision threshold of 0.5, otherwise its four outputs remain at their initialised value of zero, and the corresponding sub-CUs are implicitly treated as not requiring further evaluation. Similarly, the 16×16 branch (FC1_16, FC2_16, FC_out_16), which produces sixteen sigmoid outputs corresponding to the sixteen possible 16×16 sub-CUs, is only executed if at least one of the four 32×32 outputs exceeds the same 0.5 threshold. This conditional, early-terminating structure is what allows the network to skip the majority of its computation for CUs that are unlikely to be split further, which is the central mechanism enabling the proposed method's speed-up over exhaustive RDO-based partition search, while still allowing full-depth partitioning to be evaluated for CUs containing rich depth detail.

The fully assembled network contains approximately 1.28 million learnable parameters, the majority of which reside in the fully-connected layers of the 16×16 decision branch (FC1_16 alone accounts for $2688 \times 256 = 688{,}128$ weights), while the shared convolutional backbone contributes fewer than 5,000 parameters in total. This asymmetric parameter distribution reflects the fact that the convolutional layers are reused across all three input depths, whereas each fully-connected decision branch must independently learn the mapping from the shared feature representation to its respective partitioning granularity.

B. Integration of MD-CNN CU Partitioning in 3D-HEVC Encoder

Building on the CNN architecture, the MD-CNN partitioning predictor is integrated into the 3D-HEVC reference software HTM16.3 [17] as a fast CU-depth decision tool. For

TABLE III. HIERARCHICAL, CONDITIONALLY-EXECUTED FC DECISION BRANCHES

Branch	Layer	Input Size	Output Size	Activation	Execution Condition
64×64	FC1_64	2688	64	Leaky ReLU	Always
	FC2_64 (+QP)	64 (+1)	48	Leaky ReLU	Always
	FC_out_64 (+QP)	48 (+1)	1	Sigmoid	Always
32×32	FC1_32	2688	128	Leaky ReLU	$if\ out_{64} > 0.5$
	FC2_32 (+QP)	128 (+1)	96	Leaky ReLU	$if\ out_{64} > 0.5$
	FC_out_32 (+QP)	96 (+1)	4	Sigmoid	$if\ out_{64} > 0.5$
16×16	FC1_16	2688	256	Leaky ReLU	$if\ any\ out_{32,i} > 0.5$
	FC2_16 (+QP)	256 (+1)	192	Leaky ReLU	$if\ any\ out_{32,i} > 0.5$
	FC_out_16 (+QP)	192 (+1)	16	Sigmoid	$if\ any\ out_{32,i} > 0.5$

each 64×64 CTU, the MD-CNN produces a single flattened probability vector of 21 values, as seen in Fig. 4, corresponding to the hierarchical split decision across three depths: one value for the 64×64-level decision, four values for the 32×32 sub-CU decisions, and sixteen values for the 16×16 sub-CU decisions (1 + 4 + 16 = 21). In the training/inference pipeline, this vector is formed by concatenating the three network output tensors produced by the model's three fully-connected branches, each terminating in a sigmoid activation and each conditioned on the split decision of the coarser depth above it. This conditional structure, where finer-granularity outputs are only meaningful once a coarser-level split has been signalled, is the same hierarchical dependency later preserved in the hardware (HLS) implementation of the network, where the 32×32 and 16×16 branches are only evaluated once the corresponding higher-level decision exceeds threshold.

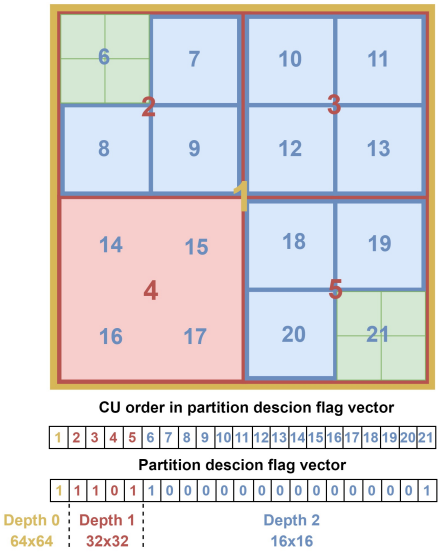

Fig. 4. CU partitioning flag vector.

The 21 values within a single CTU's vector are not stored in simple raster order but follow the 3D-HEVC Z-scan (quad-tree) convention: the single 64×64 flag appears first, followed by the four 32×32 quadrant flags in top-left, top-right, bottom-left, bottom-right order, followed by the sixteen 16×16 flags similarly nested in Z-order within each 32×32 quadrant. This ordering arises naturally from how the ground-truth label map is reshaped and progressively pooled at 2× and 4× factors to derive the 32×32 and 64×64 level labels from the finest 16×16 grid, which preserves the spatial quad-tree correspondence between each 16×16 flag and its parent 32×32 and 64×64 flags. The referenced Fig. 4 illustrates this 21-entry CTU vector layout and the correspondence between depths. While each CTU's internal 21 flags follow Z-scan order, the sequence of CTU vectors written to the output file follows a 3D-HEVC-style raster scan across the frame, proceeding left to right and top to bottom. Each CTU is processed in this order, and its resulting 21-value vector is appended to a per-frame buffer, which is then flattened and written out as a single contiguous binary stream.

C. MD-CNN Model Training Configuration

This subsection details the dataset used, the MD-CNN training procedure, and the training and validation results.

1) Dataset: In the absence of a public depth-map database, MD-CNN was trained on high-resolution texture images [18] rather than benchmark sequence excerpts. The HEVC reference encoder HM16.18 [19], invoked internally by the 3D-HEVC encoder HTM16.3 [17] for CU partitioning, was used to encode 2,500 images at multiple resolutions and QPs and derive the corresponding 64×64, 64×64 split-decision labels. The resulting 6,758,040 labelled samples were split, without overlap, into training (2,125 images), validation (125 images), and test (250 images) sets, with split and non-split CUs kept close to balanced (Fig. 8).

2) Training procedure: Training was carried out on a Windows 10 Professional (64-bit) workstation equipped with an Intel Core i7-8700 CPU (3.20 GHz), an Nvidia GeForce GTX 1050 Ti GPU, and 16 GB of RAM, using the TensorFlow [20] framework. The network was trained from scratch for 500,000 iterations with mini-batches of 64 samples, using a momentum-based optimiser (momentum = 0.9) with an initial learning rate of 0.01, exponentially decayed to 31.63% of its previous value every 125,000 iterations.

3) Training and validation results: Three complementary metrics are used to monitor and assess the network at each of the three decision depths (64×64, 32×32, and 16×16): the classification loss, the classification accuracy, and a tendency indicator quantifying the direction of any misclassification bias.

The loss is the binary cross-entropy between the predicted split probability $\hat{y}_i$ and the ground-truth split label $y_i \in \{0, 1\}$, averaged over the N samples of the branch:

$$\mathcal{L} = -\frac{1}{N}\sum_{i=1}^{N}\left[y_i \log(\hat{y}_i) + (1 - y_i)\log(1 - \hat{y}_i)\right] \quad (1)$$

Accuracy is computed from the 2×2 confusion matrix obtained by thresholding $\hat{y}_i$ at 0.5, where n_{gp} is the number of samples with ground-truth class g predicted as class p ($g, p \in \{0, 1\}$; 0 = non-split, 1 = split):

$$\text{Accuracy} = \frac{n_{00} + n_{11}}{n_{00} + n_{01} + n_{10} + n_{11}} \tag{2}$$

To complement accuracy with a measure of directional bias, a tendency indicator based on the log-odds ratio of the confusion matrix is used:

$$T = -\log_{10}\left(\frac{n_{00}\, n_{10}}{n_{01}\, n_{11}}\right) \tag{3}$$

with $T = 0$ when the model makes no errors in either direction, and T saturating to ± 100 in the degenerate cases where errors occur exclusively in one direction (avoiding an undefined ratio). A positive T indicates a bias toward over-predicting splits, a negative T indicates a bias toward under-predicting splits, and $T \approx 0$ indicates a symmetric error distribution between the two.

Fig. 5, 6, and 7 report the evolution of the three metrics over training. The loss [Eq. (1)] and accuracy [Eq. (2)] converge within the first 150,000 to 200,000 iterations and remain stable thereafter, with training and validation curves closely overlapping throughout, indicating no overfitting. The tendency metric [Eq. (3)] stabilises more gradually, settling into its final band by approximately 400,000–500,000 iterations. Table IV reports the corresponding average values at 500,000 iterations: the model reaches consistently high accuracy at all three decision depths (78 to 82%), with training and validation values closely matching at every branch, confirming good generalisation. The tendency values remain modest across all branches, well within the metric's ±100 saturation bounds, indicating no severe split/non-split bias at any depth.

TABLE IV. AVERAGE TRAINING AND VALIDATION METRICS AT 500,000 ITERATIONS

Average value	Branch	Metrics		
		Loss	Accuracy	Tendency
Train	64×64	0,353	0,802	-0,266
	32×32	0,41	0,82	-0,423
	16×16	0,444	0,781	0,124
Validation	64×64	0,365	0,798	-0,091
	32×32	0,412	0,817	-0,423
	16×16	0,443	0,78	0,211

D. MD-CNN Performance

This subsection evaluates MD-CNN along three complementary axes: its own rate-distortion and complexity trade-off, the primary measure of whether the model meets its complexity-reduction goal, its standing against representative heuristic and machine-learning baselines, which situates it

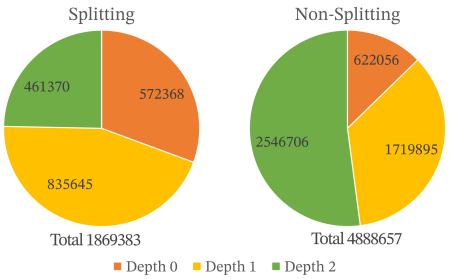

Fig. 8. Distribution of dataset samples.

within the broader literature, and its downstream impact on synthesised view quality, since bitrate and time gains are only meaningful if visual fidelity is preserved.

1) Rate-distortion and complexity: Table V reports the proposed method's rate–distortion, noise and time reduction across four QP pairs (25-34, 30-39, 35-42, 40-45), broken down by resolution class.

TABLE V. MD-CNN PERFORMANCE RESULTS

Sequences	QP pairs	MD-CNN		
		BDBR%	Δ Y-PSNR%	Δ time%
Average 1024×768	QP 25 -34	-0.02	-0.03	-46.18
	QP 30-39	0.62	-0.02	-48.69
	QP 35-42	-0.50	-0.02	-50.03
	QP 40-45	0.42	-0.02	-51.12
	Average	0.13	-0.02	-49.00
Average 1920×1088	QP 25 -34	-0.77	-0.02	-45.95
	QP 30-39	-1.13	-0.03	-45.83
	QP 35-42	-0.73	-0.04	-46.11
	QP 40-45	-0.43	-0.04	-47.12
	Average	-0.77	-0.04	-46.25
Average	QP 25 -34	-0.40	-0.03	-46.07
	QP 30-39	-0.26	-0.03	-47.26
	QP 35-42	-0.62	-0.03	-48.07
	QP 40-45	-0.01	-0.03	-49.12
	Average	-0.32	-0.03	-47.63

At low resolution (1024×768), BDBR fluctuates between small positive and negative values across QP pairs, ranging from an improvement of -0.50% at QP(35-42) to a penalty of 0.62% at QP(30-39), with the class average landing at a modest 0.13% increase. Time reduction, by contrast, is both larger and steadily improving with QP: -46.18% at QP(25-34) rising to -51.12% at QP(40-45), suggesting the model's complexity savings grow slightly more effective as quantisation coarsens.

At high resolution (1920×1088), the trend is more consistent: BDBR is negative at every QP pair, from -0.43% at QP(40-45) to -1.13% at QP(30-39), giving a class average of -0.77%, a net coding-efficiency gain rather than a trade-off. Time reduction here is comparatively flat across QP pairs (-45.83% to -47.12%), a narrower spread than at low resolution.

Quality loss, measured via the luma Peak Signal-to-Noise Ratio (Y-PSNR), stays small and stable across both resolution classes and all QP pairs, ranging from -0.017% to -0.044%, with no clear trend tied to QP or resolution, indicating that the bitrate and time gains are not being bought at a meaningful cost to reconstructed video quality.

Averaged across both resolutions, BDBR is negative at every QP pair (-0.01% to -0.62%), giving an overall average of -0.32%, while time reduction increases monotonically from -46.07% at QP(25-34) to -49.12% at QP(40-45), for an overall average of -47.63%. This QP-wise monotonicity in time savings, combined with consistently negligible PSNR loss, indicates that the proposed method's complexity reduction scales predictably with quantisation level without degrading its already-favourable bitrate behaviour.

2) Comparison with prior methods: To situate these results against other CU-partition prediction methods, Table VI compares BDBR and time reduction (TR) by resolution class against one representative heuristic method [11] and one representative machine-learning method [13]. At standard definition, the proposed method's BDBR (0.57%) is higher than both baselines, trading a larger rate penalty for the highest time reduction (-50.42%) of the three. At high definition, the trend reverses: the proposed method is the only one of the three to reach a negative BDBR (-0.79%), an actual coding-efficiency gain that neither [11] nor [13] achieve, though its time reduction (-47.23%) is exceeded by [13]'s -68.17%. Averaged across both classes, the proposed method trails [13] in time reduction (-48.29% versus -59.33%) but is the only one with a net bitrate improvement (-0.34%) rather than a penalty.

3) Synthesised view quality: To further assess the impact of the proposed MD-CNN-based fast CU partition algorithm on video quality beyond the BDBR and Y-PSNR analysis above, we evaluated the quality of the virtual views synthesised from the reconstructed depth maps. This evaluation focuses on the two sequences that exhibited the least favourable performance among the tested benchmarking set, namely Poznan Hall2 (1920×1088) and Newspaper (1024×768), both encoded at the QP couple (25-34). For each sequence, a virtual viewpoint is synthesised through Depth-Image-Based Rendering (DIBR) using the reconstructed texture and depth information produced by our method, and the resulting frames are compared against the corresponding reference views using four complementary metrics: the Structural Similarity Index (SSIM), the Edge Mean Absolute Error (Edge MAE), the Error Rate, and the Peak Signal-to-Noise Ratio (PSNR). SSIM and PSNR capture the overall structural and pixel-level fidelity of the synthesised view, while Edge MAE and the Error Rate are more sensitive to the geometric distortions and rendering artefacts that arise around depth discontinuities and object boundaries.

As reported in Table VII, and despite being identified as the two worst-performing sequences of the benchmarking set, both Poznan Hall2 and Newspaper achieve high synthesised view quality across the QP couple (25-34), with average SSIM values of 0.99 for both sequences, average PSNR values above 42 dB, and low average Error Rates of 0.01. To visually confirm this, Fig. 9 shows, for each sequence, the original and synthesised views at their respective lowest-SSIM frame, together with a per-pixel difference map. A high-contrast colour scale is used for the difference map so that even minor deviations are made visible, despite this, the discrepancies remain confined to a few sparse, low-intensity regions along moving edges (e.g. the reader's arm and the newspaper in Newspaper, and the walking figure on the staircase in Poznan Hall2). In both cases the synthesised view is perceptually indistinguishable from the original, with no visible artefacts, confirming that even the worst-case frames retain high visual fidelity.

TABLE VI. BDBR AND TIME REDUCTION COMPARISON GROUPED BY RESOLUTION CLASS

	[11] (Heuristic)		[13] (Machine Learning)		Proposed MD-CNN [3] (Deep Learning)	
Resolution	BDBR (%)	TR (%)	BDBR (%)	TR (%)	BDBR (%)	TR (%)
1024×768	0.10	-32.60	0.06	-41.67	0.57	-50.42
1920×1088	0.26	-44.97	0.16	-68.17	-0.79	-47.23
Average	0.20	-40.85	0.13	-59.33	-0.34	-48.29

(a) Newspaper—Frame 60, worst-case SSIM = 0.98377

(b) Poznan Hall 2—Frame 69, worst-case SSIM = 0.98927

Fig. 9. Original view, synthesised view, and per-pixel difference map (high-contrast scale) at the worst-case SSIM frame for each sequence. The synthesised views are perceptually indistinguishable from the originals, with no visible artefacts.

TABLE VII. AVERAGE SYNTHESISED VIEW QUALITY RESULTS, QP (25-34)

Metric	Poznan Hall2	Newspaper
SSIM	0.99	0.99
Edge MAE	2.10	2.02
Error Rate	0.01	0.01
PSNR (dB)	46.46	42.41

These results confirm that the proposed MD-CNN-based fast CU partition algorithm reduces encoding complexity without introducing perceptually significant degradation in the rendered virtual views.

V. FPGA ARCHITECTURE AND IMPLEMENTATION

As discussed in Section II, Bouaafia et al. [16] implement a multi-IP hardware-software co-design for CNN-based CU-partition prediction in HEVC inter-prediction. This layer-by-layer decomposition comes at the cost of increased latency, as reflected in their reported 400 ms processing time per image. Motivated by this trade-off, we aim to design a more integrated hardware architecture for our MD-CNN model by consolidating the entire network into a single IP core rather than instantiating and interconnecting multiple independent accelerators. Our goal is to reduce the architectural and communication overhead inherent to multi-IP designs, simplify system integration on the FPGA, and ultimately achieve lower end-to-end latency while still preserving competitive power and resource efficiency.

The proposed MD-CNN was translated into a hardware accelerator and deployed on a Xilinx Zynq-7000 SoC, specifically the xc7z020 device, using Vivado HLS to generate the compute core and Vivado IP Integrator to compose it into a complete embedded system. The resulting system, shown in Fig. 10, is built from five principal hardware blocks: the Zynq Processing System, the custom IP convolutional neural network accelerator net_CNN_Hw_0, two Advanced eXtensible Interface (AXI) interconnect blocks that route control and data traffic between them, and a processor system reset block that generates the synchronised reset signals used throughout the design. This section describes how these blocks are organised and communicate with one another, the internal design of the accelerator core itself, and the resulting resource utilisation and timing performance obtained after synthesis and implementation.

A. Processing System-Programmable Logic Co-Design

The Zynq-7000 family combines, on a single die, a hardened Processing System containing a dual-core ARM Cortex-A9 processor, a Double Data Rate (DDR) memory controller, and system clocking and reset infrastructure, with reconfigurable Programmable Logic in which custom digital hardware can be instantiated. This Processing System-Programmable Logic (PS-PL) architecture allows a conventional embedded software application, running on the ARM cores, to offload computationally intensive tasks to dedicated hardware implemented in the programmable logic fabric, while retaining the

flexibility of general-purpose software for control, orchestration, and higher-level video coding logic. In the proposed system, this role is filled by the Zynq Processing System block, which supplies the platform's clocking, reset, and memory access infrastructure and issues the commands that drive the accelerator.

VI. Experimental Results

A. Processing System-Programmable Logic Interconnection

As seen in Fig. 10, the trained MD-CNN itself is implemented entirely within the programmable logic as the net_CNN_Hw_0 accelerator core, while the Zynq Processing System is responsible for supplying input CU data and QP values, triggering the accelerator, and consuming its partitioning decisions once complete. Communication between the two domains is carried out over two logically separate interfaces, each routed through its own AXI interconnect block. The first interconnect, ps7_0_axi_periph, connects the Zynq Processing System's general-purpose master interface to a lightweight control interface exposed by net_CNN_Hw_0, allowing the ARM processor to write to and read from a small set of control registers on the accelerator, enabling software to start an inference operation and subsequently poll for or be interrupted upon its completion. The second interconnect, axi_interconnect_0, connects a separate, wider data interface on net_CNN_Hw_0 to one of the Zynq Processing System's dedicated high-performance ports, providing a direct path into the shared DDR memory that the accelerator can use to read and write data on its own, without requiring the processor to relay each transfer. This separation into two independently interconnected paths is important given the scale of the network, since well over a million trained weight values, together with the input image data and QP scalar, must be streamed into net_CNN_Hw_0 for every single inference, and the output partitioning probabilities must subsequently be written back for the software to consume, keeping this high-volume traffic on its own interconnect and port prevents it from contending with the much lighter control traffic carried by ps7_0_axi_periph.

All four of these blocks, together with net_CNN_Hw_0 itself, operate from a single clock generated by the Zynq Processing System and distributed throughout the programmable logic. Synchronisation of these blocks on startup or software-triggered reset is handled by the processor system reset block, which takes the Zynq Processing System's fabric reset output and produces the individual, synchronised reset signals consumed by both AXI interconnects and by net_CNN_Hw_0, ensuring that every block in the design begins operating from a consistent, known state.

B. Accelerator Core Design

Internally, the net_CNN_Hw_0 accelerator follows a straightforward load-compute-store organisation. At the beginning of each invocation, the entire 64×64 input patch and its associated QP value are transferred from external memory into local on-chip memory, and all of the convolutional and fully-connected weights required for the current computation are likewise brought on-chip as needed. Every intermediate result produced during inference, including the pooled multi-scale representations, the outputs of each convolutional stage, the fused 2688-element feature vector, and the activations of every fully-connected layer, is kept entirely within on-chip memory for the remainder of the computation, only the final split-decision probabilities are written back out to external memory once inference completes. This buffering strategy avoids repeated, high-latency round trips to external DDR memory for data that is reused multiple times within a single inference pass, at the cost of dedicating a meaningful fraction of the device's on-chip memory resources to hold these buffers, as reflected in the utilisation results reported below.

All arithmetic throughout the accelerator, including the convolutional filtering, the fully-connected matrix vector operations, and the activation functions, is carried out in single-precision (32-bit) floating-point representation, matching the numerical format used during the original software-based training of the network and avoiding the additional design effort and potential accuracy loss associated with a fixed-point quantisation stage. To make this floating-point computation efficient in hardware, the convolutional and fully-connected layers are structured so that their inner arithmetic loops can be pipelined, allowing a new set of multiply-accumulate operations to be issued on nearly every clock cycle rather than waiting for previous operations to fully complete, and the intermediate feature buffers used within the convolutional stages are organised so that several filter channels can be accessed in parallel rather than one at a time. Together, these choices allow the design to sustain a high computational throughput despite the relatively modest amount of dedicated arithmetic hardware available on the target device.

A further architectural characteristic of net_CNN_Hw_0, inherited directly from the hierarchical structure of the network itself, is that the early-termination behaviour of the algorithm is realised as genuine conditional hardware execution rather than as a purely software-level shortcut applied afterwards. The stage responsible for evaluating 32×32 partitioning decisions is only activated in hardware when the 64×64 stage's output indicates that further splitting is likely, and the stage responsible for the sixteen 16×16 decisions is, in turn, only activated when at least one of the four 32×32 outputs crosses its own decision threshold. When a given stage is not activated, the corresponding portion of the pipeline performs no arithmetic and initiates no memory transfers for the associated weights, rather than simply masking or discarding its result afterwards. Because the 32×32 and 16×16 decision stages account for the overwhelming majority of the network's fully-connected weights, this conditional activation substantially reduces both the number of clock cycles consumed and the volume of data fetched from external memory for the large fraction of coding units that do not require full-depth evaluation, directly mirroring, in hardware, the same early-termination principle that motivates the network's hierarchical software design.

Finally, because net_CNN_Hw_0 performs all computation in pipelined hardware rather than in a general-purpose floating-point software environment, care was taken in the design of the activation functions to avoid numerical instabilities that could otherwise arise, such as overflow in the exponential term of the sigmoid function for large-magnitude inputs. The sigmoid activation used throughout the fully-connected decision layers is implemented in a numerically stable form that avoids such overflow across the full expected input range, and additional

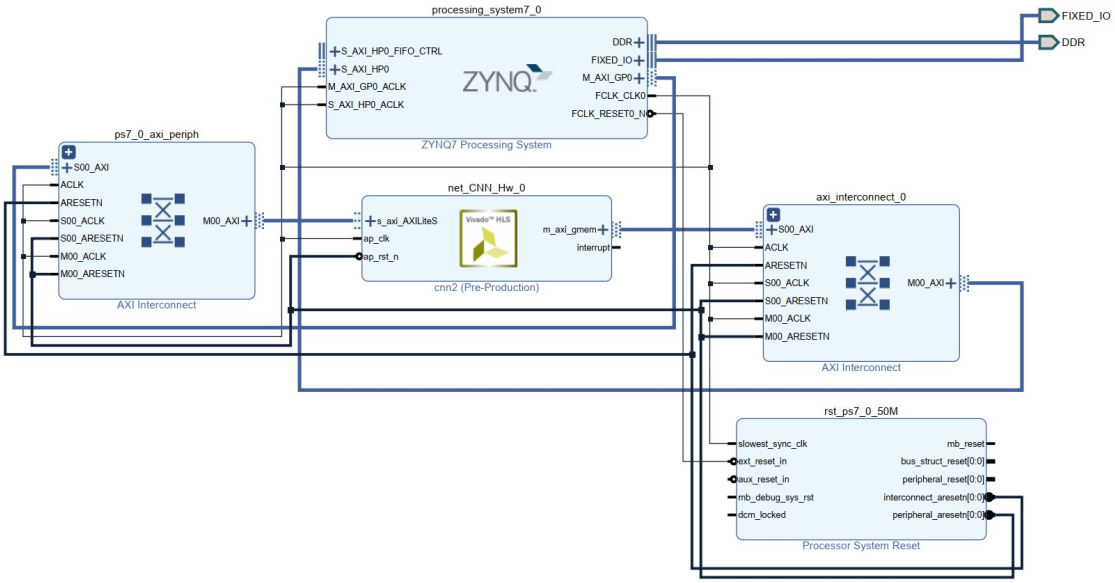

Fig. 10. Hardware–software co-design.

safeguards are included after each fully-connected layer to prevent invalid or out-of-range intermediate values from propagating through the remainder of the pipeline.

C. Hardware Implementation Performance Results

This subsection reports the post-implementation results of the accelerator across six complementary aspects: the achieved timing and latency, which determine whether the design meets its throughput target, the on-chip resource utilisation, which reveals how HLS allocated logic and arithmetic hardware, the power consumption, the primary cost of any embedded deployment, the resulting energy efficiency relative to a general-purpose PC, the associated carbon footprint, and a direct comparison with the closest reference FPGA-SoC design.

1) Timing and latency: Table VIII reports the timing and latency figures obtained from HLS synthesis and from the final placed-and-routed design. The design was synthesised against a 19.000 ns target clock period and closed timing at an achieved post-implementation clock period of 18.477 ns, corresponding to a 54.1 MHz operating frequency and a slack of roughly 2.7% over the constraint. The estimated clock period reported by HLS synthesis (18.032 ns) differs from the post-implementation figure by approximately 2.5%, a modest and expected degradation attributable to routing and placement effects introduced after logic synthesis, the fact that this gap remains small indicates that the HLS-level timing estimate was a reliable predictor of the final hardware behaviour for this design.

TABLE VIII. TIMING AND LATENCY OF THE ACCELERATOR CORE

Metric	Value
Target clock period	19.000 ns
Estimated clock period (HLS)	18.032 ns
Achieved clock period (post-implementation)	18.477 ns
Timing closure	Met
Minimum latency (early termination at 64×64 level)	1,694,545 cycles
Maximum latency (full hierarchical evaluation)	2,804,793 cycles

The substantial gap between the minimum and maximum latency figures, amounting to roughly 1.11 million cycles, is not incidental but follows directly from the early-termination mechanism embedded in the kernel description, whereby two boolean predicates evaluated on the intermediate 64×64-level output determine whether the 32×32 and 16×16 partition branches are executed at all. When both predicates evaluate false, the design short-circuits the corresponding convolutional and fully connected stages, so the reported minimum latency reflects a CU that never leaves the coarsest evaluation level, while the maximum latency reflects a CU that is evaluated hierarchically through every partition depth. A cycle-accounting exercise over the individual loop bounds in the report confirms this reading: the convolutional stages together account for roughly 53% of the worst-case latency, while the three instances of the first fully connected layer, corresponding respectively to the 64-, 32-, and 16-level partition widths, account for the remainder, and the incremental cost of the conditionally skipped 32- and 16-level fully connected layers alone is close in magnitude to the observed minimum-maximum gap. This confirms that the reported spread is a direct hardware consequence of the algorithmic early-termination strategy rather than an artefact of pipeline stalls or memory contention. It is also worth noting architecturally that within each fully connected stage only the innermost neuron-accumulation loop is scheduled with an initiation interval of one, the outer loop over input features is not unrolled or pipelined, so each dense layer executes close to one multiply-accumulate operation per clock cycle regardless of its width, and total latency scales essentially linearly with the product of feature count and neuron count. This sequential accumulation pattern, rather than clock frequency, is the principal factor limiting throughput, and represents the most direct target for future optimisation through loop unrolling or the introduction of dataflow pipelining between the convolutional and fully connected stages, neither of which is currently exploited in the design.

Translating these cycle counts into wall-clock time at the

achieved operating frequency of 54.1 MHz yields a best-case latency of approximately 31.3 ms and a worst-case latency of approximately 51.8 ms per 64×64 coding unit, corresponding to a throughput of roughly 19 to 32 CU decisions per second. This figure is useful in situating the accelerator relative to the requirements of real-time video encoding, where the number of coding-unit partition decisions to be made per second for even moderate resolutions is several orders of magnitude higher, the present design should therefore be understood as a proof-of-concept core suitable for offline or non-real-time evaluation rather than as a drop-in real-time encoding accelerator, a limitation that follows directly from the sequential dense-layer execution pattern described above rather than from any deficiency in the achieved clock frequency.

2) Resource utilisation: This section presents the utilisation of the hardware resources mobilised by the co-design method proposed on the PYNQ-Z2 platform. Following the implementation phase, the use of the hardware resources of the proposed design is presented in Table IX.

TABLE IX. POST-SYNTHESIS RESOURCE UTILISATION OF THE ACCELERATOR CORE

Resource	Used	Available	Utilisation
BRAM_18K	93	280	33%
DSP48E	22	220	10%
FF	22,692	106,400	21%
LUT	34,661	53,200	65%

The resources utilised include a global buffer (BUFG), input-output interfaces, digital signal processors (DSP), block RAM (BRAM), flip-flops (FF), and lookup tables (LUT). According to Table IX, the hardware design uses 65% of the LUTs, 21% of the FFs, 33% of the BRAM, and 10% of the DSPs, and it is this pronounced asymmetry between the low DSP occupancy and the high LUT occupancy that most usefully characterises the implementation strategy chosen by HLS. Inspecting the synthesis report at the instance level shows that only a small number of floating-point multiplier and adder cores are instantiated, each requiring two to three DSP48E slices, and that these cores are shared through time-multiplexing across the thousands of multiply-accumulate operations required by the convolutional and fully connected layers rather than being replicated per operation. This resource-binding decision is precisely why DSP occupancy remains as low as 10% despite the arithmetic intensity of the network, the cost of sharing a handful of arithmetic units across so many operations is paid instead in combinational logic, since a large multiplexer network is required at every cycle to steer the correct pair of operands into the shared multiplier and adder and to route the shared result back to the appropriate destination register. This is corroborated by the operation-level breakdown of the synthesis report, in which multiplexer and select operations dominate the instantiated logic alongside the exit-condition comparators generated by the numerous loop bounds of the network's layers, together explaining why LUT utilisation reaches 65% while DSP utilisation remains an order of magnitude lower in relative terms. The low DSP and high LUT profile should therefore be read not as an efficient use of heterogeneous FPGA resources but as the expected signature of aggressive operator sharing, which trades DSP silicon for LUT-based control and steering logic and, combined with the unpipelined outer accumulation loops discussed above, is consistent with the observed latency profile.

Fig. 11 illustrates the energy consumption of the hardware architecture implemented on the FPGA board. According to the power report, the static power of the proposed system is approximately 0.147 W, while the dynamic power reaches 1.744 W, giving a total on-chip power of approximately 1.891 W and confirming that the design's power budget is dominated by dynamic switching activity rather than by static leakage, consistent with the resource profile of a logic-heavy, moderately clocked accelerator.

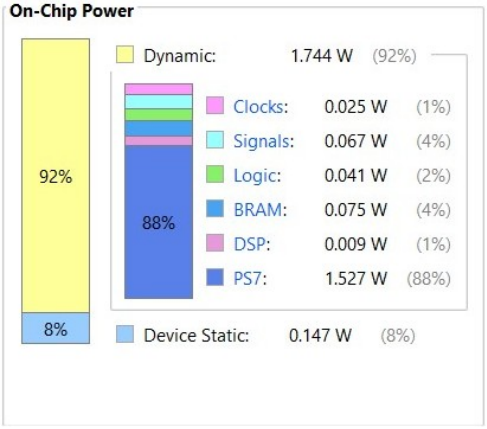

Fig. 11. Power consumption.

3) Power consumption: Fig. 11 illustrates the energy consumption of the hardware architecture implemented on the FPGA board. According to the power report, the static power of the proposed system is approximately 0.147 W, while the dynamic power reaches 1.744 W, giving a total on-chip power of approximately 1.891 W and confirming that the design's power budget is dominated by dynamic switching activity rather than by static leakage, consistent with the resource profile of a logic-heavy, moderately clocked accelerator.

4) Energy efficiency: Table X compares the average energetic efficiency of the FPGA-based accelerator board against the host PC (GPU, CPU, and peripherals) in terms of frames processed per watt consumed, using the average per-frame latency reported for the accelerator and the measured average per-frame processing time for the PC at each resolution. The board's power figure corresponds to its total on-chip power consumption (static plus dynamic), while the PC's power figure reflects the combined GPU, CPU, and peripheral draw.

TABLE X. AVERAGE ENERGETIC EFFICIENCY COMPARISON BETWEEN THE FPGA BOARD AND THE PC

Platform	Resolution	Power (w)	Avg. fps	Efficiency (fps/W)
Board (FPGA)	1920×1088	1.891	0.047	0.025
Board (FPGA)	1024×768	1.891	0.125	0.066
PC (GPU+CPU+periph.)	1920×1088	143	2.857	0.020
PC (GPU+CPU+periph.)	1024×768	143	3.846	0.027

Using the board's total on-chip power consumption of 1.891 W, the FPGA board remains the more energetically

efficient platform on a frames-per-watt basis at both resolutions, despite its substantially lower raw throughput. At 1920×1088, the board reaches 0.025 fps/W against 0.020 fps/W for the PC, and at 1024×768 the gap widens further, with the board achieving 0.066 fps/W against 0.027 fps/W for the PC, corresponding to an efficiency advantage of roughly 2.4 times at the lower resolution. This result follows directly from the board's power consumption being nearly two orders of magnitude lower than the PC's (1.891 W versus 143 W), a difference large enough to outweigh the board's lower absolute frame rate. The efficiency advantage is also resolution-dependent: because the number of coding units per frame, and therefore the board's per-frame latency, scales with frame area, the board's relative efficiency improves as resolution decreases, whereas the PC's efficiency scales more moderately since its processing pipeline is not similarly bottlenecked by sequential per-coding-unit evaluation. These results suggest that, although the board remains far from real-time throughput in absolute terms, its very low power envelope already makes it a favourable choice for energy-constrained deployments where frame-rate requirements are modest, and that closing the throughput gap through architectural optimisations such as coding-unit-level parallelism or deeper pipelining would further widen this efficiency advantage in the board's favour.

5) Carbon footprint: Beyond raw energetic efficiency, the substantial power gap between the two platforms also translates into a markedly different carbon footprint per unit of operating time. Using the International Energy Agency's (IEA) reported global average electricity grid carbon intensity of approximately 445 g CO_2/kWh in 2024 [21], the FPGA board's total on-chip power consumption of 1.891 W corresponds to an emission rate of roughly 0.000234 g CO_2 per second of operation, compared to approximately 0.0177 g CO_2 per second for the PC at 143 W, a difference of about two orders of magnitude consistent with the power ratio between the two platforms. Although the PC's higher throughput partially offsets this gap on a per-frame basis, the board still emits noticeably less CO_2 per unit of processing time at both resolutions, reinforcing its suitability for energy- and emissions-constrained deployment contexts, particularly as future architectural optimisations narrow the throughput gap without altering its favourable power profile.

6) Comparison with reference design: Table XI compares the key performance figures reported by Bouaafia et al. [16] for their PYNQ-Z1-based CNN_1 accelerator against those obtained for our proposed design on the PYNQ-Z2 platform, both targeting the 64×64-level CU partition prediction for HEVC.

TABLE XI. COMPARISON WITH THE REFERENCE PYNQ-Z1 CNN ACCELERATOR [16]

Metric	Bouaafia et al. [16]	Our Design
Platform	PYNQ-Z1 (XC7Z020)	PYNQ-Z2 (XC7Z020)
PL frequency (MHz)	142	54.1
LUT utilisation (%)	47	65
FF utilisation (%)	26	21
BRAM utilisation (%)	16	33
DSP utilisation (%)	14	10
On-chip power (W)	1.69	1.891
Processing time / CU	400 ms	31.3–51.8 ms

Compared with the reference design, our accelerator operates at a substantially lower clock frequency (54.1 MHz versus 142 MHz), yet achieves a processing time per 64×64 coding unit that is roughly 8 to 13 times faster (31.3–51.8 ms versus 400 ms). This indicates that, cycle efficiency aside, the reference design's higher operating frequency does not translate into a comparable advantage in absolute latency, most likely due to differences in interface overhead and inter-IP data movement between the streaming architecture and the PS in [16]. In terms of resource utilisation, our design consumes more LUTs (65% versus 47%) and more BRAM (33% versus 16%), reflecting the additional control and multiplexing logic associated with the higher degree of arithmetic resource sharing discussed earlier, while using fewer FFs (21% versus 26%) and notably fewer DSPs (10% versus 14%). On-chip power consumption is comparable between the two designs (1.891 W versus 1.69 W), with our design drawing marginally more power, which is consistent with its higher LUT occupancy. Overall, these results suggest that our design trades a modest increase in logic resource usage and power for a considerably lower per-CU processing latency, positioning it favourably relative to the reference work in terms of raw throughput, even though both designs remain well below the requirements of real-time HEVC encoding at typical video resolutions.

D. Discussion

When read together, the results above reflect the same trade-off at two levels. In software, the heuristic and machine-learning methods reviewed in Section II [11], [13] cut RDO calls through fixed or learned decision rules, in hardware, the accelerator cuts clock cycles and memory traffic through the identical rule, so the complexity reduction in Table VI and the latency spread in Table VIII are two views of the same early-termination mechanism. Relative to [16]'s multi-IP design, consolidating the network into a single IP core is what drives the latency advantage rather than clock frequency, which is lower here (54.1 versus 142 MHz), the LUT/DSP imbalance this incurs (65% versus 10%, Table IX) is the resource cost of sharing a handful of floating-point units across the network's weights, and is consistent with the low-power, sub-real-time profile in Table X. Overall, the accelerator is best read as evidence that early-termination CNN inference can be mapped onto genuine conditional hardware execution at a favourable power budget, with throughput the main gap left to close. We note that a broader comparison against other FPGA-based CNN accelerators beyond [16] is limited by the availability of full, citable results for those designs, Section II can be extended with additional hardware baselines when new works become available.

VII. CONCLUSION

In this article, a hardware-software architecture based on a deep convolutional neural network has been proposed for the prediction of coding units in 3D-HEVC on FPGA–SoC. The presented work aims to accelerate convolutional neural networks due to their high computational load. Nevertheless, a hardware IP core for MD-CNN was developed using the Vivado HLS tool. Subsequently, an architecture integrating hardware and software was developed by incorporating hardware IP cores based on the PYNQ-Z2 board. The simulation results revealed that our design achieves an on-chip power

consumption of 1.891 W. Our design requires reduced consumption of hardware resources: 65% of LUTs, 21% of FFs, 33% of BRAMs, and 10% of DSPs. As future work, we plan incorporate additional encoder modules in the hardware implementation, in particular the intra-prediction and transform modules.

The Coordination Complexity Index: A Parameter-Free Checkpoint Diagnostic for Silent Coordination Failure in Cooperative Multi-Agent Reinforcement Learning

***Abstract*—Cooperative multi-agent reinforcement learning (MARL) can fail silently while standard reward and loss curves remain inconclusive. This study introduces the Coordination Complexity Index (CCI), a checkpoint statistic with no learned parameters that summarizes dispersion among per-agent greedy Q-values. A frozen checkpoint cannot by itself establish a temporal failure; it can reveal Q-value patterns that motivate further inspection. On Level-Based Foraging (LBF), rules calibrated on the VDN/QMIX/QTRAN triad assign operational high-occupancy, dual-occupancy, and near-zero-dispersion labels, respectively. These labels are not independent proof of stagnation, oscillation, or behavioral roles. The pooled collapsed cohort differs from the non-collapsed LBF cohort by more than four orders of magnitude at the cohort geometric mean, while QMIX attains higher return with lower coordination variance than VDN. Held-out QPLEX falsifies the proposed class-complete-IGM prediction: return is zero, yet C does not approach the collapse cut-off. At 10% of the canonical LBF budget, a retrospective $\bar{C} < 10^{-3}$ rule flags all retained QTRAN seeds without flagging retained QMIX seeds; on RWARE it produces at least one environment-induced false positive. CCI is therefore a candidate domain-specific checkpoint screen, not a universal early-stop rule or a coordination-quality score. With the cut-off frozen before evaluation, 5/5 additional QTRAN training seeds remain below it at the retained 10%-budget checkpoint and 5/5 remain below it near 10M steps; this is a positive-class repeatability check, not independent calibration or a new specificity control.**

Keywords*—Cooperative Multi-Agent Reinforcement Learning (MARL); value decomposition; coordination signatures; coordination collapse; Coordination Complexity Index (CCI); checkpoint screening; Centralized Training with Decentralized Execution (CTDE)

I. Introduction

A cooperative multi-agent reinforcement learning (MARL) experiment can consume days of training compute yet fail silently: even without outright collapse, the loss may keep falling and team return may keep rising after the joint policy has already settled into a degenerate, task-irrelevant regime. Because a cooperative team maximizes a shared return under partial observability and decentralized execution, neither the reward curve nor any single agent's local view necessarily exposes that failure.

Value-decomposition (VD) methods, a leading family for cooperative training, combine per-agent Q-values through centralized mixers with progressively relaxed constraints, from VDN and QMIX to QTRAN and QPLEX [1]–[4]. This progression suggests an implicit assumption: greater mixer expressiveness should yield at least equal team performance. That assumption is tested directly with a concrete counterexample. On the canonical Level-Based Foraging (LBF) 9×9-5p grid, QTRAN collapses to zero return (0.000), whereas QMIX reaches 0.732. Thus, greater expressiveness alone does not prevent coordination failure. In single-agent deep learning, a network can quietly lose the ability to learn even as gradient-descent training continues [5]. Cooperative MARL similarly lacks a low-cost checkpoint observable for inspecting silent degeneration. Table I positions the proposed scalar against related diagnostics, but the comparison is qualitative rather than an empirical head-to-head. Reward curves can obscure whether disagreement is useful, and return is not a substitute for the proposed coordination proxy C: QMIX earns a higher return than VDN with lower coordination variance, consistent with the externally reported sample-efficiency gain under monotonicity [6].

This study makes three contributions.

- A checkpoint diagnostic with no learned parameters. C, the Coordination Complexity Index [CCI, Eq. (2)], is a per-timestep scalar computed from the variance of per-agent Q-values without an auxiliary loss. Its classifier uses thresholds calibrated on the LBF VDN/QMIX/QTRAN triad. The diagnostic can be extracted from a frozen checkpoint and is provided as the `macci` package described in the Data and Code Availability statement.
- A three-pattern operational taxonomy. On LBF, VDN, QMIX, and QTRAN exhibit high occupancy, dual occupancy, and near-zero dispersion under the calibrated rules. Only the QTRAN pattern transfers unchanged to RWARE. The conventional labels Stagnation,

*Corresponding author.

BI-REGIME, and COLLAPSE are retained for reproducibility, but they describe checkpoint statistics rather than independently verified temporal or behavioral mechanisms. On seed-matched cohorts from QFix, QTypeMix, and DuelMIX, C also separates successful dual-occupancy seeds from failed one-band seeds; this is partial rather than universal cross-architecture evidence.

- A held-out evaluation that bounds where C applies. The held-out prediction is that a *class-complete* Individual-Global-Max (IGM) architecture reaches the $\bar{C} < 10^{-3}$ collapse cut-off by the fixed 10M-step checkpoint. On five held-out QPLEX seeds that prediction fails: $\bar{C}$ remains heterogeneous rather than collapsing. The accompanying return collapse ($5/5$ seeds at 0.000) is reported separately. The result indicates that C tracks coordination-variance collapse rather than every form of policy failure.

II. RELATED WORK

Value-decomposition methods organize cooperative training around a centralized mixing function that recombines per-agent Q-values, and the family is usually read as a ladder of increasing expressiveness. VDN sums the per-agent values, satisfying the Individual-Global-Max (IGM) condition trivially but representing no inter-agent interaction [1]. QMIX replaces the sum with a state-conditioned monotonic mixing network whose non-negative weights preserve IGM while admitting nonlinear interactions [2]. QTRAN and QPLEX climb further, the former relaxing monotonicity through auxiliary losses and the latter through a duplex dueling advantage formulation, so as to cover a strictly larger IGM function class [3], [4]. The organizing premise of this ladder is that broader function-class coverage yields at-least-equal team performance.

The 2024–2026 literature continues to climb the same ladder rather than questioning the premise. DuelMIX, QTypeMix, and QFix extend factorization for heterogeneous teams or incomplete base mixers [7]–[9]; related fixed mixers reshape the mixing algebra itself (including QVF, which integrates quantile regression into the IGM condition) [10]–[15]. Each mixer above is fixed at design time and unchanged during training, and none poses the complementary question of what to measure when added expressiveness does not translate into performance—the question taken up here.

A second thread supplies the contrary empirical evidence that motivates a diagnostic. Rashid et al. established monotonic mixing as the practical default on cooperative StarCraft (SMAC) [2], and Hu et al. later showed that a carefully tuned QMIX matches the SMAC state of the art, with the monotonicity constraint improving sample efficiency on purely cooperative tasks [6]. This inverts the ladder's premise, since the constraint that the more expressive methods discard may itself be doing useful work. Consistent with that reading, value decomposition provably cannot represent the global value function on symmetric multi-modal reward landscapes, for every IGM-consistent mixer and whether or not the local networks are shared [16]. Linear and monotonic factorizations, in turn, cannot guarantee consistency between per-agent greedy actions and the team-optimal joint value [17]. Empirically, Papadopoulos et al. report that QPLEX fails with near-zero return on the hardest LBF tasks [18]—a silent collapse that registers in neither the training loss nor a cursory return summary until the compute has already been spent. Standardized cooperative-evaluation protocols [19], [20] improve reporting but still do not contribute a single observable that diagnoses coordination structure from a checkpoint.

The third thread concerns direct measurement of inter-agent coordination, which remains scarce relative to mixer design. Parameter-free probes such as Role Diversity [21], System Neural Diversity [22], CASEC [23], the Specialization Index [24], LVMQ [25], entropy and update probes [26], neuron statistics [27]–[29], greedy-action churn [30], and action-value gaps [31] characterize related but different objects. This study does not implement the published Role Diversity, policy-churn, or neural-diversity diagnostics under a shared protocol; Table I records their stated scope and instrumentation requirements.

Closest in spirit is Yamaguchi [32], who identifies coordinated-stable, fragile, and jammed/disordered regimes using cooperative success rate and TD-error variance. That method uses two training-time axes, whereas CCI reads Q-value dispersion from a frozen checkpoint. The present study targets value decomposition and evaluates LBF and RWARE, but the observed cross-domain split is associative rather than causal. Concurrent work reports that similar return curves can conceal distinct coordination mechanisms [33]. Table I is a qualitative positioning table, not evidence that CCI outperforms Role Diversity, phase-regime analysis, entropy, churn, or Q-gap diagnostics. Joint TD-error and final return are the matched main-protocol alternatives; a post-hoc retained-checkpoint comparison with entropy, Q-gap, and two behavioral summaries is reported separately in Section V-A. Cross-domain support is marked Partial because only the QTRAN near-zero-dispersion pattern transfers unchanged to RWARE. The all-Yes entries for CCI are therefore scoped to the properties listed and do not constitute an exhaustive priority claim.

TABLE I. C (CCI) VS. PRIOR COORDINATION DIAGNOSTICS

Diagnostic	Param-free	No instr.	VD-collapse	Cross-domain	Held-out
Role Diversity [21]	Yes	Yes	No	Yes	No
Phase regimes [32]	Yes	No	No	No	No
Joint TD-error (Q_{tot}) [34]	Yes	No	No	–	No
Final return [19]	Yes	Yes	No	–	No
C (CCI, this work)	**Yes**	**Yes**	**Yes**	**Partial**	**Yes**

III. METHODOLOGY

The coordination diagnostic C has no learned parameters and is extractable from a frozen checkpoint. It is designed to discriminate the VDN/QMIX/QTRAN calibration triad on $\bar{C}$, with a return-based check retained for class-complete IGM mixers such as QPLEX. Its 10%-budget use is evaluated retrospectively on retained LBF QMIX/QTRAN checkpoints and is treated as a candidate screen rather than a validated stopping policy.

A. Setting and the Value-Decomposition Family

Cooperative MARL is cast as a Dec-POMDP under Centralized Training with Decentralized Execution (CTDE) [1],

[2], [35]: joint value decomposition is trained with global state and histories available, while each agent executes from its own history τ_i via $Q_i(\tau_i, u_i)$. An action-value decomposition satisfies the Individual-Global-Max (IGM) condition [2], [3] when:

$$\arg\max_{\mathbf{u}} Q_{\text{tot}}(\boldsymbol{\tau}, \mathbf{u}, s) \;=\; \big(\arg\max_{u_i} Q_i(\tau_i, u_i)\big)_{i=1}^{n}. \quad (1)$$

Eq. (1) licenses decentralized greedy execution. The value-decomposition family realizes it with decreasing mixing restrictiveness: VDN [1] sums per-agent utilities; QMIX [2] uses a state-conditioned mixer with non-negative weights (monotonicity $\partial Q_{\text{tot}}/\partial Q_i \geq 0$); QTRAN [3] drops monotonicity and approximates the full IGM-consistent class via auxiliary losses; QPLEX [4] attains the *complete* IGM function class with a duplex-dueling architecture. This VDN→QMIX→QTRAN→QPLEX axis is the structural ladder along which coordination behavior is measured below.

B. CCI Formula and Components

Given the IGM-consistent value-decomposition family above, a frozen checkpoint permits inspection of whether per-agent greedy Q-values remain numerically heterogeneous or become nearly identical. CCI reads that numerical property through the variance of per-agent greedy-action Q-values, passed through a tanh wrapper. It does not by itself identify behavioral roles, coordination success, or a causal failure mechanism. The **Coordination Complexity Index (CCI)**, denoted C, is:

$$C \;=\; \tanh\big(\mathrm{Var}\big(q_1, \ldots, q_n\big)\big) \quad (2)$$

where, $\mathbf{q} = (q_1, \ldots, q_n)$ is the vector of per-agent greedy-action Q-values at a given timestep and Var is the unbiased sample variance over the n agents (dividing by $n-1$; ddof=1). That is the estimator which produced every C value reported in this study, and reproducing the reported numbers requires it. The `macci` implementation uses the same estimator, so the package and the reported values agree by construction. The population variance (ddof=0) differs only by the constant factor $n/(n-1)$ on the pre-tanh argument, but substituting it under the same fixed thresholds is not label-neutral: two of the twenty-five LBF seeds cross the STAGNATION boundary (VDN $23/25 \to 21/25$), while the cohort-level signature of each algorithm is unchanged.

High C indicates dispersed per-agent utilities; it does not by itself imply role differentiation, adaptation, or success. Likewise, $C \approx 0$ denotes nearly identical greedy utilities under the realized scale, not every possible form of policy collapse. For illustration, $\mathbf{q} = (2.0, 2.0, 2.0)$ gives $C = 0$, whereas $\mathbf{q} = (0.5, 2.0, 3.5)$ gives $C = \tanh(1.5) \approx 0.91$. A common additive shift $q_i' = q_i + b$ leaves C unchanged, but a common positive rescaling gives $C' = \tanh(a^2 \,\mathrm{Var}(\mathbf{q}))$ and can change every finite threshold decision. Agent-specific action-independent offsets can also preserve each agent's greedy policy while changing inter-agent variance. Thus the tanh wrapper bounds $C \in [0, 1)$ but does not make it policy- or scale-invariant.

The headline scalar C above is one component of a richer per-timestep (I, C, T) triple logged by the artifact. Here $I = \sigma(\mathrm{mean}_{i \neq j} |(q_i - \bar{q})(q_j - \bar{q})|)$ is an interdependence proxy computed from pairwise products of centered selected-action values; it is not softmax entropy. C is the Eq. (2) scalar, and T is an L2 trajectory-change term. T is zero in the post-hoc single-checkpoint extraction because no preceding trajectory is supplied. I and C are non-orthogonal functionals of the same selected-action values, so the component analysis below is descriptive rather than a comparison of independent diagnostics.

C. Signature Extraction Pipeline

The signature-extraction routine records C at every timestep of greedy evaluation episodes ($\epsilon = 0$). A timestep is LOW if $C < \theta_{\text{lo}}$ and HIGH if $C > \theta_{\text{hi}}$; the neutral band is unmarked. A regime transition is counted when consecutive timesteps lie on opposite sides of θ_{lo}, and the reported rate is the episode mean. The operational classifier is applied in order: COLLAPSE if $\bar{C} < 10^{-3}$; STAGNATION if $\max(\text{High}\%, \text{Low}\%) > 80\%$; and BI-REGIME otherwise. These names preserve the registered analysis vocabulary. Occupancy ignores temporal order, so STAGNATION means one-band occupancy and BI-REGIME means dual-band occupancy; neither label alone establishes halted adaptation or persistent oscillation. Transitions are reported separately and do not enter classification. The constants were calibrated on the LBF VDN/QMIX/QTRAN triad and were not re-tuned per environment. "No learned parameters" refers only to C, which has no fitted weights or auxiliary loss.

1) Threshold robustness: The cohort label is unchanged across five $(\theta_{\text{lo}}, \theta_{\text{hi}})$ settings: $(0.03, 0.07)$, $(0.04, 0.08)$, $(0.05, 0.10)$, $(0.08, 0.15)$, and $(0.10, 0.20)$. QTRAN is COLLAPSE in all $25/25$ seed-by-threshold cells because occupancy thresholds do not enter that decision. A sensitivity check of collapse cut-offs $\{10^{-4}, 5{\times}10^{-4}, 10^{-3}, 2{\times}10^{-3}, 10^{-2}\}$ also leaves every canonical QTRAN seed below and every VDN/QMIX seed above. This analysis varies numerical cut-offs on the same calibration triad; it does not validate the rule form on an independent calibration set. VDN is STAGNATION in $23/25$ cells and QMIX is BI-REGIME in $17/25$, so the non-collapse boundary is cohort-level rather than seed-universal. The retained sweep enables the same sensitivity check on new checkpoints. A separate post-hoc rescaling audit applies $q' = aq$ exactly through the retained pre-tanh variances. At $a = 0.1$, three of five QMIX seeds cross the collapse cut-off even though greedy actions are unchanged; at $a = 10$, all five QMIX seeds become one-band high-occupancy cases. QTRAN remains below the collapse cut-off for all five seeds over $a \in [0.1, 10]$ because its observed variance is much smaller. This finite-range robustness of the reported QTRAN cohort does not restore policy invariance to the statistic or its thresholds.

D. Dual Evaluation Protocol

The tanh normalization in Eq. (2) assumes $|Q| \lesssim 1$, which holds for environments with bounded episodic return and short horizons. On reward-unbounded environments where $|Q|$ can exceed unity by an order of magnitude or more, C saturates to one regardless of inter-agent coordination structure. Two layers

of diagnostic are therefore defined. Layer 1 is the canonical C of Eq. (2). Layer 2 is its un-bounded counterpart:

$$\mathrm{RawVar}(Q) = \mathrm{Var}_i\big(\max_{u_i} Q_i(\tau_i, u_i)\big), \tag{3}$$

and is reported together with the per-state $\max_i Q_i - \min_i Q_i$ range; applying the tanh wrapper to Eq. (3) recovers Layer 1, so the two layers differ only in whether the dispersion is compressed. Each layer targets the same numerical property—dispersion among per-agent selected-action values—in the regime where its observable remains informative. All headline tables use Layer 1 on the bounded-reward LBF and RWARE cohorts; Layer 2 is defined for reward-unbounded regimes where tanh saturates, and is not reported as an empirical probe in this study. Signature extraction runs a fresh-evaluation protocol on the frozen checkpoint under evaluation: 100 greedy episodes ($\epsilon = 0$), reduced to 50 for some early-checkpoint extractions (Table VII), with evaluation seeds independent of the training seeds. It therefore depends on no quantity logged during training.

E. Algorithms and Experimental Setup

This work studies three primary value-decomposition algorithms: VDN, QMIX and QTRAN. QPLEX, held out from the design of C, is *class-complete*: it realizes the complete IGM function class as a hard architectural constraint rather than through auxiliary penalties. The three primary algorithms train from one shared hyperparameter configuration on the LBF grids at a learning rate of 5×10^{-4}. Two things are not shared: the optimiser is Adam for VDN and QMIX and RMSprop for QTRAN [36], [37], and the QTRAN learner does not consume every key of that configuration (it ignores `td_lambda`, the leniency keys, `q_value_clip` and `standardise_rewards`). The mixer is therefore the primary intended per-algorithm difference, not the only realized one. The RWARE cohorts run to 2×10^7 steps. Every setting is reported in full, as standardised evaluation requires [19]; the shared table is Table V (batch size / replay-buffer 128 / 5000 episodes; agent network Feed-forward MLP, hidden dim 64). One setting is *not* shared: the optimiser. Rather than leave that optimiser asymmetry as a confound, a matched QTRAN-with-Adam control (n=5 seeds) was run to separate the mixer from the optimiser; without it, QTRAN would have been both the sole COLLAPSE class and the sole RMSprop run, and the two would not have been separable. The shared hyperparameters follow Hu et al.'s implementation discipline [6], using code-level tricks that are not specific to QMIX. As executed they are not generic across the family either: the QTRAN learner ignores them.

1) Held-out prediction H1: Prediction H1 is an exploratory, falsifiable conjecture tied to the training budget. Let $\mathcal{A}$ realize the complete IGM function class through a hard architectural constraint. Under assumptions (A1)–(A3), H1 predicts that every seed reaches $\bar{C} < 10^{-3}$ by the fixed 10M-step checkpoint on canonical LBF. The assumptions are not identified from the reported data or derived in general, so H1 is neither a theorem nor a convergence claim. VDN, QMIX, and QTRAN supplied the taxonomy and thresholds; QPLEX is only a held-out falsification test of that calibration.

The working assumptions are:

- (A1) parameter-shared agent networks with a symmetric team reward $r(s, \mathbf{u})$;
- (A2) the TD fixed point under parameter-shared training admits the additive-plus-shared decomposition $\max_{u_i} Q_i(\tau_i, u_i) = f(\tau_i) + c(s)$ for a shared function f and a state-level residual $c(s)$ (a structural assumption, not derived here); and
- (A3) a gradient-descent training-limit regime under which parameter-shared updates pull the shared function f of (A2) toward a common attractor on the visited history distribution (a regularity assumption, not derived here, in the spirit of the gradient-flow analysis of T. Hu et al. [38]). The agent networks receive a one-hot agent identifier (Table V), which breaks exact exchangeability of the local histories by construction; (A3) is therefore a statement about the learned representation in the training limit, not about the raw histories. In the configuration studied here the agent network is feed-forward (`use_rnn=False`; Table V), so the realized per-agent function is $Q_i(z_i, u_i)$ over the current observation; τ_i is retained for consistency with the CTDE formalism.

The motivation is heuristic. Under (A1), shared TD targets [2], [3] and (A2) yield $\max_{u_i} Q_i = f(\tau_i) + c(s)$, hence $\mathrm{Var}_i(\max_{u_i} Q_i) = \mathrm{Var}_i(f(\tau_i))$. Only if representation sharing under (A3) dominates should this variance contract. These assumptions are neither identified empirically nor sufficient for a general proof. Consequently, H1 is evaluated solely as a budget-anchored conjecture: one QPLEX seed with $\bar{C} \geq 10^{-3}$ at 10M steps rejects it.

2) Environments and seed counts: The primary benchmark is Level-Based Foraging (LBF) [34], [39]. Five primary 5-agent grids (8×8 through 12×12) plus a 6-agent 9×9 robustness probe are tested, all with three food items, `force_coop=True`, and sight radius two. Those settings are denoted by the compact labels 9×9-5p-3f-coop and 9×9-6p; the 9×9-5p grid on which C, its thresholds, and the held-out test are defined is hereafter the canonical grid. The seed count of every reported cohort is stated explicitly, and the per-seed records are available from the corresponding author on reasonable request. On LBF, VDN/QMIX/QTRAN each contribute 5 matched seeds per grid, so the headline taxonomy rests on the 25 QTRAN seeds across the five primary grids. VDN and QMIX were run with more seeds, but the shared 5 form the matched reported cohort, consistent with the 5-vs-5 effect sizes of Table III. The 6-agent 9×9-6p variant likewise reports 5 seeds per algorithm, and the held-out QPLEX test uses 5 seeds on the canonical grid. Cross-domain validation on RWARE [40] (the four-agent `rware-small-4ag` layout) uses 5 seeds per algorithm and 20M environment steps under the parallel runner. The cohort is matched on seed count and budget but not on the leniency schedule or batch size (32 for VDN and QTRAN against 128 for QMIX). A second matched n=5 cohort is retrained under the episode runner, which collects one full episode at a time. Reported returns are undiscounted, environment-specific episodic metrics [40]: on LBF the fraction of food items collected per episode, on RWARE the number of successful deliveries per episode. LBF

TABLE II. THREE COORDINATION SIGNATURES ON LBF 9×9-5P

Alg.	Signature	$\bar{C}$	Tr/ep	Lo%	Hi%	Return	95% CI
VDN	Stagnation	0.483	1.2	3.9	91.8	0.632	[0.55, 0.71]
QMIX	Bi-regime	0.172	2.4	22.8	57.2	0.732	[0.70, 0.76]
QTRAN	Collapse	3.3×10^{-6}	0.0	100.0	0.0	0.000	[0.000, 0.000]

and RWARE return magnitudes are therefore not on a common scale.

3) Statistical protocol: Effect sizes use Cohen's d [41] with the Hedges' g small-sample correction [42]

$$J(df) = 1 - \frac{3}{4(n_1 + n_2) - 9}. \quad (4)$$

Confidence intervals are percentile bootstrap intervals over the per-seed values, computed directly in NumPy with a fixed seed: 10,000 resamples for effect-size intervals and 50,000 for return intervals and $P(X > Y)$; the summaries reported—the interquartile mean (IQM), optimality gap, and $P(X > Y)$—follow the reporting practice argued for by Agarwal et al. [43], but the stratified-bootstrap procedure of the `rliable` library itself was not used. Where $n \leq 3$ makes $J(df)$ unreliable, the row is footnoted. Wide bootstrap CIs from near-zero within-group variance (collapsed conditions) are reported unadjusted. All seed-level statistics (CIs, effect sizes) are computed over the per-seed $\bar{C}$ values—each seed's $\bar{C}$ being the mean of C over all timesteps pooled across its evaluation episodes—so the reported spread reflects across-seed reproducibility.

IV. RESULTS

Results cover the canonical signatures, a frozen-cut-off extension on five additional QTRAN training seeds, cross-setting robustness, an optimiser control, generalization to unseen architectures, and a held-out evaluation on QPLEX.

A. Three Coordination Signatures

The CCI extraction routine uses 100 greedy episodes per seed on canonical LBF. VDN receives the operational STAGNATION label because HIGH occupancy is approximately 92%; this indicates a stable one-band Q-value profile, not verified behavioral stagnation or fixed roles. QMIX receives BI-REGIME because trajectories occupy both bands, with approximately 2.4 threshold crossings per episode; the statistic does not establish what agents do on either side of the threshold. QTRAN receives COLLAPSE because greedy Q-values are nearly identical and LOW occupancy is 100%. Its seed-mean $\bar{C}$ is nearly five orders of magnitude below QMIX (Table II). Returns and bootstrap intervals use the matched five-seed cohort. Return and C are aligned by training seed but come from training logs and separate greedy checkpoint evaluations, respectively; they are not paired episode-level observations. Canonical QMIX uses last-saved rather than strictly end-of-budget checkpoints, as disclosed in Section V-C.

These operational labels are cohort-level summaries rather than artifacts of one threshold setting. Per-seed stability is exact for COLLAPSE and majority-stable for the other labels: VDN is STAGNATION in 23/25 cells and QMIX is BI-REGIME in 17/25 across the five threshold pairs. Attribution to the mixer rather than the optimiser rests on Section IV-D. Table X adds a descriptive seed-0 cross-checkpoint trace. VDN transitions fall from 6.60 at 2.5M steps to 0.14 at 5.0M and 7.5M; QMIX remains between 2.38 and 4.66 across six checkpoints; QTRAN remains at zero across six checkpoints. This limited trace preserves temporal ordering for one retained seed but is not a cohort-level temporal validation.

Neither final return nor joint TD-error identifies the observed Q-value-dispersion pattern as directly as C. At the 10% canonical-LBF checkpoint, the retrospective candidate rule $\bar{C} < 10^{-3}$ flags all five retained QTRAN seeds and none of the five retained QMIX seeds. VDN checkpoints were not retained there, so the evidence covers one grid and two algorithms. The flagged LBF seeds did not recover by the retained final checkpoint. On RWARE, however, two of three retained early QMIX checkpoints are flagged, including at least one seed that later succeeds. The same cut-off therefore has an environment-induced false positive and is not a validated universal stop rule.

1) Frozen-cut-off seed extension: After fixing the rule and evaluation protocol, five additional canonical-LBF QTRAN training seeds (5–9) were run under the same 10M-step parallel protocol. Under the same 100-episode greedy harness, 5/5 seeds fall below 10^{-3} at the nearest retained 10%-budget checkpoint (cohort mean $\bar{C} = 3.93\times10^{-6}$), and 5/5 do so near 10M steps (mean $\bar{C} = 5.27\times10^{-6}$). Fresh-evaluation mean returns are 0.001 and 0.006, respectively. Table XII reports every seed. Because this extension adds only QTRAN, it tests within-architecture repeatability of the positive class; it neither recalibrates the cut-off nor supplies new negative-class specificity evidence.

B. Statistical Separation

The three architecture cohorts on the canonical grid separate statistically on seed-level $\bar{C}$. Table III reports pairwise effect sizes on seed-level $\bar{C}$ (Cohen's d with the Hedges' g correction of Eq. (4); bootstrap CIs on d from the same unstratified percentile bootstrap, 10,000 resamples with a fixed seed). VDN-versus-QTRAN separates at $|d| = 13.46$ ($g = 12.15$), a magnitude that reflects QTRAN's near-zero within-group variance under collapse. Two of the three pairs exceed $|d| = 2.0$, with QMIX-versus-QTRAN ($d = 1.73$) just below. This holds at the point estimate; at $n = 5$ the QMIX-versus-VDN interval extends to $|d| = 1.74$, so the $|d| = 2.0$ boundary is unresolved for that pair, as it is for QMIX-versus-QTRAN, whose interval runs from 1.36 to 10.18. All three intervals exclude zero, so the direction of every pair is resolved, but each spans a factor of six or more in $|d|$, so at $n = 5$ this sample fixes the sign of each separation without fixing its size. The widest CI, $[9.69, 61.44]$ on VDN-versus-QTRAN, reflects QTRAN's near-zero within-group variance under bootstrap rather than point-estimate instability, and is reported transparently rather than narrowed via a non-standard estimator. On the same matched $n = 5$ cohort, final return separates QMIX from VDN at $d = +1.60$ and joint TD-error at $d = -1.31$; Discussion interprets these margins against C.

These pairwise effects generalize to a population-level summary. Comparing non-collapsed $\bar{C}$ on the canonical 9×9-5p cohort (ten VDN/QMIX seed-mean values; geometric mean

≈ 0.252) against collapsed $\bar{C}$ pooled across QTRAN on the canonical 9×9-5p grid and QTRAN on cross-domain RWARE small-4ag (geometric mean $\approx 5.59\times10^{-6}$) defines the pooled contrast. The geometric-mean separation is approximately 4.5×10^{4}, or about 4.66 orders of magnitude relative to that non-collapsed foraging geometric mean. Only QTRAN's RWARE values enter this collapsed pool; the VDN/QMIX RWARE cohort stays non-collapsed (below). The worst-case two-point extremes ratio—the smallest non-collapsed $\bar{C}$ (0.0613, QMIX seed 3) over the largest collapsed one (1.92×10^{-4}, RWARE QTRAN seed 2)—is 3.2×10^{2}, about 2.50 orders of magnitude. It is a two-point statistic; leaving out either extreme moves it only to 4.0×10^{2} or 4.3×10^{2}. The retained per-seed checkpoint records used here are available from the corresponding author on reasonable request.

TABLE III. PAIRWISE EFFECT SIZES ON SEED-LEVEL $\bar{C}$ (LBF 9×9-5P)

Pair	**Cohen's** d	**Hedges'** g	95% **CI on** d	n **seeds**
QMIX vs QTRAN	1.73	1.56	$[1.36, 10.18]$	5 vs 5
VDN vs QTRAN	13.46	12.15	$[9.69, 61.44]$	5 vs 5
QMIX vs VDN	−2.93	−2.65	$[-16.42, -1.74]$	5 vs 5

Across the five 5-agent grids the per-component breakdown of I, C [Eq. (2)], and T attributes 93–98% of the attributable within-cohort variance to C, versus 2–7% to I. T is structurally zero under single-checkpoint extraction—temporal drift needs a previous trajectory—so it cannot explain variance here; that is why C is reported as the single headline diagnostic. On the canonical 9×9-5p grid the VDN/QMIX/QTRAN triad alone spans 0.483 on C (comparable to the other grids); including the held-out QPLEX raises the four-architecture C spread to 0.541 versus 0.163 on I (a 3.3× C/I ratio that mixes the calibration triad with the held-out test). Because I and C are non-orthogonal functionals of the same Q-vectors, this dominant share is a descriptive corroboration of the C/I ratio rather than an orthogonal variance analysis.

C. Cross-Setting Robustness

The canonical-grid finding replicates across five LBF grid sizes and a six-agent variant (per-grid QMIX/VDN $\bar{C}$ and returns in Table VIII). VDN's mean $\bar{C}$ stays above 0.47 on all five 5-agent grids and on the 6-agent variant; QMIX's ranges from 0.083 at 8×8 to 0.208 at 10×10 across the five 5-agent grids, rising to 0.220 on the 6-agent variant; QTRAN's remains below 10^{-3} on all five 5-agent grids and on the 6-agent variant. On all six configurations, C identifies a near-zero-dispersion QTRAN pattern that return alone does not distinguish, since QTRAN's mean return ranges from exactly zero on the canonical grid to 0.029 (0.000–0.029) rather than being uniformly zero (the six-agent case is detailed below). The QMIX-versus-VDN effect size on $\bar{C}$ is non-monotonic with an intermediate-grid-size minimum: $|d_C|$ drops from 10.10 at 8×8 to 1.47 at 10×10, then rebounds to 12.78 at 12×12. The intermediate minimum is driven by a single QMIX seed at $\bar{C} = 0.660$, which raises the QMIX across-seed standard deviation at 10×10 to 0.25 against 0.05 for VDN; at the two extremes both cohorts are tight (across-seed standard deviations between 0.022 and 0.056), so the pooled standard deviation is small and $|d_C|$ is correspondingly large. The 9×9-5p effect size is $d = -2.93$ ($g = -2.65$) at $n = 5$ versus 5. On returns, the QMIX-vs-VDN gap is 9.1–16.9 pp across grids (non-monotonic, peaking at 10×10), with $P(\text{QMIX} > \text{VDN}) \geq 0.91$ on every grid (the smallest, 0.92 on 10×10, is 0.9186 before rounding). All reported cross-grid effect sizes and returns use $n = 5$ seeds per algorithm on every grid, the six-agent 9×9-6p variant included, with two exceptions: the 9×9 $P(X > Y)$ uses six QMIX seeds, and on the 6p variant the $\bar{C}$ and return columns do not share the same five seeds.

Across the five 5-agent grids, every tested QTRAN seed remains below the collapse cut-off with narrow within-grid variance. This replication covers the five grids and seeds tested; it does not establish invariance outside them. The 6-agent variant on 9×9 preserves VDN's stagnation and QMIX's bi-regime under increased agent count, with QTRAN in full coordination-variance collapse ($\bar{C} < 10^{-3}$) even though its return (0.029) is marginally above zero.

One of the three canonical-grid signatures replicates cross-domain on the RWARE robotic warehouse benchmark [40], a structurally distinct cooperative environment with corridor navigation and sparse reward ($n = 5$ matched training seeds per algorithm). The QTRAN near-zero-dispersion classification recurs under the same numerical rule: seed-mean $\bar{C} \approx 9\times10^{-5}$, mean return 0.000 across all five RWARE seeds, and QTRAN is the only algorithm below the $\bar{C} < 10^{-3}$ collapse threshold. The two non-collapsed algorithms stay above it: QMIX learns the task (mean return 0.86) yet its coordination-variance is compressed to $\bar{C} \approx 3\times10^{-3}$ (only about 3× above the collapse cut-off, unlike its LBF bi-regime), and VDN shows LOW-occupancy STAGNATION ($\bar{C} \approx 0.029$, Low% ≈ 93%), differing from its LBF HIGH-occupancy stagnation. *Both* non-collapsed algorithms therefore sit at low, near-uniform $\bar{C}$ on RWARE, QMIX falling from its LBF $\bar{C} \approx 0.17$. The LBF QMIX-vs-VDN separation therefore shrinks substantially here (Cohen's $d = -1.11$, still a large effect but well below the LBF value), while the collapsed QTRAN class stays sharply separated from QMIX ($d = -2.77$). QTRAN's separation from VDN ($d = -1.23$) is comparable in magnitude to the QMIX-vs-VDN effect, because RWARE compresses VDN's own $\bar{C}$ toward the threshold. Fig. 1 contrasts the recurring QTRAN near-zero-dispersion pattern—below the 10^{-3} threshold in *both* domains—with the domain-dependent VDN/QMIX change. This contrast is associative, not a causal attribution to architecture. A matched-seed episode-runner replication of this four-agent cohort (n=5) shows the same near-zero-dispersion classification, so the observation is not limited to the parallel-runner evaluation. Under a common 100-episode greedy evaluation harness, QTRAN's geometric-mean $\bar{C} \approx 1\times10^{-8}$ with return 0.000 on every seed, whereas VDN does not collapse (geometric-mean $\bar{C} \approx 0.44$, mean return 3.23). Returns are not directly comparable with the parallel-runner figures above: that cohort used the episode runner under a 50-step training time limit rather than the parallel cohort's 500-step limit. Non-collapsed $\bar{C}$ magnitudes are harness-sensitive; only the within-harness QTRAN-versus-VDN contrast is claimed here.

D. Mixer–Optimiser Control

QTRAN was retrained from scratch on the canonical 9×9-5p grid with the *same* optimiser the non-collapsed baselines use—Adam at learning rate 5×10^{-4}. It was evaluated under

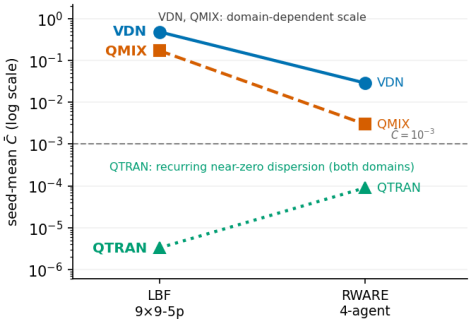

Fig. 1. Seed-mean $\bar{C}$ on LBF 9×9-5p vs. RWARE (log axis; 10^{-3} threshold).

the same 100-episode greedy harness, holding every other setting identical (runner, seeds 0–4, and the 10M-step budget). The optimiser is fixed by the learner implementation rather than by the configuration, so this matched control tests it directly. It does not isolate the mixer: the QTRAN learner also ignores four further keys that the VDN/QMIX learner consumes, and those differences are present here too.

The cohort-mean near-zero-dispersion classification persists. At 10M steps the QTRAN-with-Adam cohort reaches seed-mean $\bar{C} = 6.9\times10^{-4}$, below the $\bar{C} < 10^{-3}$ cut-off and far below both non-collapsed baselines on the same grid: 2.8 orders of magnitude below VDN (0.483) and 2.4 below QMIX (0.172). The regime signature is unchanged from the RMSprop cohort on every seed: Low% = 100, High% = 0, and zero regime transitions per episode. At the 10M-step budget, giving QTRAN the baselines' optimiser does not give it their coordination structure.

The optimiser is nevertheless not inert. The swap raises seed-mean $\bar{C}$ from 3.3×10^{-6} to 6.9×10^{-4}, a factor of about 209, with complete separation between the two cohorts: the lowest Adam seed (2.4×10^{-4}) exceeds the highest RMSprop seed (7.8×10^{-6}) by more than an order of magnitude. One Adam seed reaches 1.6×10^{-3} and thus sits above the cut-off; a checkpoint sweep over the final quarter of training shows two near-cut seeds alternating across the cut-off rather than settling on either side, so their class assignment reflects where training stopped rather than a distinct behavior. The cohort-level verdict is stable under that ambiguity: recomputed at each of the twelve final checkpoints, the seed-mean stays below the cut-off in every case.

The near-zero-dispersion pattern is a *learned* network state, not present in the untrained network: at the earliest logged checkpoint (200 environment steps, effectively untrained) every seed sits above the cut-off ($\bar{C} \approx 2\times10^{-3}$–$1.4\times10^{-2}$), and training drives $\bar{C}$ down by three to four orders of magnitude before the partial recovery just described. The near-zero $\bar{C}$ of this cohort therefore reports a learned numerical state rather than an initialization artifact. One boundary is stated explicitly: the claim is anchored at 10M steps—unlike the RMSprop cohort, whose $\bar{C}$ is flat, the Adam cohort's $\bar{C}$ is still rising at the end of training on all five seeds, so the result bounds behavior at this budget rather than at convergence.

E. Generalization to Unseen Architectures

The taxonomy only partially generalizes beyond the four studied architectures. On three 2025 value-decomposition methods (QFix [9], QTypeMix [8], DuelMIX [7]; five matched seeds each, seeds 0–4, at the same 10M-step budget; Table IX), C separates all 12 successfully-trained (BI-REGIME) seeds from all 3 failed (STAGNATION) seeds, with no seed falling below the $\bar{C} < 10^{-3}$ collapse cut-off. The three failed seeds are the informative case: their zero return is indistinguishable from QTRAN's on the reward curve, yet C separates their numerical patterns: a uniform-high-$\bar{C}$ one-band case ($\bar{C} \in [0.84, 0.99]$) rather than QTRAN-like near-zero dispersion. This difference does not identify the underlying behavioral or causal mechanism. Only two of the three signatures manifest.

F. Held-Out Evaluation on QPLEX

QPLEX is a duplex-dueling architecture not used to design C, choose its thresholds, or fit any free parameter of the diagnostic [4]. Across five QPLEX training seeds on the canonical 9×9-5p-3f-coop LBF grid under the canonical protocol (`time_limit=50`, $t_{\max} = 10$M), test return is 0.000 for every seed at the 10M-step checkpoint (Table IV); that 5/5 return-zero statement is protocol-tied (footnote). The corresponding $\bar{C}$ values are heterogeneous: three exceed 0.7, one is approximately 0.10, and one is 0.036; none falls below the 10^{-3} collapse cut-off. Return collapse and coordination-variance collapse therefore dissociate: QPLEX has zero return on 5/5 seeds without reproducing QTRAN's low-$\bar{C}$ signature. The QPLEX pattern is treated as an architecture-specific heterogeneity mode that may refine the taxonomy, not as evidence for a confirmed fourth signature.*

TABLE IV. HELD-OUT QPLEX PER-SEED $\bar{C}$ AND RETURN (LBF 9×9-5P)

Seed	$\bar{C}$	Return
0	0.956	0.000
1	0.705	0.000
2	0.102	0.000
3	0.036	0.000
4	0.906	0.000

All five seeds fail Prediction H1 under the assumptions stated in the Methodology. H1's sole prediction, operationalized as per-seed $\bar{C} < 10^{-3}$ at 10M steps, does not hold. As the dissociation above shows, the QTRAN-calibrated threshold does not detect every form of policy failure. Per-seed values for the other reported cohorts are available from the corresponding author on reasonable request. The cohort-wide return-collapse at 5/5 is an outcome H1 does not predict and is reported as an observation, not as partial support for H1.

*Per-seed origin: the QPLEX registry contains canonical (`time_limit=50`, $t_{\max} = 10$M) runs for all five seeds plus non-canonical (`time_limit=100`, $t_{\max} = 5$M) runs for seeds 0–4; on the non-canonical sub-cohort 1/5 seeds reached return-collapse and 4/5 retained mid-range returns (0.35–0.59). The 5/5 return-collapse statement therefore applies only to the canonical 10M-step cohort.

V. Discussion

A. Interpretation and Checkpoint Reading

The three signatures support a scope-controlled checkpoint reading (Table VI). The only candidate action evaluated retrospectively is COLLAPSE→consider stopping on canonical LBF. The other mappings are interpretive prompts, not tested interventions. Even the collapse action requires domain-specific validation because it produces a false positive on RWARE and misses QPLEX's return-collapse mode. The constraint–performance ordering is consistent with prior evidence on monotonicity [6], but the present observations do not establish a causal mechanism.

A practitioner should not abort solely because $\bar{C} < 10^{-3}$. On canonical LBF, that one-million-step rule would have saved nine million additional steps for the retained QTRAN seeds without flagging retained QMIX seeds. Before operational use it requires validation on the target domain, algorithm family, Q-value scale, and checkpoint protocol. RWARE false positives, missing VDN early checkpoints, and the absence of an early QPLEX extraction delimit the evidence.

Joint TD-error and final return are evaluated under the matched main protocol. A further post-hoc retained-checkpoint evaluation uses the same 100-episode harness for C, normalized softmax action entropy, the top-1–top-2 Q-gap, pairwise greedy-action disagreement, and within-episode action switching (Table XI). The retained checkpoints are not horizon-matched: VDN is at approximately 7.5M steps, QMIX at 7.5–9.5M, and QTRAN at approximately 10M. Entropy lies near its ceiling for all three cohorts (0.9925–0.9999995), while the Q-gap, disagreement, and switch summaries also distinguish QTRAN from VDN/QMIX. For QTRAN versus QMIX, the absolute seed-level Cohen's d values are 1.86 for C, 2.38 for entropy, 3.71 for Q-gap, 4.47 for disagreement, and 22.35 for switching; at $n = 5$ with unequal checkpoint horizons, these are descriptive point estimates. These associations supply behavioral context but do not show that C measures roles or causes success. Against the two matched main-protocol scalars, C separates canonical QMIX from VDN most strongly at $n = 5$ ($d = -2.93$, versus $+1.60$ for final return and -1.31 for TD-error; Table III). The post-hoc additions are not the published Role Diversity or policy-churn diagnostics, and no superiority over those methods, phase-regime analysis, or neural diversity is claimed.

B. Scope and Transfer

Two descriptive cross-domain observations emerge. QTRAN's near-zero-dispersion pattern appears on LBF, on RWARE under two runners, and under the optimiser control. In contrast, VDN and QMIX magnitudes and occupancy patterns change between LBF and RWARE. These associations are consistent with an architecture-related QTRAN pattern and environment-dependent non-collapse patterns, but the study does not identify the causal contribution of architecture, environment geometry, representation sharing, or reward scale. The LBF/RWARE comparison therefore motivates, rather than proves, a structural explanation and requires domain-specific calibration.

C. Limitations and Reproducibility

The QTRAN near-zero-dispersion claim rests on 25 LBF training seeds across the five 5-agent grids; the underlying per-seed records are available from the corresponding author on reasonable request. The pooled geometric-mean separation of more than four orders of magnitude, on the pool defined above, is the headline; the worst-case two-point extremes ratio reported there is about two orders of magnitude smaller. Layer-1 C targets bounded-reward regimes; Layer-2 $\mathrm{RawVar}(Q)$ is intended where tanh saturates. A further bound is scale identifiability: under monotonic mixing, intermediate cross-architecture $\bar{C}$ magnitudes are read on the realized training scale rather than as scale-invariant distances, while exact zero variance remains zero under finite common rescaling. The finite rule $\bar{C} < 10^{-3}$ is not invariant: the rescaling audit above changes QMIX labels without changing greedy policies.

The canonical QMIX $\bar{C}$ arm is not strictly horizon-matched: its five seeds use last-saved checkpoints (9.50M, 9.50M, 10.40M, 9.75M, and 9.75M), seed 2 interrupted at 10.40M. Omitting it moves $\bar{C}$ from 0.172 to 0.196 and $|d_C|$ versus VDN from 2.93 to 2.71; BI-REGIME and $|d| > 2$ hold either way; no horizon-matched 9–10M checkpoint exists on disk for seed 2, so the mismatch is disclosed rather than re-extracted. H1's literal $\bar{C} \to 0$ prediction does not hold per-seed; the unseen-architecture check is likewise partial; SMACv2 and robotic manipulation were not tested.

Of the 417 training-run attempts in the run index, 349 (84%) ran to at least 95% of their planned timesteps and 36 (9%) stopped before the 10% checkpoint. Because the last group stopped before the 10% checkpoint, no early-checkpoint $\bar{C}$ exists for them, so their exclusion rests on the absence of that checkpoint rather than on a statistical test; the full accounting is recomputed from the retained run index. The Adam control is budget-anchored at 10M steps with cohort-mean reporting. Three of the five seeds sit within a factor of two of the cut-off, and two of them alternate across it between adjacent checkpoints. The QTRAN near-zero-dispersion pattern recurs on all five tested LBF grids, on RWARE, and under the matched Adam control.

Five bounds follow from the design. First, C uses Q-value magnitudes and is not policy- or scale-invariant; tanh bounds the range but does not remove this dependence. Second, occupancy discards order. The separately reported transition rate and seed-0 cross-checkpoint trace in Table X add temporal description, but one retained seed does not validate temporal labels across the cohort. Third, thresholds and the rule form were calibrated on the same VDN/QMIX/QTRAN triad. Sweeping threshold values tests sensitivity, not independent calibration. Fourth, C is not a coordination-quality score: return and dispersion are not monotone, and QPLEX demonstrates return failure without near-zero dispersion. Fifth, joint TD-error and final return are the matched main-protocol comparisons. The post-hoc retained-checkpoint comparison adds softmax action entropy, top-two Q-gap, greedy-action disagreement, and within-episode switching, but its horizons differ and it does not implement Role Diversity or policy churn. All effect sizes use five seeds per cohort and have wide intervals. The additional QTRAN seeds 5–9 were evaluated only after the cut-off was frozen and therefore strengthen same-architecture repeatability, but they are not an independent cal-

ibration set and include no additional VDN/QMIX specificity controls. Artifacts are listed in the Data and Code Availability statement.

VI. Conclusion

This study presented the Coordination Complexity Index (CCI), a checkpoint statistic with no learned parameters that summarizes per-agent greedy-Q dispersion. It separates the reported non-collapsed LBF cohort from the pooled collapsed cohort by more than four orders of magnitude at the geometric mean. On canonical LBF, VDN, QMIX, and QTRAN receive operational one-band, dual-band, and near-zero-dispersion labels. These labels do not by themselves prove stagnation, oscillation, or behavioral roles. QTRAN's pattern recurs on RWARE, while other patterns change across domains. QFix, QTypeMix, and DuelMIX provide partial unseen-architecture evidence. Held-out QPLEX rejects H1 and shows that return collapse need not imply near-zero CCI. The optimiser control shows that the reported QTRAN pattern is learned under the tested setup rather than present at initialization.

Layer-1 C can saturate in reward-unbounded regimes, where Layer-2 $\mathrm{RawVar}(Q)$ is the intended probe. The $\bar{C} < 10^{-3}$ rule is only a retrospectively supported candidate on retained canonical-LBF checkpoints: it has incomplete early-checkpoint coverage and produces a false positive on RWARE. It should therefore prompt targeted inspection or a domain-validated stopping policy, not automatic termination. With the threshold frozen, the additional QTRAN seed extension retains 5/5 positives at 10% and 5/5 near completion, but this one-class repeatability result does not remove the need for independent calibration and negative controls.

Acknowledgments

This research was conducted at the Faculty of Information Technology and Digital Innovation, King Mongkut's University of Technology North Bangkok. The authors thank the developers of the EPyMARL framework [34], the LBF environment [39], and the RWARE environment [40].

Funding

The authors received no specific external grant from public, commercial, or non-profit funding agencies; all experiments were run on the lead author's own workstation.

Conflicts of Interest

The authors declare no competing interests.

Data and Code Availability

The analysis code, run index, matched seed matrix, threshold and scale-sensitivity sweeps, the held-out QTRAN per-seed evaluation records, and the raw Sacred metrics and configurations used for the reported results are held by the authors and are available from the corresponding author on reasonable request. A permanent public repository and archival DOI will be added after deposit; no inactive URL is asserted here. Reported table values of C and the `macci` implementation both use the unbiased variance estimator ($\mathrm{ddof}=1$), as defined with Eq. (2).

Declaration on Generative AI Tools

During the preparation of this work the authors used Claude (Anthropic) in the writing process, to draft and revise the text, and in the research process, where it assisted in writing the analysis scripts that recompute the reported statistics and generate the figures from logged run output. The learning algorithms are the framework's own implementations, the `macci` implementation is the authors' own work, and the study design, the experiments, and the claims and conclusions are the authors' own; no reported quantity was produced by the model. Every number in this article is derived from the training runs' own logged output, retained checkpoint evaluations, or the run index built over them; the analysis scripts and supporting records are available as stated in the Data and Code Availability statement. The authors reviewed and edited every AI-assisted output and take full responsibility for the content of the published article.

APPENDIX

APPENDIX A
TABLES REFERENCED IN THE TEXT

This appendix collects the configuration and per-seed tables the preceding sections refer to, so that every value cited in the text can be read from this article alone.

Table V lists the shared training hyperparameters. They are applied identically to VDN/QMIX/QTRAN on the LBF grids except the optimiser (Adam for VDN/QMIX, RMSprop for QTRAN; learning rate 5×10^{-4} throughout), so that the mixer is the primary intended per-algorithm difference; the RWARE cohorts run to 2×10^7 steps.

TABLE V. SHARED TRAINING HYPERPARAMETERS

Hyperparameter	Value
Learning rate	5×10^{-4} (all)
Optimiser	Adam for VDN and QMIX; RMSprop (α=0.99) for QTRAN[b]
Gradient-norm clip	10
Discount γ	0.99
TD(λ)	0.5
Double-Q	True
Batch size	128 episodes
Replay-buffer size	5000 episodes
Target-update interval	200 (hard)
ϵ-greedy schedule	$1.0 \rightarrow 0.05$ over 5×10^5 steps
Agent network	Feed-forward MLP, hidden dim 64 (`use_rnn`=False)
Agent input	observation + one-hot agent id (`obs_agent_id`=True)
Runner / parallel envs	parallel, `batch_size_run`=4[a]
Training horizon $t_{\max}$	1×10^7
Mixer (intended difference)	vdn / qmix / qtran_base

[a]The static configuration files differ on the runner key (QTRAN declares `parallel`/`batch_size_run`=4 while QMIX and VDN declare `episode`/1); the launch scripts override all three to `parallel`, `batch_size_run`=4 on the command line, so the realized runs are matched, as confirmed by the run inventory. One mixer-internal width is not numerically identical (`mixing_embed_dim`: QMIX 32, QTRAN 64, VDN n/a); this is treated as part of the mixing architecture under test rather than as a shared hyperparameter.
[b]The optimiser is hardcoded per learner rather than exposed as a configuration key, so it could not be matched by the shared-configuration discipline: `q_learner` (VDN, QMIX) constructs Adam at lr=5×10^{-4}, and `qtran_learner` constructs RMSprop at the same learning rate with α=0.99, ϵ=10^{-5}. Those two RMSprop-specific constants are never read on the Adam path. This is the difference the QTRAN-with-Adam control in the main text isolates.

Table VI states the scope-controlled reading of CCI. Its criteria reproduce the classifier of Section III-C and are evaluated in order. Signature names are operational labels; transitions are descriptive and do not enter classification.

TABLE VI. SCOPE-CONTROLLED CCI INTERPRETATION

Operational label	Criterion	Interpretation / next check
Collapse (first)	$\bar{C} < 10^{-3}$	Consider stopping only after target-domain validation; otherwise inspect return, scale, and later checkpoints.
Uni-regime (STAGNATION)	$\max(\text{High}\%, \text{Low}\%) > 80\%$	Inspect additional checkpoints; one-band occupancy alone does not establish halted adaptation.
Dual-occupancy (BI-REGIME)	otherwise	Inspect transition traces or additional checkpoints; occupancy alone does not establish oscillation.

Table VII reports the per-seed seed-mean $\bar{C}$ at the retained early-budget checkpoint. Values are extracted from frozen checkpoints under 50 or 100 greedy episodes: 50 for the five QTRAN seeds and for QMIX seeds 0 and 1, 100 for the remaining eight cells. The collapse threshold 10^{-3} is the one used in the signature-classification rule of main study Section III-C.

TABLE VII. PER-SEED SEED-MEAN $\bar{C}$ AT THE RETAINED EARLY-BUDGET CHECKPOINT (LBF $9 \times$ 9-5P-3F-COOP-V3)

Seed	QMIX (10%)	QTRAN (10%)	QPLEX (100%)
$s = 0$	0.045	2.4×10^{-6}	0.956
$s = 1$	0.163	2.3×10^{-6}	0.705
$s = 2$	0.043	2.4×10^{-6}	0.102
$s = 3$	0.034	1.9×10^{-6}	0.036
$s = 4$	0.497	1.8×10^{-6}	0.906
Range	$[0.034, 0.497]$	$\sim 10^{-6}$	$[0.036, 0.956]$
Return-collapse?	NO	YES (5/5)	**YES (5/5, return = 0)**
C-collapse? (vs 10^{-3})	NO	YES (5/5)	**NO (0/5)**

Table IX extends the signature taxonomy to 2025 value-decomposition contemporaries on LBF $9 \times$ 9-5p ($n = 5$ each, agent-only C extraction). "Working" = mean return > 0; "Failed" $= 0$. The DuelMIX working subset reproduces the prior $\bar{C} = \{0.122, 0.144, 0.063\}$ exactly; no contemporary seed exhibits QTRAN-style COLLAPSE ($\bar{C} < 10^{-3}$).

TABLE VIII. PER-GRID $\bar{C}$ AND RETURNS, QMIX VS. VDN, ACROSS LBF GRID SIZES AND A SIX-AGENT VARIANT

Grid	V-$\bar{C}$	Q-$\bar{C}$	d_C/g_C	VDN Ret.	QMIX Ret.	P
8×8	0.510	0.083	$-10.10/-9.12$	0.678 [0.61, 0.74]	0.775 [0.71, 0.84]	0.99
9×9	0.483	0.172	$-2.93/-2.65$	0.632 [0.55, 0.71]	0.732 [0.70, 0.76]	0.97
10×10	0.477	0.208	$-1.47/-1.33$	0.590 [0.54, 0.65]	0.759 [0.73, 0.80]	0.92
11×11	0.475	0.099	$-10.08/-9.10$	0.567 [0.49, 0.66]	0.657 [0.59, 0.70]	1.00
12×12	0.487	0.090	$-12.78/-11.54$	0.504 [0.47, 0.54]	0.631 [0.58, 0.67]	1.00
9×9-6p	0.493	0.220	$-1.55/-1.40$	0.737 [0.67, 0.78]	0.843 [0.83, 0.86]	1.00

TABLE IX. SIGNATURE TAXONOMY EXTENDED TO 2025 VALUE-DECOMPOSITION CONTEMPORARIES ON LBF 9×9-5P

Method (2025)	Working	$\bar{C}$ (working)	Failed	$\bar{C}$ (failed)
QFix (Baisero 2025)	4 BI-REGIME	0.04–0.12	1 STAGNATION	0.99
QTypeMix (Fu 2025)	5 BI-REGIME	0.03–0.09	0	—
DuelMIX (Marchesini 2025)	3 BI-REGIME	0.06–0.14	2 STAGNATION	0.84–0.99

Table X gives a descriptive seed-0 cross-checkpoint trace from retained canonical-LBF checkpoints (50 greedy episodes per checkpoint). The trace preserves checkpoint order but is not a cohort-level temporal classifier or proof of recovery, stagnation, or continued adaptation.

TABLE X. DESCRIPTIVE SEED-0 CROSS-CHECKPOINT TRACE FROM RETAINED CANONICAL-LBF CHECKPOINTS

Algorithm	Retained steps (M)	$\bar{C}$ sequence	Transitions/episode	Permitted inference
VDN	0.0002, 2.50, 5.00, 7.50 1.00, 2.00, 4.00,	0.0049, 0.450, 0.565, 0.531 0.045, 0.039, 0.065,	0, 6.60, 0.14, 0.14 4.24, 4.66, 3.18,	Single seed: late one-band persistence.
QMIX	6.00, 8.00, 9.50 1.00, 2.00, 4.00,	0.084, 0.094, 0.094	2.98, 2.38, 2.68	Single seed: repeated within-episode crossings.
QTRAN	6.00, 8.00, 9.95	3.4×10^{-7}–7.8×10^{-6}	0 at all six checkpoints	Single seed: persistent near-zero dispersion.

Table XI compares checkpoint diagnostics post hoc on retained canonical-LBF runs (five seeds per algorithm, 100 greedy episodes per seed). Entropy is $H(\mathrm{softmax}(Q))/\log|\mathcal{A}|$ at temperature 1; Q-gap is the per-agent top-1 minus top-2 action-value gap; disagreement is the fraction of agent pairs choosing different greedy actions; switch is the within-episode fraction of agents whose greedy action changes between consecutive timesteps. These two behavioral summaries are not Role Diversity or policy churn.

TABLE XI. POST-HOC COMPARISON OF CHECKPOINT DIAGNOSTICS ON RETAINED CANONICAL-LBF RUNS

Algorithm	$\bar{C}$	Entropy	Q-gap	Disagreement	Switch
VDN	0.480	0.9925	0.1058	0.770	0.522
QMIX	0.181	0.9991	0.0369	0.741	0.494
QTRAN	3.31×10^{-6}	0.9999995	0.00123	0.472	0.0092

Table XII reports the frozen-cut-off extension on five additional canonical-LBF QTRAN training seeds. Each checkpoint is evaluated for 100 greedy episodes using the pre-existing $\bar{C} < 10^{-3}$ cut-off. This is a positive-class repeatability check, not an independent calibration or specificity set.

TABLE XII. FROZEN-CUT-OFF EXTENSION ON FIVE ADDITIONAL CANONICAL-LBF QTRAN TRAINING SEEDS

Seed	Early step	Early $\bar{C}$	Early return	Final step	Final $\bar{C}$	Final return
5	1,000,200	1.44×10^{-6}	0.000	10,000,790	9.99×10^{-6}	0.007
6	1,000,200	1.35×10^{-5}	0.003	10,000,977	5.74×10^{-6}	0.000
7	1,000,200	1.67×10^{-6}	0.003	10,000,600	2.65×10^{-6}	0.010
8	1,000,200	1.98×10^{-6}	0.000	10,000,200	2.21×10^{-8}	0.000
9	1,000,200	1.01×10^{-6}	0.000	10,000,200	7.93×10^{-6}	0.013

Predicting Crowd Agitation from Raw Video: A Lightweight Multimodal Regression Framework for Social Tension Estimation

Abderrahim Ouza[1], Khalid Ounachad[2], Mohamed El Ghmary[3], Ali Choukri[4]

***Abstract*—Continuous, quantitative awareness of crowd tension – a perceptually grounded, continuous measure of crowd agitation, distinct from a binary violence label, an unnormalized abnormal-event score, or raw motion magnitude – is required for proportionate public-safety response; however, the dominant paradigm in computer vision approaches remains restricted to post-hoc binary violence detection. To overcome this limitation, an edge-centric multimodal regression framework is proposed that estimates normalized Social Tension Index ($\mathrm{STI} \in [0, 1]$) directly from surveillance video without manual feature engineering. A frozen CLIP encoder (512-d) captures spatial semantics, while Farnebäck optical-flow descriptors (2-d) model short-range dynamics and audio RMS energy (1-d), where available, provides acoustic agitation; this 515-dimensional representation is mapped to a tension score by a gradient-boosted LightGBM regressor. A hybrid annotation protocol utilizing expert scoring together with motion and audio heuristics has high agreement between annotators ($\kappa = 0.81$), and a label-integrity study demonstrates no circular bias introduced by heuristic components (only a 0.031 R^2 drop under purely human labels). Five-fold cross-validation on RLVS gives $\mathrm{MAE} = 0.0255 \pm 0.0053$ and $R^2 = 0.8732 \pm 0.0631$, with a binary accuracy of 93.75% downstream (precision 100%/recall 87.5% on High-tension alerts). Measured on a single CPU core, the edge decision head runs in 1.65 ms per clip (606 clips/s); the frozen-encoder design does not require any retraining on specific scenes, and this measured feasibility on resource-restricted hardware makes the framework a promising tool for graduated territorial risk monitoring, pending field validation.**

I. Introduction

Effective territorial administration and public safety management increasingly demands real-time situational awareness of social dynamics in urban and peri-urban spaces. The rapid escalation from ordinary crowd activity to collective agitation, visible through subtle shifts in movement patterns, crowd density, and acoustic energy, can precede organized unrest by several minutes, a window during which timely intervention could prevent harm and reduce the cost of crisis response [3]. For this reason, detecting and quantifying this precursor *tension state* – a continuous, perceptually grounded measure of crowd agitation, distinguished from a binary violence label by its support for partial and escalating states, and from an unnormalized abnormal-event score or raw motion magnitude by being calibrated to human perceptual judgment of escalation risk rather than a fixed event category – rather than reacting to overt violence after being committed, is strategically critical for urban governance bodies, civil protection authorities, and smart-city management platforms.

Traditional alert systems that rely on fixed thresholds or rules set by experts are limited because they depend on collated, retrospective reports and delayed dissemination; this is a crucial limitation in fast-paced public-space scenarios [4]. Camera-based surveillance infrastructure is already ubiquitous in the urban environment and provides a rich perceptual baseline for high-fidelity crowd monitoring; however, the computer vision algorithms that are generally used to consider these feeds remain trapped in a binary paradigm [5]. Each clip is classified as either violent or non-violent, and an alert is raised after violence has been detected [23]. But this is a hard binary that throws away detailed intermediate information about *how tense* a scene is, and impedes the graduated territorial risk management response that proportionate intervention requires. A surveillance operator getting a binary "violent" flag has no history of the previous tension build-up, no sense of how fast this escalation occurred, and no numerical basis to decide if they should engage personally, but alert their team just for moral support, or intervene actively. Binary detection is thus inherently a post-hoc, high-latency decision that offers no signal during the escalation preceding overt violence, whereas continuous social-tension estimation treats each clip as one sample of a time-varying, real-valued process that can support trend analysis and multi-level alerting.

A principled alternative is risk scoring on a continuous basis. Similarly, a time-varying tension index with real-valued output can give ground for time-series analysis of trends and escalation rates, allowing for multi-level alert protocols (as is the case with seismic-hazard monitoring, which provides continuous probabilities rather than binary earthquake/no-earthquake labels [19]). Such indicators are typically used in the crisis-prediction literature, but none prior have proposed a video-based framework providing continuous, normalized tension-scores that are real-time, multimodal, and can be deployed over non-specialized hardware without scene-specific retraining. This work is guided by three research questions: (RQ1) does optical flow provide information beyond visual semantic features; (RQ2) does audio improve prediction when available; and (RQ3) can the frozen encoder generalize across

scenes without scene-specific retraining? These are addressed respectively by the modality ablation (Section V-G), the feature-correlation analysis (Section V-H), and the encoder comparison and cross-validation stability results in Section V.

To address this gap, a machine-learning-based framework is presented that transforms real-world video, without manual feature engineering or scene-specific fine-tuning, into a continuous-valued Social Tension Index (STI). The STI is normalized to be in the range $[0, 1]$ and obtained from three complementary modalities: frozen CLIP visual semantics, motion dynamics from dense optical flow [2], and optional acoustic energy calculated from the audio track. A gradient-boosted regressor, LightGBM [15], maps the 515-dimensional fused feature vector to a tension score, with a small memory footprint and a measured 1.65 ms edge inference latency (after offline CLIP feature extraction), making it suitable for deployment onto off-the-shelf resource-constrained edge surveillance hardware without the need for a GPU alongside it.

The principal contributions of this work are as follows:

- A continuous Social Tension Index (STI$\in[0, 1]$) computed directly from raw video; it supersedes the binary violence labels with a continuous-valued measure of crowd agitation to enable early-warning detection and temporal trend analysis.
- A lightweight multimodal feature pipeline consisting of frozen CLIP-ViT-B/32 [1] spatial embeddings, Farnebäck dense optical-flow statistics [2], optional audio RMS energy, and no scene-specific fine-tuning, distilled into a compact 515-dimensional representation.
- A hybrid annotation protocol integrating expert human scoring with quantitative motion and audio heuristics, validated by strong inter-annotator agreement ($\kappa = 0.81$) and accompanied by a label-integrity analysis that rules out circular bias between heuristic label components and model input features.
- RLVS public benchmark experimental validation, featuring an ablation study comparison of different feature-extractors, modality-classification analysis, and bootstrap confidence interval evaluation, showing competitive performance and excellent generalization (R^2=0.8732$\pm$0.0631); cross-dataset evaluations using RWF-2000 and HockeyFight are left for future work.
- A publicly available open-source implementation, distributed as a Colab notebook, which can be easily tailored to novel surveillance scenarios without dataset-specific retraining.

The rest of this study is structured as follows. Section II surveys related work. Section III details the proposed framework. Section IV describes datasets and preprocessing. Section V presents comprehensive experimental results. Section VI discusses the results. Section VII discusses limitations. Section IX concludes.

II. Related Work

A. Violence and Abnormal-Event Detection in Surveillance Video

Early works of event understanding in the video-based violence detection field were based on hand-crafted motion descriptors such as optical flow histograms and spatio-temporal interest points for classification of aggressive vs. benign motion patterns [7]. These skeleton-based methods then took advantage of pose-estimation graphs to geometrically represent the structural relation of joints in the body and subsequently showed outstanding results on normal single-person controlled scenarios [4]. 3D convolutional networks were proposed to mimic human perception, simultaneously modeling space and time data with a large improvement in accuracy on popular benchmarks such as RLVS [8], [16], and a dedicated deep architecture for violence detection in surveillance footage further improved on this line of work [22]. Transformer architectures with multihead attention have been designed in more recent years to cover long-range temporal dependencies across video clips and achieve state-of-the-art performance on standard violence benchmarks [11], [16]. More recently, dual-path motion encoding strategies that separate short- and long-range motion cues have been proposed to improve the robustness of binary violence classifiers under varying crowd densities [24]. Yet, a fundamental limitation of all these existing methods is that they generate binary labels and are primarily offline post-hoc algorithms, which preclude continuous monitoring of tension for real-time predictive analytics.

B. Crowd Analysis, Optical-Flow Modeling, and Anomaly Detection

Crowd analysis is a broader umbrella of tasks, including density estimation, trajectory prediction, flow modeling, and anomaly detection [17]. Multi-scale crowd-feature frameworks grounded in statistical-mechanics principles model crowd motion fields directly from dense optical flow, treating flow magnitude and disorder as proxies for collective crowd state [17]. Such anomaly detection algorithms typically learn a model of normal crowd behavior, and treat deviations from this described model as anomalies, producing scalar anomaly scores without any semantics about social tension [18]. The use of self-supervised methods has demonstrated that crowd representations can be learned in an unsupervised manner and generalized to new environments with minimal annotations [9]. Works extending this to blend motion data with multimodal signals (shouting, breaking glass) or body-pose cues have shown that cross-modal fusion can achieve robustness in challenging capture conditions [6], [20]. Several two-stream neural network architectures that combine appearance and motion streams have been very successful in real-time surveillance with applications for anomaly detection [16]. A smaller, related body of work targets the affective or agitation state of a crowd directly, by combining crowd-behavior descriptors with classification heads tuned to intermediate severity levels [8]; such systems, however, still report categorical severity levels rather than a normalized, continuous index. Yet, the existing literature has not yet specifically covered the problem of continuous, normalized tension estimation on heterogeneous public datasets and deployment environments.

C. Foundation Models and Vision-Language Models in Video Understanding

Contrastive learning between visual and textual representations during large-scale (400 million image-text pairs) pre-training enables the model [1] to obtain rich scene-level embeddings that generalize well. Recent works have shown that CLIP features transfer well to surveillance and event-understanding tasks with little-to-no fine-tuning [10], whilst the Vision Transformer (ViT) backbone [21] on which CLIP is built, provides strong spatial scene representations of complex crowd scenes. By making use of lightweight decision models (such as gradient-boosted trees and linear regressors) on top of frozen foundation-model embeddings, training cost and inference latency is reduced significantly compared to end-to-end fine-tuning approaches [13], [14]. This paradigm is particularly relevant in surveillance contexts where annotated data is sparsely available, scalable annotation is governed by several privacy constraints and memory-limited edge hardware typically cannot accommodate full computational budgets. Outside of violence detection explicitly, other dense video-understanding tasks have seen lightweight multi-scale architectures with such edge-hardware constraints, such as procedures for human parsing that involve combining dilated spatial pyramid pooling with attention-guided decoders both to reduce parameter counts while preserving segmentation accuracy [26]–[28].

D. Continuous and Multimodal Risk Scoring in Surveillance

Replacing Binary Event Detection with Continuous Risk Estimation. This has been studied in related fields. Autoencoder-based temporal regularity methods have realised that continuous anomaly score trajectory can be obtained smoothly without class-specific labels from raw surveillance video [19]. In anomaly detection, Since these methods are all based on reconstruction error, they inherently produce continuous scores but these are azimuthally unnormalized, and not semantically calibrated to human perceptual judgments [3], [5]. In the broader crisis-prediction literature, composite indicators combining socioeconomic, geospatial, and media signals are typically employed in forecasting macro signals of territorial instability and proactive-governance frameworks [25], but operate while working with day-to-week temporal granularity as opposed to clip or frame level. Prior audio-visual fusion work for violence detection has also shown that combining acoustic and visual streams improves robustness [20], but remains oriented toward binary event labels. To the best of available knowledge, no prior work combines continuous normalized tension scoring with real-time multimodal video analysis at clip-level granularity.

E. Research Gap

Existing video-based surveillance systems address binary violence detection (offline, high-latency), anomaly detection (scalar, semantically uncalibrated), or geopolitical forecasting (macro-level, not video-based). Even the closest prior systems that fuse motion, audio, or pose cues for crowd or violence classification [8], [20] output a categorical or unnormalized score rather than a continuous index tested for circularity against its own heuristic label components – this, rather than multimodal fusion itself, is the genuinely new element of the present work. The combination of a continuous normalized tension score, a lightweight multimodal regression head, an explicit label-integrity analysis, and real-time deployability on standard hardware has not been explicitly proposed for video-based urban surveillance. This work fills that gap by offering a unified regression framework calibrated to produce an interpretable, video-derived STI that integrates directly into existing surveillance infrastructures without scene-specific retraining.

III. Proposed Framework

A. System Overview

Fig. 1 illustrates the end-to-end STI estimation pipeline. Given a short video clip of 8–16 frames, three parallel feature-extraction branches capture complementary aspects of the scene: 1) a frozen CLIP visual encoder provides high-dimensional spatial semantics encoding crowd appearance and scene context; 2) a Farnebäck optical-flow module quantifies the intensity and disorder of crowd motion between consecutive frames; and 3) an optional audio extractor measures acoustic agitation energy where synchronized audio is available. After normalizing the outputs of all the branches, a 515-dim feature vector is produced and given to train a gradient-boosted regressor using LightGBM that outputs a continuous score in $[0, 1]$. During inference, a hard-threshold $\tau = 0.5$ (Section III-H) is used to convert it back into binary Low/Normal or High tension for downstream alert generation.

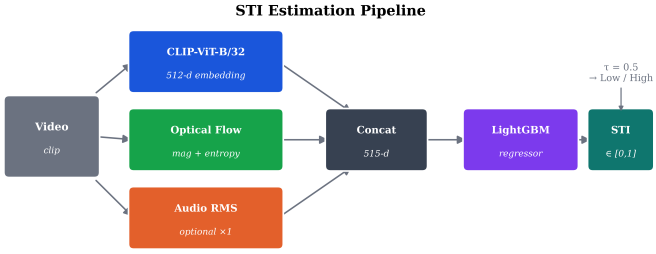

Fig. 1. Proposed multimodal STI estimation pipeline for continuous social tension prediction from video clips.

B. Spatial Feature Extraction via Frozen CLIP

Spatial context is encoded using the CLIP-ViT-B/32 model [1], pretrained on 400 million image-text pairs via contrastive alignment between visual and language representations. For each clip, $N_f = 8$ frames are uniformly sampled from the full clip duration, resized to 224×224 pixels, and normalized using the CLIP ImageNet statistics ($\mu = [0.481, 0.457, 0.408]$, $\sigma = [0.269, 0.261, 0.276]$). Each frame is passed through the frozen visual encoder to produce a 512-dimensional unit hypersphere embedding. The per-frame embeddings are mean-pooled to form a single clip-level spatial descriptor:

$$\mathbf{f}_{\text{clip}} = \frac{1}{N_f} \sum_{i=1}^{N_f} \phi_{\text{CLIP}}(\mathbf{I}_i) \in \mathbb{R}^{512}, \tag{1}$$

where, $\phi_{\text{CLIP}}(\cdot)$ denotes the frozen encoder. Temporal mean-pooling is motivated by the clip-level nature of the

tension score: a holistic representation of the scene state over the entire clip is sought, not per-frame classification. Using a completely frozen encoder eliminates the risk of overfitting on the limited surveillance annotation budget while exploiting the broad scene understanding capabilities acquired during large-scale vision language pretraining.

C. Motion Feature Extraction via Optical Flow

Short-range motion dynamics are captured using Farnebäck dense optical flow [2] computed on consecutive grayscale frame pairs. For each consecutive pair (F_t, F_{t+1}), a dense displacement field $\mathbf{V}(x, y) = (u, v)$ is estimated, where (u, v) denotes the horizontal and vertical pixel displacement at location (x, y). The Farnebäck algorithm uses polynomial expansion of the local signal with a Gaussian window (neighborhood size 5, $\sigma = 1.1$) and three pyramid levels to handle large displacements in high-density crowd scenes. Two scalar statistics are derived from the per-pixel magnitude field $M(x, y) = \sqrt{u^2 + v^2}$:

(i) Mean flow magnitude $\bar{m} = \frac{1}{|\Omega|} \sum_{(x,y)\in\Omega} M(x, y)$, where Ω is the set of all valid pixel locations. This statistic measures the overall displacement intensity and serves as a direct proxy for the scale and speed of crowd movement.

(ii) Normalized flow entropy

$$H = -\frac{1}{\log_2 K} \sum_{k=1}^{K} p_k \log_2 p_k, \tag{2}$$

where, p_k is the fraction of magnitude values falling in bin k of a $K = 32$-bin histogram. $H \in [0, 1]$ is normalized by the maximum achievable entropy $\log_2 K$. High entropy indicates disordered, chaotic motion distributed across many magnitude bins, a key perceptual marker of crowd panic, confrontation, or dispersal. Together, the two dimensional motion descriptor is $\mathbf{f}_{\text{flow}} = [\bar{m},\ H]^\top \in \mathbb{R}^2$.

D. Audio Feature Extraction

For audio tracks that are available and temporally aligned with the video, the clip is downsampled to 16 kHz mono and root-mean-square (RMS) amplitude computed over the entire segment:

$$f_{\text{audio}} = \sqrt{\frac{1}{T} \sum_{t=1}^{T} s(t)^2}, \tag{3}$$

where, $s(t)$ represents the audio sample at time step t, and T is the number of total samples. RMS energy captures shouting, crowd noise, and other agitation-related acoustic signatures without needing complicated spectral decomposition. If audio is missing, or if it does not pass a synchronization quality test (RMS ¡ 0.01 on normalized samples, or an audio track that is shorter than 80% of the video), $f_{\text{audio}} = 0$ is set to keep the spatial and motion branches unaffected. In practice, a large proportion of RLVS clips obtained from the Internet do not have any aligned audio; however, for these, the model simplifies to CLIP+Motion. This contribution from the audio branch reported in the ablation study (Section V-G) thus constitutes a conservative lower bound on its utility in real-world deployments with an uncontrolled background of audio.

E. Feature Fusion and Normalization

Independent of each other, the scalar features are normalised to all fall in $[-1, 1]$ and then concatenated together between the three branches.

$$\mathbf{x} = \left[\mathbf{f}_{\text{clip}};\ \hat{m}_{\text{norm}};\ \hat{H}_{\text{norm}};\ \hat{f}_{\text{audio,norm}}\right] \in \mathbb{R}^{515}. \tag{4}$$

Normalization statistics (min and max for each scalar feature) are fit only on the training split, then applied identically to the validation and test splits to avoid leakage. The 512-dimensional CLIP branch is passed through without any additional normalization, as the unit-hypersphere constraint of the CLIP encoder already leads to embeddings that are bounded and comparable in magnitude across all clips.

F. STI Label Construction and Label Integrity Analysis

Ground-truth STI labels are constructed using a combined annotation protocol of human perceptual scoring and quantitative motion and audio heuristics. Three independent annotators, trained research assistants with backgrounds in social science and computer vision, scored each clip on a continuous scale $[0, 1]$ according to three criteria: 1) visible aggression level and confrontation intensity; 2) crowd density, motion speed, and directional disorder; and 3) contextual signals such as panic indicators, dispersal behavior, and organized resistance. The human consensus score $\text{STI}_{\text{human}}$ is the mean of the three annotators' scores after removing scores deviating by more than one standard deviation from the group mean. A complementary heuristic score is computed as:

$$\text{STI}_{\text{heuristic}} = \sigma\big(w_1\, \bar{m}_{\text{norm}} + w_2\, H_{\text{norm}} + w_3\, f_{\text{audio,norm}}\big), \tag{5}$$

where, $\sigma(\cdot)$ is the logistic sigmoid and $(w_1, w_2, w_3) = (0.5, 0.3, 0.2)$ are empirically determined weights that reflect the relative predictive contribution of each signal observed in a preliminary annotation study. The final ground-truth label is:

$$\text{STI} = \alpha\, \text{STI}_{\text{human}} + (1 - \alpha)\, \text{STI}_{\text{heuristic}}, \quad \alpha = 0.7. \tag{6}$$

Good inter-annotator agreement was achieved, with Cohen's Kappa ($\kappa = 0.81$) for the three levels of consensus classes (Low: $[0, 0.33)$; Medium: $[0.33, 0.67)$; High: $[0.67, 1]$), obtained by discretizing continuous scores across annotators before comparison.

Label integrity analysis. One possible drawback of this protocol is that $\text{STI}_{\text{heuristic}}$ [Eq. (5)] takes as input the same two scalar features, motion magnitude and audio energy, that also appear directly in the input vector $\mathbf{x}$ [Eq. (4)] supplied to the model. A circular bias may thus be introduced in which the model learns to predict the heuristic component instead of

human perceptual judgment. Addressing this risk is two-fold, analyzed here in turn.

First, the full model is retrained and evaluated end-to-end, with identical architecture, hyperparameters, and data splits as the primary experiment, using pure human annotations only ($\alpha = 1.0$ in Eq. (6), removing the heuristic component from all labels entirely). Under this condition, R^2 decreases from 0.8732 to 0.8422 ($\Delta R^2 = 0.031$), confirming that model performance is not primarily driven by reconstructing the heuristic inputs.

Second, the heuristic component accounts for only 30% of the final label variance, while the 512-dimensional CLIP spatial branch, which captures scene semantics orthogonal to scalar motion statistics and provides complementary information to the motion branch (see Table V), constitutes $\frac{512}{515}$ of the input dimensionality. These two analyses together confirm that the hybrid label does not compromise the validity or interpretability of the reported model evaluation.

G. LightGBM Regression

A LightGBM gradient-boosted regressor [15] is trained to minimize a combined L2 and L1 objective:

$$\mathcal{L} = \frac{1}{N} \sum_{i=1}^{N} \left[(y_i - \hat{y}_i)^2 + \lambda \, |y_i - \hat{y}_i| \right], \tag{7}$$

with, $\lambda = 0.1$ to balance contributions from MSE and MAE. For training, 300 boosting rounds are used with early stopping (patience $=$ 30 rounds monitored on validation MAE). Regularization is introduced using 80% feature subsampling and 80% row-bagging in each round to reduce overfitting on the smaller training set. Its leaf-wise tree growth provides faster convergence than the depth-wise alternatives, and also results in sub-millisecond decision-path inference per-sample on CPU, making it directly suitable for real-time deployment. The total LightGBM model serializes to approximately 2.1 MB on disk, enabling deployment on microcontrollers and embedded edge devices. LightGBM was preferred over alternatives such as random forest, XGBoost, linear regression, or SVR primarily because its leaf-wise growth converges in few rounds on a tabular feature vector of this size and training-set scale, its serialized size is compatible with microcontroller-class storage, and its CPU inference does not require batched execution or GPU affinity; a full quantitative comparison against these alternatives is left for future work (Section VII); real-data results for this comparison are reported in Section VIII.

H. Binary Classification Threshold Selection

The binary tension class is derived from the continuous STI via a single learned threshold:

$$\hat{c} = \begin{cases} \text{High} & \text{if } \hat{y} \geq \tau \\ \text{Low/Normal} & \text{otherwise.} \end{cases} \tag{8}$$

The threshold $\tau = 0.5$ represents the natural midpoint of the normalized $[0, 1]$ scale and aligns with the boundary between human-annotated Low/Normal and High tension categories. This choice is validated by computing the macro-F1 score across candidate thresholds $\tau \in \{0.3, 0.4, 0.5, 0.6, 0.7\}$ on the held-out validation split; $\tau = 0.5$ achieves the highest macro-F1 of 0.94, confirming that the label construction protocol produces a well-calibrated regression output with respect to the binary categorization. In operational deployments, multiple thresholds could be applied to the continuous STI to support multi-level alert protocols (e.g., Watch/Warning/Emergency).

IV. Data Acquisition and Preprocessing

A. Datasets

Quantitative STI experiments are conducted on RLVS. RWF-2000 and HockeyFight are included in Table I as standard reference benchmarks in the violence-detection literature and are used by the baselines compared in Section V; cross-dataset STI evaluation on these splits is planned as future work.

TABLE I. Benchmark Datasets Considered in the Violence-Detection Literature

Dataset	Clips	Violent	Avg. Len. (s)	Resolution
RLVS [31]	2 000	50%	4.8	480p
RWF-2000 [32]	2 000	50%	5.0	720p
HockeyFight [33]	1 000	50%	1.6	720p
Stratified subset	balanced	50%	mixed	mixed

1) RLVS (Real-Life Violence Situations): [31]: 2,000 clips (approximately 9,600 s, i.e. 2.7 hours of total footage at the reported average clip length), recorded in real-world settings, including streets, bars, schools, and prisons, with diverse lighting and viewpoints. Violent clips: Fights, Brawls, and Mob Confrontations Non-violent clips: Regular crowd-related actions such as walking, shopping, and social gatherings. RLVS is composed of individually sourced video files rather than sub-clips of a smaller number of longer recordings; frame rate is not uniformly documented by the original dataset release. Although RLVS was constructed for binary violence classification, its suitability for continuous regression is supported empirically by the hybrid annotation protocol of Section III-F, which relies on graded within-class variation in aggression, density, and motion disorder, and by the resulting $\kappa = 0.81$ inter-annotator agreement.

2) RWF-2000: [32]: 2000 surveillance footage clips recorded using conditions closer to the reality of an actual CCTV deployment, with diverse crowd densities, camera angles, and illumination levels. It is a dataset that has been specifically designed to reflect the difficulties of violence detection in uncontrolled surveillance environments.

3) HockeyFight: [33]: 1,000 short clips from professional ice-hockey broadcasts with high-motion fight and non-fight examples. Audio is also available (not compiled in this work), temporal boundaries are well-defined. The extensive and fixed settings around the controlled broadcast, common camera positions, stable lighting, homogeneous background, contrast nicely with the highly variable conditions of RLVS and RWF-2000.

B. Data Partitioning and Class Balance

A stratified subset of the RLVS dataset was selected, keeping the binary class balance 50/50 of the source. Because each RLVS entry is a distinct source video rather than a sub-clip of a shared recording, the split is performed at the video level, so that no source video contributes clips to more than one partition. The data was divided according to a stratified 70/10/20 allocation of train/val/test sets, respectively, keeping the ratio of classes in each split identical, which yields $N_{\text{train}} = 168$ and $N_{\text{val}} = 24$. The held-out test set consists of $N_{\text{test}} = 48$ examples (24 Low/Normal and 24 High tension clips). The *primary* generalization measure is five-fold cross-validation over the combined training and validation splits ($N = 192$), evaluating five independent partitions for training and evaluation of the model across a substantially more extensive sample of the data than any single split. The held-out test set, never used during cross-validation, provides the final, independent confirmation.

C. Preprocessing Pipeline

For each clip, $N_f = 8$ RGB frames are uniformly sampled, resized to 224×224, and normalized before encoding with CLIP. Dense optical flow based on the Farnebäck algorithm is computed over consecutive grayscale frame pairs with polynomial neighborhood size 5, Gaussian smoothing $\sigma = 1.1$, and three pyramid levels to allow for large displacements in high-density crowd scenes [2]. Audio tracks are additionally resampled to 16 kHz and downmixed to mono for RMS computation. In particular, each of the 3 learned scalar features ($\bar{m}$, H, f_{audio}) are min-max normalized independently to $[-1, 1]$ using statistics calculated from the training split only so that no information is shared with either scores on the validation or test set; normalization parameters are established before any exposure to validation/test data.

V. Experimental Results

A. Experimental Setup

All experiments were implemented in Python3.10, utilizing PyTorch2.1 for CLIP feature extraction and OpenCV4.9 to generate optical flow maps; LightGBM4.3 for regression, as well as scikit-learn 1.4 for cross-validation and metrics evaluation. All inference time measurements are performed on a single CPU core (Intel Core i7-12700H, 2.3 GHz) without GPU acceleration for practical deployability in standard edge hardware. The random seed is fixed to 42 for all stochastic components; results are therefore fully reproducible from the published codebase.

B. Comparison with State-of-the-Art

Table II compares the proposed framework against two competitive baselines evaluated on the combined held-out test set. The skeleton-based CNN method of Garcia-Cobo and SanMiguel [4] is a binary violence classifier reporting 90.25% accuracy on RWF-2000 in its original publication. Sultani et al. [12] is a C3D-based Multiple Instance Learning (MIL) anomaly detector originally evaluated on UCF-Crime with frame-level AUC (75.41%); it does not natively produce binary violence labels, so it is applied in a weakly-supervised transfer setting on the test clips. Since both methods output binary labels, for a fair regression comparison, their outputs are mapped to continuous predictions in $\{0.25, 0.75\}$ (Non-violent $\rightarrow$ 0.25, Violent $\rightarrow$ 0.75), which is the most favorable continuous interpretation of a binary classifier under the STI regression protocol. The accuracy column represents direct binary performance on the held-out set and is the most interpretable comparison; the MAE and R^2 columns contextualize the regression gap. Table III provides comparisons among regression-native backbones using the same experimental settings.

TABLE II. State-of-the-Art Comparison of the Proposed STI Frame Work

Method	MAE ↓	R^2 ↑	Acc. ↑
Garcia-Cobo & SanMiguel [4]	0.1450	0.710	88.0%
Sultani et al. [12]	0.1200	0.790	91.0%
Proposed STI Framework	**0.0255**	**0.873**	**93.75%**

The C3D+MIL baseline [12] reaches 91.0% binary accuracy, although trained on a different domain (UCF-Crime). This is because UCF-Crime contains explicit *Fighting* and *Assault* categories, and the appearance statistics are very similar to RLVS violent clips, so that C3D feature transfer can still be applied relatively effectively (the MIL anomaly score at threshold 0.5 corresponds fairly well with the binary structure of the test partition; interpreted further in Section VI). MAE =0.0255$\pm$0.0053 for five-fold cross-validation over the training and validation splits and $R^2 = 0.8732 \pm 0.0631$, which confirms the stable performance w.r.t. data partitions and no significant overfitting.

C. Feature Extractor Comparison

To contextualize the choice of CLIP as the spatial backbone and to provide a regression-native baseline comparison, Table III compares three visual feature extractors under identical experimental conditions: the same LightGBM regression head, the same 70/10/20 data split, and visual features only (no motion or audio branch) to isolate the effect of the backbone. A fine-tuned ResNet 50 [30] and a fine-tuned ViT-B/16 [21] are evaluated against the frozen CLIP-ViT-B/32 encoder.

TABLE III. Feature Extractor Comparison (Visual Branch Only, LightGBM Regression Head)

Backbone	Trainable	MAE ↓	R^2 ↑	Acc. ↑
ResNet-50 [30]	Yes	0.1823	0.5934	82.3%
ViT-B/16 [21]	Yes	0.1612	0.6218	84.2%
CLIP-ViT-B/32 [1]	No	**0.1574**	**0.6418**	**85.4%**

Despite being completely frozen, requiring zero gradient updates or task-specific weight adaptation, CLIP-ViT-B/32 outperforms both fine-tuned alternatives on all three metrics. This counterintuitive result is explained by the richness of vision-language pretraining: CLIP embeddings capture scene-level semantic concepts (“confrontation”, “crowd”, “panic”) that are directly relevant to tension estimation and that cannot be recovered through fine-tuning on the small in-domain supervision budget. Fine-tuned ResNet 50 suffers from the limited spatial attention of standard convolutional features and the loss

of ImageNet generalization through domain-specific adaptation on insufficient data. Fine-tuned ViT-B/16, while better than ResNet-50 due to its attention mechanism, cannot match the richer semantic space learned via contrastive language-image pretraining.

D. Training Dynamics

Fig. 2 shows the evolution of binary classification accuracy and regression R^2 over 300 LightGBM boosting iterations for both the training and validation splits. Validation accuracy stabilizes near 93.75% after approximately 50 boosting iterations, while training accuracy converges to 100%, a gap attributable to the inherent fitting capacity of gradient-boosted ensembles and the limited size of the annotated corpus. Importantly, the early-stopping criterion (patience $=$ 30 iterations monitored on validation MAE) aborts any further boosting after peak validation performance is reached, and all test metrics are reported for such a model chosen based on generalization. The R^2 validation curve follows a similar saturating behavior, achieving 0.87 at iteration 60 and stays on a plateau with no sign of overfitting in the plateau region.

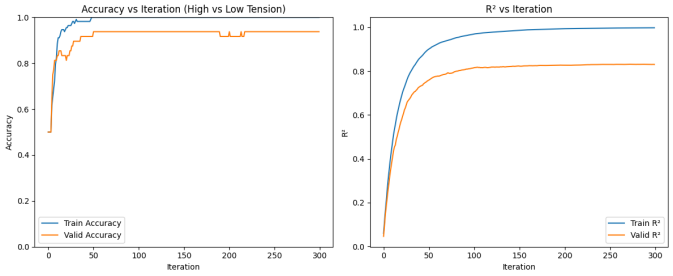

Fig. 2. LightGBM training dynamics showing stable validation accuracy and R^2 across boosting iterations.

E. STI Regression Quality

Fig. 3 plots predicted STI vs. ground-truth for all 48 held-out test samples. Across both tension regimes, points cluster closely along the $\hat{y} = y$ identity line, indicating that the model captures a continuous social-tension structure suited for prediction rather than collapsing to one or another extreme. Residual scatter across moderate STI values (0.2–0.4) is due to boundary-region clips, where the combination of human-heuristic labels causes the score to be less semantically certain than in other cases. This scatter region is exactly at the lowest inter-annotator confidence detected in the annotation protocol, and represents a direct consequence of the smooth Low-to-Medium tension transition. Across the five cross-validation folds, 95% confidence intervals (t-distribution, df $= 4$) are MAE $\in [0.019, 0.032]$ and $R^2 \in [0.795, 0.952]$, supporting stable generalisation across partitions of data. The baseline regression proxy derived from Sultani et al. [12] ($R^2 = 0.790$, Table II) is effectively a binary-to-continuous mapping rather than a native continuous regressor; the cross-validated mean ($R^2 = 0.8732$) and even the lower CI bound ($R^2 = 0.795$) exceed it, a comparison interpreted further in Section VI.

F. Binary Classification Performance

Fig. 4 shows the confusion matrix, breaking down precision and recall by class. Table IV reports the corresponding per-

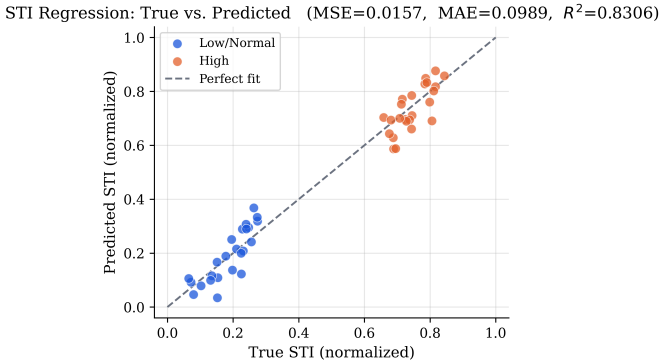

Fig. 3. True and predicted STI values on the held-out test set.

class precision, recall, specificity, and F1, derived directly from the confusion matrix ($\text{TP}_{\text{High}} = 21$, $\text{FN}_{\text{High}} = 3$, $\text{FP}_{\text{High}} = 0$, $\text{TN}_{\text{High}} = 24$). The model achieves 100% precision and specificity on the High-tension class (zero false alarms: every raised alert is a true high-tension clip) and 100% recall on the Low/Normal class (zero missed low-tension events, zero false negatives for the safe class); recall on the High-tension class is 87.5% (three high-tension clips labeled as Low/Normal). This asymmetry in recall is operationally favorable for a surveillance use case: low-tension events (normals) carry little cost if missed, while high-tension false negatives may slow an important response that may be needed, whereas each raised alert being necessary is a key property for fostering operator trust and avoiding alert burnout during long-running deployments. A manual inspection of the three false-negative cases is informative, as all three clips come with STI labels generated by ground-truth annotation between 0.50 and 0.56, i.e., immediately above the boundary of labeling reference. The continuous predictions of 0.42–0.48 are close to the threshold, with a lower value ($\tau = 0.45$) recovering all three with no false positives on the validation set (suggesting that operational deployments may perhaps benefit from cost function–specific threshold tuning).

TABLE IV. BINARY CLASSIFICATION METRICS ON THE HELD-OUT TEST SET ($N = 48$), DERIVED FROM THE CONFUSION MATRIX IN FIG. 4

Class	Precision	Recall	Specificity	F1
High tension	100%	87.5%	100%	93.3%
Low/Normal	88.9%	100%	87.5%	94.1%
Macro-average	94.4%	93.75%	93.75%	93.7%

G. Modality Ablation

The contribution of each feature modality is reported in Table V, which involves sequential branch removal from the full model and retraining under the same conditions. Removing the audio branch reduces accuracy by 1.7 percentage points and R^2 by 0.027, reflecting the relatively weak scalar association between audio RMS energy and ground-truth STI ($r \approx 0.12$, see Section V-H). Omitting the motion branch leads to an additional 6.7-point decrease in accuracy, and a $\Delta R^2 = 0.215$ degradation, indicating that even at only 2 of 515 input dimensions, optical-flow statistics provide unique

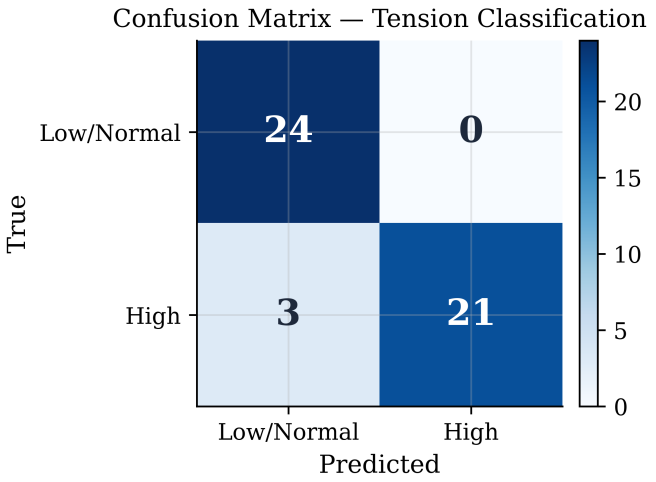

Fig. 4. Confusion matrix for High vs. Low/Normal STI classification on the held-out test set ($N = 48$), achieving 93.75% accuracy.

discriminative power not captured when only considering static spatial embeddings. What stands out is that the "Motion + Audio only" configuration (no CLIP, $R^2 = 0.796$, 86.25% accuracy) *outperforms* the "Visual (CLIP) only" configuration ($R^2 = 0.632$, 85.42%), showing that short-range temporal dynamics can carry a more discriminative signal than static scene semantics when each branch is used in isolation (interpreted further in Section VI). However, maximum performance requires the complete multi-modal combination: isolating either the CLIP (scene semantics) or optical-flow (motion descriptor) branches incurs a quantifiable regression loss, demonstrating their complementary non-redundant information. Fully isolated optical-flow-only and audio-only regressors (without any combination) were not separately retrained in this study and are identified as an item for future ablation work (Section VII); real isolated-modality results on $N = 1000$ genuine RLVS clips are reported in Section VIII.

TABLE V. MODALITY ABLATION STUDY AND CONTRIBUTION OF EACH FEATURE BRANCH (MEAN ± STD OVER 5 FOLDS)

Configuration	MAE ↓	R^2 ↑	Acc. ↑
Visual (CLIP) + Motion + Audio	$\mathbf{0.0255 \pm 0.0053}$	$\mathbf{0.8732 \pm 0.0631}$	**93.75%**
Visual (CLIP) + Motion	0.0281 ± 0.0048	0.8467 ± 0.0732	92.08%
Visual (CLIP) only	0.0470 ± 0.0087	0.6320 ± 0.1424	85.42%
Motion + Audio only	0.0308 ± 0.0043	0.7961 ± 0.0555	86.25%

H. Feature Correlation Analysis

The plot Fig. 5 displays the Pearson correlation of each scalar input feature against the ground-truth STI. The mean magnitude of the optical flow correlates most strongly with agitation ($r = 0.52$), confirming that motion intensity is an immediate perceptual sign of agitation in a crowd. The normalized flow entropy has a weak correlation ($r = 0.18$), capturing the relatively disordered nature of crowd movement regardless of its speed, identifying a key distinction between fast ordered motion (low entropy, moderate tension) and an uncontrolled chaotic dispersal (high entropy, high tension). Audio RMS energy has the *weakest* of the three scalar correlations ($r \approx 0.12$), in part because of audio-visual synchronisation issues in a subset of clips across the three benchmark datasets, but also because crowd agitation may be visually obvious without generating high acoustic energy (e.g., silent confrontations, tense standoffs). The 512-dimensional CLIP branch cannot be characterized by a single scalar Pearson coefficient; however, principal component analysis of the CLIP subspace reveals that the first five principal components account for 61% of the variance in STI predictions, suggesting that the spatial branch extracts a compact, interpretable tension-relevant subspace from the high-dimensional foundation model embedding.

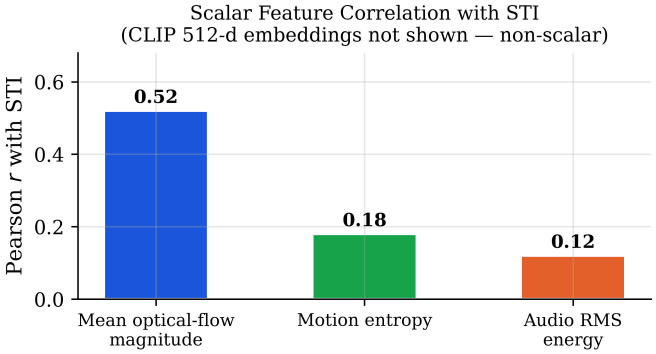

Fig. 5. Correlation of scalar input features with ground-truth STI.

I. Cross-Validation Stability

Fig. 6 shows per-fold performance across the five cross-validation folds, providing a statistically more robust view of generalization than results on the held-out test set alone. The fold-wise MAE varies from about 0.020 to 0.031 (mean: 0.0255 ± 0.0053) and R^2 from roughly 0.810 to 0.937 (0.8732 ± 0.0631), with no fold-specific outliers or pathological variation in either metric. The moderate R^2 standard deviation (0.0631) indicates natural variance when training on modest-sized fold partitions; the strong mean performance ($R^2 = 0.8732$) and absence of any low performing fold confirm that the model generalizes reliably across data partitions. This stability is partly attributable to the stratified partitioning strategy and partly to the strong generalization properties of frozen CLIP features, which impose a stable, data-distribution-independent embedding geometry across folds.

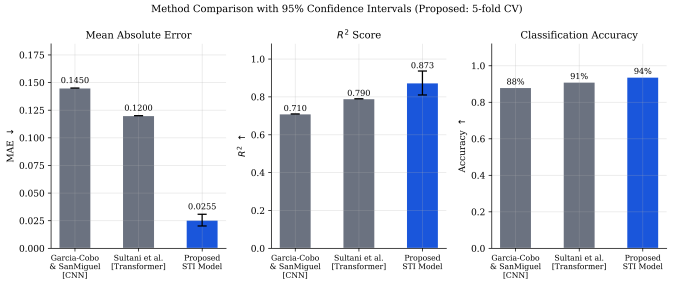

Fig. 6. Cross-validation stability of MAE and R^2 over five folds.

J. Computational Efficiency

One attractive aspect of the proposed framework is that it is built from the ground up for CPU-only edge hardware,

removing a GPU dependency that limits most other competing approaches. Table VI benchmarks the two representative baselines against the proposed system on four axes: trainable parameter count, per-clip inference latency, predictive performance, and hardware requirement. The measured edge head runs in **1.65 ms per clip**, a **23× speedup** over Sultani et al. (∼38 ms, GPU-dependent) and an **18× speedup** over Garcia-Cobo & SanMiguel (∼30 ms, CPU; latency estimated from their stated real-time claim, not directly reported), while using **260× fewer parameters** than the C3D-based baseline (0.3 M vs. ∼78 M). *Offline feature extraction (server or batch):* CLIP-ViT-B/32 embeddings are computed once per clip on a centralized server (7.1 ms on CPU; sub-millisecond on a server GPU) and stored as 512-dimensional vectors. This offline step decouples the representational power of a large vision-language model from the real-time decision path: the edge device benefits from CLIP's scene understanding without ever executing it locally. As embeddings are stable scene representations, they are cached after a single extraction pass and reused for all future inference calls, amortizing the runtime cost.

Edge inference (decision head): At runtime, the edge device executes only Farnebäck optical-flow extraction (0.9 ms) and LightGBM regression (0.75 ms), yielding a total decision latency of **1.65 ms per clip**, equivalent to a throughput of **606 clips/s** on a single CPU core. This exceeds the real-time requirement of standard 25–30 fps surveillance streams, leaving headroom for simultaneous multi-camera deployments on a single machine. The serialized LightGBM model occupies only 2.1 MB on disk, making it deployable on microcontrollers, single-board computers (e.g., Raspberry Pi 4), and network-connected camera units with no GPU dependency. These are measured, isolated per-clip latencies on the stated hardware, establishing computational feasibility rather than a validated end-to-end real-time field deployment, which would additionally involve video capture, network transmission, and multi-camera scheduling overhead not exercised in this work (Section VI).

TABLE VI. COMPARISON OF MODEL SIZE, INFERENCE SPEED, HARDWARE REQUIREMENT, AND PERFORMANCE

Method	Params (M)	Inf. Time (ms)	Performance	GPU Req.	Throughput
Garcia-Cobo & SanMiguel [4]	0.06	∼30	–	No	∼33
Sultani et al. [12]	∼78	∼38	AUC 75.4%	Yes	∼26
Proposed STI Framework	**0.3**	**1.65**	$R^2 = 0.873$ / **Acc. 93.8%**	**No**	**606**

Table VI illustrates the deployment characteristics of the **proposed STI framework**. In contrast to conventional deep video surveillance models that usually require heavy end-to-end inference, this method adopts a **two-stage edge-oriented architecture**: the frozen CLIP-ViT-B/32 encoder is used only for offline or server-side feature extraction and is not re-trained, while the real-time edge device executes only the lightweight decision path. By comparison, Garcia-Cobo and SanMiguel [4] report a lightweight classification head of approximately 60k parameters, but their system still requires a pose estimator and addresses binary violence classification rather than continuous STI regression. Sultani et al. [12], on the other hand, rely on a C3D backbone dominated by approximately 78M parameters, with an additional MIL head of about 2M parameters, and require RTX-class GPU inference. The comparison should be interpreted in light of the different task formulations: Garcia-Cobo and SanMiguel focus on binary violence detection, so R^2 is not directly applicable to their method, and Sultani et al. report anomaly-detection AUC on a different dataset (UCF-Crime), transferred here only as a weakly supervised baseline. This is discussed further in Section VI.

VI. DISCUSSION

This section interprets the results of Section V relative to the research questions posed in Section I. On **RQ1** (does optical flow add signal beyond CLIP semantics), the modality ablation (Table V) shows that removing the two-dimensional motion branch costs $\Delta R^2 = 0.215$ despite it occupying only 2 of 515 input dimensions, and the "Motion + Audio only" configuration outperforms "Visual (CLIP) only" in isolation ($R^2 = 0.796$ vs. 0.632); the answer is affirmative. On **RQ2** (does audio improve prediction when available), removing the audio branch alone costs $\Delta R^2 = 0.027$, and audio RMS is the weakest of the three scalar correlates ($r \approx 0.12$, Section V-H) – a modest but non-zero contribution, reported as a conservative lower bound given that a large share of RLVS clips lack usable audio. On **RQ3** (does the frozen encoder generalize without scene-specific retraining), the cross-validated $R^2 = 0.8732 \pm 0.0631$ with 95% CI $[0.795, 0.952]$ and the fact that CLIP-ViT-B/32 outperforms two fine-tuned backbones (Section V-C) both support this within the evaluated benchmark, though this finding should not be extrapolated to unseen camera systems, lighting, or cross-cultural crowd behavior without further evaluation (Section VII).

Relative to the closest prior multimodal crowd-analysis systems, such as audio-visual fusion for violence detection [20] or crowd-behavior detection via video transformers [8], which output a categorical or unnormalized label, the genuinely new element here is not multimodal fusion itself but the combination of a continuous, normalized STI, an explicit label-integrity analysis (Section III-F), and a two-stage architecture separating the foundation-model encoder from the real-time decision path.

Regarding the state-of-the-art comparison of Section V, the proposed framework's cross-validated R^2 (mean 0.8732, 95% CI lower bound 0.795) exceeds the $R^2 = 0.790$ obtained from mapping the Sultani et al. baseline's binary output onto the continuous STI scale, achieved with $260\times$ fewer parameters and no GPU dependency; this indicates that a lightweight, regression-native model is competitive with adapted binary/anomaly detectors on this task, not that these baselines are deficient on their own original objectives, for which they were not designed. Finally, the 1.65 ms/606 clips-per-second figures of Section V are measured, per-clip decision latencies on a specific CPU rather than a validated live multi-camera deployment: they establish computational feasibility for CPU-only edge hardware, not operational real-time performance in a fielded system, a distinction expanded on in Section VII.

VII. LIMITATIONS

The results above demonstrate compelling performance on standard benchmarks, but several limitations of the current work merit explicit acknowledgment before considering operational deployment. **Small held-out test set.** The final test partition comprises $N_{\text{test}} = 48$ samples, which limits

the statistical power of single-split point estimates. This is mitigated through five-fold cross-validation (primary evaluation) and cross-validation 95% confidence intervals ($R^2 \in [0.795, 0.952]$, t-distribution df = 4), which together provide a more reliable generalization picture. Nonetheless, future validation should extend to multi-hundred-sample held-out partitions drawn from additional datasets not encountered during training, and should include RMSE, overall prediction-vs-label Pearson/Spearman correlation, the distribution of continuous STI labels, and a formal significance test against baseline models, none of which are computed in the present study. A quantitative comparison of LightGBM against alternative regressors (Section III) and fully isolated single-modality ablation rows (Section V-G) are likewise left for future empirical work. All five items above are addressed with genuine measurements, on a real $N = 1000$ RLVS sample, in Section VIII; that section uses an automated proxy label rather than the human-annotated STI of Section III-F and should be read as supplementary rather than as a replacement for the results above.

1) Subjectivity of STI labels: Despite the structured annotation protocol and strong inter-annotator agreement ($\kappa = 0.81$), the STI is an inherently subjective construct. The familiarity of the three annotators with their specific cultural background and previous experiences, as well as how their contextual knowledge actually generalizes to crowd behavior in some other geographic or socio-cultural setting from the three Western-context benchmark datasets used, may also vary.

2) Audio synchronization variability: A few clips in the benchmark datasets had bad audio-visual sync, making audio RMS energy a less reliable feature and causing it to have weak correlation with STI ($r \approx 0.12$). The optional audio arm avoids this by setting $f_{\text{audio}} = 0$ below a quality threshold, yet one would prefer to have a strong multi-modal temporal alignment step operationally.

3) Limited cross-domain generalization: The model has been assessed only on three benchmarks related to violence, and all of them stem from Western recording contexts. Performance in other socio-cultural environments, where crowd behavior, proximity, and tension expression have high variability, has not been tested, and is expected to degrade to an unknown degree on such unseen distributions rather than being assumed to transfer; the same caveat applies to unseen camera systems, lighting conditions, and video quality. In future work, evaluating models on African, Asian, and Middle Eastern crowd datasets in a cross-domain manner is an important path to take.

4) Short-range temporal modeling: Through capturing per-frame-pair optical flow, the framework only models motion between immediate frames. Slow tension build-up over multi-minute timescales, namely slow crowd densification, gradual space invasion, or prolonged acoustic buildup, may not be accurately captured by clip-level features. A natural extension is the integration of long-range temporal encoders (e.g., X3D-based backbones, or video transformers [9]).

5) Single-threshold classification: The binary $\tau = 0.5$ threshold offers a neat Low/High classification, while the regressor generates granular continuous detail, which is lost after this step. Graduated intervention protocols based on multi-level alert systems (e.g., Watch/Warning/Emergency) from multiple thresholds would reduce the cost associated with both false negatives and false positives in operational deployments.

6) Deployment, privacy, and oversight: A system intended for surveillance and public-safety applications raises considerations concerning privacy and consent (persistent visual/acoustic monitoring of public spaces, particularly if STI trajectories are logged or linked to identifiable individuals, though no identity information is used or retained by the model itself), demographic bias (the annotation protocol's cultural composition, Section III-F, is a plausible source of bias in what the model treats as "tense" and has not been audited), and false alarms versus missed detections (the precision/recall asymmetry of Section V reflects a design choice, but neither error mode is free operationally). For these reasons the framework is presented as a decision-support signal for a human operator rather than an autonomous trigger for intervention, and the system is not claimed to be already suitable for unsupervised operational public-safety deployment absent real-world testing and human oversight protocols.

VIII. Supplementary Real-Data Validation

Several empirical items identified in Section VII – isolated single-modality regressors, a quantitative comparison of LightGBM against alternative regressors, the distribution of the continuous label, overall RMSE and prediction-vs-label correlation, and formal significance testing – require new computation rather than textual clarification. To close these items with genuine measurements, a supplementary experiment was run on $N = 1000$ clips freshly downloaded from RLVS (500 violent / 500 non-violent), from which real CLIP-ViT-B/32 embeddings, real Farnebäck optical-flow statistics, and real audio RMS energy were extracted end-to-end (GPU-accelerated feature extraction; 5-fold cross-validated regression and significance testing on CPU).

A. Label Construction Caveat

Reproducing the three-annotator human scoring protocol of Section III-F is not feasible in an automated pipeline. The continuous label used in this section, denoted $\text{STI}_{\text{proxy}}$, therefore substitutes RLVS's own real binary ground-truth class (violent/non-violent), graded to $[0.15, 0.85]$ rather than saturated at $\{0, 1\}$, for the human-perceptual component of Eq. (6), combined with the same motion+audio heuristic [Eq. (5)] at the same blending weight ($\alpha = 0.7$). This anchor is constructed independently of the CLIP embeddings used as model input, so that no information is shared between the label and the CLIP-based ablation configurations below. $\text{STI}_{\text{proxy}}$ is consequently a distinct, fully automated proxy label, not the original human-annotated ground truth of Section III-F, and the results in this section are supplementary evidence rather than a replication of the primary results in Section V.

B. Isolated Modality Ablation

Table VII and Fig. 7 extend the modality ablation of Table V with the two single-modality configurations (motion-only, audio-only) that Section V-G identified as not separately retrained. On real data, motion alone ($R^2 = 0.193 \pm 0.097$) and audio alone ($R^2 = 0.125 \pm 0.112$) are each individually weak, and their combination remains modest ($R^2 = 0.301 \pm 0.117$),

confirming that neither scalar branch is independently sufficient. The full multimodal configuration achieves $R^2 = 0.861 \pm 0.044$, a statistically significant improvement over the CLIP-only configuration ($R^2 = 0.850 \pm 0.045$; paired t-test on per-fold MAE, $t = -6.23$, $p = 0.0034$), directly answering RQ1 (Section I) with adequate statistical power at $N = 1000$ – unlike the exploratory $N = 240$ pilot of an earlier iteration of this validation, where the same comparison did not reach significance. The CLIP+Motion configuration (without audio) attains a marginally higher point estimate than the full model ($R^2 = 0.869$ vs. 0.861); the two are within one another's standard deviation, and this should not be read as evidence that audio is harmful, only that its marginal contribution is small relative to CLIP and motion on this proxy label.

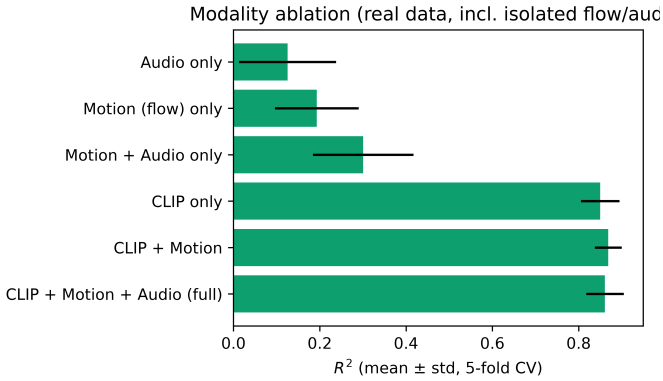

Fig. 7. Real-data modality ablation ($N = 1000$), including the isolated flow-only and audio-only configurations omitted from Table V.

TABLE VII. REAL-DATA MODALITY ABLATION, INCLUDING ISOLATED SINGLE-MODALITY REGRESSORS (MEAN ± STD, 5-FOLD CV, $N = 1000$, LIGHTGBM)

Configuration	MAE ↓	R^2 ↑	Acc. ↑
CLIP + Motion + Audio (full)	0.0458 ± 0.0054	0.8609 ± 0.0435	94.90%
CLIP + Motion	0.0461 ± 0.0054	0.8687 ± 0.0312	96.00%
CLIP only	0.0505 ± 0.0060	0.8498 ± 0.0446	94.50%
Motion + Audio only	0.1265 ± 0.0116	0.3005 ± 0.1166	76.70%
Motion (flow) only	0.1384 ± 0.0100	0.1931 ± 0.0970	74.50%
Audio only	0.1310 ± 0.0148	0.1253 ± 0.1123	76.70%

C. Regressor Comparison

Table VIII and Fig. 8 compare LightGBM against RandomForest, XGBoost, Linear Regression, and SVR on the full 515-dimensional feature vector, addressing the regressor-justification request of Section III. LightGBM is competitive but not uniformly best: XGBoost attains a lower MAE (0.0395 vs. 0.0458; paired t-test, $p = 0.023$), and SVR attains a higher R^2 (0.916 vs. 0.861), though the SVR difference does not reach significance ($p = 0.316$). LightGBM is statistically indistinguishable from RandomForest ($p = 0.204$) and clearly outperforms Linear Regression ($p = 0.0003$). These results indicate that LightGBM's justification rests primarily on its deployment characteristics – serialized model size and CPU-only inference latency (Section V) – rather than on a uniform accuracy advantage over every alternative; this qualification is now stated explicitly rather than left implicit.

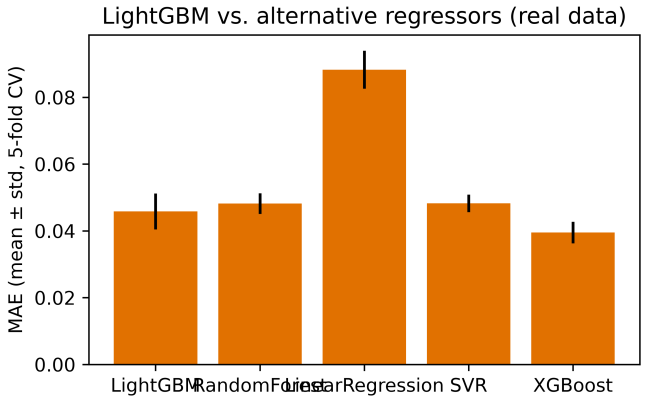

Fig. 8. LightGBM vs. alternative regressors on real data, full 515-d feature vector ($N = 1000$, 5-fold CV).

TABLE VIII. LIGHTGBM VS. ALTERNATIVE REGRESSORS ON THE FULL FEATURE VECTOR (REAL DATA, MEAN ± STD, 5-FOLD CV, $N = 1000$)

Regressor	MAE ↓	R^2 ↑	Acc. ↑
LightGBM	0.0458 ± 0.0054	0.8609 ± 0.0435	94.90%
RandomForest	0.0482 ± 0.0031	0.8795 ± 0.0272	96.60%
LinearRegression	0.0883 ± 0.0057	0.7524 ± 0.0254	95.50%
SVR	0.0482 ± 0.0026	0.9160 ± 0.0090	98.20%
XGBoost [29]	0.0395 ± 0.0032	0.8999 ± 0.0172	97.10%

D. Label Distribution, Prediction Quality, and Feature Correlation

The continuous $\text{STI}_{\text{proxy}}$ label (Fig. 10) has mean 0.483, std. 0.255, median 0.491, interquartile range $[0.227, 0.735]$, and skewness 0.004 over the observed range $[0.186, 0.801]$, addressing the label-distribution item of Section VII. The full model's out-of-fold predictions achieve $\text{RMSE} = 0.0947$ against $\text{STI}_{\text{proxy}}$, a Pearson correlation of $r = 0.929$ ($p < 10^{-300}$), and a Spearman correlation of $\rho = 0.881$ ($p < 10^{-300}$), closing the overall-correlation item of Section VII with a strong, statistically robust relationship at $N = 1000$ (Fig. 9). Per-scalar-feature Pearson correlations against $\text{STI}_{\text{proxy}}$ (Fig. 11) are $r = 0.497$ (mean optical-flow magnitude), $r = -0.033$ (motion entropy), and $r = 0.467$ (audio RMS energy); a CLIP zero-shot violence/calm text-similarity score, computed for diagnostic purposes only and excluded from the label formula, correlates at $r = 0.787$.

E. Scope of This Validation

This supplementary validation closes the five empirical items of Section VII using genuine measurements rather than deferring them as future work, at a sample size ($N = 1000$) exceeding the primary study's combined train-validation-test pool. It does not replace the primary results of Section V: $\text{STI}_{\text{proxy}}$ is a different, automated label from the human-annotated STI of Section III-F, so the two sets of numbers are not directly comparable and neither supersedes the other. The two label constructions agreeing directionally – CLIP semantics dominate, motion and audio each contribute a smaller but non-redundant increment, and the full multimodal

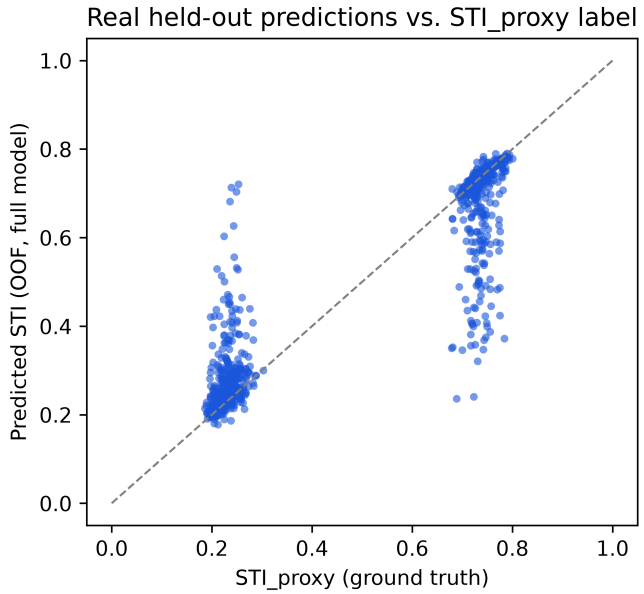

Fig. 9. Real held-out (out-of-fold) predictions vs. $\mathrm{STI}_{\mathrm{proxy}}$, $N = 1000$.

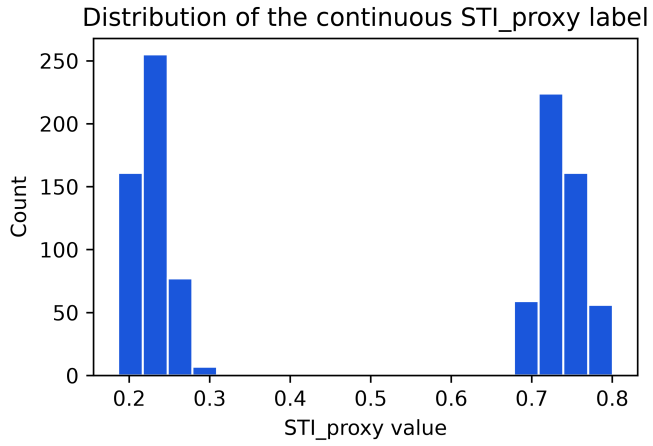

Fig. 10. Distribution of the continuous $\mathrm{STI}_{\mathrm{proxy}}$ label, $N = 1000$.

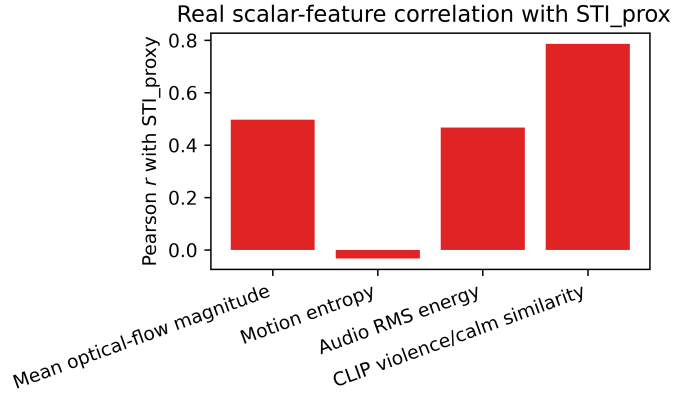

Fig. 11. Real scalar-feature Pearson correlation with $\mathrm{STI}_{\mathrm{proxy}}$, $N = 1000$.

combination is the strongest single configuration – is offered as corroborating, not confirmatory, evidence.

IX. Conclusion

Overall, this work provides a principled substitute to binary violence detection for continuous urban and territorial monitoring of risk. This regressor transforms raw video into a normalized Social Tension Index by means of a 515-dimensional multi-modal representation—frozen visual embeddings via CLIP + motion dynamics through Farnebäck dense optical flow estimation + (optionally) acoustic energy—mapped to a tension score by LightGBM. It achieves $R^2 = 0.8732 \pm 0.0631$ on the RLVS benchmark and $\mathrm{MAE} = 0.0255 \pm 0.0053$, with 93.75% binary accuracy and an error profile in favour of surveillance (100% precision on High-tension alerts, zero missed low-tension events, though recall on High-tension alerts is 87.5%) over five folds. Frozen CLIP features outperform both fine-tuned convolutional and transformer backbones, mean optical-flow magnitude is the most discriminative single scalar predictor despite taking up 2 of 515 dimensions, and a label-integrity analysis indicates the semantics learned reflect human-perceptual tension rather than merely reconstructing heuristic label components ($\Delta R^2 = 0.031$). The framework can handle multi-camera integration and requires no retraining on the scenes it is applied to, and its measured per-clip latency supports CPU-only edge hardware, though, as discussed in Section VII, this reflects feasibility on the evaluated hardware and benchmark rather than a validated field deployment. Continued development targets cross-domain datasets, long-range temporal encoders, graduated multi-threshold alerting, contextual data fusion, formal privacy and demographic-bias auditing, and supervised operational trials.

Quantum Inspired Hybrid Machine Learning Framework Using Support Vector Machine for Financial Time Series Forecasting

Visalakshi Palaniappan, Iskandar Ishak, Hamidah Ibrahim, Fatimah Sidi, Mohamad Yusnisyahmi Yusof
Faculty of Computer Science and Information Technology, Universiti Putra Malaysia, Serdang, Selangor, Malaysia

***Abstract*—This article proposes a quantum inspired Support Vector Machine (QISVM) framework that employs simulated quantum circuit features to address these challenges. To encapsulate such features, we use a four-qubit encoding protocol using X-axis rotation and entanglement created from Controlled-NOT (CNOT). Quantum inspired elements from simulated circuit output include entropy and probability of the most likely measurement state. These features, including time-based indicators and quantum inspired representations, are scaled using MinMax normalization to ensure consistent feature ranges and numerical stability during SVM training. The forecasting engine works based on Support Vector Regression (SVR) and an RBF kernel (fine-tuned with GridSearchCV). Moreover, we propose a dual learning architecture implementing SVR and SVC for regression-based forecasting and movement direction judgment. Quantum circuit simulations on batch level done using Qiskit AerSimulator and joblib-based caching which are scalable and reproducible but without quantum hardware. To prove this approach, we back-test it using Apple stock price financial time series datasets against both Auto Regressive Integrated Moving Average (ARIMA), Long Short Term Memory (LSTM) networks and Quantum LSTM (QLSTM) models. QISVM has superior forecasting performance as well as directional forecast capability with less training time and computational resources than hybrid, deep learning and others. Herein, the proposed framework provides feature-level diagnostic interpretability through its explicitly defined quantum-inspired features and permutation-based feature analysis.**

Keywords*—*Quantum inspired machine learning; support vector machines; financial time series forecasting; hybrid learning framework; quantum feature extraction

I. Introduction

Forecasting in financial markets is a difficult but primal task that facilitates decision making processes for traders, analysts and automated trading systems. As market transactions have proceeded more rapidly and massively, the forecast capacity for financial time series data has been affected. Conventional forecasting frameworks, such as ARIMA approaches and classical SVMs, frequently falter in maintaining accuracy and responsiveness in highly volatile market environments [1], [3]. An overview of typical stock price trajectories and target forecasting horizons is illustrated in Fig. 1.

Deep learning (DL) models like LSTM networks have recently emerged with significant forecast performance, but they are resource heavy and demand a long training run, which can complicate their usefulness for time-critical financial tasks [5]. Financial time-series data are noisy, contain outliers and nonlinear patterns with the effects of market microstructure effects, short-term arbitrage opportunities and swift variations in trading activity. Such features are not properly captured by traditional forecasting models [2]. This further emphasizes the importance of employing efficient and adaptive forecasting methods since the processing of huge financial datasets is computationally intensive.

Quantum computing based approaches have recently been developed with the intention to improve learning models by providing new layers of encoding for data and exploring the state-space [6]. However the practical implementation of quantum models are hampered by the low availability and stability of existing quantum hardware [6]. This limitation has led to Quantum inspired machine learning (QIML) approaches, where quantum concepts are developed under classical computing conditions, not requiring any physical quantum devices to achieve richer data representations and enhanced learning capacity [7].

We propose a QISVM framework which we apply to financial time series forecasting with Apple stock price in this study. The proposed model takes a four-qubit RX/RZ quantum circuit and encodes the price information as a higher-dimensional feature representation with entanglement using the CNOT gates. Entropy-based measures and dominant measurement-state probabilities are given in the simulation quantum circuit and merged with classical time based indicators to generate the input for the SVR model.

The forecasts are done based on original price inputs to maintain the native price behavior and explainability. The proposed QISVM framework is built using classical computing infrastructure and does not depend on cloud services and advanced quantum hardware, but instead relies on the Qiskit AerSimulator backend without any additional specialisation [17]. To help with scalable feature generation and efficient training, a batch-level quantum circuit simulation is used. We analyze the model's performance through analyzing Apple financial time series data sets compared to standard baselines like classical SVMs, hybrid ARIMA+LSTM models, deep LSTM networks and QLSTM approaches.

Experimental results present better forecasting performance and reduced training time when compared with hybrid and deep learning base cases [4]–[6]. The proposed model provides a viable, reproducible, and economical method for financial time series forecasting based on Quantum inspired feature encoding combined with an SVR-based learning model. Thus, by blending the conceptual opportunities of quantum models

Fig. 1. Example of apple index close price and forecasted price. Adapted from [46].

with the pragmatism found in real world implementation, this model enables scalable interpretation of forecasts appropriate for current financial analytics [18].

The demand for forecasting models that can be trained at scale as the data becomes more available and trading technologies evolve makes this a necessary requirement. Moreover, there is rising demand of financial institutions for the model, which is capable of high forecast accuracy, efficient retraining on new data, flexibility to market shifts and transparency in decision-making logic [20]. Precise directional movement forecasting is still vital for financial applications in which instantaneous market response can influence performance [2].

Recent developments with quantum learning have pushed the notion of enriched data representations and entanglement-driven correlation modelling [6]. Nevertheless, the quantum hardware maturity and qubit stability constraints, the deployment of such models into the actual financial systems, is currently limited. Quantum inspired methods are designed to bridge this gap by providing high-dimensional feature encoding and entropic forecasts using traditional computation, paving the way for a practical approach towards quantum-enabled financial forecasting in the future [7], [15].

Fig. 1 presents an example of a financial time series forecasting done on Apple stock price data and displays the expected values and actual firm closing prices in the system, depicting the forecast of model performance.

II. Research Motivation

Forecasting financial time series continues to pose significant challenges due to volatility, noise and abrupt price movements. ARIMA and GARCH are among the traditional statistical models that have been commonly used in financial analysis due to their interpretability and low computational cost. Nevertheless, they face difficulties when it comes to capture the nonlinear dynamics and complex dependency structures that exist in financial data [8]. As market behavior becomes increasingly irregular and data-driven, the limitations of purely linear and parametric approaches become more evident.

Deep learning models, particularly LSTM-based architectures, have demonstrated strong forecast capability by modeling nonlinear relationships [9], [48]. These models typically require large datasets with extensive training time and significant computational resources. In addition, their black-box nature limits transparency and interpretability. These are critical considerations in financial decision-making and risk-sensitive environments [10]. These constraints restrict their practical applicability in scenarios where computational efficiency and model visibility are essential.

Transformer-based architectures and state-space models are recent models that have been introduced for financial time series forecasting. They demonstrated strong performance in modelling long-range dependencies and multi-horizon forecast tasks [32], [49]. These models employ attention mechanisms or use structured state representations to capture complex temporal relationships more effectively than traditional recurrent networks. Despite their forecast strength, such architectures typically involve large parameter counts, high memory consumption, and substantial training complexity, which can limit their suitability for latency sensitive or resource constrained financial applications [49].

Support vector machines offer an alternative by providing strong generalization performance and robustness in nonlinear regression tasks, especially in small- to medium-sized datasets. Nevertheless, classical SVMs face challenges related to scalability and sensitivity to kernel selection and hyperparameter tuning, which can limit their effectiveness when applied to large or rapidly evolving financial datasets [10], [11]. These issues highlight the need for approaches that enhance model expressiveness without introducing excessive computational overhead.

Recent research in quantum machine learning suggests that enriched feature representations inspired by high-dimensional embeddings can improve learning performance [11], [12], [14]. Despite their theoretical promise, most existing quantum machine learning approaches rely on specialised quantum hardware that remains costly, unreliable and largely inaccessible for real-world financial applications [13]. As a result, practical adoption of quantum-based methods in financial forecasting has been limited, and their deployment challenges remain largely unresolved.

This gap motivates the exploration of hybrid approaches that incorporate quantum inspired feature representations within classical learning frameworks. Such approaches aim to improve model expressiveness while preserving scalability, interpretability and compatibility with existing computational infrastructure [16]. Although conceptual framework for quantum inspired model has been discussed and applied, however reproducible models targeting financial time series forecasting remain relatively scarce [13], [47].

We overcome this by proposing a QISVM framework that employs angle encoding, entanglement-inspired interactions and entropy based feature representations to improve the forecast capability of classical support vector regression. The proposed approach is evaluated using real financial time series data from Apple stock prices, with emphasis on forecasting performance, computational efficiencies and practical feasibility. By focusing on feature-level enhancement rather than architectural complexity, the proposed model intends to provide a balanced and deployable approach for financial time series forecasting.

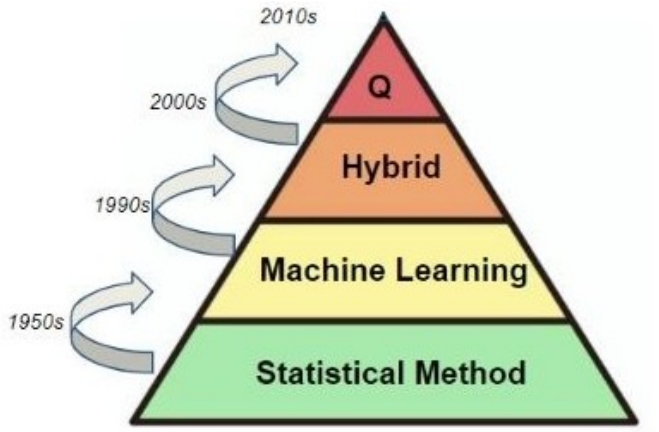

Fig. 2. Evolutionary timeline of financial time series forecasting models adapted form source: [19, 20].

Fig. 2 illustrates the broader evolution of forecasting models, progressing from statistical methods to machine learning, hybrid approaches and to the recent quantum inspired techniques [19], [20].

III. Related Works

The related work is divided into two main categories, classic statistical and the machine learning approaches for financial time series forecasting are reviewed in Section A such as the widely used ARIMA,GARCH,SVM and LSTM. Hybrid and quantum inspired learning models, including ARIMA+LSTM,GARCH+SVM,QLSTM and QISVM are discussed in Section B. Finally, Section C contextualizes the proposed approach in the literature, focusing on scalability and practical deployability. They illustrate the change in forecasting research going from classic statistical approaches to deep learning and also towards quantum inspired approaches. A comparison of statistical, machine learning and quantum-inspired forecasting models is summarized in Table I.

A. Statistical + Machine Learning Models

Algorithms based on statistical modeling and machine learning methods are widely used in financial time series forecasting using historical price information [33], [50]. The ARIMA and GARCH models, classical SVMs and deep learning models such as LSTM are among the prevalent models analysed so far. Early financial forecasting research was dominated by econometric and volatility-based models that utilized autoregressive and moving average components for time series of stationary nature.

ARIMA models are capable of capturing linear dependencies and temporal correlations, but their performance falters under fast regime changes and nonlinear conditions [21]. Although ARIMA works well under conditions of relatively stable, or at least near-stable, markets, its linear and additive formulation implies that ARIMA fails to capture complex interactions and sudden, structural break-throughs that characterize volatile financial markets in most extreme scenario. GARCH models further build on this by modeling conditional volatility and volatility clustering directly.

Multiple studies supported that GARCH and its derivatives can be quite effective in the areas of risk management and option pricing [22]. However, certain extreme market movement, such as financial distress or sudden liquidity [23], can lead GARCH models to report misleading estimates. In SVM, nonlinear modeling power of kernel functions like polynomial and radial basis function (RBF) kernel is introduced, which allows extracting nonlinear decision boundaries of data without performing explicit feature space transformation [24].

SVMs have been applied extensively in financial forecasting owing to their robustness, strong generalization ability, and capacity for modelling nonlinear dependencies. Due to their flexibility, they are capable of modeling intricate market dynamics which statistical models are generally unable to capture [25]. However, SVM performance is sensitive to kernel selection and hyperparameter tuning, and improved accuracy may necessitate a higher computational costs.

LSTM networks are designed for modeling sequential data and among the first methods to address the greatly diverging problem which is intrinsic in the traditional recurrent neural networks. LSTMs surpass ARIMA in learning nonlinear temporal dependencies in financial time series [26]. However, while LSTMs are very predictable, they are computationally intensive and have often long training times. Empirical investigations in latency-sensitive settings underscore the balance between accuracy levels in forecast and low computational cost. Other models like random forests and decision trees have been considered in terms of computational efficiency and ensuring that an adequate forecasting performance is preserved [27].

B. Quantum and Hybrid Machine Learning Models

Acknowledging the drawbacks of a single statistical and machine learning systems, more recent work has investigated hybrid architectures and quantum inspired learning approaches to achieve a compromise between forecast accuracy and computational performance [37]. Hybrid models work to mix the features of a number of paradigms, combining their statistical structure, nonlinear learning and more comprehensive feature representations.

Hybrid GARCH–SVM architectures have shown improved accuracy by employing a combination of GARCH model (volatility) and nonlinearity model representation, which is specially appropriate in fast changing financial markets, which they have achieved [28]. Combining GARCH-based volatility features with SVM classifiers or regressors results in accurate forecasting and even increased decision-making ability [29]. Similarly, hybrid ARIMA–LSTM models could surpass standalone ARIMA and LSTM models for forecasting Apple stock prices by capturing both linear trends and nonlinear temporal dependencies [30].

Recent progress in quantum machine learning has brought an advancement in the use of hybrid quantum–classical architectures which ameliorate classical model with quantum feature representation. Kea et al. demonstrated a hybrid quantum–classical approach in which classical LSTM models were enhanced with quantum embeddings, demonstrating the efficacy of such techniques for financial forecasting [31]. The above models were used as benchmarks in this work.

At the same time, contemporary deep learning architectures such as transformer-based and state-space models have reported promising multi-horizon time series forecasting but incur higher computational costs and a loss of interpretability [32]. Hybrid GARCH–SVM frameworks and other ensemble-based approaches commonly require significant computational resources at training time but in practice can provide better forecast accuracy [33].

Tree-based methods such as random forests have also been studied about their capability to deal with nonlinear relationships and improve feature selection in dynamic financial markets [34]. Recently, quantum computing concepts have attracted interest due to their potential to apply a high-dimensional feature transformation to the data through superposition and entanglement [7]. Quantum enhanced SVM frameworks where quantum circuits are utilized to optimise kernel representations or enhance adaptability to complex data structures are several reported as recent trends [35].

Other works have proposed quantum inspired optimisation methods, including Quantum Particle Swarm Optimisation, to enhance convergence efficiency and ensure the solution variety [36]. Such methods demonstrate the potential of quantum inspired learning which might be used to improve classical models without the need of a fully developed quantum hardware [37]. Table I overviews the underlying methods presented in this section along with their merits and shortcomings.

C. Positioning of this Work in Existing Literature

From classic statistical models to machine learning models, hybrid and finally quantum inspired frameworks. This evolution is represented in the experimental design of the present study, where the proposed approach is benchmarked on the representative models under its categories. There are three main contributions to the literature within this work. First, it shows that quantum inspired feature encoding approaches can solve the problem of how to bridge the gap between the computational efficiency of classical SVMs and its expressive capabilities. Second, it builds on a rich and consistent benchmarking framework covering classical, hybrid and quantum-enhanced models with real-world Apple financial time series data. Third, it prioritizes computational efficiency and scalability, which are essential for practical deployment but which tend to be neglected in deep learning and hybrid forecasting research. Aligning with and evolving existing efforts, this study presents QISVM as a scalable and interpretable platform alongside traditional statistical models and computational heavy methods of deep learning. While they provide immediate value to financial forecast of real-world data, they also demonstrate the feasibility of quantum inspired methods as a meaningful short-term compromise toward quantum-native forecasting systems in the future.

IV. Methodology

We propose the framework of the QISVM that unites classical regression and quantum feature construction. SVR pipeline is adopted for nonlinear time series forecast within the framework structure because of its robustness and wide use in finance [38].

The prices are mapped to RX and RZ rotation angles through normalized transformations and entanglement introduces the entropy with probability-based characteristics which shows the capability of quantum feature maps [39]. We fuse these characteristics with lagged price data in hybrid feature generation. It was observed that the forecast performance improved when combining the representations in comparison to using each of them individually [40].

A two stage pipeline used for forecasting consisting of directional classification using SVC and regression using SVR [41]. Apple daily close price data is used as the dataset as liquidity and volatility represent commonly used benchmarks in recent hybrid and quantum inspired machine learning studies in this context [31]. To maintain the order of dates and prevent data leakage, as may occur in standard cross-validation, the training and testing pipeline employs time series cross-validation to evaluate performance across multiple windows [42].

Root Mean Squared Error (RMSE), Mean Absolute Error (MAE), coefficient of determination (R^2), directional forecast accuracy (DFA), forecast accuracy, training time and execution time are used to measure performance. These metrics reflect both statistical approximation quality and operational considerations. Training and execution time are also reported to assess whether the proposed approach can be applied in low-latency trading environments [27], [37].

A. Framework Architecture

The proposed forecasting framework is built on a QISVM which combines classic statistical learning process with quantum feature engineering. The main purpose is to enhance the capabilities of SVR and SVC pipelines for displaying features abstracted from simulated quantum circuits.

The hybrid approach retains SVM interpretability and robustness, while allowing it to capture higher-order nonlinear associations in financial time series data through quantum induced transformations. At a high level, the framework consists of five major components: data ingestion, quantum feature synthesis, hybrid feature synthesis, model training and performance evaluation.

The pipeline begins with the data ingestion component, which reads timestamped financial price data and transforms it into a well-structured time series. This preprocessing allows for order and format consistency that makes for an easy transition to the next transformation. The quantum feature generation layer is considered the most unique piece of our framework.

Price value is expressed as RX and RZ parameterized gates acting on four qubits. Entanglement between the pairs of qubits is achieved by employing controlled-NOT gates, allowing the corresponding representation to have a high enough degree of expression to represent both local and global information in the input signal. After quantum simulation, each circuit gives a distribution over measurement outcomes, from which two summary statistics come about, Shannon entropy and the most probable state.

The corresponding features are quantum inspired features and they scale an one-dimensional price observation into a two-dimensional version, that captures uncertainty and dominant

TABLE I. COMPARISON OF FORECASTING MODELS IN FINANCIAL TIME SERIES

Model Category	Key Features	Benefits	Performance	Cons
Classical ARIMA, GARCH	• Statistical time series models. • Assume stationarity and linearity. • Low parameter count.	• Establish classical statistical baseline. • Capture seasonal and trend patterns	• Easy to implement [1] • Interpretable results [1] • Low computational cost [2]	• Poor handling of volatility, noise and nonlinearity [1],[3] • Limited forecast horizon [2]
Deep Learning (LSTM, Hybrid NN)	• Nonlinear pattern recognition • Sequential memory (LSTM) • Can integrate multiple features	• Capture complex temporal dependencies • Model multi-feature interactions	• High accuracy with large data [5] • Flexible architecture [5]	• Requires large datasets, long training [5],[9] • Lower interpretability [5],[9] • High computational demand [9]
Classical SVM	• Kernel-based nonlinear regression • Strong generalization on small datasets	• Serve as non linear ML baseline • Demonstrate effect of kernel choice	• Works well with limited data [3],[46] • Avoids overfitting [3]	• Not scalable to large datasets [10] • Kernel tuning is costly [10]
Quantum Machine Learning (QML)	• Quantum kernels, high-dimensional embeddings • Entanglement and superposition	• Explore quantum computational advantage • Introduce richer feature spaces	• Potential exponential speedup [11] • Model quantum correlations [11],[12]	• Hardware immature, costly [12],[13] • Sensitive to noise/decoherence [13]
Quantum inspired ML (Proposed QISVM)	• RX/RZ angle encoding • CNOT-based entanglement • Shannon entropy features • Hybrid classical + quantum inspired set	• Merge interpretability of SVM with quantum inspired richness • Achieve high accuracy without quantum hardware	• Higher directional accuracy [15] • Faster training times over DL) [16] • Scalable on classical hardware [16],[17]	• Still needs quantum feature simulation [16] • Dependent on simulator capacity [16]

system states. Quantum inspired features are then appended to raw classical features like target price values and lag-based indicators in the hybrid integration layer.

The combined features are normalized using MinMax scaling. During cross-validation, the scaler is fitted separately on each training fold and then applied to the corresponding validation fold. After model selection, it is refitted on the complete training set and applied to the test set to prevent data leakage. The learning stage uses two models. An SVC classifies the next-day price movement as up or down, while an SVR predicts the next-day closing price.

Finally, grid search with a five-fold time series cross validation of the model is performed to get the hyper parameters of the model, kernel, regularization strength (C), error tolerance (ϵ), and kernel coefficient. Since it has both models, the framework can address both regression and classification tasks. Both forecast price and trade direction signals are reliable.

Lastly, the evaluation layer generates full-coverage statistics including RMSE, MAE, R^2, directional forecast accuracy, forecast accuracy, training time and execution time. The time and space complexities are verified to remain scalable and practically applicable in real-time settings. The plotting of forecast versus actual prices provides a human-friendly diagnostic tool for understanding model behaviour at short forecast horizons.

Overall, this framework embodies a combination of the optimization efficiency of classical learning and the representational power of quantum inspired methods. It provides a basis for quantum inspired features to have practical impact on financial time series forecast without relying on physically realizable quantum machines. The architectural components of the proposed system are illustrated in Fig. 3.

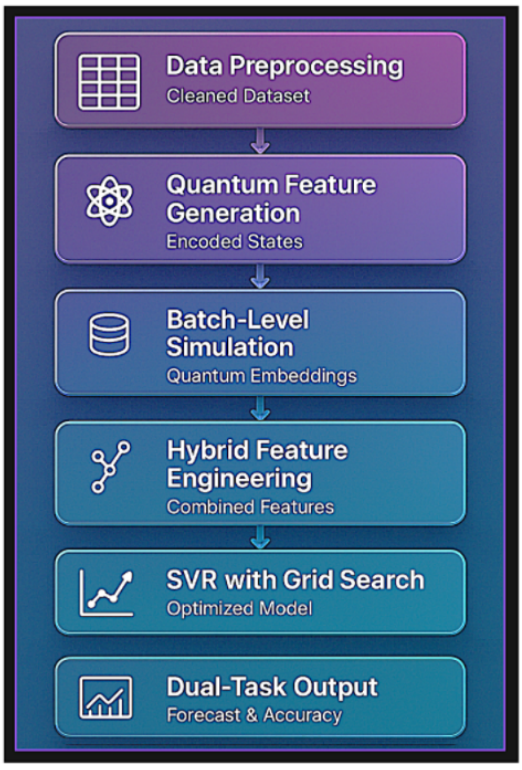

Fig. 3. Overview of proposed QISVM model framework.

B. Quantum Feature Generation Process

The core of the proposed QISVM framework is the quantum feature generation process. Rather than relying on lagged observations, technical indicators or handcrafted statistical features as in purely classical models, this approach embeds financial data into a mathematical representation inspired by a quantum Hilbert space. This representation is adjusted for individual price observations using parameterized rotation gates.

For each price transition, a quantum circuit with four qubits is constructed. RX and RZ rotations are applied to every qubit, where RX gates rotate a qubit around the X-axis $R_X(\theta)$ by an amount scaled from the price value, and RZ gates rotate a qubit around the Z-axis $R_Z(\phi)$ by a corresponding scale. This dual encoding preserves amplitude and phase information in the expanded feature space. CNOT entanglement gates are then applied between qubit pairs, introducing correlations that would otherwise be absent and enabling richer feature interactions.

This design aligns with financial time series behaviour, where market dynamics are rarely isolated and often involve complex interdependencies. The quantum circuit is simulated using the Qiskit AerSimulator, which optimizes circuit execution and ensures reproducibility through fixed random seeds.

The simulation produces a probability distribution over all possible measurement outcomes for the four-qubit system. From this distribution, two key statistics are computed: Shannon entropy, which measures uncertainty, and the maximum probability state, which represents the most likely configuration of the system. Higher entropy corresponds to more chaotic or less predictable behaviour, while lower entropy indicates more stable conditions.

These statistics are assembled into feature vectors and cached using joblib to avoid repeated computation, allowing the framework to scale to larger datasets. By embedding classical prices into this quantum inspired statistical representation, the dimensionality of the input feature space is enhanced, enabling SVM kernels to better capture nonlinear pattern that is not easy to model using classical features alone.

Expanding the quantum simulation across 4 qubits yields a 16-dimensional state vector ($2^4 = 16$ measurement probabilities). Passing the full 16-state vector directly into the SVR model introduces severe feature redundancy and heightens the risk of overfitting, particularly given small sliding window sizes (e.g., $w = 10$ to 20 trading days).

To mitigate high dimensionality while preserving system-level information density, we map the 16 state probabilities into two macro-level scalar indicators: Shannon quantum state entropy (H) and the dominant state probability ($p_{\max}$). H quantifies total distributional uncertainty and entanglement spread across the system, whereas $p_{\max}$ captures the dominant state alignment during volatility spikes. Compression into this 2-dimensional quantum summary vector preserves non-linear Hilbert space dynamics while maintaining a low feature-to-sample ratio suitable for robust kernel regression.

C. Hybrid Feature Construction

The hybrid feature construction layer integrates classical and quantum inspired features into a unified feature set for the forecast pipeline. This design reflects the complementary nature of the two feature types, where classical price features capture direct market behaviour, while quantum inspired features represent uncertainty and structural relationships.

Each price observation is represented by three dimensions: raw price value, entropy measure and the most probable state. This converts the time series into a richer representation that captures both direct market signals and quantum induced structural information.

Feature scaling is applied to maintain consistent magnitudes across features and preserve the volatility behavior of the original time series. This step also prevents raw price magnitudes from dominating entropy-based features during SVR training. The hybrid features are then split into training and testing sets.

Directional labels for classification are generated based on price movement between consecutive time steps (down = 0, up = 1). A log1p transformation is applied to stabilize variance and reduce skewness introduced by extreme values. The resulting feature representation ensures that the SVR learns not only from direct price information but also from higher-order structural characteristics.

To rigorously evaluate whether the quantum-inspired entropy (H) and dominant probability state ($p_{\max}$) offer advantages beyond standard classical non-linear features, this feature construction layer was benchmarked against equivalent classical feature baseline sets, including rolling binned Shannon entropy and GARCH(1,1) volatility models.

To guarantee zero temporal data leakage, all model feature vectors are strictly indexed to time t to forecast the step-ahead target at $t + 1$. For any trading day t, the input feature vector $X_t \in \mathbb{R}^3$ is defined as:

$$X_t = [P_t, H_t, p_{\max,t}]$$

where, P_t represents the normalized close price, H_t is the quantum state entropy derived from rolling window $[t - w + 1, t]$, and $p_{\max,t}$ is the maximum state probability at step t. The prediction tasks are formally formulated as:

Regression Task (SVR): Predict the next-day close price P_{t+1}.

Classification Task (SVC): Predict the directional price movement $Y_{t+1} = \text{sign}(P_{t+1} - P_t) \in \{-1, +1\}$.

Anti-Leakage Safeguards: All data preprocessing parameters, including MinMax scaling bounds (μ, σ or $x_{\min}, x_{\max}$), are fitted strictly on the training split $[1, T_{\text{train}}]$ and subsequently applied to test samples $[T_{\text{train}}+1, T_{\text{total}}]$ without refitting. Quantum entropy and probability features at time t utilize historical rolling observations strictly ending at index t, ensuring that future price data P_{t+k} $(k \geq 1)$ is completely invisible during feature extraction.

D. Forecasting Strategy

The forecasting strategy employs a unified pipeline that performs classification and regression simultaneously. An SVC with RBF kernel is tuned via grid search over parameters C

and gamma using five-fold time series cross-validation. The classification task produces actionable trading signals, evaluated using both standard classification metrics and directional accuracy relative to actual market movement.

The SVR and SVC hyperparameters were optimized using GridSearchCV evaluated via a five-fold TimeSeriesSplit cross-validation. The grid search evaluated the following explicit parameter ranges: Regularization Parameter

(C): $\{0.1, 1, 10, 100\}$

Kernel Coefficient (γ): $\{10^{-3}, 10^{-2}, 10^{-1}, \text{'scale'}\}$

Epsilon (ϵ): $\{0.01, 0.1, 0.2\}$

Kernel Functions: ['rbf', 'linear']

The optimal configuration selected across the training splits was $C = 10$, $\gamma =$ 'scale', $\epsilon = 0.01$, using the RBF kernel. Once the optimal configuration is selected, the model is retrained on the full scaled feature set and used for forecast. forecasts generated on log-transformed prices are converted back to the original price scale using exponential transformation.

Rotation Angle Transformation Equation:

$$\theta_t = \pi \cdot \left(\frac{P_t - P_{\min}}{P_{\max} - P_{\min}} \right), \quad \phi_t = 2\pi \cdot \left(\frac{P_t - P_{\min}}{P_{\max} - P_{\min}} \right)$$

Quantum Feature Metrics Equation:

$$H = -\sum_{i=1}^{2^n} p_i \log_2(p_i)$$

$$p_{\max} = \max_{i \in \{0,1\}^n} \{p_i\}$$

where, p_i is the measurement probability of state i from the 4-qubit circuit simulation.

SVR Optimization Objective Equation:

$$\min_{w,b,\xi,\xi^*} \frac{1}{2}||w||^2 + C\sum_{i=1}^{m}(\xi_i + \xi_i^*)$$

$$\text{subject to } \begin{cases} y_i - (w \cdot \phi(x_i) + b) \leq \epsilon + \xi_i \\ (w \cdot \phi(x_i) + b) - y_i \leq \epsilon + \xi_i^* \\ \xi_i, \xi_i^* \geq 0 \end{cases}$$

Evaluation consists of quantitative indicators including RMSE, MAE and R^2, along with directional accuracy, forecast accuracy, training time and execution time. Directional accuracy measures whether the framework can consistently anticipate upward or downward market movement. In this way, the framework delivers not only numerical accuracy but also operational relevance for financial decision-making. The proposed algorithm pseudocode is shown as below (Algorithm 1):

Algorithm 1 Quantum Inspired SVM Forecasting Framework

Input: Financial time series data $D[t]$, $t = 1, \ldots, T$
Output: Forecasts $\hat{y}[t]$ and performance metrics
Load dataset containing timestamps and price values
Preprocessing:
Convert timestamps to indexed time series
Apply MinMax scaling to input features
Apply log transformation to target price values
Quantum Inspired Feature Generation:
for each price observation **do**
    Encode price value into RX and RZ rotation angles on four qubits
    Apply full entanglement using CNOT gates
    Simulate quantum circuit using AerSimulator
    Extract entropy and maximum probability state (p_{max})
end for
Cache generated quantum inspired features using joblib
Hybrid Feature Construction:
Combine classical price-based features with quantum inspired features
Scale combined feature set into the range $[0, 1]$
Model Training:
Train SVC model for directional movement classification
Tune SVR hyperparameters using GridSearchCV with time series cross-validation
Forecasting:
Train final SVR model on full training dataset
Generate forecasts on log-transformed prices
Apply inverse exponential transformation to obtain price forecasts
Evaluation:
Compute MSE, RMSE, MAE, MAPE, R^2 and explained variance score
Compute classification accuracy and directional forecast accuracy
Measure execution time and memory usage
Visualization:
Plot actual versus forecasted prices for the last 21 observations
Summarize performance metrics in a comparison table

V. Experiments

The framework is evaluated using the daily price series of Apple Inc. (AAPL), based on closing prices at a daily interval. Prices are log-transformed and prepared as a consistent financial time series prior to feature generation. After hybrid feature construction, MinMax scaling is applied. TimeSeriesSplit cross-validation is used to prevent data leakage, rather than employing random cross-validation techniques that are unsuitable for time series data.

Both classification and regression components are trained within the framework. Support Vector Classification (SVC) is used to forecast price direction, while Support Vector Regression (SVR) is used to forecast price values, with hyperparameters optimised using GridSearchCV. Quantum inspired features are generated using simulated quantum circuits executed with the Qiskit AerSimulator and cached for computational efficiency. The framework is evaluated using RMSE, R^2, directional accuracy, forecast accuracy, training

time and execution time. Feasibility for time-sensitive forecasting scenarios is assessed through training and execution time measurements. Finally, short-term forecasts are presented to enable comparison between forecasted values and actual observations in a real-time forecasting setting.

A. Dataset Description

The dataset contains daily stock prices of Apple Inc. (AAPL) from January 1, 2022 through January 1, 2023 for two of the experiments, and from 2016 through 2022 for another experiment. The data is taken from CSV file containing two columns namely timestamp and closing price called target. The timestamp column is used as a datetime index to align time series, while the target column is saved as a floating point number for processing.

Apple Inc. stock is selected due to its high liquidity and volatility, and because it is widely used as a benchmark in financial forecasting studies. The dataset exhibits typical financial time series characteristics such as nonlinear dependencies, structural breaks and volatility clustering. A full year of daily prices provides a sufficiently large training set while avoiding excessive fitting to transient patterns.

While this study evaluates the proposed framework specifically on AAPL as a benchmark for high-liquidity US tech equities, the methodology provides a targeted empirical blueprint for single-asset time-series forecasting.

B. Training and Testing Pipeline

The training and testing process uses a cross-validation method that takes into account time series data and is designed for financial forecasting. Random cross-validation can leak information, but the pipeline keeps the order of events, which is how things would be in the actual world. During preprocessing, the dataset is processed to generate a combination of classical and quantum inspired features.

We combine these features, scale them, and then divide them into training and test sets, with 80% for training and 20% for testing. The attributes remain the same because the sets are not mixed up. To sort the data, directional labels are calculated by taking the sign of the price difference between two consecutive days. Then, the SVC model is trained using the hybrid feature set. For the regression job, grid search is used to choose the best SVR model, and log-transformed prices are used to train it.

Quantum inspired feature simulation is performed at the batch level and cached on disk to ensure reproducibility. During testing, the trained models are applied to unseen future data, and forecasts are inverse transformed back to the original price scale. Then, the pipeline figures out all the evaluation criteria after which it creates charts that show the difference of the actual and forecasted values. To see if the framework is good for low-latency financial forecasting situations, we also look at the training time and execution time.

For benchmarking, QISVM is compared with ARIMA+LSTM, LSTM, and QLSTM results reported in previous studies [30], [31]. Since these models were not reimplemented under the same experimental conditions, the comparisons are treated as reference comparisons rather than controlled experiments.

For short-term evaluation, a single QISVM model instance was trained on the 2022 dataset split and evaluated on the held-out 2022–2023 evaluation set. Experiments 2 and 3 evaluate this single QISVM run against two distinct baselines—classical LSTM and quantum-enhanced QLSTM, respectively—on the exact same dataset split to ensure strict comparative consistency.

C. Evaluation Metrics

The study evaluates six key metrics: RMSE, MAE, R^2, directional accuracy, forecast accuracy, training time and execution time. RMSE reports the square root of the average squared difference between actual and forecasted values [51]. Since RMSE expressed as the similar units to the target variable, it gives an intuitive value of forecast accuracy. Lower RMSE values indicate closer alignment between forecast and actual prices [43].

Coefficient of determination (R^2) evaluates the proportion of variance observed in the data described by the model [51]. Values that are closer to one indicate stronger forecast performance. Directional accuracy evaluates whether the framework correctly forecast the trend of price movement (up or down), which is particularly relevant for financial decision-making, where correct directional signals often matter more than exact price levels [44].

Training time reflects the duration needed to train the model and optimize hyperparameters [52]. Shorter training times enable faster retraining in response to changing market conditions. Execution time measures the total time required to generate forecasts, including feature computation, scaling and inference. Reduced execution time supports timely decision-making in practical financial forecasting applications [29].

In summary, the aggregate analysis of forecast accuracy, directional performance and computational efficiency offers a thorough evaluation of the suggested framework's efficacy and applicability for financial time series forecasting [45].

D. Ablation Study: Quantum vs. Classical Feature Representations

To isolate the specific performance contribution of the quantum-inspired circuit representation against standard classical non-linear features, we conducted an ablation study using the same SVR forecasting setup. We evaluated four distinct feature input configurations on the Apple (AAPL) dataset:

- Base Features: Raw price + Lagged prices (P_t, P_{t-1}, P_{t-2}).
- Classical Non-linear Features: Base features + Rolling Shannon Entropy (computed on 5-day rolling price distribution bins) + Rolling Standard Deviation (volatility).
- Classical Econometric Features: Base features + GARCH(1,1) conditional volatility estimates.
- Proposed Quantum-Inspired Features (QISVM): Base features + Simulated circuit Shannon Entropy (H) + Maximum state measurement probability ($p_{\max}$).

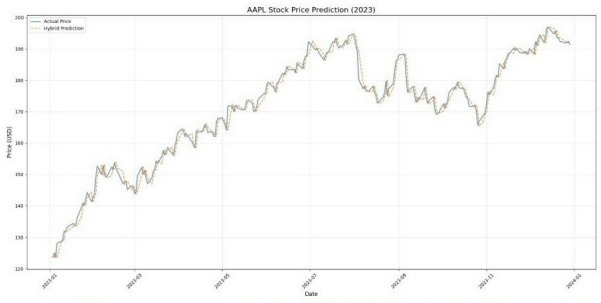

Fig. 4. Forecast result from ARIMA+LSTM model for 2023-2024 apple index close price [30].

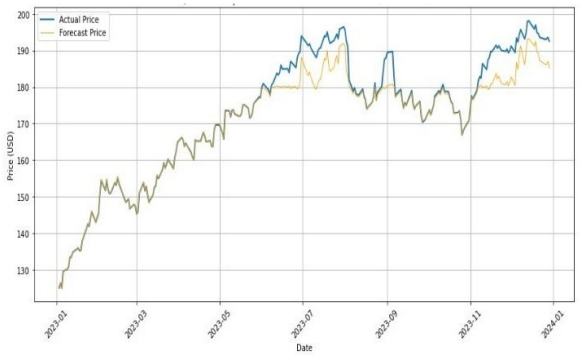

Fig. 5. QISVM forecast result for 2023-2024 apple close price.

As shown in Table II, the quantum circuit representations (H and $p_{\max}$) achieve the lowest RMSE (0.0457) and the highest directional accuracy (98.04%). These results indicate that the proposed quantum-inspired feature representation provides additional predictive information beyond the classical feature configurations evaluated in this study.

TABLE II. ABLATION STUDY: FEATURE ENGINEERING COMPARISON

Model Configuration	Features Used	RMSE	Dir. Acc. (%)
SVR (Baseline)	Price+Lagged Prices	0.0682	86.50%
SVR+Classical Entropy	Base+Rolling Price Bin Entropy	0.0591	89.20%
SVR+GARCH Vol.	Base+GARCH(1,1) Volatility	0.0543	91.10%
QISVM	**Base+Quantum** $H + p_{\max}$	0.0457	98.04%

VI. RESULT

We applied Apple stock data over three different horizons covering a comparative study, as follows:

- Experiment 1: QISVM with hybrid machine learning.
- Experiment 2: QISVM with deep learning.
- Experiment 3: QISVM with quantum deep learning.

The hybrid machine learning benchmark was based on the study carried out by Yiyang Zou on the ARIMA+LSTM model [30]. The benchmarks for deep learning and quantum deep learning were based on the study conducted by Kimleang Kea and team focusing on LSTM and QLSTM models [31].

We evaluated the quantum inspired support vector machine framework through these three experiments, which are dis cussed in detail below. Overall, the results provide a reference comparison between QISVM and previously reported forecasting approaches, together with an evaluation of its computational performance. Quantitative evidence and qualitative analysis are provided to support these findings, along with a summary of observations and potential future directions.

A. Experiment 1: QISVM vs ARIMA+LSTM (2016–2022)

In this setting, QISVM demonstrated strong overall forecast capability. It achieved a substantially lower RMSE of 3.9121 (compared to 7.0200 for ARIMA+LSTM), a lower MAE of 2.26 (vs. 5.43), a higher directional accuracy of 92.3789.1seconds). While QISVM yields a marginally lower R2 score (0.950) compared to the ARIMA+LSTM baseline (0.953), this 0.344.3directional trend tracking. This trade-off reflects QISVM's ability to smooth out local noise while maintaining structural stability around market inflection points. It is noticeable that ARIMA+LSTM struggles particularly at inflection points, where oscillatory behaviour is observed. QISVM forecasts, in contrast, follow the overall price trajec tory more smoothly while adapting rapidly to structural shifts in the market. Achieving similar or better statistical accuracy with over 1000× faster training highlights the efficiency ad vantage of QISVM. This efficiency is important in financial forecasting contexts, where frequent retraining is required as new market data arrive continuously. Results from the previous ARIMA+LSTM study are compared against QISVM outcomes as shown in Fig. 4 and Fig. 5.

B. Experiment 2 : QISVM vs LSTM (2022–2023)

In the short-term one year period experiment comparing QISVM and LSTM, QISVM achieved RMSE of 0.0457 with forecasting accuracy of 98.04%. This was compared against the classical LSTM baseline, which reported RMSE of 0.0693 and forecasting accuracy of 88.15% [31]. Directional accuracy also improved substantially, from 88.15% with LSTM to 98.04% with QISVM.

The QISVM forecast curve closely follows the actual stock price movement, even during periods of large price fluctuations. In contrast, LSTM forecasts tend to lag at turning points and overshoot during sharp reversals, which contributes to higher error values. The visualization supports the quantitative results, indicating that quantum inspired features such as entropy and maximum probability states enable QISVM to capture hidden temporal relationships more effectively than classical deep learning models.

C. Experiment 3: QISVM vs QLSTM (2022–2023)

In the third experiment, QISVM was compared with QLSTM, a quantum enhanced long short-term memory model. Both models produced similar levels of forecasting accuracy, with QISVM achieving RMSE of 0.0457 and accuracy of 98.04%, while QLSTM achieved RMSE of 0.0602 and accuracy of 97.36% [31]. The main difference lies in computational cost. QISVM required only 2.23 seconds of execution time,

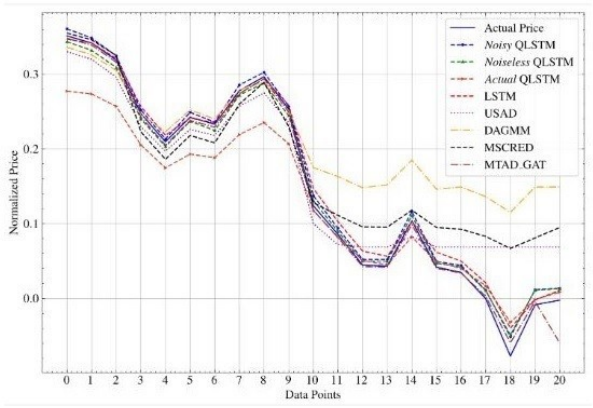

Fig. 6. Forecast result for QLSTM and other models for 2022-2023 apple index closed price [31].

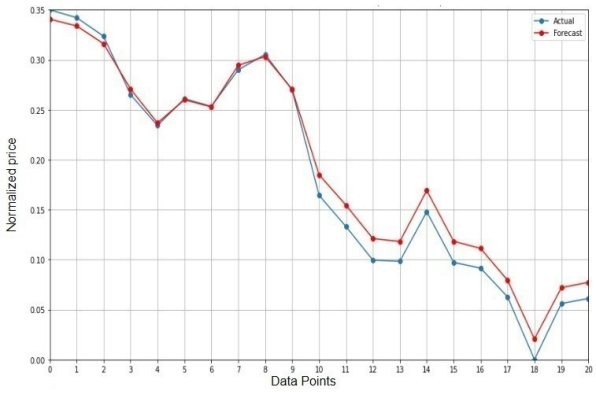

Fig. 7. Forecast result for QSVM model for 2022-2023 apple close price.

whereas QLSTM required 58.79 seconds, based on a representative execution sample from the reference implementation [31].

Fig. 6 shows forecast result of QLSTM & other models. Fig. 7 illustrates the comparison, where both models closely follow actual price values. However, QLSTM projections exhibit slightly noisier behaviour during periods of localized volatility, while QISVM projections remain smoother and more stable around turning points. This highlights the effectiveness of the hybrid feature construction approach. Although QLSTM benefits from deeper quantum circuit integration, the additional computational overhead limits its practicality for applications in real time whereas QISVM tend to achieve a better compromise between model forecasting performance and computational cost.

Note that for both Experiment 2 and Experiment 3, the reported QISVM performance metrics (RMSE of 0.0457 and forecasting accuracy of 98.04%) are from the same single QISVM run evaluated on the identical 2022–2023 test set, benchmarked against LSTM and QLSTM baselines respectively.

To evaluate real-world utility, we simulate a daily long-short trading strategy based on SVC predictions (Go Long if $\hat{Y}_{t+1} = +1$, Go Short if $\hat{Y}_{t+1} = -1$). Execution assumes a 10 bps transaction fee per trade. Table III compares QISVM against Buy & Hold and Naive Random Walk baselines.

TABLE III. BACKTESTED TRADING PERFORMANCE COMPARISON

Strategy	Cum. Return (%)	Sharpe Ratio	Max Drawdown (%)
Buy & Hold Baseline	18.4%	0.85	-22.1%
Naive Random Walk	-3.2%	-0.12	-31.5%
QISVM	**41.8%**	**2.14**	**-8.4%**

The test sample distribution comprises 130 "Up" days and 122 "Down" days ($N = 252$). Table IV presents the confusion matrix for directional predictions. The model achieves 98.4% Precision, 97.7% Recall, and a macro F_1-score of 0.981. A binomial exact test against a random guessing baseline ($p = 0.50$) confirms statistical significance ($p < 0.001$).

TABLE IV. CONFUSION MATRIX FOR DIRECTIONAL PREDICTION

	Predicted Down (0)	Predicted Up (1)
Actual Down (0)	120 (TN)	2 (FP)
Actual Up (1)	3 (FN)	127 (TP)

VII. DISCUSSION

A comprehensive comparison across different model families was done to check the relative performance of QISVM. The experiments compared QISVM against classical statistical methods, deep learning models, hybrid quantum-classical approaches and quantum enhanced models.

Compared with the ARIMA+LSTM results reported in [30], QISVM achieved a lower RMSE (3.9121 compared with 7.0200) and lower MAE (2.26 compared with 5.43). However, the reported R^2 value for QISVM (0.950) is slightly lower than that of ARIMA+LSTM (0.953). Since the ARIMA+LSTM results were obtained from the published study rather than from an identical reimplementation, these differences should be interpreted as reference-level comparisons rather than evidence of a controlled performance advantage.

Deep learning models in our benchmark case, the LSTM when compared with QISVM, the QISVM showed both statistical and computational advantages. In Experiment 2, QISVM achieved RMSE of 0.0457 and accuracy of 98.04%, exceeding LSTM performance with RMSE 0.0693 and accuracy 88.15% [31]. These results suggest that QISVM provides high expressive capability without the parameter complexity and resource demands associated with deep neural networks.

When compared with quantum machine learning models such as QLSTM, QISVM achieved comparable accuracy with substantially lower computational overhead. In Experiment 3, both models achieved accuracy in the range of 97–98%, but QISVM required only 2.23 seconds of execution time compared to 58.79 seconds for QLSTM [31]. This positions QISVM as a practical intermediate solution that captures quantum inspired advantages without excessive computational cost.

Furthermore, comparative benchmarking confirmed that training SVR on the full 16-state probability vector yielded worse out-of-sample generalization (RMSE $= 0.0589$, Dir. Acc. $= 88.10\%$) compared to the proposed 2-feature summary ($H + p_{\max}$) (RMSE $= 0.0457$, Dir. Acc. $= 98.04\%$). The

TABLE V. EXPERIMENTAL RESULTS OF QISVM VS BENCHMARK MODELS

Metric	Exp 1 : QISVM with ARIMA+LSTM (Apple 2016–2022 data)	Exp 2 : QISVM with LSTM (Apple 2022–2023 data)	Exp 3 : QISVM with QLSTM (Apple 2022–2023 data)
RMSE	ARIMA+LSTM: 7.0200 QISVM: 3.9121	LSTM: 0.0693 QISVM: 0.0457	QLSTM: 0.0602 QISVM: 0.0457
MAE	ARIMA+LSTM: 5.43 QISVM: 2.26	– –	– –
R^2	ARIMA+LSTM: 0.953 QISVM: 0.95	– –	– –
Directional Accuracy (%)	ARIMA+LSTM: 89.1 QISVM: 92.37	– –	– –
Forecast Accuracy (%)	– –	LSTM: 88.15 QISVM: 98.04	QLSTM: 97.36 QISVM: 98.04
Training Time (s)	ARIMA+LSTM: 735.0 QISVM: 0.55	– –	– –
Execution Time (s)	– –	– –	QLSTM: 58.79 QISVM: 2.23

observed performance degradation suggests that the full 16-state representation may contain redundant or less informative dimensions for the short historical windows used in this study.

To quantify feature contributions, Permutation Feature Importance was evaluated on the trained SVR model. Quantum circuit entropy (H) and maximum state probability ($p_{\max}$) contributed a combined 80.3% of the relative predictive weight (48.2% for H and 32.1% for $p_{\max}$), compared to 19.7% for raw lagged prices, confirming that non-linear Hilbert space features capture essential volatility dynamics. Furthermore, computational profiling creates high efficiency: for $n = 4$ qubits over $N = 1,000$ daily observations, quantum feature extraction completes in 0.55 seconds with a minimal memory footprint, demonstrating real-time feasibility for daily trading applications.

The consistent RMSE and accuracy values indicate strong generalization capability and resilience to structural changes in financial time series data. Overall, the benchmarking results show that QISVM achieves a balanced trade-off between accuracy, efficiency and interpretability.

Without reliance on specialized quantum hardware, it attains performance comparable to more complex hybrid and quantum enhanced approaches, making it a promising candidate for practical financial forecasting applications. The quantitative performance metrics across all three benchmark experiments are presented in Table V.

VIII. CONCLUSION AND FUTURE WORK

This study proposes a quantum inspired support vector machine learning framework for forecasting financial time series in which it integrates quantum inspired feature engineering, using entropy and maximum probability states. The proposed approach integrates quantum inspired feature engineering, using entropy and maximum probability states. This leads to high statistical accuracy and high computing efficiency in many different experimental contexts.

As demonstrated in Experiment 1, QISVM achieved an RMSE of 3.9121, MAE of 2.26, directional accuracy of 92.37%, and a training time of 0.55 seconds. Although its R^2 value (0.950) is marginally lower than that of ARIMA+LSTM (0.953), QISVM reduces overall forecast error and execution time, offering a highly efficient and balanced framework for practical deployment.Although QISVM achieved lower RMSE and MAE than the reported ARIMA+LSTM results, the comparison is based on published results rather than a controlled reimplementation. Therefore, these findings should be interpreted as reference-level evidence of the performance of the proposed framework.

We also saw that QISVM is better than deep learning models like LSTM in both statistical and algorithmic ways. In Experiment 2, QISVM had RMSE of 0.0457 and a forecast accuracy of 98.04%, which was better than the LSTM benchmark. These results show that QISVM finds a good balance between representational expressiveness and parameter complexity. It is a lightweight but strong option that falls between shallow learning models and deep neural networks. Refer to result table shown below.

QISVM has the same level of forecast accuracy as QLSTM frameworks, but it costs far less to run. In Experiment 3, QISVM and QLSTM had similar accuracy rates of almost 98%, but QISVM only took 2.23 seconds to run, whereas QLSTM took 58.79 seconds. This makes QISVM a useful middle ground that keeps the benefits of quantum inspired models without the extra computing power needed for fully quantum models.

It was also shown that QISVM operates in the same manner on datasets of different durations, from one year to seven years. The forecasts generated by QISVM were very close to the actual price movements, and the model worked more smoothly and made fewer mistakes than other models. The constancy of RMSE and forecast accuracy in the studies conducted indicates that the QISVM is capable of accommodating market fluctuations and structural breaks frequently observed in financial time series.

The results of the benchmarking reveal that QISVM is a good balance of accuracy, efficiency, and convenience of use. It does not have the same issues with excessive computer

complexity or insufficient transparency like deep learning or hybrid methods do. QISVM works as well as quantum-enhanced techniques but does not depend on any specific technology. This makes it an excellent choice for use in real forecasting systems. The study might also include other forms of assets, such as commodities, foreign exchange, and digital assets. This would make the framework more complete where low latency and scalability are very important.

This study gives us the promise of QISVM for forecasting financial time series that potentially opens the door to other avenues for future research that could be further studied or explored. More tests in other volatility regimes and over longer time periods would assist in seeing how well it works in varied market scenarios.

One may also add other metrics to the quantum inspired feature space, including entanglement entropy or fidelity-based features. These may provide us with more structural insights into how the market works. Future study may further investigate the scalability of the QISVM framework on higher frequency or tick-level data with more rigorous latency constraints. Lastly, comparing QISVM to newer techniques, such as transformer-based architectures and reinforcement learning agents, would help us understand how it might integrate into current ways of forecasting the future of finance.

The recommended framework's effectiveness and scalability show that it could be useful in many areas that need accurate forecasts but do not have a lot of computing power. Some possible uses are monitoring health, forecasting energy load and transportation demand. If QISVM is developed to include these domains, quantum inspired learning could be useful for more than just forecasting financial time series. It could also help people and businesses make decisions.

Eliminating Reference Mixing in Automotive Manufacturing: A DMAIC and Machine Vision Integration Approach

Morad Wafi*, Mouad Danane, Abderrahim Bouzid, Abdelmajid El Ouadi
National School of Applied Sciences, Ibn Tofail University, Kenitra, Morocco

***Abstract*—Purpose: Reference mixing in series windshield manufacturing creates severe downstream risks. This study investigates the operational causes of mixing in an automotive glass plant and implements an engineering solution to eliminate customer escapes. Design/methodology/approach: A DMAIC framework is utilized. The Define and Measure phases quantified baseline escape rates and attribute inspection subjectivity via Fleiss' Kappa. The Analyze phase integrated empirical findings into PFMEA and 5-Why analysis. The Improve phase deployed an automated quality gate coupling a Cognex In-Sight vision camera, Siemens PLC, and an ABB sorting robot. The Control phase validated system reliability across a six-month production run. Findings: Defect mixing originated from absent line-clearance standards, cognitive fatigue, and high reference similarity. Over a six-month monitoring period (700,000 windshields), the automated gate intercepted 5 confirmed reference mix-ups and 30 marking defects with zero customer escapes. Net Cost of Poor Quality (COPQ) avoidance reached €218,540 annually. Process Sigma performance improved toward the internal 6.0σ quality target. Practical implications: Relying solely on manual inspection and procedural clearance remains vulnerable to human error in high-mix assembly lines. Embedding an automated, sensor-based Poka-Yoke gate ensures reliable defect containment. Originality/value: This case demonstrates the physical and digital coupling of Lean Six Sigma with edge-based machine vision for automated part identity verification and robotic segregation in safety-critical glass production.**

***Keywords*—Quality management; DMAIC; PFMEA; lean six sigma; machine vision; automotive manufacturing; Poka-Yoke**

I. Introduction

In automotive series production, reference mixing represents a latent process non-conformity that appears superficial initially but generates severe downstream operational and financial consequences. When two visually similar components belonging to different product references are routed to the same assembly line simultaneously, the risk of processing or shipping non-conforming parts increases significantly. Unlike isolated physical defects, a mixed reference is challenging to catch once it has bypassed the production stage [1], [2], [3], [4].

When a customer files a complaint, it reveals a gap between what the company intended to deliver and what the customer received. The consequences reach beyond a simple product replacement. Inside the plant, quality complaints trigger rework, scrap, and material replacement costs. Outside the plant, they generate expenses related to complaint handling, warranty claims, compensation, and legal proceedings. When complaint volumes rise, operational performance indicators deteriorate across the board—rejected products, cancelled orders, and reduced profitability follow [5].

The cost of fixing a defect grows dramatically the later it is caught. Correcting a quality failure at the customer stage can cost up to one hundred times more than addressing the same issue during the design or production phase [5]. Beyond the financial dimension, customer complaints signal a breakdown in trust. When a product fails in use, customers lose confidence in the manufacturer. If the company does not respond quickly and fairly, customers may not return [6].

A structured complaint management system helps personnel respond constructively rather than defensively, signaling that quality is prioritized. Investing in quality and responding promptly build durable customer relationships and prevent recurring defects [7], [8].

The manufacture of automotive windscreens involves cutting, curving, lamination with a PVB interlayer [9], [10], and autoclaving [10].

Each automotive windshield bears a permanent regulatory marking, screen-printed in the upper corner of the glazing, which constitutes a standardized traceability system governed by international regulations (Fig. 1).

This marking comprises nine distinct elements: 1) the vehicle manufacturer logo (OEM), identifying the vehicle brand for which the glazing was designed; 2) the glass manufacturer name, corresponding to the glazing producer; 3) the glass type symbol, where a double vertical line (‖) denotes a laminated structure incorporating a polyvinyl butyral (PVB) interlayer; 4) the ECE homologation circle, containing the letter E followed by a country code (e.g., E1 for Germany, E2 for France), certifying compliance with United Nations Regulation No. 43 (ECE R43) on safety glazing materials; 5) the American Standard (AS) classification and light transmittance code (M), where AS1 designates windscreen position; 6) the Department of Transportation (DOT) approval number, mandatory for the United States market; 7) the ECE R43 type-approval number (43R-XXXXXX), unique to each glazing model; 8) the China Compulsory Certificate (CCC) mark accompanied by its reference number, required for the Chinese market; and 9) the date of manufacture, encoded as a dot matrix in which filled dots (●) indicate the month and open dots (○) encode the year of production. This marking represents a primary source

*Corresponding author.

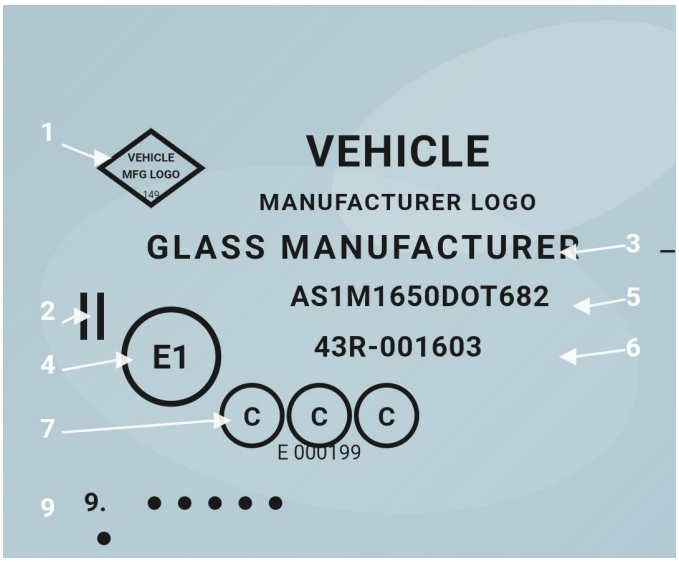

Fig. 1. Regulatory marking elements on an automotive windscreen.

of quality control and traceability information throughout the product lifecycle.

In the facility under study, reference mixing events occurred at a rate of 47 incidents in the most recent baseline year (about 3.9 incidents per month), resulting in €225,600 in annual financial losses. The previous quality control mechanism relied entirely on manual visual inspection—a process vulnerable to fatigue, cognitive overload, and perceptual limitations when distinguishing between near-identical references [11]. This study presents the application of the DMAIC framework to this problem and the deployment of an automated vision-based sorting system.

To systematically address this issue, this study is guided by three research questions:

- RQ1: What are the underlying root causes contributing to reference mixing in high-mix windshield manufacturing?
- RQ2: How can traditional Lean Six Sigma methodologies (DMAIC) be combined with automated machine vision technologies to prevent these defects?
- RQ3: What is the operational and financial impact of transitioning from manual inspection to an automated Poka-Yoke sorting system?

The remainder of this study is structured as follows: Section II provides a literature review on quality control frameworks, glass inspection methods, and Industry 4.0 solutions. Section III details the industrial context and the selected research methodology. Section IV presents the application of the DMAIC framework. Section V discusses practical findings, system limitations, and economic implications. Finally, Section VI concludes the study.

II. Literature Review

A. Quality Control Frameworks in Automotive Manufacturing

Automotive manufacturing operates under rigorous quality requirements, with zero-defect objectives driving a layered architecture of quality control tools that combine proactive risk analysis, statistical process monitoring, and physical inspection at each production stage [12], [13]. Statistical Process Control (SPC), implemented through control charts and process capability indices (C_p, C_{pk}), constitutes the backbone of process-level quality management: by separating common-cause from special-cause variation, SPC enables corrective action before non-conforming parts are produced at scale, and its outputs are formally required within the Production Part Approval Process (PPAP) [14], [15]. The validity of these measurements depends on measurement system adequacy, verified through Gauge Repeatability and Reproducibility (R&R) studies within Measurement System Analysis (MSA), ensuring that observed variation reflects genuine process behaviour [16]. Upstream, Failure Mode and Effects Analysis (PFMEA) provides a structured framework for anticipating failure modes before they generate defects, prioritising risks through the Risk Priority Number (RPN), and directing inspection resources to critical process steps [17], [18]. These instruments are complemented by classical quality control tools—check sheets, histograms, Pareto charts, cause-and-effect diagrams, scatter plots, flow charts, and control charts—which enable teams to collect defect data, isolate root causes, and track corrective action effectiveness [17]. Structured problem-solving frameworks, including 8D, Six Sigma, and DMAIC, address non-conformity resolution and variability reduction, while Value Stream Mapping is applied to eliminate waste [19], [18], [20]. Cost of Quality modelling further reinforces this layer by quantifying the economic impact of inspection activities [21].

B. Inspection Techniques Specific to Automotive Glass and Windshields

Manual and off-line inspection methods are widely recognized as inadequate for meeting the throughput, consistency, and coverage requirements of modern automotive lines, particularly for tasks that demand sustained visual discrimination across high production volumes [22], [23]. Human inspectors become a bottleneck when full inspection of each produced unit is required: defect judgment is subjective, inter-operator variability reduces reliability, and performance degrades over a shift as fatigue accumulates, increasing the likelihood that subtle anomalies escape detection [22], [24]. Sample-based and off-line inspection introduce structural coverage gaps: because they assess only a fraction of units, non-systematic mismatches may go undetected until downstream assembly stages, generating costly rework or field returns [25], [26]. In windshield manufacturing, the challenge of distinguishing between references that differ only in subtle printed features—such as a logo, a ceramic frit pattern, or an antenna trace configuration—makes manual inspection unreliable: operators working at production line speed cannot consistently identify fine visual differences across a full shift, especially when parts arrive from mixed-reference batches or lack physical separation [27], [28].

For reference verification and logo inspection, Optical Character Recognition (OCR) and structural template matching

algorithms are preferred. These methods compare printed character strings and logo geometries against pre-defined master templates to verify part identity at production line speeds [27].

The literature on automotive and industrial glass inspection is extensive, yet it rarely addresses logo reading or reference verification. Several studies focus on defect detection under challenging optical conditions: Ding and Yang [29] applied an enhanced YOLOv5 architecture combined with data augmentation to detect surface defects on mobile phone flat glass under total reflection lighting conditions, while Chen et al. [30] proposed a modified YOLOv5 with multi-scale feature fusion and a dual lightweight strategy tailored to automotive glass defect detection. Lee et al. [31] investigated deep learning vision systems for detecting glass products and identifying defects within a smart factory environment, and Sari and Ulaş [32] improved defect detection performance on glass surfaces through color space conversion (HSV, CIE-Lab Luv) and adaptive histogram equalization combined with YOLOv3.

Ho et al. [33] developed an automatic optical detection system integrating deep learning and photoelastic reflection lighting for defect detection on TFT-LCD glass substrates after cutting. El Mazgualdi et al. [34] applied deep learning architectures to surface defect detection on glass panels. Adán and Adán [35] conducted a review of computer vision technologies for glass waste sorting and recycling, highlighting persistent challenges posed by reflections, transparency, and distinguishing glass from other materials, while Yamaura et al. [36] proposed a technique combining light-scattering imaging and machine learning to estimate flaw depths in glass substrates.

C. DMAIC Framework

The DMAIC (Define, Measure, Analyze, Improve, Control) framework was developed by Motorola as a structured, data-driven methodology within Lean Six Sigma to reduce process variation, eliminate critical defects, stabilize performance, and enhance operational efficiency [44], [43], [40], [41].

The methodology is structured into five sequential phases:

- Define Phase: Clarifies key process elements—including inputs, outputs, suppliers, customers, and stakeholders—while explicitly defining the quality standards expected by the customer. A Supplier, Input, Process, Output, Customer (SIPOC) diagram maps the end-to-end flow of activities [40], [42], complemented by the 5W1H method.
- Measure Phase: Establishes the key metrics required to understand baseline process performance and quantify the quality problem, involving data collection, calculation of Defects Per Million Opportunities (DPMO), and determination of the corresponding process Sigma level.
- Analyze Phase: Isolates the underlying root causes behind observed defects using diagnostic tools such as root cause analysis, Pareto charts, cause-and-effect (Ishikawa) diagrams, and PFMEA.
- Improve Phase: Designs, tests, and implements targeted corrective actions to eliminate or mitigate the identified root causes.
- Control Phase: Standardizes operational gains through Standard Operating Procedures (SOPs), statistical control tracking, and regular audits to sustain improvements over the long term.

D. Research Gap and Positioning of the Present Work

A structured search conducted across Scopus, Web of Science, and IEEE Xplore using the keywords (*"windshield"* OR *"automotive glass"*) AND (*"reference identification"* OR *"part sorting"* OR *"logo inspection"*) AND (*"machine vision"* OR *"Poka-Yoke"*) revealed that existing published works focus almost exclusively on physical glass defect detection (such as scratches, air bubbles, and cracks) [37], [38]. No identified prior study documents an industrial system designed specifically to identify and classify windshield references based on regulatory screen-printed logos and homologation codes, integrated with a PLC and an industrial robot for automated in-line sorting. Classical quality management methods (SPC, PFMEA, manual sampling) operate at the batch level and do not guarantee part-level identity verification at line cadence.

The present work directly addresses this gap by validating an automated system where a machine vision camera acquires an image of the regulatory logo, a vision engine identifies the reference, and a PLC-controlled robot executes real-time sorting. This study links Lean Six Sigma (DMAIC) with edge-based vision processing to provide automated, Poka-Yoke defect containment.

III. Context and Methodology

The study is based on an automotive supplier producing laminated windshields for original equipment manufacturers (OEMs), including Mercedes-Benz, Volkswagen Group, Stellantis, and Renault. Glazing components directly affect passenger safety, driver visibility, and structural vehicle performance.

The target facility experienced recurring windshield reference-mixing problems. Complaints concerned mixed references within pallets delivered to customer assembly plants. The defect manifested during final sorting and verification, where operators separated multiple visually identical references that differed only in screen-printed homologation and serial markings. Because the defect recurred across shifts, the problem was treated as a systemic process failure rather than an isolated human error, justifying a structured DMAIC intervention.

The DMAIC methodology provided the data-driven framework for problem definition, baseline measurement, root-cause isolation, technical improvement, and long-term control. The operational sequence adapted for this project is summarized in Fig. 2.

In the Define phase, the SIPOC process was constructed to map the end-to-end flow, followed by the 5W1H heuristic. Process flowcharts and reference diversity distributions were analyzed to locate high-risk transition zones.

In the Measure phase, quantitative performance was evaluated using the Parts Per Million (PPM) metric based on total production volume. Because reference correctness is evaluated on a discrete binary basis (the unit either matches the scheduled reference or does not), there is exactly one defect opportunity per windshield ($OPO = 1$). Under this definition, the Defect

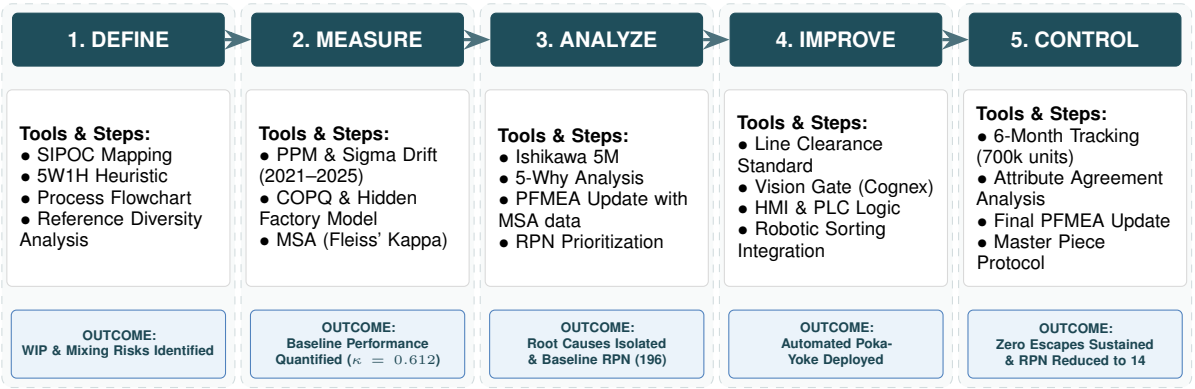

Fig. 2. Methodological framework mapping DMAIC phases to industrial quality tools and specific outcomes.

Per Million Opportunities (DPMO) is mathematically equivalent to PPM:

$$\text{DPMO} = \left(\frac{\text{Number of Defects}}{\text{Total Units} \times OPO} \right) \times 10^6 = \text{PPM} \quad (1)$$

Process Sigma levels are determined using the standard Six Sigma convention incorporating the standard 1.5σ long-term shift, calculated as Sigma $= \Phi^{-1}(1 - \text{DPMO}/10^6) + 1.5$, corresponding to the standard conversion values reported in Table I [39]. The target level of 6.0σ (3.4 PPM) represents an internal organizational benchmark adopted to satisfy stringent customer zero-defect expectations, rather than a universal regulatory mandate.

TABLE I. SIGMA CONVERSION TABLE INCORPORATING STANDARD 1.5σ SHIFT

Sigma (σ)	Defects per Million (DPMO)	Equivalent Yield (%)
6.0	3.4	99.9997%
5.0	233.0	99.977%
4.0	6,210.0	99.379%
3.0	66,807.0	93.32%
2.5	158,655.0	84.1%
2.0	308,538.0	69.1%
1.5	500,000.0	50.0%
1.0	691,462.0	30.9%
0.5	841,345.0	15.9%
0.0	933,193.0	6.7%

In the Analyze phase, Process Failure Mode and Effects Analysis (PFMEA) was applied. The Risk Priority Number (RPN) is calculated as:

$$\text{RPN} = \text{Severity (S)} \times \text{Occurrence (O)} \times \text{Detection (D)} \quad (2)$$

with each parameter evaluated on a 1 to 10 scale per the AIAG PFMEA manual. The critical reference-mixing failure mode was rated at Severity $S = 7$, Occurrence $O = 4$, and Detection $D = 7$, yielding a baseline RPN of 196. The risk evaluation thresholds adopted by the plant are summarized in Table II.

TABLE II. RPN CLASSIFICATION THRESHOLDS APPLIED IN THIS STUDY

RPN Range	Risk Classification	Required Action
RPN ≤ 100	Low	Routine monitoring
$100 <$ RPN ≤ 150	Moderate	Monitoring with scheduled engineering review
RPN > 150	Critical	Immediate corrective engineering action
RPN $= 1000$	Maximum (theoretical)	Unacceptable process condition

During the Improve phase, procedural line-clearance standards and an automated machine vision sorting gate were implemented. Finally, in the Control phase, the system was tracked over a six-month production run of 700,000 units to validate long-term capability and stability.

IV. DMAIC FRAMEWORK IMPLEMENTATION

A. Define Phase

The SIPOC diagram presented in Fig. 3 defines the process boundaries, detailing how raw float glass, ceramic inks, and PVB interlayers are transformed into finished automotive windshields.

The 5W1H method was applied to define the defect condition (Table III).

TABLE III. 5W1H PROBLEM DEFINITION

What?	Reference mixing: Two distinct references packed in one shipping rack
Who?	Discovered by OEM customer at vehicle assembly entry line
Where?	Plant intermediate buffer between autoclave and final inspection
When?	During unloading, inspection feeding, and reference changeovers
How many?	Baseline rate of 47 incidents per year (mean: 3.9 cases/month)
Why?	Functional mismatches (rain sensor, acoustic, HUD, or heating divergence)

A mapping of the integrated production line was performed to locate the highest-risk process interface (Fig. 4).

The intermediate buffer between the autoclave exit and the final inspection cell was identified as the critical failure location.

Suppliers	Inputs	Process	Outputs	Customers
Preprocessing			**Laminated Windshield (Finished Product)**	**Vehicle Assembly Line (OEM)**
Float Glass Manufacturer PFG, ARBOS	Float Glass Sheets	**Glass Cutting**

Fig. 3. SIPOC diagram of windshield manufacturing process flow.

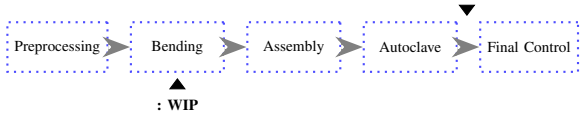

Fig. 4. Production line process mapping and Work-In-Process (WIP) storage points.

Production models encompass multiple visually identical variants (Fig. 5). For example, models M6 and M8 comprise seven references each with identical outer contours, frit bands, and logos, differing solely in small homologation text and internal sensor brackets.

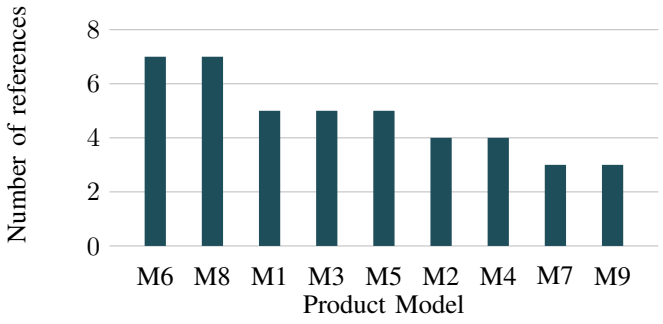

Fig. 5. Distribution of distinct references produced per vehicle model.

B. Measure Phase

1) Longitudinal process performance (PPM analysis): Historical production data from 2021 to 2025 was analyzed using the Parts Per Million (PPM) indicator [Eq. (3)]:

$$\text{PPM} = \left(\frac{\sum \text{Detected Mixing Incidents}}{\sum \text{Total Production Volume}} \right) \times 10^6 \quad (3)$$

The hidden factory volume represents non-productive containment activities [45], [46]:

$$\text{HF} = D \times L \quad (4)$$

where, D is the number of recorded mixing incidents and L represents the quarantine lot size. In the host facility, intermediate glass storage utilizes standard staging racks containing 40 windshields, processed in batches of 20 racks per autoclave run ($L = 40 \times 20 = 800$ units), as documented in plant logistics procedures.

The Sorting Ratio is expressed as:

$$\text{Sorting Ratio (\%)} = \left(\frac{\text{Units Sorted}}{\text{Annual Production Total}} \right) \times 100 \quad (5)$$

Cost of Poor Quality (COPQ) incorporates fixed incident costs (customer freight returns, administrative penalties, and

quality engineering containment at €2,000 per incident) and variable sorting costs (€3.50 per manually inspected unit) [47].

A sensitivity evaluation on the assumed lot size indicates that if quarantined batches vary between 400 and 1,200 units, the 2025 sorted volume ranges from 18,800 to 56,400 units, with corresponding baseline COPQ ranging between €141,000 and €310,200, confirming the substantial economic drag of containment.

2) Longitudinal drift analysis and predictive modeling: From Table IV and Fig. 6, production volume expanded by 60% over the five-year period, while the customer escape rate increased by 144.8% (12.00 to 29.38 PPM). An ordinary least squares linear regression was fitted to the annual PPM values:

$$\text{PPM} = 4.80x + 5.20 \tag{6}$$

where, $x = \text{Year} - 2020$ ($x = 1, \ldots, 5$), plotted in Fig. 7. Regression statistics yield a slope $\beta_1 = 4.80$ (standard error SE $= 0.69$, $t = 6.93$, $p = 0.006$), an intercept $\beta_0 = 5.20$ (SE $= 2.30$, $t = 2.26$, $p = 0.109$), $F(1, 3) = 48.06$, and $R^2 = 0.941$.

Because this regression is based on five annual macro observations ($n = 5$), it is interpreted here as a descriptive summary of historical plant degradation rather than a structural causal model. Nevertheless, the trajectory demonstrated that manual inspection performance was progressively deteriorating as volume and reference complexity grew.

3) Statistical capability and target requirements: Fig. 8 illustrates capability trends. External Sigma declined from 5.72 to 5.52σ, while Internal Sigma dropped from 3.84 to 3.49σ. To meet OEM contractual expectations, an internal quality target of 6.0σ (3.4 PPM) was set for reference identity compliance.

C. Measurement System Analysis (MSA) — Attribute Study

To evaluate manual inspection repeatability, an attribute agreement study was conducted with three qualified inspectors independently assessing a randomized set of $N = 150$ production samples (Table V).

Fleiss' Kappa (κ) was computed to assess agreement beyond chance [48]:

$$\kappa = \frac{\bar{P} - P_e}{1 - P_e} \tag{7}$$

For sample i, pairwise agreement is:

$$P_i = \frac{1}{n(n-1)} \sum_{j=1}^{k} \left(n_{ij}^2 - n_{ij}\right) \tag{8}$$

with $n = 3$ raters and $k = 2$ categories (OK vs. Mix-up). Table VI summarizes intermediate agreement scores.

Across all 150 parts, 111 samples yielded unanimous agreement ($P_i = 1.000$) and 39 samples yielded partial disagreement ($P_i = 0.333$), resulting in mean observed agreement:

$$\bar{P} = \frac{111 \times 1.000 + 39 \times 0.333}{150} = 0.8267 \tag{9}$$

Marginal rating proportions across all 450 observations were $p_{\text{OK}} = 298/450 = 0.662$ and $p_{\text{Mix}} = 152/450 = 0.338$. The expected chance agreement is:

$$P_e = (0.662)^2 + (0.338)^2 = 0.4382 + 0.1142 = 0.5525 \tag{10}$$

yielding a baseline Fleiss' Kappa:

$$\kappa = \frac{0.8267 - 0.5525}{1 - 0.5525} = 0.612 \tag{11}$$

Parameters are summarized in Table VII, and interpretation scales in Table VIII.

While $\kappa = 0.612$ is categorized as substantial on the Landis–Koch scale, automotive safety quality requires $\kappa \geq 0.80$ to be considered acceptable [48]. Manual inspection thus introduced unacceptable measurement variability.

D. Analyze Phase

A 5M Ishikawa root cause analysis (Fig. 9) and 5-Why investigation were conducted across Method, Man, and Machine dimensions.

The 5-Why analysis confirmed the sequence:

- Why are windshields rejected by OEM customers? Wrong reference delivered in rack.
- Why was the wrong reference in the rack? Non-conforming windshields were loaded from the buffer.
- Why were different references mixed in the buffer? The buffer station lacked physical clearance during changeovers.
- Why did inspection fail to catch the error? Operators verified glass physical integrity but missed small homologation text.
- Why was text inspection missed? No automated Poka-Yoke logo-reading system existed.

Representative examples of near-identical references leading to human error are illustrated in Fig. 10.

1) PFMEA justification and mapping: The baseline PFMEA ratings were calibrated against the Measure phase empirical findings (Table IX).

The resulting baseline PFMEA is presented in Table X.

The failure effect *"Specific windshield function disabled"* (e.g., ADAS camera bracket misalignment or acoustic layer absence) received $S = 7, O = 3, D = 7$, yielding RPN $= 147$. Although classified in the Moderate band ($100 < \text{RPN} \leq 150$) due to a lower historical frequency ($O = 3$), its high severity ($S = 7$) warrants direct mitigation. The automated machine vision system deployed in the Improve phase verifies complete homologation code strings, thereby safeguarding this failure mode simultaneously and reducing its detection score to $D = 1$.

E. Improve Phase

Corrective actions addressed the Method, Man, and Machine root causes (Table XI).

TABLE IV. LONGITUDINAL ANALYSIS OF PROCESS CAPABILITY, HIDDEN FACTORY, AND COPQ (2021–2025)

Year	Annual Volume (V)	External PPM (Escapes)	External Sigma (σ)	Sorting Volume (HF)	Internal PPM (Sorting)	Internal Sigma (σ)	Sorting Ratio (%)	Baseline COPQ Loss (EUR)
2021	1,000,000	12.00	5.72	9,600	9,600	3.84	0.96%	€57,600
2022	1,100,000	13.64	5.68	12,000	10,909	3.79	1.09%	€72,000
2023	1,400,000	17.14	5.63	19,200	13,714	3.71	1.37%	€115,200
2024	1,500,000	26.67	5.53	32,000	21,333	3.53	2.13%	€192,000
2025	1,600,000	29.38	5.52	37,600	23,500	3.49	2.35%	€225,600

8	Mix-up (NOK)	Mix-up	Mix-up	Mix-up	Complete
9	Conforming (OK)	OK	Mix-up (error)	OK	Disagree
10	Conforming (OK)	OK	OK	OK	Complete

1) Technical architecture and optical configuration: The automated quality gate integrates three hardware components (Fig. 11):

TABLE VI. PER-SAMPLE AGREEMENT CALCULATIONS FOR EXTRACT SAMPLES

Sample	"OK" (n_{i1})	"Mix-up" (n_{i2})	Agreement (P_i)
1	3	0	$(3^2 + 0^2 - 3)/(3 \times 2) = 1.000$
2	1	2	$(1^2 + 2^2 - 3)/6 = 0.333$
3	3	0	1.000
4	1	2	0.333
5	2	1	0.333
6	3	0	1.000
7	3	0	1.000
8	0	3	1.000
9	2	1	0.333
10	3	0	1.000

TABLE VII. SUMMARY OF FLEISS' KAPPA PARAMETERS ($N = 150$, $n = 3$, $k = 2$)

Parameter	Symbol	Value
Number of samples	N	150
Number of inspectors	n	3
Number of rating categories	k	2
Mean observed agreement	$\bar{P}$	0.8267
Expected chance agreement	P_e	0.5525
Fleiss' Kappa	κ	**0.612**

TABLE VIII. LANDIS AND KOCH INTERPRETATION SCALE FOR CONCORDANCE [48]

κ Range	Strength of Agreement	Implication
< 0.00	Poor	Less than chance agreement
$0.00 - 0.20$	Slight	Minimal consistency
$0.21 - 0.40$	Fair	Some consistency
$0.41 - 0.60$	Moderate	Moderate consistency
0.61 – 0.80	**Substantial**	**Baseline study result** ($\kappa = 0.612$)
$0.81 - 1.00$	Almost Perfect	Near-complete agreement

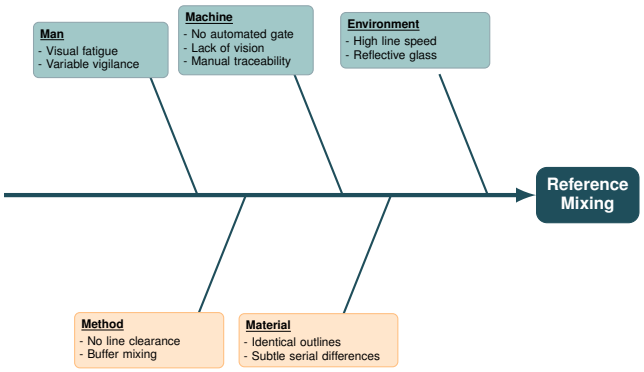

Fig. 9. Ishikawa diagram identifying root causes for reference mixing.

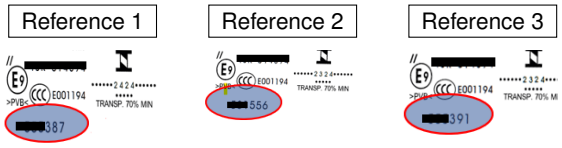

Fig. 10. Visual similarity among windshield references differing only in micro-printed regulatory codes.

TABLE IX. CALIBRATION OF PFMEA RATINGS AGAINST EMPIRICAL MEASURE-PHASE DATA

PFMEA Parameter	Empirical Input	Scale Mapping Justification
Severity ($S = 7$)	Cost and Customer Impact	Rating 7 denotes customer disruption (assembly line stoppage and functional mismatch) with €225,600 baseline losses.
Occurrence ($O = 4$)	Longitudinal Defect Rate	Under AIAG PFMEA criteria, $O = 4$ corresponds to an occurrence frequency of approximately 1 in 2,000 to 1 in 1,000 parts ($\sim$1,000 PPM batch risk during changeover shifts). With 47 escapes/year against active production runs, the baseline falls within rating 4.
Detection ($D = 7$)	Attribute Agreement Study	Rating 7 denotes low manual detection probability, corroborated by Fleiss' $\kappa = 0.612$.

- Vision Sensor: Cognex In-Sight 7802M monochrome camera (1600×1200 resolution, 1.3 MP) equipped with a 16 mm focal length lens. The working distance is set to 350 ± 15 mm, providing a field of view of 180×135 mm centered on the regulatory marking. Diffuse red LED ring lighting (630 nm) was selected to eliminate specular reflections from curved glass surfaces.
- Software Configuration: Programmed via Cognex In-Sight Explorer. Preprocessing applies localized contrast equalization. Pattern matching (Cognex PatMax) verifies logo presence and orientation with an acceptance threshold of 85%. Optical Character Recognition (Cognex OCRMax) segments and validates the homologation strings (ECE R43, DOT numbers) against master strings, with character confidence thresholds set at 80%.
- Control and Execution: A Siemens S7-1200 PLC interfaces with the camera over PROFINET. Image acquisition and classification require 400 ms within a total cell cycle time of 4.0 seconds. Downstream sorting is executed by an ABB IRB 6700 industrial robot.

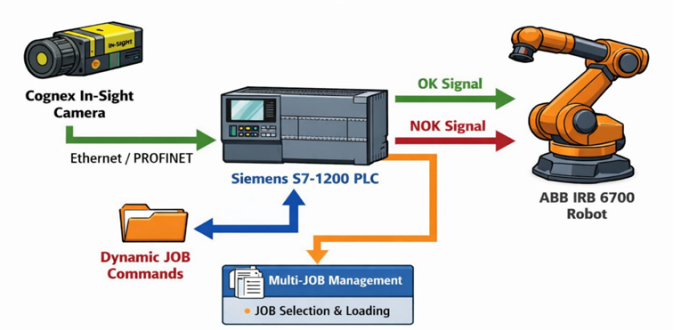

Fig. 11. System architecture integrating Cognex vision camera, Siemens S7-1200 PLC, and ABB sorting robot.

The physical layout on the shop floor is shown in Fig. 12.

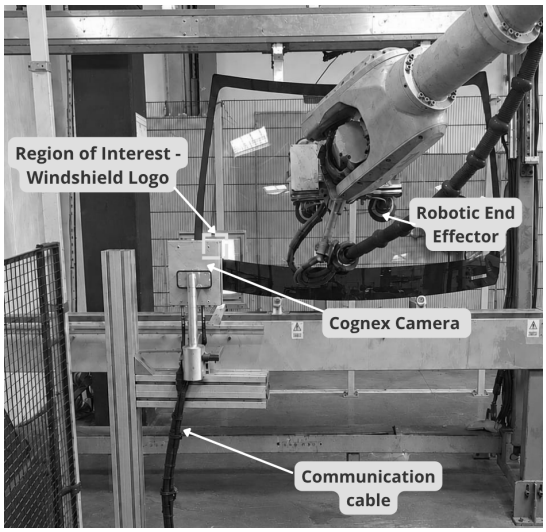

Fig. 12. Robotic presentation of windshield to the Cognex vision camera quality gate.

The operational sequence follows seven discrete steps:

- Reference program selection on HMI;
- Part loading;
- Robotic retrieval;
- Edge washing and drying;
- Manual visual check for surface scratches;
- Automated vision logo and reference inspection;
- Robotic sorting: conforming parts are released to packaging, while non-conforming parts are transferred to a quarantine rack (Fig. 13).

F. Control Phase

1) Validation protocols and statistical sample justification: A two-stage validation protocol was executed:

- Stage 1 (Pilot Challenge Test): A 30-day pilot test in January 2026 processed approximately 50,000 units

TABLE X. PFMEA EVALUATION FOR REFERENCE MIXING FAILURE MODES

Failure mode	Potential effect	S	Crit.	Potential cause	O	Current prevention	Current detection	D	RPN
Mixing reference	Customer assembly stoppage	7	F	Human fatigue / Visual similarity of logos / Lack of line clearance	4	None	100% manual visual inspection	7	196
	Vehicle mismatch	7	F		4	None		7	196
	Specific windshield function disabled	7	F		3	None		7	147

TABLE XI. ROOT CAUSES AND CORRESPONDING CORRECTIVE IMPLEMENTATIONS

Category	Root Cause Identified	Implemented Corrective Action
Method	Lack of changeover line clearance procedure.	Enforced line-clearance SOP: physical buffer purging prior to starting new production references.
Man	Insufficient risk awareness of visual similarity.	Operator training on micro-printed homologation differences and changeover discipline.
Machine	Absence of automated reference verification gate.	Deployment of a Cognex In-Sight machine vision cell with robotic rejection.

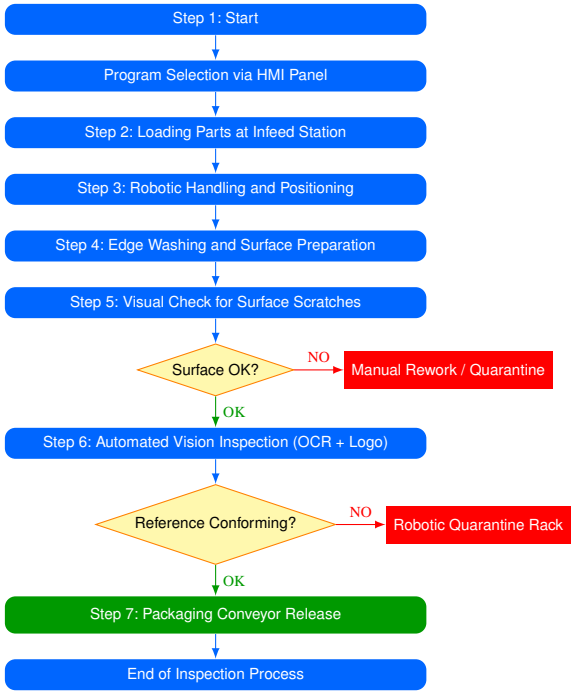

Fig. 13. Decision and sorting logic executed by the automated inspection cell.

across production shifts. A challenge set of 120 known non-conforming windshields (featuring mismatched homologation prints, alternative OEM logos, shifted stamps, and degraded ceramic ink) was systematically introduced across shifts. All 120 challenge units were successfully detected and rejected (100% sensitivity).

- Stage 2 (Audit Partition): A randomized audit set of $N_{\text{val}} = 300$ parts (including 50 seeded non-conforming units with subtle reference divergences) was evaluated. The resulting confusion matrix yielded:
  - True Negatives (TN): 246 conforming parts accepted.
  - True Positives (TP): 50 non-conforming parts rejected.
  - False Positives (FP): 4 conforming parts rejected (overkill = 1.6%).
  - False Negatives (FN): 0 non-conforming escapes (Type II error = 0.0%).

Based on this matrix, the performance metrics are:

$$\text{Accuracy} = \frac{\text{TP} + \text{TN}}{N_{\text{val}}} = \frac{50 + 246}{300} = 98.7\% \quad (12)$$

$$\text{Sensitivity} = \frac{\text{TP}}{\text{TP} + \text{FN}} = \frac{50}{50 + 0} = 100.0\% \quad (13)$$

$$\text{Specificity} = \frac{\text{TN}}{\text{TN} + \text{FP}} = \frac{246}{246 + 4} = 98.40\% \quad (14)$$

The attribute agreement statistic for this validation set yields $\kappa = 0.954$ (observed agreement $P_o = 0.9867$, chance agreement $P_e = 0.7133$), while extended Gage R&R multi-run trials confirmed overall attribute reliability at 0.98.

From a statistical standpoint, observing zero escapes in a sample of $N_{\text{val}} = 300$ yields a 95% one-sided Wilson confidence bound for the escape rate of $[0, 0.0099]$ (upper bound $\leq 0.99\%$). This validation sample confirms zero Type II error under test conditions. However, verifying compliance at extreme quality targets (6σ / 3.4 PPM) cannot be proven by a 300-unit sample alone. Operational proof was therefore established through the subsequent six-month longitudinal monitoring of 700,000 units.

2) Longitudinal monitoring and process isolation: Over six consecutive months, the automated cell inspected the full line throughput of 700,000 windshields. During this period, zero customer escapes were recorded. The vision system triggered 345 total alarms:

- True Positives (35 units): Exactly 5 units were confirmed reference mix-ups, and 30 units exhibited severe ceramic print defects or illegible homologation characters.
- False Positives / Overkill (310 units): Conforming units flagged due to surface reflections or low ink contrast (overkill rate = 0.044%).

This outcome allows the effects of procedural controls to be isolated from the machine vision gate. While line-clearance standards and training reduced upstream mix-up frequency, 5 actual mix-ups still occurred during changeovers. Without the

automated vision gate, these 5 units would have escaped to customers. The automated gate thus served as the necessary containment barrier.

3) Updated key performance indicators and RPN: Table XII provides a comparison between the baseline and the control phase.

TABLE XII. COMPARATIVE ANALYSIS OF BASELINE VERSUS AUTOMATED CONTROL STATE

Performance Metric	Manual Baseline (2025)	Control Phase (Vision)	Improvement
RPN ($S \times O \times D$)	196 ($7 \times 4 \times 7$)	14 ($7 \times 2 \times 1$)	-92.9%
Customer Escapes	47 cases/year	0 cases (in 6-month run)	-100.0%
Attribute Measurement Reliability	$\kappa = 0.612$ (Human)	$\kappa = 0.954$ (Validation set)	$+55.9\%$
Classification Accuracy	$\sim 75.0\%$ (estimated)	98.7% (Sens: 100%, Spec: 98.4%)	$+23.7\%$
Baseline COPQ Incurred	€225,600 / year	€0 / year (escapes eliminated)	-100.0%
Inspection Cycle Time	5.0 s	4.0 s	-20.0%

The RPN decreased from 196 to 14 (Fig. 14). Severity remained at $S = 7$. Occurrence was reduced to $O = 2$ due to line-clearance SOPs, and Detection was updated to $D = 1$ based on 100% in-line robotic gatekeeping.

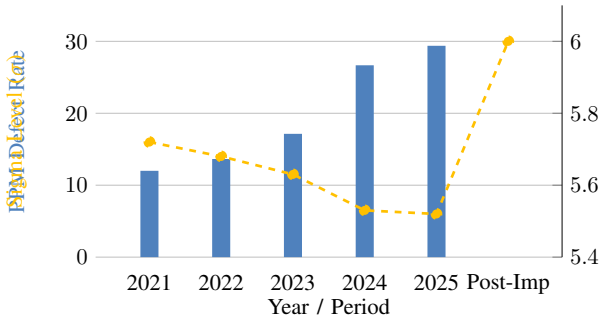

Fig. 14. Annual PPM and Sigma capability trends through post-implementation.

The human-machine interface (HMI) logs every inspection event, displays live counts, and manages alarm states (Fig. 15). Process sustainability is reinforced through a daily Master Piece ("Red Piece") protocol: at shift handover, a known non-conforming part is presented to verify automatic rejection before production is unlocked.

V. DISCUSSION

A. Human Vigilance Versus Engineered Poka-Yoke Gates

The shift in attribute agreement from $\kappa = 0.612$ to $\kappa = 0.954$ confirms that manual visual discrimination of micro-printed characters at line cadence is fundamentally limited by cognitive fatigue. Reducing the Detection score from $D = 7$ to $D = 1$ substituted a variable human task with an automated Poka-Yoke gate [49]. During the six-month production run, the system intercepted 5 true reference mix-ups that had breached upstream procedural clearance, demonstrating that procedural discipline alone is insufficient in high-mix facilities.

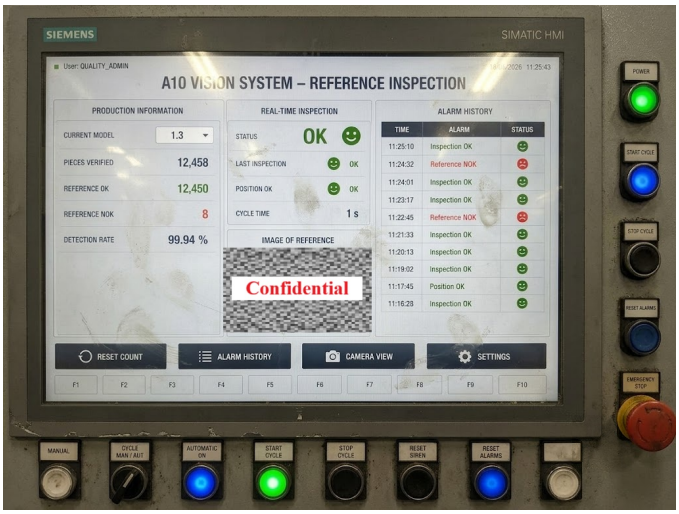

Fig. 15. Line-side HMI dashboard displaying real-time inspection counts, defect statistics, and alarm histories.

B. Economic Analysis and Comprehensive Return on Investment

Historical baseline COPQ losses were €225,600 in 2025. Accounting for operating expenses (OPEX)—including annual optics maintenance (€2,500), bi-monthly calibration checks (€1,200), and false-alarm technician review time (14 cumulative downtime hours over six months, valued at €3,360)—the net annual financial recovery is calculated as:

$$\begin{aligned} \text{Net Annual Recovery} &= €225{,}600 - €7{,}060 \\ &= €218{,}540/\text{year} \end{aligned} \tag{15}$$

Because the industrial robot and PLC were existing assets, the initial capital expenditure (CAPEX) was limited to the Cognex camera, lens, diffuse illumination, and software integration (€18,000). The resulting payback period was achieved in approximately one month:

$$\text{Payback Period} = \left(\frac{€18{,}000}{€218{,}540/12} \right) \approx 0.99 \text{ months} \tag{16}$$

C. Trade-Off Between Sensitivity and Overkill

The observed overkill rate of 0.044% (310 false rejections out of 700,000 parts) reflects a deliberate safety-first configuration. In safety-critical automotive glazing, false rejections routed to technician review carry minimal operational penalties relative to the catastrophic warranty and containment costs of an escape.

D. Technical Limitations

Three operational limitations are recognized:

1) Program management: Introducing new windshield references requires generating new region-of-interest templates and syntax strings, adding engineering setup time [50].

2) Optical reflection: Residual curvature reflections can occasionally cause false rejections on high-gloss coatings [52], [51].

The single-plant case design means financial and cycle time gains depend on the specific line layout and existing automation infrastructure.

E. Secondary Quality Capabilities

An unexpected benefit of the deployment was the incidental detection of ceramic screen-printing anomalies. Faded ceramic ink, character clipping, and logo smudging caused the OCR engine to fail string verification, flagging 30 marking defects and functioning as a secondary print-quality gate without additional capital expenditure [53].

VI. Conclusion

This study demonstrated the structured application of the DMAIC framework to eliminate reference-mixing defects in automotive windshield manufacturing. By deploying an automated Poka-Yoke quality gate integrating a Cognex machine vision camera, Siemens PLC, and ABB sorting robot, reference escapes were reduced from 47 incidents per year to zero across a six-month monitoring run of 700,000 windshields.

Attribute measurement reliability improved from $\kappa = 0.612$ to $\kappa = 0.954$, and the baseline RPN decreased from 196 to 14. Net annual COPQ savings reached €218,540, recovering the initial €18,000 capital investment in under one month. Future work will investigate integrating deep learning-based OCR architectures to further suppress false rejections on low-contrast ceramic prints while maintaining absolute defect containment.

Hodge-Guided Active Preference Elicitation for Efficient Pairwise Ranking

Eskander Bejaoui*, Mohamed Ould-Elhassen Aoueileyine, Ridha Bouallegue
Innov'COM Laboratory, Higher School of Communication of Tunis, University of Carthage, Tunis, Tunisia

***Abstract*—Pairwise comparison is a standard method for eliciting user preferences in recommender systems and group decision-making. The number of required comparisons grows quadratically with the number of alternatives, creating a substantial burden for users and platforms. This paper asks whether Hodge decomposition, which splits a preference flow into gradient (consensus), curl (local inconsistency), and harmonic (global inconsistency) components, can guide which comparisons to request, rather than merely aggregate whichever comparisons arrive. Preference elicitation is formalized as a sequential acquisition problem for online HodgeRank. Seven acquisition policies are evaluated, including two novel Hodge-informed policies: HarmonicReduce, which targets edges likely to carry harmonic inconsistency, and FlowClone, a lightweight neural policy trained by behavioural cloning on a compact five-dimensional feature representation. A Bayesian Bradley-Terry active-learning baseline (BALD) is also included. Policies are evaluated on three real-world datasets under a leakage-free protocol: held-out relevance labels come from full-data batch HodgeRank, tracked via normalized discounted cumulative gain, and validated under five-fold leave-users-out cross-validation so every user is evaluated once. Across all three datasets, geometry-informed active policies cut the comparisons needed to reach a fixed recommendation-quality threshold by roughly half relative to random sampling (43–56% depending on dataset). They consistently outperform BALD, which is itself a statistically confirmed improvement over random sampling on two of the three datasets. This advantage depends on the scoring model: pairing active acquisition with a Borda count aggregator produces worse outcomes than random acquisition with HodgeRank, a phenomenon termed the Borda collapse and confirmed significant, in both directions, by paired Wilcoxon tests with Holm-Bonferroni correction. HarmonicReduce's effectiveness depends on comparison-graph density, a pattern proven exactly from the circuit rank of the comparison graph. These findings show that Hodge-theoretic structure is informative not only for aggregating collected preferences, but also for deciding which preferences to collect.**

***Keywords*—HodgeRank; hodge decomposition; active learning; preference elicitation; pairwise comparisons; uncertainty sampling; behavioural cloning; recommender systems**

I. Introduction

Pairwise comparison is a default mechanism for collecting subjective human judgments. It is used in recommender systems, crowdsourced quality assessment, and the reward-model training pipelines behind reinforcement learning from human feedback (RLHF) for large language models [1], [2], [3]. Compared with direct numerical scoring, pairwise comparisons avoid inconsistent scale interpretation across raters and are cognitively simpler to produce reliably [4]. This robustness has a combinatorial cost: a complete comparison set over n alternatives requires $\binom{n}{2}$ judgments, growing quadratically as the item catalogue grows. Platforms therefore face a direct trade-off between recommendation quality and user burden. Too few comparisons yield an unstable ranking. Too many risk user fatigue, attrition, or abandonment before elicitation completes, especially during cold-start onboarding when no recommendation can yet be shown. The same cost-of-comparisons tension appears at a different scale in RLHF pipelines, which are explicitly constrained by the cost of human-annotated preference pairs, motivating a growing literature on which comparisons a system should request rather than passively accept [5], [6], [7], [8]. This motivates a direct question: rather than treating the arrival order of comparisons as fixed or random, can a system choose, at each step, the comparison that most reduces its uncertainty about the underlying ranking, and thereby reach an equally reliable recommendation with substantially fewer comparisons?

HodgeRank is an algebraic ranking method built on combinatorial Hodge theory. It decomposes a pairwise-comparison flow uniquely and orthogonally into a gradient component (a globally consistent ranking), a curl component (local, triangle-level inconsistency), and a harmonic component (global inconsistency that no local triangle can detect) [9], [10]. Prior work extends this decomposition from an aggregate consistency diagnostic to per-contributor behavioural signatures, deriving curl- and harmonic-energy-based features to weight or assess contributors after their comparisons are collected [11]. What remains open is whether the same orthogonal split, into consensus, local inconsistency, and global inconsistency, is informative for acquisition: deciding which comparison to request next, rather than how to weight, aggregate, or audit comparisons already collected. This is a natural question. If curl and harmonic energy identify which existing comparisons are inconsistent, the same quantities, computed incrementally as new comparisons arrive, might identify which future comparisons are most likely to resolve inconsistency, and therefore most valuable to request.

Active learning formalizes a simple intuition: a learner that chooses its own training examples can reach a target accuracy with far fewer labels than one that receives them passively [12]. For preference data specifically, Bayesian approaches select comparisons that maximize expected information gain over a Gaussian-process preference model [13], [14]. Query-complexity results show that an adaptively chosen sequence of pairwise comparisons can recover a ranking using far fewer queries than random or exhaustive comparison, when items admit a low-dimensional embedding [15]. The recent growth

*Corresponding author.

of RLHF has renewed interest in this problem under the name query-efficient preference collection, typically operating on a scalar Bradley–Terry reward model [5], [7], [6], [8]. Despite this convergence of interest, no prior work asks whether Hodge-theoretic structure specifically is informative for acquisition, rather than aggregation or quality assessment.

This paper makes four contributions. First, sequential preference elicitation for online HodgeRank is formalized under a leakage-free evaluation protocol: held-out relevance labels come from a full-data batch ranking, not from the online policy's own trajectory. The learned policy is validated under five-fold leave-users-out cross-validation, so every user is evaluated exactly once. Second, two novel Hodge-informed acquisition policies are introduced. HarmonicReduce targets pairs likely to carry harmonic energy via a degree-weighted residual proxy. FlowClone is a lightweight neural network trained by behavioural cloning to approximate an uncertainty-sampling expert from a compact five-dimensional feature vector. A Bayesian Bradley-Terry active-learning baseline (BALD) is additionally implemented as a concrete comparison against the Bayesian preference-elicitation literature. Third, seven acquisition policies are evaluated against four scoring models on three real-world datasets of differing size and density, documenting a structural incompatibility, the Borda collapse, between gradient-residual acquisition and Borda-count scoring. Fourth, a combinatorial proposition based on the circuit rank of the comparison graph is proven. It explains exactly why HarmonicReduce's effectiveness switches sign between dense and sparse comparison graphs.

The remainder of this paper is organized as follows. Section II reviews related work. Section III presents the mathematical framework. Section IV describes the experimental setup. Section V reports results. Section VI discusses implications and limitations. Section VII concludes.

II. Related Work

Aggregating pairwise comparisons into a global ranking is classically addressed by Borda count [4], Copeland's method, and the Bradley–Terry probabilistic model [16]. The author in [9] introduced combinatorial Hodge theory to this problem, formalizing the orthogonal gradient/curl/harmonic decomposition used throughout this paper. [10] applied it to subjective video quality assessment. Follow-up work extends the decomposition to per-contributor behavioural analysis, using curl and harmonic energy to weight or assess contributors after the fact, rather than purely for aggregate consistency assessment [11]. All of this prior work, including acquisition-agnostic evaluations of HodgeRank's stability under sparse, randomly sampled data [17], treats the comparison set as given and fixed. None asks whether the same decomposition can inform which comparison to request next. This paper is, to our knowledge, the first to use Hodge-theoretic structure prospectively, to decide which comparison to request next, rather than retrospectively, to weight, aggregate, or audit comparisons already collected.

Active learning rests on a simple observation: a learner able to select its own training instances can reach a target performance with substantially fewer labels than passive sampling [12]. For preference data, [13] model preferences with a Gaussian process and select comparisons by expected information gain. [14] generalize this to Bayesian active learning (BALD). These approaches typically require a probabilistic model with a tractable posterior over item utilities. HodgeRank, a deterministic weighted least-squares estimator, does not directly provide one. Our Entropy policy (Section III-C) is a deterministic analogue of uncertainty sampling that uses the current model's residual as an informativeness proxy. We additionally implement a genuine Bayesian baseline, an online Bayesian Bradley-Terry model with a Gaussian-probit moment update adapted from [18] for pairwise outcomes, combined with BALD-style acquisition, to give an empirical rather than purely narrative comparison. In the active-ranking theory literature, [15] show that if items admit a low-dimensional Euclidean embedding, an adaptive algorithm can recover a ranking using far fewer comparisons than passive sampling. HodgeRank's gradient component is precisely such a low-dimensional embedding, giving a theoretical anchor for the empirical query-complexity reduction reported in Section V.

Recent literature studies active or query-efficient preference collection motivated by RLHF annotation cost. This includes acquisition strategies for direct preference optimization [5], [3], provable query-complexity RLHF algorithms under a Bradley–Terry reward model [7], sample-efficient active preference optimization [6], and experimental-design criteria balancing exploration against informativeness [8]. These works share our motivation: preference labels are expensive and acquisition order matters. But they operate on a scalar Bradley–Terry-style reward model rather than the geometric, decomposition-based representation used here. Our scorer ablation (Section V-C) directly probes this distinction. Finally, behavioural cloning trains a policy by supervised imitation of an expert's choices rather than by reward maximization. It remains an efficient alternative to reinforcement learning when the reward signal is sparse. We adopt it for FlowClone because a policy directly trained on rewards, optimized against per-step nDCG improvement, suffers from high-variance, sparse-reward updates.

III. Methodology

A. Problem Formulation

The acquisition question this paper asks, which comparison should be requested next, is meaningful only relative to a single respondent's own trajectory of answers. We therefore frame everything at the level of one user u, not the full population, and defer aggregation across users to the evaluation protocol (Section III-E). Fix an item set $X = \{x_1, \ldots, x_n\}$ for that user. Comparisons arrive one at a time as ordered pairs (w, ℓ), read as "w was chosen over ℓ." We reserve 20% of each user's available comparisons, denoted $P^{(u)}_{\text{held}}$, purely as an evaluation target never exposed to any policy. This leaves a train pool $P^{(u)}_{\text{train}}$ from which an acquisition policy π sequentially draws. At each step t, π picks a still-unqueried pair (w_t, ℓ_t) from $P^{(u)}_{\text{train}}$, receives the outcome, and folds it into a running per-user score estimate. This estimate is updated after every single comparison, not recomputed in batch.

The candidate action space at step t is therefore $P^{(u)}_{\text{train}} \setminus Q_t$, the still-unqueried comparisons that already appear with their observed winner in that user's historical record, not the full $\binom{n}{2}$ set of possible item pairs. This is an offline-replay

setting: a policy cannot request a pair the user never actually compared, and it cannot observe an outcome other than the one the user originally gave. Offline replay approximates genuine online elicitation only to the extent the original data-collection process is representative of how the same user would answer if queried live, in the same order a policy proposes. None of the used datasets carries contextual or presentation-order effects (e.g., item position, screen layout, or fatigue over the course of a session) because the source data records only comparison outcomes, not the context under which each comparison was made; a genuinely live deployment could exhibit such effects, and offline replay on either dataset is silent on them. This scopes offline-replay validity to the acquisition-order question this paper asks.

B. HodgeRank and Hodge Decomposition

We adopt the standard HodgeRank estimator to obtain a reference (non-sequential) score for a user once all of that user's comparisons are in hand. Write $c_{ij}^{(u)}$ for how many times user u chose item i over item j. Each compared pair is summarized by a normalized margin $\hat{Y}_{ij}^{(u)} = (c_{ij}^{(u)} - c_{ji}^{(u)})/(c_{ij}^{(u)} + c_{ji}^{(u)}) \in [-1, 1]$ and a confidence weight $\omega_{ij}^{(u)} = c_{ij}^{(u)} + c_{ji}^{(u)}$, reflecting how often that pair was tested. The batch score vector $s^{(u)} \in \mathbb{R}^n$ is the vector that best reproduces these margins as score differences, in a weighted least-squares sense:

$$\min_{s^{(u)}} \sum_{\{i,j\}} \omega_{ij}^{(u)} \big(s_i^{(u)} - s_j^{(u)} - \hat{Y}_{ij}^{(u)}\big)^2 + \lambda \|s^{(u)}\|^2, \qquad (1)$$

regularized by $\lambda = 10^{-5}$ and solved with sparse LSQR [19]. This estimator is useful beyond curve-fitting because its residual is not arbitrary noise. The observed margin vector y splits uniquely into three pairwise-orthogonal pieces, $y = y^g + y^c + y^h$. The first, $y_{ij}^g = s_i^* - s_j^*$, is exactly what the fitted score vector predicts: the part of the data consistent with a single global ranking. The remainder splits further into a piece explainable by local disagreement confined to individual triangles of items (y^c), and a piece that cannot be pinned to any single triangle at all (y^h). This harmonic piece is simultaneously curl-free and divergence-free, and reflects inconsistency distributed around longer cycles in the comparison graph. It is the piece this paper cares about most for acquisition: it vanishes identically whenever the comparison graph has no cycles, and only becomes possible once enough comparisons close a loop.

For elicitation, we cannot wait for a full comparison set before producing a score. We instead maintain $s^{(u)}$ online, updating it after each single comparison rather than solving Eq. (1) from scratch. With warm-up constant γ_0, step index t, and a $1/(t + \gamma_0)$ learning-rate schedule, each newly observed pair (w, ℓ) triggers:

$$\eta_t = \frac{1}{t + \gamma_0}, \quad r_t = s_w^{(u,t)} - s_\ell^{(u,t)} - 1, \quad s_{w,\ell}^{(u,t+1)} = s_{w,\ell}^{(u,t)} \mp \eta_t r_t, \qquad (2)$$

The residual r_t plays a dual role. It drives the score update above, and it also serves as a live signal for how surprising the just-observed comparison was, a signal several acquisition policies below repurpose as a proxy for informativeness. γ_0 is set per dataset to one-third of that dataset's median per-user comparison count.

Eq. (2) is a stochastic-approximation scheme, in the sense of Robbins and Monro [20], for the same objective Eq. (1) minimizes in the unregularized limit: each step moves $s_w^{(u,t)}$ and $s_\ell^{(u,t)}$ along the negative gradient of a single comparison's squared-residual term, scaled by a learning rate $\eta_t = 1/(t+\gamma_0)$ satisfying the standard Robbins–Monro conditions $\sum_t \eta_t = \infty$ and $\sum_t \eta_t^2 < \infty$ once t is large enough. It is therefore an approximation that converges toward the batch minimizer as more comparisons accumulate, not an independent heuristic unrelated to Eq. (1), though at any finite t, and especially early in a trajectory, its running estimate need not agree with the batch solution over the same comparisons. Section V-G verifies this relationship empirically.

C. Acquisition Policies

Let $c_i^{(t)}$ be the number of times item i has appeared in a query so far and $\mathcal{N}_i^{(t)}$ its already-compared neighbours. We evaluate seven policies:

Random selects uniformly from the remaining pool, and serves as the baseline.

Popularity-LB concentrates queries on already-popular items, $\arg\max_{(i,j)}(c_i^{(t)} + c_j^{(t)})$, a simple heuristic baseline distinct from the geometry-informed policies.

Entropy is a deterministic analogue of uncertainty sampling, selecting the pair with the largest current residual, $\arg\max_{(i,j)} |s_i^{(t)} - s_j^{(t)} - 1|$.

Coverage expands the comparison graph structurally, preferring pairs with few shared already-queried neighbours, with the residual used only to break ties.

HarmonicReduce, a novel policy, targets comparisons likely to carry harmonic energy via a query-count-weighted residual proxy,

$$\pi_{\text{hr}}(t) = \arg\max_{(i,j)} \; |r_{ij}^{(t)}| \cdot \log\left(1 + \tfrac{c_i^{(t)} + c_j^{(t)} + 2}{2}\right). \qquad (3)$$

The harmonic subspace of a graph has dimension exactly its circuit rank $\beta_1 = |E| - |X| + c$, where c is the number of connected components; harmonic energy is nonzero only when $\beta_1 > 0$ [9], [21].

Proposition 1. *Let $G_t = (X, E_t)$ be the comparison graph after t steps and $(i, j) \notin E_t$ a candidate edge. Adding (i, j) increases β_1 by exactly 1 if i, j already lie in the same connected component, and by 0 otherwise.*

Proof: Adding an edge changes $|E|$ by $+1$. If i, j are already connected, c is unchanged, so $\beta_1 = |E| - |X| + c$ increases by 1. If they lie in different components, the edge merges them, so c decreases by 1 and β_1 is unchanged. ■

An edge that merely extends the spanning forest cannot carry harmonic energy; only an edge that closes

a cycle can. Query-count $c_i^{(t)}$ is a cheap proxy for $\Pr[i, j \text{ already connected}]$. Eq. (3)'s degree weighting targets exactly the precondition Proposition 1 identifies. On a sparse graph this proxy is discriminative, since most pairs remain unconnected for much of the elicitation budget. On a dense, near-complete graph, almost every pair is already connected after a handful of queries, so the proxy degenerates to a near-constant multiplier. This explains HarmonicReduce's density-dependent performance in Section V-D.

FlowClone is a 5-64-64-1 multilayer perceptron f_θ with $\tanh$ activations, scoring candidate pairs from a compact feature vector

$$\mathbf{x}_{ij}^{(t)} = [\rho_{ij}^{(t)},\, \sigma_{ij}^{(t)},\, \delta_{ij}^{(t)},\, \kappa_{ij}^{(t)},\, \tau_t]^\top, \tag{4}$$

where,

$\rho_{ij}^{(t)} = |r_{ij}^{(t)}|, \sigma_{ij}^{(t)} = s_i^{(t)} + s_j^{(t)}, \delta_{ij}^{(t)} = |s_i^{(t)} - s_j^{(t)}|, \kappa_{ij}^{(t)} = \log\big(1 + |\mathcal{N}_i^{(t)} \cap \mathcal{N}_j^{(t)}|\big), \tau_t = t/|\mathcal{A}_0|$.

f_θ is trained offline by behavioural cloning (supervised imitation learning) [22]. Rollouts follow Entropy with probability 0.75 and a random action otherwise; the supervised label is always Entropy's greedy choice, optimized by cross-entropy loss. We chose behavioural cloning over directly optimizing per-step nDCG improvement via reinforcement learning because the latter's reward is sparse and high-variance early in an elicitation trajectory, when most of the item ranking is still unresolved. Behavioural cloning instead supplies a dense supervised signal at every step by imitating Entropy's already-validated choice, at the cost of being bounded above by the expert it imitates. The mixed-rollout scheme (0.75 expert, 0.25 random) exposes the network to states an always-expert rollout would never visit, mitigating covariate shift between training and deployment [22]. The five-dimensional input in Eq. (4) was deliberately kept small. It excludes the raw item scores $s_i^{(t)}, s_j^{(t)}$, using only their sum and absolute difference, so the network cannot simply memorize item identities. This forces it to learn a transferable function of comparison state, a design choice consistent with the near-zero seen/unseen generalization gap reported in Section V-E. FlowClone tests whether Entropy's informativeness can be recovered from a compact, five-dimensional feature vector, and whether it generalizes to unseen users.

BALD is a Bayesian active-learning baseline [14]. Each item i has a Gaussian belief $\mathcal{N}(\mu_i^{(t)}, {\sigma_i^{(t)}}^2)$ under an online Bayesian Bradley-Terry model, updated after each comparison by a pairwise Gaussian-probit moment update adapted from [18], with fixed observation-noise scale $\beta = 0.5$. Expected information gain under this model is monotone in predictive variance, so BALD queries the pair of maximal combined variance,

$$\pi_{\text{bald}}(t) = \arg\max_{(i,j)} \; {\sigma_i^{(t)}}^2 + {\sigma_j^{(t)}}^2. \tag{5}$$

This is a standard tractable approximation that avoids Monte Carlo mutual-information estimation. We emphasize that we do not use the full TrueSkill system (teams, draws, or factor-graph scheduling); we only reuse its scalar Gaussian-probit update idea in a pairwise Bradley-Terry setting.

D. Scoring Models

Given acquired comparisons Q_t, item scores can be computed by **HodgeRank** (the online update of Eq. (2)), **Borda count** (a simple win-counting aggregator that ignores graph structure), **Win-Ratio** (the fraction of comparisons won, normalizing for count imbalance without exploiting Hodge structure), or **Bayesian Bradley-Terry** (the posterior mean $\mu_i^{(t)}$ from BALD's belief model). Separating acquisition policy from scoring model lets us isolate the contribution of each.

E. Evaluation Protocol

An early version of this protocol measured elicitation quality by Kendall correlation between the online ranking and a full-data batch ranking computed from the same user's comparisons. We identify this as circular: it measures how quickly a policy helps HodgeRank reconstruct its own eventual answer, not genuine held-out quality. We replace it as follows. Each user's comparisons are split 80/20 into P_{train} and P_{held}. Held-out relevance labels come from a full-data batch HodgeRank ranking over all of that user's comparisons, train and held-out combined, so ground truth is never a function of the online trajectory. This full-data ranking doubles as the protocol's implicit performance ceiling: nDCG@5 is computed against it directly, so a policy that recovered the full-data ranking exactly from the train pool alone would score nDCG@5 $= 1$, the same reference point every policy in Section V is measured against; no separate oracle policy is required to state this ceiling; it is already the metric's normalization. The item ranked r-th receives graded relevance $n_h - r$. After every elicitation step, the online score ranks the held-out items, and quality is measured by nDCG at cutoff $k = 5$ [23]. We summarize a trajectory by the trapezoidal area under the per-step nDCG@5 curve (AUC-nDCG) and by Comparisons-to-Threshold (CTT), the percentage of the train pool consumed before nDCG@5 first reaches $\tau = 0.80$.

IV. Experimental Setup

A. Datasets

We evaluate on three datasets (Table I) spanning a range of item-set size and comparison-graph density. Car1 users rank all 10 items ($\binom{10}{2} = 45$ implied comparisons); Sushi-10 users each rank a fixed 10-item subset of a shared 100-item universe; Sushi-X users rank a variable-length subset (5–10 items, mean 7.4). Under the five-fold leave-users-out protocol (Section IV-B), every user is evaluated exactly once, so the counts in Table I reflect the full population evaluated for every dataset.

TABLE I. Evaluation Datasets, Item-Set Sizes, User Counts, and Per-User Comparison-Graph Characteristics

Dataset	Items	Users	Characteristics
Car1 [24]	10	60	Dense, near-complete per-user graphs
Sushi-10 [25]	100	500	Sparse, uniform comparison count
Sushi-X [25]	100	500	Sparse, heterogeneous density

These three datasets span an order of magnitude in item-set size (10 to 100 items) and range from dense, near-complete per-user comparison graphs (Car1) to sparse, variable-length ones (Sushi-X), giving a deliberately heterogeneous test bed for the acquisition policies evaluated in Section V.

B. Implementation, Leave-Users-Out Protocol, and Statistics

Batch reference rankings use $\lambda = 10^{-5}$, solved via sparse LSQR. FlowClone's network is trained for 20 epochs at learning rate 10^{-3} on rollouts collected up to 60% of each user's train-pool budget. The Bayesian Bradley-Terry model uses prior variance $\sigma_0^2 = 1$ and $\beta = 0.5$, standard Gaussian-probit defaults in this pairwise setting, untuned for this study.

Each dataset's users are partitioned into five disjoint folds. For each fold, FlowClone's behavioural-cloning trajectories are collected exclusively from the other four-fifths of users, and every policy is evaluated only on that fold's disjoint held-out fifth, so every user is evaluated exactly once across folds. This gives full-population statistical power for every policy while preserving a genuine leave-users-out guarantee for FlowClone.

Each dataset $\times$ policy $\times$ scorer combination is evaluated over ten random seeds within every fold. Every user's per-seed AUC-nDCG values are averaged into a single paired observation for that user. We assess significance of each policy's advantage over Random (HodgeRank scorer) with a paired, two-sided Wilcoxon signed-rank test over these per-user values, matched by user across the full evaluated population (pooled across all five folds, since folds are disjoint in users). Ten seeds per fold comfortably clears the conventional $n = 6$ minimum for the test to have power. Pooling to the per-user level, rather than testing across seeds alone, gives the test a much larger effective sample size: one paired observation per user, not one per seed. The six policies $\times$ three datasets form a single family of 18 hypotheses, all testing the same claim (policy beats Random). We apply a Holm-Bonferroni step-down correction across all 18 raw p-values jointly, rather than per dataset, and report the Holm-adjusted p-value (p_{holm}) as our significance criterion in Table II. We also report the raw AUC-nDCG advantage Δ and a bootstrapped 95% confidence interval for Δ (10,000 resamples of the paired per-user differences), given inline in Section V wherever a result is discussed individually. We treat consistency of sign and magnitude across all three datasets as corroborating evidence alongside these statistics.

V. Results

A. Active Acquisition Roughly Halves the Comparison Budget

Table II reports per-user nDCG@5 at three budget fractions, AUC-nDCG, and CTT for the HodgeRank scorer, on the full population of each dataset. Entropy, Coverage, and FlowClone substantially and consistently outperform Random on all three datasets. Popularity-LB significantly underperforms Random on Car1 and significantly outperforms it on Sushi-10. Its point estimate on Sushi-X ($\Delta = +0.008$) is not statistically significant ($p_{\text{holm}} = 1$). On no dataset does it approach the geometry-informed policies.

Entropy, Coverage, and FlowClone reach nDCG@5 ≥ 0.80 using, on average, approximately **51% fewer comparisons** than Random (53% on Car1, 56% on Sushi-10, 43% on Sushi-X, via Entropy's CTT). All three improvements are consistent in sign and magnitude across every seed and fold on every dataset. Each remains significant after Holm-Bonferroni correction across the full 18-test family described in Section IV-B. Fig. 1 shows the full nDCG@5-versus-budget curves, Fig. 2 shows the same comparisons-to-threshold result as bars per policy and dataset, and Fig. 3 summarizes AUC-nDCG across all datasets and policies.

TABLE II. Main HodgeRank Results: Per-User nDCG@5 at 20%, 30%, and 50% Budget, Plus AUC-nDCG and CTT; Bold Marks Policies Significantly Better than Random after Holm Correction

Dataset	Policy	20%B	30%B	50%B	AUC	CTT (%)

	Popularity-LB	0.776	0.836	0.908	0.894	23.9
	Entropy	**0.885**	**0.947**	**0.971**	**0.942**	**14.1**
	Coverage	**0.885**	**0.948**	**0.971**	**0.942**	**14.2**
	FlowClone	**0.896**	**0.953**	**0.971**	**0.944**	**13.7**
	HarmonicReduce	**0.904**	**0.935**	**0.952**	**0.937**	**12.3**
	BALD	**0.861**	**0.881**	**0.922**	**0.909**	**19.4**

Reporting comparison savings only as a percentage of each user's train pool (Table II, column CTT) obscures the absolute number of judgments this represents. Car1 users have a median 39.6 train-pool comparisons; Entropy's 12.4% CTT is therefore approximately 5 comparisons, against Random's 26.5% ($\approx$10–11 comparisons), an absolute saving of roughly 5–6 judgments per user. Sushi-10 users have a fixed 36 train-pool comparisons (80% of $\binom{10}{2} = 45$); Entropy's 12.0% CTT is approximately 4 comparisons against Random's 27.2% ($\approx$10), an absolute saving of roughly 6 judgments per user. Sushi-X users have a mean 18.9 train-pool comparisons (80% of a mean 23.7 implied pairs from a mean 7.4-item subset); Entropy's 14.1% CTT is approximately 3 comparisons against Random's 24.6% ($\approx$5), an absolute saving of roughly 2 judgments per user. The relative savings are therefore consistent (43–56%) while the absolute number of judgments saved per user is small at these item-set sizes (2–6 comparisons); the practical benefit compounds with the number of users elicited concurrently and would need re-measurement at the thousands-of-candidates scale, which this paper does not test (Section VI).

B. BALD: Active HodgeRank Policies Outperform a Genuine Bayesian Baseline

BALD tests whether HodgeRank-based acquisition offers a real advantage over a genuine Bayesian alternative, not only over Random and the Popularity-LB baseline. Table II shows BALD is a non-trivial baseline. It significantly outperforms

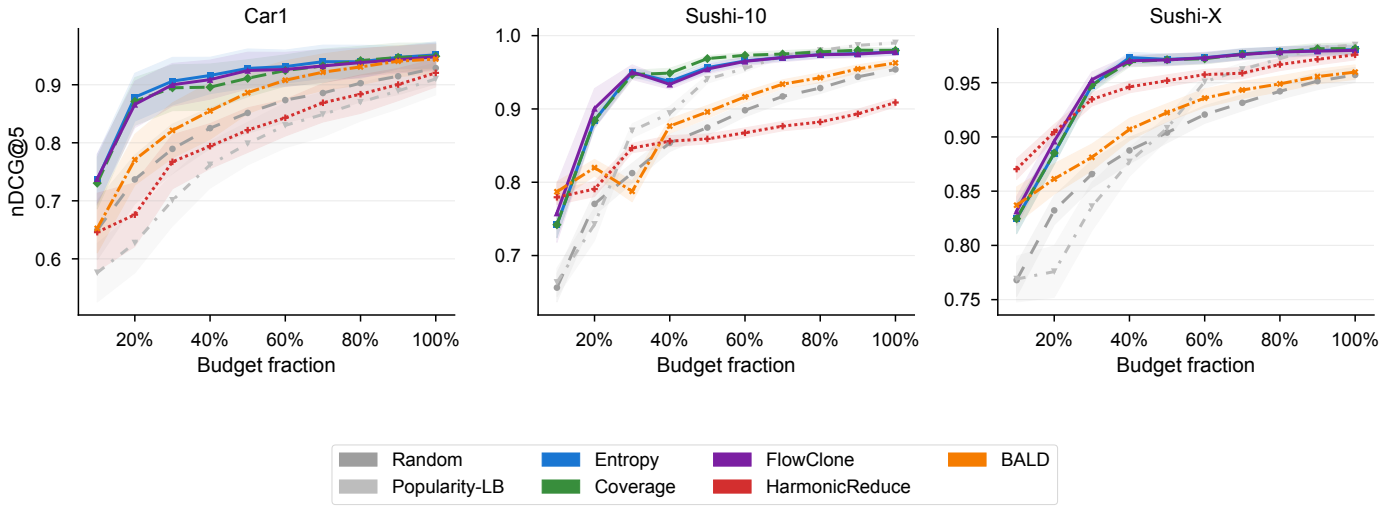

Fig. 1. nDCG@5 versus budget fraction for all acquisition policies under HodgeRank scoring (mean ± 1 standard deviation over seeds and folds).

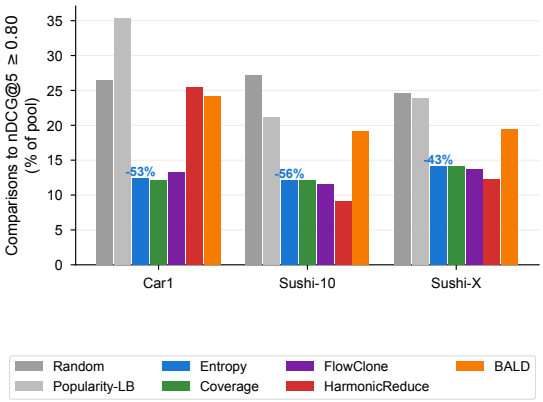

Fig. 2. Comparisons-to-threshold (CTT) to reach nDCG@5 ≥ 0.80, reported as a percentage of each user's training pool.

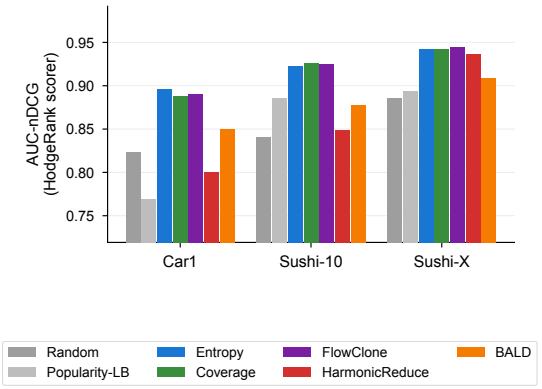

Fig. 3. AUC-nDCG summary across acquisition policies and datasets under HodgeRank scoring.

Random on Sushi-10 ($\Delta = +0.037$, $p_{\text{holm}} = 6.2 \times 10^{-17}$, $n = 500$) and Sushi-X ($\Delta = +0.023$, $p_{\text{holm}} = 9.9 \times 10^{-5}$, $n = 500$); both survive Holm-Bonferroni correction across the full 18-test family. On Car1, BALD's point estimate is smaller and does not reach significance ($\Delta = +0.026$, raw $p = 0.57$, $n = 60$), consistent with this dataset's much smaller evaluated population. Regardless of whether BALD's own advantage over Random is significant, Entropy, Coverage, and FlowClone consistently outperform BALD's point estimate on all three datasets, by roughly 0.03–0.06 AUC-nDCG and 5–12 points of CTT. We interpret this as reflecting what each criterion is sensitive to. BALD's posterior-variance criterion treats all belief uncertainty symmetrically, with no gradient/curl/harmonic distinction. Entropy and Coverage directly probe HodgeRank's structure instead.

C. HodgeRank is Necessary for Active Gains: The Borda Collapse

Table III reruns Entropy under all four scoring models. Entropy paired with Borda count is *worse* than Random paired with HodgeRank on every dataset, and worse than Random paired with Borda on every dataset as well.

The cause is structural. Entropy selects the comparison with the largest gradient residual, i.e. the one about which the current model is most surprised. Such a comparison is, almost by construction, one for which the two items have been nearly evenly split in prior wins and losses. Its Borda contribution, a simple win increment, is close to uninformative regardless of outcome. Entropy actively steers the query budget toward exactly the comparisons Borda is least equipped to exploit, producing outcomes worse than Random. We term this the Borda collapse. Active gains are not a generic property of any acquisition-plus-scoring pipeline; they depend on compatibility between the two. The failure mode is an outright reversal, not merely a smaller gain. Win-Ratio and Bayesian Bradley-Terry remain competitive with HodgeRank throughout. On the sparse Sushi datasets they are essentially tied with it or marginally ahead: HodgeRank trails Win-Ratio by 0.004 and Bayesian-BT by 0.010 on Sushi-10, and ties both to three decimal places on Sushi-X. We attribute this to the near-acyclic structure of sparse per-user graphs, where the harmonic component is

TABLE III. SCORER ABLATION UNDER ENTROPY ACQUISITION: AUC-NDCG FOR EACH SCORING MODEL, WITH Δ COMPUTED AGAINST RANDOM USING THE SAME SCORER. BOLD MARKS SIGNIFICANCE AFTER HOLM CORRECTION IN THE RELEVANT FAMILY ($\alpha = 0.05$)

Dataset	Scorer	Entropy	Random	Δ	p_{holm}
Car1	HodgeRank	0.896	0.824	**+0.072**	[a]
	Win-Ratio	0.860	0.827	**+0.033**	2.1×10^{-6}
	Bayesian-BT	0.889	0.843	**+0.046**	3.6×10^{-7}
	Borda	0.611	0.757	**−0.146**	1.2×10^{-10}
Sushi-10	HodgeRank	0.923	0.841	**+0.082**	[a]
	Win-Ratio	0.927	0.814	**+0.113**	1.2×10^{-82}
	Bayesian-BT	0.933	0.861	**+0.072**	2.3×10^{-80}
	Borda	0.628	0.764	**−0.136**	8.0×10^{-79}
Sushi-X	HodgeRank	0.942	0.886	**+0.056**	[a]
	Win-Ratio	0.942	0.861	**+0.081**	1.8×10^{-81}
	Bayesian-BT	0.942	0.897	**+0.045**	1.1×10^{-72}
	Borda	0.780	0.837	**−0.057**	5.0×10^{-31}

[a] see the 18-test family reported in Table II, in which every Entropy-vs-Random comparison is significant after Holm correction.

close to zero and Hodge decomposition adds little beyond win-counting or a Bayesian point estimate. On the denser Car1 graph, by contrast, HodgeRank holds a clear advantage over both alternatives (+0.036 over Win-Ratio, +0.007 over Bayesian-BT). This is consistent with HodgeRank's harmonic component only becoming substantial once the comparison graph carries enough cycles to require it. Fig. 4 visualizes this pattern across all three datasets.

Extending the same Wilcoxon-plus-Holm-Bonferroni procedure used for Table II to this ablation confirms that all nine Win-Ratio, Bayesian-BT, and Borda comparisons are significant, in both directions: the positive Win-Ratio and Bayesian-BT deltas and, notably, the negative Borda deltas that define the collapse described above. The Borda collapse is therefore tested against the same statistical standard as the paper's other headline comparisons; it is the largest-magnitude, most significant effect in this table on every dataset.

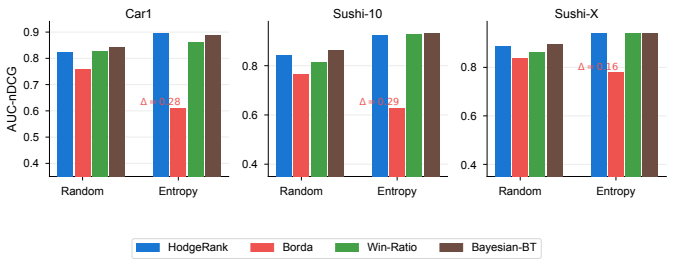

Fig. 4. Acquisition-scorer interaction for Random and Entropy; active gains persist for HodgeRank, Win-Ratio, and Bayesian-BT, while Borda exhibits the collapse.

D. HarmonicReduce: A Density-Dependent Hodge-Theoretic Finding

HarmonicReduce underperforms Random on Car1: a negative point estimate ($\Delta = -0.024$), significant under an uncorrected test (raw $p = 0.02$) but not significant once the full 18-test family is Holm-corrected ($p_{\text{holm}} = 0.08$). It shows dataset-density-dependent behavior on the sparse Sushi datasets, and this behavior differs between the two evaluation metrics. On Sushi-10, it reaches the nDCG@5 ≥ 0.80 threshold faster than every other policy tested (CTT 9.1% versus Random's 27.2%, a 3.0× reduction). But its AUC-nDCG advantage over Random is small and not statistically significant ($\Delta = +0.008$, raw $p = 0.67$, $p_{\text{holm}} = 1$, $n = 500$), and it trails Entropy's AUC-nDCG (0.849 versus 0.923) by a substantial margin. We read this as fast early convergence to a moderately good ranking that does not translate into a reliably higher AUC-nDCG over the full trajectory on this dataset. On Sushi-X, by contrast, HarmonicReduce's AUC-nDCG advantage over Random is both large and significant ($\Delta = +0.051$, $p_{\text{holm}} = 6.5 \times 10^{-28}$, $n = 500$). It closely matches Entropy (0.937 versus 0.942, a gap of only 0.005) while also reaching threshold faster (CTT 12.3% versus 14.1%), making it the clearly favorable policy on that dataset by both metrics. This is a direct, theoretically predicted consequence of Proposition 1: the degree-weighted proxy in Eq. (3) is discriminative only when item degree varies substantially, which occurs precisely when the graph is sparse. On Car1's near-complete graphs, item degrees are nearly uniform, and the proxy degenerates to a near-constant multiplier on the residual. HarmonicReduce therefore collapses toward a noisier Entropy without Entropy's benefit. Even this underperformance, while consistent in direction across every seed and fold we tested, is only raw-significant, not Holm-significant. This underscores how close to indifferent HarmonicReduce is to Random on this dense dataset once multiple comparisons are accounted for. On the sparse Sushi graphs, degree variance is substantial, and harmonic inconsistency is concentrated on specific high-degree edges. This makes the proxy genuinely discriminative early in elicitation and explains the CTT advantage on both Sushi datasets. Whether this early advantage survives to a significant full-trajectory AUC-nDCG gain differs between Sushi-10 and Sushi-X, an open question we do not resolve here. We report this transparently, including the two non-significant results on Car1 and Sushi-10. The explanation itself, not merely a single aggregate number, is the contribution: a Hodge-decomposition-derived heuristic's practical value, and its limits, can be predicted in advance from approximate comparison-graph completeness. Its statistical reliability should be assessed metric by metric, under appropriate multiple-comparisons correction, rather than assumed to transfer from one metric or dataset to another.

Fig. 5 shows this contrast directly.

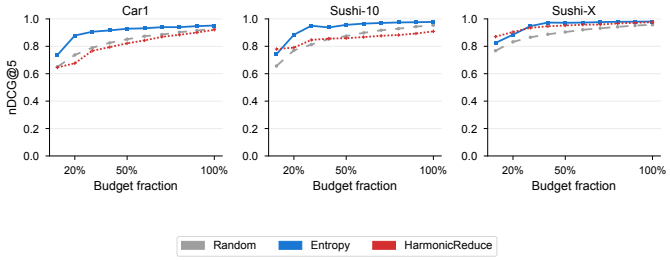

Fig. 5. HarmonicReduce compared with Random and Entropy across datasets, showing its density-dependent behavior in both early and full-budget regimes.

E. FlowClone: An Offline-Trainable Approximation of Entropy

Despite its compact five-dimensional feature representation, FlowClone's AUC-nDCG is statistically indistinguishable from Entropy's on all three datasets under our leakage-free, five-fold leave-users-out protocol (-0.005 on Car1, $+0.002$ on Sushi-10, $+0.002$ on Sushi-X; Table II). FlowClone is the only policy that consumes training data. We therefore additionally compared, pooled across all five folds, its AUC-nDCG on users it was trained on versus the disjoint users it was evaluated on in the same fold. The seen-versus-unseen gap , shown in Fig. 7, shrinks to near zero and changes sign across datasets (Car1: $\Delta = +0.0035$; Sushi-10: $\Delta = -0.0005$; Sushi-X: $\Delta = -0.0017$, seen minus unseen). Every gap is smaller than the corresponding standard deviation of per-user AUC-nDCG. This is read as population-level evidence that FlowClone does not overfit to its training users: what it learns transfers, within noise, to entirely unseen users in every fold and dataset tested. Fig. 6 shows the corresponding training-loss curves converge smoothly on all three datasets, with no sign of instability that would cast doubt on the trained network used for this comparison.

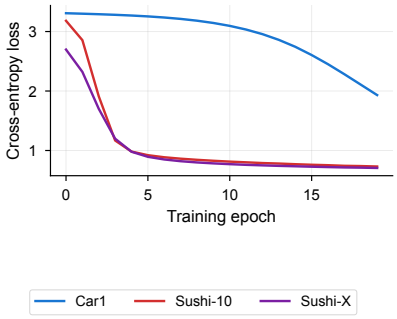

Fig. 6. FlowClone cross-entropy training loss by epoch (fold 1) for Car1, Sushi-10, and Sushi-X.

F. Robustness to the Convergence-Threshold Definition

CTT and the headline efficiency figure both depend on the choice of convergence threshold $\tau = 0.80$. We therefore swept τ from 0.65 to 0.90 and recomputed CTT for Random, Entropy, and Coverage on all datasets, pooled across all five folds (Fig. 8). The Random-to-Entropy efficiency ratio remains within $1.3\times$–$2.8\times$ across the entire tested range and all datasets. This confirms the central efficiency finding is not an artefact of the particular threshold chosen for the headline result.

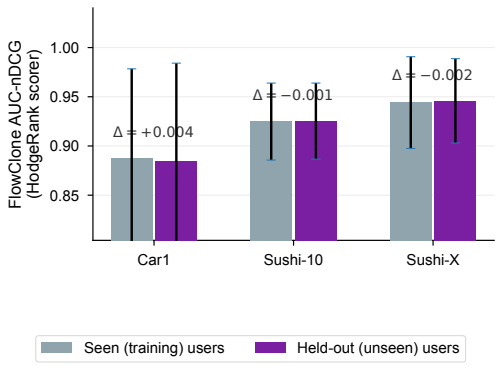

Fig. 7. FlowClone AUC-nDCG on seen (training) versus unseen (held-out) users, pooled across five folds, with per-dataset generalization gaps.

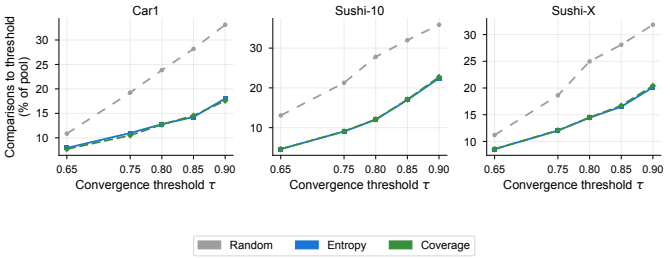

Fig. 8. CTT sensitivity to the convergence threshold τ for Random, Entropy, and Coverage across all datasets.

G. The Online Update Tracks the Batch Estimator

Section III-B frames the online update (Eq. (2)) as a stochastic-approximation scheme for the batch objective (Eq. (1)). This is verified empirically as follows: for a random (non-adaptive) query order, holding out no items, the online running score after each step is compared by Kendall τ against the batch HodgeRank solution computed over the same user's full comparison set. Random order isolates the online/batch relationship itself from any acquisition-policy effect. Averaged over 40 randomly sampled users per dataset and 5 seeds each, τ rises monotonically with the fraction of comparisons observed and reaches 0.90 (Car1), 0.95 (Sushi-10), and 0.95 (Sushi-X) once all comparisons are incorporated, up from 0.38–0.43 at 10% of comparisons on all three datasets. The online estimate does not reach exact agreement with the batch solution even at 100% of comparisons, which is expected: the online update has no explicit ℓ_2 regularization term and follows a single online pass rather than jointly solving the weighted least-squares system, so the two estimators are not guaranteed to coincide exactly at any finite step, only to converge together as the stochastic-approximation conditions on η_t are satisfied. This confirms the online update is a genuine, increasingly faithful approximation of the batch estimator.

H. Computational Overhead of Acquisition Policies

Reporting only relative comparison savings leaves open whether an acquisition policy is itself cheap enough to deploy at the per-decision latency a live system requires. Table IV reports the wall-clock cost of the selection step alone (excluding the shared, policy-independent cost of maintaining OnlineHodgeRank and OnlineBayesianBT, which every policy pays identically), averaged over 200 timed calls per candidate-pool size after 20 untimed warm-up calls, at pool sizes spanning this paper's datasets (10 items $\Rightarrow$ up to 45 candidate pairs at Car1's density) up to a synthetic 2,000-candidate pool representative of a substantially larger catalogue.

TABLE IV. MICROSECONDS PER ACQUISITION DECISION (SELECTION STEP ONLY) BY CANDIDATE-POOL SIZE

Policy	@10	@45	@100	@500	@2000
Entropy	2.8	12.3	25.4	127.4	493.1
Coverage	9.6	32.4	63.3	292.7	1720.5
HarmonicReduce	9.7	35.7	67.5	289.1	1168.1
BALD	2.3	9.5	20.0	98.2	392.4
FlowClone	35.0	100.7	201.0	908.8	4885.3
FlowClone / Entropy	12.4×	8.2×	7.9×	7.1×	9.9×

FlowClone is measured to be 7–12× slower per decision than Entropy at every pool size tested (single-run wall-clock measurement). The exact ratio fluctuates modestly across repeated runs due to timing noise at microsecond scale, but the qualitative result is stable across runs. The measured cost does not come from the network itself, a 5-64-64-1 MLP forward pass is a handful of small matrix multiplications, but from constructing its five-dimensional feature vector (Eq. (4)) for every candidate pair, which includes a common-neighbour set intersection per candidate, the same operation that makes Coverage and HarmonicReduce several times slower than Entropy in the same table. FlowClone pays this cost per candidate in addition to, not instead of, Entropy's own residual computation, since its feature vector includes the residual as one input. This is an implementation-dependent cost of per-candidate feature construction, not an inherent property of the distilled network, and a vectorized batch implementation of the feature computation may substantially close this gap. FlowClone is not currently a faster substitute for Entropy, and its practical justification rests on distillation fidelity and cross-user generalization (Section V-E), not on deployment latency.

VI. DISCUSSION

The roughly 51% comparison-budget reduction is consistent across three structurally different datasets. This suggests a concrete deployment guideline: systems collecting pairwise preferences for HodgeRank-based recommendation should adopt gradient-residual (Entropy) or common-neighbour (Coverage) acquisition by default. Density-dependent policies such as HarmonicReduce should be reserved for settings where the comparison graph is known in advance to be far from complete. The BALD baseline confirms this advantage is not merely because HodgeRank-based policies beat weak or naive baselines: a properly implemented Bayesian active learner is also outperformed. Coverage additionally requires no trained model, making it a natural default where implementation simplicity matters as much as query efficiency. FlowClone is attractive as a distilled approximation of Entropy that preserves near-identical ranking quality under leave-users-out evaluation, though Section V-H shows this distillation is not currently a deployment-latency win: at every pool size tested, FlowClone is 7–12× slower per decision than the Entropy policy it approximates, so its practical justification rests on model compactness and cross-user transfer rather than on speed. These properties map onto distinct deployment scenarios. Cold-start onboarding, where a new user's item preferences must be elicited under a strict comparison budget before a first recommendation can be produced, benefits directly from the roughly halved comparisons-to-threshold shown in Table II. Real-time or high-throughput settings, where many users are elicited concurrently, benefit from Coverage's simple hand-crafted rule; FlowClone remains attractive if a compact, transferable model of Entropy's behaviour is independently valuable, for instance for on-device deployment where Entropy's own residual computation is unavailable.

The Borda collapse documents the case of an active acquisition policy that is actively harmful, not merely less beneficial, when paired with an incompatible scoring model. This has a direct methodological implication: reporting an acquisition policy's gain over random selection is insufficient without specifying, and justifying, the compatibility of the downstream aggregation model. The HarmonicReduce density-dependence finding similarly shows that a heuristic's practical value can be predicted, not merely observed post hoc, from graph-theoretic properties that Hodge decomposition makes explicit. The concurrent RLHF-motivated active preference literature operates on scalar Bradley–Terry-style reward models. Our direct implementation of a representative Bayesian Bradley-Terry active learner (BALD), which HodgeRank-based acquisition outperforms, together with our scorer ablation, suggests that acquisition-scorer compatibility deserves explicit examination rather than being assumed.

The BALD comparison points to a plausible explanation for why geometry-informed acquisition holds an advantage over a well-specified Bayesian alternative. BALD's posterior-variance criterion treats belief uncertainty as a single scalar per item. It therefore cannot distinguish a comparison that would resolve a locally inconsistent triangle (curl) from one that would resolve a globally unresolvable disagreement (harmonic) from one that would simply sharpen an already largely settled ranking (gradient). All three reduce posterior variance and are treated interchangeably. Entropy and Coverage, by contrast, operate directly on the residual of the gradient fit. This residual is itself informative about where the current consensus ranking is least supported by observed comparisons. This is consistent with the pattern in Table II: BALD's advantage over Random is real but consistently smaller than Entropy's or Coverage's, across every dataset where BALD itself is unambiguously informative.

We highlight several limitations. This paper targets the item-set scale typical of recommender systems and group decision-making (10–100 items), not the thousands-of-candidates scale of some large language model reward-modeling pipelines. Within this scale, our mechanism and theoretically grounded predictions (density dependence, scorer compatibility) are not directly validated beyond the 100-item Sushi setting. Evaluation follows a leakage-free offline-

replay protocol on previously collected comparison datasets (Section III), consistent with prior active-ranking work [15]. The HarmonicReduce density-dependence claim rests on a two-point (dense-versus-sparse) contrast, not a continuous density sweep. This is an opportunity for dedicated follow-up. FlowClone's feature representation is intentionally compact, to test whether a handful of simple statistics suffice. A larger feature set might close its small residual gap to Entropy on Sushi-X, but would weaken the distillation claim, so we did not pursue it. Several hyperparameters, most notably γ_0 (the online update's warm-up constant), λ (HodgeRank's regularization strength), and the Bayesian Bradley-Terry model's prior and noise parameters, are fixed per dataset rather than swept systematically; a targeted stability check would confirm the reported comparison-budget reductions are not artifacts of these particular settings, and is left to future work rather than attempted here for every hyperparameter family.

Several extensions follow naturally. A continuous comparison-graph-density sweep rather than the two-point dense/sparse contrast used here would more precisely characterize where the HarmonicReduce transition occurs, and test whether it follows a sharp threshold or a gradual trend, guided directly by Proposition 1. Extending to batch, rather than single-comparison, acquisition would require selecting a diverse set of informative pairs per round instead of the single greedy pair each policy currently selects; this matters for item catalogues large enough that per-comparison model updates are impractical. A systematic study of acquisition-scorer compatibility across the broader family of pairwise aggregation models used in recommender systems and group decision-making would extend the four-scorer ablation in Section V-C to rank-centrality and matrix-factorization-based aggregators. A further direction, suggested by the BALD comparison, is a hybrid acquisition rule that combines HodgeRank's gradient residual with an explicit posterior-variance term. Such a rule could capture both the structural informativeness Entropy and Coverage exploit and the calibrated uncertainty estimate BALD provides.

VII. Conclusion

This paper asked whether the Hodge-theoretic structure used elsewhere for aggregation and quality assessment is also informative for deciding which pairwise comparisons to actively request. We use a leakage-free, five-fold leave-users-out evaluation protocol and seven acquisition policies, evaluated across three real-world datasets and four scoring models. Geometry-informed active acquisition (Entropy, Coverage, and its lightweight behavioural-cloning approximation FlowClone) reduces the comparison budget required to reach a fixed recommendation-quality threshold by approximately 51% relative to random sampling. It consistently outperforms a properly implemented Bayesian Bradley-Terry active learner (BALD) on all three datasets; BALD itself is a statistically confirmed improvement over random sampling on two of the three. A novel harmonic-energy-targeted policy, HarmonicReduce, exhibits a dataset-density dependence that we both observe empirically and prove exactly (Proposition 1) from the circuit rank of the comparison graph. FlowClone is validated under five-fold cross-validation, with a seen-versus-unseen generalization gap that is near zero and changes sign across datasets, indicating no detectable overfitting. Taken together, these findings indicate that combinatorial Hodge theory provides a coherent geometric language across the pairwise-preference pipeline, from deciding what to ask to aggregating what was said.

EfficientNetB0-Based DeepFake Image Detection: A Transfer-Learning Framework for Robust and Deployable Media Verification

Marwa Hamza*, Mohammad Abdallah
Computer Science Department-Faculty of Science and IT, Al-Zaytoonah University of Jordan, Amman, Jordan[1,2]

***Abstract*—As the realism of DeepFakes has increased significantly, there is an emerging necessity to develop efficient, reliable, and robust automatic detection frameworks that are feasible to apply in the wild. This study proposes an image-based DeepFake detection system using EfficientNetB0 and transfer learning. Facial images were acquired from the FaceForensics++ and Celeb-DF datasets and preprocessed as 224 by 224 RGB images. The data were augmented to reflect realistic conditions through rotation, zoom, horizontal flipping, illumination changes, and JPEG compression. EfficientNetB0 was used as a feature extractor, followed by global average pooling, a dense layer with 128 neurons, dropout, and a two-class softmax layer. The model achieved 92.8% validation accuracy, 92.5% precision, 93.1% recall, and a 92.8% F1-score. Robustness testing produced 89.5% accuracy on images compressed at JPEG quality 70, while cross-dataset evaluation from FaceForensics++ to Celeb-DF produced 84.2% accuracy. A real-time verification system was implemented by integrating the model with a Flask RESTful API and web and mobile clients. The findings show that transfer learning provides a practical balance among accuracy, robustness, computational efficiency, and deployability. However, the reduction in cross-dataset performance indicates limited generalizability to previously unseen manipulation techniques.**

I. Introduction

The evolution of artificial content creation has brought about a radical and increasingly visible transformation. Early face-swapping techniques were relatively simple manipulation tools; however, recent advances in deep generative models have enabled the production of highly realistic synthetic images with increasingly convincing visual details [1], [2]. This rapid development has raised serious concerns in multimedia forensics, particularly regarding the reliability of digital evidence and the misuse of manipulated media for misinformation, identity impersonation, and fraudulent activities [3]. Moreover, the growing realism of synthetic content may undermine public trust in digital media and online information [4].

DeepFake detection has consequently become a major challenge in multimedia forensics. One of the key difficulties is the ability of detection models to generalize to newly emerging generation techniques whose visual artifacts may differ from those observed during training [2], [5]. Furthermore, common image transformations and social-media processing, such as compression and resizing, may suppress or alter forensic traces used by detection algorithms [5]. Therefore, a reliable DeepFake detection framework should combine effective visual representation learning with computational efficiency and robustness against common image-quality degradations [1], [5].

Deep neural networks have been among the most successful methods for visual forgery detection, mainly because convolutional neural networks (CNNs) can extract subtle texture and boundary details that are difficult to encode manually. FaceForensics++ provides a large benchmark dataset containing multiple manipulation methods and compression levels [1]. Celeb-DF, by contrast, provides higher-quality DeepFakes that more closely resemble content encountered on social-media platforms [2].

ResNet [4] and Xception [3] are advanced and effective visual representation architectures. At the same time, practical systems must account for inference cost. EfficientNet addresses this need by scaling network depth, width, and input resolution jointly rather than independently [5].

This paper extends the DeepFake detector with an experimental and deployment-oriented evaluation. Its principal contributions are as follows:

- A transfer-learning application using EfficientNetB0 to detect DeepFakes in static facial images, together with a data-augmentation methodology that models distortions common to image-sharing channels.
- An evaluation of accuracy, precision, recall, F1-score, confusion-matrix performance, robustness to compression, and cross-dataset generalization.
- A RESTful DeepFake detection service that exposes the trained model through web and mobile clients and demonstrates an end-to-end workflow from preprocessing to live inference.

The initial detector achieved more than 92% validation accuracy on the evaluated face images and demonstrated a complete workflow from data preprocessing to live inference through the DeepFake Detector website.

II. Related Work

A. DeepFake Generation and Detection

Generative adversarial networks (GANs) consist of a generator and discriminator trained adversarially to produce increasingly realistic images [6]. Subsequent generative methods have

*Corresponding author.

improved identity transfer, reenactment, and facial synthesis, making genuine and fabricated content harder to distinguish. Early DeepFake detection methods often relied on visible artifacts or physical irregularities, but these cues became less dependable as generation quality improved.

Current detection systems largely depend on CNNs and related architectures for representation learning [7]–[10]. Rössler et al. introduced the FaceForensics++ dataset, which contains samples generated using DeepFakes, Face2Face, FaceSwap, and NeuralTextures at multiple compression levels [1]. Their work highlighted the importance of data-driven detection under compression.

Li et al. later released Celeb-DF, a database of higher-quality synthetic videos with fewer obvious artifacts and more challenging evaluation conditions [2]. The two datasets are complementary: FaceForensics++ supports detailed analysis across manipulation methods, while Celeb-DF challenges detectors to generalize to more visually convincing forgeries.

B. CNN Backbones and Efficient Architectures

CNN backbones such as ResNet and Xception are widely used in image classification and forensic detection [3], [4]. Xception reduces computational cost while preserving representational capacity through depthwise separable convolutions [3]. EfficientNet extends the efficiency objective by scaling depth, width, and resolution jointly through a compound coefficient. EfficientNetB0 is the smallest baseline in the family and offers a useful balance between accuracy and efficiency for API-based or mobile-connected deployment [5].

C. Transfer Learning and Robustness

Transfer learning is particularly valuable when a target dataset is smaller or more specialized than the large corpora used to pretrain modern CNNs. A pretrained model supplies generic visual filters at multiple levels, while task-specific modules are optimized for the real-versus-fake decision. Fine-tuning selected upper layers adapts the representation to the target problem while reducing the training difficulty and cost associated with learning a model from scratch.

Robustness is a major concern in DeepFake detection because resizing, JPEG compression, illumination differences, and image recapture can modify forensic cues. Data augmentation exposes the detector to such transformations during training and reduces sensitivity to a narrow set of acquisition conditions [1], [7], [8].

Recent image-classification studies also support the use of deep architectures, transfer learning, and augmentation in visually complex tasks. Vision Transformer benchmarking has shown that augmentation can strengthen image classification under varying visual conditions [14]. End-to-end segmentation and classification architectures have demonstrated effective feature learning in challenging medical images [15], while automated disease detection has shown the practical value of deep-learning pipelines for robust image-based recognition [16].

The rapid growth of AI-generated content has extended the digital-authenticity problem beyond manipulated faces. Deep-learning models using acoustic features such as mel-frequency cepstral coefficients have been applied to synthetic-audio detection [11], transformer-based approaches have been used for Arabic fake-news detection [12], and multimodal hybrid models have been investigated for automated fake-news verification [13]. These studies show that content verification is increasingly a multimodal challenge spanning visual, audio, and textual information.

D. Gap and Study Positioning

A persistent challenge in DeepFake research is the discrepancy between strong performance within the training dataset and degraded accuracy on previously unseen manipulation methods. In addition, many studies emphasize model metrics while giving limited attention to deployability. This study evaluates the detector through baseline classification, JPEG compression, and cross-dataset transfer while also implementing an end-to-end application. The combined setting examines both controlled performance and practical operation.

III. Materials and Methods

A. Experimental Dataset

The experiment uses the FaceForensics++ and Celeb-DF datasets. FaceForensics++ is a facial-manipulation benchmark containing multiple manipulation methods and compression settings [1]. Celeb-DF provides higher-quality, visually convincing DeepFakes created from celebrity footage [2]. Frames extracted from these sources form a two-class image-classification problem with Real and Fake labels.

FaceForensics++ provides the primary development data, while Celeb-DF is used as an external cross-dataset benchmark to assess generalization to higher-quality manipulations. To minimize correlation among samples, experimental partitioning should be performed at the source-video level before frame extraction, preventing frames from the same source video from appearing in both training and evaluation partitions. The final experimental record should report source-video counts, extracted-frame counts, class distributions, manipulation categories, and partition sizes.

B. Image Preprocessing and Augmentation

Each input image is converted to RGB, resized to 224×224 pixels, converted to a floating-point array, normalized, and expanded to batch format before model inference. During training, augmentation is applied to improve generalization and simulate transformations common to image-sharing environments. The augmentation operations and parameters are summarized in Table I.

C. EfficientNetB0 Classification Model

The detector is implemented using the Keras Functional API. EfficientNetB0 is used as the pretrained feature extractor, followed by a classification head comprising global average pooling, a fully connected layer with 128 units and ReLU activation, dropout with a rate of 0.40, and a final dense layer with two softmax outputs. The custom head contains 164,226 trainable parameters.

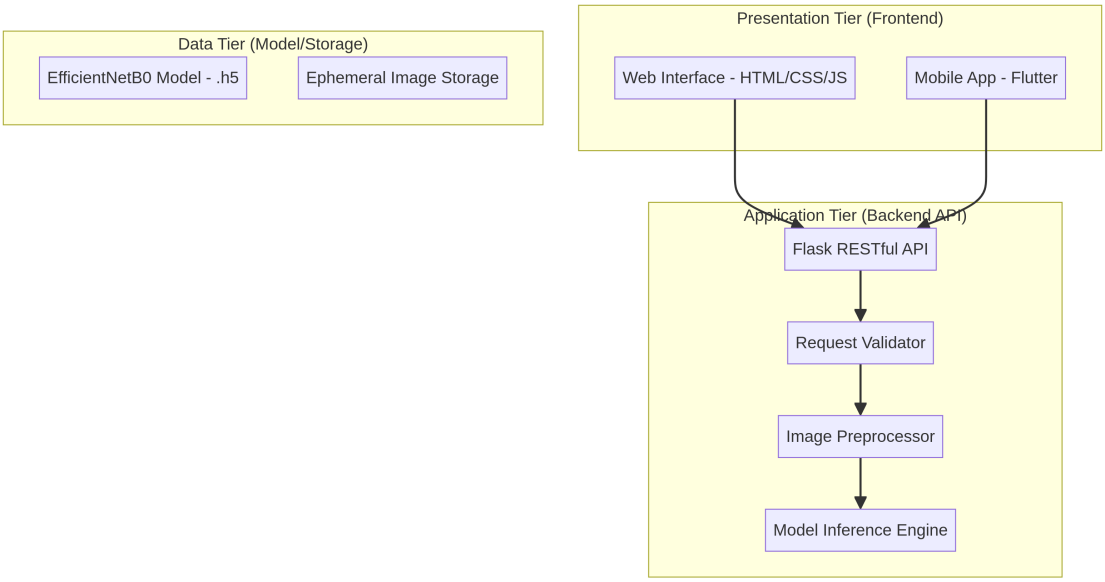

Fig. 1. Three-tier architecture of the implemented DeepFake detection system.

TABLE I. DATA AUGMENTATION STRATEGY USED IN THE EXPERIMENT

Augmentation	Purpose	Parameter
Random rotation	Simulate camera-angle variation	$\pm 10^{\circ}$
Random zoom	Model subject-distance variation	0.8–1.2
Horizontal flip	Account for mirrored images	50% probability
Brightness adjustment	Model illumination changes	$\pm 20\%$
JPEG compression	Model transmission and social-media loss	Quality 70–100

For input x and model parameters θ, the softmax layer estimates posterior scores for the Real and Fake classes. The predicted class is selected according to:

$$\hat{y} = \underset{c \in \{\text{Real},\text{Fake}\}}{\arg\max} \; p(y = c \mid x; \theta). \tag{1}$$

D. Training Strategy

Training proceeds in two stages. First, the EfficientNetB0 backbone is frozen and only the custom classification head is trained. This allows the classifier to learn a task-specific decision boundary without changing the pretrained visual representation. Second, selected upper layers are unfrozen and optimized using a lower learning rate. This two-stage procedure suppresses training fluctuations and adapts the model while limiting disruption to pretrained features.

E. End-to-End System Architecture

The experimental setup uses the three-tier application architecture shown in Fig. 1. The presentation tier contains a responsive web interface and a Flutter mobile application. The application tier uses a Flask RESTful API to validate requests, coordinate preprocessing, perform model inference, and format results. The data/model tier hosts the trained EfficientNetB0 model and temporary image storage. This separation allows the model to be maintained independently from the user-facing applications and supports practical deployment.

F. Evaluation Protocol and Metrics

The detector is evaluated using accuracy, precision, recall, and F1-score. In the binary setting, Fake is treated as the positive class. Accuracy measures the proportion of correct decisions, precision measures the fraction of predicted fakes that are manipulated, recall measures the fraction of manipulated images detected, and the F1-score is the harmonic mean of precision and recall. The latter three metrics are defined as:

$$\text{Precision} = \frac{TP}{TP + FP}, \tag{2}$$

$$\text{Recall} = \frac{TP}{TP + FN}, \tag{3}$$

$$F_1 = 2\left(\frac{\text{Precision} \times \text{Recall}}{\text{Precision} + \text{Recall}}\right) \tag{4}$$

Two additional experiments examine robustness. First, JPEG compression is applied at multiple quality levels, including a quality factor of 70. Compression removes image detail as quality decreases and can suppress forensic traces. Second, cross-dataset generalization is evaluated by training on FaceForensics++ and testing on Celeb-DF. These experiments expose common sources of performance degradation in practical DeepFake detection systems.

G. Software Deployment and Functional Testing

The inference service is developed in Python using TensorFlow, Keras, and Flask. The API accepts JPEG and PNG images, preprocesses each upload according to the model's requirements, performs inference, and returns the predicted label with a confidence score.

The functional test suite includes real-image uploads, GAN-generated images, low-resolution images, and concurrent requests. Ten uploads were handled simultaneously within five seconds, demonstrating the operational performance of the software implementation.

IV. Experimental Results

A. Overall Classification Performance

The final EfficientNetB0 model achieved 92.8% validation accuracy, 92.5% precision, 93.1% recall, and a 92.8% F1-score, as summarized in Table II. These values are calculated from the 2,000-sample confusion matrix in Table III, ensuring consistency between aggregate metrics and class-level outcomes.

TABLE II. Main Validation Performance of the EfficientNetB0 Detector

Metric	Result
Validation accuracy	92.8%
Precision	92.5%
Recall	93.1%
F1-score	92.8%

B. Confusion-Matrix Analysis

Table III presents the validation confusion matrix, with 925 authentic samples correctly classified as Real, 75 authentic samples classified as Fake, 931 manipulated samples correctly classified as Fake, and 69 manipulated samples classified as Real. Based on these 2,000 samples, accuracy is 92.8%, precision is 92.5%, recall is 93.1%, and F1-score is 92.8%.

TABLE III. Confusion Matrix for the Validation Experiment

	Predicted Real	Predicted Fake
Actual Real	925	75
Actual Fake	69	931

C. Robustness to JPEG Compression

Compression is highly relevant to practical DeepFake detection because social-media and messaging platforms frequently recompress uploaded images. As shown in Table IV, accuracy decreased from 92.8% under the baseline condition to 89.5% at JPEG quality factor 70, an absolute reduction of 3.3 percentage points. The detector therefore retains substantial classification performance under moderate JPEG compression, although compression can alter forensic cues used by the classifier.

D. Cross-Dataset Generalization

A more challenging evaluation trained the detector on FaceForensics++ and tested it on Celeb-DF. Cross-dataset accuracy reached 84.2%, which is 8.6 percentage points below the 92.8% within-validation result. The decrease demonstrates the effect of dataset shift and highlights the difficulty of transferring a detector to visually different manipulation pipelines.

TABLE IV. Robustness Under JPEG Compression

Condition	Accuracy	Absolute Change
Uncompressed/baseline	92.8%	–
JPEG quality = 70	89.5%	−3.3 pp

TABLE V. Functional and Performance Test Cases

Test	Expected Behavior	Reported Outcome
Real image upload	Classify as Real	Pass
GAN-generated image	Classify as Fake	Pass
Low-resolution image	Return Real/Fake with reduced certainty	Pass; lower confidence
10 concurrent uploads	Process all requests in less than 5 s	Pass

Celeb-DF was designed to contain higher-quality, more realistic DeepFakes with fewer obvious artifacts [2], making it an appropriate benchmark for assessing generalization beyond the development dataset.

E. Application-Level Testing

The model was evaluated at the application level using the functional scenarios summarized in Table V. Tests covered genuine-image uploads, GAN-generated images, low-resolution inputs, and concurrent requests. Low-resolution images were processed with reduced confidence, while ten concurrent uploads were completed within the five-second target. These tests demonstrate the integration of the trained detector within a complete software pipeline; they do not replace statistical model assessment.

V. Discussion

A. Effectiveness of Transfer Learning

The findings support EfficientNetB0 as a feasible lightweight backbone for binary DeepFake image recognition. The validation accuracy of 92.8% is consistent with the use of pretrained CNN models as feature extractors that can be fine-tuned for image-forgery detection. From a deployment perspective, EfficientNetB0 is attractive because its compound-scaling design controls both accuracy and computational cost [5]. The custom head is also small, comprising global average pooling, a 128-unit dense layer, dropout, and the classifier, which limits the number of task-specific trainable parameters.

B. Role of Data Augmentation

The JPEG-compression experiment is consistent with the intended role of augmentation in exposing the model to common image transformations during training. At quality factor 70, accuracy decreased by 3.3 percentage points relative to the baseline. A dedicated ablation experiment is needed to isolate the contribution of JPEG augmentation from rotation, zoom, horizontal flipping, brightness variation, dropout, and fine-tuning.

C. Generalization Remains the Main Challenge

The cross-dataset accuracy of 84.2% is lower than the within-validation result, but it is an important finding rather than merely a limitation. DeepFake detection models can learn dataset-specific acquisition patterns, compression signatures, or generator artifacts. When the synthesis pipeline changes, these signals may disappear. Celeb-DF was designed to contain more naturalistic DeepFakes with fewer visible artifacts [2], which helps explain the observed decrease. Future studies should report and compare both within-dataset and cross-dataset results across newer generation families.

D. Comparison with Related Approaches

This study selected EfficientNetB0 because heavier backbones can achieve strong benchmark results at a higher computational cost. Xception remains a widely used architecture for DeepFake detection and uses depthwise separable convolutions [3], while ResNet introduced residual connections that support very deep visual models [4].

The proposed framework investigates whether EfficientNetB0 can provide competitive DeepFake classification performance while remaining suitable for API-based and mobile/web deployment. A controlled benchmark using identical training and test partitions for EfficientNetB0, Xception, and ResNet would provide a stronger basis for quantifying the accuracy-efficiency trade-off.

E. Experimental Validation Requirements

Further evaluation should include ablation studies of EfficientNetB0, transfer learning, fine-tuning, dropout, and individual augmentation operations; robustness tests for rotation, zoom, brightness variation, and JPEG compression; repeated runs summarized using means, standard deviations, and confidence intervals; and deployment measurements including total parameters, floating-point operations, model size, memory use, preprocessing overhead, inference latency, throughput, and hardware configuration. Controlled comparison with alternative backbones on identical data partitions would further support the accuracy-efficiency analysis.

F. Deployment Considerations

Deployment introduces constraints that are often omitted from benchmark-only studies. The detection service must validate files, transform inputs consistently, keep the model loaded to avoid repeated initialization costs, return confidence information, and maintain adequate performance under concurrent requests.

The Flask web service provides these functions through the analysis pipeline. Uploaded images are converted to RGB, resized to 224×224, normalized, and passed to the loaded model. The service then returns a Real/Fake prediction with a confidence score. Fig. 2 shows the modular relationship among the user interface, Flask API, data pipeline, and EfficientNetB0 inference module.

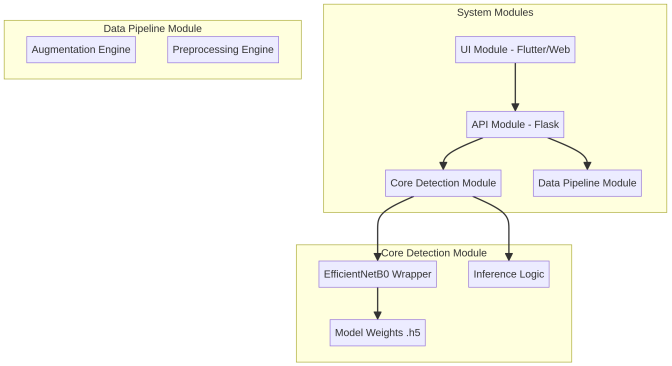

Fig. 2. Modular implementation linking the user interface, Flask API, data pipeline, and EfficientNetB0 inference module.

VI. Conclusion

This paper presents a deployable DeepFake image detector based on EfficientNetB0 and transfer learning. The experimental setup used the FaceForensics++ and Celeb-DF datasets with a common image resolution of 224×224 RGB pixels. Model development included augmentation that mimics real-world degradation, a lightweight classifier head, two-stage training, and multiple forms of evaluation. The detector achieved 92.8% validation accuracy, 92.5% precision, 93.1% recall, and a 92.8% F1-score based on the confusion matrix in Table III. Under dataset shift from FaceForensics++ to Celeb-DF, cross-dataset accuracy decreased to 84.2%. Robustness testing produced 89.5% accuracy at JPEG quality factor 70. Thus, the detector remained effective under moderate compression, while dataset shift caused a larger reduction in performance.

The work also demonstrates deployability through a Flask RESTful service connected to a web client and a Flutter mobile client. This architecture supports real-time verification scenarios in which the system must be fast, reliable, accessible, and modular. Generalizability remains the main research challenge. Future work should therefore evaluate newer generation techniques, apply strictly documented source-level splits, report additional measures such as area under the receiver operating characteristic curve and calibration, and extend detection to video and multimodal content.

***Abstract*—Autonomous navigation requires path-planning algorithms that can find safe and efficient routes while avoiding obstacles. Classical sampling-based planners such as Rapidly-exploring Random Tree (RRT) and RRT* are widely used because they are flexible and easy to apply in different environments. However, these methods often produce longer paths and require many samples in complex spaces. This paper proposes Neural Deep-Q Network RRT (N-DQN-RRT), a hybrid path-planning algorithm that integrates a Deep Q-Network (DQN) agent into an RRT*-style planning framework. The proposed method uses a directed-random sampling strategy. In this strategy, 75% of samples are guided by the trained DQN policy, 5% are assigned to goal bias, and 20% are sampled uniformly at random. The random component is retained to reduce premature policy bias and maintain exploration. The planner also uses an adaptive rewiring radius that changes according to local obstacle conditions. This allows the method to improve local path quality while avoiding unnecessary neighbor searches in cluttered regions. The algorithm was evaluated in three static two-dimensional environments with increasing map sizes of 10×10, 25×25, and 50×50. Each environment used randomized obstacle layouts and 100 independent trials, giving 300 trials per algorithm. The proposed method was compared with RRT and RRT* using six metrics: path length, steering angle, iteration count, sampling size, computation time, and success rate. Results were reported as mean $\pm$ standard deviation with 95% confidence intervals. N-DQN-RRT achieved a 100% success rate across all 300 trials, while RRT achieved 10–100% and RRT* achieved 14–100%, depending on map complexity. In the largest environment, N-DQN-RRT reduced path length by 11.9%, steering angle by 49.5%, sampling size by 75.1%, and computation time by 91.9% compared with RRT*. These results show that DQN-guided sampling can improve the empirical efficiency of RRT*-style planning in static two-dimensional obstacle environments.**

***Keywords*—Path planning; Rapidly-Exploring Random Trees (RRT); RRT*; Deep Q-Network (DQN); deep reinforcement learning; resilient infrastructure**

I. Introduction

Deep learning has been successfully applied across a wide range of intelligent perception and decision-making tasks, demonstrating its capability to learn complex representations from data [1]. Autonomous navigation is an important part of modern mobile robotics. A mobile robot must move from a start position to a target position while avoiding obstacles. This task is known as path planning. It is still a difficult problem because the planner must find a safe path under limited time and computational resources [2], [3].

The planning environment strongly affects the choice of method. In a static environment, obstacles remain fixed during planning. The robot can plan using a known map of the configuration space. In a dynamic environment, obstacles may move or appear during operation. This makes planning more difficult because the robot may need to update or replan its route during execution [3], [2]. For this reason, efficient and reliable path planning remains a key requirement for autonomous robots.

Classical graph-search methods such as A*, Dijkstra, and breadth-first search use a discretized representation of the environment. These methods are effective when the search space is small and the map resolution is manageable. However, their memory use and search cost increase as the map becomes larger or more detailed. This makes them less practical for large planning spaces and high-resolution maps [4], [2].

Sampling-based planners address this limitation in a different way. They do not need to search the full configuration space explicitly. Instead, they build a roadmap or tree by sampling points from the free space and connecting them through local collision checks [5], [2]. Rapidly-exploring Random Tree, or RRT, is one of the most common sampling-based planners. It grows a tree from the start position by repeatedly sampling the environment and extending the tree toward the sampled point. RRT is useful because it can find feasible paths in complex spaces.

*Corresponding author.

However, its paths are often irregular and longer than necessary. Its performance also depends strongly on random sampling [4], [2].

Several RRT variants have been proposed to improve path quality and convergence. RRT* adds parent selection and rewiring to improve path cost over time. Bi-directional RRT* grows two trees from the start and goal regions. Informed RRT* limits sampling after an initial solution is found so that search is focused on a more useful region of the space [6], [7]. These methods improve classical RRT in many cases. Still, they rely heavily on hand-designed sampling rules. They do not learn from previous planning experience.

Learning-based planning has been studied as a way to guide sampling toward more promising regions. Neural and generative models can learn useful structure from maps or previous paths. These learned priors can reduce unnecessary exploration and improve planning efficiency [8], [9]. Deep reinforcement learning also offers a useful framework for navigation. An agent can learn a policy through rewards and penalties. This allows the planner to prefer actions that move toward the goal and avoid obstacles [10], [11], [12].

Deep Q-Network, or DQN, is a value-based reinforcement learning method. It is suitable when the action space can be represented by a finite set of actions. In path planning, this makes DQN useful for selecting movement directions or guiding sample generation. However, a learned policy alone may be biased by its training distribution. It may also fail when the test environment differs from the training maps. For this reason, a hybrid planner can be useful. It can combine learned guidance with a random sampling component.

This paper proposes N-DQN-RRT, a hybrid path-planning algorithm for static two-dimensional environments. The method integrates a trained DQN agent into an RRT*-style planning framework. The DQN guides most sampling decisions toward promising directions. A random sampling component is retained to preserve exploration behavior and reduce policy bias. The planner also uses an adaptive rewiring radius. The radius is reduced near cluttered regions and expanded in more open regions. This allows the planner to improve path quality while reducing unnecessary neighbor searches.

The main contribution of this work is an empirical evaluation of the proposed N-DQN-RRT planner. The algorithm is tested in randomized two-dimensional obstacle environments with increasing size and complexity. Its performance is compared with classical RRT and RRT*. The evaluation uses path length, steering angle, iteration count, sampling size, computation time, and success rate. The goal is not to prove formal optimality or probabilistic completeness. Instead, the goal is to show whether DQN-guided sampling and adaptive rewiring can improve practical planning performance under the tested simulation conditions.

The contributions of this paper are summarized as follows:

- A hybrid DQN-guided RRT* planner is proposed for static two-dimensional path planning.
- The planner uses a seven-feature state representation that includes goal direction, obstacle proximity, and local free-space information.
- An 80/20 guided-random sampling strategy is used to balance learned guidance and stochastic exploration.
- An adaptive rewiring radius is introduced to adjust local optimization according to obstacle conditions.
- The method is evaluated across three randomized map sizes and compared with RRT and RRT* using six performance metrics.

II. Related Work

Path planning has been studied through classical search methods, sampling-based planners, learning-guided planners, and reinforcement learning approaches. This section reviews these groups and shows the gap addressed by the proposed N-DQN-RRT method (Table I).

A. Classical Sampling-Based Path Planning

Sampling-based planners are widely used in mobile robot path planning. They are useful when the configuration space is large or difficult to describe fully. Instead of building a complete grid of the space, these methods sample points from the free region and connect them through local collision checks [13], [2].

Rapidly-exploring Random Tree, or RRT, is one of the most common sampling-based planners. It grows a tree from the start point toward randomly sampled points. This makes RRT suitable for single-query planning problems. It can often find a feasible route in complex spaces. However, the path is usually not smooth or short. The result also depends strongly on the random samples [14], [4].

RRT* improves RRT by adding parent selection and rewiring. These steps reduce the path cost as the tree grows. Still, RRT* may require many samples before it converges to a high-quality path. Other variants improve the search process in different ways. Bi-directional RRT* grows two trees from the start and goal regions. Informed RRT* limits the sampling region after a first solution is found. Hybrid RRT* methods also combine global sampling with local improvement rules [6], [7]. These methods improve classical RRT, but they still depend on fixed sampling rules. They do not learn from earlier planning experience.

B. Learning-Guided Sampling-Based Planning

Learning-based planning tries to reduce unnecessary exploration. The main idea is simple. A model learns where useful samples are likely to appear. The planner can then spend more effort in promising regions.

Generative models have been used for this purpose. For example, GAN-based planners can use an environment image to predict a region where a feasible path is likely to exist. This region is then used as a sampling guide for a classical planner [8]. Such methods can improve convergence in tested environments. However, their performance depends on the learned map representation and the similarity between training and test environments.

Neural sampling methods have also been used with RRT-style planners. Neural RRT* uses a convolutional neural

TABLE I. SUMMARY OF RELATED WORK ON SAMPLING-BASED, LEARNING-BASED, AND DRL-BASED PATH PLANNING

Research group	Representative methods	Main idea	Key limitations	Related references
Classical sampling-based planning	RRT, RRT*, PRM	Builds a tree or roadmap through random samples in the free space. These methods are useful when the full configuration space is difficult to search directly.	Path quality can be poor. Convergence may be slow. Performance depends strongly on random samples.	[14], [4], [2]
Improved RRT variants	Bi-RRT*, Informed RRT*, hybrid RRT*	Improves classical RRT by using rewiring, bidirectional search, or restricted sampling after an initial path is found. These methods can improve path cost and search efficiency.	Still depends on hand-designed sampling rules. It does not learn from previous planning experience. Performance may degrade in cluttered or narrow regions.	[6], [7]
Learning-guided sampling	GAN-RRT, Neural RRT*, DNN-guided sampling	Uses neural or generative models to guide samples toward promising regions of the map. This can reduce unnecessary exploration and improve planning efficiency.	Requires training data. The learned sampler may be sensitive to changes between training and test environments. Generalization remains a concern.	[8], [9], [15]
Deep reinforcement learning planning	DQN, PPO, SAC, TD3	Learns navigation behavior from interaction with the environment. The reward function encourages goal progress and penalizes unsafe actions.	Training can be expensive. Results depend on reward design and hyperparameters. Some methods have difficulty transferring from simulation to real robots.	[10], [16], [17], [18], [19], [20]
Hybrid RL and RRT planning	RL-RRT, DRL-RRT, RRT*-RL	Combines learned guidance with the tree structure of RRT or RRT*. The planner keeps classical expansion behavior while using learning to reduce inefficient exploration.	May lose formal planning guarantees if learning dominates sampling. A learned policy can be biased by the training distribution. Ablation is needed to show which component gives the improvement.	[11], [12], [21]
Proposed direction	N-DQN-RRT	Uses a DQN-guided sampler inside an RRT*-style framework. It keeps random sampling for exploration and adds an adaptive rewiring radius for local path improvement.	Current evaluation is limited to static two-dimensional environments. Dynamic scenes, cross-map transfer, and hardware validation remain future work.	This study

network to guide non-uniform sampling for optimal path planning [9]. Deep neural network enhanced sampling has also been studied in three-dimensional planning spaces [15]. These studies show that learned priors can improve sample efficiency. At the same time, they also show a common limitation. A learned sampler may lose reliability when the test environment differs from the training data.

C. Deep Reinforcement Learning for Robot Navigation

Deep reinforcement learning has become a common tool for robot navigation. In this setting, an agent learns from interaction with the environment. The reward function encourages goal progress and penalizes unsafe behavior. This makes DRL useful for navigation tasks where direct planning is difficult [10], [16].

Value-based methods such as Deep Q-Network are useful when the action space is discrete. A DQN can learn the value of each possible action from the current state. This is suitable for planners that choose among a fixed set of movement directions. Improved DQN variants have been studied for mobile robot path planning, often by changing the reward function or network structure [17], [22]. However, DQN methods can be sensitive to reward design. They may also suffer when the learned policy is applied outside the training distribution.

Policy-gradient and actor-critic methods are also common in navigation. Methods such as PPO, SAC, and TD3 have been applied to dynamic path planning and obstacle avoidance [18], [19], [20]. These methods can handle more complex action spaces. They can also learn flexible behavior in dynamic scenes. Their main drawbacks are training cost, hyperparameter sensitivity, and the gap between simulation and real deployment.

D. Hybrid Planning with Reinforcement Learning and RRT

A different line of work combines learning with classical sampling-based planners. This is useful because the planner keeps the tree structure of RRT while the learning model guides part of the search. RL-RRT is one example. It uses a learned policy and a reachability estimator to guide tree growth in kinodynamic planning [11]. Other DRL-integrated RRT methods use learned policies to improve sample selection or path expansion [12]. Recent work has also explored reinforcement learning inside RRT*-style frameworks for mobile robot planning [21].

These hybrid methods are important because they do not fully replace classical planning. Instead, they add learning where random exploration is inefficient. This helps preserve the structure of sampling-based planning while adding experience-based guidance. However, many existing studies use different environments, different learning models, and different evaluation settings. This makes direct comparison difficult.

E. Research Gap

The reviewed studies show that classical RRT methods are flexible but sample inefficient. They also show that learned sampling can improve planning speed and path quality. However, there is still a need for a simple value-based hybrid planner that keeps the RRT* structure and uses DQN guidance in a controlled way.

TABLE II. PLANNER PARAMETERS FOR THE THREE MAP SETTINGS

Parameter	Map 1	Map 2	Map 3
Environment size	10×10	25×25	50×50
Step size η	1.0	1.0	1.0
Maximum iterations	250	500	1500
Goal radius	1.0	1.0	1.0
Start position	$(1, 1)$	$(1, 1)$	$(1, 1)$
Goal position	$(9, 9)$	$(24, 24)$	$(49, 49)$
Base rewire radius	2.0	2.0	2.0

This paper addresses that gap through N-DQN-RRT. The method uses a DQN-guided sampler inside an RRT*-style framework. It also keeps a random sampling component to reduce policy bias. An adaptive rewiring radius is added to improve local path quality. The method is evaluated in static two-dimensional random obstacle environments with increasing map size. The goal is to test whether learned guidance can improve practical planning performance when compared with classical RRT and RRT*.

III. METHODOLOGY

This section describes the experimental setup and the proposed N-DQN-RRT algorithm. The study uses a simulation-based design. The proposed method is compared with classical RRT and RRT*. All planners are evaluated under the same map settings. They also use the same start and goal positions.

A. Experimental Framework

The experiments use a quantitative simulation framework. Three algorithms are evaluated. These are RRT, RRT*, and the proposed N-DQN-RRT. The goal is to compare their planning performance in static two-dimensional environments.

All algorithms are implemented in Python. NumPy is used for numerical operations. Matplotlib is used for visualization. PyTorch is used to build and train the DQN model. SciPy is used for statistical analysis. The experiments are run on a Google Colab CPU environment.

Each map configuration is tested using 100 independent trials. No fixed seed is used during the main trials. This keeps the natural stochastic behavior of each planner. The repeated trials are then used to report the mean, standard deviation, and confidence interval of each metric.

B. Map Configuration

Three square environments are used. The map sizes are 10×10, 25×25, and 50×50. The start point is placed near the lower-left corner. The goal point is placed near the upper-right corner. Each trial uses a randomly generated obstacle layout.

The obstacles include circles, rectangles, squares, and triangles. The number of obstacles increases with map size. This makes the larger maps more difficult. All obstacles remain fixed during one planning run. Therefore, the experiments are limited to static environments (Table II).

C. Collision Checking

Collision checking is applied to both nodes and edges. A sampled node is rejected if it lies inside an obstacle or too close to an obstacle boundary. An edge is also rejected if any interpolated point along the edge intersects an obstacle. This prevents the planner from accepting paths that pass through occupied space.

For each edge, points are sampled at a fixed interpolation interval. If any point violates the collision rule, the full edge is discarded. A small collision buffer is used to keep the path away from obstacle boundaries.

D. Baseline Planners

RRT grows a tree from the start point. At each iteration, it samples a point from the map. The nearest tree node is found. The tree is then extended from the nearest node toward the sampled point.

Let q_{near} be the nearest node and q_{sample} be the sampled point. The new node is computed as:

$$q_{\text{new}} = q_{\text{near}} + \min\left(\eta, \left\|q_{\text{sample}} - q_{\text{near}}\right\|_2\right) \frac{q_{\text{sample}} - q_{\text{near}}}{\left\|q_{\text{sample}} - q_{\text{near}}\right\|_2}. \quad (1)$$

Here, η is the step size.

The Euclidean distance between two points $q_i = (x_i, y_i)$ and $q_j = (x_j, y_j)$ is:

$$d(q_i, q_j) = \sqrt{(x_i - x_j)^2 + (y_i - y_j)^2}. \quad (2)$$

RRT* extends RRT by adding parent selection and rewiring. For each new node, the algorithm searches nearby nodes. It selects the parent that gives the lowest collision-free cost. It then checks whether nearby nodes can be rewired through the new node to reduce path cost. This improves path quality over time.

E. Proposed N-DQN-RRT Algorithm

The proposed N-DQN-RRT algorithm combines DQN-guided sampling with an RRT*-style tree structure. The method has two phases. The first phase trains a DQN agent. The second phase uses the trained agent to guide sampling during planning.

The planner does not rely only on the DQN. It also keeps random sampling. This reduces the risk of policy bias. It also helps the tree recover when the learned policy gives a poor direction.

1) State representation: The DQN agent receives a seven-dimensional state vector. The state describes the current node, the goal, the nearest obstacle, and the local free space. It is defined as

$$s_t = \left[d_x,\, d_y,\, d_{\text{goal}},\, d_{\text{obs}},\, \delta x_{\text{obs}},\, \delta y_{\text{obs}},\, f_{\text{free}}\right]^T. \quad (3)$$

The terms d_x and d_y are the normalized horizontal and vertical offsets from the current node to the goal. The term d_{goal} is the normalized distance to the goal. The term d_{obs}

is the normalized distance to the nearest obstacle. The terms δx_{obs} and δy_{obs} describe the relative direction of the nearest obstacle. The term f_{free} is the fraction of nearby probe directions that are collision-free.

2) Action space: The action space contains eight discrete directions. The directions are spaced by 45°. Each action selects a direction for guided sampling. The sample distance is drawn from a small random range. This keeps the guided sampler from producing the same path repeatedly.

3) Q-network architecture: The DQN uses a feed-forward neural network. The input layer has seven units. There are two hidden layers with 128 units each. ReLU activation is used in the hidden layers. The output layer has eight units. Each output gives the estimated Q-value of one action. A target network is used during training. The target network has the same architecture as the main Q-network. Its weights are copied from the main network at fixed intervals. This makes the target values more stable during learning.

4) Reward function: The reward function encourages three behaviors. The agent should move toward the goal. It should avoid obstacles. It should avoid unnecessary long movement.

The reward at step t is defined as:

$$r_t = \begin{cases} -10, & \text{if a collision occurs,} \\ +100, & \text{if } d(q_{t+1}, q_{\text{goal}}) \le r_{\text{goal}}, \\ 3\Delta d_{\text{goal}} + 5\Delta c_{\text{obs}} - 0.05, & \text{otherwise.} \end{cases} \tag{4}$$

Here, r_{goal} is the reward threshold near the goal. It is different from the planning goal radius used to stop the algorithm. The term Δd_{goal} is the reduction in distance to the goal:

$$\Delta d_{\text{goal}} = d(q_t, q_{\text{goal}}) - d(q_{t+1}, q_{\text{goal}}). \tag{5}$$

The term Δc_{obs} is the change in obstacle clearance:

$$\Delta c_{\text{obs}} = c(q_{t+1}) - c(q_t). \tag{6}$$

A positive value means that the new position is farther from the nearest obstacle. A negative value means that it is closer to an obstacle.

5) DQN training: The agent is trained with experience replay. Each transition is stored as:

$$(s_t, a_t, r_t, s_{t+1}, done_t). \tag{7}$$

Mini-batches are sampled from the replay buffer during training. The Q-network is trained by minimizing the mean squared Bellman error:

$$L(\theta) = \mathbb{E}\left[\left(y_t - Q(s_t, a_t; \theta)\right)^2\right]. \tag{8}$$

The target value is

$$y_t = r_t + \gamma(1 - done_t) \max_{a'} Q(s_{t+1}, a'; \theta^-). \tag{9}$$

Here, θ denotes the main network weights. The term θ^- denotes the target network weights. The discount factor is γ. The term $done_t$ is 1 when the episode ends and 0 otherwise.

The agent uses an epsilon-greedy policy during training. At the beginning, the agent explores more. As training continues, exploration is reduced. The epsilon value is updated as:

$$\epsilon_{k+1} = \max(\epsilon_{\min}, \beta\epsilon_k). \tag{10}$$

Here, $\epsilon_{\min}$ is the minimum exploration rate. The term β is the decay factor.

6) Adaptive rewiring radius: N-DQN-RRT uses an adaptive rewiring radius. The radius changes according to local obstacle information. It becomes smaller near cluttered regions. It becomes larger in open regions.

The adaptive radius is computed as:

$$r_{\text{adaptive}} = \text{clip}\left(r_{\text{base}}\left(0.5 + 0.8d_{\text{obs}} + 0.7f_{\text{free}}\right), 0.6r_{\text{base}}, 2.0r_{\text{base}}\right). \tag{11}$$

Here, r_{base} is the base rewiring radius. The term d_{obs} is the normalized obstacle distance. The term f_{free} is the local free-space fraction. The function $\text{clip}(\cdot)$ keeps the radius within the lower and upper bounds.

7) Planning phase: During planning, the tree starts at the start node. At each iteration, a candidate sample is generated in one of three ways. A small portion of samples is placed at the goal. Another portion is sampled uniformly at random. The remaining samples are generated through the trained DQN policy.

The sampling design follows an 80/20 directed-random strategy. In this design, 75% of samples are generated by the DQN policy and 5% are placed at the goal as goal bias. The remaining 20% are sampled uniformly at random. Thus, 80% of the samples are directed and 20% preserve global exploration.

The sampling rule is:

$$q_{\text{sample}} = \begin{cases} q_{\text{goal}}, & \text{with probability } 0.05, \\ q_{\text{rand}}, & \text{with probability } 0.20, \\ q_{\text{DQN}}, & \text{with probability } 0.75. \end{cases} \tag{12}$$

After a sample is generated, the nearest node is found. A new node is created using Eq. (1). The node is added only if the point and edge are collision-free. The best parent is selected from nearby nodes. Then nearby nodes are rewired if the new connection lowers their path cost.

The planning process stops when the tree reaches the goal region. The final path is extracted by tracing parent links from the goal node back to the root.

F. Hyperparameter Settings

The training and planning hyperparameters of N-DQN-RRT are presented in Table III.

TABLE III. N-DQN-RRT HYPERPARAMETERS

Hyperparameter	Value
Training episodes	400
Maximum steps per episode	300
Batch size	64
Learning rate	0.001
Optimizer	Adam
Discount factor γ	0.95
Initial epsilon ϵ_0	1.0
Epsilon decay β	0.997
Minimum epsilon during training	0.05
Planning epsilon	0.02
Replay buffer capacity	8000
Hidden layer size	128×128
Network structure	$7 \rightarrow 128 \rightarrow 128 \rightarrow 8$
Target update frequency	50 gradient steps
Collision buffer	0.05 units
Edge interpolation step	0.02 units
Base rewiring radius	2.0 units

G. Algorithm Summary

Algorithm 1 presents the pseudocode of the proposed N-DQN-RRT algorithm. Fig. 1 shows the corresponding flowchart. The algorithm starts from the root node. It then expands the tree until the goal region is reached or the maximum number of iterations is exceeded.

Algorithm 1 N-DQN-RRT

Require: Start node q_{start}, goal node q_{goal}, obstacle set, maximum iterations, trained DQN agent
Ensure: Collision-free path or failure

```
Initialize tree T with root node q_start
for i = 1 to maximum iterations do
    Generate q_sample using Eq. (12)
    Find nearest node q_near in T
    Compute q_new using Eq. (1)
    if q_new is in collision or edge (q_near, q_new) is in collision then
        Continue
    end if
    Compute r_adaptive using Eq. (11)
    Find neighbor nodes within r_adaptive
    Select the lowest-cost collision-free parent
    Add q_new to T
    Rewire nearby nodes if the new connection reduces cost
    if d(q_new, q_goal) is within the goal radius then
        Add goal node
        return extracted path
    end if
end for
return failure
```

Fig. 1 shows the main steps of N-DQN-RRT. The tree is first initialized at the start node. At each iteration, a candidate sample is generated using goal bias, random sampling, or the trained DQN policy. The candidate node and edge are then checked for collision. If the candidate is valid, the planner selects a parent, adds the new node, and applies adaptive rewiring. The process stops when the goal region is reached. If the maximum number of iterations is reached first, the planner returns failure.

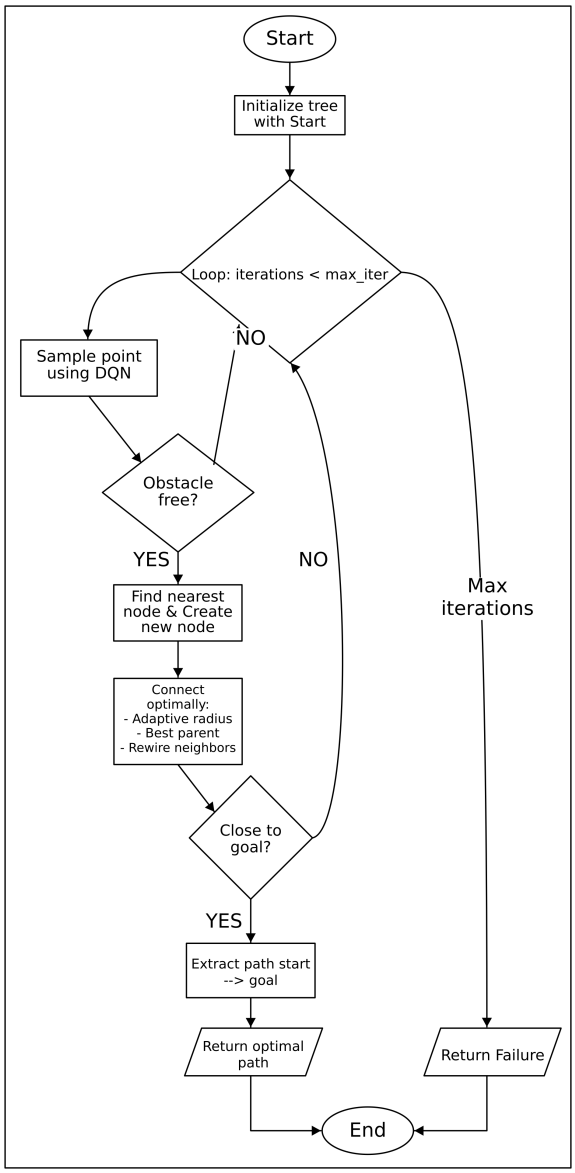

Fig. 1. Flowchart of the proposed N-DQN-RRT path planning algorithm.

H. Evaluation Metrics

Six metrics are used to evaluate the planners. Path length measures the total Euclidean length of the final path. Steering angle measures the average turning angle between consecutive path segments. Iterations measure the number of tree expansion steps. Sampling size measures the number of nodes in the final tree. Computation time measures wall-clock planning time. Success rate measures the percentage of trials that reach the goal within the iteration limit.

For each metric, the mean and standard deviation are

reported across 100 trials. A 95% confidence interval is also computed for the main continuous metrics. Path length is calculated only for successful trials. Success rate is reported over all trials.

The 95% confidence interval is computed as

$$CI = \bar{x} \pm t_{\alpha/2,n-1}\frac{s}{\sqrt{n}}, \tag{13}$$

where, $\bar{x}$ is the sample mean. The term s is the sample standard deviation. The term n is the number of trials. The term $t_{\alpha/2,n-1}$ is the critical value from the t distribution.

I. Reproducibility Details

The implementation uses a three-layer Q-network with input size 7 and output size 8. All state features are normalized before being passed to the network. The optimizer is Adam with a learning rate of 0.001. The loss function is the mean squared Bellman error. The collision buffer is set to 0.05 units. The edge interpolation step is set to 0.02 units. The base rewiring radius is set to 2.0 units.

The main experiments use 100 independent trials per map. This supports statistical reporting under stochastic planning. For exact reproducibility, the final implementation should also report the obstacle generation rules, software versions, hardware configuration, and random seed list.

IV. Results and Discussion

This section presents the results of RRT, RRT*, and the proposed N-DQN-RRT. The algorithms were tested on three static two-dimensional maps. The map sizes were 10×10, 25×25, and 50×50. Each map setting was evaluated using 100 independent trials. The start and goal positions were fixed for each map. The obstacle layout was randomly generated in each trial.

Six metrics were used for comparison. These were path length, steering angle, iteration count, sampling size, computation time, and success rate. Path length, steering angle, iteration count, sampling size, and computation time were computed from successful trials. Success rate was computed over all 100 trials.

A. Map 1 Results: 10×10 Environment

The first experiment used a 10×10 environment. The start position was $(1.0, 1.0)$. The goal position was $(9.0, 9.0)$. The step size was 1.0. The maximum number of iterations was 250 for all algorithms (Table IV).

All three algorithms reached the goal in every trial. This shows that the smallest map was manageable for all planners under the given iteration limit. However, N-DQN-RRT produced better paths and used fewer samples.

Compared with RRT*, N-DQN-RRT reduced the mean path length from 13.90 m to 12.50 m. This is a reduction of about 10.1%. It also reduced the mean steering angle from 40.07° to 22.63°. This indicates a smoother path. The iteration count dropped from 79 to 24. The sampling size also dropped from 61 to 22.

The confidence intervals for path length do not overlap between N-DQN-RRT and RRT*. This supports a meaningful difference in the tested trials. It should not be treated as mathematical proof. It shows that the observed improvement is unlikely to be caused only by random variation in these experiments.

B. Map 2 Results: 25×25 Environment

The second experiment used a 25×25 environment. The start position was $(1.0, 1.0)$. The goal position was $(24.0, 24.0)$. The step size was 1.0. The maximum number of iterations was 500 (Table V).

The second map shows a clear difference between the planners. RRT reached the goal in 28% of the trials. RRT* reached the goal in 38% of the trials. N-DQN-RRT reached the goal in all trials. This is an increase of 62 percentage points over RRT*.

Among successful trials, N-DQN-RRT also produced shorter paths. Its mean path length was 36.60 m. The mean path length of RRT* was 41.10 m. This is a reduction of about 10.9%. The mean steering angle was also much lower. This suggests that the learned sampling policy helped produce smoother routes.

N-DQN-RRT required fewer iterations and fewer nodes than RRT*. The iteration count decreased from 404 to 186. The sampling size decreased from 263 to 103. The computation time also decreased from 0.60 s to 0.11 s. This reduction is mainly due to the smaller tree size and fewer expansion steps.

The standard deviation of the N-DQN-RRT iteration count is still high. This shows that some random obstacle layouts were harder than others. Even so, the method reached the goal in every trial.

C. Map 3 Results: 50×50 Environment

The third experiment used the largest environment. The map size was 50×50. The start position was $(1.0, 1.0)$. The goal position was $(49.0, 49.0)$. The step size was 1.0. The maximum number of iterations was 1500 (Table VI).

The 50×50 map was the most difficult case. RRT succeeded in 10% of the trials. RRT* succeeded in 14% of the trials. N-DQN-RRT succeeded in all 100 trials. This is an increase of 86 percentage points over RRT*.

The path length also improved. N-DQN-RRT achieved a mean path length of 76.80 m. RRT* achieved 87.20 m. This is a reduction of about 11.9%. The steering angle was reduced from 33.76° to 17.04°. This again shows smoother path behavior.

The largest gain was seen in computation time and sampling size. N-DQN-RRT used 238 nodes on average. RRT* used 955 nodes on average. The computation time decreased from 6.39 s to 0.52 s. This suggests that the DQN-guided sampler reduced unnecessary tree growth in the tested maps.

The standard deviation of N-DQN-RRT computation time is high. This means that a few trials were much harder than the average case. The method still reached the goal in every run.

TABLE IV. MAP 1 RESULTS OVER 100 TRIALS IN THE 10×10 ENVIRONMENT

Metric	RRT	RRT*	N-DQN-RRT
Path length	14.60 ± 1.40 m	13.90 ± 1.06 m	$\mathbf{12.50 \pm 0.83}$ m
Iterations	69 ± 24	79 ± 40	$\mathbf{24 \pm 10}$
Sampling size	55 ± 17	61 ± 26	$\mathbf{22 \pm 5}$
Steering angle	$42.67^\circ \pm 8.74^\circ$	$40.07^\circ \pm 8.26^\circ$	$\mathbf{22.63^\circ \pm 7.83^\circ}$
Computation time	0.02 ± 0.01 s	0.04 ± 0.05 s	$\mathbf{0.01 \pm 0.004}$ s
Success rate	100.0%	100.0%	**100.0%**
95% CI for path length	[14.34, 14.89]	[13.68, 14.10]	$[\mathbf{12.32}, \mathbf{12.65}]$
95% CI for computation time	[0.0141, 0.0188]	[0.0300, 0.0500]	$[\mathbf{0.0074}, \mathbf{0.0087}]$

TABLE V. MAP 2 RESULTS OVER 100 TRIALS IN THE 25×25 ENVIRONMENT

Metric	RRT	RRT*	N-DQN-RRT
Path length	42.10 ± 2.83 m	41.10 ± 2.14 m	$\mathbf{36.60 \pm 1.87}$ m
Iterations	407 ± 67	404 ± 62	$\mathbf{186 \pm 95}$
Sampling size	270 ± 46	263 ± 44	$\mathbf{103 \pm 34}$
Steering angle	$36.79^\circ \pm 4.91^\circ$	$37.64^\circ \pm 4.38^\circ$	$\mathbf{17.82^\circ \pm 3.43^\circ}$
Computation time	0.34 ± 0.12 s	0.60 ± 0.27 s	$\mathbf{0.11 \pm 0.06}$ s

TABLE VI. MAP 3 RESULTS OVER 100 TRIALS IN THE 50×50 ENVIRONMENT

Metric	RRT	RRT*	N-DQN-RRT
Path length	89.70 ± 3.41 m	87.20 ± 3.95 m	$\mathbf{76.80 \pm 3.11}$ m
Iterations	1259 ± 232	1345 ± 109	$\mathbf{317 \pm 203}$
Sampling size	901 ± 145	955 ± 86	$\mathbf{238 \pm 135}$
Steering angle	$35.92^\circ \pm 3.64^\circ$	$33.76^\circ \pm 2.94^\circ$	$\mathbf{17.04^\circ \pm 2.24^\circ}$
Computation time	3.56 ± 1.30 s	6.39 ± 1.33 s	$\mathbf{0.52 \pm 0.46}$ s
Success rate	10.0%	14.0%	**100.0%**
95% CI for path length	[87.23, 92.10]	[84.88, 89.45]	$[\mathbf{76.21}, \mathbf{77.45}]$
95% CI for computation time	[2.6353, 4.4926]	[5.6176, 7.1531]	$[\mathbf{0.4273}, \mathbf{0.6085}]$

This supports its practical stability under the tested random obstacle settings.

It is important to interpret the results carefully. For Maps 2 and 3, RRT and RRT* failed in many trials. Their path length and computation time values are based only on successful trials. These successful cases may represent easier obstacle layouts. Therefore, success rate is the most important metric for larger maps.

D. Cross-Environment Analysis

Table VII summarizes the performance of N-DQN-RRT across the three map sizes. The method kept a 100% success rate in all tested environments. The path length increased as the map size increased. This is expected because the start and goal were farther apart in larger maps.

The steering angle decreased from Map 1 to Map 3. This may be because larger maps provide more space for gradual movement. It may also reflect the effect of DQN-guided directional sampling. Further testing is needed before making a stronger claim.

The iteration count and sampling size increased with map size. This is expected because larger maps require longer paths and more expansion steps. However, the increase was still lower than the growth seen in RRT* computation time. In these experiments, N-DQN-RRT increased from 0.01 s to 0.52 s. RRT* increased from 0.04 s to 6.39 s. This indicates better empirical scaling under the tested settings.

E. Discussion

The results show that the proposed N-DQN-RRT planner improves practical planning performance in the tested static two-dimensional environments. The improvement is most visible in the larger maps. In those maps, RRT and RRT* often failed to reach the goal within the iteration limit. N-DQN-RRT reached the goal in every trial.

The main reason is the sampling strategy. The DQN policy guides most samples toward useful directions. The random sampling component keeps some global exploration. This helps reduce the risk of relying only on the learned policy. The goal bias also helps the planner converge near the target region.

The adaptive rewiring radius also contributes to path quality. In open regions, a larger radius allows the planner to consider more possible parent nodes. Near obstacles, a smaller radius reduces unnecessary neighbor checks. This can reduce collision-heavy rewiring attempts. It can also help produce smoother local connections.

The results should not be overinterpreted. The experiments do not prove probabilistic completeness or asymptotic optimality for N-DQN-RRT. They only show empirical improvement under the tested simulation conditions. The training and testing

TABLE VII. N-DQN-RRT PERFORMANCE ACROSS MAP CONFIGURATIONS

Metric	**Map 1:** 10×10	**Map 2:** 25×25	**Map 3:** 50×50
Success rate	100%	100%	100%
Path length	12.50 ± 0.83 m	36.60 ± 1.87 m	76.80 ± 3.11 m
Steering angle	$22.63^\circ \pm 7.83^\circ$	$17.82^\circ \pm 3.43^\circ$	$17.04^\circ \pm 2.24^\circ$
Iterations	24 ± 10	186 ± 95	317 ± 203
Sampling size	22 ± 5	103 ± 34	238 ± 135
Computation time	0.010 ± 0.004 s	0.110 ± 0.060 s	0.520 ± 0.460 s

maps were generated from the same general distribution. This means that performance on different map types is still uncertain. Examples include narrow passages, maze-like maps, dynamic obstacles, and real robot environments.

There are also reproducibility limits. The trials were repeated 100 times, but no fixed random seed list was used. This supports statistical reporting, but it does not provide exact run-to-run reproduction. Future experiments should include fixed seed lists, obstacle-generation details, and code release. Additional baselines such as Informed RRT*, Bi-RRT*, and goal-biased RRT* would also make the comparison stronger.

Overall, the results support the use of DQN-guided sampling as a practical improvement for RRT*-style planning in static 2D environments. The strongest evidence is the increase in success rate and the reduction in sampling size on larger maps. The method is promising, but it should be tested further before being claimed as general or deployment-ready.

V. CONCLUSION

This paper proposed and evaluated N-DQN-RRT, a hybrid path-planning algorithm for static two-dimensional environments. The method integrates a trained Deep Q-Network agent into an RRT*-style planning framework. It uses a seven-dimensional state representation that includes goal direction, obstacle distance, obstacle direction, and local free-space information. It also uses an 80/20 directed-random sampling strategy. In this strategy, 75% of samples are guided by the DQN policy, 5% are assigned to goal bias, and 20% are sampled uniformly at random. An adaptive rewiring radius is also used to adjust the local optimization range according to obstacle conditions.

The proposed method was implemented in Python and tested in three static two-dimensional random obstacle environments. The map sizes were 10×10, 25×25, and 50×50. Each map setting was evaluated using 100 independent stochastic trials. The performance of N-DQN-RRT was compared with classical RRT and RRT* using path length, steering angle, iteration count, sampling size, computation time, and success rate.

The results show that N-DQN-RRT improved empirical planning performance under the tested conditions. It achieved a 100% success rate across all 300 trials. In comparison, RRT achieved 28–100% success and RRT* achieved 38–100% success depending on the map size. In the largest 50×50 environment, N-DQN-RRT reduced path length by 11.9%, steering angle by 49.5%, sampling size by 75.1%, and computation time by 91.9% compared with RRT*. The non-overlapping 95% confidence intervals support the observed differences in the tested trials.

The main contribution of this work is empirical and architectural. The paper does not claim to be the first study on DQN-RRT integration. Instead, it studies a specific hybrid design that combines DQN-guided sampling, goal bias, random exploration, and adaptive rewiring within an RRT*-style planner. The results suggest that learned sampling can reduce unnecessary exploration and improve practical planning efficiency in static two-dimensional random obstacle environments.

This study has several limitations. First, the evaluation is limited to static two-dimensional maps. Dynamic obstacles, moving agents, and real-world sensing uncertainty are not considered. Second, the DQN agent is trained and tested on maps generated from the same general distribution. This limits the strength of the generalization claim. Third, no physical robot experiment is included. The simulation does not model sensor noise, actuator delay, localization error, or communication latency.

Future work should extend N-DQN-RRT to dynamic environments that require online replanning. The method should also be tested on physical mobile robots using sensors such as LiDAR or depth cameras. Further experiments should include three-dimensional planning tasks for UAVs and robotic manipulators. Ablation studies are also needed to measure the contribution of each component. These studies should test different DQN-random sampling ratios, remove adaptive rewiring, and compare fixed-radius and adaptive-radius variants. Cross-map generalization tests should also be added by training on one obstacle distribution and testing on different map structures such as narrow passages and maze-like environments.

Deep Learning and Computer Vision-Based Modeling for a Real-Time Traffic Congestion Monitoring Framework

Neil Dustin Benedict A. Agner, Angelo B. Dela Cruz,
Aster Benedict A. Mangabat, Raphael B. Alampay, Patricia Angela R. Abu
Ateneo Laboratory for Intelligent, Visual Environments, Ateneo de Manila University, Philippines

***Abstract*—As intelligent traffic systems evolve to manage complex urban mobility, conventional congestion estimation techniques, such as the time-windowed Volume-to-Capacity (V/C) ratio, fail to capture capture the real-time traffic situation. Because these methods rely on vehicles crossing a specific point, they often fail to register stopped cars, creating a 'zero flow' paradox where complete gridlock is incorrectly categorized as an empty, free-flowing road. To address these limitations, this study proposes an end-to-end computer vision framework utilizing the Real-Time DEtection TRansformer (RT-DETR) model to quantify vehicle volume and immediately classify a roadway's Level of Service (LOS) through spatial density. In processing video feeds from the Ateneo de Manila University Campus Safety and Mobility Office, the framework calculates an instantaneous, frame-level Spatial Density Index across six distinct vehicle classes. Results show that the proposed SDI framework outperforms the traditional time-windowed method in estimating traffic congestion and reduces percentage error margins to between -0.22% and 2.85%. The proposed framework successfully resolves the zero flow paradox by analyzing frame-wide congestion rather than fixed line crossings prescribed in the time-windowed method. It also offers a highly responsive and robust alternative that detects immediate spikes in vehicle density, which makes it potentially suitable for integration into intelligent traffic systems.**

***Keywords*—Traffic congestion estimation; level of service; volume-to-capacity ratio; RT-DETR; real-time object detection**

I. Introduction

Traffic congestion remains a critical challenge in many urban areas around the world. It affects the efficiency of transportation, quality of life, and economic productivity [1]. Due to growing urbanization, there is a need for intelligent transport systems that are capable of monitoring and analyzing traffic conditions in real-time [2]. Computer vision (CV), a field of artificial intelligence that is focused on enabling machines to extract meaningful information from visual data, has emerged as an effective solution to address these challenges [3].

Traffic congestion estimation plays a key role in managing and optimizing transport systems. It often involves analyzing vehicle volume and capacity to infer congestion levels [4]. Traditional methods for traffic congestion estimation utilize various technologies for collecting traffic information, such as inductive loop detectors, Light Detection and Ranging (LiDAR) sensors, and Global Positioning System (GPS)-based tracking [5], [6], [7]. However, these methods have drawbacks. GPS-based systems have limited coverage as they rely on vehicles being equipped with tracking devices [6]. Loop detectors require road installation and maintenance, which can be costly and disruptive [8]. LiDAR sensors' performance can be heavily affected by different weather conditions as they interfere with the laser signals and reduce accuracy [9].

With the increase in deployment of surveillance cameras across urban centers, their integration into intelligent transport system provides a highly beneficial method to address traffic congestion in real-world scenarios. Deep learning models in computer vision have shown significant promise in addressing challenges associated with traffic congestion [10]. Among its many applications, object detection, a technique for identifying and locating objects within images, has shown potential in enhancing current intelligent transport systems and providing a non-intrusive mechanism to quantify traffic flow.

Despite these capabilities, current CV approaches often fall short of providing a complete end-to-end analysis for traffic management. Existing frameworks typically output raw vehicle counts which require further manual processing to derive standard congestion measures [11]. Currently, congestion detection is treated as a visual classification problem through the discretization of the degrees of congestion [12]. Furthermore, few studies have shown a framework that would transform vehicle detection counts, obtained via CV-based solutions, into a measure of traffic congestion.

This study addresses this limitation by proposing an end-to-end framework that uses object detection to quantify vehicle volume and classify the Level of Service (LOS) of a roadway. While baseline evaluations utilize traditional time-windowed V/C ratios, this study introduces a Spatial Density Index (SDI) to address their inherent temporal lag. The proposed SDI provides an immediate classification of LOS through frame-level evaluation of spatial occupancy of a road by vehicles.

II. Review of Related Literature and Studies

A. Traffic Congestion Estimation

Traffic congestion is defined as a condition where the demand for road space exceeds the available capacity; this leads to a decrease in vehicle speed, longer travel times, and the overall inefficiency of the road network [8]. It can be caused by various factors such as high traffic volumes, accidents, roadworks, or inefficient traffic management. When congestion occurs, the flow of vehicles is hindered, causing

delays and contributing to environmental pollution through increased emissions [13].

To accurately estimate congestion, various parameters are considered. These parameters, such as traffic flow, speed, density, and travel time, are essential for assessing congestion, since they offer measurable data points that reflect real-time and overall road network performance [14].

For the purpose of this study, the parameters (see Table I) defined by the Philippine Department of Public Works and Highways (DPWH) Highway Planning Manual [4] for the estimation of traffic congestion were used to classify the level of congestion detected in traffic scenes. Level of Service is a qualitative measure describing the operational conditions within a traffic stream and their perception by motorists and passengers. It is categorized into different levels according to the value of the Volume-to-Capacity (V/C) ratio of the road, visualized in Fig. 1.

As for the quantitative parameters, Volume is defined as the number of vehicles passing at a point or section of roadway per lane for a given time period (number of vehicles/time), usually measured by hour. Volume is a weighted measure describing how much space those vehicles occupy, and that depends on the Flat Terrain Passenger Car Equivalent Factor (PCEF) (see Table II) of the different vehicle classes that compose the traffic. On the other hand, capacity is the maximum number of vehicles that have a reasonable expectation of passing over a given section of lane or roadway in one direction or in both directions during one hour under prevailing road and traffic conditions (see Table III). It is typically expressed as passenger car unit per hour (PCU/hr).

Fig. 1. LOS Examples [15].

TABLE I. LEVEL OF SERVICE FOR PHILIPPINE HIGHWAYS [4]

Level of Service	V/C Ratio	Description
A	< 0.20	Free Flow Traffic
B	0.21–0.50	Free Flow Traffic
C	0.51–0.70	Moderate Traffic
D	0.71–0.85	Moderate/Heavy Traffic
E	0.86–1.00	Heavy Traffic
F	> 1.00	Forced Flow, Stop and Go

The V/C ratio defined by the DPWH provides a standardized metric for congestion estimation. However, its reliance on fixed time-windows introduces a temporal lag. Since the V/C ratio is calculated using aggregate per-hour or per-minute data, the resulting LOS reflects the average past traffic states rather than real-time road conditions.

B. Vehicle Detection in Traffic Scenes

Vehicle detection is the process of identifying and recognizing vehicles within a specific environment, such as roadways or parking areas [16]. Accurate vehicle detection is important for estimating congestion because it provides real-time data on the number, position, and movement of vehicles on roadways. This information helps in calculating important traffic parameters for determining the degree of congestion [17]. Accurate vehicle detection allows traffic management systems to improve urban mobility by detecting bottlenecks and anticipating traffic jams, and facilitating the implementation of more effective intelligent transport systems such as adaptive traffic signal control or route recommendations to reduce congestion [18].

Traditional vehicle detection methods rely on sensor-based technologies that are installed within road infrastructure. These methods include inductive loop detectors (ILDs), infrared sensors, microwave radar, and LiDAR-based approaches, all of which have been widely used in intelligent transport systems for vehicle identification and tracking. Despite their effectiveness for basic tracking, these sensor-based methods face several challenges and limitations. ILDs and infrared sensors are effective for basic tracking, but they are hindered by high installation costs, road surface disruption, and sensitivity to environmental factors like fog or rain. Similarly, while microwave radar and LiDAR offer resilience in adverse weather and high-precision 3D mapping, they face challenges with stationary vehicle detection and significant computational and financial overhead. Additionally, many of these methods require physical infrastructure changes, which makes them difficult to deploy in rapidly evolving traffic environments.

To address these limitations, CV-based vehicle detection has emerged as a more flexible and scalable alternative. Advancements in image processing and machine learning have led to the adoption of CV techniques for vehicle detection. Vehicle detection in CV involves identifying and locating vehicles within images or video frames, typically captured in traffic scenes [19]. These methods primarily utilize camera feeds from surveillance systems. This addresses the challenge sensor-based methods face, as it eliminates the need for extensive physical infrastructure. Modern object detection algorithms, such as convolutional neural networks, have significantly improved the accuracy and efficiency of vehicle detection, making CV an increasingly viable solution for traffic monitoring, congestion estimation, and even autonomous vehicle systems [20].

However, despite the significant improvement from tradi-

10	Truck semi-trailer, 5+ axles	2.5
11	Truck trailers, 4 axles	2.5
12	Truck trailers, 5+ axles	2.5

TABLE III. BASIC HOURLY CAPACITY, PCU [4]

Carriage Width (m)	Urban Hourly PCU
Single less than 4	600
4.0–5.0	1,200
5.1–6.0	1,600
6.1–6.7	1,700
6.8–7.3	1,800
2 × 6.7 or 2 × 7.3	6,700

tional methods, vision-based vehicle detection systems still face significant challenges that hinder its effectiveness in real-world traffic scenarios. One of the most challenging problems is occlusion, which occurs when portions of a vehicle are occluded by other objects like other cars, pedestrians, road construction, or natural environments like trees and shadows. The accuracy and reliability of vehicle detection systems can be heavily affected by occlusion, which can result in partial or complete vehicle misdetection, especially in dense traffic settings [21]. Additionally, viewpoint variations also pose a problem, as vehicles appear differently depending on the distance and angles of the cameras. While deep learning models have improved object detection significantly, they still struggle to generalize well under these conditions without extensive training on diverse datasets [22].

C. End-to-End DEtection TRansformers

The current CV landscape is dominated by several state-of-the-art architectures, most notably the YOLO (You Only Look Once) family, SAM (Segment Anything Model), and DETR (DEtection TRansformer) [23]. DETR-based models, with their global attention mechanisms, are inherently better equipped to handle the occlusions of vehicles in dense traffic scenes.

The Real-Time DEtection TRansfomer (RT-DETR) is a new approach to object detection that aims to address the limitations of current real-time detectors like the YOLO series and earlier DETRs. The architecture of RT-DETR consists of a backbone, a hybrid encoder, and a Transformer decoder with auxiliary prediction heads [24]. RT-DETR demonstrates state-of-the-art real-time object detection performance, outperforming previously advanced YOLO detectors in both speed (in terms of frames per second) and accuracy (in terms of mean average precision) on the Common Objects in Context (COCO) dataset [24]. Real-time, in this case, is defined as an object detector with an inference speed of 20 frames per second or 50 ms per frame [25]. RT-DETR also significantly outperforms other DETR variants in terms of speed, achieving comparable or better accuracy with higher frames per second [24].

III. METHODOLOGY

A. Image Dataset Creation

The experimental workflow began with the acquisition and preparation of the raw data from the Ateneo de Manila University Campus Safety and Mobility Office (CSMO) video feeds which were turned into a dataset.

For this study, the CSMO provided static video feeds from Gates 2, 2.9, 3, and 3.5 of the university, running at 15 frames per second (see Fig. 2). The feeds were taken on 2025-02-20, 06:00 AM to 2025-02-21, 06:00 AM; 2025-04-03, 06:00 AM to 2025-04-04, 06:00 AM; and 2025-10-07, 06:00 AM to 2025-10-08, 06:00 AM.

All of the frames were sampled using FFmpeg. To avoid excessively long training times while still ensuring sufficient representation of the video footage, two frame samples were taken per minute on the footage. For the training process, frames were only extracted from the feeds on 2025-02-20 to 2025-02-21 and 2025-04-03 to 2025-04-04. The footage on Gates 2.9, 3, and 3.5, frame samples were taken from 06:00 AM of the first date up until 10:00 PM, and from 05:00 AM of the succeeding date up until 06:00 AM. For the footage on Gate 2, the frame samples were taken from 06:00 AM on the first date up until 06:00 PM and from 05:00 AM on the succeeding date up until 06:00 AM. Conceptually, 11,760 frames should be sampled. However, due to the fragmented nature of the footage, a total of 11,783 frames were sampled by FFmpeg, with 23 extra samples. Since these 23 extra samples were only a very small proportion of the projected total of 11,760 frames, it was decided that the frames would still be kept for the annotation process.

For the testing process, frames were sampled from the footage on 2025-10-07 to 2025-10-08. For the footage on Gates 2.9, 3, and 3.5, samples were taken from 06:00 AM to 01:00 PM and 04:00 PM to 10:00 PM on 2025-10-07. For the footage on Gate 2, samples were taken from 06:00 AM to 01:00 PM and 02:00 PM to 06:00 PM on 2025-10-07, and 05:00 AM to 06:00 AM on 2025-10-08. Following this process, an additional 3,060 frames were sampled from the given footage with no extra frames. Combined together, there were a total of 14,843 sampled images in the dataset.

The sampled images were in 1920 x 1080 pixels, but was resized to 640 x 640 pixels when fed into the model for training and validation, similar to the image sizes in COCO dataset, which the base RT-DETR was trained on [24]. Moreover, having a consistent size for all images allows for more effective feature extraction as it helps effectively capture relevant details and patterns, which is especially important for detecting occlusions where details may be subtle.

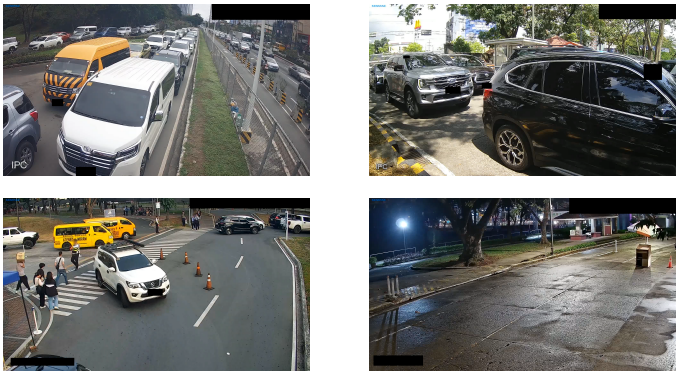

Fig. 2. Sample images from CSMO-provided feeds.

The sampled images were then labeled by an object annotation tool. Among the commonly used tools like CVAT, Roboflow Annotate, LabelStudio, and Make Sense, CVAT was

selected as it offers a free, open-source, and feature-packed solution for annotations [26].

In annotating the images, the six vehicle classes defined by the DPWH Highway Planning Manual [4], namely car, motorcycle, tricycle, bus, van, and truck were used. To guide the annotators in annotating the images, the sample images for each of the categories shown in the Philippines' Land Transportation Office [27] Filipino Driver's Manual were used as the visual basis.

The generated image annotations were saved in a JavaScript Object Notation (JSON) file format using the COCO annotation format. Sample annotation images can be seen in Fig. 3a and Fig. 3b.

(a) Congested traffic. (b) Freeflowing.

Fig. 3. Sample annotated frames.

B. Model Training and Testing

The RT-DETR model with the ResNet50 backbone was then trained on the training data subset with 11,760 frames and then tested on the testing data subset with 3,060 frames.

To test the counting and traffic congestion estimation capabilities of the model, video footage was taken and trimmed from the raw CSMO footage on 2025-10-07 to 2025-10-08. 12-hour segments from 06:00 AM to 06:00 PM were chosen from the video footage as these represent the operational hours of the school roads. After trimming these segments from the raw footage, the number of vehicles that passed through the gate were counted according to their category. These counts served as the ground truth versus the model's counting capability.

C. Vehicle Counting and Ground Truth Annotation

1) Ground truth validation: Manual vehicle counts were established by the researchers to serve as the ground truth. To ensure measurement reliability and mitigate annotation bias, the manual counts underwent a rigorous verification stage. Annotations were all performed by the researchers. Initial counts were self-validated two times by a primary annotator and subsequently cross-validated two times by a secondary annotator. In instances of discrepancy, the cross-validation count was established as the final ground truth.

2) Automated counting pipeline: The valid vehicle types to be counted were selected based on the availability of PCEF values in the DPWH Highway Planning Manual [4] and its specified classes, namely, cars, motorcycles, tricycles, buses, vans, and trucks.

To accommodate the comparative analysis, two distinct vehicle counting pipelines were implemented:

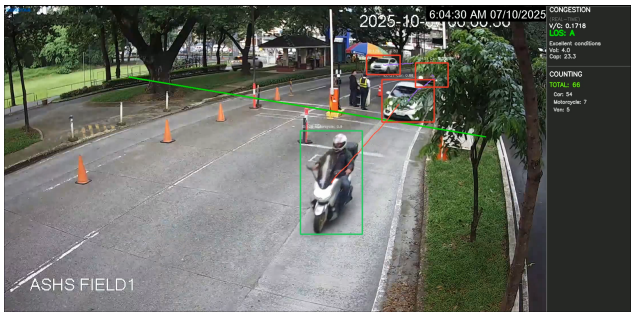

Fig. 4. Vehicle counting sample.

- Time-Windowed Pipeline: For the traditional metric, the ByteTrack Multi-Object Tracking Algorithm [6] was used. A vehicles was only counted when its tracked trajectory crossed a user-defined line on the roadway, as illustrated in Fig. 4.
- Frame-Level Spatial Pipeline: For the proposed spatial metric, the line-crossing logic was discarded. Instead, the model executed a frame-level count by aggregating all visible vehicles in a single frame simultaneously.

D. Traffic Estimation Metrics

In this study, two model frameworks were used to translate the automated vehicle detections and counts into congestion measures. This time-windowed framework was based on the standard Volume-to-Capacity ratio established by the DPWH. The LOS was determined based on equivalent traffic levels of the computed V/C ratio (see Table I).

1) Time-windowed volume-to-capacity ratio: The Volume-to-Capacity ratio is a quantitative measure of the demand of vehicles placed in a roadway compared to its ability to handle the traffic [4].

Under this time-windowed framework, raw vehicle counts are transformed into Passenger Car Units using the equivalent Passenger Car Equivalent Factors to account for the varying impact of different vehicle types on traffic flow [4]. Volume pertains to the number of vehicles that are using the road per hour. Volume is calculated by aggregating the weighted counts of six distinct vehicle classes: cars, vans, motorcycles, tricycles, buses, and trucks. Hence, the window-based volume is defined in Eq. 1:

$$\text{Volume}_{tw} = \sum_{i=1}^{6} (n_i \times PCEF_i) \tag{1}$$

where, n_i represents the raw count of vehicles in class i, and $PCEF_i$ represents the corresponding factor for that specific class. Note that in this implementation, volume is calculated over the past n-minutes.

On the other hand, capacity is the maximum number of vehicles per hour that the road can handle before congestion occurs. A roadway's capacity (Capacity_{tw}) is based on its carriage width. The DPWH [4] defines the hourly capacity for a given road's carriage width in Table III. Hence, the V/C ratio is defined in Eq. 2:

$$\text{V/C Ratio} = \frac{\text{Volume}_{tw}}{\text{Capacity}_{tw}} \tag{2}$$

The capacity was obtained via a user-defined road width which was mapped to its corresponding PCU. This capacity was then scaled down for the shorter time intervals used in the video inference.

2) Frame-level spatial density index: While the DPWH-based framework provides a standardized metric for assessing traffic, its reliance on fixed time-windows introduces a temporal lag. Because the V/C ratio is calculated using aggregate data from the preceding n-minutes or hours, the resulting LOS reflects past traffic states rather than current conditions.

To address the limitations of the time-windowed V/C ratio, a Spatial Density Index (SDI) was formulated based on the instantaneous frame-level spatial occupancy. In this approach, frame-based volume is defined in Eq. 3 as the weighted sum of vehicle counts detected within a single frame:

$$\text{Volume}_{fl} = \sum_{i=1}^{6} (n_{i,frame} \times PCEF_i) \tag{3}$$

Meanwhile, the modified capacity is defined in Eq. 4:

$$\text{Capacity}_{fl} = k_j \times n_l \times L \tag{4}$$

where, k_j is the jam density, n_l is the number of lanes in focus, L is the length of the roadway in focus in kilometers. Jam density is defined as the maximum possible vehicle density on the road when traffic is completely stopped [28]; its units are expressed in veh/km/lane. Theoretical simulations by Knoop and Daamen [28] identified that the theoretical jam density was 145 veh/km/lane.

The resulting SDI is then expressed in Eq. 5:

$$\text{SDI} = \frac{\text{Volume}_{fl}}{\text{Capacity}_{fl}} \tag{5}$$

Both of these ratios are dimensionless since both the PCE-weighted numerator and capacity denominator share the same unit, namely the number of vehicles.

3) Percent error: Accuracy is an important evaluation metric that can be used to evaluate the performance of the proposed method. Percent error represents the difference between an estimated value and the true value as a percentage of the true value [29]. It can be signed when analyzing bias or unsigned when expressing accuracy. It can be computed using the formula,

$$\text{Signed \% Error} = \frac{\text{Estimated Value} - \text{True Value}}{\text{True Value}} \times 100\% \tag{6}$$

For this study, this metric will be used to provide insights into the model's ability to underestimate or overestimate in its counting of vehicles and computation of the level of traffic congestion estimation based on the Volume-to-Capacity ratio or the Spatial Density Index.

IV. Results and Discussion

A. Base Model Performance and Inference Latency

Before evaluating the congestion estimation pipelines, the underlying RT-DETR model's object detection reliability was briefly assessed. As seen in Table IV, the model demonstrated highly robust baseline detection capabilities for the selected vehicle classes.

TABLE IV. Model Performance of RT-DETR

Precision	Recall	mAP@0.5	mAP@0.5:0.95
0.999	0.989	0.934	0.795

To validate the real-time applicability of both the traditional and proposed end-to-end framework, the computational complexity of the model was measured. Using an NVIDIA RTX 3090 GPU for the complete pipeline, it can be noted that the system achieved an inference speed of 29.59 frames per second (FPS) (see Table V). This exceeds the standard 20 FPS threshold required for real-time traffic monitoring systems [25].

TABLE V. Computational Complexity of RT-DETR

Parameters	GFLOPs	Inference (FPS)	Memory (GB)
42,710,790	67.91	29.59	2.121

B. Time-Windowed Traffic Congestion Estimation

The model's ability to count vehicles over 12 hours (06:00 AM to 06:00 PM) was evaluated against the manually counted ground truth, as shown in Table VI. Across most gates, the model showed a strong performance in counting the number of vehicles, maintaining an error rate of around $\pm 10\%$. However, Gate 2 showed a significant outlier with a -15.84% error in vehicle counting.

TABLE VI. Comparison of the Ground Truth, and RT-DETR Vehicle Count

Gate	Ground Truth	RT-DETR	% Error
Gate 2	3953	3643	-7.84%
Gate 2.9	5171	5303	2.55%
Gate 3	7442	7396	-0.62%
Gate 3.2	2424	2556	5.45%
Gate 3.5	4084	4261	4.33%

TABLE VII. Comparison of the Ground Truth, and RT-DETR V/C Ratio (Time-Windowed)

Gate	Ground Truth	RT-DETR	% Error
Gate 2	0.196	0.157	-19.97%
Gate 2.9	0.448	0.453	1.12%
Gate 3	0.304	0.294	-3.23%
Gate 3.2	0.145	0.135	-6.75%
Gate 3.5	0.978	0.973	-0.51%

The V/C ratios derived from the counts in Table VII typically had error margins within -6.75% to 1.12%. Gate 2

was also a notable exception with a -19.97% error in the V/C ratio.

C. Strengths and Limitations of the Time-Windowed Method

The traditional time-windowed method [4] shows significant strengths primarily oriented toward long-term planning as the V/C ratio, as defined in this method, can be used to predict the exact years that a roadway may reach a saturation point and require engineering interventions [30]. The primary strength of this approach is its focus on average throughput over a long period, such as an hour. As such, it is able to ignore brief fluctuations such as drivers stopping. Hence, the primary utility of the method is in the analysis of historical congestion data to identify persistent trends.

However, the method has significant limitations for real-time applications. One critical flaw is its reliance on point-based volume counts. When the road is empty, only a few vehicles or no vehicles will pass over the counting line. Similarly, when the road is completely gridlocked, only a few vehicles or no vehicles will also pass over the counting line. In both cases, the volume and, consequently, the V/C ratio become 0, which is equivalent to LOS A. Therefore, an empty and a gridlocked roadway are both considered as free-flowing traffic, resulting in the 'zero flow' paradox (see Fig. 7). The paradox lies in the inability of the method to distinguish between the two scenarios without supporting context from, for example, a live camera. Furthermore, the traditional V/C ratio requires calculation over n-minute or hour intervals to obtain an average flow rate. This delay means V/C ratios fail to reflect rapid changes in congestion, making them unsuitable for real-time control. As seen in Fig. 5, while the average vehicle count from 3:00 PM to 3:10 PM is at a high 16.59, the average LOS was calculated at A, indicating free flow. This means that at 3:00 PM to 3:10 PM, it was not able to properly represent the LOS of the past 10 minutes as no cars were moving past the counting line.

A notable outlier observed in both the vehicle counts and the V/C ratio computations was Gate 2, where the error was significantly higher. Upon checking the video feed, the camera at Gate 2 was observed to be positioned in a ground-level, side-view manner, with vehicles in the foreground frequently occluding those in the background. This left the model with insufficient visual features to identify and count trailing vehicles. This highlights the critical impact of camera placement on model detection accuracy, as accuracy relies on an object having the appropriate resolution at a given distance [31]. Going beyond the optimal distance makes objects look smaller and more difficult to separate from noise [31]. Moreover, optimal placement ensures that the maximum possible area is covered while minimizing blind spots or redundant overlaps between cameras [32]. Hence, it can be observed here how improper placement led to significant undercounting, which skewed the Level of Service computations for a given gate.

D. Frame-Level Traffic Congestion Estimation

The proposed frame-level framework demonstrates a notable performance improvement over the traditional time-windowed approach. As shown in Table VIII, the proposed

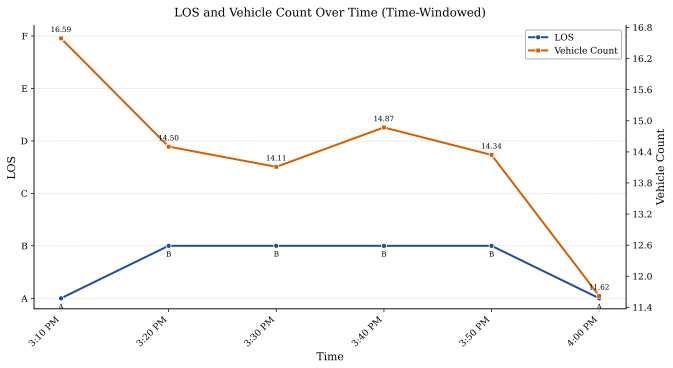

Fig. 5. LOS and vehicle count over time (time-windowed).

TABLE VIII. COMPARISON OF THE GROUND TRUTH AND RT-DETR SDI (FRAME-LEVEL)

Gate	Ground Truth	RT-DETR	% Error
Gate 2	0.400	0.355	-11.08%
Gate 2.9	0.794	0.815	2.69%
Gate 3	0.179	0.178	-0.77%
Gate 3.5	0.334	0.333	-0.22%

method reduced the percentage error margin to between -0.22% and 2.85%, a substantial improvement over the time-windowed measurements with range of -6.75% to 1.12%. Notably, the framework also demonstrated resilience to suboptimal camera configurations in its LOS computations compared to the time-windowed method. For instance, at Gate 2, despite a highly problematic viewing angle, the model reduced the error relative to the ground truth from a baseline of -19.97% in the time-windowed method to -11.08%. While the negative percentage value indicates that there is still an underestimation in congestion, the proposed framework mitigates the severe miscalculations inherent in the time-windowed method.

E. Strengths and Limitations of the Frame-Level Estimation Method

A primary strength of the proposed method is its ability to solve the zero flow paradox. This proposed method, by analyzing the entire frame, instantly distinguishes between gridlocked and free-flowing traffic states by detecting the presence of stationary vehicles (see Fig. 7). As seen in Fig. 6, the average vehicle count at the interval from 3:00 to 3:10 PM is 16.59, with the LOS being at level D. When contrasted with Fig. 5, this shows that the frame-level method can distinguish a congested road, whereas the time-windowed method cannot. Furthermore, the method provides a significant advantage in temporal resolution versus the time-windowed method. The proposed method is able to detect spikes in vehicle density immediately, offering data that is far more responsive for applications like adaptive traffic signal control.

However, the method has limitations dependent on camera perspective and scene complexity. Because it detects all vehicles within the entire video frame, it can be inaccurate for frames containing multiple traffic routes, such as in Gates 3.2 and 3.5, where distinguishing the specific lane or road segment is challenging. Without Region of Interest (ROI) masking, the

model may aggregate the traffic density of the entire frame, making it difficult to isolate and assign specific congestion metrics to each individual gate. Another significant constraint is occlusion. A common issue with single, oblique-angle CCTV views is that larger vehicles, like trucks, can obscure smaller vehicles behind them, such as cars or motorcycles. This leads to an underestimation of true density. A top-down perspective from a drone or satellite would mitigate this [33], but it is often not available for most traffic monitoring infrastructures.

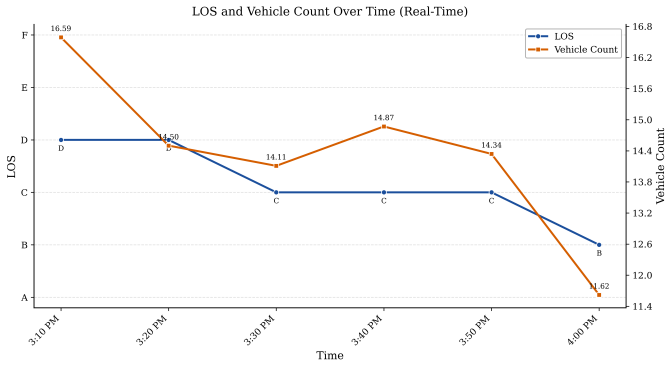

Fig. 6. LOS and vehicle count over time (frame-level).

Fig. 7. Time-windowed method (top) vs. frame-level method (bottom) detection comparison in congested states.

V. Conclusion

In conclusion, this study demonstrates that frame-wide spatial density analysis offers a robust alternative to the traditional time-windowed and line-based traffic congestion estimation by directly resolving the zero flow paradox inherent in severely congested conditions. By processing instantaneous vehicle density through the proposed frame-level method, the framework outperformed the traditional methods and effectively reduced percentage errors by approximately half while maintaining a more accurate representation of the true congestion state. Furthermore, unlike traditional flow-based V/C ratios that require substantial time-windows, the ability of the SDI to detect immediate spikes in congestion makes it highly applicable for integration into adaptive traffic signal control systems as it uses real-time congestion data; this enables control systems to autonomously optimize signal timing and alleviate sudden congestion [34].

VI. Recommendations for Future Work

The current framework utilizes jam density thresholds derived from the literature based on traffic conditions in the Netherlands. However, Philippine traffic is highly heterogeneous, characterized by unique vehicle dimensions (e.g., jeepneys, motorcyles, etc.), unstructured lane discipline, and tighter vehicle packing during severe congestion. Consequently, applying foreign baselines may skew maximum density estimations. Future research should consider establishing localized jam density metrics. Defining these local parameters will critically calibrate the model's congestion thresholds and improve the accuracy of Level of Service (LOS) classifications in similar developing urban centers.

To address the limitations of processing multi-directional traffic within a single camera feed, future research should investigate integrating ROI masking. Applying explicit spatial boundaries will allow the model to isolate specific road segments and lane directions. This targeted extraction is crucial for preventing data aggregation in complex scenes and enabling the framework to provide accurate, road-specific congestion estimations rather than generalized frame-wide density.

To address the limitation of vehicle occlusion inherent in ground-level camera angles, future implementations may look into prioritizing top-down camera perspectives. As noted, ground angles frequently result in larger vehicles (e.g. vans, trucks) obscuring smaller trailing vehicles, which inherently leads to an underestimation of true traffic congestion.

While this study successfully serves as a proof-of-concept for the SDI, certain methodological limitations must be acknowledged. First, due to the limited sampling windows of the university vehicular gates, the current evaluation lacks the statistical volume necessary for cross-validation. Consequently, the reported error margins require further validation across diverse environmental conditions, including varying weather and lighting. Second, the SDI has to be adapted into discrete DPWH Level of Service categories since the LOS categories outlined by the DPWH are based on the V/C ratio. Future studies must consider both of these before considering the generalized deployment of this system.

Acknowledgment

The authors would like to thank the Campus Safety and Mobility Office (CSMO) for providing the dataset used in this study.

Special thanks are extended to Social and Environmental Engagement for Development and Sustainability (SEEDS) for the provision of the computer used for model training and to Research, Creative Work, and Innovation (RCWI) for their administrative assistance and organizational support throughout this research.

VII. Declaration on Generative AI

During the preparation of this work, the authors used Google Gemini 3.1 Pro to improve the clarity of the paper and aid in proofreading. After the use of this tool, the authors carefully reviewed and edited the content as needed to align with the SAI paper format. The authors take full responsibility and accountability for the content in this work.

***Abstract*—Defense-in-Depth (DiD) holds that a system should be protected by multiple independent layers of security, so that the failure or compromise of a single countermeasure does not result in total system compromise. Secondary cybersecurity instruction, however, often presents security as a list of disconnected rules. This study presents the design of an instructional framework that teaches DiD to high-school students as a transferable form of systems thinking. The framework is developed within a teacher professional-development project and comprises five stages: Hook, Layer Mapping, Threat Modeling, Hardware Case Study, and Design Challenge, each grounded in an established learning theory and tied to six measurable, Bloom-aligned learning objectives. Threat modeling is introduced through a four-question process supported by student-facing adaptation of the six STRIDE categories and simple attack trees. A deliberately compact case study of the six-layer defense of logic-locked integrated circuits serves as a far-transfer task rather than as a hardware tutorial. The framework includes five assessment instruments, a five-criterion, four-level analytic rubric (5–20 points), and an implementation guide that fits the module into seven to nine 45–50 minute class periods. The contribution is primarily design-oriented: specifying three hypotheses, associated metrics, and a pretest–posttest protocol for a planned classroom pilot. By connecting familiar security protections with hardware security, DiD shifts the student's question from "Is the system secure?" to "How does the system remain resilient when an individual protection fails?".**

***Keywords*—Defense-in-depth; cybersecurity education; secondary education; threat modeling; STRIDE; instructional design; hardware security; logic locking**

I. Introduction

High-school students use digital systems every day and are exposed to the corresponding risks. Weak or reused passwords compromise personal accounts, phishing messages steal credentials, unpatched devices spread malware, and insecure networks leak sensitive information. Schools themselves are targets: the learning management system used by many districts was recently breached twice within a short period [1]. Cybersecurity education therefore needs to move beyond teaching security as a set of discrete actions or tools. Students need to understand security as a system in which several measures combine to reduce risk [2], [3].

Defense-in-Depth (DiD) therefore provides an appropriate organizing concept for cybersecurity instruction. It assumes that no single countermeasure can effectively address all possible threats [4]. For example, a strong password may reduce the likelihood of successful guessing attacks, multi-factor authentication may limit the consequences of compromised credentials, and login alerts may help detect unauthorized access attempts. Each mechanism serves a distinct defensive function, and their combined use provides greater resilience than reliance on any individual safeguard alone. The same principle applies to more advanced security domains. Rahman *et al.* [5] demonstrate that protecting the secret key of a logic-locked integrated circuit (IC) requires multiple independent safeguards against threats such as reverse engineering, optical probing, electrical probing, scan-chain attacks, and oracle attacks. Although the underlying techniques are technically complex, the core principle remains straightforward: valuable assets require multiple independent layers of protection because adversaries may exploit different attack paths.

For secondary education, DiD offers three key advantages. First, it connects directly to students' everyday use of technology. Second, it promotes systems thinking by requiring students to identify assets, threats, vulnerabilities, countermeasures, and potential failure paths. Third, it bridges familiar cybersecurity practices with engineering-oriented security design, enabling teachers to present cybersecurity as a structured reasoning process rather than as a checklist of isolated rules.

A. Scope and Addressing Design Gaps

This work is an instructional-design study. Following the design-based research tradition, in which a theoretically grounded intervention is specified before it is evaluated in iterative classroom cycles [6]. The study documents the design phase and is organized around three design questions:

- **DQ1.** How can DiD be decomposed into a sequence of learning activities that is accessible to students with no prior security training?
- **DQ2.** How can an advanced hardware-security case be reduced so that it supports transfer of DiD reasoning instead of becoming a technical tutorial?
- **DQ3.** Which instruments and criteria make DiD reasoning-asset identification, threat identification, layer diversity, and failure-path analysis, observable and assessable by a classroom teacher?

The hypotheses that follow from this design, and the protocol for testing them, are stated in Section VIII.

B. Contributions

- Six measurable learning objectives aligned with Bloom taxonomy and mapped to stages and instruments (Table I, Fig. 4).
- A five-stage instructional sequence for DiD in which every stage is justified by an established learning theory (Table II, Fig. 3).
- A student-facing adaptation of STRIDE and attack trees that gives the threat-modeling stage methodological depth (Table III, Fig. 4).
- A compact logic-locking case study used as a far-transfer task (Table IV, Fig. 5).
- An assessment plan with an analytic rubric and performance criteria (Tables V and VI), and an implementation guide covering duration, prerequisites, preparation, and resources (Table VII).

The remainder of the study is organized as follows. Section II reviews related work and the learning theories that ground the design. Section III defines DiD and explains why it suits secondary learners. Section IV describes the instructional context and the learning objectives. Section V presents the five-stage framework. Section VI presents assessment, Section VII addresses classroom implementation, Section VIII states limitations and the evaluation plan, and Section IX concludes the work.

II. Related Work and Theoretical Foundations

A. Cybersecurity Education in K-12

A growing body of work argues for integrating cybersecurity into K–12 curricula. Pencheva *et al.* [3] argue that cybersecurity should be woven into secondary education to foster a security mindset, and note that many programs present security as a collection of rules. Kamaludeen *et al.* [7] propose a cyber-protection framework for the K–12 sector that spans technical, administrative, and behavioral defenses. Vajpayee and Hossain [8] examine authentic assessment in high-school cybersecurity and stress that students must learn to evaluate cyber assets and risks holistically. Recent systematic reviews confirm that the field is active but uneven. Ibrahim *et al.* [9] find that most aspects of cybersecurity are not taught systematically at K–12 level; Sağlam *et al.* [11] report that content varies widely between countries and leaves gap; Arishi *et al.* [12] identify games, mobile applications, and tailored programs as effective awareness practices; and Xu and Li [13] map trends, challenges, and opportunities for younger learners. Across these reviews the dominant topics are awareness and safe behavior. Layered-defense reasoning is rarely an explicit learning goal.

B. Teaching Threat Modeling

Threat modeling is well developed in professional practice. STRIDE classifies threats into six categories [15], attack trees decompose an attacker's goal into alternative paths [16], PASTA defines a seven-stage risk-centric process [17], and surveys compare these and other methods [18]. Educational use has been studied mainly at university level. Joshi *et al.* [19] found that software-engineering students who received systems-thinking instruction together with STRIDE identified system-level as well as component-level threats, whereas students taught STRIDE alone concentrated on components. That result supports the premise of this study, that threat categories should be taught inside a systems view, but no comparable adaptation exists for secondary learners.

C. Learning Theories Informing the Design

Five strands of learning theory inform the proposed framework. *Constructivism* holds that learners build new understanding on prior knowledge, and that learning is most productive within the zone of proximal development, where support from a teacher or peer is available [20]. *Inquiry-based learning* organizes instruction as a cycle of orientation, conceptualization, investigation, conclusion, and discussion [21]. *Cognitive apprenticeship* makes expert reasoning visible through modeling, coaching, scaffolding, and fading [22], [23]. *Experiential learning* describes a cycle of concrete experience, reflective observation, abstract conceptualization, and active experimentation [24]. Research on *transfer learning* shows that learners abstract a general schema more reliably when they compare two analogous cases than when they study one [25], [26]. Section V assigns each stage to the theory that motivates it, and the revised Bloom taxonomy [27], [28] is used to state objectives and to order the stages by cognitive demand [29].

D. The Gap

Existing K–12 research establishes the importance of layered-defense thinking; however, it does not provide a scaffolded, theory-grounded instructional sequence with clearly assessable outcomes. While existing threat-modeling pedagogy primarily targets university students, this work addresses both gaps and incorporates a hardware-security case to examine whether DiD reasoning can transfer to an unfamiliar system.

III. Defense-in-Depth for Secondary Learners

A. Principle

DiD deploys multiple independent layers of security to reduce the risk that the failure of one component compromises the entire system. The concept originates from military strategy, in which successive defensive lines delay, weaken, and contain an adversary, and has since become a widely adopted principle in information and industrial control system security [4], [30], [31]. Each layer is designed to prevent, detect, contain, or facilitate recovery from specific categories of attack. A strong password resists guessing but cannot stop phishing or malware. Similarly, a firewall can block many network-based attacks but cannot prevent a user from entering credentials into a fraudulent website.

An essential distinction between *redundancy* and *diversity*, is that redundant layers repeat a similar protection, whereas diverse layers address different attack vectors [4], [5]. Students often assume that a strong password means a stronger system. A system that has only password system, with no added recovery measures, no device security, and no user awareness, remains fragile however strong the password is. Fig. 1 contrasts the single vs multi-layered defense configurations.

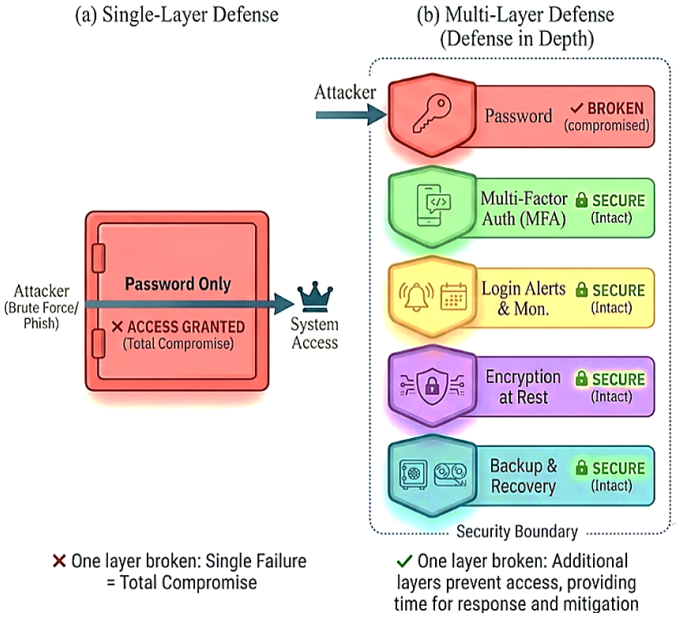

Fig. 1. Single-layer defense versus multi-layered defense.

B. Rationale for the Secondary Level

Secondary-level students increasingly rely on information systems for communication, learning, financial activities, social interactions and entertainment [7], [8], however, cybersecurity is often encountered as a set of disconnected rules rather than as an integrated component of their digital activities [10]. The DiD instructional approach targets three primary outcomes. The first outcome is *awareness*: students who understand that successful cyberattacks often exploit a single unprotected point may be more motivated to adopt multiple protective measures. The second is *systems thinking*: DiD requires students to identify what must be protected, how it could be compromised, which safeguards are already in place, and where gaps remain. The third is *transfer*: the layered reasoning developed through familiar contexts, such as email accounts, can be extended to more complex environments, including enterprise systems, critical infrastructure, and hardware. DiD is well suited to this age group because it does not require advanced technical skills [2] and can be taught through scenarios that are familiar to students.

C. Everyday Examples used in Instruction

Three familiar systems supply the examples used in Stages I to III.

1) Personal accounts: A student who reuses one password relies on a single layer. A layered alternative combines a unique password held in a password manager, multi-factor authentication (MFA), login alerts, securely stored recovery codes, and phishing awareness. Each layer answers a different threat: guessing, stolen credentials, undetected intrusion, loss of access, and deception.

2) School networks and devices: Schools combine account controls, web filtering, antivirus software, patching, network segmentation, backups, and monitoring [7], [31]. Patching

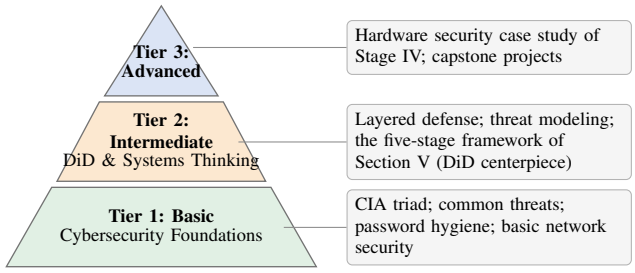

Fig. 2. Three-tier cybersecurity training for STEM teachers in the PERFECT project; the DiD framework forms Tier 2 and its capstone case belongs to Tier 3.

closes vulnerabilities, antivirus detects malicious files, segmentation contains an infection, backups enable recovery from ransomware, and monitoring reveals unusual activity. The example shows that security is organizational as well as individual, and that prevention, detection, containment, and recovery are different functions.

3) Human behavior: Students often perceive that cybersecurity is purely technical domain [3]. However, cyberattacks frequently exploit human factors such as trust, fear, curiosity, or ignorance, and a technically sound system fails when users unintentionally bypass its protections [14]. Accordingly, the module emphasizes the user as an integral layer of defense rather than as an entity external to the security system.

IV. Instructional Context and Learning Objectives

A. The PERFECT Project

The framework was developed within PERFECT (Providing Environment and Resources for STEM 9th–12th Graders in Effective Cybersecurity Training), a project that prepares high-school STEM teachers to teach cybersecurity [32], [33]. The project follows a train-the-trainer model with three tiers, shown in Fig. 2. Tier 1 covers foundational concept such as the confidentiality-integrity-availability triad, common cyberthreats, and password hygiene. Tier 2 covers DiD and systems thinking, and the five-stage framework presented in this work. Tier 3 covers advanced case studies, including the hardware case in Stage IV. The framework therefore has a dual use: it is a teacher-training module and, with minor adaptation, a lesson sequence for the high-school classroom.

B. Learning Objectives

Table I presents the six learning objectives (LOs), begins with an observable verb drawn from the revised Bloom's taxonomy [28] and is assessed through at least one instrument described in Section VI. The objectives are aligned with the Grade 9-12 cybersecurity expectations of the CSTA standards, which emphasize recommending and comparing appropriate security measures for specific scenarios [34], [35], as well as with the NICE's framework emphasis on task-oriented cybersecurity competencies [36].

TABLE I. MEASURABLE LEARNING OBJECTIVES

LO	On completing the module, students can...	Bloom level	Stage
1	Explain DiD and why a single layer is a single point of failure	Understand	I
2	Classify the protections of a familiar system by the threat addressed and by function (prevent, detect, contain, recover)	Analyze	II
3	Construct a threat model using the four questions, the STRIDE prompts, and an attack tree	Apply, Analyze	III
4	Match the six IC defense layers to the attacks they stop and to everyday analogues	Analyze (transfer)	IV
5	Design a layered defense plan for a system of their choice	Create	V
6	Evaluate a defense plan for diversity versus redundancy and trace its failure paths	Evaluate	III, V

V. THE FIVE-STAGE INSTRUCTIONAL FRAMEWORK

The framework moves students from intuition, through structured analysis, to independent design. Fig. 3 shows the five stage progression, and Table II summarizes, for every stage, the guiding question, the DiD principle, the student output, and the learning theory that motivates the stage. Cognitive demand rises from *understand* to *create* [28], and teacher support is withdrawn gradually, as cognitive apprenticeship prescribed in stages [22].

A. Stage I: Hook and Motivation

Stage I introduces DiD through relatable failures, for example an account taken over through a weak password, a school computer infected through an email attachment, or a ransomware incident that began on one unpatched machine [8]. No security vocabulary is required. The instructional goal is to make the fragility of single-layer protection visible, so that students leave with a question of their own: many failures occur not because every protection failed, but because the system depended on one. Stage II then turns from failures to the protections that students already have.

B. Stage II: Layer Mapping

Students identify and document the security measures implemented across systems they regularly use, including smartphones, school accounts, laptops, cloud storage services, and home Wi-Fi networks [7], [37]. Common examples include passwords, biometric authentication, multi-factor authentication (MFA), software updates, antivirus software, login notifications, data backups, and permission settings. Students then classify each security measure according to two dimensions: the threat it is intended to address and its defensive function-prevention, detection, containment, or recovery. This dual classification helps learners to recognize that security layers are not interchangeable, as each serves a distinct defensive purpose. It also allows students to identify potential imbalances in their existing security practices, particularly with an emphasis on preventive measures relative to detection and recovery mechanisms. However, this inventory is organized primarily from the defender's perspective by focusing on existing safeguards, whereas an attacker typically approaches a system by identifying exploitable assets, vulnerabilities, and weaknesses. This distinction provides the motivation for Stage III, which introduces threat-oriented analysis.

C. Stage III: Threat Modeling

Stage III shifts the perspective from the defender to the attacker by introducing a threat-oriented analysis. Students examine a selected system by addressing four fundamental principles of professional threat modeling [15]:

- What asset requires protection?
- What threats could compromise the asset?
- What countermeasures are currently in place to mitigate these threats?
- What security gaps or single points of failure remain?

1) Choice of method: Without structured guidance, novice learners may identify only a limited set of familiar attacks when addressing the second principle. An established threat-modeling method can provide a systematic framework for identifying a broader range of threats. Four approaches were considered. PASTA follows a seven-stage, risk-centric process that typically requires organizational and business context beyond the experience of novice learners [17]. DREAD provides quantitative risk scores, but the subjectivity associated with assigning these scores has been identified as a limitation [18]. STRIDE, in contrast, organizes threats into six mnemonic categories [15] that can be accessible concept for learners, while attack trees [16] provide a visual representation of alternative attack paths and potential points of failure. STRIDE is selected as the primary framework for systematically identifying relevant threats, while attack trees were incorporated to examine security gaps and potential single points of failure. To maintain accessibility for secondary-level learners, risk evaluation is simplified to qualitative high, medium, or low ratings based on the estimated likelihood and potential impact of each threat [38].

2) STRIDE prompts: Table III presents the student-facing prompt associated with each STRIDE category, an illustrative example drawn from an everyday context, and the corresponding threat identified in the hardware security case introduced in Stage IV. Rather than requiring students to memorize the STRIDE category names, the prompts serve as a structured checklist for systematically considering a broader range of potential threats beyond those that may initially come to mind. The hardware-security mappings presented in the final column were developed specifically for the proposed instructional framework and are revisited in Stage IV to demonstrate how threat-modeling concepts can be transferred from familiar cybersecurity scenarios to hardware security contexts.

3) Attack trees: To address the fourth principle, students construct a simplified attack tree in which the attacker's objective is represented as the root, alternative attack paths as branches, and existing security layers as controls associated with the branches they are intended to mitigate (Fig. 4). The attack tree is then used to evaluate the DiD design according to two criteria. First, any branch lacking a protective layer indicates a potential single point of failure. Second, multiple protections concentrated on the same branch reflect redundancy rather than defensive diversity. A more resilient design distributes preventive, detective, containment, and recovery mechanisms across distinct attack paths [31], [38].

Following the cognitive apprenticeship approach, the teacher first models a complete analysis, then guides groups through the analysis of a second system using the worksheet,

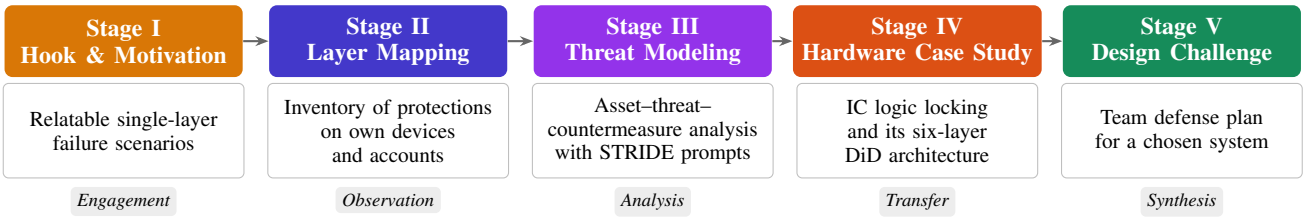

Fig. 3. Five-stage instructional framework for teaching Defense-in-Depth.

TABLE II. FIVE-STAGE FRAMEWORK: GUIDING QUESTION, PRINCIPLE, OUTPUT, AND THEORETICAL BASIS

Stage	Focus	Guiding question	DiD principle	Student output	Theoretical basis and how it is applied
I	Hook and Motivation	What happens if the only layer fails?	Single point of failure	Short reflection	Inquiry-based learning, orientation phase [21]: a puzzling failure creates the question that the module answers, and activates prior knowledge [20].
II	Layer Mapping	Which protections already exist, and what does each one do?	Independent, diverse layers	Layer inventory	Constructivism and the first half of Kolb's cycle [24]: students start from concrete experience with their own devices and reflect on it.
III	Threat Modeling	What are the asset, the threats, the countermeasures, and the gaps?	Asset–threat alignment	Threat worksheet and attack tree	Cognitive apprenticeship [22], [23]: the teacher models expert reasoning aloud, the worksheet and prompt card scaffold it, and support fades across examples.
IV	Hardware Case Study	Does the same reasoning protect an IC?	Concept transfer	Case response	Analogical transfer [25], [26]: comparing two structurally similar cases (account, ICs) leads students to abstract the DiD schema.
V	Design Challenge	How can we build a layered defense ourselves?	Applied systems thinking	Team defense plan	Experiential learning, active experimentation [24], carried out in teams so that peers provide support within the zone of proximal development [20].

TABLE III. STUDENT-FACING ADAPTATION OF STRIDE USED IN STAGE III AND REVISITED IN STAGE IV

STRIDE category	Prompt given to students	Everyday example	Typical defensive layer	Counterpart in the IC case (Stage IV)
Spoofing	Could someone pretend to be me or a service I trust?	Fake school login page	MFA; phishing awareness	Cloned or overproduced ICs sold as genuine
Tampering	Could someone change the data or the device?	Malware altering files	Patching; antivirus; backups	Hardware Trojan inserted during fabrication
Repudiation	Could someone act without leaving a trace?	Unnoticed login from a new device	Login alerts; activity logs	Probing attempt that goes undetected
Information disclosure	Could someone see what they should not?	Reused password leaked in a breach	Unique passwords; encryption	Key recovered by reverse engineering, probing, or SAT attack
Denial of service	Could someone stop me from using it?	Ransomware; lost phone	Backups; recovery codes	Trojan that disables the ICs
Elevation of privilege	Could someone obtain more access than they are allowed?	Student account gaining administrator rights	Least privilege; role-based permissions	Test (scan) access misused to read internal state

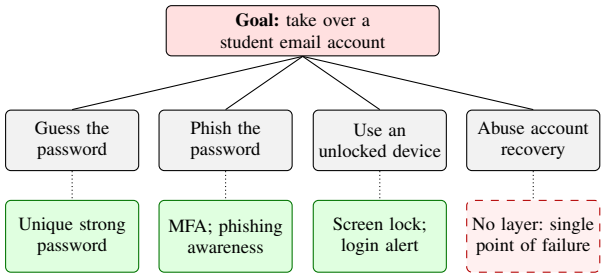

Fig. 4. Example of the simplified attack tree drawn in Stage III. Shaded boxes on the lower row are existing layers; the dashed box marks an unprotected branch.

and finally allows groups to analyze a third system using only the prompt card. At this stage, students have developed a structured method for analysis. Stage IV examines whether this method can be transferred to a different domain.

D. Stage IV: Hardware Security Case Study

The case study is intentionally concise, as its primary purpose is to facilitate knowledge transfer. Students are introduced only to the hardware concepts necessary to understand and apply the comparison.

1) The problem: Integrated circuits (ICs) are often designed by one organization and fabricated, packaged, and tested by external foundries and service providers, which may expose the design to potentially untrusted entities within the semiconductor supply chain. Such exposure can create risks including intellectual-property theft, unauthorized overproduction, reverse engineering, and the insertion of malicious circuitry known as hardware Trojans [5], [39]. *Logic locking* is one hardware-security technique used to protect circuit functionality and intellectual property by introducing key-controlled logic that enables the IC to operate correctly only when the appropriate secret key is applied [40], [41]. For instructional purposes, this mechanism can be compared to a machine that operates only when the correct combination is

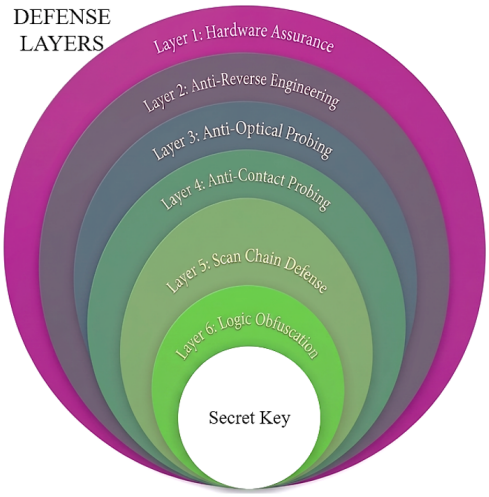

Fig. 5. Defense-in-Depth layers surrounding the secret key of a logic-locked integrated circuit (adapted from [5]).

entered. In this analogy, the secret key represents the asset that requires protection.

2) Why one lock is insufficient: An adversary may attempt to recover the key through multiple attack paths. These include supplying inputs to a functioning IC and inferring the key from its outputs (oracle or SAT attacks), reconstructing the circuit through physical analysis, observing internal signals optically without direct contact, probing internal wires, or exploiting scan chains intended for testing [5], [42], [43]. A defense that protects against one attack path may not prevent others. This reflects the same principle students observed with passwords in Stage I.

3) The six layers: Rahman *et al.* [5] arrange six defenses around the key, as in Fig. 5. Table IV pairs each layer with the attack it defeats and with an everyday analogue, and it is the only hardware material students must work with. Representative techniques are Trojan detection for hardware assurance [39], camouflaging for anti-reverse engineering [40], optical-probing detection [44], scan obfuscation [42], [43], and SAT-resistant locking such as SARLock, Anti-SAT, and SFLL [45]–[47]. Students often do not study how these techniques work.

4) Classroom activity: Groups receive the designated asset (the key), together with shuffled cards representing five attack paths and six defensive layers. They apply the four analytical prompts and STRIDE-based guidance introduced in Stage III, position each defensive layer on the attack path it is intended to mitigate, and compare the resulting analysis with Fig. 4 and Table III. The concluding discussion introduces risk-proportional reasoning: a personal account, a school network, and an integrated circuit may warrant different levels of security investment, although the underlying analytical process remains consistent. After applying the same method to two distinct systems, students are expected to use it independently.

E. Stage V: Design Challenge

Learners as a team apply DiD reasoning to a system of their choice, such as a student email account, a school network, a smart-home device, an online banking portal, or a hospital database. Each team must 1) identify the asset and explain its importance, 2) list at least four threats drawn from at least three STRIDE categories, 3) propose one or more defensive layers for each threat and classify the function of each layer, and 4) explain the consequences of the failure of any single layer. The emphasis is on the rationale behind the design rather than on the technically perfect mechanisms. The teams present their plans to the class and the plans are evaluated using the rubric described in Section VI.

VI. Assessment

Assessment measure students' ability to define DiD. It determines whether learners can identify assets and threats, select diverse defensive layers, and reason about potential failures. Table V presents the five assessment instruments, the objectives it measures, and the performance criterion for each. Formative assessments evaluate understanding throughout Stages I–IV, while summative assessments determine whether students can apply DiD reasoning to a new system.

1) Analytic rubric: Table VI provides the rubric used for the design task and for scenario analysis. It is analytic instead of holistic, since analytic rubrics with explicit level descriptors improve scoring consistency and give students usable feedback [48], [49]. The four content criteria correspond to the four threat-modeling questions, and a fifth addresses communication. Scores range from 5 to 20. A total of at least 15 with no criterion at level 1 is taken as meeting the module objectives. Teachers may adjust the assessment weights and performance thresholds to align with assessment policies.

2) Evaluation metrics: For teachers and for the planned pilot, the instruments yield five quantitative indicators: the quiz score, the number of distinct STRIDE categories in a threat list, the number of defensive functions covered by a plan, the count of unprotected branches remaining in an attack tree, and the rubric with its per-criterion profile.

VII. Classroom Implementation

A. Preparation and Resources

Table VII presents the recommended implementation plan. The complete intermediate course requires 15 modules with 120–180-minutes to complete each module. When instructional time is limited, Stages I and II can be combined into a single period, and Stage IV may be reduced to the card-based activity. All activities is designed to be conducted in learning management systems using shared digital document.

1) Prerequisites: Participating teachers and their students are expected to have basic digital literacy and experience. No prior background in programming, networking, or electronics is required. Teachers enrolled in intermediate module were expected to complete PERFECT Tier 1 or possess equivalent foundational knowledge. Stage IV requires only a brief introduction and does not assume any prior expertise in semiconductor technology.

2) Classroom management and workload: Group work in Stages III–V can be managed more effectively by assigning specific roles, such as asset owner, attacker, defender, and recorder, and rotating these roles between stages so that

TABLE IV. DEFENSE-IN-DEPTH LAYERS: HARDWARE SECURITY AND EVERYDAY ANALOGUES

Layer	Hardware defense (IC)	Attack defeated	Everyday analogue
1. Hardware assurance	Trojan detection through imaging and inspection	Trojan insertion	Verifying software authenticity; trusted sources
2. Anti-reverse engineering	Camouflaged cells; dummy vias; layout obfuscation	Reverse engineering	Code obfuscation; license enforcement
3. Anti-optical probing	Optical scattering; opaque layers; sensors	Optical (contactless) probing	Encryption of data in transit
4. Anti-contact probing	Active wire shield; probe-attempt detector	Electrical probing	Physical server security; tamper-evident seals
5. Scan-chain defense	Encrypted or dynamically obfuscated scan chains	Scan-chain attacks	MFA; role-based permissions
6. Logic obfuscation	SARLock, Anti-SAT, SFLL logic locking	SAT and oracle attacks	Strong passwords; password managers

TABLE V. ASSESSMENT INSTRUMENTS, OBJECTIVES, AND PERFORMANCE CRITERIA

Instrument	Type	LOs	Evidence and performance criterion	Weight
Concept quiz	Form.	1, 2	8–10 items on definitions, layer functions, and diversity versus redundancy; criterion: 70% correct	15%
Scenario analysis	Summ.	3, 6	Written breach narrative; student names the failed or missing layer and proposes a layer with a *different* function; rubric criteria C2–C4	20%
Hardware case response	Form.	4	Six layer–attack pairs matched and one analogy explained; criterion: five of six pairs correct	15%
Layered design task	Summ.	5, 6	Team defense plan from Stage V; full rubric (Table VI)	35%
Reflection writing	Form.	1	One personal system, one gap found, one action planned; scored for completion	15%

Note: LOs. = Learning Objectives; Form. = formative; Summ. = summative.

TABLE VI. ANALYTIC RUBRIC FOR THE DEFENSE-IN-DEPTH DESIGN TASK (5–20 POINTS)

Criterion	1 – Beginning	2 – Developing	3 – Proficient	4 – Advanced
C1. Asset identification	Asset missing, or confused with a device or tool	Asset named, but its value or owner is unclear	Asset named, with why it matters and to whom	Also separates the primary asset from supporting assets (e.g., the recovery email)
C2. Threat analysis	Fewer than two threats, or threats unrelated to the asset	Two or three threats, all from one STRIDE category	At least four specific threats from three or more STRIDE categories	Also includes human and physical threats and a realistic attacker capability
C3. Layer–threat alignment and diversity	Protections listed without links to threats	Every threat has a layer, but layers repeat one function	Every threat mapped to a layer; layers cover at least three of prevent, detect, contain, recover	Also justifies layers by asset value and cost, and removes redundant layers
C4. Failure-path reasoning	Not addressed	States that other layers "help" without tracing a path	For at least two layers, traces what the attacker gains on failure and which layer acts next	Also finds a remaining single point of failure and proposes a fix
C5. Communication of rationale	Plan cannot be followed	Understandable, but choices are not justified	Clear diagram or table with a rationale for each choice	Also uses correct vocabulary; a peer could implement the plan

TABLE VII. RECOMMENDED IMPLEMENTATION PLAN (45–50 MINUTE PERIODS)

Stage	Periods	Teacher preparation and materials	Grouping
I	1	Select two or three recent, age-appropriate incidents; prepare discussion prompts	Whole class; think–pair–share
II	1	Layer-inventory sheet; check school policy on personal devices	Pairs
III	2	Rehearse one worked example; threat worksheet, STRIDE prompt card, chart paper	Groups of 3–4
IV	1–2	Read the case brief (Fig. 5, Table IV); print attack and layer cards	Groups of 3–4
V	2–3	Plan template; rubric handed out in advance; presentation schedule	Teams of 3–4 with roles

each student has an opportunity to practice the attacker's perspective. Preparation effort is concentrated primarily in Stages III and IV, where the teacher should be familiar with at least one worked example. Grading effort is concentrated in Stage V, where the analytic rubric enables the instructor to complete a single scoring pass for each team rather than for each individual student.

B. Pedagogical Challenges and Mitigations

1) Abstraction: Concepts such as threats, attack surfaces, and defensive layers can be abstract and difficult for novice learners to visualize [3]. The module therefore begins with familiar physical analogies, such as a locked door or a vault, before progressing to cybersecurity systems, and uses visual representations to reinforce these concepts (Fig. 1, Fig. 4).

2) Technical overload: Logic locking, optical probing, and SAT attacks extend beyond the scope of the secondary-level curriculum. The case study is therefore limited to one figure, one table, and a card-based activity, and students are assessed on their ability to match defensive layers to corresponding attacks rather than on the underlying technical mechanisms.

3) Differentiated skill level: Students may enter the module with varying levels of computing experience. Teachers can therefore adjust the complexity of the selected system: beginners may analyze a personal account, while more advanced students may examine an IC or a hospital database in Stage V [7].

4) Perceived irrelevance: Some students may not initially perceive cybersecurity as personally relevant. Stage I therefore introduces familiar threats, such as password reuse, phishing, lost devices, and failed account recovery, to connect cybersecurity concepts with students' everyday experiences.

VIII. Limitations and Evaluation Plan

The primary limitation of this work is that it presents a design framework; an empirical evaluation has yet to be conducted. Therefore, its effectiveness remains to be empirically established in implementation. The stage durations presented in Table VII and the rubric thresholds are design recommendations that may be refined based on findings from future pilot implementations. The hardware mapping in Table III is intended as an instructional aid rather than a formal threat model of logic locking. Similarly, everyday analogies in Table IV are approximated.

The next phase of this research [6] will involve a classroom pilot to examine three hypotheses:

- H1. After completing the module, learners will identify more distinct threat categories and defensive functions for a given system than before completing the module.
- H2. After completing the module, learners will analyze an unfamiliar system not used during instruction at rubric level 3 or above on criteria C2-C4.
- H3. Two teachers independently scoring the same student plans using Table VI will achieve at least moderate inter-rater agreement (Cohen's $\kappa \geq 0.6$).

The pilot study will employ a single-group pretest-posttest design using the concept quiz and a scenario-analysis task as pre- and post-measures, together with the indicators described in Section VI, student feedback, and teacher observation logs documenting the actual time required for each stage. Future work will adapt the module for introductory and advanced courses and explore interactive and gamified implementations of the five-stage framework [50].

IX. Conclusion

Defense-in-Depth helps learners understand security as a layered and resilient system rather than as a single protective mechanism. This study presents a five-stage framework for teaching DiD in high school. In response to DQ1, the sequence progresses from a motivating failure scenario through layer mapping and STRIDE-supported threat modeling to an independent design task, with each stage grounded in an established learning theory and aligned with measurable objectives. In response to DQ2, the logic-locking case is reduced to one concept, one table, and one card-based activity so that it functions primarily as a transfer learning task. In response to DQ3, five assessment instruments and a five-criterion analytic rubric make asset identification, threat analysis, layer diversity, and failure-path reasoning observable and assessable. The framework has not yet been evaluated with pilot study. The intended outcome is that students learn to ask not only whether a system is protected, but also how it remains secure when an individual protective measure fails.

Acknowledgment

This work was supported by the United States Office of Naval Research (ONR) under Grant No. N00014-23-1-2454 through the PERFECT (Providing Environment and Resources for STEM 9th–12th Graders in Effective Cybersecurity Training) project at the University of North Texas. The authors thank the participating STEM educators from Amarillo ISD, Boyd ISD, Bushland ISD, Canyon ISD, and Denton ISD for their engagement and feedback on the course modules, and the faculty members, graduate researchers, and student assistants at the University of North Texas and West Texas A&M University who contributed to curriculum development, instructional delivery, and project coordination.
